CHRONOLOGICAL LIST OF SESSIONS

(see page xi for Thematic List of Sessions)

WEDNESDAY

THURSDAY

FRIDAY

SATURDAY

Thematic List of Sessions

(Includes slide and poster sessions, symposia, and workshops only.)

Theme A: Development and Plasticity

Session Number	Session Title	Type	Day and Time
408.	Aging and dementia: anatomy	Slide	Fri PM
124.	Aging and dementia: function I	Poster	Wed AM
452.	Aging and dementia: function II	Slide	Sat AM
230.	Aging and dementia: molecular biology I	Slide	Thu AM
366.	Aging and dementia: molecular biology II	Poster	Fri AM
316.	Aging and dementia: plaques, tangles, amyloid	Poster	Thu PM
123.	Aging and dementia: transmitters	Poster	Wed AM
191.	Autonomic nervous system	Poster	Wed PM
257.	Biochemical and pharmacological correlates of development I	Poster	Thu AM
313.	Biochemical and pharmacological correlates of development II	Poster	Thu PM
339.	Biochemical and pharmacological correlates of development III	Slide	Fri AM
55.	Cell lineage and differentiation I	Slide	Tue PM
195.	Cell lineage and differentiation II	Poster	Wed PM
248.	Cell lineage and differentiation III	Poster	Thu AM
309.	Cell lineage and differentiation IV	Poster	Thu PM
409.	Cell lineage and differentiation V	Slide	Fri PM
200.	Development and plasticity: aging	Poster	Wed PM
168.	Development of invertebrates I	Slide	Wed PM
314.	Development of invertebrates II	Poster	Thu PM
442.	Developmental disorders	Poster	Fri PM
192.	Endocrine control of development I	Poster	Wed PM
423.	Endocrine control of development II	Poster	Fri PM
449.	**Hormonal Organization and Reorganization of Neural Circuits**	**Symp.**	**Sat AM**
315.	Limbic system	Poster	Thu PM
217.	**Molecular Genetic Analysis of Neuronal Development**	**Symp.**	**Thu AM**
74.	Morphogenesis and pattern formation I	Poster	Tue PM
308.	Morphogenesis and pattern formation II	Poster	Thu PM
419.	Motor systems	Poster	Fri PM
280.	Neural plasticity in adult animals I	Slide	Thu PM
341.	Neural plasticity in adult animals II	Slide	Fri AM
441.	Neural plasticity in adult animals III	Poster	Fri PM
462.	Neural plasticity in adult animals IV	Poster	Sat AM
269.	Neural plasticity in adult animals: hippocampus	Poster	Thu AM
47.	Neural plasticity in adult animals: spinal cord	Poster	Tue AM
7.	Neuronal death I	Slide	Tue AM
255.	Neuronal death II	Poster	Thu AM
220.	Neurotoxicity I	Slide	Thu AM
258.	Neurotoxicity II	Poster	Thu AM
466.	Neurotoxicity III	Poster	Sat AM
24.	Neurotoxicity: MPTP and ethanol	Poster	Tue AM
194.	Neurotoxicity: metals	Poster	Wed PM
193.	Nutritional and prenatal factors I	Poster	Wed PM
416.	Nutritional and prenatal factors II	Poster	Fri PM
6.	Process outgrowth I	Slide	Tue AM
75.	Process outgrowth II	Poster	Tue PM
130.	Process outgrowth III	Poster	Wed AM
337.	Process outgrowth IV	Slide	Fri AM
413.	Process outgrowth V	Poster	Fri PM
414.	Process outgrowth VI	Poster	Fri PM
104.	Process outgrowth: growth cone behavior	Slide	Wed AM
82.	Regeneration I	Poster	Tue PM
291.	Regeneration II	Slide	Thu PM
331.	Regeneration: PNS	Poster	Thu PM

Theme B: Cell Biology

357.	Messenger RNA regulation IV	Poster	Fri AM
472.	Messenger RNA regulation V	Poster	Sat AM
182.	Metabolic studies	Poster	Wed PM
448.	**New Insights into the Structure and Function of Receptors**	**Symp.**	**Sat AM**
99.	**Proto-Oncogenes in the Nervous System**	**Symp.**	**Wed AM**
158.	**The Role of Nectins (Cell Binding Molecules) in Neural Development**	**Symp.**	**Wed PM**
189.	Staining and tracing techniques I	Poster	Wed PM
190.	Staining and tracing techniques II	Poster	Wed PM
420.	Structure and function of identified cells I	Poster	Fri PM
421.	Structure and function of identified cells II	Poster	Fri PM
422.	Structure and function of identified cells III	Poster	Fri PM

Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Session Title	Type	Day and Time
29.	Action potentials and ion channels I	Poster	Tue AM
30.	Action potentials and ion channels II	Poster	Tue AM
31.	Action potentials and ion channels III	Poster	Tue AM
32.	Action potentials and ion channels IV	Poster	Tue AM
53.	Action potentials and ion channels V	Slide	Tue PM
147.	Action potentials and ion channels VI	Poster	Wed AM
148.	Action potentials and ion channels VII	Poster	Wed AM
163.	Action potentials and ion channels VIII	Slide	Wed PM
222.	Action potentials and ion channels IX	Slide	Thu AM
281.	Action potentials and ion channels X	Slide	Thu PM
374.	Action potentials and ion channels XI	Poster	Fri AM
375.	Action potentials and ion channels XII	Poster	Fri AM
401.	Action potentials and ion channels XIII	Slide	Fri PM

206.13 SALT LOADING ENHANCES PRESSOR RESPONSE TO INTRAVENOUS ADMINISTRATION OF A DOPAMINE D2 RECEPTOR AGONIST, QUINPIROLE, IN THE SPONTANEOUSLY HYPERTENSIVE RAT. Y. Igarashi*, Y.F. Chen, S. Oparil (SPON: J. Brown). Hypertension Research Program, University of Alabama at Birmingham, Birmingham, AL 35294.

Previous studies in our laboratory demonstrated that intravenous (i.v.) administration of the selective dopamine (DA) D2 receptor agonist quinpirole (LY171555) induces a pressor response in conscious Sprague-Dawley rats and DOCA/NaCl hypertensive rats through a central DA mechanism. This pressor response was attenuated in the DOCA/NaCl rat. To test the hypotheses that 1) the pressor effect of quinpirole is blunted in a second hypertensive model, the spontaneously hypertensive rat of the Okamoto strain (SHR), and 2) pressor responsiveness to quinpirole is further altered by NaCl loading in SHR, quinpirole was administered i.v. (1 mg/kg) or intracerebroventricularly (i.c.v.) (0.1 mg/kg) to SHR and control WKY maintained on 8% or 1% NaCl diets for 3 wks beginning at age 7 wks. Results (mean ±SEM):

IV	NaCl	Basal MAP	Δ MAP post quinpirole 2 min	30 min	60 min
SHR	8% (10)	174±4++	29±2ΔΔ++	-11±3Δ	-9±3Δ
	1% (10)	155±4	18±2ΔΔ	-9±2Δ	-6±2Δ
WKY	8% (10)	112±3	20±1ΔΔ	1±2	0±1
	1% (10)	113±2	20±2ΔΔ	2±1	1±1
ICV			2 min	30 min	60 min
SHR	8% (10)	175±4++	24±3ΔΔ	7±2Δ	-3±2
	1% (10)	155±3	21±2ΔΔ	5±2Δ	-3±2
WKY	8% (10)	105±2	22±1ΔΔ	2±1	1±1
	1% (10)	103±1	22±1ΔΔ	3±1	1±1

Δp<0.05; ΔΔp<0.01, compared to basal value; ++p<0.01, compared to 1% NaCl group. MAP= mean arterial pressure.

The pressor response to i.v. quinpirole was significantly greater in the 8% NaCl SHR than in the 1% NaCl SHR or either WKY group; the quinpirole-induced pressor response was followed by a delayed depressor response in SHR but not WKY. The DA D2 antagonist flupentixol (0.3 mg/kg, i.v.) blocked the response to quinpirole in both SHR and WKY. Pretreatment with domperidone (2.5 mg/kg, i.v.), a peripheral D2 antagonist, enhanced the pressor response and blocked the depressor response to quinpirole in 8% NaCl SHR. These data do not indicate that the pressor response to quinpirole is blunted in SHR, nor do they suggest that dietary NaCl loading alters this centrally mediated pressor response in either SHR or WKY. Rather, these results suggest that peripheral mechanisms are responsible for the enhanced pressor response to quinpirole observed in NaCl loaded SHR.

206.14 URINARY CATECHOLAMINE EXCRETION IN SALT-SENSITIVE AND SALT-RESISTANT SHR AND WKY. M.J. Meldrum and R. Dawson, Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610

Dietary sodium has been implicated in humans as well as several animal models as a risk factor in the pathogenesis of hypertension. Humans with salt-sensitive essential hypertension have also been shown to be unable to increase their urinary dopamine excretion when challenged with high salt diets. These studies were designed to evaluate the effects of elevated dietary sodium on salt-sensitive and salt-resistant forms of SHR and WKY. Groups of 9-10 week old salt-sensitive SHR and WKY rats were obtained from Taconic Farms (Germantown, NY) while salt-resistant SHR and WKY were obtained from Charles Rivers (Wilmington, MA). Animals were placed in metabolism cages and acclimated to the basal sodium diet for 7 days. High sodium diet (3.15% Na, Ralston Purina) was then given for 7 days after which the basal diet was again given. The following 24 hr parameters were measured: Food intake; water intake; urine volume; urinary Na+ and K+; and urinary catecholamines. Blood pressure (indirect tail cuff method) were measured at the beginning, and at 7 day intervals. Salt-sensitive SHR showed a significant increase in blood pressure after 7 days of salt treatment (172 ± 3.2 v. 199.0 ± 6.2 mmHg) while salt-resistant SHR showed no significant changes (174.2 ± 3.0 vs. 175.5 ± 2.3 mmHg) in blood pressure. Urinary Norepinephrine (NE) levels were significantly lower in both salt-sensitive and salt-resistant SHR compared to their WKY controls. Urinary NE levels in both sensitive and resistant SHR were significantly elevated by salt treatment compared to basal diet. Urinary dopamine (DA) levels were significantly lower in salt-sensitive SHR than their controls, while salt-resistant SHR were not different than their WKY controls. Exposure to high salt diets increased urinary DA levels in salt-sensitive SHR to levels seen in their WKY controls while salt exposure in salt-resistant SHR increased DA levels in both SHR and WKY to the same extent. These studies suggest that differences in salt handling occur in SHR, those SHR which respond to salt with increased blood pressure show differences in urinary DA excretion from their WKY controls, while salt-resistant SHR respond similarly to their WKY controls. This difference in renal DA handling may play a role in the salt-sensitivity effects on blood pressure.

Supported in part by a PMA Foundation Research Starter Grant and a Florida heart Association grant.

206.15 EFFECTS OF DOCA-SALT TREATMENT AND DEHYDRATION ON RAT ATRIAL NATRIURETIC FACTOR (ANF) CONTAINING CARDIOCYTES. B.H. Hwang, W.B. Severs and T. Inagami. Terre Haute Center for Medical Education, Indiana University School of Medicine, Terre Haute, IN 47809; Depts. of Anatomy & Pharmacology, The Pennsylvania State University, Hershey, PA 17033; and Dept. of Biochemistry, Vanderbilt University, Nashville, TN 37232.

The ANF is rich in the right atrium and has vasodilation, diuretic, and natriuretic effects. However, it is unknown as to whether/how ANF-containing cardiocytes are affected by deoxycorticosterone acetate (DOCA)-salt treatment and dehydration.

For the dehydration study, male Wistar rats were deprived of drinking water for 5 days and sacrificed for studying catecholaminergic (CA) terminals and ANF-containing cardiocytes in the right atrium. For the DOCA-salt study, animals were treated with DOCA and allowed to drink 1% NaCl solution. The CA terminals, ANF-containing cardiocytes and ANF-containing granules per cardiocyte were evaluated 2 weeks and 4 weeks after experiments. In addition, ANF contents in the plasma and right atrium were determined by radioimmunoassay.

Dehydration caused the increase of the number of ANF-containing cardiocytes. However, the number of ANF-containing granules/cardiocyte was not significantly different between the control and dehydrated groups. The CA terminal-cardiocyte distance was about 1.3 μ, not significantly different between the control and experimental groups.

The DOCA-salt treatment also caused the increase of ANF-containing cardiocytes. However, the number of ANF-containing granules/cardiocyte was reduced in the DOCA-salt treated rats at the 4-week stage. ANF content in the right atrium of DOCA-salt treated rats was also reduced at the 4-week stage, whereas the plasma ANF content was increased. The CA terminal-cardiocyte distance was not significantly different between the control and experimental animals. The results suggested that DOCA-salt treatment can stimulate both the increased ANF synthesis and the increased release of ANF. Such changes were not observed to be associated closely with CA neurons.

In conclusion, our preliminary data suggest that dehydration causes preservation of ANF in the cardiocytes, whereas DOCA-salt treatment induces the increased release of ANF. Although the right atrium is heavily innervated by CA terminals, effects of dehydration and DOCA-salt treatment mentioned above are not closely associated with the catecholaminergic nervous system (supported by American Heart Association grant 851334).

206.16 AMOUNTS OF ANTIGENICALLY ACTIVE ATRIAL NATRIURETIC PEPTIDE IN ATRIAL CELLS OF NORMAL AND SYMPATHECTOMIZED MALE AND FEMALE RATS. L.C. Zoller*, L. Wright and C. Waring* (SPON: E. Yetarian). Department of Anatomy, Boston University School of Medicine, Housman Research Center, Boston, Massachusetts 02118

In order to study the effects of sympathectomy on the control of atrial natriuretic peptide (ANP) in atrial cells, eight days following birth a group of male and female Sprague-Dawley rats received a bilateral transection of the cervical sympathetic trunk whereas littermates were incised and then closed without transection of the trunk. The trunk was avulsed proximally to insure that regeneration would not occur. On postnatal day 15 all animals were killed, the atria removed, immersion fixed in 4% paraformaldehyde in phosphate buffer (pH 7.4) for 2 hours, rinsed in buffer, dehydrated and embedded in paraffin. Five micron sections were cut, the paraffin removed and the tissue reacted with antibody to ANP (kindly provided by M. Cantin) using the Sternberger method and the antibody-antigen reaction visualized using 4-chloro-1-naphthol (4-Cl-1-N). The blue product was quantified using a scanning and integrating microdensitometer at 570nm, a wavelength specific for 4-Cl-1-N. Product was measured in cells from both atria. Amounts of product are given as integrated extinction which is the absolute absorbance as measured on the densitometer divided by a constant absorbance obtained through a neutral density filter. This enables results from various machines to be compared. For each animal examined, more than 10 sections were analyzed with reaction product being measured in over 100 cells per section. Differences in the mean of product amount between normal and sympathectomized males and females were considered significant at a probability level of 0.05 as analyzed by ANOVA and Tukey's test. The N represents the number of sections analyzed.

	Male		Female	
	Control	Sympathec	Control	Sympathec
N	34	34	34	34
Mean	0.097	0.152	0.149	0.123
Standard Error	0.011	0.012	0.008	0.008

Levels of ANP reactive product in atrial cells of control rats were significantly higher in females (54%) than in males. Following sympathectomy, levels in males significantly increased (57%) to identical levels found in control females. Levels in sympathectomized females, compared to controls showed a slight (19%) but significant decrease. It appears that sympathectomy has paradoxical effects on ANP content in atrial cells of male and female rats. Furthermore, normal female rats appear to have more atrial ANP than males. We are presently examining the implications of this study on the interaction between the autonomic nervous system and the heart and the role of ANP in the control of blood pressure and hypertension.

206.17 ROLE OF 5-HT_2 RECEPTORS IN THE PRESSOR AND RENIN RESPONSES TO QUIPAZINE. R. H. Alper and J. M. Snider*. Dept. Pharmacol., Tox. and Therap., Univ. Kansas Medical Center, Kansas City, KS 66103.

Studies have shown that the indirect serotonin (5-HT) agonist para-chloroamphetamine increases arterial pressure (AP) and plasma renin activity (PRA). Most of the hypertensive response is due to a peripheral effect and was neither 5-HT nor renin dependent. Quipazine is a direct 5-HT agonist which also increases PRA. It has been recently demonstrated that several other 5-HT agonists increase PRA through central 5-HT_2 receptors. It was the purpose of these studies to determine the role of 5-HT_2 receptors in mediating the effects of quipazine on AP and PRA.

AP, heart rate (HR), and PRA were determined in conscious, unrestrained rats 2 or more days after catheters were placed in the femoral artery and vein. Blood samples (0.5 ml) were withdrawn through the arterial catheter prior to and at various times after iv injections of quipazine, LY 53857 (a 5-HT_2 antagonist), or their vehicles. In a preliminary experiment rats were administered the 2 vehicles 5 min apart. AP, HR and PRA were measured prior to any treatment and 5, 15, 30 and 60 min after the second vehicle injection; all 3 parameters remained constant. Quipazine (0.3-3.0 mg/kg) caused dose- and time-dependent increases in AP and PRA with a negligible effect on HR. AP was elevated by all 3 doses; the peak response was approximately 55 mmHg 5 min after the highest dose. PRA was increased at 1 and 3 mg/kg at a maximum of approximately 10 fold. The peak pressor response to quipazine (3 mg/kg) was blocked by LY 53857 at doses as low as 0.03 mg/kg. A partial attenuation was noted at 0.01 mg/kg while 0.003 mg/kg was ineffective. LY 53857 was about 10 times more potent in blocking the renin response in these same rats. LY 53857 at 0.003 mg/kg totally abolished the quipazine-induced increase in PRA while at 0.001 mg/kg the 5-HT antagonist reduced the renin response by about 50%.

The data show that in conscious, unrestrained, normotensive rats, the non-selective 5-HT agonist quipazine produces marked increases in AP and PRA, although the duration of the pressor response was greater than the renin response. The selective 5-HT_2 antagonist LY 53857 inhibited both responses, but had no effect on AP or PRA per se. The difference in the potency of LY 53857 to block these effects suggest that quipazine may act at different sites or receptor subtypes to increase AP and PRA, or just that the pharmacokinetics are more favorable to antagonism of the renin response.

REGENERATION: SPINAL CORD II

207.1 ADULT DORSAL ROOT GANGLION AXONS THAT CONTAIN CALCITONIN GENE RELATED PEPTIDE (CGRP) REGENERATE INTO TRANSPLANTS OF EMBRYONIC SPINAL CORD. B.T. Himes* and A. Tessler, Philadelphia VA Medical Center and Departments of Anatomy and Neurology, The Medical College of Pennsylvania, PA 19129, and J. Houle and P.Reier, Departments of Neurosurgery and Neuroscience, College of Medicine, University of Florida, Gainesville, FL 32160.

Dorsal roots transected in adulthood grow beyond the site of injury but fail to regenerate into spinal cord. We have previously used HRP-tracing methods to show that the central processes of adult DRG neurons regenerate into embryonic spinal cord transplanted into adult host spinal cord suggesting that transplants enhance the ability of dorsal roots to regenerate by (1) providing a more suitable terrain and/or (2) providing factors that augment the neurons' regenerative responses. It is unclear however whether regenerating neurons maintain their normal characteristics and also whether all DRG neurons share this regenerative capacity. DRG neurons can be classified into subsets based on several criteria including their content of CGRP. CGRP in normal adult spinal cord is found in primary afferent fibers and is abolished in the dorsal horn by dorsal rhizotomy, allowing it to serve as a marker for regenerating primary afferent axons. We have therefore studied the dorsal roots that regenerate into transplants using CGRP immunocytochemistry. Adult rats had one side of the L4-5 spinal cord replaced by a transplant of E14 or E15 spinal cord without its DRGs, and the cut dorsal roots were juxtaposed to the transplant. 2-9 months after transplantation CGRP was demonstrated in the grafts. CGRP immunoreactive fibers entered the transplant from the host dorsal root, arborized extensively, and displayed varicosities along their length. Most remained within 0.4mm of the site of entry, but occasional processes penetrated more deeply and some traversed the entire dorsal-ventral extent of the transplant (app. 1mm). Occasional immunoreactive neurons were seen in the transplant but only rarely in the region of these fibers. The results show that DRG neurons which regenerate into embryonic transplants maintain or reestablish their normal capacity to synthesise CGRP and that transplants enhance the capacity to regenerate of at least one subpopulation of DRG neurons.

Supported by the VA Medical Research Service, USAMRDC grant 51930002 and NIH grants NS22316 and NS24707.

207.2 EVIDENCE FOR RUBROSPINAL PLASTICITY IN THE DEVELOPING OPOSSUM. X.M. Xu*, R. Waltzer* and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State Univ., Coll. of Med., Columbus, Ohio 43210.

Rubral axons do not grow around or through spinal lesions in neonatal kittens, although cortical axons do so readily (Bregman and Goldberger, Science, 217:553-555). Rubral axons innervate the spinal cord well before cortical ones, however, (Cabana and Martin, Develop. Brain Res., 15:247-263) and they may simply have lost their potential for plasticity. This hypothesis would be difficult to test in placental mammals because rubrospinal development occurs prenatally, but should be testable in the North American opossum because rubrospinal development occurs after birth. The opossum is born 12 days after conception. We report here on the results of experiments designed to determine if rubrospinal axons are capable of plasticity in the North American opossum.

The rubrospinal tract was lesioned at cervical or thoracic levels in anesthetized adult and pouch-young opossums. Approximately 30 days later, one group of anesthetized animals was subjected to injections of Fast Blue or wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) several segments caudal to the lesion in an attempt to retrogradely label rubral neurons. In another group, the red nucleus contralateral to the lesion was injected with WGA-HRP to orthogradely label rubrospinal axons. In adult animals and older pouch-young, rubral neurons could not be labeled contralateral to the lesion and in the older pouch-young, there was evidence that many axotomized rubrospinal neurons underwent retrograde degeneration (the Gudden effect). In animals subjected to lesions at approximately postnatal day (PD) 20, however, rubral neurons were labeled contralateral to the lesion although evidence for some neuronal loss was still present. In the orthograde transport experiments at the same age, rubrospinal axons could be labeled caudal to the lesion and they seemed to take the most direct route around it. The position of rubrospinal axons caudal to the lesion varied and in one case they were present in the dorsal funiculus. Regardless of position, rubral axons appeared to innervate those areas of the grey matter supplied normally and in several cases they traversed the length of the cord. We have interpreted our results to suggest that rubrospinal axons are capable of plasticity at early stages of development. It is our working hypothesis that all descending spinal pathways are capable of plasticity at some stage of development although differences in critical period may exist. Differences in critical period may reflect differences in developmental history. (Supported by NS-10165).

207.3 REGENERATION OF BULBOSPINAL AXONS DURING REGNERATION OF THE LIZARD TAIL SPINAL CORD. B.M. Davis, M. T. Duffy* and S.B. Simpson, Jr. Dept. of Biological Sciences, Univ. of Illinois at Chicago, Chicago, Il, 60680.

Transection of the lizard (*Anolis carolinensis)* spinal cord at mid-back levels is followed by the infiltration of dense connnective tissue, formation of glial scar, cystic outgrowths of the ependyma, and degeneration of nerve axons separated from their perikarya. No nerve fibers regenerate across the site of injury as demonstrated by Boudain stained sections of the lesioned area. Functional losses are permanent. However, autotomy or transection of the lizard tail results in tail regeneration as well as concomitant CNS axon regeneration. The spinal cord at tail levels regenerates but consists of a simple ependymal tube surrounded by white matter. The radial processes of the ependyma cells form channels through which regenerating axons grow and form fascicles. Electron microscopic analysis reveal up to 2,000 regenerating central axons in tail spinal cord.

Using HRP labeling we have demonstrated that up to 450 bulbospinal axons are found in the normal tail spinal cord. Following regeneration of the tail, few (usually < 20) of the CNS axons that regenerate arise from bulbospinal neurons. In each regenerated animal examined, axons arising from different bulbospinal nuclei were identified indicating that many if not all of the bulbospinal regions are capable of growing regenerate axons. Application of HRP immediately rostral to the regenerating tail labeled a normal number of brainstem neurons. This suggests that the minimal regeneration of bulbospinal axons within the regenerate tail is not due to retraction of bulbospinal axons or to death of bulbospinal neurons. However, the majority of the regenerating axons have a local origin arising from primary sensory or spinal neurons.

These results demonstrate that although long descending bulbospinal axons can regenerate during tail regeneration they do not regenerate following cord transection at mid back level. These regenerating bulbospinal axons can be used as an unequivical criterion to assess CNS axon regeneration in experiments designed to induce spinal cord regeneration at higher cord levels. (MTD, BMD, SBS supported by NS24162 to SBS)

207.4 BULBOSPINAL AND PROPRIOSPINAL CONNECTIONS IN THE SALAMANDER REGENERATED SPINAL CORD M. T. Duffy*, B.M. Davis and S.B. Simpson, Jr. Dept. of Biological Sciences, Univ. of Illinois at Chicago, Chicago, Il, 60680.

Recently, a number of studies have shown that mammalian central nervous system axons can regrow following lesion if given the proper environment (Richardson, 1980; David and Aguayo, 1981; Bently and Aguayo, 1982; Silver and Ogawa, 1983; Goldberg et al., 1986, Bregman, 1986). These findings have renewed interest in regeneration of central nervous system neurons with much of the attention focused on inducing regeneration in species that under normal conditions exhibit little capacity for recovery of function, e.g., rats. While these experiments have produced dramatic and exciting results, they have not revealed the requirements for, or the mechanisms of, successful regeneration. The experiments described here are the first of a series of experiments designed to provide a detailed description of naturally occurring regeneration in an adult system, the salamander spinal cord.

Adult salamanders (*Triturus viridescens)* were completely transected rostral to the lumbar spinal cord. Animals recovered for at least 60 days at which time they swam and walked normally. Animals were then transected 1.0cm caudal to the first transection (mid-lumbar enlargement) and a pledget of HRP was placed between the cut ends of the spinal cord. In the 9 animals that have been examined between104 and 450 HRP labeled bulbospinal neurons were found. In normal animals 700-800 bulbospinal neurons are labeled by HRP application to the lumbar enlargement. The HRP labeled brain stem neurons were found in the hypothalamus, mesencephalon, and myelencephalon. Examination of regenerated axons projecting from the brachial enlargement to the lumbar enlargement showed that, in most cases, a normal number of descending cells reconnected the limb associated regions of the spinal cord.

These results indicate that all regions of the brainstem which normally project to the lumbar spinal cord are able to regenerate axons which grow at least 1.0cm past a spinal transection. The projection arising from the brachial enlargement is also reestablished following low thoracic transection. We conclude from these experiments that the ability to regenerate CNS axons is present in all salamander neurons. Histological examination of the center of the regenerated region revealed that recovery of function in a number of cases was accompanied by restoration of only a small percentage of the white matter found in normal animals. Taken together these results indicate that partial regeneration of descending axons is sufficient to restore locomotion and that rewiring of local spinal circuits may play an important role in recovery of function. (MTD, BMD, SBS supported by NS24162).

207.5 DEVELOPMENT OF CERVICAL SPINAL CORD DENDRITE BUNDLES IN THE RAT. J.B. Taylor*, W.J. Anderson, D.L. Bellinger. (Spon. E.P. Finnerty) Indiana University School of Medicine and Indiana State University, Terre Haute, IN 47809.

Previous studies from our laboratory have revealed three discrete dendrite bundles in the ventral horn of the 30 day old rat cervical spinal cord. A midline dendrite bundle (MDB) in the ventromedial gray matter, (C3-6), a central dendrite bundle (CDB) coursed the medial aspects of the ventral horn, (C3-5), and a lateral dendrite bundle (LDB) in the ventrolateral gray matter, (C2-4). These dendritic bundles were composed of longitudinally oriented dendrites in close apposition. Smaller transverse dendrite bundles radiated from the longitudinal dendrite bundles at right angles and appeared to interconnect the MDB, CDB and LDB. This study was performed to determine whether the cervical dendrite bundles develop postnatally, the degree of dendritic differentiation at birth and the possibility of catecholaminergic axon involvement in bundle formation. Long-Evans hooded rats were bred and at birth litters were reduced to eight pups and assigned an age group. Animals were sacrificed at days 1, 3, 5, 8, 10, 15, 20, 30 and 60. Cervical spinal cords wer dissected from the medullary obex to C8 and prepared for routine histology, Golgi-Cox method, and histofluorescence histochemistry. Our results differed considerably from work done with 30 day old rats. At birth and 5 days the motoneurons appeared to have minimal dendritic growth in all the bundles. Dendritic orientation appeared to be more transverse than longitudinal. A medial and a lateral column of dendritic bundles appeared to be present at the level of C1 and seemed to arise from a single column of motoneurons in the medullary region. At C1 there was a definitive transverse dendritic bundle interconnecting the MDB and LDB. The LDB was found to be present from C1-C7. The CDB was present from C3-C5 and the MDB appeared to be irregular and composed of separate cell groups rather than being continuous. At various cervical levels dendritic subunits appeared to interconnect obliquely the MDB, CDB and LDB. Transverse subunits radiated from the longitudinal bundles at right angles but did not appear as numerous as the oblique subunits. Catecholaminergic fibers were present at birth throughout the dendrite bundles. The CDB appears clearly to represent the phrenic nucleus while the MDB and LDB appear related to both cervical and accessory respiratory musculature. Recent studies indicate these motoneurons are related to cervical and accessory respiratory muscles. The presence of these dendrite bundles may permit the fine tuning of motoneuron activity for better coordination of movements involving synergistic and antagonistic muscle groups.

207.6 LAMININ DISTRIBUTION DURING CORTICOSPINAL TRACT DEVELOPMENT AND AFTER SPINAL CORD INJURY. A. Sosale*, J.A. Robson, and D.J. Stelzner (spon: G.H. Collins). Dept. of Anatomy and Cell Biology, S.U.N.Y. Health Science Center, Syracuse, NY 13210.

The corticospinal tract in the rat is a very useful model for studying development and regeneration in the central nervous system (CNS). The time course of CST development has been well delineated. It enters the spinal cord at birth and its development is completed by postnatal day 14 (P14). Growth of the CST after cutting its normal pathway is also age dependent. After postnatal day 6 (P6), the ability of the CST to grow around spinal injury is greatly diminished. Developing neurites and regenerating axons both require a specific microenvironment in which to grow. In vivo and in vitro studies show that adhesive molecules in the extracellular matrix are of primary importance in neurite outgrowth and elongation. One of the matrix molecules implicated to have a significant impact on neurite outgrowth is laminin.

This study examines the temporal and spatial distribution of laminin normally and after spinal injury during the period of CST elongation. Standard immunofluorescence techniques, staining frozen sections with anti-laminin polyclonal antibody were employed. Over 70 rats of different age groups (newborns, P3,6,9, 12,15 adults and embryos) were used. Particular attention was paid to the dorsal funiculus (dF) where the CST normally grows and the dorsal part of the lateral funiculus (dLF) - a pathway used mainly by the CST after spinal injury. Midthoracic spinal overhemisection lesions were performed on newborn and adult operates. This lesion is similar to injury where developing CST axons have been found to grow abnormally until P6. These animals were sacrificed 3,5,9 and 15 days after surgery and stained and compared together with normal controls. Adequate controls were maintained for each experiment.

Our results indicate that laminin is not present in the dF or the dLF postnatally when the CST is still growing down the spinal cord, though there is some diffuse overall reactivity seen at early embryonic stages. In the normal cord only the spinal roots, vasculature and meninges show laminin reactivity. Laminin is induced at the lesion site and around blood vessels near the lesion in newborn and adult operates at all the time periods examined. There is no increased laminin within the cord either rostral or caudal to the lesion site, ipsilaterally or contralaterally. From our studies it appears that during CST elongation laminin is not a requirement for growth. After injury laminin is localized to the lesion site and since it is induced equally in newborn and adult operates, it apparently is also by itself unrelated to the growth of the CST axons after spinal injury. (Supported by grants EY-03490 and NS14096.)

207.7 THE SWOLLEN NERVE FIBERS FOLLOWING MINOR SPINAL CORD INJURY: REGENERATING OR DEGENERATING ? Y.Naka*, K.Nakai, T.Itakura*, M.Ueno*, T.Okuno*, N.Komai*. Dept. of Neurol. Surg., Wakayama Med. Col., Wakayama 640 Japan. (SPON: T. Shirokawa)

We reported the appearance of swollen fibers immunoreactive to dopamine beta hydroxylase(DBH), vasoactive intestinal polypeptide(VIP) and substance P(SP)in the white matter near the primary lesion in 3 to 14 day-survived animals following the minor spinal cord injury (Naka et al. Soc.Neurosci.Abst. 11 :591, 1985).We regarded those swollen fibers as regenerative. In the present study we examined the alteration of each nerve fibers in later stages following the spinal cord injury and observed suggestive finding that they were regenerative nerve fibers.

Five adult female guinea pigs (250-300 g) were used. In 7 and 12 months after the minor spinal cord injury, the animals were perfused with 2 % paraformaldehyde and 0.25 % glutaraldehyde in cold phosphate buffer (PH 7.4). Parasagittal sections of the injured spinal cord were then processed for peroxidase antiperoxidase immunohistochemistry using antisera against DBH(gifted from Dr.J.Morrison), SP, and VIP. The cytochrome oxidase activity was also examined in the alternative sections.

The most prominent finding in the spinal cord of the long term (7,12 month) survival was the continued existence of similar swollen fibers as in the early stage with intense immunoreactivity against each of the antisera, although their size was larger and more lobulated. They were located in the white matter around the gliotic scar formation caused by the primary cord injury. The swollen axoplasm showed the elevated cytochrome oxidase activity in both early and late stages. Because the degenerating fibers are generally believed to retract and disappear in a relatively short period, it is speculated that the continued existence of swollen fibers with high metabolic activity in the later stages may not be degenerating but regenerating in nature, which is an interpretation consistent with that reported in the cat visual cortex(Nakai, Neurosci.Res. in press).

207.8 USE OF AN ELECTROMAGNETIC FIELD FOCUSSING PROBE TO GENERATE LESIONS IN THE SPINAL CORD OF THE RAT. S.H. Spillers, A.A. Patil*, W.S. Yamanashi*, and D.L. Hill*. Oral Roberts University School of Medicine. Tulsa, OK 74137

Recent reports have described the use of an electromagnetic field focussing (EFF) probe as a neurosurgical tool for cutting, coagulating, and vaporizing (Patil et al in press). The instrument functions as a resonance maximizing current sink and when applied to tissue in a near field of an electromagnetic field results in Eddy current convergence at the point of contact between tissue and probe tip. An insulated stainless steel needle serves as the probe. Hence the heat generated is both intense and focal; and because it is generated by convergent energy, there is very little spread to the surrounding tissues, limiting edema formation and tissue damage. This is in contrast to the laser which generates heat via penetrating energy resulting in more edema and tissue damage.

We are now using the EFF probe to transect the spinal cord of the rat in our ongoing regeneration studies. Because it functions via convergent current the probe can be used at higher wattages than a laser, resulting in focal vaporization of tissue producing a clean section without significant damage to adjacent tissue or edema formation; two factors thought to contribute to scar formation. Further, disruption and distortion of adjacent tissue encountered with a scalpel is avoided because significant pressure is not necessary for vaporization. Any vessels that may be severed during the procedure are coagulated, reducing blood loss. Finally, the size of the probe facilitates the severing of the cord while leaving the major dorsal artery intact, preserving the blood supply to the cord distal to the lesion.

We have begun to use the EFF probe to transect the spinal cord of the rat in regeneration studies. Preliminary results indicate that the EFF probe is superior to either the laser or scalpel, both in generating a clean cut and reducing subsequent scar formation.

207.9 A TEST OF THE ABILITY OF LUMBOSACRAL DORSAL COLUMN AXONS TO GROW AFTER OVERHEMISECTION INJURY OF THE CERVICAL SPINAL CORD IN THE NEWBORN RAT. S.P. Lahr* and D.J. Stelzner. Dept. of Anat. and Cell Biol., SUNY Health Science Center, Syracuse, NY 13210.

The developing corticospinal tract (CST) of the neonatal rat grows around a high cervical or mid-thoracic spinal overhemisection lesion which interrupts its normal pathway in the dorsal funiculus. These axons maintain an aberrant position in the dorsal part of the lateral funiculus, but innervate appropriate areas of gray matter caudal to the lesion for many spinal segments (Bernstein and Stelzner J., Comp. Neurol. 221:382, Stelzner et al., Neurosci. Abst. 12:11). Ascending axons from dorsal root ganglion (DRG) cells are located in the dorsal funiculus adjacent to the CST. We are investigating whether DRG axons will also survive this same spinal lesion in the neonate and grow around it to innervate their normal target, the nucleus gracilis.

A spinal right overhemisection, which cuts the right half of the cord and the left dorsal funiculus, was performed at a high cervical level (C2) in neonatal rat pups within twenty-four hours of birth (n=5). Degeneration from such a lesion is cleared rapidly and is no longer apparent after 3 p.o. days (Gilbert and Stelzner J., Comp Neurol. 184:821). Three months after surgery, and in adult controls (n=2), the cauda equina was exposed and all the dorsal roots from L5 and caudal segments were cut bilaterally. Four days after the dorsal root lesion the animals were sacrificed and processed for Fink-Heimer staining of degenerating axons. Light microscopocic examination revealed degeneration argyrophilia within the dorsal funiculus and dorsal root projection zones of the lower lumbar and sacral segments, and within the postero-medial portion of the dorsal funiculus of thoracic and cervical cord to within 1-2 segments of the cervical overhemisection. Unlike controls, the projection thinned rostrally in thoracic and cervical regions as it approached the lesion and was apparent only along the postero-medial edge of the dorsal funiculus. No degeneration staining was seen in experimental animals rostral to the lesion in the cervical cord or in the nucleus gracilis, except for one animal which had an incomplete cervical lesion.

In this experiment ascending DRG axons, which lie adjacent to the CST, do not show the same ability to grow around an interruption of their normal pathway. We are currently repeating the experiment with a more sensitive transganglionic anterograde labelling technique using a cholera toxin-HRP conjugate. Previous experiments show that the DRG projection is more mature at birth than is the CST. We are presently determining if DRG axons from the caudal levels of the spinal cord have reached the nucleus gracilis at birth and whether these DRG cells survive axotomy by our lesion. Supported by NIH Grant NS 14096 (D.J.S.).

207.10 THE RESPONSE OF CORTICOSPINAL TRACT FIBERS FOLLOWING INJURY AND TRANSPLANTATION IN THE ADULT RAT SPINAL CORD. L. Jakeman and P.J. Reier. Departments of Neuroscience and Neurosurgery, University of Florida, Gainesville, FL, 32610.

Several laboratories have reported that developing corticospinal tract (CST) fibers can grow around lesion sites in neonatal rats. Also, when a graft of fetal spinal cord (FSC) tissue is placed into the immature spinal cord, CST axons will grow into and through the transplant. Together, these findings suggest that developing spinal cord tissue provides a suitable environment for CST elongation. Based upon these observations, we were interested in determining whether FSC grafts could stimulate the persistence or regeneration of adult CST axons which typically retract or die-back after injury. Partial spinal cord aspiration lesions, involving bilateral section of the CST, were made at the C6-C7 level in adult rats. One group received solid tissue transplants of E14 spinal cord tissue, while another group served as lesion controls. Six weeks later, CST fibers were labeled with bilateral application of combined HRP and WGA-HRP to the cortex. Histological examination of lesioned animals showed small cysts and/or areas of tissue necrosis interposed between the caudal border of the labeled CST and the margin of the lesion. The tract exhibited a tapered appearance, with some fibers terminating closer to the cut edge than others. No labeled axons were present directly at the edge of the lesion. A similar degeneration pattern was observed in most of the graft recipients, and consequently, direct apposition between the lesioned tracts and grafts was not routinely achieved. In a limited number of cases, however, fusion of host CST and graft tissues had occurred with no intervening cysts or necrosis. Under these more favorable conditions axons within the tract were observed at the edge of the interface, and in one example, a few axons had extended a short distance into the graft. Although limited, the results of this study suggest that under optimal conditions of host-graft apposition, FSC tissue may promote the persistence of injured CST fibers or stimulate their elongation. The graft recipients that did not differ from lesioned rats in their response to injury suggest that the timing of this apposition may be critical in the influence of embryonic transplants on injured spinal cord axons. Supported by NIH grants NS 22316 and MH 15737.

207.11 TRANSPLANTATION OF FETAL RAT SPINAL CORD INTO LONGSTANDIN CONTUSION INJURIES OF ADULT RAT SPINAL CORD. D. Winialski*, J. Houle', L. Jakeman, & P. Reier. Departments of Neurological Surgery and Neuroscience, University of Florida College of Medicine, Gainesville, FL 32610.

Studies carried out in this laboratory have established that grafts of fetal rat spinal cord tissue will survive and establish some neuronal interactions with host tissue in both acute and longstanding aspirative hemisection cavities of adult rat spinal cord. The current study was carried out in order to evaluate the capacity of fetal tissue grafts to achieve anatomical integration with host tissue in contusion-induced cavitation lesions. Such lesions were made in female rats at the thoraco-lumbar region by a modified Allen weight-drop apparatus in which a 3.25 gram weight was dropped from a height of 20 cm onto an impounder placed on the dorsal spinal cord surface. At 2 to 14 months post-injury E14 fetal rat spinal cord tissue was grafted into the resulting cystic cavities. Transplant recipients were then sacrificed after 2 to 13 months for histological and immunocytochemical analysis.

Two months after contusion lesion, characteristic hemorrhagic necrosis with cavitation extending 5-6 mm in rostral-caudal extent was observed. Only a rim of white matter surrounding the cavity was visible. Greater than 90% of the grafts survived, growing to fill cavities up to 7mm in length. While the grafts appeared to be well interfaced with host tissue, glial fibrillary acidic protein [GFAP] immunocytochemistry revealed a dense matrix of astrocytic processes intervening between host and donor tissue. However, there were several zones of apposition displaying minimal scar formation, allowing direct fusion of host and graft tissue. Examination of 2mm plastic sections revealed regions of neuronal processes traversing the interface. Serotonin immunocytochemistry identified one specific axonal population crossing the rostral host-graft interface, extending into transplant tissue for distances of less than 2mm. This study documents the feasibility of using fetal spinal cord grafts to repair the severely contused spinal cord. Supported by NIH NS22316, PVA NBR 588-6, and APA TC 86-05

EXCITATORY AMINO ACIDS: MECHANISMS

208.1 EXCITATORY AMINO ACID SENSITIVITY OF NEURONAL CULTURES MAINTAINED IN MEDIA CONTAINING POTENT AGONISTS AND MODULATORS. K. Sugiyama and M.L. Mayer. Lab. Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892.

Neuronal cultures of mammalian spinal cord and hippocampus normally express receptors for three classes of glutamate receptor, classified by use of the selective agonists kainate, quisqualate and NMDA. Some recent reports have described culture preparations in which neuronal responses to NMDA were either absent or attenuated (Jahr & Jessell, J. Neurosci **5**, 2281; Lambert & Jensen, Neurosci. Lett **26**, S149). In these studies neurons were maintained in culture media containing either potent modulators of excitatory amino acid responses (DMEM: 400 μM glycine) or both modulators and excitatory amino acid agonists (Ham's F-12: 3 μM Zinc and 100 μM each of glycine, aspartic acid and glutamic acid).

We have examined the sensitivity of hippocampal neurons to kainate and NMDA. Sets of sister cultures were grown in media based on Eagles MEM with an insulin, transferrin nutrient supplement; 3 conditions were tested: 5% horse serum; 5% horse serum + 400 μM glycine; serum free + 400 μM glycine. These conditions were chosen to be similar to DMEM. A second set of cultures was grown in media based either on Ham's F-12 or MEM, to which the nutrient supplement and 5 % horse serum was added. Electrophysiological recording from coded cultures was performed without knowledge of growth conditions, using tight seal whole cell recording and CsCl filled pipettes for voltage clamp.

In the first set of experiments, using DMEM-like growth conditions, no difference in the amplitude of responses to kainate (100 μM) or NMDA (100 μM) was detected between the growth conditions. Responses were assayed on days 7,10 and 15 in culture, and showed a normal development in all media presumablely reflecting an increase in neuronal cell surface area (Mitchell and Westbrook, Soc. Neurosci Abstr **11**, 105).

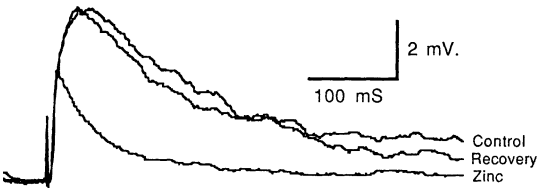
In the second set of experiments on day 7 in culture, no statistical difference was observed in the amplitude of responses to kainate or NMDA between cells grown in F12 medium and MEM medium. However, on days 10 and 15, responses to both kainate and NMDA recorded from neurons maintained in F12 medium became progressively larger than those in MEM medium. The average increase in amplitude compared to responses from cells grown in MEM was: kainate, 86 % on day 10 and 90 % on day 15 in culture; responses to NMDA was also increased by 41 % on day 10 and 60 % on day 15 in culture.

These results indicate that in hippocampal neurons, the sensitivity to kainate or NMDA is not decreased by chronic exposure to high concentrations of glycine. However the sensitivity to both excitatory amino acids increases following prolonged exposure to Ham's F-12 medium, containing both aspartic and glutamic acids. This was unexpected given O'Brien & Fischbach's suggestion (J. Neuroscience **11**, 3290) that L-glutamate down regulates the expression of excitatory amino acid receptors.

208.2 GLYCINE POTENTIATES AND ZINC BLOCKS A SLOW EPSP BETWEEN HIPPOCAMPAL NEURONS IN CULTURE. I.D. Forsythe, G.L. Westbrook and M.L.Mayer. Lab. of Dev. Neurobiology, NICHD, NIH, Bethesda MD. 20892.

Monosynaptic EPSPS mediated by excitatory amino acids can be separated into two kinetically distinct components: A fast conventional EPSP and a slow component which is voltage sensitive, calcium permeable and antagonised by 2-amino-5-phosphonovalerate, indicating that it is mediated by NMDA receptors (Forsythe & Westbrook, J. Physiol. submitted). Recent evidence suggests that the NMDA receptor channel is modulated by several endogenous substances. Sub-micromolar concentrations of glycine have been shown to potentiate NMDA responses by increasing the probability of channel opening via a strychnine insensitive mechanism (Johnson & Ascher, Nature,325:529, 1987). Zinc, on the other hand blocks NMDA channels by a non-competitive mechanism (Westbrook & Mayer, see adjacent abs.). Zinc is present in mossy fibre terminals and is released during synaptic stimulation, while glycine is present in the extracellular fluid. To examine the extent to which synaptic transmission can be modulated by these compounds; we have studied the effect of both glycine and zinc at an excitatory synapse in culture.

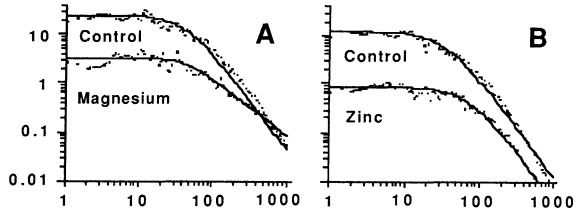
In low density cultures of hippocampal neurons monosynaptic EPSPs were recorded during perfusion of control medium and on the addition of glycine or zinc. The extracellular medium contained 1 mM Ca, no added Mg and 10 μM picrotoxin. Pairs of whole cell patch recordings were made with potassium methyl-sulphate filled electrodes at 25° C. Before perfusion the two components of the EPSP are unaffected by local perfusion of control medium from puffer pipettes; however perfusion of the whole bath by the same medium results in the abolition of the slow, NMDA receptor-mediated component. Switching the perfusion to control medium plus 1 μM glycine restores the slow component to control levels. Local application or perfusion of zinc (50 μM) also substantially reduces the slow component of the EPSP even in the presence of added glycine, as illustrated below. Each trace is the average of 16 sweeps at -67 mV. These results show that glycine and zinc, endogenous neuromodulators, have opposing actions on synaptically-activated NMDA-receptors, and that when the NMDA receptor is blocked by zinc it cannot be potentiated by glycine.



208.3 ZINC AND MAGNESIUM ACT AT SEPARATE SITES ON NMDA-RECEPTOR CHANNELS
G. Westbrook & M.Mayer. Lab.Dev.Neurobiol., NICHD, NIH, Bethesda, MD 20892.

Divalent cations in the extracellular fluid play a critical role in determining the impact of NMDA-receptor activation on neuronal function in that magnesium ions block the channel in a voltage-dependent manner, and calcium is highly permeable with an estimated relative permeability of PCa : PNa of 10.6 (Mayer & Westbrook, J. Physiol., in press). Although other divalent cations such as Ni and Mn can also interact with NMDA channels, this is of little physiological relevance since they are present only in trace quantities. An exception to this is Zn which is present in high concentrations in nerve terminals especially the hippocampal mossy fibers. Of particular interest to receptor function, Zn is released with stimulation with estimated concentrations in the synaptic cleft reaching several hundred micromolar. It is conceivable that synaptic release of Zn may affect synaptic transmission since we have recently found that Zn at micromolar concentrations blocks responses to NMDA, but not to kainate or quisqualate on cultured hippocampal neurons (Mayer & Westbrook, Biophys. J. 51:64a 1987). The effects of zinc are rapidly reversible and thus unlikely to result from reduction of sulfhydryl bonds. Complex formation between zinc and either glycine or agonists is also insufficient to explain the antagonism of responses to NMDA.

The antagonism by zinc is non-competitive, and unlike Mg, the block by Zn is not relieved by depolarization suggesting that Zn and Mg act at separate sites. We have used fluctuation analysis to examine the effects of Zn and Mg on the single channel properties of NMDA-evoked currents. NMDA (1-10 μM) was applied by a large bore flow pipe to evoke a steady inward current at -50 or -60 mV in the presence or absence of either 150 μM Mg or 30 μM Zn. Control spectra of agonist-evoked currents were well fit by a single Lorentzian. In Mg, two Lorentzians were required to adequately describe the power spectra (**A**), consistent with a channel blocking action of Mg. However, similar degrees of antagonism by Zn did not produce a distinct two Lorentzian spectra (**B**), but compared to the action of D-AP5 (5 μM) on the same neurons, Zn did cause a small but consistent reduction in the single channel lifetime and conductance.



208.4 ANALYSIS OF GLUTAMATE CURRENTS AND GLUTAMATE CURRENT NOISE OF CULTURED NEURONS DISSOCIATED FROM SEPTUM OF RAT.
R.Shingai, Y.Ebina*, S.Nagaoka* and T.Ban*.
Dept. of Pharmacology, Sch. of Med. and Dept. of Electric Engineering,Faculty of Engi.,Yamaguchi Univ.,Ube 755 Japan.

Membrane currents induced by pressure applications of L-glutamate (Glu), kainate (Ka), quisqualate (Qa) and NMDA were recorded from cultured neurons dissociated from septal area of rat under the whole cell clamp conditions. All neurons (70 cells) responded to Glu or the agonists. Current-voltage relations showed the Ka-current was larger than the Qa-current when Ka or Qa of 50 uM concentration was applied, however the Qa-current was larger than or equal to the Ka-current when the concentration was reduced to 20 uM or less. The currents induced by a puff of 100 uM NMDA were of similar magnitude to those by 20 uM Qa. Fluctuations of currents were analyzed to study the behavior of the whole glutamate channels of cells. The power spectrum density functions (PSDs) of the fluctuations had the following properties. In almost every case, the high frequency component of PSD had $1/f^{\alpha}$, $1 \leqq \alpha \leqq 2$ properties, however in rare cases α was -0.7(1 cell), 2.2(1 cell), 2.9(1 cell) at some holding potentials. The value of α changed when the holding potential was changed, depending on unknown conditions of cells. The mean of α's for holding potenitals between -20 and -120 mV was 1.7, except the cases of more than 100uM NMDA where α was alwatys 2.0. When the PSDs were fitted by a single Lorenzian or a sum of two Lorenzians (a sum of more than two Lorenzians did not improve the fitting), the cut-off frequencies of them were 22 and 70 msec. Effective conductance was culculated when PSD was fitted well to single Lorenzian which ranged from 1 to 6 pS for Ka, from 0.3 to 5 pS for Qa, from 9 to 35 pS for NMDA. Pressure applications of 10uM Glu and one of three agonists were conducted alternatively to the same cell to find the differences between PSDs for the drugs. These paired applications showed that PSDs by Glu and by an agonist for the same cell had strong correlations, that is, in 16 cells out of 17 cells both PSDs of the pair shifted upward or downward in parallel on the graph of PSD, by the change of the holding potential. It seems that the activation and the kinetics of channels strongly depend on the internal state of the cell.

208.5 NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES ARE REGULATED BY Mg AND GLYCINE.
N. W. Kleckner*, T. A. Verdoorn* and R. Dingledine (SPON: J. Wilson). Dept. Pharmacology and Neurobiology Curriculum, Univ. North Carolina, Chapel Hill, N. C. 27514.

The Xenopus oocyte translation system has been used recently to study the properties of mammalian amino acid receptors, and as a cloning tool for these receptors. RNA preparations that include mRNA encoding NMDA receptors have been notoriously difficult to obtain, perhaps due to the size and/or complexity of NMDA receptor mRNA. We have succeeded in this task. mRNA was isolated from primary cultures of rat brain by the guanidinium thiocyanate - CsCl method and oligo-dT cellulose chromatography. Each oocyte (stage V or VI) received 40-80 ng of mRNA by microinjection and was assayed by voltage clamp after 1-4 days of culture at 19°C in modified Barth's solution. For testing, oocytes were perfused with culture medium and voltage clamped with one or two microelectrodes; drugs were applied by perfusion.

Many mRNA preparations that induced the expression of receptors for kainate and AMPA did not induce NMDA responses in oocytes; only a few mRNA preparations encoded NMDA receptors. At a holding potential of -60 mV, NMDA evoked a smooth, nondesensitizing inward current that was readily reversible on washout. The EC50 of NMDA was approximately 40 μM. The NMDA receptor antagonist, D-2-amino-5-phosphonovaleric acid (D-APV, 10 μM), reduced the amplitude of the ionic current evoked by 100 μM NMDA by 83% (mean of 6 cells). Current-voltage curves of NMDA responses constructed in the presence of 1 mM Mg showed a nonlinear region between -80 and -20 mV, which was nearly eliminated when Mg was omitted from the perfusion fluid. The ratio of chord conductances at -60 mV and -30 mV was 0.13 in Mg but 0.91 without Mg (n=5), attesting to strong voltage dependent block by Mg. The maximum current evoked by NMDA was increased approximately 9-fold by 3 μM glycine, without a marked lateral shift of the NMDA concentration-response curve. Responses to ibotenate (100 μM), but not kainate (100 μM) or AMPA (50 μM) showed a similar voltage-dependence and potentiation by glycine.

These results demonstrate that both regulatory components of the mammalian NMDA receptor - its voltage-dependent block by Mg and potentiation by glycine - are preserved in frog oocytes injected with the appropriate mRNA. This preparation lends itself well to quantitative studies of the regulation of NMDA receptor activation, and may be useful for purification of mRNA(s) encoding these receptors. 208.6 MODULATION OF INTRACELLULAR FREE CALCIUM IN ISOLATED FOETAL BRAIN CELLS: MEASUREMENTS WITH FURA-2.
I. Szekelyhidi, J. F. MacDonald and M. E. Morris. Department of Pharmacology and the Playfair Neuroscience Unit, University of Toronto, Toronto, Canada, M5S 1A1.

Studies using fluorescence analysis have identified two types of calcium-permeable channels in mammalian prenatal brain cells. Brain slices from 12-14 day-old mouse embryos were used to prepare isolated cells in suspension (*Morris et al., Exp. Brain Res. 65: 520, 1987*). After treatment with trypsin/trypsin inhibitor, collagenase and histopaque, separated cells were incubated with 4 μm fura-2/AM at 37° for 90 min to achieve a final intracellular concentration of ≈ 0.1 mM fura-2, and then washed and resuspended in a Ringer solution containing 3 mM KCl, 10 mM glucose and 0.2 mM EGTA. Fluorescence cuvette measurements were made with 4 x 10^6 cells/ml and excitation and emission wavelengths of 339 (±4) and 499 (±8) nm. Limits of calcium binding of the ligand were determined by consecutive additions of ionomycin (1 μM) and Mn^{2+} (3 mM) in the presence of extracellular calcium ($[Ca^{2+}]_o$). Initial levels of intracellular calcium ($[Ca^{2+}]_i$) were 99 (SE ±3, n = 54) nM and increased to 197 (SE ±6) nM when $[Ca^{2+}]_o$ was raised to 1 mM. Subsequently, increasing extracellular potassium ($[K^+]_o$) (between 1-80 mM) evoked dose-dependent accumulations of $[Ca^{2+}]_i$ -- with a maximal increase of ≈ 50 nM at $[K^+]_o$ = 40 mM. These did not occur in the absence of $[Ca^{2+}]_o$ and were attenuated by TTX (200 nM) and nitrendipine (≤ 50 nM) and blocked by verapamil (2.5 μM). Small dose-dependent increases in $[Ca^{2+}]_i$ were seen with hexanol (2-20 mM), pentobarbital (5-200 μM) and ethanol (800 mM), but no changes with ketamine (5-200 μM). Although no changes were observed with either quisqualic acid or the kainate-like *Lathyrus* neurotoxin, L-3-oxalyl-2-aminopropionic acid (50-400 μM), N-methyl-D-aspartate (NMDA) (50-800 μM) evoked increases of 60-80 nM which could be blocked by Mg^{2+}, ketamine (≤ 20 μM) and 2-amino-phosphonovaleric acid (100 μM). A significant and dose-dependent potentiation of submaximal NMDA-evoked responses was produced by glycine (10-1000 nM); and a parallel shift of the NMDA concentration-response curve was apparent. The direct measurement of intracellular calcium in these experiments demonstrates (i) the existence in prenatal brain cells of both voltage-dependent calcium channels and NMDA receptor-activated channels which are permeable to Ca^{2+}, (ii) the ability to modulate influx and accumulation of $[Ca^{2+}]_i$ (by specific organic and inorganic blockers/antagonists, anaesthetic agents, glycine and changes in ion levels), and (iii) the development of a preparation which can be used to assess pharmacological blockade of anoxic/ischaemic brain damage.

208.7 AMPA-ACTIVATED CHANNELS IN MAMMALIAN CEREBELLAR NEURONS. J.L. Christiansen and L.M. Nowak. Dept. of Pharmacology, College of Vet. Med., Cornell University, Ithaca, NY 14853.

It was reported recently that quisqualate, N-methyl-D-aspartate and kainate each activate ion channels with multiple conductance states (Cull-Candy & Usowicz, 1987; Jahr & Stevens, 1987; Ascher & Nowak, in press) and that each agonist activated some conductance states shared by other agonists. One hypothesis is that shared conductance states arise because agonists such as quisqualate and glutamate activate more than one receptor subtype and as mixed agonists they stimulate channel activity consistent with their affinity for the different receptor subtypes. This hypothesis assumes that each receptor is associated with a different channel protein each of which may have multiple conductances. We have approached this problem by studying the pharmacological profiles of quisqualate-activated ion channels in cultured neurons and quisqualate receptors in rat brain membranes by combining patch clamp electrophysiology and radioligand binding assays.

Microexplants of cerebella from one day old rat pups were grown in culture for at least 10 days before use in patch clamp recordings. Whole cell and outside-out patches were made with pipettes containing (in mM): 145 CsCl, 10 EGTA/1.0 $CaCl_2$ and Hepes-K (pH 7.2) from presumptive Purkinje neurons. The extracellular solution contained (in mM): 145 NaCl, 2.8 KCl, 1.0 $CaCl_2$, 10 Hepes-Na (pH 7.2) and 0.3 µM tetrodotoxin. Drugs were applied to cells by fast perfusion (U-tube method) and by bath exchange. Noise analysis was done on whole cell records to estimate channel open time (τ) and current-voltage plots were made from single channel data to measure channel conductance (γ). Radioligand binding assays were performed on well washed rat brain membranes and binding of ^{3}H-AMPA was done in the presence of 100 mM KSCN as described by Murphy et al. (1987). Displacement and saturation binding assays were done using the filtration method.

AMPA (5-10 µM) evoked large whole cell currents associated with a small increase in noise. Power spectra of AMPA noise were fitted by a single Lorenzian in some cells with a τ of near 10ms, or by two Lorenzians in other cells where there was a faster τ of about 1 ms. The single channel data showed predominantly small conductance channels similar to the 8-10 pS channels activated by quisqualate. This channel is also activated by L-glutamate (10-100 µM). Preliminary binding studies reveal that AMPA has a saturable, high affinity binding site with a 20-30 nM K_D on rat brain membranes which was displaceable by L-glutamate with an IC_{50} of roughly 0.3 µM. Further comparisons of the pharmacology of the binding sites and ion channel activation are in progress.

This research was supported by NIH grant #NS24467 to LMN and JLC was supported by a PMA predoctoral fellowship award.

208.8 ACTIONS OF EXCITATORY AMINO ACIDS ON MEMBRANE PROPERTIES OF DEVELOPING PURKINJE NEURONS IN CULTURE. M. Joels*, A.J. Yool, and D.L. Gruol, Div. Preclin. Neurosci. and Endocrin., Scripps Clinic and Res. Foundation, La Jolla, CA 92037.

In previous extracellular studies it has been shown that mature Purkinje neurons (PNs) in culture display a multiphasic response to glutamate (GLU). The response is characterized by an immediate increase in simple spike firing followed by a phase of bursting discharges, reduced activity and finally return to baseline activity (Franklin and Gruol, Neurosci. Abstr. 12, 1986). The effects of the excitatory amino acid agonist quisqualate (QUIS) were similar to those of GLU. Kainic acid (KA) on the other hand only induced an increase in simple spike firing. Immature PNs (7 days in culture) were excited by GLU, QUIS and KA but did not display the complex responses seen in the mature cells. With whole cell and single channel recording techniques we have investigated the changes in membrane properties and ion channel activity that may underlie the extracellularly observed responses. Recordings were made from neurons at two developmental stages; 7-9 days in culture, when PNs have only thin neurites and at 12-16 days in culture, when branching dendrites are present. GLU (10 µM), QUIS (1 µM) or KA (10 µM) were ejected from glass pipettes by pressure. In whole cell recordings from identified PNs (n=32) mean resting membrane potential was -56.7±1.2mV (±SEM). Mean input resistance (Rin) was 466±136MΩ for the immature PNs (7-9 days) and 260±37MΩ for the older PNs (~15 days). At both ages, GLU induced a depolarization (24.0±1.9mV) accompanied by a decrease in Rin. In approximately half of the cells the depolarization was followed by a small (3-4mV) hyperpolarization. In mature PNs the total duration of the responses (116±31sec) was longer than in immature cells (50±8.5sec). QUIS evoked prolonged depolarizations (22.1±2.5mV) accompanied by a decrease in Rin followed by a pronounced hyperpolarization (5.9±1.8mV). The GLU and QUIS depolarizations were characterized by an initial burst of spikes, a period of decreased spike-amplitude, gradual recovery of spike amplitude, then increased firing relative to control. During the subsequent repolarizing and hyperpolarizing phases, spike frequency was reduced. In contrast to GLU and QUIS, KA mainly induced a small (13±1.3mV) and short lasting (~25sec) depolarization and increase in spike frequency. These data indicate that PNs show differential membrane responses to the excitatory amino acid agonists, QUIS being the most potent. In preliminary single channel studies using the cell attached configuration, activation of a small conductance K+ channel was associated with the inhibitory phase of the QUIS response. Further studies of amino acid evoked changes in channel activity are in progress. (Supported by NIAAA Grant AA06665 to DLG and AA07456; C & C Huygens Grant H88-145 from the Dutch ZWO to MJ).

208.9 QUANTITATIVE STUDY OF THE USE DEPENDENT BLOCK OF EXCITATORY AMINO ACID CURRENTS BY KETAMINE AND PHENCYCLIDINE. J.F. MacDonald, P. Pahapill, I. Mody and P.S. Pennefather. Playfair Neurosci. Unit, The Toronto Hosp. & Dept. Physiology & Faculty of Pharmacy, Univ. Toronto, Toronto, Ont. M5T 2S8.

We have shown previously that ketamine will block the response to NMDA agonists in a use-dependent manner. Both the onset and offset of blockade is enhanced by repeated activation of NMDA receptors. This suggests that ketamine interacts selectively with the open channel state of the receptor and if the channel closes while blocked, the ability of ketamine to dissociate is greatly reduced. In effect, ketamine becomes trapped on the channel. The guarded receptor hypothesis proposed by Starmer et al. (Biophys. J. 49, 913, 1986) provides equations to describe this type of blockade. We have applied these equations to the use-dependent blockade of excitatory amino acid currents.

Currents evoked by brief pressure applications of L-aspartate were recorded in cultured murine hippocampal neurones with a patch electrode in the whole-cell configuration and a discontinuous voltage-clamp. Responses rose rapidly and decayed with a time constant of 1 to 2 s. The equations allow the rates of interaction during and between the response to be calculated from the fractional decrease per pulse of agonist, the steady state level of blockade and the frequency-dependence of the blockade. The analysis was simplified because the blockade by ketamine was independent of the frequency of agonist application, suggesting that the interaction was negligible between pulses.

At -60 mV, the calculated forward and reverse rates of interaction with the open channel for ketamine were 2×10^4 M^{-1} s^{-1} and 0.1 s^{-1}, respectively. These rate constants were independent of ketamine concentration and predict an affinity of 5 µM. Changing the pH from 7.4 to 9.0 reduced the fraction of ketamine that is positively charged (pK_a=7.5) and decreased the forward rate constant, implying that it is the charged form of ketamine that is most potent. With phencyclidine, the forward rate constant was similar to ketamine but the reverse rate constant was ten times slower; thus, accounting for the greater potency of this agent. The channel activated by L-aspartate has a mean open time of 5 ms and therefore we would predict that in the presence of a half-maximal concentration of ketamine an individual channel would have to open or close on average 2000 times before becoming blocked or unblocked.

The guarded receptor hypothesis provides a useful model for interpreting the actions of ketamine and phencyclidine on the NMDA-gated channel. Supported by MRC of Canada.

208.10 EFFECTS OF EXCITATORY AMINO ACIDS ON Ca^{2+}- AND K^+-CHANNELS IN RAT BRAIN SYNAPTOSOMES. M. Simonato*, R. Jope and L. Beani* (SPON: M. Koenig). Department of Pharmacology, University of Alabama at Birmingham, Birmingham, AL 35294 and Institute of Pharmacology, University of Ferrara, 44100 Ferrara, Italy.

Recent evidence indicates that excitatory amino acids play an important role in the normal activity of the mammalian CNS and in neuronal damage associated with a number of disorders. An association has been established between excitatory amino acid-induced cell death and elevated intracellular calcium. In this study we examined the effects of glutamate, kainate and N-methyl-D-aspartate (NMDA) on synaptosomal flux of calcium and rubidium (as an indicator of K^+ flux). This approach allows the measurement of direct effects on cation fluxes in nerve terminals, the site of presynaptic modulation of release and a possible site of action of excitatory amino acids.

Ca^{2+} influx mediated by fast channels (1 sec) has been studied in rat cortical and hippocampal synaptosomes by measuring influx in low K^+ and high K^+ media. The rate of Ca^{2+} influx in low K^+ and the net stimulation by high K^+ in cortical synaptosomes are 0.127 ± 0.015 and 0.607 ± 0.060 nmoles/mg prot, respectively, while in hippocampal synaptosomes they are 0.381 ± 0.057 and 0.397 ± 0.036, respectively.

Glutamate (5 mM) significantly increased the resting influx of $^{45}Ca^{++}$ in cortical synaptosomes (146 ± 8% of control), and decreased the net uptake after depolarization (76 ± 6%); glutamate did not have a significant effect in the hippocampus. Kainic acid (5 mM) did not alter cortical synaptosomal $^{45}Ca^{2+}$ flux, but decreased resting influx (73 ± 3%) and increased the net uptake (137 ± 18%) in the hippocampus. NMDA (5 mM) had no significant effect on any of these measures.

K^+ channels were studied by measuring $^{86}Rb^+$ efflux from synaptosomes purified from rat forebrain and preloaded with $^{86}Rb^+$ by the method of Bartschat and Blaustein (J. Physiol. 361, 419, 1985). The effects of glutamate, kainic acid and NMDA were measured at 1, 3 and 5 sec, in media containing low K^+, high K^+ without Ca^{2+} and high K^+ with Ca^{2+}. These results will be discussed with regard to the direct effects of excitatory amino acids on cation fluxes in nerve endings.

208.11 PHARMACOLOGICAL MANIPULATION OF GLUTAMATE-INDUCED CALCIUM INFLUX IN CULTURED NEURONS. A. W. Probert* and F. W. Marcoux (SPON: J. Marriott). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

The excitatory amino acid, glutamate, exerts neurotoxic effects in vitro when present in high concentrations. These excitotoxic effects have been linked to the NMDA-type glutamate receptor and reported to involve calcium accumulation intracellularly. Whereas NMDA antagonists have been shown to prevent glutamate-induced excitotoxicity, less is known regarding their effects on calcium influx. We studied the effects of NMDA antagonists and other drugs on calcium influx induced by excitotoxic concentrations of glutamate in mammalian cultured neurons. Eighteen day old cortical neurons isolated from fetal rat brain were co-incubated in 100 μM L-glutamate and varying concentrations of test compounds. Calcium influx was assessed by measuring neuronal accumulation of $^{45}Ca^{++}$ from the culture medium.

Compounds examined included the competitive NMDA antagonists, 2-amino-7-phosphonoheptanoic acid (7-APH), 4-(3-phosphonopropyl)-2-piperazinecarboxylic acid (CPP) and gamma-D-glutamylglycine (DGG) and the non-competitive NMDA antagonists, ketamine (KET), phencyclidine (PCP) and (+)-10,11-dihydro-5-methyl-5H-dibenzo [a,d] cyclohepten-5,10 imine (MK-801).

CPP, DGG and 7-APH inhibited glutamate-induced $^{45}Ca^{++}$ influx with IC_{50}s of 28, 156 and 245 μM, respectively. MK-801, PCP and KET inhibited $^{45}Ca^{++}$ influx more potently with IC_{50}s of 0.10, 0.16 and 6.8 μM, respectively. These results with known NMDA antagonists parallel in rank order of potency other reports on the antiexcitotoxic actions of the compounds; this suggests that inhibition of Ca^{++} influx is involved in the antiexcitotoxic effects of NMDA antagonists.

208.12 ROLE OF NMDA-ACTIVATED AND VOLTAGE-DEPENDENT CALCIUM CHANNELS IN THE INDUCTION OF HIPPOCAMPAL LONG-TERM POTENTIATION. A.H. Ganong and T.H. Brown. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The induction of long-term synaptic potentiation in hippocampal CA1 pyramidal neurons requires conjuctive pre- and post-synaptic activity (Kelso, S.R., Ganong, A.H., and Brown, T. H., PNAS, 83: 5326-5330, 1986). Several lines of evidence suggest that one of the critical steps in the induction mechanism may involve increases in intracellular free calcium in the postsynaptic neuron. One formal model predicts that calcium entry through voltage-dependent calcium channels in the spine head can account for the spatiotemporal features of associative LTP (Gamble, E., and Koch, C., Science, in press). An alternative model suggests that calcium entry through the channel coupled to the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor is necessary for the induction of LTP. We have begun to test differential predictions of these models in the Schaffer-CA1 synapse.

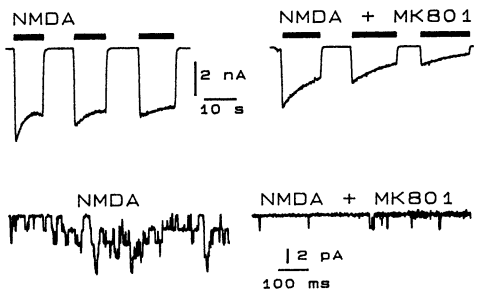
Intracellular recordings were from CA1 pyramidal neurons in rat hippocampal slices. The medium contained picrotoxin to reduce the synaptic inhibition that accompanies stimulation of the Schaffer excitatory input. The intracellular electrode contained 2 M CsCl and 50 mM QX-314 or QX-222 in order to suppress sodium spikes and help maintain postsynaptic potential control. Stimulus intensity was adjusted to elicit EPSPs of about 5 mV peak amplitude at a holding potential of -80 mV. As we have shown previously, high frequency presynaptic stimulation (100 Hz for 200 msec, 5 repetitions) during application of a voltage clamp to the postsynaptic neuron did not produce LTP. LTP was induced if the presynaptic stimulation was paired with an outward current step sufficient to elicit a QX-314-resistant spike, or a voltage-clamp step to -20 mV (which elicited a large inward current). LTP was not induced by either an outward current step alone (which elicited a QX-314-resistant spike), or a voltage-clamp step sufficient to induce a inward current.

Application of the NMDA receptor antagonist 2-amino-5-phosphonopentanoate (AP5) blocked the induction of LTP even if the intensity of the stimulation was sufficient to produce a QX-222-resistant spike during the depolarization caused by the high frequency afferent stimulation. The presence of AP5 prevented the induction of LTP even when strong afferent stimulation was paired with additional postsynaptic depolarization from the intracellular electrode.

These results are less easily explained by the Gamble-Koch model than the alternative. (Supported by NRSA NS08042-02, the McKnight Foundation, and AFOSR Contract F49620.)

208.13 NMDA-ACTIVATED CURRENTS IN RAT NEOCORTICAL NEURONS ARE BLOCKED BY THE ANTICONVULSANT MK-801. J.E. Huettner and B.P. Bean. Dept. of Neurobiology, Harvard Medical School, 25 Shattuck St., Boston, MA 02115

We have used whole-cell and single channel recording to study the action of MK-801 (Wong et al., PNAS 83:7104, 1986) on currents elicited by excitatory amino acids. Cortical neurons from young rats were maintained in cell culture for 1-3 weeks. Electrodes contained (in mM) Cs-methanesulfonate 120; HEPES 10 pH 7.4; EGTA 10; Mg 5; ATP 4 and GTP 0.3. Cells were clamped at -60 to -80 mV and drugs were applied at 1-50 uM (in NaCl 160; HEPES 10 pH 7.4; CaCl2 2) for 1-10 sec by local perfusion. NMDA (+1uM glycine), kainate and quisqualate (Quis) evoked inward currents in every cell. Application of 2 uM MK-801 +1 uM glycine for 10-20 sec had no effect on the response evoked by subsequent application of NMDA, kainate or Quis. When NMDA and MK-801 were applied simultaneously, the inward current elicited by NMDA decreased steadily with a time constant of several seconds. After washout with control solution, responses to NMDA recovered very slowly. Exposure to NMDA speeded the recovery. These results suggest that MK-801 blocks the channel activated by NMDA and that binding and unbinding of the drug are facilitated when the channel is open. MK-801 did not diminish currents elicited by kainate or Quis. Application of NMDA to outside-out patches activated channels of 45 pS. MK-801 reduced channel activity without changing unitary conductance.



208.14 EXCITATORY AMINO ACID RECEPTORS FROM RAT BRAIN EXPRESSED IN XENOPUS OOCTYES: SINGLE CHANNEL RECORDINGS. A.M.J. VanDongen(*), G. Frech(*), R. Joho(*) and A.M. Brown. Dept. Physiol. and Molec. Biophys., Baylor College of Medicine, 1 Baylor Plaza, Houston, TX 77030.

Frog oocytes microinjected with mRNA can express exogeneous glutamate receptors (Gundersen et al, 1984, Proc.R.Soc.B211:127). We are using this powerful expression system to study the electrophysiological and molecular biological properties of excitatory amino acid receptors. At least three distinct types of glutamate receptors, characterized by the specific agonists NMDA, kainate and quisqualate have been proposed for the mammalian central nervous system. Reports by Jahr and Stevens (1987, Nature 325:522) and Cull-Candy and Usowicz (ibid p525) on single channel currents have shown that all agonists activate the same set of multiple conductances. However, each agonist predominantly activates one subset of conductances. Direct transitions between all the levels were observed. Taken together, the existence of a complex molecular entity, consisting of a set of receptors coupled (conjointly or separately) to an ionophore with multiple conductance states is suggested.

We micro-injected oocytes from Xenopus laevis with total mRNA isolated from whole rat brain or with size-fractionated mRNA. After 2-6 days at 19°C, whole cell two-electrode voltage clamp experiments showed inward currents following bath perfusion of kainate, glutamate, quisqualate and aspartate. Single channel current measurements were performed using outside-out patches excised from the oocyte membrane. Application of kainate activated multiple conductance levels with similar characteristics as those reported for native neuronal membranes. Preliminary data indicate that the response to glutamate may be different.

208.15 MECHANISMS BY WHICH QUISQUALATE SUPPRESSES KAINATE INDUCED ELEVATIONS OF CEREBELLAR CYCLIC GMP. P.P. McCaslin* and W.W. Morgan. Dept. of Cellular & Structural Biology, The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Primary cultures of cerebellar neurons from 8 day old rat pups were grown for 14 days in vitro in antibiotic-free media and then analysed for changes in both cyclic guanosine monophosphate (cGMP) and the influx of ^{45}Ca in response to several excitatory amino acids (EAA) or related antagonists. We have previously reported that kainic acid (KA), N-methyl-d-aspartate (NMDA) and quisqualic acid (QA; listed in order of potency) produce dose-, time- and calcium-dependent elevations of cGMP in these cultures. The effects of QA and NMDA on this parameter were additive as were the effects of KA and NMDA, however, 100 μM of QA completely prevented the KA-induced elevation of this cyclic nucleotide. Here, using Shield's analysis, we report that concentrations of QA as low as 2.5 μM (which has no effect on cGMP at this concentration) significantly reduced the elevations of cGMP induced by 100 μM KA by 25%. By contrast, 100 μM concentrations of the EAA antagonists, cis-2,3-piperidine dicarboxylic acid (PDA) and glutamylaminomethylsulphonic acid (GAMS), were required to reduce the effect of KA by an equivalent amount. Since binding studies have shown that KA has a 30-fold greater affinity for the KA-receptor than does QA, it is possible that the effect of QA on preventing the KA-induced elevation of cGMP is at some site removed from the KA receptor recognition site(s). Therefore, the EAA-stimulated influx of ^{45}Ca into these neuronal cultures was examined. Each of the three EAA agonists produced dose- and time-dependent increases in the influx of calcium and in the same order of potency as that seen with cGMP production. Additionally, QA prevented the KA-induced influx of ^{45}Ca in a similar manner to its antagonism of the KA-induced cGMP elevation. On the other hand, QA did not alter the stimulation of ^{45}Ca influx induced by NMDA. Collectively, these data suggest that QA selectively antagonizes the stimulatory effects of KA at least on cGMP formation in cultured cerebellar neurons and does so at least in part by suppressing KA-mediated calcium influx. Supported by DA 00083 and DA 00755 to WWM.

208.16 PERINATAL HYPOXIA-ISCHEMIA ENHANCES QUISQUALIC ACID(QA) STIMULATED PHOSPHOINOSITIDE(PPI) TURNOVER. C. K. Chen*, F. Silverstein*, S. K. Fisher, D. Statman* and M. V. Johnston, Neuroscience laboratories, Univ. of Michigan, Ann Arbor, MI 48104

Several lines of evidence indicate that enhanced release of the excitatory neurotransmitter glutamic acid contributes to the pathogenesis of hypoxic-ischemic neuronal damage. In neonatal animals, using in vitro autoradiography with ^{3}H-glutamate(GLU), we found that a focal cerebral hypoxic-ischemic insult leads to marked inhibition of GLU binding in target areas for irreversible ischemic damage(e.g., hippocampus and striatum) 24 hrs after injury(Silverstein F. et al., Dev. Br. Res., in press). At this developmental stage, Nicoletti et al(PNAS., 83:1931, 1986) showed that excitatory amino acid recognition sites are coupled to inositol phospholipid metabolism and that the GLU agonist quisqualic acid(QA) potently stimulates PPI hydrolysis. To assess the functional correlates of the acute reduction in GLU binding we observed, in this study, we assayed QA stimulated PPI turnover in hypoxic-ischemic tissue.

7 d.o. rat pups underwent right carotid artery ligation(RCL), followed by exposure to 8% oxygen for 2.5 hrs; this procedure predictably results in unilateral forebrain injury ipsilateral to ligation. Pups and litter-mate controls were sacrificed 24 hrs post-hypoxia, hippocampus(HIP) and striatum(STR) were dissected out and brain slices were prepared. For each anatomic region, tissue samples from the side of ligation, the contralateral hemisphere, and unoperated controls were prepared. In tissue preincubated with ^{3}H-myo-inositol, the accumulation of inositol phosphates(IPs) was measured, in the presence of Li, with addition of QA(10^{-4} or 10^{-6} M) or the cholinergic agonist carbamoylcholine(10^{-4} or 10^{-2} M).

We found that QA(10^{-4} M) preferentially stimulated PPI hydrolysis in HIP and STR ipsilateral to ligation. For each tissue sample, total IPs were expressed as % of basal. In HIP, agonist stimulated IPs accumulation was 1053±237% ipsilateral to RCL, 588±134% in the contralateral hemisphere and 631±147% in controls(N=9 assays, $p<0.005$, one-tailed paired t test); in STR, corresponding values were: 801±157%, 474±89%, and 506±115%($p<0.05$). In contrast, with the lower concentration of QA(10^{-6} M) and with both doses of carbamoylcholine there was no preferential stimulation of IP hydrolysis in ischemic tissue.

The data suggest that hypoxia-ischemia enhances coupling between the reduced number of glutamate binding sites remaining in the injured brain and PPI turnover. The changes in QA stimulated PPI turnover provide additional evidence for selective involvement of glutamate synapses in the evolution of neuronal damage. Enhanced PPI turnover may be related to altered neuronal excitability and/or regenerative responses which follow hypoxic-ischemic injury.

208.17 EFFECTS OF EXCITATORY AMINO ACID ANALOGUES ON PHOSPHOINOSITIDE HYDROLYSIS IN RAT BRAIN. F.T. Crews and M.R. McElhaney*. Department of Pharmacology, College of Medicine, Box J-267, JHMHC, University of Florida, Gainesville, FL 32610.

Glutamate stimulates the hydrolysis of phosphoinositides (PI) in the cerebral cortex, hippocampus and striatum. The glutamate analogues ibotenate, quisqualate, and N-methyl-D-aspartic acid (NMDA) were studied in all three brain regions to determine which glutamate receptors were involved. Quisqualate was the most potent compound in all three brain regions. The dose response curve in the cerebral cortex was sigmoidal with an ED_{50} of approximately 15nM. In the striatum and hippocampus the curve was biphasic with the first phase similar to the cerebral cortex curve and a second phase at higher concentrations. Ibotenate was more effective at stimulating PI hydrolysis than quisqualate or NMDA in the cerebral cortex. All three agents were equally effective in the hippocampus and NMDA was much less effective than either of the other two agents in the striatum. Ibotenate and NMDA were additive in all three brain regions, whereas neither ibotenate and quisqualate, nor NMDA and quisqualate were additive. Glutamate receptor subtype coupling to PI hydrolysis will be discussed. (Funded by AA06069)

209.1 IONIC DEPENDENCE DISTRIBUTION, AND PHARMACOLOGICAL PROPERTIES OF QUISQUALATE-SENSITIVE [^{3}H]GLUTAMATE BINDING SITES IN RAT BRAIN
J T Greenamyre, J J Cha, J B Penney, and A B Young. Department of Neurology and Neuroscience Program, University of Michigan, Ann Arbor MI 48104

Quisqualic acid, an analog of glutamic acid, selectively interacts with a subclass of glutamate receptors. Quantitative autoradiographic techniques were used to study quisqualate-sensitive [^{3}H]glutamate receptors in rat brain. Adult rat brains were cut into 20µm sections and thaw-mounted onto gelatin-coated glass slides. Brain sections were then incubated with [^{3}H]glutamate (200nM) in the presence of varying concentrations of quisqualate or competitors. After rinsing with cold buffer and drying, glass slides were apposed to tritium-sensitive film and allowed to expose for 2-3 weeks. The resultant film images were analyzed via computer-assisted densitometry.

Quisqualate-sensitive [^{3}H]glutamate binding sites were found to be distributed throughout all parts of the rat brain. The relative distribution of quisqualate-sensitive [^{3}H]glutamate binding sites was: cerebellar molecular layer > stratum moleculare of the dentate gyrus = entorhinal cortex > stratum radiatum of CA$_1$ > cerebellar granule layer > striatum. No displacement of binding was observed in precentral cortex. Of these areas, the cerebellar molecular layer had the highest proportion (79%) of [^{3}H]glutamate binding sites displaceable by quisqualate followed by cerebellar granule layer (62%), striatum (34%), entorhinal cortex (31%) and stratum moleculare and stratum radiatum of the hippocampus (27%).

Binding of [^{3}H]glutamate was influenced by both calcium and chloride ions. Chloride ions (at concentrations up to 86mM) exerted a marked effect on quisqualate-sensitive [^{3}H]glutamate binding, with a maximal stimulation by chloride occurring at 40mM. Calcium (0.1uM to 100mM) also stimulated quisqualate-sensitive binding, but only in the presence of chloride. The maximal amount of stimulation by calcium occurred at 10mM for all concentrations of chloride tested. The stimulation of binding exerted by chloride did not depend on the presence of calcium. Calcium- and chloride-enhanced binding was completely quisqualate-sensitive: in the presence of 2.5µM quisqualate, no ionic-dependent increase in binding was observed.

[^{3}H]Glutamate binding in the cerebellar molecular layer was reduced 60% by 100µM L-serine-O-sulphate, 45% by 100µM N-acetylaspartyl-glutamate, 21% by AMPA and 16% by 100µM N-methyl-D-aspartate. There was no significant reduction of binding by kynurenate, GAMS, L-aspartate, or L-2-aminophosphonobutyrate (APB), all tested at 100µM. The calcium- and chloride-stimulated quisqualate-sensitive binding site thus does not appear to be an NMDA or APB receptor.

209.2 QUANTITATIVE AUTORADIOGRAPHY OF GLUTAMATE RECEPTORS IN THE FELINE MOTOR THALAMUS.
G.R. Zuercher*, T. DeBoon* and K. Kultas-Ilinsky. (SPON: I. Ilinsky) Dept. of Anatomy, University of Iowa College of Medicine, Iowa City, IA 52242.

Though evidence points to glutamate (Glu) as the neurotransmitter in corticothalamic projections, specific Glu receptor subtypes associated with these pathways in individual thalamic nuclei remain unknown. In these studies we used quantitative receptor binding autoradiographic techniques with computer-assisted image analysis to determine the presence, binding parameters, and topography of Glu receptor subtypes in the ventral anterior (VA), ventral medial (VM), and ventral lateral (VL) thalamic nuclei. Binding assays were performed on serial coronal sections of the thalamus using an incubation medium consisting of 50 mM Tris-HCl buffer, pH 7.4, with 2.5 mM $CaCl_2$ containing varying concentrations of ^{3}H-Glu and one of the following displacers: quisqualate (QUIS), N-methyl-D-aspartate (NMDA), kainate (KA), homocysteine (HO), and amino-3-hydroxy-5-methyl-4 isoxazolepropionate (AMPA). In a separate series of experiments, ^{3}H-N-acetyl-aspartyl-glutamate (^{3}H-NAAG) was used as a ligand. The binding parameters (Bmax, K_D) were determined from the data obtained from the thalamic regions of interest of digitized images of autoradiographs. Autoradiographic tritium standards (Amersham) were used for construction of calibration curves.

The ^{3}H-Glu binding under the incubation conditions employed was saturable and a high density of binding sites was found throughout the thalamus without much variation between individual thalamic nuclei. A 40% inhibition by 5.0 µM QUIS of specific ^{3}H-Glu binding indicated that this receptor subtype was indeed present in the motor thalamus. Only 12% inhibition was observed with 10 µM HO, whereas addition of 30 µM KA or 100 µM NMDA induced enhancement of ^{3}H-Glu binding under the same conditions. We are now studying the effect of the same agents on ^{3}H-Glu binding with the use of Cl^- and Ca^{++} free incubation medium in an attempt to dissect the KA and NMDA sites from the total ^{3}H-Glu binding. Moreover, digital subtractions of images of ^{3}H-Glu binding with and without displacers are being performed to determine the distribution pattern of individual Glu receptor subtypes in the cat motor thalamus.

The ^{3}H-NAAG binding experiments demonstrated an extremely low density of ^{3}H-NAAG receptor sites in the thalamus. This was in contrast to a high concentration of these sites in the caudate present in the same sections. This suggests an insignificant role of the NAAG receptors in the cat motor thalamus. (Supported by NIH NS RO1 19280.)

209.3 EFFECTS OF SPIDER VENOM ON VERTEBRATE CNS GLUTAMATE BINDING.
Jean Hollis*, L.M. Kerr, J.K. Wamsley, T.N. Parks, and H. Jackson. Departments of Psychiatry and Anatomy, University of Utah School of Medicine, Salt Lake City, Utah 84132.

Certain spider venoms have been shown to suppress glutamate-mediated synaptic transmission in both insects and vertebrates. Particularly in the case of the vertebrate CNS, however, very little is known about the mechanism of these effects. In order to investigate the site of action of spider toxins and their possible applications as probes for the study of glutamate-mediated transmission, we have begun examining effects of spider venoms on [3H]-glutamate binding. Partially-purified fractions of venoms from several species have been tested against glutamate binding to sections of both rat and chick brain (after the methods of Halpain et al., J. Neurosci. 4:2247). In most experiments, non-radioactive glutamate was used as the displacer to determine specific binding, which ranged from about 65-75%. Results were similar using either rat or chick tissue.

We have previously shown that partially-purified material from the venom of the Hololena curta spider suppresses synaptic transmission mediated by non-NMDA receptors in chick brain. In the present study, we found that this material also produces dose-dependent reduction of specific glutamate binding to either chick or rat brain with a 50% reduction at a concentration of about 0.5%. To examine whether the toxin might be acting preferentially at particular classes of glutamate receptors, we tested its effects when combined with either NMDA, kainate, or quisqualate. The expectation was that we might observe a greater reduction in binding when the toxin was combined with a ligand specific for a class of receptor not affected by the toxin alone. Surprisingly, we found that glutamate binding increased to control levels in the presence of the spider toxin and any of these three ligands. When tested alone, kainate (1 mM) reduced glutamate binding by 94% and quisqualate (1 mM) reduced binding by 85%. NMDA (1 mM) alone had little effect on glutamate binding but nonetheless appeared capable of eliminating the effects of the spider toxin on binding. Pending further study, we suggest these findings may reflect a complex allosteric interaction between binding sites for these ligands. Such an interpretation is consistent with the recent hypothesis that the various classes of glutamate receptor-channel complexes may in fact reflect different functional states of a single structure (Jahr and Stevens, Nature 325:522).

209.4 **L-GLUTAMATE BINDING SITE ON N18-RE-105 NEUROBLASTOMA HYBRID CELLS REPRESENTS A SEQUESTRATION PROCESS.**
L. M. Boland, B. Berry*, and R. Dingledine. Dept. of Pharmacology and Neurobiology Curriculum, Univ. North Carolina, Chapel Hill, N.C. 27514

An L-glutamate (L-glu) binding site was described on the neuroblastoma x retina hybrid cell line, N18-RE-105, (Malouf et. al., JBC, 259:12756, 1984), and evidence was presented that this site is an aminophosphonobutyric acid (APB)-sensitive, quisqualate-type of excitatory amino acid (EAA) receptor. We performed electrophysiological and radioligand binding studies on these cells in order to directly test the idea that the binding site discovered is an EAA receptor.

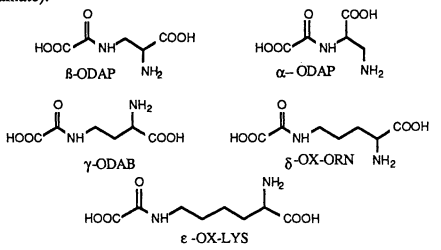
N18-RE-105 cells demonstrate many neuronal properties. These cells were strongly immunofluorescent for neurofilament but not for glial fibrillary acidic protein. In whole cell patch clamp experiments, cells had a resting potential up to -56 mV. They exhibited a number of voltage-dependent ionic currents, including a TTX-sensitive Na current, a 4-AP-sensitive K current, and a slow Ca current that could be blocked by cobalt. However, even when cells were grown in the absence of glutamine or in conditions that enhanced process growth (2% DMSO, 0-1% serum), perfusion with L-glu (3-300µM), L-glu plus glycine (3-20µM), or kainate (5-300µM) did not evoke the inward current expected of a glutamate receptor/channel complex.

Specific binding of [3H]-L-glu to washed membranes at 37°C demonstrated saturable binding sites with an apparent Kd of 0.64 µM and Bmax of 69 pmoles/mg protein. Binding was inhibited by quisqualate (Kd = 0.25 µM), DL-APB (Kd = 5.4 µM), and L-cystine (Kd = 0.17 µM), but not reduced by 1 mM kainate or N-methyl-DL-aspartate. Glutamate binding was subjected to similar tests described by Kessler et. al. (J. Neurochem., 48:1191, 1987) to distinguish binding from an exchange process. Binding of 100 nM [3H]-L-glu was stimulated by chloride (2-fold by 10 mM NaCl) but reduced by Na (half-maximal inhibition at 20 mM Na methylsulfate). Binding was also reduced 54% by 0.01% digitonin and 42% by hyperosmotic (400 mM glucose) assay medium. [3H]-L-glu bound to equilibrium at 37°C could be released from membranes much more effectively in the presence of a saturating concentration (100 µM) of unlabelled glutamate (53% released after 20 min.) than unlabelled quisqualate (30% released after 20 min.), but often there remained a non-releasable pool of [3H]-L-glu.

Although N18-RE-105 cells possess many neuronal properties, the results obtained are not those expected from reversible binding of L-glutamate to a channel/receptor complex, but are consistent with a chloride-activated sequestration or exchange process. Supported by NS22249 and NS23804.

209.5 **N-OXALYL-DIAMINO-CARBOXYLIC ACIDS ARE POTENT INHIBITORS OF GLUTAMATE RECEPTOR BINDING.** R.J. Bridges, M. Kadri*, D.T. Monaghan, P.B. Nunn*+, J.C. Watkins*++, and C.W. Cotman., Dept.of Psychobiology, University of California, Irvine, CA 92717, and +King's College London and ++University.of Bristol, England.

β-N-Oxalyl- α,β-diamino-propionic acid (β-ODAP) is an excitatory amino acid that has been identified as a major causative agent in the pathogenesis of human neurolathyrism (Chase et al., Neurosci. Lett., 55, 1985. This disease is associated with the excessive consumption of seeds containing the neurotoxin (e.g., *Lathyrus sativus, L. clymenum, and L. cicera*) and is characterized by a permanent spastic paralysis of the lower limbs. β-ODAP and several structurally related derivatives (see below) have been prepared and tested for their ability to inhibit the binding of radioligands to the three major excitatory amino acid receptor classes: NMDA (N-methyl-D-aspartate), QA (quisqualate) and KA (kainate).



QA, KA, and NMDA receptors in synaptic plasma membranes were assayed with specific ligands (^{3}H-AMPA, ^{3}H-KA and ^{3}H-L-Glutamate, respectively) as described (Monaghan et al.,PNAS, 83, 1986). Of the compounds listed above, including α-L-ODAP and β-D-ODAP, only β-L-ODAP was found to potently inhibit the binding of ^{3}H-AMPA (IC_{50} near 1 μM). Similarly, β-L-ODAP also selectively inhibited the binding of ^{3}H-KA (IC_{50} near 50 μM). In contrast, β-L-ODAP did not exhibit substantial inhibition of binding to the NMDA receptor. Binding to this receptor was most potently inhibited by L-and D-γ-ODAB (N-oxalyl-α,γ-diamino-butyric acid), δ-D-OX-ORN (δ-N-oxalyl-ornithine) and ε-D-OX-LYS (ε-N-oxalyl-lysine). Electrophysiological studies in the spinal cord neurons suggested the site of action of β-L-ODAP is at non-NMDA receptors (MacDonald and Morris, Expt. Brain Res., 57, 1984).. The findings reported here are consistent with that model and further suggest that at low concentrations the toxic action of β-L-ODAP may be a specifically attributable to the interaction with QA receptors. Structure-function studies with these derivatives should also provide insight into ligand specificity differences between KA and QA receptors.

209.6 IMMUNE LABELING AND PURIFICATION OF A 71 kDa GLUTAMATE BINDING PROTEIN IN BRAIN SYNAPTIC MEMBRANES. E.K. Michaelis, J.-W. Chen*, M.D. Cunningham and N. Galton*, Dept. of Biochemistry and Human Development and Center for Biomedical Research, Univ. of Kansas, Lawrence, KS 66045.

Immunoblot studies of synaptic membranes isolated from rat brain using antibodies raised against a previously purified glutamate binding protein (GBP) indicated labeling of an ~70 kDa protein band. Since the antibodies used were raised against a 14 kDa GBP, the present studies were undertaken to explore the possibility that the 14 kDa protein may have been a proteolytic fragment of a larger M_r protein in synaptic membranes. Protease activity during protein purification was prevented by introducing five protease inhibitors and a three-step purification procedure was developed that yielded a high degree of purification of glutamate binding proteins. The major protein enriched in the most highly purified fractions was a 71 kDa glycoprotein, but a 63 kDa protein was co-purified during most steps of the isolated procedure. The 71 kDa protein interacted very strongly with concanavalin A-biotin complex, whereas the 63 kDa bound this complex weakly. Antibodies raised against the 71 and 63 kDa proteins labeled most strongly a 71 kDa protein band in synaptic membranes. The 63 kDa protein appeared to be a proteolytic fragment of the 71 kDa glycoprotein. The isolated protein fractions did not have any glutamate-metabolizing activity and their glutamate-binding characteristics were very similar to those previously described for the 14 kDa GBP, including estimated dissociation constants for L-glutamate binding of 0.25 and 1 μM, inhibition of glutamate binding by azide and cyanide, and a selectivity of the ligand binding site for L-glutamate and L-aspartate. The neuroexcitatory analogs of L-glutamate and L-aspartate, ibotenate, quisqualate, and D-glutamate, inhibited L-[^{3}H] glutamate binding to the isolated proteins, as did the antagonist of L-glutamate-induced neuronal excitation, L-glutamate diethylester. The transport carrier inhibitor threo-hydroxyaspartic acid did not inhibit significantly the binding activity of the protein. Excitatory amino acid analogs of glutamate such as kainate, domoate, NMDA and AMPA produced weak inhibition of L-glutamate binding to these proteins. In terms of ligand selectivity the purified glutamate binding proteins resembled most closely the binding sites on cerebellar granule cells described by Drejer et al. [Life Sci. 38, 2077, 1986]. (Supported by grants DAAL03-86-K0086 from the ARO, AA04732 from the NIAAA, and KS-86-G-22 from the AHA-KS Affiliate).

209.7 PURIFICATION OF KAINIC ACID BINDING SITES FROM FROG BRAIN USING ION EXCHANGE AND LIGAND AFFINITY CHROMATOGRAPHY. D. R. Hampson and R. J. Wenthold. Laboratory of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20892

Binding sites for the neurotoxin, kainic acid, may represent a subset of receptors for the endogenous excitatory amino acids glutamate, aspartate, or a related compound. Previous studies have indicated that these binding sites are concentrated at synapses and have a unique distribution in the central nervous system.

We have established a protocol for solubilizing kainic acid binding sites from frog (and rat) brain using a combination of the detergents, Triton X-100 and digitonin in 0.5M phosphate buffer, pH 7.0. The solubilized binding sites from frog brain displayed a high affinity (K_D = 4.8) and low affinity (K_D = 39) component. Both the dissociation constants and the competition profiles are similar to those found in membranes and solubilized preparations from rat brain. Although the pharmacological properties of the solubilized binding sites from frog brain are similar to those observed in rat brain, the density of binding sites was 5-10 fold greater in the frog. The B_{max} values for the solubilized binding sites in frog brain were 3782 pmol/mg protein and 12756 pmol/mg protein for the high and low affinity sites respectively.

The solubilized binding sites were purified by ion exchange chromatography followed by ligand affinity chromatography using the high affinity kainic acid analog, domoic acid. Ion exchange chromatography on DEAE sepharose using a linear 0-0.2M NaCl gradient resulted in more than a 15-fold purification over the crude solubilized preparation. Pooled fractions from the ion exchange column containing binding activity were applied to the domoic acid affinity column; binding sites were eluted using kainic acid. The specific activity of the binding sites eluted from the domoic acid affinity column was several hundred fold greater than that of the crude solubilized preparation. Both the crude solubilized and the partially purified kainic acid binding sites from frog brain eluted from a Sepharose 6B gel filtration column in the presence of detergent, with molecular weights of 650,000 daltons. The calculated molecular weight of the crude solubilized binding site from rat was the same as that for the frog binding site.

The kainic acid binding sites from both rat and frog brain appear to be glycoproteins based on their binding to a variety of agarose-conjugated lectins, including wheat-germ agglutinin, Concanavalin A, and lentil lectin. The majority of the sites bound to wheat-germ agglutinin could be eluted with 0.35M N-acetyl-D-glucosamine, while none of the sites bound to Concanavalin A could be eluted using 0.35M α-methyl-D-mannoside.

209.8 NANOMOLAR AND SUBMICROMOLAR BINDING OF L-(H) PROLINE TO MOUSE BRAIN SYNAPTIC MEMBRANES. J.G. Ortiz, A.E. Negrón* and María S. Bruno*. Department of Pharmacology, Univ. of Puerto Rico School of Medicine, San Juan, Puerto Rico 00936.

L-proline has been shown to exert a variety of physiological and behavioral effects that are consistent with its possible role as either a neurotransmitter and or a neuromodulator. Some of these effects are: (a) inhibition of memory consolidation (Cherkin et al., 1981), (b) excitatory actions on hippocampal pyramidal neurons (Keller et al., 1981), (c) high-affinity synaptosomal uptake (Hauptmann et al., 1983), and (d) K^+-stimulated release (Nickolson, 1982). Recently, Greene et al., (1986) have described the micromolar binding of proline to hippocampal synaptic membranes.

In this study, the nanomolar and submicromolar binding of L-(^{3}H) proline to mouse brain synaptic membranes has been examined. We have been able to identify two additional binding sites to those described by Greene et al., 1986. Preliminary kinetic analysis reveals a binding site(s) with an apparent K_d of 2.9 nM and B_{max} of 2.5 fmole/mg protein. On the other hand, another binding site is also observed with an apparent K_d of 0.29 uM and B_{max} of 500 pmole/mg protein.

In contrast to the binding of pipecolic acid, (^{3}H) proline binding is inhibited by NaCl. The latter point suggests that these compounds are binding to different site(s). At 10 uM; L-proline, ornithine and pipecolic acid displaced approximately 50% of the bound proline; followed by glutamate, GABA and glycine (30-40%). Although there are many similarities between the binding of glutamate and proline, kainic acid (10 uM) was ineffective in displacing bound proline.

These results suggest the possibility that proline may bind to its own binding sites.

209.9 EFFECT OF INSULIN-INDUCED HYPOGLYCEMIA ON EXCITATORY AMINO ACID RECEPTORS IN RAT NEOSTRIATUM

E. Westerberg and T.W. Wieloch (SPON: J.K. Deshpande). Lab. for Exp. Brain Research, Lund Hospital, University of Lund, S-221 85 Lund, Sweden.

Hypoglycemia, when severe enough to cause EEG isoelectricity, leads to delayed neuronal necrosis in the caudate nucleus. With increasing severity of the hypoglycemic insult, the damage to small and medium sized neurons first appear in the lateral part of the striatum, and spreads medially into the structure. Lesioning of the glutamatergic cortico-striatal pathway, as well as intrastriatal injection of an NMDA receptor antagonist (AP-7) protect against hypoglycemic damage. These results indicate that receptors for excitatory amino acids may play an important role in the development of the damage.

Autoradiographic methods were used in order to study possible changes in the properties of different glutamate receptors before onset of EEG isoelectricity (burst suppression EEG pattern), during EEG silence (10 and 30 min isoelectric EEG) as well as after different periods of glucose induced recovery (30 min isoelectric EEG with 1 h, 1 week or 4 weeks survival). NMDA displaceable 3H-glutamate, 3H-AMPA and 3H-kainic acid binding to 6 µm brain tissue sections was quantified by computer aided densitometry.

Male Wistar rats were injected with 9-22 IU/kg insulin and EEG silence was awaited (2-3 hours). Control rats were given an equal amount of insulin supplemented with glucose in order to maintain a normal plasma glucose level. The animals were sacrificed by *in situ* freezing of the brain with liquid nitrogen. The brains were removed and sectioned at -20°C. Paralell sections were used for *in vitro* binding of the tritiated ligands and for histological evaluation of neuronal damage.

Our results revealed a biphasic pattern in AMPA binding. Following 30 min of EEG silence, AMPA binding decreased to 50 % of control in both lateral and medial striatum. One hour following glucose administration, AMPA binding was no longer different from control binding, while prologation of the recovery period to 1 or 4 weeks resulted in a binding decrease compared with controls only in the more vulnerable lateral portion of the caudate.

NMDA displaceable glutamate binding was enhanced by approximately 30 % after 10 min of isoelectric EEG. The binding was thereafter normalized during the isoelectric and early recovery periods, while a reduction in binding was found 1 and 4 weeks following 30 min of severe hypoglycemia. No changes in kainic acid binding was found during EEG silence or in the early recovery phase. As the recovery period was extended to 1 or 4 weeks, a significant drop in binding was found in the lateral caudate.

We conclude that the early decrease in AMPA binding probably reflects a reversible desensitization of the quisqualate receptor due to increased extracellular concentrations of excitatory amino acids during EEG isoelectricity. The second decrease in AMPA binding as well as the loss of binding to NMDA and KA sites correlates with the distribution of damage and probably reflects cell death. The significance of the increase in binding to NMDA receptors at 10 min of isoelectricity is elusive, but is in accordance with an NMDA-receptor involvement in the mechanisms of hypoglycemia induced neuronal damage.

209.10 FUNCTIONAL STUDIES OF A NEW NON-NMDA ANTAGONIST (FG 9041) IN NEURONAL CELL CULTURE MODELS.

J. Drejer* and T. Honoré* (SPON: ENA). Ferrosan Research Division, DK-2860 Soeborg, Denmark

We have recently developed a series of potent and competitive inhibitors of ^{3}H-AMPA and ^{3}H-kainate binding sites. (T. Honoré et al., this meeting). The pharmacological profiles of these substances including FG 9041 were evaluated using a newly developed model of excitatory amino acid (EAA) induced ^{3}H-GABA release from cultured mouse cortex interneurons (Drejer et al., J. Neurosci., in press).

The EC_{50} values for stimulation of ^{3}H-GABA release were for quisqualate 75 nM; NMDA 16 µM; kainate 29 µM and L-glutamate 12 µM. Responses to 20 µM NMDA were potently blocked by the NMDA selective antagonist D-APV (IC_{50} = 1.5 µM; and by the PCP/sigma opiate type of compounds (IC_{50} values were for PCP: 2 µM; MK 801: 3 µM; ketamine: 8 µM and cyclazocine: 11 µM). Responses induced by 500 nM quisqualate could be blocked effectively by the new EAA antagonist FG 9041 (IC_{50} = 3 µM) whereas other non-NMDA antagonists such as cis-2,3-PDA, GAMS, GDEE and kynurenic acid were very weak or ineffective (IC_{50} values higher than 500 µM). Schild analyses of FG 9041 inhibition of responses to quisqualate, kainate and NMDA indicated a competitive inhibition at all receptor subtypes with pA_2 values of 6.2, 5.9 and 5.4, respectively.

EAA neurotoxicity was studied in similar neuronal cultures using the blue formazan formed from MTT (a tetrazole compound) as a stain for surviving neurons. In this model FG 9041 (10 µM) effectively blocked quisqualate (50 µM) and kainate (50 µM) toxicity without protection against NMDA (50 µM) or L-glutamate (50 µM) toxicity.

FG 9041 was a potent inhibitor of quisqualate (10 µM) and kainate (25 µM) responses in a model of EAA induced ^{22}Na efflux from rat striatal slices (IC_{50} values were 4 µM and 2 µM, respectively) with weaker effects on NMDA responses (IC_{50} = 40 µM).

These results indicate that FG 9041 is a competitive EAA-antagonist with a selectivity for non-NMDA receptors and a potency several orders of magnitude higher than for known non-NMDA antagonists.

209.11 DIFFERENTIAL PHARMACOLOGICAL RESPONSES TO THE CIS AND TRANS ISOMERS OF 1-AMINO-3-PHOSPHONOCYCLOPENTANECARBOXYLIC ACID (CYCLOPENTYL APB).

J.F. Koerner. Dept. of Biochemistry and Neuroscience Graduate Program., Univ. of Minnesota, Minneapolis, MN 55455.

The L-glutamate analogue L-2-amino-4-phosphonobutanoic acid (L-APB) antagonizes synaptic responses at micromolar concentrations for a very limited subgroup of putative glutamatergic pathways. It also acts as an excitant for ON-bipolar retinal cells and it becomes a potent excitant for hippocampal and prepyriform cortical neurons after they are exposed to quisqualate [The Quis effect: Robinson et al., Brain Res., 381 (1986) 187]. We previously synthesized two conformationally-restricted analogues of APB, cis- and trans-1-amino-3-phosphonocyclopentanecarboxylic acid (cis- and trans-cyclopentyl APB) and demonstrated that the trans isomer is more potent for inhibition of the APB-sensitive lateral perforant path in rat hippocampal slices [Crooks et al., J. Med. Chem., 29 (1986) 1988]. I wish to report differential pharmacological responses to these compounds for three other neural systems. The trans isomer is also a more potent inhibitor of the most APB-sensitive component of the extracellular synaptic field potential of rat prepyriform neurons activated by stimulating the lateral olfactory tract. Thus 10 µM L-APB or 300 µM trans-cyclopentyl APB inhibited this response 15-20%, whereas 300 µM cis-cyclopentyl APB inhibited less than 6%. [The synaptic responses which are not inhibited at these concentrations have very low sensitivity to higher concentrations of L-APB [Hearn et al., Brain Res., 379 (1986) 372]. In superfused retinal eyecup preparations from the red-eared turtle (Pseudymus elegans), 250 µM trans cyclopentyl APB inhibited the ON-bipolar extracellular response of the intraretinal electroretinogram more than 80% whereas the cis isomer inhibited 50% (data obtained by M.M. Slaughter). In contrast to these systems, the cis isomer of cyclopentyl APB was more potent for eliciting agonist-induced synaptic blockade in rat hippocampal CA1 pyramidal cells after exposure to 16 µM quisqualate (Quis effect; cis-cyclopentyl APB: IC_{50} = 120 µM; trans-cyclopentyl APB: IC_{50} = 1.8 mM; L-APB: IC_{50} = 70 µM). This is the first observation of differentiation of responses of L-APB-sensitive functions by conformationally-restricted APB analogues.

209.12 INTERACTIONS OF AP4 WITH GLUTAMATE RECEPTOR AND UPTAKE SITES IN RETINA.

Cheryl K. Mitchell* and Dianna A. Redburn. Department of Neurobiology and Anatomy, The University of Texas Med. Sch. at Houston, Houston, TX 77025.

Analysis of glutamate transmission in the vertebrate retina has been greatly facilitated by the use of compounds which bind with a high degree of specificity to distinct subclasses of glutamate receptors. AP4 (2-amino-4-phosphonobutyric acid, previously designated 2-APB) is a particularly useful compound which has been shown to block the activity of the ON channel presumably by acting as an agonist at glutamate receptors on ON bipolar cells (J. Neurosci., 1985, 5:224 - 233).

We have analyzed the binding properties of AP4 at glutamate receptors in rabbit retina and we find a good correlation between the pharmacological/kinetic characteristics of in vitro binding, and those reported for the electrophysiological effects of AP4. AP4 displaces ^{3}H-glutamate from a set of binding sites a) is sensitive to freeze-thaw procedures, b) requires chloride ions and c) is stereoselective for the L isomer.

However, recent reports from other CNS areas have suggested that AP4 may also interact with glutamate uptake sites. We have therefore examined the effect of AP4 on both the Na-dependent and the Cl-dependent glutamate uptake systems in rabbit retina synaptosomes. AP4 inhibits ^{3}H-glutamate uptake in both systems, thus suggesting that AP4 may have multiple effects on glutaminergic transmission in rabbit retina.

AP4-sensitive ^{3}H-glutamate binding to post-synaptic receptors cannot be differentiated from binding to uptake sites on the basis of in vitro binding assays. Both sites demonstrate temperature and chloride dependence and their pharmacological specificities are very similar.

AP4 preferentially blocks ^{3}H-glutamate uptake into the potassium-releasable pool of retinal synaptosomes. Thus, applications of AP4 in intact retina could alter intracellular and extracellular concentrations of endogenous glutamate. These findings raise the possibility that multiple sites may contribute to the functional responses seen with AP4.

209.13 QUISQUALATE-INDUCED SENSITIVITY TO AP4 IN HIPPOCAMPAL SLICES IS ANTAGONIZED BY L-α-AMINO ADIPATE AND SERINE-O-SULFATE. E.W. Harris[1] and C.W. Cotman (Spon: W. Makous). Dept. Psychobiology., Univ. Calif., Irvine, CA 92717 & [1]Pharmacology Dept., Pharmaceut. Div., Pennwalt Corp., Rochester, NY 14623.

The functional role of the most-studied CNS glutamate binding site remains unclear. It is now being argued that this chloride-dependent binding site, sensitive to 2-amino-4-phosphonobutyrate (AP4) and quisqualate, may be a uptake site. We have suggested (Harris & Cotman, Brain Res., in press) that a recently reported interaction between quisqualate and AP4 (Robinson et al., Brain Res. 381: 187, 1986) may be mediated by this site, and provides evidence of a transport role for this site. To further test this hypothesis, we have examined the interaction between the quisqualate "priming effect" and other compounds that are potent ligands at the chloride-dependent binding site.

Compounds were applied at known concentrations to submerged hippocampal slices. Extracellular synaptic field potentials were recorded in CA1 stratum radiatum or stratum pyramidale after stimulation of stratum radiatum near CA2. Slices were "primed" by a single 2-4 minute application of 10-20 μM quisqualate. Priming is evidenced by 1) a lasting reduction in synaptic response amplitude apparent after quisqualate is washed out, and 2) sensitization to AP4 - a pronounced reduction of the synaptic potential during subsequent application of as little as 100 μM AP4; this is associated with CA1 pyramidal cell depolarization. Such sensitivity to AP4 is not seen in untreated slices.

We now report that quisqualate also sensitizes slices to the potent chloride-dependent site ligand L-α-Aminoadipate (LαAA), although this compound had effects different from AP4. In primed slices, 100 μM LαAA caused only a small decrease in synaptic potential that faded within 1-2 minutes, and a second application of LαAA had little effect on the synaptic response. LαAA also greatly reduced the sensitivity to application of AP4. Including 100 μM LαAA during quisqualate treatment blocked the priming effect although sensitivity to AP4 could be induced by subsequent application of quisqualate. L-serine-O-sulfate (LSOS) also antagonized the priming effect of quisqualate. In control slices, LSOS (up to 300 μM) had no pronounced effect on Schaffer responses, but application of LSOS to primed slices consistently reversed the persisting decrement in the synaptic response, and reduced the sensitivity to subsequent application of AP4.

These data provide further pharmacological evidence that the priming effect of quisqualate on hippocampal slices in mediated by the chloride-dependent glutamate binding site. But, most important, we have demonstrated antagonism by LαAA and LSOS of the priming effect of quisqualate, which will greatly facilitate the study of its underlying mechanism(s).

209.14 QUANTITATIVE STUDIES ON THE ANTAGONISM OF QUISQUALATE, KAINATE AND NMDA RESPONSES BY PENTOBARBITONE. J.A. Kemp*, S. Grimwood*, C. Wardell* and A.C. Foster, (Spon: L. Iversen). Merck Sharp and Dohme Research Laboratories, Terlings Park, Eastwick Road, Harlow, Essex, UK.

Barbiturates have been suggested to block receptor-operated Na^+-K^+ conductances regardless of the receptor type involved (Barker, Brain Res., 92: 35, 1975). Thus, it is of interest that in mammalian CNS preparations, barbiturates are reported to antagonise quisqualate and kainate responses more potently than NMDA receptor mediated responses (Teichberg et al, Brain Res., 291: 285, 1984; Miljkovic and MacDonald, Brain Res., 376: 396, 1986). In order to study this antagonism of excitatory amino acids more quantitatively, we have examined the ability of pentobarbitone to antagonise quisqualate, kainate and NMDA responses using a rat cortical slice preparation.

Approximately 1mm wide cortical wedges (0.5mm thick) were mounted in a two compartment bath with the ventral margin of the cortical tissue traversing a greased slot, so that the cortical tissue lay almost entirely within one chamber and the white matter entirely within the other. The potential between the chambers was monitored using Ag/AgCl electrodes and continuously displayed on a chart recorder.

Pentobarbitone (30-300μM) produced concentration dependent shifts to the right of the quisqualate concentration-response curve (usually 3-30μM). Concentration-ratios estimated from the middle part of the control curve produced a Schild plot with a slope = 1.37 ± 0.26 (± 95% confidence limits) and a pA_2 = 4.7. At 300μM pentobarbitone, the quisqualate concentration-response curve appeared to be initially flattened but then steepened at concentrations above 300μM quisqualate. Addition of the competitive NMDA receptor antagonist, D-2-amino-5-phosphono valerate (D-AP5; 30μM), reduced the size of the responses to high concentrations of quisqualate. This was further investigated by examining the effect of pentobarbitone on full concentration-response curves to quisqualate in the presence of the selective, non-competitive NMDA antagonist, MK-801 (3μM), which completely blocked depolarising responses to NMDA. Under these conditions, pentobarbitone (300μM), reduced the slope of the mean concentration-response curve (n = 4 slices) from 0.91 to 0.58 and the maximum from 2.94 to 1.68 mV. In contrast, pentobarbitone (300μM) had little effect on kainate responses, producing a mean concentration-ratio of 2.99 ± 0.27 (n = 4) and had less effect on responses to NMDA, mean concentration ratio = 1.62 ± 0.21 (n = 12).

These results suggest that on rat cortical cells barbiturates preferentially block quisqualate receptor-mediated responses, in a non-competitive manner. They also indicate that at high concentrations quisqualate is not a selective agonist and activates NMDA, as well as quisqualate, receptors.

209.15 [^{3}H] MK801 BINDING TO THE EXCITATORY AMINO ACID RECEPTOR COMPLEX FROM RAT BRAIN IS ENHANCED BY GLYCINE. S.N. Murphy*, I.J. Reynolds, W.Hartwig* and R.J.Miller. (SPON. D.C. U'Prichard) Dept. Pharmacol. and Physiol. Sci., Univ. Chicago, Chicago IL 60637.

The excitatory amino acid glutamate (GLU) acts on at least three receptor types in the mammalian brain. These receptors are characterized by the actions of relatively selective agonists N-methyl-D-aspartate (NMDA), kainate and quisqualate. The novel anticonvulsant MK801 selectively inhibits the actions of NMDA by blocking the NMDA-operated calcium-selective ionophore. We have studied the binding of [^{3}H] MK801 to rat brain membranes to further investigate drug action at this site.

Binding assays employed membranes that had been washed a total of ten times in 20mM HEPES, pH 7.4, and had undergone 2 freeze-thaw cycles. [^{3}H] MK801 binding of this extensively washed membrane preparation had an affinity of 27nM and a density of 0.62pMol/mg protein of receptors. GLU and glycine (GLY) enhanced binding by increasing the affinity but and negligible effects on the density of receptors. Half maximal concentrations were 1.28 and 0.31μM respectively. GLU (100μM) and GLY (30μM) increased the affinity to 8.1 and 10.2nM. Maximal concentrations of the two were additive, and in combination the affinity was increased to 3.0nM. This indicates that GLU and GLY act at separate sites on the NMDA receptor complex.

The binding of [3H] MK801 was regulated by other drugs that are believed to interact with the NMDA receptor-ionophore complex. Thus, phencyclidine, CPP+ and Mg^{2+} inhibited binding with half maximal concentrations of 34.7nM, 540nM and 10mM respectively. By contrast, NMDA mimicked the effects of GLU by increasing binding in the concentration range 1-100μM.

Several other amino acids produced GLY-like effects in this assay. D-Serine was most effective, and D-alanine was also potent. L-amino acids were generally less effective. B-alanine and taurine had very little effect, and strychnine did not block the effects of GLY at concentrations of 10μM.

We have also studied the effects of amino acids on the increase of cytoplasmic free calcium produced by NMDA in single cultured mouse striatal neurons. Glycine increases the effects of threshold concentrations of NMDA, and increases the potency of NMDA in the range 0.01-10μM The amino acids D- and L-serine mimicked the effects of GLY, while taurine was ineffective.

We have demonstrated that GLY can potently interact with the NMDA receptor-ionophore complex, and that GLY can modulate the actions of agonists at this receptor. These results support the suggestion (Johnson & Ascher, Nature 325:529, 1987) that GLY may be an important modulator of the actions of GLU at the NMDA receptor in vivo.

209.16 **GLYCINE BINDING SITES RECIPROCALLY INTERACT WITH GLUTAMATE BINDING SITES AT THE NMDA RECEPTOR COMPLEX.** L. Nguyen*, D. T. Monaghan, and C.W. Cotman. (SPON: E. E. Mena) Dept. Psychobiology, Univ. California, Irvine, CA, 92717.

Agonist induced responses at the N-methyl-D-aspartate excitatory amino acid receptor have recently been shown to be potentiated by low concentrations of glycine. Using quantitative autoradiography, we have found that 0.1 to 10 μM concentrations of glycine enhance L-[^{3}H]glutamate binding (procedure: PNAS 83 (1986) 7532) at the NMDA receptor complex, while higher concentrations reduce the levels of binding. Likewise, D-serine was also active at increasing the levels of NMDA-sensitive L-[^{3}H]glutamate binding. These effects were neither mimicked nor blocked by 10 μM strychnine.

Conversely, L-glutamate alters [^{3}H]glycine binding. [^{3}H]Glycine has been reported to bind to a strychnine-insensitive binding site which has a distinct anatomical distribution similar to the NMDA receptor's and a high affinity for glycine and D-serine (Bristow et al., Eur. J. Pharmacol., 126:303 (1986). We have evaluated these binding sites using quantitative autoradiography (100 nM [^{3}H]glycine, NEN, incubated with thaw-mounted Sprague-Dawley rat brain tissue sections for 20 min. at 0-4 C in 50 mM Tris-citrate pH 7.2. followed by a 20 s wash) The anatomical distribution of these sites is very similar to that previously reported for NMDA-sensitive L-[^{3}H]glutamate binding sites. These sites appear to be closely associated with the L-glutamate binding site because L-glutamate and other NMDA agonists (L-aspartate, NMDA, and ibotenic acid) enhance binding at the [^{3}H]glycine binding site. In addition to being readily displaced by glycine and D-serine, binding at the [^{3}H]glycine site is also reduced by the NMDA antagonists 2-amino-5-phosphonopentanoate and 2-amino-7-phosphono-heptanoate (measured in the presence of 10 μM L-glutamate), but not by the inactive 4, 6, and 8 carbon analogues. Noncompetitive NMDA antagonists MK801 and ketamine also reduce the glutamate-stimulated [^{3}H]glycine binding.

NMDA antagonists, however, do not inhibit [^{3}H]glycine binding uniformly throughout the brain. Regions such as the striatum and septum appear to be more greatly affected than [^{3}H]glycine binding in the granule cell layer of the cerebellum. This regional variation may correspond to the differing classes of NMDA binding sites (see abstract by Monaghan et al., these proceedings). These results confirm that [^{3}H]glycine binds to a separate site on the NMDA receptor complex, and indicates that the glutamate and glycine sites reciprocally interact with each other in the NMDA receptor complex.

209.17 HIPPOCAMPAL NEURONAL LOCALIZATION OF NMDA AND TCP RECEPTORS. W.F. Maragos, J.B. Penney and A.B. Young, Dept. of Neurology and Neuroscience Program, University of Michigan, Ann Arbor, MI 48104.

Substantial evidence has accumulated that dissociative anesthetics exert some of their CNS effects by interacting with a site close to the ionic channel of the N-methyl-D-aspartate (NMDA) receptor. The NMDA receptor labeled with [3H]glutamate and the dissociative anesthetic receptor labeled with [3H]-N-1[(2-thienyl)-cyclohexyl]3,4-piperidine (TCP) have similar distributions in rat and human brain. The synaptic localizations of these sites, however, is unknown. We have investigated NMDA and TCP receptors in serial sections of rat hippocampus after lesions of the perforant pathway and of the dentate gyrus.

Eight Sprague-Dawley male rats (200 grams) were anesthetized, placed in a stereotaxic frame and a unilateral knife cut made through the angular bundle to sever the perforant path. Four additional animals were anesthetized and 2 injections of 2.5 ug colchicine (5 ug/µl) were made unilaterally into the dentate gyrus. After one week, the animals were decapitated, the brains rapidly removed and frozen on dry ice. Twenty micron sections were assayed for [3H]glutamate binding to NMDA receptors (Greenamyre et al., J. Pharm. Exp. Therap. 233:254, 1985) and [3H]TCP binding to dissociative anesthetic receptors (Maragos et al., Neurosci. Lett. 74:371, 1987). The sections were exposed to Ultrofilm 3H for 2-3 weeks, then developed and analyzed by computer assisted densitometry.

After perforant path lesions, NMDA binding in dentate gyrus was 4.0 ± 0.6 pmol/mg protein ipsilateral to the lesion as compared to 4.4 ± 0.6 pmol/mg protein on the control side. [3H]TCP binding was significantly decreased by 9% (0.35 ± 0.02 pmol/mg protein vs 0.32 ± 0.02) on the lesioned side. After dentate gyrus lesions, NMDA receptor binding was decreased by 84% (4.1 ± 0.23 vs 0.67 ± 0.21) and [3H]TCP binding by 92% (0.25 ± 0.02 vs 0.02 ± 0.01) on the lesioned side.

These data support the hypothesis that NMDA and TCP binding sites are closely linked anatomically since both receptors respond similarly to lesions. Furthermore, the results suggest that a very small percentage of NMDA/TCP receptors are presynaptic on perforant pathway terminals and that the majority of sites are postsynaptic on dentate neurons.

Supported by USPHS grant NS 19613.

209.18 COMPLEX INTERACTIONS BETWEEN A GLYCINE BINDING SITE AND NMDA RECEPTORS. M.Kessler, M.Baudry, T.Terramani* and G.Lynch. Center for the Neurobiology of Learning and Memory, University of California, Irvine CA 92717.

Glycine has been reported to modify the electrophysiological characteristics of the NMDA receptor (Nature 325 (1987) 529-531). This prompted us to investigate the effect of glycine on glutamate binding to the NMDA site and to test for the presence of a glycine binding site associated with the NMDA receptor. Binding assays were done by incubating detergent-treated membranes isolated from rat telencephalon with radiolabeled ligands at 0°C for 30 min, followed by filtration.

In agreement with previous reports (J.Neurochem. 37 (1981) 1015-1024), 3H-glycine bound to a single strychnine-insensitive site with a K_d of 0.3 uM, a B_{max} of 4-8 pmoles/mg protein and a high affinity for serine (K_i: 0.8 uM). Glycine binding to this site was found to be highly sensitive to NMDA-receptor specific ligands; however, agonists and antagonists exerted opposite effects on glycine binding. Agonists like NMDA, glutamate and homocysteate increased glycine binding by 10-20%; the antagonists AP5, AP7 and CPP reduced glycine binding by up to 80%; in both cases, the change in glycine binding was primarily due to a change in B_{max}. The IC50 of the NMDA-receptor antagonists for inhibiting glycine binding corresponded closely with their K_i for the NMDA site; however, the maximum inhibition of glycine binding differed for each antagonist, reaching 80% for AP5, but only 30% for CPP. The inhibition of glycine binding by NMDA receptor antagonists was completely reversed by high concentrations of glutamate.

Glycine binding was also inhibited with high affinity by kynurenate ($K_i \approx 8$ uM). Inhibition by kynurenate differed from that produced by the NMDA-receptor antagonists in several aspects: (i) it was competitive, (ii) it was complete at saturating kynurenate concentrations, and (iii) it was not reversed by addition of high concentrations of glutamate. This suggests that kynurenate directly binds to the glycine site.

Glycine and serine increased binding of 3H-glutamate to the NMDA site. Conversely, kynurenate inhibited glutamate binding and the inhibition was, at least at kynurenate concentrations below 50 uM, reversed by high concentrations of glycine. Thus, kynurenate might act as an antagonist of the glycine site.

These results indicate that the NMDA and the glycine site are mutually interdependent. It is suggested that the glycine binding site exists in a low and a high affinity state and that NMDA receptor agonists and antagonists shift the equilibrium between these two states in opposite direction.

209.19 **AUTORADIOGRAPHIC VISUALIZATION OF NMDA-TYPE RECEPTORS USING [3H]CPP: PHARMACOLOGICAL CHARACTERIZATION AND COMPARISON WITH [3H]TCP BINDING SITES IN RAT BRAIN.** Deborah E. Murphy, Michael F. Jarvis, Williams J. Brooks*, Matthew A. Sills and Michael Williams. Drug Discovery Division, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

[3H]CPP (3-(±)-(2-carboxypiperazin-4-yl) propyl-1-phosphonic acid) selectively labels the N-methyl-D-aspartate (NMDA)-type excitatory amino acid (EAA) receptor with relatively high affinity in rat brain. [3H]CPP binding is highest in the hippocampus (CA-1) followed by cortex > thalamus ≥ granule cell layer of the cerebellum. The activity of a number of EAA agonists and antagonists as well as phencyclidine (PCP)-type compounds was examined in hippocampal CA-1 stratum radiatum, parietal cortex and thalamus using quantitative autoradiography. The most active compound examined was the newly described NMDA-antagonist, CGS 19755 (Lehmann et al., this meeting) with an IC-50 value of 73 nM in the stratum radiatum, being twice as active as CPP and AP5. The pharmacological activity of NMDA-type ligands, both agonists and antagonists, was highly correlated between the three brain regions ($r = 0.99$, $P < 0.01$). EAA ligands were most active in the parietal cortex with a rank order: CGS 19755 > L-glutamate ≥ CPP > DAP5 > L-aspartate ≥ AP7 > NMDA > L-homocysteic acid. Quisqualate had weak activity (IC-50 > 62 µM). AMPA and kainate, as well as the dissociative anesthetics PCP, dexoxadrol and tiletamine were without significant activity at 100 µM. The pharmacology of [3H]CPP binding to NMDA-receptors using autoradiography agrees well with data obtained from homogenate assays (Murphy et al., J. Pharmacol. Exp. Ther. 240: 778, 1987). The regional distribution of NMDA receptors labeled with [3H]CPP in general showed a good correlation ($r = 0.88$, $P < 0.01$) with the distribution of PCP receptors labeled with [3H]TCP. However, differences were observed in the percent of maximal binding in different brain areas. For example, a greater relative proportion of [3H]CPP binding was observed in the cerebral cortex and cerebellar granule cell layer than with [3H]TCP. These results suggest that there may not be a 1:1 ratio of NMDA and PCP sites in all brain regions and that the proposed NMDA/PCP receptor complex may be specific for discrete brain regions.

209.20 DEVELOPMENTAL CHANGES OF NMDA RECEPTORS IN CHICKEN CEREBELLUM. A.U. KLEIN[1]*, P. FREY[2]*, P.L. HERRLING[2], K.H. WINTERHALTER[3]*, M. CUENOD[1] and P. STREIT[1] (SPON: European Neuroscience Association). [1]Brain Res. Inst., Univ. of Zurich, CH-8029 Zurich, [2]Sandoz Res. Inst., CH-3001 Bern, [3]Lab. of Biochem I, Swiss Fed. Inst. of Technol., CH-8092 Zurich, Switzerland.

In adult rat, pigeon and chicken cerebellum, no signs for functional N-methyl-D-aspartate (NMDA) receptors can be found in [$^{22}Na^+$] efflux experiments. However, in chick cerebellar slices around hatching NMDA stimulated [$^{22}Na^+$] efflux was present at a considerable level, i.e. at about 50% of the value determined in adult rat hippocampus. NMDA stimulated [$^{22}Na^+$] efflux rapidly decreased during the first week to reach about 20% of the maximal level in 3 week old animals. - In extensively washed chick cerebellar homogenates, stored frozen at -20°C and thawed before use, NMDA displaceable L-[^{3}H]-glutamate binding could be measured only after incubation day 14, reached its maximum at hatching (430 fmol/mg protein) and decreased to about 30% of this level 3 weeks later. The time-course of this decrease was similar to that found in [$^{22}Na^+$] efflux experiments. The time-course of the increase, on the other hand, was the same as that observed for specific L-[^{3}H]-glutamate binding which also reached its maximum (440 fmol/mg) at hatching but did not decrease thereafter in frozen material. A higher maximal level of specific L-[^{3}H]-glutamate binding (920 fmol/mg) was reached already on incubation day 20 in experiments on freshly prepared homogenates and was maintained later. About 70% of this value were reached as early as on incubation day 14. - The freeze-labile component of specific L-[^{3}H]-glutamate binding may represent terminal uptake or APB binding sites. This site, thus would develop first and would be followed by NMDA receptors. The findings that NMDA receptors decrease after hatching and that the maximal levels of specific L-[^{3}H]-glutamate binding are maintained suggest that NMDA receptors would be replaced postnatally by other types of binding sites for excitatory amino acids. The role played by cerebellar NMDA receptors around hatching will have to be determined in the future.

210.1 SPECIFIC GLUTAMATE RECEPTORS IN THE BARORECEPTOR REFLEX ARC. W.T. Talman and P.A. Grieve*, Department of Neurology, V.A. Medical Center and University of Iowa, Iowa City, Iowa 52242.

In previous studies we and others have suggested that the excitatory amino acid glutamate is a neurotransmitter integral to the baroreceptor reflex arc in the nucleus tractus solitarius (NTS). We have shown that the baroreceptor reflex can be completely blocked by the microinjection of glutamate diethylester (GDEE) bilaterally into the NTS. However, the doses of GDEE required to block the baroreflex also inhibit other putative transmitters in the NTS. In this study we have sought to determine if the selective blockade of N-methyl-D-aspartate (NMDA) and kainic acid (KA) receptors by kynurenic acid (KYN) alters the baroreceptor reflex. Thirty-four adult male rats were anesthetized with pentobarbital (50 mg/kg) and instrumented for recording intra-arterial pressure and for administering intravenous drugs. Glass micropipettes filled with 0.9% saline vehicle, sodium L-glutamate (L-GLU), KA, NMDA, quisqualate (QUIS), acetylcholine (ACh), or KYN were stereotaxically placed unilaterally or bilaterally into the NTS after exposure of the dorsal medulla through an occipital craniotomy. Baroreflexes were tested by determining the reflex fall in heart rate to a 55 mm Hg rise in mean arterial pressure after the injection of phenylephrine intravenously. Microinjections (50 nl for agonists and 100 nl for KYN) were made into the NTS unilaterally or bilaterally. NMDA, QUIS, KA and L-GLU each produced a significant decrease in arterial pressure. After the microinjection of a 2 nmol dose of KYN the hypotensive response to NMDA was reduced from 39.2 ± 7.4 mm Hg to 6.6 ± 5.4 mm Hg (mean ± SEM) ($p < .01$), the hypotensive response to 3 pmol of KA was reduced from 43.7 ± 2.2 to 10.0 ± 5.6 mm Hg ($p < .01$), but the response to the microinjection of 10 pmol of QUIS was not changed (31.8 ± 4.2 mm Hg before KYN; 37.6 ± 5.3 mm Hg after KYN). The response to L-GLU was reduced by 60%. The bilateral injection of a 2 nmol dose of KYN into the NTS eliminated any significant baroreflex. Before KYN phenylephrine increased arterial pressure 60.8 ± 3.3 mm Hg with a decreased heart rate of 47.5 ± 16.1 bpm. After KYN blood pressure increased 54.5 ± 2.9 mm Hg and heart rate fell 8.8 ± 6.3 bpm. Microinjection of 20 nmol of KYN did not significantly alter the hypotensive response to the microinjection of ACh into the NTS. These studies confirm that the bilateral injection of kynurenic acid into the NTS blocks the cardiovagal limb of the baroreceptor reflex and suggests that NMDA and KA receptors, but perhaps not QUIS receptors, are integral to neural elements in the baroreceptor reflex. 210.2 EXCITATORY AMINO ACIDS CONTRIBUTE TO SYNAPTIC EXCITATION IN RAT STRIATAL NEURONES IN VITRO

L. Lanfumey, P. Stanzione*, P.L. Herrling and E. Cherubini.
INSERM U.029, 123 Boulevard de Port-Royal, 75014 Paris, France.

The nature of the excitatory transmitter released after local stimulation in striatal slices is still uncertain. Previous studies suggested that the excitatory post synaptic potential (e.p.s.p.) evoked by intrastriatal stimulation is mediated either through the activation of a cholinergic nicotinic receptor (Misgeld, U. et al., Brain Res., 253, 317, 1982), or an excitatory amino acid receptor (Cordingley, G.E. and Weight, F.F., Br. J. Pharmac., 88, 847, 1986). Our experiments were aimed at further elucidating the nature of this excitatory transmitter in the in vitro slice preparation using intracellular recording techniques and a recently described broad spectrum and specific excitatory amino acid antagonists kynurenic acid (KYAC) and (D,L) 2-amino-7-phosphonoeptanoic acid (D,L)-AP-7.

In the presence of bicuculline (10-30 μM) intrastriatal stimulation evoked a pure e.p.s.p.. The relationship between e.p.s.p. and membrane potential was not linear. It decreased in amplitude and duration for values of membrane potential more negative that -80 mV and increased in amplitude and duration for values of membrane potential more positive than -50 mV. The mean reversal potential (with K+methylsulphate electrodes) was -9.2 ± 1.7 mV ($\bar{X}$ ± S.E.M., n = 4). Amplitude and duration of the e.p.s.p. were reduced in a dose dependent way by the endogenous excitatory amino acid antagonist KYAC (100-300 μM). However a residual depolarization remained even at high antagonist concentrations. In normal ACSF, the specific NMDA receptor antagonist (D,L)-AP-7 (30 μM) reduced the amplitude and duration of the e.p.s.p.s at depolarized membrane potentials (-50 mV or more)

but not at resting membrane potential. When Mg^{++} was removed from the bathing solution, the e.p.s.p.s. increased in amplitude and duration. Under these conditions, addition of (D,L)-AP-7 (30 μM) reduced the amplitude and duration of the e.p.s.p. even at resting potential. We conclude that the e.p.s.p. evoked by intrastriatal stimulation is mediated at least in part by the activation of excitatory amino acid receptors of the non-NMDA type in normal medium and resting membrane potential ; NMDA type receptors will be activated when the membrane is depolarized or in absence of Mg^{++}.

210.3 THE EFFECT OF EXCITATORY AMINO ACID AGONISTS ON RAT STRIATAL NEUROPEPTIDE-Y AND CHOLINERGIC NEURONS. R.J. Boegman and A. Parent. Department of Pharmacology and Toxicology, Queen's University, Kingston, Canada; and Laboratoire de Neurobiologie et Departement d'Anatomie, Universite Laval, Quebec, Canada.

The response of rat striatal neurons to excitatory amino acid agonists and an antagonist was studied by means of NPY immunocytochemistry, NADPH-diaphorase histochemistry, DFP histochemistry for acetylcholinesterase (AChE), and biochemical determination of choline acetyltransferase (ChAT) activity. Intrastriatal infusion of 0.5 μl of each drug dissolved in saline (pH 7.4) was carried out with the aid of a microinfusion pump attached to a cannula stereotaxically placed in the striatum. The injection coordinates were lateral 3.2 mm, anterior 0.12 mm and ventral 4.00 mm to bregma.

Striatal NPY neurons were more sensitive than cholinergic neurons to the neurotoxic action of kainic acid (KA, 6 nmoles/μl), quinolinic acid (QA, 120 nmoles/μl) or L-glutamic acid (GA, 2 μmoles/μl). All three compounds produced a marked loss of NPY neurons, but only a moderate decrease in the number of AChE neurons or ChAT activity. While KA resulted in a 45% reduction in striatal ChAT and QA in a 30% reduction, GA gave no significant change in striatal ChAT activity. Co-injection experiments indicated that the neurotoxicity of QA and GA, but not that of KA, could be antagonized by the specific NMDA receptor antagonist 3-((±)-2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP). Removal of cortical afferents to the striatum, which are thought to be glutamatergic, by cerebral decortication protected striatal NPY and cholinergic neurons against the neurotoxicity of intrastriatal KA.

In the rat striatum the enzyme NADPH-diaphorase is considered a histochemical marker for neurons expressing NPY-like and somatostatin-like immunoreactivity. Following intrastriatal infusion of the excitatory amino acid agonists listed above, NADPH-diaphorase positive cells were found to be as sensitive to the neurotoxic effect of the infused drug as were the NPY immunoreactive neurons. Our experiments present the first morphological evidence that the NPY immunoreactive neurons in the striatum which belong to the medium-sized aspiny type I neurons receive prominent cortical amino acid afferents. Our data also supports previous reports that the AChE positive striatal neurons which correspond to the large aspiny type II neurons also receive glutamatergic cortical afferents. In addition, these neurons express excitatory amino acid receptors on their surface which mediate the neurotoxic response.

210.4 RETARDATION OF AMYGDALOID KINDLING BY AND THE BEHAVIORAL EFFECTS OF KYNURENIC ACID, AN ANTAGONIST OF EXCITATORY AMINO ACIDS; A PRELIMINARY REPORT. Z. Dennison and D.P. Cain. Dept. of Psychology, U. of Western Ontario, London, Ontario, CANADA N6A 5C2.

Much can be discovered about the role of the dicaboxylic amino acids in epileptic phenomena by investigating the effects of antagonists of these compounds. Kynurenic acid, a tryptophan metabolite, has been shown to suppress epileptiform activity in an acute model (Ganong,Lanthorn, & Cotman, 1983). The present study was designed to examine the effects of kynurenic acid in a chronic model, amygdaloid kindling. In addition, the effects of an excitatory amino acid antagonist on motor behavior were quantified using a Digiscan activity monitor.

Male hooded rats were implanted with bipolar stimulating-recording electrodes aimed at the amygdala, and bilateral guide cannulae aimed at the cerebral ventricles. Between 1-2 weeks following surgery, an afterdischarge (AD) threshold was determined using 1 sec. trains of 60 Hz biphasic square waves of increasing intensity. Every 48 hours, KYNA rats received an icv injection of 63 ug kynurenic acid in 3.3 ul saline, using an infusion pump, and were then placed in the activity monitor for 30 minutes. Forty minutes following injection, the rats were stimulated at a frequency 50 microamps above AD threshold. Control animals received 3.3 ul of saline alone. Stimulation continued for 19 sessions,or until the animal reached a second stage 5 convulsion. Animals were tested in the activity monitor every 3rd stimulation session.

Saline animals reached a stage 5 convulsion after a mean of 10 stimulations, while KYNA animals reached a stage 5 after a mean of 16.6 stimulations [$t=8.57, p<.0005$]. These results indicate a significant retardation in rate of kindling development by pretreatment with kynurenic acid. In comparing movement time, as recorded by the activity monitor, the KYNA animals showed less spontaneous movement compared to controls. The strongest effect was seen in the first session, where the KYNA animals had a mean of 20.62 seconds of movement in a 5 minute block compared to a mean of 93.7 seconds of movement in a 5 minute block in controls. This effect decreased in strength and by the 10th session, the two groups were not distinguishable based on movement, as the mean movement time for KYNA animals was 82.3 seconds per 5 minute block and the mean movement time for controls was 86.5 seconds per 5 minute block. These results indicate that strong motor impairment is evident with the initial administration of kynurenic acid, but tolerance develops to this effect with repeated administration.

210.5 **ANTAGONISM OF NORMAL AND ABNORMAL ACTIVITY OF RELAY NEURONS IN THE RAT'S VENETROBASAL THALAMUS USING EXCITATORY AMINO ACID ANTAGONISTS.** D.T. Ross. Department of Clinical Neurosciences, Brown University, Providence, RI

Relay neurons in the thalamic ventrobasal complex (VB) axotomized by ablation of the primary somatosensory cortex (SI) exhibit abnormally high levels of spontaneous activity and an enhanced responsiveness to tactlile evoked stimulation in their peripheral receptive field (Angel and Clarke, 1975; Ross and Ebner, 1986). The observed hyperexcitability of axotomized relay neurons together with other anatomical and physiological alterations which occur within the thalamus suggest that thalamic retrograde degeneration following cortical injury may be an excitotoxic process. The present experiments were designed to examine the role of excitatory amino acid neurotransmission in the activity of normal and axotomized thalamic relay neurons.

Iontophoresis of the broad spectrum excitatory amino acid antagonist kynurenic acid (KYN) into the ventrobasal thalamus completely blocked the response of relay neurons to tactile stimulation in their peripheral receptive fields. Spontaneous activity was also somewhat decreased following KYN iontophoresis but bursting with spindle rythmicity (6-10 Hz) was not prevented. Stimulation of neurons in layer VI of the somatotopically corresponding region of the SI cortex by local iontophoresis of NMDA drove the firing of VB neurons. The response of the relay neurons to this corticothalamic stimulation was also antagonized by iontophoresis of KYN into the VB. These results are consistant with those of numerous other studies which suggest that both the corticothalamic and lemniscal synapses upon relay neurons in the ventrobasal thalamus may use an excitatory amino acid neurotransmitters.

Iontophoresis of KYN into the ventrobasal thalamus 6-8 hours after ablation of the SI cortex antagonized both the abnormal spontaneous activity and the abnormal response of the axotomized relay neurons to tactile stimulation in their peripheral receptive field. Iontophoresis of KYN onto identified VB units firing at spontaneous rates from 30-40 Hz totally abolished activity within 5 seconds of the onset of iontophoresis at 150-300 nA. Iontophoresis of 10-30 nA of L- glutamate reversed the blockade within 5-10 seconds. Spontaneous activity returned to 30-40 Hz within 5-10 minutes after cessation of KYN iontophoresis with 5 nA retaining current on the glutamate barrel. The response of the axotomized relay neurons to tactlie stimulation in their peripheral receptive fields was characterized by bursts of 4-12 very fast spikes which followed stimulation up to 10 Hz with very high fidelity . Within 20 seconds after the onset of KYN iontophoresis at 300nA these same units failed to follow the same tactile stimulation at any frequency. Responsiveness to tactile stimulation on the unit's peripheral receptive field returned within 5-10 minutes after the cessation of KYN iontophoresis or within 5-10 seconds after the onset of glutamate iontophoresis at 10-30 nA.

These results suggest that the axotomized relay neurons' abnormal levels of spontaneous acitvity and burst type response to stimulation are due to a derrangement in excitatory amino acid neurotransmission. Studies in progress will examine 1) the relative contribution of different excitatory amino acid receptor classes to the increased excitability of axotomized relay neurons, and 2) the efficacy of long term excitatory amino acid antagonist infusion on decreasing excitability and preventing retrograde degeneration of axotomized VB relay neurons. (Supported by NIH postdoctroal fellowship NS 07419-02).

210.6 OPIOID INHIBITION OF KAINIC ACID INDUCED-SCRATCHING: NALTREXONE SENSITIVE AND INSENSITIVE COMPONENTS R.C. Coghill,* H. Frenk,[1] D.F. Bossut, D.E. Kellstein, and D.J. Mayer. Department of Physiology, Medical College of Virginia, Richmond, VA 23298 and [1]Department of Psychology, Tel Aviv University, Ramat Aviv, Israel

Intrathecal (IT) injection of kainic acid to rats results in a behavioral syndrome characterized by vigorous scratching of the flanks with the hind paws and caudally directed biting and licking. Morphine inhibits scratching induced by IT kainic acid and strychnine, but not that induced by substance P. To further delineate the receptor type by which opioids inhibit scratching, we examined the effectiveness of mu, delta, kappa, and sigma agonists on reducing kainic acid-induced behavior.

Adult male rats (400-500g; Hilltop) were implanted with IT catheters terminating in the lumbosacral region of the spinal cord. After 5 days of recovery, animals were pretreated with morphine (90 nmol), levorphapol (30 and 90 nmol), dextrorphan (90 nmol), [D-ala^2, N-Met-Phe^4, Gly^5-ol]- enkephalin (DAGO, 0.4 and 1.1 nmol), [D-Pen^2-D-Pen^5]-enkephalin (PEN, 90 nmol), [D-ala^2, D-leu^5]-enkephalin (DADL, 10 and 30 nmol), dynorphin (DYN, 1.1 nmol), ethylketocyclazocine (EKC, 90 nmol), phencyclidine (PCP, 90 nmol), or saline ten minutes prior to injection of 0.468 nmol kainic acid. All drugs were administered IT in 10 microliters of saline except naltrexone (30 mg/kg) which was injected intraperitoneally.

The mu agonists morphine, DAGO, and levorphanol produced substantial reductions in kainic acid-induced scratching. The delta agonists DADL and PEN also reduced scratching elicited by kainic acid, while the kappa opioids EKC and DYN had no effect. Naltrexone, an antagonist known to reverse the behavioral effects of mu and delta agonists, partially reversed morphine-induced scratch reduction, but failed to alter scratch reductions produced by levorphanol. These findings indicate that opioid reduction of kainic acid-induced scratching is composed of naltrexone reversible and naltrexone irreversible components. The existence of a naltrexone insensitive mechanism is further supported by the ability of dextrorphan, the dextrorotary isomer of levorphanol, to reduce kainic acid-induced scratching. Such a naltrexone insensitive mechanism may be mediated through a sigma site, since both dextrorphan and levorphanol are known to bind to the sigma receptor. PCP, however, failed to reduce kainic acid-induced scratching, indicating that dextrorphan and levorphanol may elicit their effects via PCP-insensitive mechanism(s), such as the haloperidol/sigma receptor.

210.7 AUTORECEPTOR REGULATION OF ASPARTATE AND GLUTAMATE RELEASE FROM THE SCHAFFER COLLATERAL-COMMISSURAL PROJECTION TO HIPPOCAMPAL AREA CA1. G. Bustos*, S. Bray* and J.V. Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Glutamate and/or aspartate is the probable transmitter released by synaptic terminals of Schaffer collateral, commissural and ipsilateral associational fibers in the hippocampal CA1 area. We have employed slices of the CA1 area to test the hypothesis that transmitter release in these pathways is regulated by feedback of the transmitters onto presynaptic excitatory amino acid receptors.

The CA1 area, excluding stratum lacunosum-moleculare, was dissected from 475 um-thick rat hippocampal slices. CA1 slices were transferred to small superfusion chambers, 5 slices per chamber, and superfused with artificial CSF at 32°C for 60 min. Transmitter release was provoked by increasing the K^+ concentration of the medium to 53.5 mM for 1 min at this point and then again 40 min later. Under the conditions of this study, aspartate and glutamate release is better than 90% Ca^{2+}-dependent and originates predominantly from the CA3-derived pathways. Samples of superfusate collected immediately prior to and during the K^+ pulses were analyzed for amino acid content by HPLC of the o-phthalaldehyde derivatives. Excitatory amino acid receptor ligands were added to the medium 5 min before the second K^+ pulse and their effect upon the ratio of amino acid released by the second pulse as compared to the first was determined.

Kainate (10-800 uM) and AMPA (20 uM) significantly reduced the K^+-evoked release of aspartate, but not of glutamate. The maximum reduction obtained (800 uM kainate) was about 50%. Neither kainate nor AMPA by itself evoked glutamate or aspartate release. N-Methyl-D-aspartate (NMDA; 100 uM) did not significantly affect excitatory amino acid release, even in the absence of Mg^{2+}. The relatively non-selective excitatory amino acid antagonist kynurenate (2 mM) enhanced the release of both aspartate and glutamate by about 25%. Conversely, the selective NMDA receptor antagonist CPP (20 uM) reduced aspartate release by about 23%, but only in the absence of Mg^{2+}.

These results suggest that the activation of NMDA and non-NMDA receptors has opposite effects on excitatory amino acid transmitter release in area CA1; NMDA receptor activation enhances release, whereas activation of non-NMDA receptors inhibits release. The actions of antagonists suggest that elevated K^+ releases enough endogenous amino acid to activate many of these receptors. Thus transmitter release at Schaffer collateral-commissural synapses may normally be regulated, in part, by the transmitters themselves. The transmitters may not only modulate the total quantity of amino acid released, but may also change the ratio of aspartate release to glutamate release. (Supported by NIH grant NS 16064.)

210.8 KAINIC ACID INHIBITS HIPPOCAMPAL CHOLECYSTOKININ RELEASE AND HAS DIFFERENT EFFECTS ON SYNAPTIC TRANSMISSION IN CA3 REGION OF RATS AND GUINEA PIGS. P.G. Aitken, G. Bustos*, P.Lee*, D.B. Jaffe*, J.-S. Hong, J.V. Nadler. Depts. of Physiology and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710 and Laboratory of Behavioral and Neurological Toxicology, N.I.E.H.S., Research Triangle Park, NC 27709.

We have previously suggested that the effects of kainic acid (KA) in the CA3 area may be mediated by disturbances in the endogenous cholecystokinin (CCK) system. To further address this possibility, the present research asked (1) Do the rat and guinea pig, which differ in the distribution of CCK in the hippocampal CA3 area, also differ in their response to KA?, and (3) Does KA alter CCK release from hippocampal slices?

For electrophysiology, hippocampal slices from Sprague-Dawley rats or Hartley guinea pigs were maintained at 35.5°C in an interface chamber. A stimulating electrode was positioned to activate the mossy fibers, and the postsynaptic extracellular field response was recorded in stratum pyramidale of area CA3b. Input/output (I/O) curves were generated by plotting the amplitude of the mossy fiber-evoked response against stimulus current over a range of stimulus intensities.

KA (50-200µM) was applied in the bath. Slices were monitored for spontaneous synchronous activity ("bursts"), and I/O curves were generated before, during, and after KA application. In both rat and guinea pig slices, KA caused bursting at frequencies from 26 to 64/min. In rat slices, KA increased the area under the I/O curve by 43%, indicating increased synaptic efficiency and/or postsynaptic excitability. In guinea pig slices, KA had no effect on I/O curves. All KA effects reversed upon washout. This difference in the effects of KA may be related to the presence of CCK in guinea pig, but not rat, mossy fibers.

For release experiments, slices of rat hippocampus were maintained in small chambers (4 slices/chamber, 32°C)and superfused with artificial CSF. CCK release was provoked by increasing the K^+ concentration of the superfusion medium to 53.5mM for two-1 minute intervals spaced 40 minutes apart. Samples were collected before and during each K^+ pulse and analyzed for CCK content by radio-immunoassay. In some experiments, KA was present during the second K^+ pulse; its effects on CCK release were assessed by comparing pulsel/pulse2 ratios from control and KA experiments.

In control chambers K^+ evoked the release of 92.8 ± 8.6 pg/min over baseline release of 17.7 ± 4.0 pg/min. KA, at 100µM and 1µM, reduced K^+-evoked CCK release by 64% and 22% respectively, but did not affect basal release. Because CCK appears to have a net inhibitory effect in area CA3 of rats, inhibition of CCK release may contribute to the epileptogenic and excitotoxic effects of KA in this region. (Supported by NIH grant 17771)

210.9 DIFFERENTIAL EFFECTS OF ACIDIC AMINO ACID ANTAGONISTS ON EPILEPTIFORM ACTIVITY IN THE IN VITRO HIPPOCAMPAL SLICE. G.B. Watson* R.K. Rader, and T.H. Lanthorn. Searle Research & Development, Chesterfield, MO. 63198

N-methyl-D-aspartate (NMDA) receptors are involved in some epileptiform burst firing in the hippocampus. Compounds which decrease the efficacy of NMDA receptors can inhibit epileptiform activity. Recently, we have begun to examine the effects of such compounds on epileptiform activity induced by different means in the hippocampal slice. Here we describe the abilities of D-2-amino-7-phosphonoheptanoate (D-AP7, 100μM), phencyclidine (PCP, 30μM) and kynurenate (KYN, 500μM) to alter epileptiform activity induced by penicillin (PEN, 3.4mM) and increased potassium (high K^+, 9.25mM).

Epileptiform bursts, recorded extracellularly in area CA1, were induced by stimulation of the Schaffer collateral/commissural fibers. All experiments were performed in a submersion chamber and all compounds were applied to the perfusate.

D-AP7, PCP, and KYN decreased the rate of spontaneous occurring potentials, decreased the duration of evoked bursts and decreased the number of population spikes per evoked burst in both PEN and high K^+ media. KYN decreased the amplitude of the remaining evoked population spikes in all slices examined. PCP either decreased or did not affect the amplitude of remaining evoked population spikes in both PEN and high K^+ media. Unexpectedly, D-AP7 increased the amplitude of the remaining evoked population spikes. This effect was more readily seen in PEN induced epileptiform activity (75% of slices examined) but was also seen in high K^+ medium (40% of slices examined; amplitude unaffected in remaining slices).

KYN was able to block all components of the epileptiform burst. This is consistent with its ability to block NMDA and non-NMDA acidic amino acid receptors and to block synaptic transmission at the Schaffer collateral/commissural-CA1 synapse. PCP and D-AP7 both selectively block NMDA responses. As expected, both compounds reduced the burst duration. However, D-AP7 was also able to increase the amplitude of the remaining population spikes, an effect not mimicked by PCP. This finding may suggest that PCP and D-AP7 can act on separate, as well as a common mechanisms.

210.10 EFFECT OF LOW GLUCOSE CONCENTRATIONS ON SYNAPTIC TRANSMISSION TO CA1 PYRAMIDAL NEURONS IN THE RAT HIPPOCAMPUS SLICE. J.C. Szerb, P. Fan* and P.A. O'Regan*. Dept. of Physiology and Biophysics, Dalhousie Univ. Halifax, N.S. B3H 4H7, Canada.

Severe hypoglycemia in vivo is known to slow down and then to abolish reversibly the EEG (Auer et al. *Diabetes* 33:1090, 1984). At the same time, there is a large increase in the extracellular concentration of potassium (Harris et al. J.Cerb.Bl.Flow Metab.4:187,1984) and of amino acids, especially that of aspartate (Sandberg et al. *J.Neurochem.* 47:178, 1986). In hippocampal slices a low glucose concentration (0.2 mM) increases the Ca-dependent, TTX sensitive evoked release of both aspartate and glutamate but that of aspartate is increased about three times more (Szerb and O'Regan, *Synapse*, in press). The purpose of these experiments was to reconcile electrophysiological and neurochemical observations on the effects of hypoglycemia on neuronal function by measuring synaptic transmission from Schaffer collaterals to CA1 pyramidal cells in the rat hippocampal slice in different glucose concentrations. Changing the glucose content of the superfusion fluid from 5 to 0.2 mM reversibly depressed the population spike and the dendritic focal EPSP, without affecting the size of the presynaptic volley. The maximal glucose content of the medium that resulted in a reduction of the population spike was about 1 mM, the same concentration of glucose that was just sufficient to increase the ratio of aspartate to glutamate released. The population spike of CA1 pyramidal cells stimulated antidromically from the alveus was depressed only slightly by low glucose. In contrast to low glucose, 5-10 μM ouabain or 10-12 mM K^+ intitially increased the size of the population spike, then depressed the presynaptic volley, along with the focal EPSP and population spike. These observations suggest that the loss of electrical activity in hypoglycemia is not due either to the failure of action potential conduction, or of transmitter release but to the blocking of the postsynaptic action of the released transmitter.

210.11 EFFECT OF PROLONGED GLUTAMATE (GLU) APPLICATION ON POSTSYNAPTIC RESPONSES TO GLU AGONISTS IN RAT HIPPOCAMPAL NEURONS. A.E. Cole, J.M.H. ffrench-Mullen and R.S. Fisher, Dept. of Neurology, Johns Hopkins Hospital, Baltimore, MD 21205.

Prolonged exposure (3-5 min) of rat hippocampal slices to perfusate containing 1-2 mM GLU induces a reversible and relatively selective blockade of excitatory transmission, with little effect on inhibitory pathways (Bernstein et al., Neurosci. Lett. 1985). This action is also seen when GLU is applied by ionophoresis into mid-stratum radiatum, the site of excitatory synaptic input from the Schaffer-collateral fibers (Cole et al., Neurosci. Abst. 1986). The present study examines the effect of prolonged application of GLU on postsynaptic responses to GLU agonists, at a time when the EPSP is depressed.

Multibarreled ionophoretic electrodes were positioned in stratum radiatum while recording intracellularly from CA1 neurons. Pulses of agonists (50 ms-1 sec) were ejected at 30 sec intervals with pipette concentrations of GLU (200 mM), quisqualate (QUIS,10 mM), N-methyl-d,l-aspartate (NMA,30 mM) and kainate (KA,10 mM). Ejection currents were selected to produce postsynaptic membrane depolarizations of equal amplitude. At a time when the EPSP was depressed to 37% of control (n=15;p<.001) by prolonged GLU application (115.6±10.9sec), the depolarization to a pulse of GLU was depressed to 43% of control (p<.005). The responses to pulses of QUIS(n=7), NMA(n=6) and KA(n=5) were also significantly depressed (p<.001 for QUIS and NMA; p=.02 for KA). An identical protocol was followed using prolonged ionophoresis of QUIS, NMA and KA. QUIS (n=7) selectively depressed the EPSP to 37% of control with little effect on the IPSP, and depressed the depolarizations to both NMA and KA (p<.05). In contrast, although prolonged NMA application selectively reduced the EPSP (n=9) to 52% of control, it had no significant effect on the brief depolarizations to QUIS or KA (p>0.1). Although KA (n=6) depressed the brief QUIS and NMA responses, this was always accompanied by a non-selective depression of the EPSP and IPSP.

These results show that prolonged QUIS and KA application decreased postsynaptic responses to GLU agonists,in addition to the EPSP. Conversely, NMA blocked the evoked EPSP but did not decrease postsynaptic responses to QUIS, KA or GLU. This suggests a primarily postsynaptic locus of action for QUIS and KA, and a presynaptic locus for NMA. The action of GLU, a mixed agonist, is likely to be a combination of pre- and postsynaptic actions. These findings support the presence of an intrinsic mechanism with both pre- and postsynaptic components that may regulate excessive excitatory transmission in the CNS.

210.12 EFFECT OF GLUTAMATE AGONISTS AND ANTAGONISTS ON CALLING IN DOMESTIC CHICKS. L. Normansell, D. Zeisloft * and J. Panksepp. Department of Psychology, Bowling Green State Univ., Bowling Green, OH 43403.

Localized infusions of glutamate have been reported to induce vocalizations in both cats and squirrel monkeys, presumably by activating synaptic fields where vocalization pathways are relayed. We have investigated the effects of intracerebroventricular administration of glutamate, as well as several glutamate receptor agonists and antagonists, on calling in domestic chicks.

Glutamate, at doses from 25 to 500 μg/3μl, decreased calling in a dose-dependent manner. Administration of N-methyl-D-aspartate (NMDA), on the other hand, had no effect on vocalizations when the animals were tested in plain boxes, but doses of .5 and 1.0 μg induced dramatic increases in calling frequency (> 400 %) when the birds were placed into mirrored boxes, an environmental situation which has a quieting effect on control animals. Kainate (KA) had an effect similar to NMDA: No changes in vocalization frequency were detected in the plain boxes at any dose tested (.05, .1, .25, .5 μg), but dose-dependent increases occurred in the mirrored boxes. In contrast, quisqualate (QA) produced a dose-dependent decrease in the number of calls, except at the highest dose (1.0 μg) where calling frequency increased back to control levels.

The effects on vocalization of glutamate receptor antagonists have also been assessed. Both D-2-amino-5-phosphonovalerate (APV), a selective NMDA receptor antagonist, and gamma-D-glutamylglycine (DGG), a broad spectrum/QA-KA receptor antagonist, produced dose-dependent decreases in calling. Administration of either NMDA (1.0 μg) or KA (.25μg) completely reversed the suppression of calling that followed APV (.1μg) treatment. KA partially reversed the DGG-induced suppression of calling, whereas NMDA did not.

The finding, that NMDA and KA seem to effect vocalization frequency in one direction, whereas QA shifts the propensity to call in the other, may partially explain the vocalization reduction observed following glutamate administration. If an NMDA or KA system serves an activational role, while a QA system acts in a counteracting manner, the relative density of the receptor subtypes in the area near the injection site of the general agonist could result in either an increase or decrease in calling. The finding that all three agonists had behavioral effects suggests they are all present near the area of the 4th ventricle (the target site for the injection). Additionally, that the highest dose of QA produced an increase in vocalizations would seem to suggest that the specificity of agonists for a particular receptor occurs only within a limited concentration range.

210.13 LAMINAR DISTRIBUTION OF EXCITATORY AMINO ACID-INDUCED EXTRACELLULAR K^+ AND Ca^{2+} CHANGES IN THE ISOLATED TURTLE CEREBELLUM. M.E. Rice* and C. Nicholson. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Excitatory amino acid (EAA) receptor subtypes are regionally distributed in the rat cerebellum (Greenamyre et al. JPET. 233: 254, 1985). Quisqualate (Quis) receptors are concentrated in the molecular layer, whereas N-methyl-D-aspartate (NMDA) receptors are mainly in the granular layer. Kainate (Kai) receptors are more evenly distributed, but are denser in the granular than molecular layer. Using ion-selective microelectrodes (ISMs) and iontophoresis, we have examined the correlation between these distributions and EAA-induced changes in $[K^+]_o$ and $[Ca^{2+}]_o$ in the isolated turtle cerebellum. Electrode assemblies consisted of a central double-barrelled pipette with two of five EAAs (200 mM, pH 7.6 glutamate (Glu), aspartate (Asp), Kai, NMDA, Quis) with a Ca^{2+}- and a K^+-ISM glued 50-60 µm away. Ion changes during EAA-iontophoresis were recorded at 100 µm steps through the cerebellar cortex. Kai was found to be the most potent EAA, producing large ion changes throughout the cerebellum, with the largest response in the granular layer. Quis and NMDA had more distinct response patterns. Quis produced larger changes in $[Ca^{+2}]_o$ and $[K^+]_o$ during iontophoresis in the molecular layer than in the granule cell layer, while NMDA induced ion changes in the granular layer, but had little effect in the molecular layer.

Glu and Asp were indistinguishable from each other and had laminar response patterns that mirrored the profile for Kai. The maximum increase in $[K^+]_o$ (4-6 mM) and decrease in $[Ca^{2+}]_o$ (0.3-0.4 mM) with Glu or Asp were seen in the granular layer, 200-300 µm from the ventral surface. The largest $[K^+]_o$ increase in the molecular layer (just above the Purkinje cell bodies) was 50% of the maximum granular layer response, while that in the Purkinje cell layer was 40%. To eliminate secondary effects from Ca^{2+} entry, 5 mM Mn^{2+} (1 mM Ca^{2+}) was included in the bath. Here, synaptic transmission was inhibited (indicated by elimination of the second component of peduncle-evoked fields) and $[Ca^{2+}]_o$ decrease was blocked, except in the granular layer at the site of maximum $[K^+]_o$ increase. Granular and molecular layer increases were reduced 20-40% and the Purkinje cell layer response was unaltered, however the largest increase remained in the granular layer. In summary, the functional locations of EAA receptors in the turtle cerebellum correspond well with those predicted by autoradigraphy. Moreover, Glu and Asp appear to act at Kai receptors, with little discrimination between Quis and NMDA sensitive sites. (NINCDS NS-13742 and NS-07745.)

210.14 REGIONAL SELECTIVITY OF EXCITATORY AMINO ACID ANTAGONISTS IN THE VERTEBRATE DORSAL HORN. R.L. Gannon and R.B. Leonard. Department of Pharmacology and Toxicology, Department of Physiology and Biophysics and the Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550,

Spinal cord physiology is being investigated in our lab using an in vitro spinal cord preparation from the Atlantic stingray, Dasyatis sabina, a vertebrate model for locomotion. Current research is directed to determining the role of putative excitatory amino acid neurotransmitters in the production of spinal reflexes. Stingrays are anesthetized and a length of spinal cord with spinal nerves attached to one side is removed, placed in a recording chamber, and superfused with a modified Ringer's solution. A laminectomy is performed to expose the dorsal surface and the side contralateral to the intact spinal nerves. Standard electrophysiological techniques using suction electrodes are employed to stimulate the sensory component of the spinal nerve and to record the volley on the dorsal root. Capillary glass electrodes (6-10 MΩ, 3M NaCl) are used to record field potentials in superficial and deeper areas of the dorsal horn, corresponding to small Aδ and larger Aα,β afferent fiber terminal projections, respectively. Dorsal horn field potentials produced by small Aδ fibers are inhibited by the non-selective excitatory amino acid antagonists kynurenate and DL-2-amino-4-phosphonobutyrate (APB), but not by D-α-aminoadipate (DAA). The inhibitory action of APB was further shown to reside in the L(+) isomer. The N-methyl-D-aspartate (NMDA) antagonist DL-2-amino-5-phosphonovalerate (APV) and its D(-) and L(+) isomers were found to have little affect. Phencyclidine and etoxadrol at high concentrations (300 µM) also inhibited the Aδ field potentials. Field potentials in deeper areas of the dorsal horn were also inhibited by kynurenate and etoxadrol at the same concentrations effective in superficial areas, but not by APB, APV, DAA, or phencyclidine. Dihydrokainate reduced the amplitude of field potentials produced by both fiber types. These results suggest that both Aδ and Aα,β primary afferent fiber types are releasing excitatory amino acid transmitters, but that presynaptic and/or postsynaptic receptor types may be different for the two afferent populations. Supported by NIH NS11255.

210.15 RESPONSE OF NEONATAL RAT LATERAL HORN CELLS TO GLUTAMATE AND N-METHYL-D-ASPARTATE IN VITRO. T. Miyazaki*, N. Mo* and N. J. Dun. Dept. of Pharmacol. Loyola Univ. Med. Ctr., Maywood, IL 60153

Intracellular recordings were made from lateral horn neurons including antidromically identified sympathetic preganglionic neurons situated in thin (500 µm) thoracolumbar spinal cord slices obtained from neonatal (10-20 days) rats. Glutamate (Glu) and N-methyl-D-aspartate (NMDA) were applied to lateral horn cells by pressure ejection. In normal Krebs solution containing 1.3 mM Mg, Glu and NMDA evoked a phasic depolarization with an amplitude of several to more than 10 mV. The responses were not appreciably affected by low Ca (0.25 mM) solution or Krebs solution containing tetrodotoxin (TTX, 0.1 µM). In a number of lateral horn cells, the Glu or NMDA-induced depolarization was accompanied by burst of small hyperpolarizing potentials resembling inhibitory postsynaptic potentials (IPSP's). The frequency of IPSP's induced by Glu or NMDA could be enhanced by changing to a Mg-free Krebs solution. As IPSP's were reversibly eliminated by superfusing the slices with a low Ca solution or solution containing TTX or strychnine (0.1-1 µM), they were probably due to the release of glycine from an interneuron(s) activated by Glu or NMDA. The Glu and NMDA-induced depolarizations were associated with a small decrease, increase or no apparent change of membrane input resistance in different cells studied. By changing to a Mg-free solution, the Glu and NMDA-induced depolarizations were consistently and markedly increased, often giving rise to intense cell discharge. In Mg-free solution, the NMDA-induced depolarization was associated with decrease of input resistance and the response was made larger on membrane hyperpolarization. The mean extrapolated reversal potential was about -20 mV. D-2-amino-5-phosphonovalerate (APV, 5-10 µM), DL-APV (50-100 µM) or ketamine (5-10 µM) reversibly blocked the NMDA-induced depolarizations in Mg-free solution. The Glu-induced depolarizations evoked in Mg-free solution on the other hand appeared to be less straightforward insofar as antagonists were concerned. For example, APV, DL-APV and ketamine in concentrations effective in blocking the NMDA-induced depolarizations only partially suppressed the Glu-induced responses. These findings suggest that rat lateral horn cells are endowed with NMDA receptors whose electrophysiological and pharmacological characteristics appear to be similar to those reported in other central neurons as well as non-NMDA excitatory amino acid receptors. While NMDA activates selectively the NMDA receptors, Glu appears to activate both the NMDA and non-NMDA receptors. In addition, inhibitory interneurons in the lateral horn seem to be endowed with NMDA and non-NMDA receptors the activation of which causes a release of glycine. (Supported by NS18710).

210.16 GLUTAMATE-SENSITIVE SITES CONTROLLING SLOW AND FAST MODULATIONS OF THE FREQUENCY OF ELECTRIC ORGAN DISCHARGES: LOCATION, MORPHOLOGY AND RESPONSE PROPERTIES OF PREPACEMAKER NEURONS. G. Rose, M. Kawasaki, L. Maler and W. Heiligenberg. Neurobiology unit, Scripps Institution of Oceanography, La Jolla, CA 92093, Dept. of Anatomy, Univ. of Ottawa, Ottawa, Ontario, K1H 8M5.

Certain types of South American electric fish produce rhythmic electrical discharges for the purpose of spatial orientation and social communication. These electric organ discharges (EODs) are controlled by a group of cells in the medulla, the pacemaker nucleus; each action potential of the pacemaker neuron triggers a single EOD cycle. The pacemaker maintains a rhythmic discharge even when isolated and placed in vitro. Modulations of discharge frequency of pacemaker neurons, and therefore of EODs, occur during social behaviors. Two forms of modulations can be distinguished: smooth frequency shifts with a time constant on the order of a second, and fast rises, or 'chirps', that may lead to a brief cessation of the pacemaker.

The objectives of the present study were: 1) Determine which neurons are afferent to the pacemaker N. by using retrograde tracing methods. 2) Identify sites that, when stimulated by iontophoretic application of L-glutamate, elicit the slow or fast modulations in the EOD frequency. 3) Record from single units in these glutamate-sensitive sites while presenting sensory stimuli that produce slow or fast EOD modulations. Experiments were conducted on two genera of electric fish, Eigenmannia and Apteronotus.

Modulations of the EOD frequency could be elicited by iontophoresis of L-glutamate at several sites in the midbrain tegmentum. One of these sites corresponds to the prepacemaker nucleus, a region where labelled cells are observed following WG-HRP injections into the pacemaker nucleus. The response properties of single units in the prepacemaker nucleus suggest that different types of neurons control smooth frequency shifts and chirps. Supported by grants NS 07261-02 to G.R. and BNS 82-05454 to W.H.

210.17 HOMOCYSTEATE AS A NEUROTRANSMITTER CANDIDATE IN THE BRAIN - PRESYNAPTIC AND POSTSYNAPTIC CHARACTERISTICS. C. Tsai*, P.L. Wood, and J. Lehmann(SPON: P. Etienne). Research Dept., Pharmaceuticals Division, CIBA-GEIGY Corp., Summit NJ 07901.

Homocysteic acid (HCA) has been proposed as an endogenous neurotransmitter acting at N-methyl-D-aspartate-preferring (NMDA-type) receptors, for two reasons. First, there is measurable depolarization-evoked release of HCA from brain tissue. Second, HCA produces the bistable depolarizing shifts characteristic of NMDA-type receptor activation when it is iontophoresed in the brain (K.Q. Do et al., J. Neurosci. 6:2226, 1986). We have pharmacologically characterized the actions of the stereoisomers of HCA at NMDA-type receptors on striatal cholinergic interneurons, and also examined the uptake system for [^{3}H]DL-HCA in crude synaptosomes.

Like NMDA, HCA evoked the release of [^{3}H]acetylcholine (ACh) formed from [^{3}H]choline in striatal slices. The concentration-response curve to L-HCA was virtually superimposable on that to NMDA, yielding equal EC_{50} values (18 uM) and maximal responses. However, D-HCA was weaker, with an EC_{50} value of 170 uM, and an apparently smaller maximal response. L-HCA evoked [^{3}H]ACh release was inhibited by the same categories of compounds which inhibit NMDA-evoked [^{3}H]ACh release: the divalent ion Mg (IC_{50}=14 uM), competitive NMDA antagonists DL-AP7 (IC_{50}=49 uM) and CPP (IC_{50}=17 uM), and dissociative anesthetics tiletamine (IC_{50}= 4.9 uM) and MK-801 (IC_{50}=0.09 uM).

L-HCA inhibited high affinity [3H]L-glutamate uptake with an IC_{50} of 2 mM, while D-HCA was inactive up to and including 10 mM.

[^{3}H]DL-HCA was accumulated by crude synaptosomal fractions from brain, but by a low velocity system. Whereas high tissue-to-medium ratios were obtained for the uptake of [^{3}H]L-glutamate (116), that for [^{3}H]DL-HCA was only 3.5 under optimal conditions, which was closer to the values obtained for [^{3}H]dopamine (10.5), and [^{3}H]choline (9.6). The regional distribution of [^{3}H]DL-HCA uptake did not parallel that of [^{3}H]L-glutamate uptake. It is questionable if the major route of inactivation of synaptic HCA would involve a high affinity uptake system. Rather, there may exist specific enzymes to inactivate HCA.

210.18 PARTIAL PURIFICATION OF N-ACETYLATED-ALPHA-LINKED ACIDIC DIPEPTIDASE (NAALADASE): A QUISQUALATE-SENSITIVE PEPTIDASE THAT CLEAVES N-ACETYL-ASPARTYL-GLUTAMATE TO N-ACETYL-ASPARTATE AND GLUTAMATE *IN VITRO*. M. B. Robinson, B. L. Stauch*, and J.T. Coyle. Dept. of Neuroscience, The Johns Hopkins School of Medicine, Baltimore, MD, 21205

The heterogeneous regional distribution of N-acetyl-aspartyl-glutamate (NAAG) and its ability to depolarize specific neurons which receive proposed glutamate afferents suggest that NAAG may act, in part, as an excitatory neurotransmitter at a subpopulation of putative glutamatergic synapses.

Metabolic studies using rat forebrain synaptosomes suggest a potentially rapid mechanism of inactivation whereby the peptide is degraded to N-acetylaspartate (NAA) and glutamate with subsequent glutamate reuptake (Blakely et al. J. Neurochem. 47 (1986) 1013-1019). Similiarly, striatal injections demonstrate a parallel route of NAAG catabolism *in vivo*. We have recently identified and characterized a quisqualate-sensitive, chloride-dependent, membrane bound, metallopeptidase activity which demonstrates a high apparent affinity for NAAG with a K_m = 540 nM and a V_{max} = 180 nM/mg protein per min (Robinson et al. Eur. J. Pharm. 130 (1986) 345-347). This activity demonstrates specificity for **N**-Acetylated **A**lpha-**L**inked **A**cidic **D**ipeptides, and therefore has been named "**NAALADase**".

NAALADase was partially purified from lysed synaptosomal membranes prepared from frozen rat forebrains and solubilized with Triton X-100 (0.5 %) followed by sequential column chromatography in Tris-Cl buffer (10 mM, pH 7.8) with 0.05 % Triton. NAALADase activity was assayed by quantitating the liberation of [^{3}H] Glu from [^{3}H] NAAG in a Tris-Cl buffer, followed by resolution of product and substrate by anion exchange chromatography.

The accompanying table summarizes the results of these sequential purification steps. Maximal selective solubilization of NAALADase activity was achieved at a Triton X-100 : protein ratio of 10:1. The peptidase eluted in the void volume of the anion exchange column and at 0.25 M NaCl from the cation exchange column suggesting that NAALADase has an unusually high isoelectric point.

	Purification Factor	% Yield
Crude Homogenate	1	100
Lysed Synaptosomal Mem.	4.1	69
Triton X-100 Extract (0.5 %)	9.7	73
DEAE-Sepharose	96	77
CM-Sepharose	950	32

Preliminary data from a Sepharose size exclusion column suggest a molecular weight of 180 kDa. Silver stained SDS gels of fractions surrounding the NAALADase peak of activity from a CM column and material from each purification step show enrichment of a 90 kDa band.

Under these chromatographic conditions only one peak of activity was observed; futhermore, this activity was quisqualate-sensitive, as was found in lysed synaptosomal membranes. These data support the hypothesis that this quisqualate-senstive activity is responsible for NAAG catabolism *in vivo* and may function to inactivate neurotransmitter pools of NAAG. [Supported by USPHS # NS 13584 and a postdoctoral fellowship (# 07870) to MBR]

210.19 MECHANISM OF ANTICONVULSANT AND CEREBROPROTECTIVE ACTIVITY OF U-50488H and U-54494A. M.Camacho Ochoa, T.A. Jackson*, C. S. Aaron* and P.F. Von Voigtlander. The Upjohn Company, Kalamazoo, MI 49001.

Recent investigations have linked excitatory amino acids to the etiology of epilepsy and other neurodegenerative diseases. We have previously showed that U-50488H blocks (H3)Kainic acid ((H3)KA) binding in the presence of Ca++ and Cl- ions.

We have used 45Ca++ uptake, 2-Deoxyglucose (2-DG) uptake, (H3)KA binding and KA-induced lesions in the mouse hippocampus to study the mechanisms underlying the anticonvulsant and cerebroprotective activity of U-50488H and U-54494A, a diamine analogue of U-50488H. The results revealed that the calcium uptake in K+ depolarized synaptosomes was significantly reduced by these two compounds only at concentrations of 10^{-4} - 10^{-6}M. (H3)KA binding was significantly decreased in the presence of Ca++ and Cl- ions in a mouse synaptic membrane preparation. Both the total specific and the high affinity binding were decreased when similar concentrations of these two compounds were used (10^{-4} to 10^{-5}M). The KA-induced 2-DG uptake increase in various regions of mouse brain was minimally affected by U54494A and U-50488H. Cerebroprotective activity was measured by image analysis as the decrease of area of vacuolization in the CA3 region of the mouse hippocampus lesioned with intracerebroventricular KA. Both compounds afforded a high degree of protection.

Hence, although the biochemical data on calcium uptake, (H3)KA binding and 2-DG uptake do not provide us with a precise cellular mechanism by which these compounds protect the brain, the morphological data clearly suggest that a cytoprotective mechanism is at play. This may be related to the anticonvulsant activity of U-50488H and U-54494A.

210.20 NETWORK BURSTS TRIGGERED BY SINGLE CELL STIMULATION IN THE RAT HIPPOCAMPUS. R.S. Neuman, E. Cherubini and Y. Ben-Ari. INSERM U.29, 123 Bd. de Port-Royal, 75014 Paris, France.

In the present experiments we examined the action of N-methyl-D-aspartate (NMDA) and low Mg2+ on burst generation in CA3 neurones.

Transverse hippocampal slices (500 μM) from 100-150 gram rats were used. Standard intracellular and extracellular recordings from CA3 pyramidal neurones were obtained from submerged slices.

Superfusion of slices with Mg2+ free medium or NMDA (5-10 μM) first induced endogenous (pacemaker) bursts followed by network driven bursts. Endogenous and network bursts were readily distinguished as the former were not accompanied by burst in the extracellular recordings. Furthermore, hyperpolarization abolished endogenous but not network bursts.

As the endogenous bursts always preceeded the network bursts we wondered if the former triggered the later. More specifically, did any CA3 neurone, impaled at random, possess the appropriate follower circuitry to trigger a population response. To test this hypothesis, bursts of action potentials were produced by current pulses applied to the intracellular electrode. As expected, in control medium, this single cell stimulation did not induce network bursts. However, in Mg2+ free medium activating a single neurone could trigger network bursts which were evident both in the intracellular and extracellular recordings. CsCl filled electrodes were more effective in triggering bursts, as Cs+ blocked the K+ conductance and thereby prolonged the directly evoked spike discharge.

From our observations we conclude that there is no requirement for a special group of neurones to act as "pacemakers" for burst production. Instead, any neurone (at least in CA3) can trigger a network burst providing the excitability of the tissue is such that the appropriate follower circuitry is activated.

R.S.N. was the recicipent of a Canadian MRC Traveling Scientist Award.

210.21 **EXCITATORY AMINO ACIDS IN THE RETINO-TECTAL SYSTEM OF XENOPUS LAEVIS.** B.E.S. Fox and S.E. Fraser. Dept. of Physiol. Biophys., Univ. of Calif, Irvine, CA 92717.

Glutamate (GLUT) has been proposed to be the major excitatory transmitter in the CNS of mammalian and nonmammalian species. Two classes of receptors have been characterized by the artificial agonists, either kainic acid (KA) or n-methyl-d-aspartate (NMDA), which selectively bind them. In some cases, KA is such a potent agonist that neurotoxicity results from excessive membrane depolarization (Olney, Rhee & Ho, 1974, Brain Res., 77, 507).

We have investigated whether GLUT acts as a transmitter in the Xenopus retino-tectal system in either young adults or stage 47-50 tadpoles. Laminar field potentials were recorded with a saline filled micropipet in the optic tectum and retina in response to a flash of white light (200ms duration). Evoked potentials 75-90% greater than noise level were recorded from each animal prior to drug administration. GLUT, KA, NMDA, and the NMDA specific antagonist, amino-phosphono-valeric acid (APV) were administered by squirting small volumes (0.002-1ml) of the drugs onto the exposed tectal surface of the adults or bath applying it to the tadpoles.

The agonists and antagonists both blocked the evoked tectal laminar field potentials. This was the result of disruption of local membrane potential shifts by either continuous depolarizations caused by the agonists or elimination of membrane potential shifts by the antagonists. GLUT (5mM,) and KA (10um) completely blocked the evoked field potentials in the adults in 1-5min and 10-15 min respectively. APV (5mM) however, blocked only 60% of the response in 15-20 min. In tadpoles, 300uM APV blocked 55-70% of the response in 15-30min. 100uM APV blocked 40-70% of the response in 10-20min, and 10uM APV blocked 50-70% of the response in 35-40min. 100uM NMDA completely blocked the response within 2 min, while 10uM NMDA had no effect. 100uM KA completely blocked the response within 5 min. 10 uM NMDA and 10uM KA, when microinjected into the cranial cavity, blocked the reponse within 1 min. Retinal field potentials were maintained in all animals up to 1 hr following drug administration.

The effects of KA are reversible. Retinal and tectal potentials could be evoked in tadpoles which received 10uM KA injections 5-24 hrs earlier. An 80uM KA injection also failed to block the response when tested 24 hrs. later. The LD-50 for this drug, when injected into the cranium, was determined to be 50uM.

We suggest, based on the actions of the excitatory amino acids tested, that GLUT is the primary transmitter of the Xenopus retino-tectal system. In light of the proposed role of GLUT/NMDA receptors in longterm changes in synaptic strength and its presence in this system, we suggest that GLUT/NMDA receptors may be involved in activity dependent retinotectal patterning. (Supported by NSF.)

OPIATES, ENDORPHINS AND ENKEPHALINS: PHYSIOLOGICAL EFFECTS II

211.1 MORPHINE EFFECTS ON LOCUS COERULEUS NEURONS ARE DEPENDENT ON THE STATE OF AROUSAL AND AVAILABILITY OF EXTERNAL STIMULI: STUDIES IN ANESTHETIZED AND UNANESTHETIZED RATS.
Rita J. Valentino and Richard Wehby*. Department of Pharmacology, George Washington University, Washington, D.C. 20037

Since the physiological characteristics of noradrenergic locus coeruleus (LC) neurons differ in anesthetized and unanesthetized rats, the effects of morphine (MOR) on LC activity recorded in both conditions were compared. Intracerebroventricular (i.c.v.) administration of MOR inhibited spontaneous LC discharge in both halothane-anesthetized and un-anesthetized rats. However, MOR was at least 10 times more potent in anesthetized rats suggesting that the state of arousal can affect the potency of opiates on LC activity. LC discharge in anesthetized rats was also evoked by repeated presentation of sciatic nerve stimulation (footshock). This stimulation resulted in a consistent pattern of LC discharge characterized by a brief period of excitation (80 - 100 msec duration) occurring shortly after the stimulus (10-20 msec), followed by a longer duration postactivation pause. The excitatory component of this response was insensitive to doses of MOR (0.03 or 0.1 ug) that inhibited spontaneous discharge recorded during the presentation of stimuli. Only the highest dose of MOR (0.3 ug) which completely inhibited tonic activity significantly decreased evoked discharge. In parallel experiments the presentation of auditory stimuli to unanesthetized rats evoked a pattern of LC discharge similar to that evoked by sciatic nerve stimulation in anesthetized rats. While MOR (1.0 and 3.0 ug) decreased both tonic and evoked discharge in these rats, tonic LC discharge was more sensitive to MOR as was observed with anesthetized rats. For example 3.0 ug MOR significantly decreased tonic LC discharge but not discharge evoked by auditory stimuli. In some LC neurons recorded in both anesthetized and unanesthetized rats spontaneous discharge which was completely inhibited by MOR could still be evoked by presentation of sensory stimuli. Quantitative analyses of these effects indicated that MOR tends to alter the temporal pattern of LC discharge to sensory stimuli such that the signal-to-noise ratio (ratio of evoked:tonic activity during stimulus presentation) is increased. MOR effects were reversed by naltrexone, 1.0 mg/kg, s.c., in anesthetized rats, and 1.0 ug i.c.v., in unanesthetized rats. The present results indicate that the degree of arousal and the availability of environmental stimuli are important determinants of opiate effects on LC cells and can antagonize the effects of opiates on these neurons. 211.2 INTRACELLULAR GTPγS RESTORES MORPHINE HYPERPOLARIZATION OF RAT LOCUS COERULEUS (LC) NEURONS AFTER BLOCKADE BY PERTUSSIS TOXIN.
Y.-Y. Wang* and G.K. Aghajanian, Depts. of Pharmacol. and Psychiat., Yale Univ. Sch. of Med. and the Ribicoff Res. Facilities, New Haven, CT 06508.

Pertussis toxin, an inactivator of certain G proteins, is widely used as a tool to study the link between receptors and the class of G proteins which are substrates for this toxin (e.g., G_i, G_o, G_t). A previous study on noradrenergic neurons of the LC has shown that pertussis toxin blocks the hyperpolarizing effect of the opiate agonist morphine (Aghajanian and Wang, Brain Res., 371:390, 1986). In the present study, we examined whether the hyperpolarizing effect of morphine on LC neurons could be restored in brain slices from pertussis toxin-pretreated rats by intracellular guanosine 5'-O-(3-thiotriphosphate) (GTPγS), a hydrolysis resistant analog of GTP.

Male albino rats were injected in vivo with pertussis toxin (1 μg in 5 μl) or vehicle in a lateral cerebral ventricle; LC slices were obtained for recording 1-5 days later. Slices were perfused with artificial CSF composed of (in mM): NaCl, 126; KCl, 5.0; Na_2HPO_4, 1.25; D-glucose, 10; $NaHCO_3$, 26; $CaCl_2$, 2.5; $MgSO_4$, 2.0 (95% O_2/5% CO_2). Intracellular recordings were performed using an Axoclamp-2 and low resistance electrodes (15-20 MΩ) filled with 2M KCl, or 2M KCl with 2 mM GTPγS or 2 mM GTP.

As previously reported, when electrodes containing 2 M KCl were used, the hyperpolarizing effect of morphine on LC neurons was blocked in slices from pertussis toxin-pretreated rats; only a partial suppression of firing rate could be seen. In the same slices, when electrodes containing 2 mM GTPγS were used, the ability of morphine to hyperpolarize LC neurons was restored and responses were similar in magnitude to those in control slices using 2 M KCl electrodes. Morphine responses obtained with GTPγS containing electrodes were not reversible by drug washout. GTPγS (2 mM) alone also caused a hyperpolarization of LC neurons in slices from pertussis toxin-treated rats, but the response developed much more slowly than in the presence of morphine. GTP (2 mM), unlike GTPγS, did not restore the effect of morphine in slices from pertussis toxin-treated rats, nor did it alone have any effect on the LC neurons from either pertussis toxin-treated or control rats.

As the hyperpolarizing effect of morphine on LC neurons was restored by intracellular GTPγS but not GTP, we conclude pertussis toxin impairs receptor-mediated activation of G protein(s) by GTP but not GTPγS. This would suggest that coupling between opiate receptors and G protein(s) can still occur even after pertussis toxin treatment.

211.3 μ, δ, AND κ OPIOID ACTIONS IN THE RAT HIPPOCAMPUS. J. F. Neumaier and C. Chavkin. Dept. of Pharmacology, University of Washington, Seattle, WA 98195.

The purpose of this study was to characterize the electrophysiological effects of opioids on dentate granule cells, to determine which opioid receptor types mediate these actions, and to determine whether the mechanism of opioid action in the dentate gyrus is similar to that observed in the CA1 region. Extracellular recordings were made from rat hippocampal slices; dentate population spikes were evoked by medial perforant path stimulation and CA1 population spikes were evoked by Schaffer collateral stimulation. Selective opioid agonists were applied either by bath superfusion or pressure micropipette, and opioid antagonists (naloxone or ICI-174,864) were applied by superfusion. Agonist dose-response curves were constructed and antagonist K_e values were determined by Schild analysis.

Opioids had similar actions in the CA1 and dentate regions, although some differences were apparent. Biphasic stimulus-response (S-R) curves were detected in the dentate gyrus; we interpret these to have been due to the recruitment of inhibitory inputs as stimulus intensity was increased. Opioids induced a change from a biphasic to a sigmoidal S-R curve in a reversible and naloxone-sensitive manner. Unlike the case in CA1, opioids did not shift the S-R curve to the left in dentate recordings. In the dentate region, μ, δ, and κ agonists all increased cell excitability in a manner which resembled the action of bicuculline; therefore, opioids appear to act via disinhibition in the dentate gyrus, as they do in CA1. Opioids also induced secondary afterpotentials in both CA1 and dentate recordings; this is also consistent with a disinhibitory mechanism.

The potencies of bath applied selective agonists suggested that μ, δ, and κ receptors were activated in the dentate gyrus, but only μ and δ receptor mediated opioid actions were observed in CA1. The μ agonist PL017 induced a greater response than the δ agonist DPLPE in both the CA1 and dentate regions. DSLET induced a complete response in both regions; however, the dose-response curves were shallow, suggesting that both δ and μ receptors were activated. The δ selective antagonist ICI-174,864 blocked DPLPE actions with a K_e in the low nanomolar range, but did not antagonize PL017. Dynorphin-A(1-17) (DYN) also had a shallow dose response curve in the dentate gyrus; this result is consistent with activation of both κ and μ receptors by DYN. In CA1, DYN had only low potency actions via μ receptors with a dose-response curve of normal steepness and a naloxone K_e of 1 nM. U-50,488H and tifluodom had low potency in both dentate and CA1 regions and sometimes produced depressions of the primary spike. We interpret these data to suggest that κ receptors can be activated in the dentate gyrus, but that maximal activation of the κ receptors induced a lesser response than μ receptor activation.

Preliminary evidence suggests that naloxone may intensify the biphasic nature of dentate S-R curves; this would suggest that endogenous opioids play a role in modulating the inhibition induced at moderately high stimulus intensities. The presence of functional μ, δ, and κ receptors in the rat dentate gyrus and the demonstration of a naloxone sensitive component of perforant path transmission suggests that enkephalin and dynorphin peptides may act as neurotransmitters in the dentate gyrus. This work was supported by NS23483, GM07266, and the Poncin Fund.

211.4 **EFFECTS OF DYNORPHIN ON EXCITABILITY OF CA1 AND CA3 PYRAMIDAL CELLS IN RAT HIPPOCAMPAL SLICES.** S.B. Ryan* and H.C. Moises. Dept. of Physiology, University of Michigan, Ann Arbor, MI 48109.

In keeping with the immunohistochemical localization of dynorphin peptides within the mossy fiber projection from dentate granule neurons to hippocampal pyramidal cells (HPCs) in CA3 is the recent demonstration of calcium dependent release of endogneous dynorphin from rat hippocampal slices. Electrophysiological studies, however, have failed to establish a clear role for these peptides in hippocampal synaptic transmission. To address this issue we sought to determine the actions of dynorphin on the resting membrane properties and excitability of HPCs in vitro.

Intracellular recordings were obtained from pyramidal cells in the CA1 and CA3 cellular fields of rat hippocampal slices maintained under submersion. Dynorphin A1-17 (DYN) was applied to the slice by addition to the perfusate (concentrations of .1nM to 1μM) or by pressure ejection through a micropipette (containing 1 to 100 μM DYN) positioned immediately above the stratum radiatum. Application of DYN had no consistent effect on resting membrane properties (membrane potential, input resistance, rheobase) in the majority of cells tested. In the cells which did respond to exogenous DYN application, the predominant action of the peptide was manifested by a change in both spontaneous and current evoked action potential discharges. These effects were characterized by: 1) an elicitation of more spikes in response to depolarizing current injection through the electrode, and 2) a shift in spontaneous firing from single spikes to bursts, accompanied by the appearance of pronounced after-hyperpolarizations (AHPs) which sometimes gave way to depolarizing afterpotentials.

To test whether DYN might directly enhance neuronal burst generating properties, we examined calcium action potentials (recorded during superfusion of media containing 1μM TTX and 5 mM TEA) in the absence and presence of the peptide. TTX-resistant calcium spikes were elicited in 12 HPCs by injecting depolarizing current (400 msec, .5-2 nA) through the recording electrode. DYN (100nM) appeared to potentiate calcium spikes in 3 of the 12 neurons as evidenced by decreases in spike latency, increases in spike amplitude, and enhancement of spike AHPs. These changes in calcium spike and AHP morpology were not associated with any consistent changes in resting membrane potential.

The present data suggest that DYN might exert subtle effects on neuronal excitability which could be important in regulating the efficacy of mossy fiber input to CA3 pyramidal cells. (Supported by NIDA grant DA03365 and a career development award to H.M. from the Chicago Community Trust/Searle Scholars Program).

211.5 A MU-SPECIFIC OPIATE AGONIST, D-ala^2-mePhe^4-gly-ol^5, INCREASES EXCITABILITY OF HIPPOCAMPAL PYRAMIDAL NEURONS. A.M. Moudy and M.B. Laskowski. Dept. of Physiology, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

The rat hippocampus contains all major subtypes of opiate receptors, mu, delta and kappa. Previous studies have demonstrated that delta-selective ligands, such as [D-Ala^2, D-Leu^5] enkephalin, (DADL), and generally mu-specific ligands, such as morphine and morphiceptin increase the excitability of hippocampal pyramidal cells. Here we report the effects of a highly mu-specific opiate peptide D-ala^2-mePhe^4-gly-ol^5 (DAGO), on the electrical activity of pyramidal cells in the CA1 region of the hippocampus. Slices of the hippocampus were perfused with artificial cerebrospinal fluid while stimulating afferents in the Schaffer collaterals and while recording population spikes in stratum pyramidale and EPSPs in stratum radiatum. Superfusion of slices with DAGO produced a concentration - dependent increase in the amplitude of population spikes recorded in stratum pyramidale. No change was observed in the corresponding EPSP slope recorded simultaneously in stratum radiatum. This selective increase in population spike amplitude leads to a left - shift in the derived input - output curve. At a concentration of 10-6M, DAGO - perfused slices showed an average population spike output 20% greater than control slices in response to the same EPSP input. In addition, DAGO superfusion led to extra spiking at higher stimulus intensities. Naltrexone reversed the DAGO - induced increase in excitability, as well as prevented additional spikes. This supports the conclusion that opiate receptors mediate the observed response. The results also suggest that the excitatory response to mu receptor - specific opiate peptides in the hippocampus is not dependent upon extra - hippocampal input but is a result of changes in activity within intrinsic neuronal circuitry. Moreover, it suggests that the increased population spike is independent of enhanced transmitter release by afferents to pyramidal cells. 211.6 ENKEPHALIN EFFECTS IN THE CA3 REGION OF THE RAT HIPPOCAMPUS IN VIVO. B.E. Derrick *, S.T. Cunningham* and J. L. Martinez, Jr. (SPON: H. Rigter). Dept. of Psychology, Univ. of Calif., Berkeley, CA 94720

Enkephalins excite hippocampal pyramidal cells, in contrast to their depressant effects in most other CNS regions. Studies of evoked responses, primarily in the CA1 region in vitro, show that enkephalins produce an increase in the amplitude and number of population spikes (PSs), without an increase the field EPSP.

In the CA3 region, an area not extensively studied, there are circumscribed opioidergic pathways. We assessed the effects of enkephalins in the CA3 region in vivo. Bipolar nichrome stimulating electrodes were placed stereotaxically in anesthetized (urethane, 1 g/kg) male Sprague-Dawley rats in the hilus of the dentate gyrus (AP -5.0, ML 2.9, DV -3.5). A cannula adjacent to a nichrome recording electrode was placed in the CA3 pyramidal layer (AP -3.5, ML, 2.9, DV -3.7). Following equilibration (1 hr) and collection of baseline data (30 min), [leu]enkephalin (LE, 100 μM or 100 mM) or D-ala^2-[D-leu^5]enkephalin (DADLE, 10 or 100 μM) was applied (0.5 μl) via pressure-ejection into the CA3 pyramidal layer. Test pulses were collected for 2 hrs, followed by a second application of the same drug. Responses to paired pulses were taken before the first, and after the second, drug application.

The primary PS increased from 30 - 350% following application of DADLE (10 μM or 100 μM) or LE (100 mM), and in 2 of 4 rats given 100 μM LE. Double PSs were seen in only 4 of 18 drug-treated animals. CA3 population EPSPs increased as much as 100% following either DADLE (10 μM and 100 μM) or LE (100 mM), and in 2 of 4 rats given 100 μM LE. These effects were of short duration (less than 10-15 min).

DADLE enhanced paired-pulse facilitation at inter-stimulus intervals (ISIs) of 50-300 msec in 6 of 10 rats; this effect was not seen with LE. At ISIs of less than 50 msec, the usual attenuation of the PS amplitude following the second pulse was either unchanged or enhanced by both LE (4 of 6 animals) and DADLE (6 of 8 animals).

These results suggest that the effects of enkephalins in the CA3 region are different from those observed in the CA1 region, in terms of both the increase in population EPSPs and the lack of attenuated PSs in the second response at paired-pulse ISIs of less than 50 msec. These findings suggest that opioids may act through mechanisms other than disinhibition in the CA3 region.

211.7 SPECIFIC OPIOIDS CAN PROLONG THE CALCIUM COMPONENT OF ACTION POTENTIALS OF MOUSE DORSAL ROOT GANGLION (DRG) NEURONS IN CULTURE* BY DECREASING VOLTAGE-SENSITIVE POTASSIUM CONDUCTANCE. K.-F. Shen & S.M. Crain. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Prolongation of the duration of the calcium component of the action potential (APD) occurs in about 1/3 of the DRG neurons in mouse DRG-spinal cord explants when exposed acutely to the opioid peptide, D-ala-D-leu enkephalin (DADLE) at 1-10uM (in BSS with 5mM Ca, 5mM Ba), whereas the APD is shortened in about 50% of the DRG cells. Tests were made to determine if opioid-induced APD prolongations of DRG neurons are mediated by activation of specific excitatory opioid receptor subtypes that result in an increase in voltage-sensitive Ca-conductance or a decrease in K-conductance. Recordings were therefore carried out under conditions where most types of K-channels were blocked: 5-10mM TEA, 5mM Ba, no Ca in bath; 2M CsCl in recording microelectrode. Under these test conditions, only 1 out of 13 DRG neurons (8%) in DRG-cord explants showed APD prolongation in 1-10uM DADLE, while 11 out of 13 cells (84%) showed APD shortening. Similar attenuation of DADLE-induced APD prolongation was observed in chronic DADLE-treated DRG neurons tested in the presence of K-channel blockers (Crain et al, SN Abstr. 13, ´87).

The results suggest that DADLE-induced APD prolongation of DRG neurons is mediated by excitatory opioid receptor subtypes that decrease a voltage-sensitive K-conductance. Our data also suggest that the DADLE-induced APD shortening which is unmasked during more complete K-channel blockade in DRG neurons is mediated by inhibitory opioid receptor subtypes in the same cells that reduce a voltage-sensitive Ca-conductance. These inhibitory effects were mimicked by low concentrations (1-10nM) of the kappa agonist, dynorphin (1-13), which shortened the APD of most neurons, when tested in Ca, Ba/BSS as well as in the presence of additional K-channel blockers. In contrast to dynorphin, the specific mu and delta opioid agonists, DAGO and DPDPE, appeared to be more selective in eliciting APD prolongations in DRG neurons when applied at low concentrations (1-10nM in Ca, Ba/BSS) that were subthreshold for initiating inhibitory effects (see also Chen et al, SN Abstr. 13, ´87).

The APs of some sensory neurons may therefore be modulated by multiple subtypes of both excitatory and inhibitory opioid receptors functioning within the same cell. These opioid receptor subtypes appear to be coupled to voltage-sensitive K- and/or Ca-conductances via specific GTP-binding proteins in the DRG neurons (Chen et al., ibid.; Shen et al., SN Abstr. 12:1011, ´86). (Supported by grant DA-02031 to S.M.C.)

211.8 INHIBITOR OF CYCLIC AMP-DEPENDENT PROTEIN KINASE BLOCKS OPIOID PROLONGATION OF THE ACTION POTENTIAL OF DORSAL ROOT GANGLION (DRG) NEURONS. G.-G. Chen*, A. Chalazonitis, K.-F. Shen* & S.M. Crain, (SPON: S. Green). Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Application of the opioid peptide, D-ala-D-leu enkephalin (DADLE; 1-10uM), to mouse DRG-spinal cord explants prolongs the duration of the calcium component of the action potential (APD) in about 35% of the DRG neurons and shortens the APD in about 50% of these cells (Shen & Crain, SN Abstr. 13, ´87). In order to determine if the opioid prolongations of the APD are mediated by a cAMP second messenger system, opioid responsivity tests were made on DRG neurons after intracellular application of a protein inhibitor of cAMP-dependent protein kinase (PKI). Monolayer cultures of dissociated fetal mouse DRG neurons were used so that neuron perikarya were accessible to whole-cell patch recording pipettes and intracellular dialysis. The cultures were maintained for 3-5 wks in media modified from that used for the DRG-cord explants.

Control tests were made (current clamp recordings) on 15 DRG neurons (in 6 cultures) via patch pipettes filled with, in mM: 140 K-gluconate, 2$MgCl_2$, 1.1EGTA, 5HEPES. Bath perfusion of 1uM DADLE (in BSS with 5mM Ca, 5mM Ba) prolonged the APD of 5 DRG neurons and shortened the APD of 7 neurons (similar to the effects of DADLE in DRG explants). These changes were reversible by washing. In contrast, in a matched group of 21 DRG neurons (in 5 cultures) tested with similar patch pipettes containing PKI (Sigma, 0.1-1ug/ml), none of the cells showed APD prolongations in 1uM DADLE, whereas the APDs of 50% of the cells were still shortened.

More DRG neurons responded with APD prolongations at lower concentrations of DADLE (as in adult nodose ganglia: Higashi et al, ´82). In a control group of 19 neurons (in 8 cultures), 10nM DADLE prolonged the APD in 16 neurons (reversible by washing) and none showed APD shortening. In a matched group of 12 DRG neurons (5 cultures), when PKI was applied via patch pipettes (1 ug/ml), again none of the cells showed DADLE-induced APD prolongation (nor shortening). The APD prolongations elicited by 10nM DADLE were not reversed by naloxone (3-10uM; n=5). However, the increased proportion of DRG neurons showing these excitatory responses: 84% at 10nM vs. 34% at 1 uM suggests mediation by opioid receptors (see also Shen & Crain, ibid.).

These preliminary data suggest that DADLE-prolongation of the APD of mouse DRG neurons may be mediated by excitatory opioid receptor subtypes that are positively coupled via G_s to the adenylate cyclase/cAMP second messenger system (see also Crain et al, SN Abstr. 13, ´87). The elevated levels of cAMP may in turn result in a decreased voltage-sensitive K-conductance (Shen & Crain, ibid.) or an increased Ca-conductance (Reuter, ´83). (Supported by grant DA-02031 to S.M.C.).

211.9 OPIOIDS EXCITE RATHER THAN INHIBIT SENSORY NEURONS AFTER CHRONIC OPIOID EXPOSURE OF MOUSE DORSAL ROOT GANGLION (DRG)-SPINAL CORD EXPLANTS. S.M. Crain, K.-F. Shen* & A. Chalazonitis. Dept. of Neuroscience, Albert Einstein Coll. Medicine, Bronx, N.Y. 10461

Tests were carried out to determine if the tolerance that develops in dorsal-horn network responses of DRG-spinal cord explants after chronic exposure to opioids (Crain et al. Life Sci. 25,´79) could be due to alterations in the excitability and responsivity of the afferent DRG cells. Intracellular recordings were made from DRG neurons in fetal mouse DRG-cord explants after chronic treatment with 1 uM D-ala-D-leu enkephalin (DADLE) for >3 days starting at 2 wks in vitro. Acute application of 10 uM DADLE (in BSS with 5 mM Ca, 5 mM Ba) shortened the duration of the Ca component of the somatic action potential (APD) in only 5% of the treated neurons, in contrast to 50% of the cells in naive explants (Chalazonitis & Crain, Neurosci. 17, ´86). Furthermore, 77% of the treated cells showed prolongation of the APD in response to increased DADLE concentration vs 36% in naive explants. However, when the DADLE-responsivity tests were carried out in the presence of multiple K-channel blockers (5-10 mM TEA, 5 mM Ba, no Ca in bath; 2 M CsCl, in recording microelectrode), only 13% of the chronic DADLE-treated DRG neurons (2 out of 15 cells) showed APD prolongation and 80% showed APD shortening (as observed in naive DRG neurons: Shen & Crain, SN Abstr. 13, ´87). The results suggest that: 1) DADLE-induced APD-prolongation of the treated DRG neurons is mediated by excitatory opioid receptor subtypes that decrease a voltage-sensitive K-conductance; 2) DADLE-induced APD-shortening effects which are unmasked during more complete K-channel blockade are mediated by inhibitory opioid receptor subtypes in the same neurons that reduce voltage-sensitive Ca-conductance (resembling kappa-opioid effects of 1-10 nM dynorphin on these cells).

The decreases in the proportion of DRG neurons showing opioid-inhibitory responses and increases in opioid-excitatory responses after chronic opioid exposure are remarkably similar to the effects of forskolin or pertussis toxin treatments (Shen et al, SN Abstr. 12:1011, ´86) and suggest that these plastic cellular alterations may be mediated by related mechanisms. Similar increases in excitatory vs. inhibitory opioid receptor functions may also occur at central presynaptic terminals of DRG neurites during chronic opioid exposure, thereby enhancing transmitter release. These in vitro studies may provide clues to compensatory processes (perhaps mediated by enhanced cAMP levels; see Chen et al, SN Abstr. 13, ´87) that could attenuate or block opioid-inhibitory effects on primary afferent synaptic networks in the spinal cord and account for some of the hyperexcitability properties associated with opioid tolerance and dependence.

(Supported by NIDA research grant DA-02031 to S.M.C.)

211.10 SEROTONIN RECEPTOR SYSTEMS IN SPINAL CORD AND SENSORY GANGLIA: RELATION TO OPIOID ACTION, TOLERANCE AND CROSS TOLERANCE. X.-C. Qiu*, S.M. Crain and M.H. Makman* (SPON: R.W. Ledeen). Depts. of Biochemistry, Neuroscience and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY 10461

We have examined cellular mechanisms of opioid analgesia, tolerance and dependence in fetal mouse spinal cord-dorsal root ganglia (DRG) explant cultures as well as in fetal and adult mouse and rat tissues obtained directly from the animal. We previously found that opioids acutely depressed sensory-evoked dorsal-horn synaptic network responses of explant cultures. Chronic exposure of cultures to opioids attenuate these depressant responses, a phenomenon that may correspond to tolerance that develops in vivo; chronic exposure to opioids also attenuated responses to serotonin (5HT), possibly representing a type of "cross tolerance". The acute depressant effect of opioids was attenuated by cyclic AMP analogs, forskolin (an activator of adenylate cyclase (AC)) and by treatment of cultures with pertussis toxin (PTX). PTX inactivates certain guanine nucleotide regulatory proteins, e.g. the G_i protein that links opioid and $5HT_{1A}$ receptors to AC. We find that forskolin-stimulated AC of explants is inhibited by opioids or $5HT_{1A}$ receptor agonists. Chronic exposure of explants to morphine attenuates opioid inhibition and enhances total activity of AC; PTX treatment attenuates both opioid and 5HT inhibition and enhances total AC.

In addition to $5HT_{1A}$ receptor-mediated inhibition of AC, cord-DRG cultures contain $5HT_{1A}$ binding sites labeled by the selective ligand ^{3}H-8-OH-2-(di-n-propylamino) tetralin (DPAT) (B_{max}: 32 fmoles/mg protein; K_D:1.1nM). High affinity ^{3}H-DPAT binding sites were also found in spinal cord of adult rats (B_{max}: 75 fmoles/mg; K_D:4.5 nM). In rat cord ^{3}H-5-HT itself was found to label both $5HT_{1A}$ sites sensitive to DPAT (B_{max}: 75 fmoles/mg) and additional sites characterized as $5HT_{1C}$ on the basis of sensitivity to mianserin (K_i:5.5 nM in the presence of 10^{-7} M DPAT) as well as insensitivity to DPAT and $5HT_{1B}$ agonists. B_{max} for the mianserin-sensitive component of ^{3}H-5HT binding was 104 fmoles/mg. In order to explore possible mechanisms of cross-tolerance, $5HT_{1A}$ receptors were assessed with 1.2 nM ^{3}H-DPAT as ligand in control cultures and in cultures exposed to 1 μM morphine for 7 days. Specific binding was significantly lower in the treated cultures (9.0 ± 3.0 fmoles/mg) compared with the control (23.1 ± 5.9 fmoles/mg) (n=6). A possible influence of morphine on $5HT_{1A}$ receptor-mediated inhibition of AC remains to be determined. On the basis of the binding studies it is postulated that cross-tolerance to 5HT following morphine treatment involves alteration of a pool of G_i coupled to either opioid or to $5HT_{1A}$ receptors and utilized in common for transduction of morphine and 5HT actions. (AG-00374 and DA-02031)

211.11 OPIOID RECEPTOR SUBTYPES INVOLVED IN THE INHIBITION OF DEPOLARIZATION-INDUCED NA AND ACH RELEASE FROM SLICES OF DIFFERENT RAT BRAIN REGIONS. A.L. Frankhuijzen, F.P.Jansen, A.N.M.Schoffelmeer and A.H.Mulder (SPON: ENA).Department of Pharmacology, Medical Faculty, Free University. v/d Boechorststraat 7, 1081 BT Amsterdam. One of the possible functional consequences of activation of opioid receptors at the cellular level appears to be presynaptic modulation of neurotransmitter release. Recently, we have shown that selective activation of different opioid receptors may in fact differentially modulate neurotransmitter release in a particular brain region. Thus, the depolarization-induced release of (3H)DA and that of (14C)ACh from striatal slices were inhibited selectively by activation of k and δ-opioid receptors respectively, whereas activation of μ-receptors had no effect. However, μ-opioid receptor activation inhibited the release of (3H)NA from cortex, whereas activation of δ or k-receptors was ineffective. In the present study we examined the effects of opioid receptor activation on the release of (3H)NA and (14C)ACh from slices of the amygdala.

Similar to the results obtained in cortex the release of (3H)NA from amygdala slices was inhibited (by 45%) by the selective μ-opioid receptor agonist morphine (pD2 value of 6.50), whereas the highly selective δ-opioid receptor agonist DPDPE (D-Pen2-D-Pen5 enkephaline) and the k-opioid receptor agonist bremazocine were ineffective. However, in contrast to previous results obtained with rat striatal slices, the release of (14C)ACh from the amygdala was not affected by selective δ-opioid receptor activation using DPDPE. Only DADLE and morphine were active (77% and 64% inhibition resp.) in this respect (resp. pD2 values of 7.35 and 6.60). Furthermore, naloxone potently antagonized the effects of morphine and DADLE on the release of both NA and ACh (pA2 value of 8.75 irrespective of the agonist used), while FIT (Fentanyl isothiocyanate), a highly selective irreversible δ-opioid receptor agonist, was ineffective in this respect. However, the release of (14C)ACh from cortex slices was not affected by any of the opioid receptor agonists used.

It is concluded that the opioid receptors involved in the modulation of the release of both NA and ACh in the amygdala are of the μ-type. Moreover, the data indicate that a specific subtype of opioid receptors is not necessarily connected with a specific neuronal system but that regional differences may exist.

211.12 EFFECT OF OPIATES ON THE ACTION POTENTIAL OF NEUROBLASTOMA CELLS. J.W.Day. Department of Neurology, University of California School of Medicine, San Francisco, California 94143.

Opiates hyperpolarize, or shorten the action potentials (APs) of neurons. The hyperpolarization is due to increased potassium conductance (g_K); in dorsal root ganglion (DRG) cells APs are shortened by either increasing g_K (mu- and delta-receptors), or decreasing the calcium conductance (g_{Ca}, kappa-receptors). Opiate receptors have been thoroughly studied biochemically in neuroblastoma cells, specifically the neuroblastoma x glioma hybrid NG108-15. Recent reports show that delta-receptors on these cells decrease g_{Ca}. I have done constant-current experiments on NG108-15 cells to further delineate the effects of opiates on these cells.

NG108-15 cells, plated on coverslips, were studied 5-10 days after inducing differentiation by adding 1mM dibutyrl cAMP or 1mM sodium butyrate to conventional medium. For physiological recordings, cells were continuously perfused with HEPES-buffered saline containing 20mM tetraethylammonium (TEA). Intracellular electrodes filled with 4M K Acetate had resistances of 40-60 MOhms; morphologically well differentiated cells, 40-75 microns in diameter, were studied. Agonist and antagonist solutions were applied from different barrels of a 3-barrel micropipette; micropipette tips were broken to 10 microns (single barrels of 5 microns). Micropipettes were positioned within 10 microns of the cell body, and drugs were ejected by applying 10-15 psi pressure. APs were evoked by anodal break, using the intracellular electrode to both stimulate and record. Voltage signals were digitized and analyzed by computer.

APs had rapid rise and fall times; the duration was greatly increased by the addition of TEA. A 2s application of D-Ala-D-Leu-Enkephalin (DADLE, 200nM in the pipette) caused a 50% diminution in AP duration, a 5% decrease in AP amplitude, and no change in resting potential, rise time or input resistance. APs recovered to near normal in 15 seconds, and fully within 2 min. Ejection of naloxone alone (10 microM in the pipette) did not affect the AP, but blocked the action of DADLE.

These results show that DADLE affects APs in NG108-15 cells much as it does in DRG cells. Whether this is solely due to direct changes in g_{Ca} remains to be determined. Also, this system will allow investigation of opiate receptor function following a prolonged exposure of the cells to ethanol or opiate agonists.

211.13 EFFECT OF MORPHINE MODULATING PEPTIDE (FLFQPQRF-NH_2) ON ELECTROPHYSIOLOGICAL PROPERTIES OF CULTURED MOUSE SPINAL CORD CELLS. A. GUZMAN*, P.LEGENDRE*, F. DEMOSTES*, S. GEOFFRE*, G. PRECIGNIOUX*, J.D. VINCENT & G. SIMONNET*. I.N.S.E.R.M. U.176, 33077 BORDEAUX cedex France ; Lab. de Cristallographie. Univ. de Bordeaux I, TALENCE, France.

The morphine modulating peptide FMRF-NH_2 was originally isolated from ganglia of venous clam. More recently an octapeptide FLFQPQRF-NH_2 that crossreacts with an antiserum against FMRF-NH_2 was purified from bovine extract (Yang et al., PNAS, 82:7757, 1985). It was found to attenuate the prolongation of the tail-flick latency induced by morphine. The present investigation was done to study the effect of FLFQPQRF-NH_2 on the electrophysiological properties of cultured spinal cord neurones (Legendre et al.Neurosci., 16:753, 1985). Intracellular recordings were made using micropipettes filled with 3M KCl or 4M CH_3COOK. The peptide was applied by pressure from 1μm tip diameter micropipettes (10μM). Application of FLFQPQRF-NH_2 caused a hyperpolarization followed by a long lasting depolarization. This biphasic response was underlied by an increase of the input resistance. No clear reversal potential was observed. However the extrapolated reversal potential for the hyperpolarizing phase was close to -35 mV, while it was close to -90 mV for the deplolarizing phase. In the presence of $BaCl_2$ (6mM) the first phase of the response was increased and the second phase was suppressed. Extrapolated reversal potential of the hyperpolarization was then shifted to + 30 mV. Application of TEA (50mM) or 4AP (10mM) decreased the hyperpolarization and magnified the subsequent depolarization. Furthemore, $CoCl_2$ (3mM) reversibly blocked the hyperpolarization and decreased the amplitude of the subsequent depolarization. Our results suggest that FLFQPQRF-NH_2 has a neurotransmittor-like effect on mammalian spinal cord cells in culture. This biphasic response might be underlied by a decrease in calcium conductance and an increase in K^+ conductance, followed by a decrease in calcium-dependent K^+ conductance.

211.14 **OXYMORPHONE-NALTREXONAZINE, A POTENT MIXED AGONIST-ANTAGONIST.** S. Galetta*, J.A. Clark* and G.W. Pasternak [SPON: R. Price] The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Cornell U. Medical College, New York, NY 10021.

Previous studies from our laboratories have reported the synthesis and pharmacological characteristics of a series of symmetrical opiate azines: naloxonazine, oxymorphonazine and naltrexonazine. These compounds selectively and in a long-lasting manner label mu_1 sites both in vivo and in vitro. To examine the actions of the mixed agonist-antagonist azines of these 14-hydroxydihydromorphinones, we have now synthesized and characterized in binding assays and in vivo two asymmetrical azines: oxymorphone-naltrexonazine and oxymorphone-3-methoxynaltrexonazine. Oxymorphone-naltrexonazine, which theoretically could interact with the receptor as either an agonist or antagonist, displayed antagonist properties in vitro and in vivo. In binding studies, it had a sodium shift indicative of an antagonist. In vivo it antagonized morphine (5 mg/kg, sc) analgesia and had no analgesic activity administered alone. Previous studies have established that blockade of the hydroxyl group at the 3-position virtually destroys the ability of opiates to bind to the receptor. Therefore, oxymorphone-3-methoxynaltrexonazine theoretically can bind only as an agonist since the 3-position of the antagonist portion of the molecule has been substituted with a methoxy moiety. In binding studies, it possessed agonist properties and in vivo 1 mg/kg (sc) elevated tailflick latencies from a baseline of 1.9 * 0.2 to 9.3 * 0.9 sec. These results clearly indicate that the agonist portion of the molecule is capable of binding to the receptor as an agonist. In summary, a compound able to label a receptor as either anagonist possesses antagonist properties both in vivo and in vitro. Chemical inactivation of the antagonist portion of the molecule uncovers a potent agonist activity.

211.15 THE AMINOMORPHINONE DERIVATIVE RX77989 IS A POTENT, SHORT-ACTING OPIATE ANALGESIC. M.H. Ossipov, F. Rudo*, R.L. Wynn*, and T.C. Spaulding*. Anaquest/BOC Health Care, Murray Hill, NJ 07974 and Department of Pharmacology, School of Dentistry, University of Maryland, Baltimore, MD 21201.

The antinociceptive activity of RX77989 (14-β-pentylamino-morphinone) was assessed in standard analgesiometric procedures, including the mouse hot plate (MHP), mouse Haffner assay (MHA), rat hot plate (RHP), rat tail flick (RTF) and rabbit tooth pulp (RTP) tests. After intravenous administration, the potency of RX77989 ranged from 1.5 to 8.2 times that of fentanyl and from 296 to 2590 times that of morphine (see table).

	ED50 (mg/kg)		
Test	RX77989	Fentanyl	Morphine
MHP	0.0039	0.018	10.1
MHA	0.0014	0.01	2.22
RHP	0.0025	0.0086	2.77
RTF	0.0028	0.0043	1.11
RTP	0.0009	0.0074	1.11

The dose-response curves of RX77989, fentanyl, and morphine were parallel within each test.

The durations of the antinociceptive activity of RX77989 in the RHP and RTF tests ranged from 0.7 to 1.5 times that of fentanyl and were considerably shorter than those of morphine at several equi-effective doses.

After intramuscular injection, the ED50's of RX77989 were 0.010 mg/kg (RHP) and 0.003 mg/kg (RTF), indicating a potency 3 to 5 times that of fentanyl and 30 to 1000 times that of morphine. The duration of action was short (1/2 fentanyl) at the lowest maximally effective dose.

When administered intrathecally to mice, RX77989 had an ED50 of 0.012 mcg and was 12 and 21 times more potent than fentanyl and morphine, respectively. Its duration of antinociceptive activity was 20 min while that of fentanyl was 16 min at an equi-efficacious dose.

The antinociceptive effect of RX77989 administered intravenously was completely blocked by naloxone pretreatment in the MHP test. In addition, naloxone caused a 4-fold parallel shift to the right of the dose-response curve for RX77989 in the RTF test, suggesting competitive inhibition at the opiate receptor site.

These data strongly suggest that RX77989 is a very potent, short-acting analgetic agent, pharmacologically similar but chemically dissimilar to fentanyl.

211.16 OPIOID AGONIST PROPERTIES OF TWO NALTREXONE DERIVATIVES, NPC 831 AND NPC 836. K.M. Komer*, J.A. Peterson*, B. Mavunkel*, W.J. Rzeszotarski* and D.L. DeHaven. Nova Pharmaceutical Corporation, 5210 Eastern Avenue, Baltimore, MD 21224.

Two novel oxime derivatives of naltrexone, NPC 831 (6-[2-phenylethyl]-oximino naltrexone) and NPC 836 (6-[3-phenyl-propyl]-oximino naltrexone) are potent agonists at opioid receptors. Both NPC compounds demonstrated nanomolar potency in vitro at all three opioid receptor subtypes, with slight selectivity for the kappa site. These two drugs were equi-potent to morphine and more potent than the kappa-selective agonist U-50,488H to produce analgesia. ED_{50} values of 4.02 mg/kg for NPC 831 and 2.24 mg/kg for NPC 836 were generated for inhibition of the tail flick response in the rat, and ED_{50} values of 0.05 mg/kg for NPC 831 and 0.02 mg/kg for NPC 836 were calculated for inhibition of the writhing response in the mouse. The bombesin-scratch test, proposed as an in vivo measure of agonist activity at kappa sites (Gmerek and Cowan. J. Pharmacol. Exp. Ther. 230: 110, 1984), was used to evaluate the kappa agonist activities of NPC 831 and NPC 836. The A_{50}, defined as the percent antagonism of the bombesin-induced response, was 1.76 mg/kg for NPC 831 and 0.08 mg/kg for NPC 836, compared to an A_{50} of 1.54 mg/kg for U-50,488H. NPC 836 at a dose of 0.6 μg i.c.v. also stimulated total 2 hr food intake by 157%, whereas administration of 10 μg i.c.v. of dynorphin$_{1-13}$ increased food intake by 164%. These data suggest that NPC 831 and NPC 836 possess potent kappa agonist properties, with NPC 836 being approximately twice as potent as NPC 831 to produce analgesia, and twenty times as potent as NPC 831 to inhibit the scratching response produced by bombesin.

211.17 INTERACTION OF A BENZOMORPHAN OPIATE WITH THE CATALYTIC SUBUNIT OF ACETYLCHOLINESTERASE. B.A. Coleman and R.E. Oswald. Dept. of Pharmacology, Cornell University, Ithaca, NY 14853.

The benzomorphan opiate, N-allylnormetazocine [ANMC, SKF10047], has been previously shown to bind two distinct sites in acetylcholine receptor (AChR)-rich membranes from *Torpedo* electroplaque (1). The low affinity site seems to correspond to the site for noncompetitive blockers on the AChR whereas the high affinity site, which can be photoaffinity labeled using UV irradiation, was distinct from this site. Labeling and binding to the latter site were stereospecific with (-)ANMC exhibiting higher affinity than (+)ANMC. Binding of both isomers is inhibited by cholinergic agonists such as carbamylcholine. In the presence of ß-mercaptoethanol, the protein has an apparent MW of 66K daltons on 8% SDS-polyacrylamide gels. The labeled band runs as a dimer in the absence of reducing agents. Results of FPLC gel filtration and sucrose sedimentation velocity gradients of Triton X-100 solubilized protein show that the ^{3}H-ANMC labeled protein and acetylcholinesterase (AChE) activity co-migrate. Further studies indicate that AChE activity is inhibited by ANMC at μM concentrations with the (-) isomer being more potent than the (+) isomer. Classic AChE inhibitors such as physostygmine, neostygmine, and edrophonium inhibited binding of (-)ANMC in a concentration-dependent manner. Propidium, a compound which binds to the regulatory site of AChE, also inhibited binding but at higher concentrations. (-)ANMC was further found to photoaffinity label purified 11S ("lytic") AChE of *Electrophorus*. Antibodies to 11S also precipitated (-)ANMC labeled protein from *Torpedo* electroplaque. Results of these and other experiments indicate that the high affinity binding site of ANMC is the active center of the catalytic subunit of AChE found in these membranes.

211.18 BEHAVIORAL EFFECTS OF THE l AND d ENANTIOMERS OF U-50,488 (A KAPPA OPIATE RECEPTOR AGONIST) FOLLOWING INTRAVENTRICULAR INJECTIONS. L.B. Estall*, B.de Costa*, K. Rice* and A Pert. (SPON: C.T. Bennett). Biological Psychiatry and NIADDK, Bethesda, MD 20892.

Stereoisomers are often used to discriminate the specific effects of drugs. Recently it has been possible to resolve the racemic U-50,488 into (l) and (d) enantiomers. Preliminary findings indicate that the l enantiomer is 4,000 times more potent than the d enantiomer in kappa receptor binding assays (Rothman et al., in preparation). The purpose of the following studies was to evaluate the behavioral effects of these two compounds following intraventricular injections.

In a 75 min test of motor activity, repeated administration of different doses of d-U-50,488 (10,25,50,100 nmol) had no effect on rats horizontal activity, however 50 nmol did significantly decrease vertical activity ($p< 0.05$). Repeated administration of different doses of l-U-50,488 (10,25,50,100 nmol) significantly increased horizontal activity at the 25 ($p< 0.05$) and 100 nmol ($p< 0.01$) doses. The effects of 100 nmol of l-U-50,488 on horizontal activity were antagonized by 5.0 mg/kg (l.p) naloxone.

In a separate study, the acute administration of 100 n moles of d-U-50,488 produced a significant depression of locomotor activity which was not antagonized by naloxone. The l enantiomer also produced a modest but not statistically significant depression of locomotor output which was surprisingly enhanced by naloxone. The initial depressant effects of the l-U-50,488 were followed by locomotor excitation which was antagonized by naloxone. The d-enantiomer again had no excitatory effect on locomotor output.

Increases in the intake of a highly palatable food were seen in non food-deprived animals after i.c.v. injections of l-U,50-488 (25 & 100 n moles). The increase in food intake induced by l-U,50-488 (100 nmoles) was antagonized by 1.0 mg/kg naloxone (i.p.) the d enantiomer had no effect on food intake.

Depression of water intake was seen in 21 hr water-deprived animals following repeated administration of different doses of l-U,50-488 (25 & 100 n moles). Repeated administration of different doses of the d enantiomer had no effect on deprivation-induced drinking.

These findings clearly demonstrate that some of the centrally mediated behavioral effects of the kappa agonist U-50,488 are stereospecific. The l enantiomer enhanced locomotor activity, increased food intake and decreased water intake. The d enantiomer did not produce similar effects. These compounds will undoubtedly prove useful in analyzing the specific effects of kappa receptor mediated behaviors.

211.19 MORPHINE WITHDRAWAL "IN VITRO": ENHANCEMENT OF AGONIST-DEPENDENT PHOSPHOLIPASE C ACTIVATION. F.Moroni, M.Ruggiero*, S.Giannelli*, V.Chiarugi* and D.E.Pellegrini-Giampietro*. Departments of Pharmacology and General Pathology, University of Florence, viale Morgagni 65, 50134 Firenze, Italy.

Morphine abstinence syndrome has been associated with a number of neurochemical changes including an increase in transmitter release (Collier, Nature, 283:625,1980) and in the function of the adenylate cyclase (Sharma et al., P.N.A.S., 72:3092,1975). No information is available on the morphine withdrawal-induced modification of the phosphoinositide metabolism. In the present study we show that in an "in vitro" model of withdrawal syndrome the norepinephrine (NE)-induced activation of phospholipase C is significantly enhanced.

Rats were made dependent by implanting s.c.morphine base pellets (75 mg X 3). Cortical slices were prepared from dependent animals and incubated in a morphine containing Ringer solution until the withdrawal was challenged by placing the slices in a solution in which naloxone replaced morphine. The slices were pre-incubated in Ringer containing trace amounts of ^{3}H-NE in order to evaluate the transmitter release. Other slices were incubated for 2 h in the presence of ^{3}H-myoinositol (10 uCi/ml) or alternatively in the presence of ^{32}P (20 uCi/ml) in order to subsequently study the breakdown of the formed polyphosphoinositides.

Slices pre-incubated with ^{3}H-NE released an increased amount of label when challenged with K^{+} (30 mM) in the presence of naloxone (10^{-9}-10^{-5} M). The narcotic antagonist did not change ^{3}H-NE release when applied to slices taken from non-dependent animals, thus indicating that the preparation we are using shows a withdrawal-induced increase of transmitter release.

In subsequent experiments, the NE-induced phospholipase C activation was evaluated. Inositolphosphates (IP, IP2 and IP3) and the corresponding phospholipids were separated and measured according to Lapetina et al. (J. Biol. Chem., 260:7078,1985) and to Corradetti et al. (Brain Res., in press). NE (1-100 uM) activated phospholipase C and increased the slice content of both inositolphosphates and phosphatidic acid. This increase was significantly potentiated in slices taken from dependent animals and challenged with naloxone.

Thus, cortical slices taken from dependent rats and incubated in a naloxone containing solution release an increased amount of ^{3}H-NE and have an enhanced activation of phospholipase C.

BLOOD-BRAIN BARRIER I

212.1 DEVELOPMENTAL ASPECTS OF POTASSIUM TRANSPORT BY THE CHOROID PLEXUS IN THE RAT. J.T. Parmelee, M.H. Epstein* and C.E. Johanson. Dept. of Clinical Neurosciences, Brown University, Rhode Island Hospital, Providence, RI. 02902.

The neonatal rat serves as an appropriate model for the study of the maturation of mammalian CSF production because of its immature level of choroid plexus development at birth. We have begun an in vitro study of the ion transport mechanisms in these young animals. In potassium flux experiments ^{86}Rb was used as a tracer for K, and ^{3}H-inulin was included as an extracellular space marker. All flux data were corrected for extracellular label.

Uptake of potassium into lateral choroid plexuses isolated from Sprague-Dawley rats is an active, saturable process the kinetics of which change with development. We have shown that the steady-state accumulation of K per mg wet weight of isolated choroid plexus tissue is 50% higher in young rats aged 11-19 days than in neonatal animals aged 3-7 days. However, the time at which K uptake is half maximum is similar, suggesting that the K uptake transporter (Na,K-ATPase) has a similar affinity but a higher capacity in the more mature animals. The ouabain-inhibitable component of this uptake is approximately 90% in all groups.

Potassium efflux was measured with ^{86}Rb loading and washout experiments in isolated plexuses. After initial, rapid loss of about 40% of the label in the first two minutes of sampling, the percent of label lost from the tissue was linear with time on a semi-log scale. The efflux rate coefficient (ERC) decreased slightly in older animals, suggesting that the cells may become less passively permeable to potassium as the animals mature.

Taken together these data indicate that K transport mechanisms are immature and of limited capability and capacity in the lateral choroid plexus of neonatal rats, but that they develop rapidly in the first 2-3 weeks after birth.

212.2 IDENTIFICATION AND DIFFERENTIATION OF CULTURED CEREBRAL CAPILLARY ENDOTHELIAL CELLS IN THE PRESENCE OF GROWTH FACTORS AND IN CO-CULTURE WITH GLIAL CELLS. U. Tontsch* and H.C. Bauer. Inst. f. Molekularbiologie, ÖAW, 5020 Salzburg, Austria.

Endothelial cells (EC) of cerebral microvessels represent the blood-brain barrier by specific structures (e.g. tight junctions, no fenestrae) of cell membranes. It is proposed that the differentiation of those specific characteristics of brain EC are induced during brain development by the presence of neuronal cells.

An in vitro culture system for porcine and murine cerebral capillary EC was established in order to study differentiation processes of EC and to co-cultivate them with glial cells and neurons from syngeneic animals.

Capillary EC were isolated after several steps of homogenization and centrifugation and were subsequently cultivated under various conditions with respect to media and substrates. Addition of several growth promoting factors (acidic fibroblast growth factor, endothelial cell growth supplement (ECGS) and mouse sarcoma S-180 conditioned medium) resulted in different proliferative responses but did not select for one cell type. Prolonged treatment with ECGS (20 µg/ml) + heparin (100 µg/ml) generated cells of "cobblestone" appearance, which were negative for glial fibrillary acidic protein and desmin, and positive for factor VIII and acetylated low density lipoprotein (Dil-ac-LDL) at given times. These cells retained their phenotype for months and could be passaged up to 11 times. Omission of ECGS and heparin produced spindle-shaped cells similar to smooth muscle cells, but only some of them stained for desmin.

2-D analysis and fluorography of those two different cell types showed significant differences.

Co-culture of murine EC with syngeneic astroglial cells enhanced the proliferation of EC; the same results were achieved by treating them with conditioned medium of the glial cells.

We raised monoclonal antibodies against cultivated capillary EC and against freshly isolated capillaries. These antibodies are tested on cell cultures and sections in order to locate specific, differentiation dependent cell surface antigens.

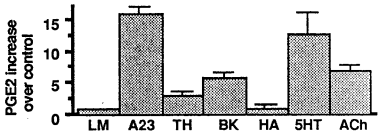
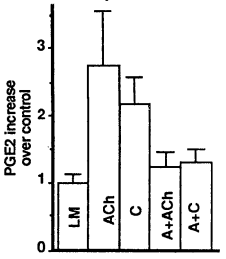
212.3 CEREBRAL ENDOTHELIA RELEASE PROSTAGLANDINS IN RESPONSE TO THROMBIN, BRADYKININ, SEROTONIN AND ACETYLCHOLINE. S.A. Moore, A.A. Spector*, and M.N. Hart*. The University of Iowa, Iowa City, IA 52242

Several hormones, neurotransmitters, and mediators of inflammation and coagulation are known to stimulate prostaglandin (PG) release in endothelium from noncerebral vessels. Many of these same compounds are vasoactive in the cerebral circulation. While acetylcholine (ACh) acts through an endothelial dependant relaxing factor that is not prostacyclin, little else is known about the role endothelial derived PG may play in mediating or modifying these vasoactive responses. Recent studies in our laboratory demonstrating the production of prostacyclin and PGE2 by cultured cerebromicrovascular endothelia in response to exogenous arachidonic acid or calcium ionophore A23187 have suggested that these cultured endothelia may be a useful model for the investigation of PG-mediated events in the cerebral circulation. Endothelial cells are derived from murine brain microvessel isolates and characterized by a monolayer growth pattern, thrombomodulin activity, and Griffonia simplicifolia agglutinin binding. Triplicate cultures of confluent endothelia in passages 6 to 12 were incubated 15 min with serum free Lewis media (LM) or one of the following agents: 2μM ionophore A23187 (A23), 1 unit/ml thrombin (TH), 10μM bradykinin (BK), 50μM histamine (HA), 2μM serotonin (5HT), 20μM ACh, 10μM angiotensin II, 2ng/ml atrial natiuretic factor, and 10μM epinephrine. PGE2 release was quantified by radioimmunoassay.



The graph (to the right) of selected experiments shows that PGE2 release ranged from 3- to 15-times control (mean ± SEM) by TH and A23, respectively. BK, 5HT, and ACh gave intermediate responses. No response was detected with HA (as shown) or the other agents tested (not shown). The ACh response was further characterized by 15 min incubations of triplicate cultures with serum free LM, 20μM ACh, and 100 μM carbamylcholine (C). Both ACh and C stimulated PGE2 release that was inhibited by atropine (A) (fig at right). These cultured cerebromicrovascular endothelia have not only maintained the ability to produce PG, but also appear to have retained receptors for several vasoactive compounds. Specifically, they have muscarinic receptors through which ACh stimulates PG release. These cells should provide a useful model for further investigations into the role of cerebromicrovascular endothelia in the control of the cerebral circulation. [support from NIH grants NS01096 and HL14230]



212.4 SODIUM EFFLUX FROM ISOLATED BRAIN CAPILLARIES IS DEPENDENT ON EXTRACELLULAR POTASSIUM CONCENTRATION. G.P. Schielke, A.L. Betz*, and H.C. Moises. Depts. of Physiology, Pediatrics, Surgery and Neurology, University of Michigan, Ann Arbor, MI 48109

Brain capillary endothelial cells have structural and transport properties which allow them to control the passage of substances into and out of the brain. The presence of Na,K-ATPase primarily in the abluminal membrane, suggests that the brain capillary is capable of pumping Na, K and water across the blood brain barrier. Previous studies in isolated brain capillaries, demonstrated that Na,K-ATPase mediated K transport is half maximal at a K concentration of 3mM (Goldstein, *J. Physiol.* 286:185,1979). We studied the effect of varying extracellular potassium concentration, $[K]_o$, on the kinetics of Na efflux to determine if brain capillary Na transport is also regulated by $[K]_o$ in the physiologic/pathologic range.

Brain capillaries from male rats were prepared by homogenization, dextran gradient centrifugation and glass bead filtration. The rate of ^{22}Na efflux from preloaded capillaries was measured over 6 min. Preliminary studies demonstrated that the rate of efflux was linear for this period. Efflux was terminated by filtration and washing with iced $MgCl_2$. ^{3}H-mannitol was used to correct for trapping or release from the extracellular space.

When capillaries were incubated in K-free buffer, ^{22}Na efflux was stimulated by increasing the extracellular Na concentration, and this effect was inhibited by 1mM amiloride. This finding is consistent with ^{22}Na leaving the capillaries through Na:Na exchange mediated by the Na:H exchanger as reported previously (Betz, *J. Neurochem.* 41:1150, 1983). Efflux of ^{22}Na into buffer containing NaCl, amiloride and varying $[K]_o$ demonstrated a K-dependent efflux which was inhibited by 5mM ouabain. This stimulation in sodium efflux was half maximal at a $[K]_o$ of 2-4mM.

These results demonstrate that the activity of the brain capillary Na,K-ATPase, *in vitro*, is dependent on $[K]_o$ in the physiological range. It has been previously hypothesized (Betz and Goldstein, *Ann. Rev. Physiol.* 48:241, 1986) that blood to brain transport of Na and water is mediated by capillary Na,K-ATPase and, therefore, these processes may be sensitive to changes in $[K]_o$. Since $[K]_o$ may increase markedly during neuronal activity, seizures, spreading depression, and ischemia, our results suggest that brain uptake of Na and water may also be stimulated in these conditions.

212.5 ADRENERGIC EFFECTS ON 2,4,5-TRICHLOROPHENOXYACETIC ACID (2,4,5-T) TRANSPORT IN THE RABBIT CHOROID PLEXUS. S. McMichael* and C.S. Kim* (SPON: T.J. McCown). Biol. Sci. Res. Ctr., Univ. of N. Carolina Sch. of Med., Chapel Hill, NC 27514

Edvinsson et al. have provided evidence that there is a sympathetic neural influence on CSF production (Exp. Neurol. 48:241, 1975). The sympathetic nerve terminals within the choroid plexus innervate both the resistance vessels and the secretory epithelium. This finding led us to undertake the effects of adrenergic agents on the organic acid transport system in the choroid plexus using the organic acid herbicide, 2,4,5-T. Adult rabbits (New Zealand) were sacrificed by exsanguination and lateral ventricular choroid plexuses were removed. Individual choroid plexus was placed in 2.5 ml of artificial CSF for the control and for the experimental media containing ^{14}C-2,4,5-T 0.02 uCi/ml (sp. act. 23 mCi/mmol) and incubated for 10 min. Tissue uptake was expressed as tissue-to-medium ratio (T/M). T/M ratio of 37.2 ± 4.1 was achieved in the control media. The uptake of ^{14}C-2,4,5-T in the choroid plexus was enhanced in a dose-related manner by the presence of isoproterenol. This enhancement started at 10^{-6} M with maximum enhancement (25%) seen at 10^{-4} M ($p < 0.05$). Unexplainably, the enhancing effect of isoproterenol disappeared and returned to control level at 10^{-3}M. The specific beta-adrenergic antagonist, propranolol, inhibited significantly (50%) 2,4,5-T uptake at 10^{-3}M ($p < 0.001$) and enhanced (22%) the uptake at lower concentration, 10^{-7}M ($p < 0.05$). These results suggest the possibility of selective neurogenic modulation of organic acid herbicide, 2,4,5-T, transport in the choroid plexus. Further study of such interactions may give new insights into the pathogenesis of neurotoxicity and more selective treatment of neurotoxic encephalopathies. Supported in part by NIH grants: HD-03110 and ES-03458.

212.6 LOW CEREBROVASCULAR PERMEABILITY OF VINCRISTINE AND VINBLASTINE LIMIT THEIR BRAIN UPTAKE IN THE RAT. Nigel H. Greig*, Seiji Momma*, Quentin R. Smith, Stanley I. Rapoport. (SPON: Robert Steinman). Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

The vinca alkaloids, vincristine and vinblastine, are widely used in the treatment of neoplastic disease, particularly in acute lymphoblastic leukemia and in lymphomas, usually in combination with others drugs. Both agents are lipophilic, with octanol/water partition coefficients of log 2.14, for vincristine sulfate, and of log 1.68, for vinblastine sulfate. Neither, however, demonstrates significant activity within the brain, although neurotoxicity is the dose-limiting toxicity for vincristine. The cerebrovascular permeability surface area product, PA, of both agents was quantified using an isolated brain perfusion technique (Takasato et al., Am. J. Physiol. 247: H484, 1984) to measure brain uptake in relation to drug binding to plasma constituents and/or drug degradation. In barbiturate anesthetised rats, the right cerebral hemisphere was perfused with physiological saline or plasma containing either 3H-vincristine or 3H-vinblastine, 0.5 nmol/ml. After 20 s, the rat was decapitated and 6 brain areas and perfusion fluid were analysed for radioactivity. Samples of perfusion fluid and blood were chromatographed and showed no metabolites. The mean PA's of vincristine and vinblastine were 1.2 ± 0.2 (S.E) x 10^{-4} s^{-1} and 5.3 ± 1.1 x 10^{-4} s^{-1}, respectively, using saline perfusion. These values are far lower than would be predicted from their octanol/water partition coefficients. The binding of vincristine and vinblastine to plasma constituents was measured by centrifugal ultrafiltration and equal 60.4% and 83.7%, respectively. The PA's of vincristine and vinblastine fell to 0.5 ± 0.1 x 10^{-4} s^{-1} and an unmeasurable value, respectively, during their brain perfusion with plasma. These data demonstrate that the brain uptakes of both vincristine and vinblastine are extremely low, despite their lipophilicity. We suggest that for these compounds, the additive rules that determine lipid solubility (Hansch, Acc. Chem. Res. 2: 232, 1969) are inapplicable to diffusion across the blood-brain barrier, in so far as a small hydrophilic region will prevent transfer of the entire molecule across the vascular endothelial membranes. The minimal brain entry of vincristine and vinblastine is primarily a result of their low cerebrovascular permeabilites and not their binding to plasma constituents or degradation. However, it is probable that the neurotoxicity of vincristine is due to a metabolite that enters the brain but does not possess significant anticancer activity.

212.7 MOVEMENT OF VINCRISTINE ACROSS THE BLOOD-BRAIN BARRIER OF THE RAT AS AFFECTED BY THE PRESENCE OF ALCOHOL IN THE PRESENCE OR ABSENCE OF ACETYLCHOLINE OR HISTAMINE. F.R. Domer and M.E. Smith. Department of Pharmacology, Tulane Univ. Sch. of Med., New Orleans, LA 70112

Vincristine sulfate is an alkaloid from the periwinkle plant that is used in the treatment of leukemia and gliomas in the central nervous system. Access to the central nervous system is limited by the function of the blood-brain barrier (BBB). Because alcohol has effects both in the central nervous system and on permeability of a number of tissues, its effect on the movement of vincristine across the BBB was thought to be of interest. Additionally, possible interactions with acetylcholine or histamine might be of importance in the movement. Male Sprague-Dawley rats weighing 260 to 390 g were anesthetized with pentobarbital sodium (50 mg/kg) intraperitoneally. The femoral artery was cannulated to permit the recording of the mean systemic blood pressure and the juqular vein was cannulated to permit the administration of saline, drugs and radioactivity. The permeability of the BBB to vincristine was evaluated by the use of ^{3}H-labeled vincristine sulfate. Ten µCi were given intravenously 5 minutes after the intraperitoneal administration of 13.3 ml/kg of saline or 3% ethanol. One minute after the administration of the vincristine, either saline, acetylcholine (1 or 2 µg/kg) or histamine (1.25, 2.5 or 5 µg/kg) was given intravenously. At 15 minutes the thoracic cavity was opened, a sample of blood was obtained from the right ventricle, the venae cavae were cut, and 125 ml of saline was infused into the left ventricle to remove blood from the cerebral vasculature. The brain was removed and samples of cerebral cortex, midbrain and cerebellum were placed in vials, dissolved with Soluene and placed in a liquid scintillation counter to permit determination of the content of radioactivity. The permeability of the BBB was assessed as the ratio of ^{3}H-vincristine in brain relative to that in plasma. That ratio was 0.48 in cerebellum, 0.53 in cerebral cortex and 0.66 in midbrain in control animals. When ethanol was given and resulted in a concentration of 20.3 mg/dl at the end of the experiment, the ratios decreased significantly, i.e. 0.088 for cerebellum, 0.044 for cerebral cortex and 0.063 for midbrain. When acetylcholine was given to rats that had also received ethanol, the permeability was increased somewhat and significantly only selectively. Likewise, histamine caused selectively variable changes in the permeability of the BBB, but the changes weren't as large or as consistent as those obtained with acetylcholine. Ethanol significantly decreased the permeability of the BBB to ^{3}H-vincristine sulfate. In the presence of ethanol acetylcholine and histamine caused rather small, variable changes in the permeability. 212.8 ALTERED CERERROVASCULAR PERMEABILITY AND ULTRASTRUCTURE FOLLOWING THE INFUSION OF rIL-2 AND/OR ITS VEHICLE. M.D. ELLISON*, J.T. POVLISHOCK, and R.E. MERCHANT* (SPON: J. ASTRUC). Dept. of Anat., VA. Commonwealth Univ., Richmond, VA 23298

Clinical trials have shown that rIL-2 administration can induce marked regression of metastatic lesions in some patients. At efficacious doses, however, rIL-2 exhibits significant toxic effects many of which appear to be secondary to increased systemic microvascular permeability. Moreover, patients receiving rIL-2 therapy have exhibited neurological abnormalities including disorientation, somnolence and coma. Despite such clinical reports, to date, the effects of IL-2 on the cerebral vasculature and brain parenchyma have not been investigated. This study, performed in cats and rats, examined the effects of rIL-2, infused at clinical dosage levels, upon blood-brain barrier (BBB) status and cerebral vascular/parenchymal ultrastructure. Animals were infused i.v. with either rIL-2 or rIL-2 vehicle alone. Following transcardial perfusion with aldehydes, brains were processed for ultrastructural visualization of either horseradish peroxidase (HRP), injected prior to IL-2 infusion, or endogenous IgG. Blood-borne HRP and IgG are normally restricted to the intravascular compartment by the BBB. In both species, following light microscopic examination, brain tissue from all rIL-2 infused animals and from the majority of vehicle-infused animals showed extravasated HRP or IgG reaction product throughout the brain, predominately within subcortical white matter. Ultrastructural examination of brain tissue from animals with increased permeability revealed reaction product within perivascular basal laminae and within the brain parenchymal extracellular space. The observation that numerous endothelial cells were completely or partially inundated by tracer suggested direct transendothelial passage. Neither junctional cleaving nor increased pinocytotic activity was observed. All animals studied, regardless of permeability status, exhibited perivascular glial and neuronal swelling together with an expansion of the associated extracellular compartment. Additionally, highly vascuolated periarteriolar phagocytic cells were identified in all brains examined. These dramatic effects of a single rIL-2/vehicle infusion suggest that multiple infusions, used in man, may have a profound impact on the cerebral vasculature and the surrounding brain parenchyma. Furthermore, it appears that many of the cerebrovascular consequences may be mediated by the vehicle itself. In the interest of accelerating the development of an effective cancer therapy, free of adverse effects, these findings indicate that further study of cerebrovascular rIL-2/vehicle toxicity is mandated.

212.9 BRATTLEBORO RATS DEMONSTRATE NORMAL CEREBROMICROCIRCULATORY RESPONSIVITY TO ALTERATION IN ARTERIAL C02. Sheldon H. Preskorn, M.D., Steve J. Bupp, M.D.*, Melissa Croskell*, Heather Croskell*, Department of Psychiatry, University of Kansas School of Medicine-Wichita, Wichita, KS 67214.

A central adrenergic system (CAS) has been implicated in the regulation of: 1) cerebral capillary permeability to diffusion-limited substance (PS), 2) the surface area of the capillary bed, and 3) cerebral blood flow (CBF). There are several reasons to postulate that the CAS may mediate these effects indirectly through the release of vasopression (VP). First, the VP rich areas of the hypothalamus receive dense CAS innervation. Second, intracerebroventricular administration of arginine VP produces qualitatively similar effects on PS and CBF as CAS stimualtion. Third, effects of CAS stimulation on local glucose consumption has been reportedly blocked by CAS denervation of the hypothalmus.

We therefore elected to test whether PaC02-induced changes in PS, which we have previously shown is dependent on an intact CAS, are also dependent upon an intact VP system. Given that the previously reported surgical means to denervate the hypothalamus causes appreciable damage to other systems, we elected to first test this hypothesis in the Brattleboro rat which is genetically deficient of VP.

A dual label isotope procedure (Irwin and Preskorn, Brain Res., 1982) was used to simultaneously measure CBF and PS to water. Rats were passively ventilated with 02, N02, and varying amounts of C02. PS and CBF were measured in five brain regions: rostral telencephalon, caudal telencephalon, diencephalon, medulla-pons, and cerebellum. Three strains of rats were studied in an identical fashion in a latin square manner: Sprague-Dawley (SD), Long-Evans (LE), and brattleboro (BB). The SD strain has been used in our other studies. The BB is the pivotal strain to test the hypothesis. The LE strain is the one from which BB was derived. The LE and BB strains were obtained from the same supplier. All three strains were housed and handled in a similar manner.

Our results demonstrated no differences between these three strains in terms of PaC02 induced changes in PS or CBF in any brain region studied. In fact, the curves were superimposable. While PaC02-induced changes in these parameters are dependent on an intact CAS, they do not require an intact VP system. These findings are consistent with our theory that the CAS affects these parameters through adrenergic receptors located on cerebral capillaries.

212.10 **PERMEABILITY INCREASES CORRELATE WITH CHANGES IN LUMINAL SURFACE ANIONIC BINDING SITES IN THE RETINAL MICROVASCULATURE OF SPONTANEOUSLY DIABETIC RATS.** M.E.C. Fitzgerald and R.B. Caldwell, Department of Anatomy and Neurobiology, The University of Tennessee, Memphis, TN. 38163.

In diabetes, changes in microvascular barrier functions may contribute to the development of serious visual disability. Previous horseradish peroxidase (HRP) studies in diabetic rats suggest that permeability of the retinal microvasculature increases due to an increase in pinocytotic transport (Ishibashi et al., 1980). In brain arterioles of hypertensive rats, increases in pinocytotic transport are associated with decreases in anionic binding sites along the endothelial cell luminal surfaces (Nag, 1984). To see whether permeability increases in the diabetic retinal vasculature are also associated with alterations in endothelial cell luminal surface charge distribution, we studied cationized ferritin binding and HRP permeability in the diabetic rat retina.

We injected HRP (Type VI) into tongue veins of spontaneously diabetic (BB-WorUtm) rats. Animals were intracardially perfused with fixative at various time intervals after the injections, and the posterior pole of the retina was cut into 20-40 micron sections. HRP was then visualized using a diaminobenzidine reaction, and the tissue was processed for electron microscopy. Tissue sections from HRP injected animals were also incubated in cationic ferritin (0.5 mg/ml, 37°C, 1hr). All levels of the retinal microvasculature (outer plexiform, inner plexiform and nerve fiber layer) showed a greater HRP uptake in the diabetic endothelial cells as compared with the control vessels from the same regions. The tight junctions in all animals were intact. In control rats, HRP was confined to vesicles, cisternae, and multivesicular bodies. Cationized ferritin binding appeared generally uniform on the plasmalemma. Particles were also observed in coated pits, on the stomata of pinocytotic vesicles, in membrane pits continous with the plasmalemma, and on the luminal end of the interendothelial space. In the diabetic animals, HRP label was present in the same structures as the controls; however, some HRP-filled cisternae and vesicles were open to the basal lamina. Cationized ferritin binding in the diabetic animal was similar in distribution to that of the control, but the luminal surface binding was reduced in all levels of the retinal microvasculature. Particle-free areas were commonly observed. Furthermore, in the blood vessels where HRP-labeled cisternae or vesicles opened to the basal lamina, ferritin binding was not only reduced but also appeared patchy.

The presence of HRP-labeled vesicles and cisternae fusing with the basal lamina in the endothelial cell may signify early changes in the breakdown of the blood-brain barrier. The concomitant reduction of anionic binding sites on the luminal surface of the retinal microvasculature suggests that alterations in plasma membrane proteins or associated cell surface proteins may contribute to the permeability increases in the diabetic retina.

212.11 GLUCOSE INFLUX IS SUPPRESSED DURING CHRONIC HYPERGLYCEMIA IN RATS. R.B. Duckrow. Department of Medicine, Division of Neurology, The Pennsylvania State University, Hershey, PA 17033.

Chronically hyperglycemic diabetics may have cerebral symptoms if their plasma glucose is corrected suddenly. These symptoms could be caused by a relative substrate limitation to brain energy metabolism. This would imply that the kinetics of the facilitated diffusion of glucose from blood to brain is subject to adaptation. There are data indicating that the maximum rate of glucose transport into the brain decreases during chronic hyperglycemia. These data rely on the consistancy of cerebral blood flow and cerebral blood volume during acute and chronic hyperglycemia. Because cerebral blood flow and blood volume may change during hyperglycemia, the effect of acute and chronic hyperglycemia on glucose influx and cerebral blood volume was re-examined. Male Sprague-Dawley rats (350 g) were prepared for study using halothane-nitrous oxide anesthesia and restrained with plaster hip-casts to allow measurements to be made with the rats awake. Wounds were infiltrated with 1% procaine and all experiments ended with rapid decapitation. Acutely hyperglycemic rats were studied 10 minutes after intraperitoneal injection of d-glucose. Chronically hyperglycemic rats were studied at 1 and 3 weeks after intravenous injection of streptozotocin (60 mg/kg). The plasma glucose was 30 μm/ml in hyperglycemic rats and 10 μm/ml in sham-injected control rats. Cerebral blood volume was measured using [^{3}H]inulin and [^{14}C]sucrose. Glucose influx was measured using the intravenous tracer injection method described by Bachelard and by Ohno as modified by Hawkins (J. Neurochem. 40:1013, 1983). Clearance is measured at multiple time points up to 18 seconds after tracer injection in separate rats and the instantaneous influx expected at time zero is calculated. This method is relatively insensitive to changes in cerebral blood flow. Cerebral blood volume did not change from control measurements during acute or chronic hyperglycemia. Glucose influx increased and was similar during acute hyperglycemia and chronic hyperglycemia of 1 week duration. However, after 3 weeks of chronic hyperglycemia, glucose influx returned to levels equal to that measured in control animals with lower plasma glucose concentrations. This relative reduction in glucose influx implies that the kinetics of glucose transport is altered during chronic hyperglycemia. This "down-regulation" requires more than 1 week to occur and does not involve a change of cerebral blood volume. Because cerebral blood flow is decreased during both acute and chronic hyperglycemia it is unlikely that blood flow changes are involved in this adaptive process. (Supported in part by PHS NS24109. 212.12 ACUTE LOW DOSE MICROWAVE IRRADIATION ALTERS METHYL-NALTREXONE POTENCY IN MICE. D.G. Lange, A.M. Phelan, C. Fredricks, H. Kues and R.M. Quock. Department of Anesthesiology, and Applied Physic Laboratory, The Johns Hopkins Medical Institutions, Baltimore, MD 21205, and Department of Basic Sciences, Marquette University, Milwaukee, WI 53233.

Previous studies by a number of groups have suggested that acute as well as chronic microwave exposure may alter the CNS availability of systemically administered drugs. This alteration is thought to be due to changes in blood-brain barrier (BBB) permeability. These earlier studies have required high, thermogenic, doses of microwave exposure to achieve measurable changes in BBB permeability. Male ICR mice (20-25g) received morphine sulfate (MS), 10 mg/kg, ip (10 mg/ml). Five minutes after MS, saline, the narcotic antagonist naltrexone (0.2 mg/kg, ip), or its quaternary derivative methyl-naltrexone (2.5 mg/kg, ip) were administered and the animal placed into the microwave anechoic exposure chamber. Five minutes following exposure to sham or far-field microwave irradiation (2.45 gHz, 5 mW/cm^2, SAR = 3 W/kg, duration of 10 min) the animals were tested for nociceptive responsiveness on a hot plate. Both continuous and pulsed microwave exposures were examined. Microwave irradiated animals given morphine/methyl-naltrexone showed a significant decrease in the time to respond to applied nociceptive stimulus (16.46 $\pm$ 1.37 sec, n=8) versus sham exposed morphine/methyl-naltrexone treated animals (24.59 $\pm$ 1.96 sec, n=12). Neither microwave irradiation nor methyl-naltrexone administration alone altered morphine's antinociceptive activity. Thus, microwave irradiation, at power densities and exposure durations designed to avoid a hyperthermic response in the animal model produces a change in the CNS pharmacologic potency of methyl-naltrexone, an agent normally excluded from the brain. It is suggested that low dose microwave irradiation may significantly alter BBB function, in the absence of hyperthermia. (Supported by ES 03386).

212.13 MIDDLE CEREBRAL ARTERY THROMBOSIS: ACUTE BLOOD-BRAIN BARRIER CONSEQUENCES. W.D. Dietrich, R. Prado, B.D. Watson and H. Nakayama. Cerebral Vascular Disease Research Center, Departments of Neurology, Anatomy and Neurosurgery, University of Miami School of Medicine, Miami, FL 33101.

The effect of middle cerebral artery (MCA) thrombosis on the behavior of the blood-brain barrier (BBB) was studied in rats. MCA thrombosis was produced by a dye-light insult and the BBB assessed by the protein tracer horseradish peroxidase (HRP). The beam of a tunable argon ion laser operated at 514.5 nm at a power level of 25 mW was first focused onto the MCA of anesthetized rats just proximal to the olfactory tract. Rose bengal (1 mg in 0.133 ml saline/100 g animal weight) was infused simultaneously with the start of irradiation. On an average, 2-3 min were required for partial occlusion while 5 min of irradiation was carried out for complete occlusion of the MCA. Rats were then injected intravenously with 20 mg/ml HRP. Fifteen min following the end of the irradiation period, rats were perfused for scanning (SEM) and transmission electron microscopy (TEM). The irradiated MCA segment was removed from the surface of the brain, cut longitudinally, and processed for SEM. Vibratome sections were incubated with 3,3' diaminobenzidine and processed for light or TEM analysis.

In sham-operated control rats (irradiation without rose bengal infusion), the MCA appeared unremarkable and no extravasation of HRP was observed. In rats which underwent complete occlusion of the MCA, a large platelet thrombus occupying the entire vessel lumen was seen with SEM. Proximal and distal to the thrombus, the artery appeared constricted and the endothelial cell layer was damaged. Vibratome sections demonstrated widespread protein leakage in both ipsilateral and contralateral hemispheres. HRP staining was most intense within the ipsilateral striatum and deeper layers of the neocortex. A similar but less intense pattern of HRP leakage was apparent in rats following non-occlusive thrombosis. In addition to diffuse barrier leakage, focal sites of HRP leakage within both gray and white matter were seen in 3 out of 4 rats. With TEM, enhanced endothelial transport of HRP was demonstrated. In summary, experimentally induced MCA thrombosis results in an immediate breakdown of the BBB to HRP. The extent of barrier leakage was widespread and not confined to the occluded MCA territory. It is hypothesized that unidentified neurohumoral substances or factors released at the thrombotic site and not cerebral ischemia are responsible for the acute barrier alterations. Supported by NIH grants NS5820 and NS23244. WDD is an Established Investigator of the American Heart Association.

212.14 BLOOD-BRAIN BARRIER BREAKDOWN AND RESTITUTION FOLLOWING BRAIN INJURY J.B. Farrell*, G.S. Sarna*, and M.E. Carey* (Spon. J.S. Soblosky) Department of Neurosurgery, LSU Medical Center, New Orleans, LA. 70112.

Brain injury may be associated with damage to the blood-brain barrier (BBB) and vasogenic brain edema (VBE). In prior experiments studying the occurrence of VBE following a 0.9 Joule missile wound we determined that VBE peaks at 24-48 hours, then recedes (Abstract: Annual Meeting of the American Association of Neurological Surgeons, 1986). Repair of the damaged BBB, whereby plasma electrolytes, water and proteins are prevented from entering the extracellular fluid, is necessary for the resolution of VBE. We recently studied BBB breakdown and restitution following an experimental missile wound to the brain by means of Evans blue dye (EBD)(MW 68,000) to ascertain when BBB integrity was reestablished to the large EBD-albumin molecule and to learn whether BBB damage occurred only locally about the missile track or in distal areas as well.

Cats were anesthetized with pentobarbital (44 mg/kg) and placed in a stereotaxic frame. We created a fronto-occipital right cerebral hemisphere wound using a 31 mg steel sphere fired by a custom made gun at $\simeq$ 240 m/sec (0.9 Joules). The cats were injected intravenously with 2% EBD (2.5 cc/kg) at 10 minutes and 1, 6, 24, 48 and 72 hours after injury. The cats were then painlessly euthanized and their brains fixed-perfused. The brains were then removed, sliced and photographed in order to make a permanent record of BBB breakdown.

We observed EBD extravasation about the missile track up to 24 hours after wounding, but not thereafter. For large molecules such as EBD-albumin, the BBB regains its integrity at about 24 hours after a 0.9 Joule missile wound. This time interval correlates well with peak occurrence of VBE which we have documented in our model, as well as with the beginning of VBE resolution after this time. Our EBD studies have shown areas of BBB breakdown distally in the brain stem in some animals. Thus, structural damage appears to occur in the brain stem, which may be associated with "brain stem effects" commonly seen after wounding (i.e. hypertension, respiratory depression and bradycardia).

212.15 ALTERATIONS IN SPINAL CORD VASCULATURE AFTER SPINAL CORD INJURY. L.J. Noble, J.A. Ellison* and M. Kwok*. Dept. of Neurology, Sch. of Med., University of California, San Francisco, Ca 94122.

We have previously examined the permeability of spinal cord vasculature to the protein horseradish peroxidase (HRP) after transection and reported that there was an axial spread of tracer both proximal and distal (caudal) to the injury. Vascular permeability to the tracer was maximal at 1 day after transection. However, by 2 weeks the barrier to HRP was re-established (Brain Res., In Press). Because the neural axis undergoes degeneration for an extensive period of time, we postulated that although spinal cord vessels are no longer "leaky" to HRP, they may still be influenced by these degenerative events.

In an initial study we wished to determine whether the vascular response to injury is altered in segments of spinal cord undergoing degeneration. One month after transection at the T2 segmental level, a second transection was made 2-3 segments distal to the first. The barrier response to HRP was evaluated at 1, 3, and 6 h and 1 day after the second transection. The distribution of reaction product (RP) and hemorrhage was examined at the light microscopic level in samples at 0.5, 1.0, and 2.0 cm distal to the second transection and 0.5, 1.0, and 2.0 cm proximal to the first transection. The areas of RP and hemorrhage were determined at each sampling site. These results were compared with the same parameters at sites distal to a single transection.

The pattern and extent of hemorrhage was similar in the distal cord after either a single or double transection. Hemorrhage was typically restricted to a central zone in the dorsal columns and only rarely extended into the adjacent gray matter. In contrast, there appeared to be a marked increase in RP after a double transection as compared to a single transection. RP was associated with dorsal column hemorrhage, appearing as a halo around the extravasation. In addition, it was also noted in the gray matter and in the peripheral white matter in the absence of hemorrhage. Although RP was primarily extracellular, it also appeared to be present in neurons, ependymal cells, and glia.

After a double transection, RP was not restricted to sites distal to the second transection, but was also present in segments of cord proximal to the first transection. RP appeared as early as 3 h after the second transection and became more extensive with time. It was typically located in the peripheral white matter, dorsal columns, and occasionally within gray matter.

This data indicate that there is a prolonged and extensive sensitivity of the barrier after spinal cord injury. It is not readily apparent until challenged, in this case by a second transection, and then responds with marked permeability to protein along the axis of the cord.

This research was supported by NIH NINCDS RO1NS23323-03.

212.16 IgG, IgM, AND ALBUMIN BLOOD NERVE BARRIER INDICES IN HUMAN DIABETIC NEUROPATHY.
Joseph F. Poduslo, Geoffry L. Curran*, Kurt R. Brunden*, Peter J. Dyck (Spon: A. G. Engel) Membrane Biochemistry Laboratory, Peripheral Nerve Center, Mayo Clinic and Mayo Foundation, Rochester, MN 55905 USA

A highly sensitive and specific solid-phase antibody-capture assay was developed to measure IgM and IgG in fascicular biopsies of human sural nerve from healthy controls and patients with diabetic neuopathy. Assay amplification was obtained by utilizing biotin-labeled anti-IgM or anti-IgG antibody and ^{125}I-streptavidin. When this assay was applied to normal fascicular biopsies from human sural nerve, the percent of IgM and IgG, respectively, of the total endoneurial protein was 0.021±0.005% and 0.50±0.21% (Mean ± SD; N=3). When these endoneurial concentrations of IgM and IgG were correlated with the plasma concentrations (mg IgM or IgG/mg total plasma protein), an IgM-BNB-Index of 3.17±0.48% and an IgG-BNB-Index of 3.82±1.67% were obtained (Mean ± SD; N=3). These values were also correlated with the albumin (Alb) concentration in the biopsies (1.58±0.18% mg) and with the Alb-BNB-Index (2.53±0.61%) (Mean ± SD; N=3).

The Alb and IgG concentrations in the endoneurium of fascicular sural nerve biopsies were significantly elevated in 5/5 diabetic neuropathy patients, and the IgM concentration was significantly elevated in 3/5 patients. Plasma concentrations of these macromolecules in patients was normal, except for a significant increase in the IgG of 4/5 patients. After normalization to total endoneurial protein and plasma protein, BNB indices were significantly increased for Alb (19.20±7.70%; P=0.006; 5/5), IgG (8.61±3.42%; P=0.034; 5/5), and IgM (6.65±1.57%; P=0.011; 3/5). The endoneurial compartments containing these plasma proteins consist of the endoneurial space occupied by the endoneurial fluid, the vascular compartment, and the cellular compartment. Since it is likely that these compartments are not altered in diabetic neuropathy patients, it is hypothesized that the observed increase of these plasma proteins in patients results from altered transport through the capillary endothelial barrier. Increased routes of entry might involve leaky tight junctions and/or plasma membranes, or an increase in intracellular vesicle transport. The endoneurial ratio of Alb/IgG was decreased 2.5 fold, even though plasma IgG was elevated, and the endoneurial ratio of Alb/IgM was decreased 3.3 fold compared to controls. Although the endoneurial IgG and IgM levels are increased in diabetic neuropathy patients, the Alb increase is greater suggesting a mechanism other than extravasation of plasma proteins. (Supported by NINCDS Grant NS-14304 and by the Borchard Fund).

212.17 MORPHOMETRIC ANALYSIS OF FROG BLOOD-NERVE BARRIER DURING CHRONIC WALLERIAN DEGENERATION. C.H. Latker*, K. Wadhwani, A. Weerasuriya, A. Balbo and S.I. Rapoport (Spon:Don Newman) Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

The entry of water-soluble substances into the endoneurial compartment of the peripheral nerve is limited by endoneurial blood vessels and by the perineurium, which together comprise the blood-nerve barrier (BNB). We previously showed that during chronic Wallerian degeneration (WD), there was an increase in permeability of the BNB to [14C]sucrose and horseradish peroxidase (HRP) and an increase in the vascular space (Latker et al., Soc. Neurosc. Abst, '86). Proliferation of non-neuronal cells of the peripheral nerve also occurred. In this study we investigated during chronic WD proliferation of BNB cells in relation to changes in the endoneurial vascular space and BNB permeability. Sciatic nerves of adult frogs were severed in the abdominal cavity, ligated to prevent regeneration, and examined at distal points in the thigh at intervals of 3 days to 7 months. One day after intraperitoneal injection of [3H]thymidine, the animals were killed and the nerves were processed for autoradiography, and light and electron microscopy. The cells in the endoneurium and perineurium that incorporated [3H]thymidine and the number and area of endoneurial blood vessels were quantified. In endothelial cells (EC) of endoneurial blood vessels proliferation occurred at 7 days, corresponding to the increased permeability to [14]sucrose and HRP. Both vascular permeability and EC proliferation increased to day 14, returned toward normal at 6 weeks and continued at near normal levels to 7 months. The blood vessels increased in number and frequently in size resulting in an increased vascular space. Proliferation of perineurial cells was seen at 7 days, but incresed perineurial permeability was not detected until 10 days. After 6 weeks proliferation ceased, but perineurial permeability remained elevated for 7 months. This study suggests that following WD: 1) the permeability of the endoneurial vasculature increased temporarily in tandem with proliferation of the EC cells, 2) the increase in vascular space was due to EC proliferation, and 3) after proliferation ceases, the perineurial cells did not form a tight barrier. The presence of nervous elements may be necessary for the maintenance of the perineurial, but not the vascular, component of the BNB.

212.18 IRREVERSIBLE INCREASE OF PERINEURIAL PERMEABILITY AND WATER CONTENT OF THE FROG PERIPHERAL NERVE DURING WALLERIAN DEGENERATION. K.C. Wadhwani, C.H. Latker, and S.I. Rapoport. Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

In the vertebrate peripheral nerve, the perineurium and endoneurial blood vessels form a blood-nerve barrier (BNB), which limits entry into the endoneurial compartment of proteins and water-soluble substances from blood. This study investigates whether the integrity of the perineurial barrier requires the presence of neuronal factors. Lumbo-sacral plexuses in the abdominal cavity of adult female frogs, R. pipiens, were cut and tied to prevent regeneration. At 7, 10, 14, 21, and 147 days, during Wallerian degeneration, perineurial permeabilities to ^{3}H-sucrose and ^{14}C-dextran (MW=70,000) of the sciatic nerve were determined and compared with the contralateral uncut nerve. Water content, nerve conduction velocity and maximal voltage of compound action potential (CAP) of the degenerating nerve were also measured. Seven days after transection, the water content of the degenerating nerve [(73.5 ± 0.6) % wt wt] (mean ± S.E., n=8) was significantly higher ($p<0.05$) than in the contralateral uncut nerve (71.9 ± 0.4 % wt wt), but the maximal voltage and conduction velocity of CAP, as well as the perineurial permeabilities to sucrose and dextran were unchanged. After 10 days, the degenerating nerve showed significant increases in permeabilities of the perineurium to ^{3}H-sucrose [$(3.71 \pm 1.00)\times10^{-7}$ cm/sec] and ^{14}C-dextran [$(2.37 \pm 0.29)\times10^{-7}$ cm/sec] when compared to values in the uncut nerve [$P_{sucrose} = 0.78 \pm 0.09$ and $P_{dextran} = 1.12 \pm 0.19$] ($p<0.05$). Similarly, the maximal voltage and the conduction velocity of CAP was significantly decreased. Between 14 days and 147 days, no CAP was detected and perineurial permeability as well as water content of the degenerated nerve increased with time. After 147 days, perineurial permeabilities to ^{3}H-sucrose and ^{14}C-dextran in the degenerated nerve were 7 fold higher than in the uncut nerve. The water content [(83.4 ± 0.8) % wt wt] also was significantly higher [(73.5 ± 0.7) % wt wt]. We conclude that: 1) the perineurium of the frog peripheral nerve may need neuronal factors to maintain its barrier function, and 2) the edema observed in the degenerated nerve may be a consequence of increased perineurial permeability.

213.1 ANATOMICAL DISTRIBUTION OF IMMUNOREACTIVITY FOR PRE-PRO-TRH160-169, A POSSIBLE MARKER FOR TRH NEURONS. M.W. Wessendorf, R. Wohlhueter*, and R. Elde, Dept. Cell Biology and Neuroanatomy, and Inst. Human Genetics, Univ. Minnesota, Minneapolis, MN 55455

Attempts at immunohistochemical staining for thyrotropin-releasing hormone (TRH) have frequently been unsuccessful. In addition, even when staining has been obtained different antisera have sometimes produced different patterns of staining. For instance, not all groups have observed staining for TRH in the superficial dorsal horn of the spinal cord. Because of these considerations, an alternate method of localizing TRH would be desirable. Recently, the sequence for the precursor to rat TRH was described. Within one molecule of pre-pro-TRH were 5 molecules of pro-TRH, each separated by one of several novel peptide sequences. It was decided to test whether an antiserum directed against one of these intervening peptide sequences might be useful for localizing TRH-synthesizing cells and axons.

The decapeptide pre-pro-TRH160-169 (SFPWMESDVT; abbreviated ppT) was synthesized by solid-phase methods and purified using HPLC. Amino acid analysis was used to confirm the identity of the purified fraction. ppT was conjugated to bovine thyroglobulin (BTG) using glutaraldehyde, and rabbits were hyperimmunized with the conjugate. Rat brain and spinal cord were examined for ppT-like immunoreactivity using fluorescence immunohistochemistry.

The neuronal distribution of ppT-like immunoreactivity closely resembled that reported for TRH. Fibers and terminals strongly immunoreactive for ppT were observed in the median eminence of the hypothalamus. Strongly-labeled fibers and terminals were also observed in the spinal cord in the ventral horn, the intermediolateral cell column, and around the central canal. Fibers and terminals more lightly stained for ppT were also observed in the superficial dorsal horn. In rats pretreated with colchicine, ppT-immunoreactive cell bodies were visible in the paraventricular nucleus and in the medullary raphe nuclei. Using simultaneous 2-color immunofluorescence it was found that ppT-immunoreaactive cell bodies in the vicinity of the medullary raphe frequently were also immunoreactive for serotonin. Using the same technique in the spinal cord it was found that fibers and terminals immunoreactive for serotonin were generally also immunoreactive for ppT. However, such double-labeling was seldom observed in the superficial dorsal horn. ppT-like immunoreactivity was abolished when tissue was stained with antiserum preincubated with 10 µg/ml ppT-BTG conjugate.

It is concluded that the distribution of ppT closely resembles that of TRH, and that ppT may be useful as a marker peptide for neurons containing TRH. In addition, the presence of ppT-like immunoreactivity in the superficial dorsal horn suggests that TRH is also present in that region.

213.2 7-AMINO-4-METHYLCOUMARIN-3-ACETIC ACID (AMCA): A BLUE FLUOROCHROME USEFUL FOR THREE-COLOR IMMUNOHISTOCHEMISTRY. N. Appel, M. Wessendorf and R. Elde. Dept. Cell Biol. Neuroanatomy, U. Minn. Mpls. MN 55455

We have been investigating the hypothesis that the neurochemical identity of a population of neurons may reflect its anatomical and physiological character. To this end we characterized a method of two-color fluorescence immunohistochemistry in order to observe pairs of neurotransmitter-related antigens in single sections of nervous tissue (Wessendorf and Elde, *J. Histochem. Cytochem.* 33:894, 1986). Recently, Khalfan *et al.* (*Histochem. J.* 18:497, 1986) and Staines *et al.* (in press) suggested the use of 2° antibodies labeled with coumarin derivitaves for fluorescence immunohistochemistry. These substances appear blue under ultraviolet (UV) excitation. We found that AMCA-labeled 2° antibodies could be used in combination with 2° antibodies labeled with fluorescein and with lissamine rhodamine to observe simultaneously three neurotransmitters in single tissue sections.

Transverse, slide-mounted cryostat sections of spinal cord from rats which had been perfused with Zamboni fixative were rehydrated with phosphate-buffered saline (PBS) and incubated for 10 min with 50 µl of10% normal goat serum in PBS/0.3% Triton X-100. Subsequently they were incubated overnight at 4°C with 50 µl of a solution containing rabbit antiserum to serotonin (5HT), rat antibody to substance P (SP) and mouse antibody to leucine enkephalin (Enk) (1:100, 1:100 and1:50) in PBS/0.3% Triton X-100. The following day they were incubated for 1 hr at room temperature with AMCA-labeled goat immunoglobulins directed against rabbit IgG (GAR), 1:24 in PBS/0.3% Triton X-100, in combination with fluorescein labeled goat antibody to rat IgG (1:10; preabsorbed with mouse liver powder) and lissamine rhodamine labeled antibody to mouse IgG (1:30; preabsorbed with rat liver powder). AMCA (BioCarb, Lund Sweden) was conjugated to GAR as described by Khalfan *et al.*

Under UV illumination, blue AMCA-stained 5HT-immunoreactive fibers were visible in ventral horn, around the central canal and in the intermediolateral cell column. Under green or blue illumination Enk- or SP-immunoreactive fibers, respectively, were observed in superficial dorsal horn, lateral spinal nucleus, intermediolateral cell column, ventral horn and around the central canal. In some of these areas we observed fibers and terminals immunoreactive for combinations of these neurotransmitters. Specifically, in ventral horn we observed single motor neurons apposed by one fiber labeled for both coexisting SP and Enk, but not 5HT and another fiber labeled for both coexisting SP and 5HT, but not Enk. In addition, when sections containing neurons previously retrogradely labeled with Fluoro-Gold (FG) were immunostained in this manner, we could observe the retrogradely labeled neurons in addition to their immunostained neuropil. Thus, a four-color fluorescence histochemical detection system had been accomplished. Moreover, since FG and AMCA are both excited by UV light, FG labeled neurons and the AMCA-stained fibers apposing them were visible simultaneously.

This technique offers a convenient method for simultaneously detecting three neurotransmitter- related antigens in single tissue sections. In addition, it provides an increased level of resolution for establishing the neurochemical identity of a population of neurons. Supported by grants DA 05275, NS 22665 and DA 02148.

213.3 DIRECT SIMULTANEOUS VISUALIZATION OF GABA INNERVATION AND SEROTONIN UPTAKE IN ADRENAL MEDULLARY CELLS. M.F. Franzoni,+ M. Beltramo,+ M.L.Sapei,+ C.Decavel+ and A.Calas (SPON:ENA).Dip.Biol.Animale Università,10123 Torino,Italy; Lab.Physiol.Interactions Cell. UA339CNRS,Université Bordeaux I,33405-Talence,France.

We have previously demonstrated the presence of a content and of a selective neuronal uptake of ^{3}H serotonin (5-HT) by adrenaline cells of mouse and rat adrenal medulla (AM). Biochemical approaches have shown that rat AM cells contain,take up,release and bind GABA which can control the catecholamine secretion. Moreover GAD has been detected in AM cells and fibers by immunohistochemistry.

In order to further determine in a comparative approach possible relations between GABA and 5-HT in the AM we have combined a radioautographic (RAG) study of ^{3}H 5-HT uptake with a simultaneous detection of endogenous GABA content. Either mice and frogs were intracardially injected with 3.7 10^{6}Bq of 10^{-4}M ^{3}H 5-HT together with 10^{-3}M cold Noradrenaline (NA)or adrenals were in vitro incubated in 10^{-6}M ^{3}H 5-HT with 10^{-5} M NA. The fixative was 4% glutaraldehyde.Vibratome sections were treated with 1:5000 anti-GABA antibodies(Immunotech,Luminy,France) revealed by Fab coupled with peroxidase,then radioautographied with K5 Ilford Nuclear emulsion exposed for 20 days. Intense,although variable RAG reactions occurred on AM cells of all species,especially at the periphery of the gland in the mouse. Noticeable bundles of nerve fibers and terminals among the AM labeled cells were immunopositive in the mouse and in the frog,although with a lesser density and a thinner aspect.The GABA immunoreactivity of the AM cells was difficult to assess although silver grains seemed to occur either on immunopositive as well as negative cells.

These techniques suggest in both groups intercellular relations between GABA innervation and 5-HT related AM cells which can be further explored at E.M. level. They can help to define other types of interrelations between these transmitters. (Work supported by NATO 86/0796)

213.4 GOLGI STAINING AND CHOLINE ACETYLTRANSFERASE IMMUNOHISTOCHEMISTRY ON THE SAME BRAIN SECTION. L.K. Gorman, T.W. Farris, N.J. Woolf, and L.L. Butcher. Department of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024-1563, U.S.A.

A procedure has been developed for routine use that permits the exquisite morphologic detail evinced by use of the Golgi technique to be demonstrated on the same brain section processed immunocytochemically for various neurochemical indices. Using a modification of the single-section Golgi method of Gabbott and Somogyi (1984, J. Neurosci. Meth. 11: 221-230) and choline acetyltransferase (ChAT) immunohistochemistry (e.g., Gould and Butcher, 1986, Neurosci. Lett. 63: 315- 319), we have examined the morphologies of putative cholinergic and non-cholinergic neurons in the basal forebrain and caudate-putamen complex. Rats aged 25-30 days were perfused transcardially with a 4% paraformaldehyde-2% picric acid solution and postfixed for 24 hrs in a solution with the same composition as the perfusate. Sections 100 µm thick were then prepared on a Vibratome. Free-floating sections were processed for ChAT-like immunoreactivity (Eckenstein-Thoenen monoclonal antibody; gift of Dr. Felix Eckenstein) according to the avidin-biotin method. Following immunostaining, brain sections were Golgi stained as follows: sections were rinsed once in phosphate- buffered saline (pH, 7.4) and then placed into 3.5% potassium dichromate for 24 hrs. Sections were then mounted onto a coverslip, and another coverslip was placed over the mounted sections. This assembly was then placed between two standard-size glass slides. The resulting "Golgi sandwiches" were then put into a Coplin jar containing a 1.5% silver nitrate solution. At least 4 days were allowed for neuronal impregnation. Microscopic analyses were performed on fully impregnated cells, and photographs were taken of these neurons. The tissue sections were then removed carefully from the coverslips, mounted onto pig-gelled slides, and affixed to a petri dish. The entire preparation was then covered with a 5% sodium thiosulfate solution and microscopically examined during the dissolving of the silver chromate deposits. Spiny neurons in the caudate-putamen complex and basal forebrain were not found to be ChAT positive. Some Golgi impregnated cells that were large (20-40 µm in maximum soma extent) and aspiny or sparsely spined were demonstrated to be ChAT positive, thereby confirming previous suggestions that cholinergic neurons in the striatum and basal forebrain cholinergic system evince few or no spines (Woolf and Butcher, 1981, Brain Res. Bull. 7: 487-507; Bigl, Woolf, and Butcher, 1982, Brain Res. Bull. 8: 727-749). [Support: NS 10928 to L.L.B.].

213.5 SERIAL 2 MICRON CRYOSTAT SECTIONS: A MODIFIED COLOCALIZATION TECHNIQUE FOR IMMUNOCYTOCHEMISTRY. B. Quinn & E. Weber. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

Three general approaches are available in light microscopy for the colocalization of different antigens within the same cell: (1) differential visualization of primary antibodies generated in different species; (2) repeated staining of the same section after elution of previous antibodies; and (3) use of serial sections in which the same cell is visible on several sections. The serial method requires no special reagents, but demands thin sections with good morphology. Because polyethylene glycol (PEG) is used in immunohistochemistry as a water-soluble wax (Smithson et al., J. Neurosci. Meth. 7:27, 1983), we investigated its use in thin cryostat sectioning.

Rats were perfused with 4% buffered paraformaldehyde/4% sucrose and blocked brains were immersed overnight in one of four cryoprotectants: 20% sucrose, 5% sucrose, 3% PEG (MW 400), or 20% sucrose + 3% PEG. Tissues were frozen in freon at either dry ice or liquid nitrogen temperature, stored in sealed vials at -70°, and sectioned at -20° to -30° C. Unlike 20% sucrose, 5% sucrose allowed sectioning in the 3-5 micron range, but morphology was somewhat poor. 3% PEG alone had a plasticizing effect and thus allowed 1 micron sections, but with very poor morphology. The combination of 20% sucrose and 3% PEG allowed routine cutting of 1-2 micron sections with good morphology, when tissue was frozen in freon/N_2 and sectioned at -25° to -30°.

In summary, we found that combined PEG/sucrose infiltration can be readily incorporated into existing frozen section protocols, and provides a simple and rapid method of evaluating possible antigen colocalizations. This approach should also be compatible with the multiple-species antisera or serial elution methods, possibly allowing the analysis of four or more antigens when those methods are available.

213.6 **MICROWAVE POST-FIXATION ENABLES RAPID PROCESSING OF CNS TISSUE FOR ULTRASTRUCTURAL AND IMMUNOHISTOCHEMICAL STUDIES.** A.J. Hodgson, I. Llewellyn-Smith*, J. Minson*, J.P. Chalmers*, P. Pilowsky*. Centre for Neuroscience, Flinders University, Bedford Park 5042, South Australia.

The treatment of brain and spinal cord with microwaves enables rapid fixation and preserves antigenic and ultrastructural integrity. Adequate fixation of fine structure with preservation of immunoreactivity is often difficult to achieve. Commonly used aldehyde mixtures can give poor preservation of heavily myelinated regions (Peters, In:Contemporary Research Methods in Neuroanatomy, pp 56, 1970). Furthermore, high concentrations of glutaraldehyde, whilst giving good ultrastructure, are acknowledged to affect many antigens adversely. We explored the utility of post-fixation by microwave treatment. We reasoned that, by speeding the fixation and reducing the time that tissue is exposed to aldehydes, both good ultrastructural and antigenic preservation would be achieved. Rats were anaesthetized and perfused briefly through the descending aorta with tissue culture medium gassed with 95% O_2 and 5% CO_2 followed by a fixative containing 10% formalin, 0.5% glutaraldehyde, 0.2% picric acid in phosphate buffer pH 7.4, at a rate of 200-300ml/min for 2-4 mins. The brain and spinal cord were rapidly removed, divided longitudinally, immersed in the same fixative, and rapidly heated to 60-65°C in a domestic microwave oven operating at full power (1 kW, 2.45 GHz). This took 20-60 sec. depending on the volume of fixative. The fixative was maintained at 60-70°C in the microwave oven ("defrost" setting) for 2,4,8 or 16 minutes. Post-fixation continued for a further 15,30 or 60 minutes. Different fixation protocols were compared using semithin (1um) and ultrathin sections of osmicated, plastic-embedded tissue. The preservation of the cell bodies, neuropil and myelin sheaths, particularly in large fibre tracts, was evaluated. The optimal fixation was produced by heating rapidly to 60-65°C, maintaining this temperature for at least 8 minutes followed by 60 minutes in the cooling fixative. With this rapid fixation protocol the fine structure of neuronal perikarya, axons and dendrites, myelin sheaths, mitochondria, synapses, synaptic vesicles, ribosomes and microtubules was well preserved. In light microscopic studies using 50um Vibratome sections labelled in the presence of 0.3% Triton X-100, immunoreactivity for substance P, neuropepide Y and serotonin was present. Microwave post-fixation has the following advantages. (1) The method is rapid, with tissue being fixed for ultrastructural studies within 90 minutes. For LM studies the material can be cut on a Vibratome after only 4-8 minutes of fixation. (2) Ultrastructure is well preserved. (3) Immunoreactivity for neuropeptides and serotonin is retained. (Supported by grants from the NH & MRC of Australia).

SOMATIC AFFERENTS II

214.1 A FINK-HEIMER STUDY OF THE MEDULLARY PROJECTIONS OF CERVICOTHORACIC DORSAL ROOTS IN THE CAT, WITH SPECIAL REFERENCE TO C1 FIBRES. C.K. Tan* and W.C. Wong. Department of Anatomy, National University of Singapore, Kent Ridge, Singapore 0511.

20 adult cats (1.5 - 3.0 kg) were used for the present study. All animals were anaesthetized with sodium pentobarbitone at a dosage of 30 mg per kg body weight both for operation and sacrifice. Intradural rhizotomies of C1 to T2 dorsal roots were performed through a hemilaminectomy under aseptic conditions (3 cats for C1, 2 for C2, 2 for C3, 2 for C4, 1 for C5, 1 for C6, 3 for C7, 1 for C8, 1 for T1 and 1 for T2). Sham operations were carried out in 3 cats in which C3, C5 and C8 dorsal roots, respectively, were exposed but not cut. All cats were sacrificed five days after operation by vascular perfusion with 10% formalin and processed by the Fink-Heimer method to demonstrate terminal degeneration.

The present study confirms the findings of other previous studies that the dorsal root fibres of cervicothoracic origin terminate both in the dorsal cell nest region as well as in the ventrocaudal and rostral, reticular regions of the ipsilateral cuneate nucleus. In the cell nest region, the upper cervical fibres terminated more laterally than the lower ones but the ventrocaudal and rostral regions of the nucleus, no somatotopia was observed.

After C2 and C3 dorsal rhizotomy, terminal degeneration was observed not only in the ipsilateral cuneate nucleus but also in the ipsilateral nucleus of the tractus solitarius. But after C1 dorsal rhizotomy, terminal degeneration was observed to be more widespread. Degeneration was observed bilaterally in both the cuneate and gracile nuclei and was more dense ipsilaterally. In the ipsilateral cuneate nucleus, terminal degeneration was observed in the lateralmost part of the dorsal cell nest region; in the ventrocaudal and rostral, reticular zones of the nucleus, it was less dense. In the contralateral cuneate nucleus, terminal degeneration was sparse and was observed only in the ventralmost part of the nucleus. In the gracile nucleus, no degeneration was observed rostral to the obex. In the ipsilateral gracile nucleus, terminal degeneration was most dense in the region of the obex but in the contralateral nucleus, it was sparse. Terminal degeneration was also observed throughout the entire rostrocaudal extent of the ipsilateral nucleus of the tractus solitarius. Degeneration was also observed in the dorsal part of the ipsilateral spinal nucleus of the trigeminal nerve above the rostral end of the pyramidal decussation. Sparse degeneration, was also observed in the dorsolateral part of the ipsilateral medullary reticular formation.

The present findings indicate that the first three cervical dorsal roots project not only to the dorsal column nuclei but also to a cranial nerve visceral afferent nucleus (nucleus of the tractus solitarius), and a cranial nerve general somatic afferent nucleus (spinal nucleus of the trigeminal nerve). Of particular interest is the observation that C1 dorsal root fibres, unlike others, also terminate in the medullary reticular formation. These observations suggest that the first three cervical dorsal roots, in particular C1, are concerned not only with afferents arising from the neck but possibly also with others arising from areas supplied by the cranial nerves.

This study was supported by a grant from the Singapore Turf Club.

214.2 TERMINATIONS WITHIN THE CENTRAL NERVOUS SYSTEM OF PRIMARY JOINT AFFERENTS FROM THE RAT KNEE AND ANKLE. C.N.R. Henderson* and S. Saporta. Dept. of Anat., Coll. of Med. Univ. of S. Fla., Tampa, FL 33612.

The rat has become a promising animal model for the study of rheumatoid arthritis and chronic joint pain. This has served to focus interest on joint receptors and their central terminations. We have used the transganglionic transport of wheatgerm agglutinin conjugated to horseradish peroxidase (WGA-HRP) to demonstrate the central nervous system terminations of primary afferents from the joint capsules of the rat knee and ankle. Rats of either sex were anesthetized with methohexitol sodium (50 mg/kg). Each joint capsule was injected twice, under fluoroscopic guidance (Levine, J.D. et al., Science, 226:547, 1984), with 5% WGA-HRP dissolved in radiocontrast medium (43% iothalamate meglumine). The knee was initially injected with 20 µl of WGA-HRP, followed 24 hours later by a second 20 µl injection. The contralateral ankle was given two 10 µl injections following the same time sequence. Seventy-two hours after the initial injection, each animal was anesthetized with sodium pentobarbital (40 mg/kg) and perfused transcardially with saline, followed immediately by cold 1% paraformaldehyde-2% glutaraldehyde in phosphate buffer (pH 7.4). Frozen 40 µm sections of the caudal medulla, spinal cord segments T8 through L6 (inclusive), and dorsal root ganglia L3, L4 and L5 were reacted with tetramethylbenzidine (TMB) to demonstrate the presence of WGA-HRP.

Small, medium and large perikarya were labeled in the dorsal root ganglia. Ankle injections produced a large number of labeled cells in both L3 and L4 ganglia, while only L4 was heavily labeled by the knee injections. Three distinct areas of terminal label were observed within the central nervous system from injection of either the knee or ankle joints. Knee injections produced a small cluster of terminal label in the medial portion of the medial half of spinal dorsal horn laminae I and II. Ankle injections produced a larger cluster of terminal label in the lateral portion of the medial half of laminae I and II. In some sections, terminal label from the ankle extended into lamina III. Label was present in the central portion of the nucleus gracilis caudal to the obex following knee or ankle injections. As in the spinal cord, more reaction product was present in the nucleus gracilis from the ankle injection, as compared to label from injection of the knee. Terminal label was also present in the nucleus dorsalis following knee or ankle injections. In all instances, label was only present ipsilateral to the side of joint injection.

Supported by BRSG S07 RR05749.

214.3 CALCITONIN GENE-RELATED PEPTIDE CONTAINING NERVES IN PERIOSTEUM MAY BE PRIMARY AFFERENT IN ORIGIN. Esther L. Hill and Robert Elde. Dept. of Cell Biology and Neuroanatomy, Univ. of Minnesota, Minneapolis, MN 55455

Recently, it has been suggested that peptidergic neurons play a role in the local regulation of bone mineralization. The neuropeptide vasoactive intestinal peptide (VIP) increases bone resorption in vitro, while calcitonin gene-related peptide (CGRP) has been shown to inhibit bone resorption in vitro and, at high doses, to reduce plasma calcium levels in vivo. CGRP and VIP circulate at levels too low to evoke hormonal responses from bone. However, nerve fibers may release high concentrations of neuropeptides into small areas of tissue . Sympathetic nerves with VIP- immunoreactivity innervate bone and periosteum. We sought to determine if CGRP fibers, like VIP fibers, exist in periosteum and what their origin might be.

Male rats (175-200g) were anesthetized and the lateral mandibular periosteum subjacent to the molars and beneath the deep portion of the masseter was exposed. Fast Blue or Fluorogold (2-3µl) was injected into the subperiosteal space. Fast Blue and Fluorogold were used interchangeably. In some animals injected subperiosteally with one tracer, the other was injected into the surrounding masseter muscle as a control. Animals were allowed to recover and after 4--7 days were perfused with Zamboni's fixative and tissues prepared for immunohistochemistry. Routinely, the following tissues were taken: brainstem, trigeminal, nodose and superior cervical ganglia. Cryostat sections (10µ) were incubated with antiserum to CGRP, substance P (SP), and VIP. After rinsing, sections were then incubated with fluorophore-labeled secondary antisera, rinsed and coverslipped. Sections were examined with epifluorescence and ultraviolet illumination for coexistence of peptide immunofluorescence and retrograde tracer. In other rats, fresh periosteum was removed from the mandible in the region subjacent to the molars, immersed in Zamboni's fixative, and processed for whole mount immunofluorescence for CGRP, SP, and VIP.

In all animals with subperiosteal injections retrogradely labelled cells were seen in ipsilateral trigeminal ganglia, superior cervical ganglia, and nodose ganglia. In animals injected in both the masseter and subperiosteal space with different labels, both labels were seen in cell bodies in these same areas. Additionally the label injected into the masseter was also seen in the mesencephalic trigeminal nucleus (MeV).

In animals with subperiosteal injections only, cells double-labelled with CGRP-immunoreactivity and retrograde tracer were seen only in the mandibular portion of the trigeminal ganglion. In animals injected in masseter muscle a few moderately CGRP-immunoreactive cells were also observed in the retrogradely labelled cells in MeV.

In periosteal whole mounts, nerve fibers immunoreactive for CGRP and VIP were present. In preparations using two-color immunofluorescence most CGRP- immunoreactive fibers were also immunoreactive for substance P. Although the CGRP- and VIP- immunoreactive fibers were primarily perivascular, small collaterals could be seen to depart the vascular trunk and approach the bone surface.

These data suggest that CGRP-immunoreactive nerve fibers in periosteum may be of primary afferent origin. Given the reported effects of CGRP on bone mineralization , the present results suggest that primary afferent nerves containing CGRP and SP, as well as sympathetic nerves containing VIP, may play a role in focal bone remodeling. Supported by a grant from 3M.

214.4 QUANTITATIVE STUDIES OF PEPTIDE-CONTAINING VARICOSITIES ASSOCIATED WITH PRIMARY AFFERENT NEURONS IN THE DORSAL HORN OF THE RAT SPINAL CORD. M.M.Tuchscherer and V.S. Seybold. Univ. of Minnesota, Dept. of Cell Biology and Neuroanatomy , Minneapolis, MN 55455 USA.

Many peptides have been localized in primary afferent neurons of the rat. Some of these peptides include calcitonin gene related peptide (CGRP), galanin (GAL), dynorphin A(1-8) (DYN), somatostatin (SOM) and substance P (SP). We determined the proportion of immunoreactive (IR) varicosities for each of these peptides in the spinal cord which are of primary afferent origin. In addition we determined the percentage of coexistence for each of the peptides with SP. Two groups of animals were used: one (n=6) underwent unilateral dorsal rhizotomy (L1-L6) to destroy primary afferent input to spinal segment L4; the other (n=4) received no surgery and served as a control. The contralateral side of the spinal cord from animals which underwent dorsal rhizotomy also served as a control. Tissue sections (5um) through spinal segment L4 were immunostained for SP and one of the other peptides using a method for the simultaneous visualization of two antigens by immunofluorescence. Serotonin (5-HT) immunoreactivity was also studied as a control. Computerized image processing was used to quantify the densities of the IR varicosities within the superficial laminae of the dorsal horn. For the analysis, these laminae were divided into two equal portions: Laminae I+II outer (LI/IIo) and Lamina II inner (LIIi). With respect to the total number of varicosities immunoreactive for each substance, the data from normal animals indicated that LI/IIo contained higher densities of varicosities immunoreactive for SP, GAL, SOM, CGRP, and 5HT in comparison to LIIi. The density of DYN-IR varicosities was the same in both LI/IIo and LIIi. To determine the proportion of IR-varicosities for each peptide which are associated with primary afferent neuron input, densities of IR varicosities from normal animals were compared with those determined following dorsal rhizotomy. In LI/IIo, densities of varicosities IR for SP, SOM, and GAL were reduced approximately 50% following rhizotomy. The density of CGRP-IR varicosities was reduced by 85% in LI/IIo, while the density of DYN-IR varicosities was unaffected by rhizotomy. Within LIIi following dorsal rhizotomy, no change was seen in the density of varicosities IR for GAL, SOM, DYN, or 5HT. In contrast, the density of SP-IR varicosities was reduced by one third, and the density of CGRP-IR varicosities was reduced by 90-95%.

The extent of coexistence of SP with the other substances within varicosities was also quantified. Approximately 30% of the total varicosities immunoreactive for GAL, DYN, and CGRP also contained SP in both LI/IIo and LIIi of normal animals. Following dorsal rhizotomy, densities of varicosities IR for SP+CGRP and SP+GAL were depleted from both LI/IIo and LIIi. In contrast, the density of varicosities IR for SP+DYN was unaffected in either LI/IIo or LIIi ipsilateral to the rhizotomy. Interestingly, the density of varicosities IR for SP+DYN in both LI/IIo and LIIi of the side contralateral to the lesion was reduced following dorsal rhizotomy. Five conclusions can be made from these studies: 1) GAL- and SOM-containing axons of primary afferent origin project primarily to LI/IIo; 2) CGRP- and SP-containing axonsof primary afferent origin project to both LI/IIo and LIIi; 3) Very few, of the DYN-containing axons in LI/IIo or LIIi arise from primary afferent origin; 4) Varicosities exhibiting SP+GAL and SP+CGRP coexistence are primarily of primary afferent origin; and 5) Significant amounts of SP-, SOM-, GAL-, and DYN-containing varicosities are of intrinsic or descending origin in the laminae studied. These studies were funded by NS17702.

214.5 BOTANICAL LECTINS AS HIGHLY SPECIFIC PROBES FOR VISUALIZATION OF PERIPHERAL NON-PEPTIDERGIC NOCICEPTIVE AXONS. J.D. Silverman* and L. Kruger. Depts. of Anatomy & Anesthesiology & the Brain Res. Inst., UCLA Center for Health Sciences, Los Angeles, CA 90024.

Small sensory ganglion (SG) cells giving rise to thin, predominantly nociceptive axons, comprise a biochemically and functionally diverse class of neurons whose peripheral terminals subserve a variety of afferent and efferent roles. These neurons have been roughly grouped into those containing one or more known neuropeptides vs. those displaying fluoride-resistant acid phosphatase (FRAP) activity. While the cell bodies and central terminals of these cells have been further characterized through labeling with carbohydrate-specific monoclonal antibodies and plant lectins, progress in understanding their structural and functional relations in the periphery has been limited by the difficulty in specifically visualizing the large FRAP(+), non-peptidergic axon population.

In searching for a specific marker of non-peptidergic thin fibers, we initially compared FRAP staining patterns in formaldehyde-fixed rat SG and spinal cord (SC) sections adjacent to those stained with: a) calcitonin gene-related peptide (CGRP) immunoreactivity (IR), the most prevalent of the neuropeptides; b) monoclonal antibody 2C5 IR, known to co-localize with FRAP; and c) several plant lectins specific for α-D-galactose (GAL) or N-acetyl-D-galactosamine (D-galNAc). FRAP and CGRP labeled distinct, minimally overlapping SG cell subsets, but taken together stained virtually all small cells. The less numerous 2C5(+) cells comprised a subset of the FRAP(+) population. The GAL-specific lectin griffonia simplicifolia I B_4 (GSA) labeled most FRAP(+) and 2C5(+) cells, but also co-localized with a small number of CGRP(+) cells. The D-galNAc lectin sophora japonica stained a subpopulation of GSA(+) neurons. In SC dorsal horn, CGRP labeled the marginal zone and outer substantia gelatinosa (sgel), while the lectins were primarily restricted to sgel, with FRAP and 2C5 confined to inner sgel. Therefore, using 2C5 and the lectins as probes for FRAP(+) non-peptidergic axons, we then stained whole mounts of peripheral tissues innervated primarily by thin fibers, including cornea, tympanic membrane, meninges, cerebral vessels and testicular vascular sheath. 2C5 IR axons were demonstrable in cornea, whereas both lectins readily labeled numerous presumptive thin fibers in all regions examined.

We conclude that, although the significance of distinctive carbohydrate expression by small SG cells is unclear, lectin histochemistry appears to serve as a valuable and highly specific tool for examining non-peptidergic thin fiber innervation in the periphery, and for developing a more complete taxonomy of small sensory ganglion cells. (Supported by the National Institutes of Health NS-5686 and DE-5447.)

214.6 CGRP INNERVATION OF TEETH AND JUNCTIONAL EPITHELIUM: DEVELOPMENT CORRELATES WITH UNUSUAL TISSUE SPECIALIZATION. M. R. Byers Anesthesiology & Biological Structure, Univ. Washington, Seattle, WA 98195

Trigeminal nerve fibers labeled by axonal transport innervate dentin of erupting rat molars (Byers, J.Comp.Neurol 191:431, 1980) and develop extensive innervation of molar dentin and adjacent junctional epithelium (JE) (Byers and Kish, J. Dent. Res. 55:419, 1976; Byers and Holland, Anat. Rec. 188:519, 1977). A subpopulation of those fibers have calcitonin gene-related peptide-like (CGRP) immunoreactivity (Silverman et al, Anat. Rec. 214:122A, 1986). Developing rat molars and JE have been studied here to determine the initial sites of CGRP innervation and subsequent development in relation to tissue maturation. Molars of rats aged 21,28, 35, or 49 days were compared with those of 3-6 mo. old adults. Anesthetized rats were perfused with p-formaldehyde/picric acid and the excised jaws were post-fixed, decalcified, frozen sectioned and reacted by standard immunocytochemistry for CGRP, using primary antisera raised against synthetic CGRP, 0.5% Triton-X 100, avidin-biotin and diaminobenzedine, with appropriate controls.

Just before rat molars erupt, dentin begins to be innervated by CGRP fibers. The developing innervation patterns are not symmetrical in each cusp but focus at particular regions characterized by columnar odontoblasts, wide predentin, and numerous patent dentinal tubules. Maxillary and mandibular first molar cusps are oriented at opposing angles; innervated patches are most prominent on the side closest to the occlusal plane-.i.e. the anterior side for max. cusps and posterior side for mand. cusps. As the maturing teeth are used, their surfaces wear down exposing larger areas of crown to occlusal contact. The CGRP innervation territory increases to match the progressively wider tooth surfaces. The number of dentinal tubules, their patency, and the continual outflow of fluid from pulp through dentin are greatest in the innervated zones. Junctional epithelium (JE) is specialized to allow leukocyte transmigration into the oral cavity and fluid outflow, in addition to tooth attachment to gum. CGRP innervation is present as soon as JE begins to develop (during tooth eruption), and reaches mature density when JE is fully formed in young adults. The extent of JE and its CGRP innervation do not change in older adults.

CGRP sensory fibers have been shown to be involved in vasodilation and neurogenic inflammation in other tissues, in addition to nociceptive functions. The patterns of CGRP innervation in developing rat molars and junctional epithelium appear to correlate with sites of greatest fluid outflow from those tissues. Since dental crowns and JE are continually exposed to oral bacteria, their CGRP innervation may be involved in regulating the response to infection. In addition, the vitality of dentin and JE may depend on special fluid dynamics, which could be influenced or controlled by the CGRP innervation. Finally, the fluid outflow in dentin and JE may simply form a permissive environment allowing CGRP fibers to innervate for somatosensory functions. (Supported by NIH grant DE05159.)

214.7 ALTERATIONS IN MYSTACIAL DEVELOPMENT: CHANGES IN THE SPATIAL SEQUENCE FOLLOWING MANIPULATION OF THE TRIGEMINAL GANGLION.
T.E. Jones* and B.L. Munger*. (SPON: NORGREN) The Milton S. Hershey Medical Center of The Pennsylvania State University, Department of Anatomy, Hershey, PA

It has been shown that for some peripheral structures (e.g., rete ridges and muscle spindles), proper development is dependent on sensory innervation. Critical periods exist in which manipulation of the nervous innervation of these structures results in a significant alteration in their normal development, and for certain structures, sensory innervation is essential for initiation of development. The present study was undertaken to determine the relationship between sensory innervation from the trigeminal ganglion and normal development of mystacial vibrissae.

The model takes advantage of the precocious birth and relative immature development of the neonate opossum, Monodelphis domesticus. The neonate opossum is an "extrauterine embryo" roughly equivalent to a rat embryo of 15.0 days or a mouse embryo of 13.5 days. Manipulation of the neonate nervous system effectively alters the normal trigeminal influence at a time before development has been completed. In this manner, we can assess the role of sensory innervation on the development of peripheral structures.

Monodelphis domesticus pups were operated on 18-24 hours after birth; the delay helped prevent cannibalization. The left trigeminal ganglion, located immediately below the skin surface in the neonate, was removed by surgical cauterization with no adverse affect on feeding observed.

Vibrissal development on the lesioned side was altered. Follicles of the rostral part of the horizontal rows were neither found in the characteristic pattern nor the normal number of structures seen in the adult, although every animal demonstrated follicular development. Rete ridge development, characteristic of glabrous snout skin, failed to develop on the operated side.

We conclude that sensory innervation is not critical for the initiation of mystacial development, but does play an important role in determining the spatial sequencing of follicular development.

214.8 RESPONSES OF LAMB SPINAL TRIGEMINAL NUCLEUS NEURONS TO MECHANICAL, THERMAL AND CHEMICAL STIMULATION OF THE ORAL CAVITY AND EPIGLOTTIS. R.D. Sweazey and R.M. Bradley. Dept. of Oral Biology, Sch. of Dentistry, Univ. Michigan, Ann Arbor, MI 48109.

We have shown previously that neurons in the lamb nucleus of the solitary tract (NST) receive converging inputs from the oral cavity and epiglottis, and respond to more than one stimulus modality. We have now recorded neural responses from an area of the spinal trigeminal nucleus (SPVn) where primary afferent fibers from the oral cavity and epiglottis terminate. The locations of receptive fields were determined for each neuron and its response to mechanical, thermal and chemical stimuli recorded.

Forty-eight neurons with receptive fields on the tongue, palate or epiglottis were isolated in the dorsomedial interpolaris and caudalis subnuclei of SPVn. Thirty-seven percent of the cells had receptive fields restricted to the tongue, 39% to the palate, and 13% of the neurons responded to stimulation of the epiglottis. Only 10% of SPVn neurons received converging inputs from anatomically separate receptive fields. This is a smaller percentage than that observed for lamb NST neurons (17%). Furthermore, neurons with opposing receptive fields observed frequently in the NST were rarely found in SPVn.

All neurons isolated in the SPVn responded to either mechanical or thermal stimuli. No multimodal responses were observed. In addition, no responses to stimulation with 0.5 or 1.0 M KCl, NH_4Cl, NaCl, 0.01 N HCl or water (epiglottis) were observed in SPVn neurons. The most effective stimulus for SPVn neurons was mechanical which produced responses in 80% of the cells. The majority of these neurons had a rapidly adapting response. The remaining neurons responded to thermal stimulation showing increases in activity to cooling and decreases to warming. These results are quite different from those observed in the NST where over 69% neurons were multimodal.

While the presence of convergence and multimodal neurons in the NST suggested an important role in the integration of sensory information important to upper airway reflexes, the area of the SPVn sampled in the present study appears to function as a modality specific relay for mechanical and thermal information from the oral cavity and epiglottis.

Supported by NIH Grant DE05728.

214.9 THE JAW-OPENING REFLEX EVOKED BY TOOTH-PULP STIMULATION IN THE RAT AND THE EFFECT OF NEONATAL CAPSAICIN TREATMENT.
B.Matthews and P.Kraivaphan*, Department of Physiology, University of Bristol, Bristol BS8 1TD, England.

Rats were prepared under general anaesthesia (alphaxalone and alphadolone acetate; Saffan, Glaxo Laboratories) by placing wire electrodes into one anterior digastric muscle and a stimulating electrode into each lower incisor (Matthews,B. and Myslinski,N., J.Physiol. 365:14P,1985). We have confirmed previous findings that a long latency (20-45ms, depending upon stimulus intensity) digastric reflex is produced by electrical stimulation of nerves in the incisor pulp and that a shorter latency (6-14ms) reflex replaces this when the stimulus spreads to excite nerves in the periodontal tissues. The reflex due to stimulation of pulpal nerves is seen only under optimal conditions and the short latency response alone may be obtained if the electrodes are placed too close to the gingival margin, the animal is too deeply anaesthetized or if it has been subjected to more than minimal surgery, as noxious stimulation even in remote areas of the body depresses the pulpal reflex for several hours. In several recent papers it is implied that the short latency reflex may, at least in part, be due to pulpal nerves (e.g. Tal,M., Behav. Brain Res. 13:197,1984; Vassel,A. et al., Archs oral Biol. 31:159, 1986).

Almost all the nerve fibres throughout the length of the pulp of the rat incisor are unmyelinated (Bishop,M.A., Am. J. Anat. 160:213,1981), which would account for the long latency of the reflex they evoke. Neonatal capsaicin treatment is known to destroy a large proportion of the non-myelinated axons in peripheral nerves. However, contrary to the results of Tal, we were able to evoke long latency reflexes by stimulating incisor pulp in 5 rats that had been treated neonatally with capsaicin (50mg/kg I.P.). There were no significant differences between the thresholds of the reflex in these animals and in untreated, age-matched controls. Counts of the numbers of unmyelinated fibres in the saphenous nerves and incisor tooth-pulps are in progress and preliminary results indicate that the numbers in the saphenous nerves were reduced markedly in the treated animals. It has been shown that the ratio of the numbers of unmyelinated to myelinated fibres in the pulps of rat molars is not affected by capsaicin treatment (Holje,L. et al., Brain Res., 266:133,1983).

The results could be explained if either rat tooth-pulp was innervated by C-fibres which were resistant to capsaicin or, at least in the case of the afferents responsible for the jaw-opening reflex from incisor pulp, they were myelinated outside the tooth but had unmyelinated terminals throughout the length (appox. 20mm) of the pulp.

214.10 RESPONSES OF UNMYELINATED NOCICEPTIVE AFFERENTS TO HISTAMINE.
A. A. Khan*, R. A. Meyer, and J. N. Campbell. Dept. Neurosurgery and Applied Physics Lab., Johns Hopkins U., Baltimore, MD 21205

The peripheral neural basis for itch sensation is not well understood. Although several lines of evidence indicate that itch is signalled by activity in C-fibers, a specific cutaneous receptor which responds preferentially to pruritic agents has not been identified. In this study, we sought to determine if a subclass of C-fiber nociceptors preferentially responded to a pruritic substance. Standard teased-fiber techniques were used to record single fiber activity from 24 C-fiber nociceptors in monkey with cutaneous receptive fields sensitive to both mechanical and heat stimuli (CMHs). Intradermal injections of 5 nmoles (1 μg) of histamine dihydrochloride in 10 μl of normal saline (pH = 7.4) were used as the pruritic agent. Similar injections in human subjects have been reported to produce itch sensation without pain (Simone, et al., Somatosensory Res., 1987). Two of the 24 CMHs in this study developed a pronounced response following the injection. Immediately after the injections, both fibers responded with rates as high as 10 impulses/s. Within 30 s, the response decreased to a plateau with an average response of 2 impulses/s for the next 5 min. The total discharge during the five minutes after the injection was 656 and 674 impulses for these two fibers. The response waxed and waned during this time with responses ranging from 0 to 26 impulses per 5 s sampling interval. During the next 5 minutes, the response gradually decreased to a rate of approximately 1 impulse/s. In contrast, the other 22 CMHs responded markedly less to the histamine. The total discharge of these fibers during the 5 min. after the injection ranged from 0 (n=5) to 103 impulses (mean ± SEM = 24 ± 7 impulses). The two histamine-sensitive CMHs did not differ from the other 22 CMHs with respect to mechanical or heat threshold, receptive field size, or conduction velocity. We previously reported that C-fiber nociceptors could be classified into two distinct groups based on their quickly adapting (QC) or slowly adapting (SC) response to stepped heat stimuli (Meyer and Campbell, Brain Res., 1981). Fibers in both groups responded to histamine, though there were more low-responders (i.e., 5 impulses during 5 min. after injection) in the QC group (7 of 10) than in the SC group (2 of 14). We conclude that a small subset of the CMH population exhibit a high sensitivity to histamine and likely signal itch sensation. Further studies are needed to determine the prevalence of these histamine-sensitive CMHs and whether they have other distinguishing properties. (Funded by N.I.H. grant # NS-14447)

214.11 EFFECT OF BRADYKININ AND [DES-ARG9]-BRADYKININ ON CULTURED HUMAN AND MOUSE DORSAL ROOT GANGLION NEURONS. D. M. Rock, C. P. Taylor, and M. J. McLean Dept. Pharmacology, Warner Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor MI 48105 and Dept. Neurology, Vanderbilt Univ., Nashville, TN 37232.

Bradykinin (BK) is a naturally occurring nine-amino-acid peptide that is enzymatically formed following tissue injury. Experiments were undertaken to study the response of cultured dorsal root ganglion neurons to BK.

Dorsal root ganglion neurons were obtained from humans by selective ganglionectomy for intractable pain (experiments approved by Vanderbilt Hospital Human Use Committee) or from mature mice and were maintained in primary dissociated culture for 4 to 16 weeks. Conventional intracellular recording techniques were used and BK or [des-Arg^9]-BK were applied by pressure ejection from blunt micropipettes within 100 μm of the impaled cell. Neurons with electrophysiological properties similar to those of A- and C-fiber dorsal root ganglion neurons of intact ganglia were observed in cell culture. A-like neurons fired single tetrodotoxin-sensitive action potentials of less than 2 msec duration in response to 450 msec depolarizing current steps. C-like neurons fired action potentials (3-8 msec duration, tetrodotoxin-resistant) throughout 450 msec depolarizations. Both A- and C-like cells were quiescent at rest.

Application of BK (5-10 sec, 10^{-7} M) did not change resting potential or elicit action potentials in 5 of 5 mouse A-like cells. BK ejection (10^{-9} to 10^{-6} M) caused concentration-dependent depolarizations (up to 20 mV) in 21 of 24 human C-like cells that began after 2-4 sec and lasted up to 120 sec after BK application. BK responses were usually reduced in amplitude with repetition and could not be repeated at intervals less than about 3 min. Rapid trains of action potentials (up to 80 Hz) were usually elicited. Similar responses were seen with mouse dorsal root ganglion neurons. Application of 10^{-6} M [des-Arg^9]-BK (a selective agonist of B1 bradykinin receptors) had no effect on 4 human C-like cells that responded to BK.

These findings suggest that the response of C-like dorsal root ganglion neurons to bradykinin is mediated by B2 bradykinin receptors. Cultured dorsal root ganglion neurons may be a useful model to study cellular mechanisms of sensory transduction and inflammation mediated by BK.

214.12 DIFFERENTIAL EFFECTS OF POTASSIUM AND CALCIUM CHANNEL BLOCKERS ON ACTION POTENTIALS OF FROG DORSAL ROOT GANGLION (DRG) NEURONS. S. David Stoney, Jr., Dept. of Physiology & Endocrinology, Med. Coll. of Georgia, Augusta, GA 30912

Somatic action potential (AP) shape and axon conduction velocity (CV) of frog sensory neurons correlate with the least conduction interval for pairs of impulses through their axon branchpoint in DRG. Branchpoints of neurons with fast, smooth somatic APs had short least conduction intervals (LCIs) regardless of axonal CV. Neurons whose APs had a hump on the falling phase had significantly slower CVs and longer LCIs (Stoney, Neuroscience Letters 59, 1985). These in vitro experiments on Rana pipiens DRG neurons aimed to establish ionic determinants of AP shape. Most were carried out on F neurons (fast, smooth AP; average CV=22.6 m/s; average LCI=1.8 msec), H1 neurons (fast AP with -dV/dt inflection; CV=27.6 m/s; LCI=1.7 msec) and H2 neurons (significantly broader AP with hump on falling phase; CV=17.7 m/s; LCI=2.2 msec). APs were recorded in 5-10mM Mn^{++}, 10mM TEA, combined TEA & Mn^{++}, and in TEA & 10mM Ca^{++}. Mn^{++} eliminated the shoulder or -dV/dt inflection on the falling phase and significantly increased the maximum rate of repolarization (Rmax = -dV/dtmax) for H1 & H2, but not F, neuron APs. TEA significantly increased AP duration and decreased Rmax for all neurons, but enhanced or caused the appearance of or a hump only for H neuron APs. H1-Ca^{++} increased the duration of H neuron TEA APs by enhancing the shoulder. Mn^{++} significantly decreased duration and increased RFmax of TEA APs only for H1 & H2 neurons. The results suggest that Ca^{++} involvement in somatic spikes is ordered H2>H1>F. Mn^{++} did not eliminate the hump on H4 neuron APs (very broad; CV=0.36 m/s; LCI=9.1 msec). Experiments are underway to see if H4 neurons have TTX-insensitive Na^+ channels like C-fiber DRG neurons of mice (Yoshida & Matsuda, J. Neurophysiol. 42, 1979). Yoshida has suggested that TTX-insensitivity and Ca^{++} components in the somatic spike are indicative of relatively undifferentiated types of DRG neurons. If that is the case, then relatively undifferentiated neurons, at least in frog DRG, can also be regarded as relatively poor neural signalers. The maximum frequency of APs they can conduct to the CNS ($<LCI^{-1} \times 1000$) is limited by a high degree of filtering action imposed by their axon branchpoints. (Supported by BRS 2 S07 RR 05365 23)

214.13 DEPENDENCE OF C-FIBER PRIMARY AFFERENT AND MAST CELL-EVOKED PLASMA EXTRAVASATION ON SYMPATHETIC POSTGANGLIONIC NERVE TERMINALS. T.J. Coderre, A.I. Basbaum and J.D. Levine*. Depts. of Medicine & Anatomy, Univ. of California, San Francisco, CA 94143.

Although plasma extravasation can be produced by substances released from the peripheral terminals of C-fiber primary afferents (PAs), and mast cells (MCs), the underlying mechanisms are unknown. In this study we assessed the extent of plasma extravasation produced by pharmacological activation of C-fiber PAs and MCs, in rats in which either PAs, MCs or sympathetic postganglionic neurons (SPGNs) were eliminated.

We used a push pull perfusion (rate: 0.15 ml/min) of the rat knee joint to study extravasation of Evans Blue (50 mg/kg, i.v.) in response to PA stimulation by capsaicin (5 mg/ml) or MC degranulation elicited by compound 48/80 (0.1 mg/ml). These doses produced equivalent extravasation, as measured by absorption at 650 nm. To destroy PAs, rats were treated with capsaicin (50 mg/kg, s.c.) on neonatal day 2. To deplete MCs, a total dose of 0.25 mg i.v. of compound 48/80 was injected over 3 days, ending two days before testing. To deplete SPGNs, 6-OHDA was injected over 7 days (50 mg/kg day 1 & 2; 100 mg/kg day 6 & 7, i.p.), ending one day before testing.

Compared with untreated rats, the peak of capsaicin evoked extravasation was reduced by 48% in rats pretreated with neonatal capsaicin, by 67% with compound 48/80 and by 47% with 6-OHDA. Compared to controls, the extravasation induced by compound 48/80 was reduced by 78% in rats pretreated with compound 48/80 and by 65% with 6-OHDA, but was increased by 2.5% in rats pretreated with neonatal capsaicin.

The data not only confirm a dependence of PA effects on MCs but, importantly, suggest that PA and MC effects are dependent on the presence of intact SPGNs. We, therefore, repeated the studies using pharmacological activation of SPGNs with 6-OHDA (50 mg/ml) and tyramine (25 mg/ml). Extravasation in response to sympathetic stimulation, by either agent, was not significantly reduced by a combined pretreatment with neonatal capsaicin and compound 48/80 (18% and 6% reductions for 6-OHDA and tyramine, respectively) but was significantly reduced--in comparison to control rats--by 58% and 82%, respectively, in 6-OHDA sympathectomized rats.

These data support previous studies which indicate that substances released from primary afferents can degranulate MCs. In addition, they suggest a focal role for the SPGN in the production of plasma extravasation. Together, the data suggest that there is a sequential and unidirectional activation of C-fiber PAs, MCs and SPGNs in the production of plasma extravasation.

214.14 **SPATIAL FREQUENCY TUNING IN CUTANEOUS TYPE I MECHANORECEPTORS**, Fred J. Looft, Department of Electrical Engineering, Worcester Polytechnic Institute, Worcester MA 01609

Swept period grating stimuli were used to study cat, hairy skin, slowly adpating Type I (T1) mechanoreceptors. These receptors are of interest because of their similarity to the primate SA I units, their multiple dome puncate organization and the possibility of action potentials (APs) from one dome resetting and/or blocking the AP responses of other domes. It was hypothesized that this would result in the receptors being tuned to specific periods of a grating stimulus.

The swept period grate had 39 periods (40 grates), a minimum period of 0.25 mm and a maximum period of 2.0 mm over a stimulus length of 40 mm. The period between successive sets of grates was a constant distance increment larger than the period between a previous set of grates. Different scan directions and velocities were used to study directional and spatio-temporal frequency response sensitivities. Data analysis consisted of the generation of cycle histograms showing the probability of a unit firing as a function of stimulus position.

Single domes exhibited no spatial frequency tuning and could easily encode the minimum grate period (250u) for all scan velocities (10-80mm/sec) and scan directions. Multi-dome receptors exhibited a spatial frequency tuning characteristic that was dependent on the scan diretion, the scan velocity and the number and organization of a receptor's domes. Under ideal conditions, the matched spatial frequency encoding characteristics of two dome units could be predicted from the spatial organization of the domes.

A computer program was developed to model the tuning characteristics of two dome T1 receptors. The model was based on the single assumption that the first dome to generate APs completely blocked the AP responses of the other dome. Although not exact, the model results compared favorably with the results from several experiments. For other data sets, the experimental results could not be fitted or predicted form the model.

While the T1 and primate SA I units are not identical, it is hypothesized that the more graded SA I response profiles will result in less definition to the tuning regions, but that they will still exist.

214.15 REPRESENTATION OF GRATINGS IN THE FINE STRUCTURE OF MECHANORECEPTIVE AFFERENT DISCHARGE. K. Sathian*, A.W. Goodwin, K.T. John* and I. Darian-Smith. Department of Anatomy, University of Melbourne, Parkville, Victoria 3052, Australia.

When gratings are run sinusoidally across the monkey's fingerpad, the mean response rate, in all three major classes of mechanoreceptive afferents innervating the fingerpad - slowly adapting (SA), rapidly adapting (RA) and Pacinian (PC) afferents, increases as a monotonic function of groove width (Sathian et al, Soc. Neurosci. Abstr. 12: 90.2). Apart from the mean afferent response rate, information can also be conveyed by the fine structure of afferent discharge. Gratings were run sinusoidally across the fingerpad of anesthetized macaque monkeys, with a constant indentation amplitude of 1.0 mm. The groove width (G) of the gratings was varied systematically while keeping ridge width (R) constant, and vice versa. The motion, being sinusoidal, varies in speed throughout the sinusoidal cycle. However, over the central 42-degree segment of each half-cycle, the speed is constant to within 6.6% of its peak value. These segments were chosen for systematic analysis of the fine structure of afferent discharge. Since grating temporal frequency f is given by s/P where s is speed and P is spatial period, and since P = G+R, f decreases as G (or R) increases when s is constant. In order to separate the effects of temporal and spatial parameters, the gratings were run both at constant s and at constant f.

Afferent responses to moving gratings are phase-locked to the occurrence of successive grating spatial cycles. A measure of the fine structure of afferent discharge that lends itself to quantitative analysis is the mean number of impulses per grating spatial cycle (ipg). The mean number of ipg increased as a monotonic function of groove width when ridge width was constant. This held whether s or f was constant, for all three afferent classes. The mean number of ipg increased as a monotonic function of ridge width when groove width and s were constant, in the case of RAs as well as SAs. When groove width and f were constant, however, the mean number of ipg was relatively invariant as a function of ridge width for these two afferent types, indicating that f rather than ridge width was represented in this measure of response. PCs did not fit into this pattern of response. Thus the stimulus parameters represented in the mean number of ipg, for RAs and SAs, are groove width and grating temporal frequency. It was possible to describe the mean number of ipg concisely in terms of these two parameters by simple empirical models.

214.16 SELECTIVE ACTIVATION OF THERMAL NOCICEPTORS BY RADIANT ENERGY --- A THERMODYNAMIC MODEL. D. L. Tanelian, and J. D. Murphy*. Dept. of Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA 94305 and NASA Ames Research Center, Moffitt Field, CA 94035

A method to noninvasively and selectively activate nociceptors has been difficult to achieve, but would be of great value in studying the transduction process of sensory afferents and also integral to the development of nociceptive sensory evoked potentials. Radiant energy can produce a thermal noncontact stimulus with a rapid rise time and be easily controllable for energy delivered, duration and stimulus area. Because the receptor endings of sensory afferents are located below the surface of cutaneous tissues and at a superficial depth, determination or prediction of the temperature rise at the receptor portion of the nerve ending is difficult to obtain and influenced by the wavelengh of energy used and the thermal transport and optical properties of the tissue.

To determine the ideal set of stimulus parameters necessary to activate thermal nociceptors in a given tissue, we have developed a mathematical model which can calculate the temperature distribution in tissue following a pulse of radiant energy. The thermodynamic equation used is the basic one-dimensional Fourier heat conduction law , $\partial T/\partial t = a^2 \partial^2 T/\partial x^2 + I/\rho c$ where $I = pHe^{-px}$ is the energy deposition per unit volume in a semi-transparent medium by laser light. The boundary conditions and initial conditions are : at t=0, $T=T_0$ for all x; at x=0 , $-\partial T/\partial x = h/k\,(T_{surface} - T_{ambient}) + \epsilon \sigma T^4$ surface ; at $x = x_{max}$, $T = T_0$ for all t . T_0 = tissue temperature, t = time, x = distance measured from the tissue surface, p = absorption coefficient, a = thermal diffusivity, ρ = the tissue density, σ = the Stefan-Boltzmann constant, ϵ = emissivity, c = specific heat, H =power density per unit area , h / k = surface heat transfer coefficient .

The accuracy of the one-dimensional approximation depends on the fact that the depth of concern (0-200um) is very small compared with the radius (2-5mm) of the area to be stimulated. A numerical solution based on the Crank- Nicolson time marching procedure is used and spatial discretization is carried out by means of splined cubic Hermite polynomials. The resulting matrix is solved by a special solution technique which takes advantage of the special sparcity structure resulting from the Hermite formulation (Murphy and Prenter, 1985).

Solving the conduction equation with and without the convective and radiative heat loss terms demonstrates that > 99% of the heat loss following a pulse of radiant energy is due to conductive heat loss alone. By using the appropriate thermodynamic values for skin we are able to identify the combinations of stimulus parameters necessary to reach the thermal nociceptive threshold of 45° C .

Variation of the absorption coefficient (p), which is a function of wavelengh for a given tissue, enables maximization of heat deposition at the receptor terminals while minimizing energy delivery to adjacent tissue elements. This wavelengh optimization allows for minimal tissue damage,temporally discrete receptor activation and minimizes bulk tissue heating after multiple stimulus applications. A value of 50-100 cm^{-1} for p maximizes heat deposition to nociceptive receptors located at 150-200um below the surface of human skin.

With this model one can design a radiant energy source with the appropriate stimulus parameters (wavelengh, pulse duration, rise-time, interstimulus interval, power input) to activate thermal nociceptors in any tissue type for the study of pain transduction and perception.

214.17 THE EFFECT OF VOLUNTARY ISOMETRIC CONTRACTION ON THE DETECTION THRESHOLD OF ELECTRICAL AND PAINFUL THERMAL STIMULI IN MAN. J.S.Feine*, C.E.Chapman, M.C.Bushnell, G.Duncan and J.P.Lund. Département de stomatologie et Centre de recherche en sciences neurologiques, Univ. Montréal, Québec H3C 3J7.

Previous experiments have shown that the ability to detect the presence of weak electrical shocks is diminished during isotonic movement of the stimulated arm (Chapman et al., Exper. Brain Res., In press). Although the suppression is much greater during active than passive movement, it is not known if the sensory threshold changes during motor acts in which there is little movement about the joints. Indeed, cortical evoked potentials that are reduced by movement are reported to be unchanged during isometric contraction (Lee, R.G., and White, D.G., EEG Clin. Neurophysiol., 36: 53, 1974). Thus, in an initial series of experiments, we compared the effects of isotonic and isometric contractions about the elbow at a frequency of 0.5 Hz on the ability to detect the occurrence of weak electrical shocks applied to the ipsilateral forearm and hand (n=8 subjects). The results indicate that the detection of stimuli applied to the forearm is signicantly reduced during isometric contractions of muscles acting about the elbow (Wilcoxon, $p < 0.01$), although not to the extent occurring during isotonic movement. The effects on stimulation of the dorsum of the hand were weaker, but again more pronounced during isotonic than isometric movement ($p < 0.02$). In conclusion, it appears that isometric, as well as isotonic, contractions modify the perception of electrical shocks, and that this effect increases with proximity to the fulcrum.

Since sensory fibers of several modalities are simultaneously activated by an electrical stimulus, the functional significance of these results is unknown. Therefore, we have begun to study the effects of movement upon the ability to detect natural events by stimulating small-diameter fibers using near-painful and painful heat (43° to 48°C). Isometric contractions were performed with the right arm as described above, and subjects were asked to detect pain and to rate the intensity of the thermal stimulus. Preliminary results indicate that the pain threshold increases during muscle contraction. These results suggest that the reduction in sensory transmission is not restricted to pathways conveying information from large diameter cutaneaous afferents.

214.18 TACTILE DISCRIMINATION OF SOFTNESS. M.A. Srinivasan*, J.M. Whitehouse*, and R.H. LaMotte (SPON:J.G. Collins) Dept. of Anesthesiology, Yale University Sch. of Med., New Haven, CT 06510.

A measure of the softness of an object is the ratio of the depth of indentation of the object to the force causing the indentation. During active touch, information about both the force and indentation depth of the object is available to the subject through sensory receptors in skin, joint and muscle. In contrast, when an object is applied to the passive skin surface, the subject can assess the force from the cutaneous receptor response, but the depth of indentation of the object is unknown. In order to determine the importance of non-cutaneous cues in judging softness, we investigated the capacity of humans to discriminate softness under both active and passive touch.

Twelve transparent cylindrical disks (35mm dia. x 10mm thick) made of silicone rubber of varying softness (controlled by varying the amount of a diluent) were cast. Objective measures of softness, or compliance, were determined by measuring the average slopes of force versus displacement traces obtained by constant velocity indentations with a rigid, flat probe (6mm diameter).

When human subjects actively indented each specimen with the fingerpad, their subjective ranking of softness was the same as the ordering based on the objective measure of compliance. Five specimens (2.8, 4.1, 5.7, 9.2, and 10.2 μm/gm), 100% discriminable with active touch, were chosen for passive touch discrimination. In pairwise discrimination tasks, each specimen of the pair was brought onto the subject's stationary fingerpad at a constant velocity, maintained steady for 1 s and then withdrawn. The subject stated which one of the pair was softer. Subjects could discriminate only the specimens 2.8 and 10.2 from the 5.7um/gm specimen at levels greater than 75% correct. In separate tests, when one member of each pair was applied at a slower or faster velocity than the other, threshold discriminations of softness were not possible even between specimens of 2.8 and 5.7 um/gm compliance. Thus human discrimination of softness was significantly better under active than passive conditions. Passive discrimination deteriorated when indentation velocity was varied.

In order to determine the relevant cutaneous cues for discrimination, contact areas between the passive fingerpad and the specimens were videotaped. Off-line analyses indicated that the variation in contact area versus time for the specimens was quite small, but the corresponding traces of total force (and thus pressure) versus time were distinct from each other. Thus active softness discrimination may be based on the combined responses of mechanoreceptors in skin (encoding the rate of change of pressure) and joint or muscle (providing the velocity of indentation of the object). The absence of the proprioceptive information leads to a considerable deterioration of discriminability.(PHS grant 15888).

214.19 EFFECT OF TIMING OF INSPIRATORY OCCLUSION ON SPINAL AND CEREBRAL EVOKED POTENTIALS. W. Robert Revelette and Paul W. Davenport*. Dept. of Physiology and Biophysics, Univ. of Ky., Lex, Ky. 40536 and Dept. of Physiological Sciences, College of Vet. Med., Univ. of Fla., Gainesville, Fla. 32610.

Davenport et al. (J. Appl. Physiol. 60:1843-1848, 1986) reported that interruption of airflow (occlusion) from the onset of inspiration (OCC-ONSET) was associated with cerebral evoked potentials in the awake human subject. Revelette et al. (Fed. Proc. 46:826, 1987) found that mid-inspiratory occlusion (OCC-MID) was associated with spinal and cerebral evoked potentials. The peak latencies of the cerebral potentials were similar to those reported by Davenport et al. It is unclear from these studies whether there is any significant difference in the results obtained using these two methods.

This study was designed to determine if the abrupt decrease in mouth pressure (and rise in inspiratory muscle pressure) associated with OCC-MID alters the amplitudes and peak latencies of spinal and cerebral evoked potentials, and the latency for detection. The present study involved random presentations of 64 OCC-ONSET and 64 OCC-MID to five subjects. Recordings (bandpass 3-300 Hz) were made from electrode pairs Cz-C3, Cz-C4 (scalp) and Fz-spC5 (spinal). Data were stored and averaged by computer. Occlusions were performed by the computer using a Rudolph balloon occlusion assembly connected to the inspiratory port of a two-way non-rebreathing valve. The results indicated there was no difference in the mean peak latencies of the evoked potentials recorded at electrodes Cz-C3 and Cz-C4. The amplitudes of the potentials recorded from Cz-C4 were 30% greater than those recorded from Cz-C3. There was no difference in the mean peak latencies of the evoked potentials for OCC-ONSET and OCC-MID. However, the amplitudes of the potentials were 205% greater for the data recorded during the OCC-MID. The mean detection latency was 310 msec for OCC-ONSET and 245 msec for OCC-MID. From the results of this study it appears that: the afferents responsible for the initial potentials project bilaterally to the cerebral cortex; despite the more abrupt stimulus, the peak latencies for cerebral and spinal potentials are not shorter with OCC-MID; OCC-MID produces evoked potential waveforms of significantly greater amplitude. We suspect that the greater amplitude with OCC-MID is the result of recruitment of afferents and/or elevation of the activity of responsive afferents. Supported by UK PSP RR05374 and NIH HL33163.

214.20 EFFECTS OF SEXUAL AROUSAL ON RESPONSES TO DORSAL PENILE NERVE STIMULATION. S. Hendricks, B. Graber, D. Fitzpatrick*, J. Gartner*, M. Fleisher*. Dept. of Psychiatry, Univ. of Nebr. Med. Ctr., Omaha, NE 68105.

Electrophysiological measures were obtained in response to percuteneous stimulation of the dorsal penile nerve (DPN) and the posterior tibial nerve (PTN) stimulation in human males before and during sexual arousal, and after orgasm. Stimulation of the PTN was by 5 mm silver disk electrodes 2 cm apart, applied at the ankle. DPN stimulation was via 5 mm tin disk electrodes taped to the glans of the penis. The subject initiated stimulus delivery by button press and was instructed not to stimulate faster than once every two seconds. Recordings were obtained from segments of the nerves proximal to stimulation sites and from the scalp. Measures were obtained during a baseline condition, an arousal condition with full erection, a condition just after ejaculation, and a condition 15 minutes after ejaculation.

A marked decrease in the amplitudes of the somatosensory evoked potentials measured at the scalp to DPN but not PTN stimulation was seen during penile erection. Subjects also reported reduced sensation to DPN stimulation during arousal, possibly related to the degree of erection. Further results to be presented will be from evoked potential to DPN stimulation on the shaft of the penis during the same conditions and effects of these conditions on conduction velocities in the DPN.

SPECIAL LECTURE

215 SPECIAL LECTURE. EXCITATORY NEUROTRANSMISSION. Charles F. Stevens, Yale Medical School, New Haven, CT.

Excitatory neurotransmission has been studied in cultures of hippocampal neurons using whole cell and single channel recording. These neurons express several classes of excitatory amino acid receptors and develop synaptic connections that can be studied in identified pairs of cells.

217 SYMPOSIUM. MOLECULAR GENETIC ANALYSIS OF NEURONAL DEVELOPMENT. C.S. Goodman, Stanford Univ. (Chairperson); S. Artavanis-Tsakonas*, Yale Univ.; Y.N. Jan, U.C.S.F.; G. Rubin, U.C. Berkeley.

The last few years have witnessed great progress in the application of molecular genetic approaches to the study of neuronal development, particularly in simple organisms with advanced genetics such as Drosophila and the nematode. Here we focus on four examples of such developmental studies using a simple genetic system: the fruitfly Drosophila.

We will first examine the development of the embryonic nervous system. We begin with two talks on the molecular mechanisms controlling neurogenesis. The first talk by Artavanis-Tsakonas will focus on neurogenic genes such as Notch which are involved in the decision of whether a cell becomes a neuronal precursor cell (neuroblast) or a non-neuronal cell in the CNS; he will also describe the expression of other genes which share the EGF sequence homology with Notch and which are transiently expressed by subsets of cells during neurogenesis. The second talk by Jan will describe genes such as Cut which are involved in the decision of which types of neurons a neuronal precursor cell generates in the PNS; he will focus on the network of genes that are involved in specifying cell fates and the overall pattern of neurons in the developing PNS. The third talk by Goodman will describe genes such as fasciclin I and III which encode surface glycoproteins which are expressed on subsets of axon fascicles during development; genetic analysis indicates that these proteins are involved in the recognition of specific axonal surfaces by neuronal growth cones. The final talk by Rubin will examine many of these same events during the development of the visual system, focusing in particular on genes such as sevenless which are involved in the cell surface interactions which specify particular neuronal cell types. He will also discuss genes such as disco which are involved in guiding retinal growth cones towards their targets.

218 WORKSHOP: INFORMATION PROCESSING IN THE MACAQUE RETINA

Robert Shapley, New York University (Chairman); David Williams*, University of Rochester; William Merigan, University of Rochester, V. Hugh Perry, Oxford University; Ehud Kaplan, Rockefeller University; Stan Schein, Harvard Medical School; Barry Lee, Max-Planck-Institut Goettingen

The initial stages of vision seem remarkably similar in Old World monkeys and man. This similarity has stimulated a surge of research on the visual pathways of the macaque monkey and in particular has motivated speakers in this Workshop to study the monkey's retina as a model for the human retina. Several characteristics of human visual perception may be explicable in terms of retinal processes and structures. One of the striking features of human vision is high visual acuity. Dr. Williams will describe the arrays of cone photoreceptors in the eyes of macaques and will relate cone densities, which vary with distance from the fovea, to acuity. Another facet of human vision is a human observer's ability to see both black-white and color contrast with high sensitivity. These independent abilities may result from activity in different neural channels that arise in the retina. Such channels have been studied by the remaining speakers in the Workshop. Dr. Merigan compares chromatic and achromatic contrast sensitivity in macaques with severe loss of small P-type retinal ganglion cells. Dr. Perry stains different functional classes of macaque ganglion cells with HRP, and defines the dendritic morphology of the P and M (the large ganglion cells) types as well as their central visual connections. Dr. Kaplan (in collaboration with Dr. Shapley) finds that M cells have a higher sensitivity for black-white contrast than P cells, while P cells are more sensitive for coarse patterns of color contrast. The mechanisms of these differences in achromatic and chromatic contrast sensitivity will be discussed. Dr. Schein studies the spatial scaling of receptive field size and ganglion cell density in the P and M populations and compares this scaling with spatial scaling of human performance. Dr. Lee measures the responses of P and M ganglion cells to heterochromatic exchange in an attempt to understand which cell type underlies perception of brightness. In these talks, the relation of macaque retina to human vision is a repeated theme. New understanding of the monkey's retina is leading to a clearer view of how humans see.

TRANSPLANTATION FOR MOVEMENT DISORDERS

219.1 SURGICAL TRIALS ON TREATMENT OF PARKINSON'S DISEASE IN MICE. K. Shimizu*, N. Tsuda*, Y. Matsui*, Y. Okamoto*, Y. Miyao*, K. Tamura*, S. Nakatani*, H. Mogami* Department of Neurosurgery, Osaka University Medical School, Osaka 553, Japan (SPON: T. Tsumoto)

Attempts to reconstruct the damaged nigrostriatal pathway in experimental models of Parkinson disease have thus far been carried out in animals with neurotoxically induced dopamine deficiency. Our study established that unilateral 6-hydroxydopamine (6-OHDA) lesions of the nigrostriataldopamine (DA) neurons produced a well-characterized functional asymmetry in the behavior of the C57BL/6 ($H\text{-}2^b$) mice.The intraperitoneal administration of methamphetamine induced ipsilateral rotation at 7-20 turns/min. $1x10^6$ syngenic DA-rich cells of embryonic ventral mesencephalon were stereotaxically transplanted in the caudate-putamen. A complete recovery of methamphetamine-induced rotational response was produced around the 60th day after the syngenic cell suspension graft. And a complete compensation of the rotational response was also brought about with the DA-rich cells from embryonic ventral mesencephalon (crown-rump length; 10-13 mm)of allogenic C3H/HeN ($H\text{-}2^K$) mice. The FACS IV analysis revealed no H-2 (K^K and Ia^K) antigens before transplantation of these embryonic cells. Immunohistochemistry showed that the dopaminergic fibers had grown predominantly into the ipsilateral caudate-putamen. These results provide evidence of integration of syngenic and allogenic grafts and host tissue. And the immunological response in the transplanted brain are under investigation.

219.2 EFFECT OF DOPAMINE NEURONAL GRAFTS ON THE LOCOMOTOR AND COGNITIVE DEFICITS INDUCED BY 6 HYDROXYDOPAMINE LESIONS OF THE MESOLIMBO-CORTICAL DOPAMINE SYSTEM. R. E. Strecker, P. Brundin*, F. H. Gage and A. Björklund. Dept. of Histology, Univ. of Lund, Lund, Sweden. (RES Current address: Hana Biologics, Alameda, CA).

In Parkinsons disease, although the reduction of dopamine (DA) levels is greatest in the mesostriatal DA system, there are also significant DA reductions in cortical and limbic regions of the mesolimbocortical DA system, which receive their inputs from DA neurons in the ventral tegmental area (VTA, A10 of Dahlström and Fuxe). This system has been experimentally implicated in a variety of behaviors including regulation of locomotor activity and cognitive performance, functions that may also be involved in the clinical symptomology of Parkinson's disease.

Lesion experiments: Consistent with previous reports, we found that extensive bilateral 6-hydroxydopamine (6OHDA) lesions of the VTA DA cell bodies produced a blockade of amphetamine-induced locomotor activation and an increased locomotor activity in response to apomorphine. We also found that lesioned rats could not learn a conditioned rotation task, and had deficits in cognitive performance as measured in the Morris watermaze. In the watermaze rats with lesions showed a prolonged latency to find the hidden escape platform and generally exhibited reduced swim speeds. In addition, these rats showed little indication of using spatial cues to find the platform. Neurochemical analysis revealed a strong correlation between DA depletion in limbic forebrain/anteromedial caudate and these cognitive deficits in the watermaze. Note that these behavioral effects were not related to a depletion of norepinephrine, since rats were treated with desmethylimipramine prior to 6OHDA injection. Compared to normal rats, these lesioned rats were also unable to learn a conditioned learning paradigm, in which water-deprived rats were placed in a hemispherical bowl and trained to turn in circles for a sucrose-water reward.

Graft Experiments: Lesioned rats showing deficits in the watermaze received bilateral suspension grafts of DA-rich rat fetal ventral mesencephalon (donor age 13-15 days) into both the nucleus accumbens and caudate-putamen. These grafts completely reversed the lesion induced hyporesponsiveness to amphetamine. However, the grafts did not improve the performance of lesioned rats on either of the more complex behaviors tested, i.e., cognitive performance in the watermaze or conditioned learning in the rotation paradigm. Possible explanations for the intractability of these latter deficits to amelioration with DA grafts include either the need to replace DA in cortical areas, or alternately, the innervation of the graft by host afferents may be insufficient to regulate these more complex behaviours, even though amphetamine-induced locomotor behavior was completely normalized.

219.3 COULD GRAFTED HUMAN FETAL DOPAMINE NEURONS PROVIDE A THERAPY FOR PARKINSON'S DISEASE ? - AN EXPERIMENTAL STUDY IN THE RAT. P. Brundin*, R.E. Strecker, D.J. Clarke*, H. Widner*, O.G. Nilsson*, B. Åstedt*, O. Lindvall* and A. Björklund. Dept. of Histology, Univ. of Lund, Biskopsgatan. 5,S- 223 62 Lund, Sweden. (SPON.: B. Ehinger)

Recent studies with autografts of adrenal medullary tissue to the basal ganglia of patients with Parkinson's disease (PD) have reported of some beneficial graft effects. As experimental studies indicate that neural tissue grafts have a greater functional potential in animal models of PD it seems warranted to try to develop sources of *neural* donor tissue. Two of the critical issues concern the choice of donor tissue, and the possible need for immunosuppression of the patient. We have investigated human fetal dopamine (DA) neurons as a potential donor tissue. Ventral mesencephalic tissue was obtained from aborted human fetuses of 6.5-19 weeks gestation. The tissue was grafted to the striatum of cyclosporin A immunosuppressed rats with 6-hydroxydopamine lesions of the mesostriatal DA pathway. There evidently exist donor age restrictions as only rats receiving cell suspension grafts from the 9-week old or younger fetal donors reliably showed reversal of amphetamine-induced motor asymmetry and contained large numbers of surviving grafted mesencephalic DA neurons (Brundin et al. Exp. Brain Res. 65 (1986) 235-240). The need for immunosuppression is supported by data showing that grafted rats were immunized against human antigens and that if the recipient rats were not immunosuppressed the human DA neuron grafts did not survive. Estimates of the number of DA neurons innervating the human striatum and estimates of the survival rate of grafted human DA neurons in the rat taken together suggest that the grafting of one fetal human ventral mesencephalon may be enough to reinstate a functional unilateral DA reinnervation in a PD patient. The functional effects in the rats appeared much later (12-15 weeks after grafting) than with similar transplants utilizing rodent donors (2-4 weeks after grafting). One group of recipients also showed compensation of spontaneous motor asymmetry and apomorphine-induced rotation. Moreover, using the intracerebral dialysis technique we have monitored spontaneous DA release from grafted human DA neurons. The intrastriatally grafted DA neurons grew an an extensive terminal network stretching several millimetres throughout the host caudate-putamen, nucleus accumbens and globus pallidus, whereas when the grafted DA neurons were located in the neocortex overlying the striatum they exhibited little fiber outgrowth. The DA neurons seemed to retain some human morphological characteristics in that they were larger and possessed more prominent dendrites than their rodent counterparts. Electron microscopy revealed that the grafted human DA neurons form abundant tyrosine-hydroxylase (TH) immunoreactive synaptic contacts with host striatal neurons. In addition, TH-immunoreactive dendrites, that extended from the graft into the host, received non-labelled afferents, possibly arising from the host. These results show that DA neurons from 6.5-9 week old human fetuses survive cell suspension grafting to immunosuppressed hosts, reinnervate the host striatum, form synapses with host striatal neurons, spontaneously release DA and can reverse drug-induced and spontaneous motor asymmetry. These results thus clearly indicate the potential usefulness of human fetal mesencephalic DA neurons for clinical grafting in PD patients.

219.4 INTRACEREBRAL GRAFTING AND CULTURE OF CRYOPRESERVED PRIMATE AND RAT DOPAMINE NEURONS. T.J. Collier, M.J. Gallagher*, B.F. Daley*, W.F. Silverman, D.E. Redmond Jr., R.H. Roth, C.D. Sladek and J.R. Sladek Jr. Departments of Neurobiology and Anatomy and Neurology, University of Rochester School of Medicine, Rochester, N.Y. 14642 and Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT. 06510.

The availability, storage and transportation of donor tissue are significant practical problems associated with the potential use of grafted neural cell replacements in human neurodegenerative diseases. In connection with ongoing studies utilizing dopamine neuron grafts to ameliorate the experimental parkinsonism produced by MPTP in African green monkeys, we have begun to assess the applicability of cryopreservation techniques to the storage of neural tissue. Mesencephalic dopamine neurons were frozen (Houle and Das, Brain Res. 192:570, 1980), stored in liquid nitrogen (1-70 days), thawed, and tested for survival and growth in intrastriatal grafts and in culture. Ventral midbrain tissue was obtained from 3 fetal African green monkeys (CRL: 8.0, 17.5 and 19.0 cm). Tissue placed in culture was derived from the 19.0 cm CRL fetus and tissue from all three donors was used for intrastriatal grafting into 3 adult monkey hosts. Within the storage intervals examined (4 and 28 days), recently thawed fetal neural tissue yielded suspensions of intact cells (99% viable by trypan blue exclusion) that developed normal neuronal morphology and stained for tyrosine-hydroxylase (TH) after 2 weeks in culture. Grafted TH-positive neurons derived from all 3 donors also were identified in the striata of host monkeys. Grafts of frozen-thawed tissue appeared to be smaller and contain fewer TH-positive neurons than grafts of fresh tissue, but the neurons that were present exhibited extensive neurite outgrowth. We pursued evaluation of the cryopreservation technique utilizing midbrain tissue from 32 15-day gestation F344 rats. Estimates of cell density from suspensions of rat mesencephalon made prior to culturing or implantation suggest that frozen-thawed tissue yields fewer total cells, but appears to have no significant effect on the proportion of TH stained neurons counted in culture two weeks later. Samples of rat midbrain tissue freeze-stored for 1, 14 or 70 days exhibited a 50% decline in cell density as compared to fresh tissue. Comparisons of staining for TH and neuron specific enolase indicated no marked change in the percentage of neurons expressing TH; ranging from 72-89% fresh and frozen samples. Thus, a marked loss of dopamine neurons does not appear to be a consequence of freeze-storage. Intrastriatal implantation of fresh versus freeze-stored (70 days) midbrain tissue into nigrostriatal-lesioned rats (6 each) confirmed our impression from the primate studies that cryopreserved tissue yielded smaller grafts containing fewer TH-positive neurons. As in the primates, the neurons that were present exhibited normal morphology at both the light microscopic and ulturastructural levels. While further evaluation of the physiological and behavioral efficacy of transplanted cryopreserved tissue is needed, our initial findings indicate that both primate and rat midbrain dopamine neurons remain viable in culture and survive intracerebral grafting following cryopreservation periods of up to 70 days. (ADRDA FSA-85-015, NS24032, AG00847, 1-F32-AG05384)

219.5 BEHAVIORAL EFFECTS OF FETAL DOPAMINE CELL TRANSPLANTATION IN BONNET MONKEYS WITH MPTP-INDUCED PARKINSONISM C.R. Freed, J.B. Richards, C. Hutt*, J. Whalen*, R. Peterson*, and M. Reite, Depts. of Med., Pharm., and Psych., Univ. Colo. Health Sci. Ctr., Denver, CO 80262.

The neurotoxin N-methylphenyltetrahydropyridine (MPTP) which produces a Parkinsonian syndrome in man and other primates has provided a useful model for studying new therapies for Parkinson's disease. Preliminary reports indicate that fetal substantia nigra dopamine cells may survive when transplanted into Parkinsonian monkeys (Bakay et al., Soc. Neurosci. Abstracts 11: 1160, 1985; Redmond et al., Lancet i, 1125, 1986) although behavioral improvement is uncertain. We have studied the behavioral effect of fetal substantia nigra tissue transplanted unilaterally into caudate and putamen of five MPTP lesioned Bonnet monkeys (maccaca radiata). Animals were food deprived and trained to pull a lever for a food reward. Because preliminary experiments showed that MPTP lesions eliminated trained behavioral responses in some animals, simpler tasks were also tested. Animals were timed as they reached for food pellets in their field of view. After training, animals were lesioned with MPTP 0.5 mg/kg i.m. every other day for 5 injections. All animals which survived the acute effects of MPTP showed spontaneous improvement over weeks to months. Most required repeat courses of MPTP (up to 4 courses of 2.5 mg/kg) to establish persistent deficits. Fetal tissue was obtained from 18 to 45 mm crown-rump embryos with substantia nigra dissected from the ventral third of the mesencephalic arch and disrupted by passage through a needle. Recipient animals were injected with tissue unilaterally into caudate and putamen at a total of 20 sites along 5 tracks. The side of transplant was randomly chosen. Motor performance was assessed with lever pulling, with the reach tasks and with amphetamine 0.5 mg/kg i.m. Because of spontaneous improvement, transplant effects were measured as a change in the slope of behavioral improvement. Four to 6 months after transplant, animals were killed and tissues examined for transplant survival with tyrosine hydroxylase immunocytochemistry. Results showed that behavioral improvement was gradual, appearing 4 to 8 weeks after transplant. While there was greater motor improvement on the side contralateral to the transplant, most animals also showed improvement on the ipsilateral side. One severely affected animal regained the ability to maintain a posture, to feed and drink, to display paw preference with the hand contralateral to the transplant, and to circle after amphetamine to the side contralateral to the transplant. The animal showed no restoration of trained behavior. Animals with milder deficits had recovery to normal in trained pull tasks in the extremity contralateral to the side of transplant.

219.6 GRAFTS OF ADRENAL MEDULLA PROMOTE RECOVERY OF TYROSINE HYDROXYLASE IMMUNOREACTIVE (TH-IR) FIBERS IN STRIATUM OF THE MPTP TREATED MOUSE. M.C.Bohn, F.Marciano*, L.Cupit*, and D.M.Gash. Dept.Neurobiology and Behavior, State Univ. of New York, Stony Brook, N.Y. 11794 and Dept. Neurobiology and Anatomy, Rochester Medical Center, Rochester, N.Y. 14642.

The drug, MPTP, depletes striatal dopamine (DA) in primates and certain rodents, and produces Parkinsonian-like symptoms in humans and non human primates. In mice, the dopaminergic neurons in the substantia nigra are severely damaged resulting in a rapid loss of striatal dopamine (DA) and catecholamine fluorescence. However, some neurons survive and slowly recover.

To investigate the consequences of grafting adrenal medulla tissue into the brain of a rodent model of Parkinson's disease, adult mouse adrenal medulla was grafted unilaterally into mouse striatum 1 week after MPTP treatment (2x50mg/Kg,16hrs.apart). This MPTP treatment depleted DA levels by 86% at 5 weeks and caused the virtual disappearance of TH-IR fibers in the striatum at 2 weeks. In contrast, at 2,4 and 6 weeks after adrenal grafting, dense TH-IR fibers were observed in the grafted striatum and only sparse fibers in the contralateral striatum. Sham grafts of gelfoam were without effect. The TH-IR fibers were dopaminergic since they did not stain for dopamine B-hydroxylase(DBH) and appeared to arise from the host rather than from the grafts in which only a few cells survived. Grafted cells which survived expressed TH, DBH, PNMT (phenylethanolamine N-methyltransferase) and/or leu-enkephalin. Some surviving cells retained their chromaffin cell morphology while others had neuronal-like processes. These processes remained within the graft and did not penetrate into the brain parenchyma.

These observations suggest that, in mice, adrenal medullary grafts exert a neurotrophic action on the host to promote recovery of dopaminergic neurons, an observation which may be pertinent to similar approaches presently being taken to treat humans with Parkinson's disease.

219.7 STRIATAL TRANSPLANTS PROMOTE CENTRALLY-MEDIATED BEHAVIORAL EFFECTS OF N-METHYL-SCOPOLAMINE WHICH DOES NOT NORMALLY CROSS THE BLOOD-BRAIN BARRIER. P.R. Sanberg, S.F. Calderon,* E.M. Weissman,* M. Giordano and A.B. Norman, Laboratory of Behavioral Neuroscience, Depts. of Psychiatry, Neurosurgery, Psychology and Physiology, University of Cincinnati Medical Center, Cincinnati, OH 45267.

Neural tissue transplants have proven to be very exciting as a potential method of treatment for many CNS disorders. Recently, however, it has been reported that the blood-brain barrier (BBB) does not develop normally within the transplanted tissue. Thus, compounds such as horseradish peroxidase, which do not normally enter the brain following systemic injections can be found within the transplanted tissue, surrounding host tissue and CSF (Rosenstein, Science, 230, 772-774, 1987). We examined whether N-methylscopolamine (NMS), which does not normally pass the BBB, but has psychoactive properties when administered intracerebrally, can influence behavior in animals following systemic injections, presumably by entering the brain via an altered BBB within the transplant.

Day 17 fetal striatal tissue or vehicle alone was injected either bilaterally (2 ul per side), or unilaterally (4 ul) into the striatum of adult male Sprague Dawley rats. Two to four weeks later, the animals were put into automated Digiscan Activity Monitors (Omnitech Electronics), habituated for one hour, and then injected i.p. with NMS (vehicle 2, 4 and 8 mg/kg) and their locomotion was tested for one more hour.

In the control animals NMS did not produce any locomotor changes. However, in the transplant groups, especially the bilateral groups, there was a significant change in the pattern of locomotion and a small hyperactivity. Present studies are examining the extent to which systemically injected [^{3}H](-)NMS will label transplant and host brain tissue.

It is possible that these differences in behavior may be due to the differential responsiveness of the transplanted and host tissue to the relatively small concentrations of NMS which may cross an intact BBB. Alternatively, these preliminary data suggest that transplants which are located at a pharmacologically active site may serve as a potential access point for allowing some drugs which do not normally enter the brain to produce a centrally-mediated behavioral effect. If this latter hypothesis is correct, this may have important clinical significance by allowing possible therapeutic agents which would not normally cross the BBB to have a direct effect within the brain via neural transplants. Supported by Pratt Family and Friends, Hereditary Disease Foundation, Huntington's Disease Society of America and Omnitech Electronics.

219.8 EXPERIENCE WITH ADRENAL MEDULLARY AND FETAL MESENCEPHALIC TRANSPLANTATION FOR THE TREATMENT OF BILATERAL AND UNILATERAL MPTP PARKINSONISM IN PRIMATES. R.A.E. Bakay, M.S. Fiandaca, K. Sweeney*, P.M. Invone and D.C. Collins, Dept. of Surgery Div. Neurological Surgery, Yerkes Regional Primate Research Center and Veterans Administration Medical Center, Emory Univ. Sch. of Med., Atlanta, GA 30322.

We have gained experience with both the bilateral and unilateral MPTP nonhuman primate Parkinson model. In both model systems spontaneous recovery does occur Most of this recovery is within the first two weeks but may occur up to two months. Both models appear to more reliably maintain an appropriate level of Parkinson like features by titrated multiple dose applications administered two to four weeks apart. Properly prepared animals can be maintained for many months with very little behavioral variability.

The bilateral model displays the complete array of Parkinson-like features whereas the hemiparkinson model features very few. The hemiparkinson animals have a contralateral neglect of the upper extremity. Differentiation from a hemiplegic extremity can be made by noting the increased tone and ability to use the extremity when aroused similar to the paradoxical kinesia. The clear advantage of the hemiparkinson model is the ease of preparation and maintenance.

We have experience with both the adrenal and fetal tissue transplantation for correction of the MPTP induced Parkinson-like behavior. Most of our experiences with fetal mesencephalic tissue which we have been able to demonstrate significantly improves clinically observable behavior ($P<.001$). The younger animals appear to recover more function than do older animals and those less severely appear to recover more function than those with the most severe deficits. There is a correlation with the degree of recovery and the elevation of CSF catecholamine metabolites as determined by HPLC.

This project was funded by the American Parkinson Disease Association and supported by the Veteran's Administration, Yerkes Regional Primate Research Center, Emory University, (NIH Core Grant RR-00-165) and NIH Grant ROI-NS17524 to PMI.

219.9 **ATTENUATION OF APOMORPHINE-INDUCED ROTATIONAL BEHAVIOR BY FETAL STRIATAL TISSUE TRANSPLANTS IN RATS WITH UNILATERAL STRIATAL KAINIC ACID LESIONS.** A.B. Norman, T. McGowan,* S.F. Calderon,* M. Giordano and P.R. Sanberg. Laboratory of Behavioral Neuroscience, Departments of Psychiatry, Neurosurgery, Psychology and Physiology, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Transplants of rat fetal striatal tissue into rats with bilateral striatal kainic acid (KA) lesions reverses the lesion-induced spontaneous locomotor abnormalities suggesting a functional integration of host and transplanted tissue (Sanberg et al., Pharm. Biochem. Behav. 25, 297, 1987). However, it is unclear at present whether the transplanted tissue develops similar pharmacological properties as the original host tissue.

Rotational behavior is produced in response to apomorphine and other dopamine receptor agonists in unilateral KA-lesioned rats (Schwarcz et al., Brain Res. 170, 485, 1979) presumably by an asymmetry in the dopamine effector systems. Any reduction in this asymmetry might be expected to reduce the rotational behavior. We therefore assessed the effects on apomorphine-induced turning behavior of rat fetal striatal tissue transplants into the lesioned striatum.

Male Sprague Dawley rats (180-220 g) were stereotaxically administered KA (5nmol) unilaterally into striatum. Between 4 and 6 weeks post-lesion, rats were injected s.c. with 0.5-0.75 mg/kg apomorphine and the number and topography of rotations assessed in an open-field environment. Rats were tested at 4-5 day intervals on three occasions prior to transplantation in order to obtain an accurate baseline for rotational behavior. Interestingly, rats turned contralateral to the lesion in contrast to the results obtained by Schwarcz et al. Day 17-19 fetal striatal tissue (4 ul) was stereotaxically implanted into the lesioned striatum. Three and five weeks post-transplant, apomorphine-induced rotational behavior was reassessed using the previous dose. Post-transplant the topography of the rotations changed from tight pivotal rotations to walking in a circle, with a marked reduction in both the total number and maximal rate of rotations. Stereotypic behavior in one location tended to replace ambulation.

These results suggest that the transplanted tissue reduced the asymmetry in the dopamine effector systems in the rat striata and, therefore, that the developing transplanted tissue possesses similar pharmacological properties as the original host tissue with respect to dopaminergic neurotransmission. Fetal striatal tissue transplants, therefore, appear to be capable of functionally and pharmacologically restructuring damage to a complex neurochemical system.

219.10 AFFERENTS TO AND EFFERENTS FROM SEROTONERGIC CELL SUSPENSIONS TRANSPLANTED IN THE CAUDATE-PUTAMEN COMPLEX OF THE YOUNG AND MIDDLE AGED RAT. A COMBINED IMMUNOHISTOCHEMICAL AND ANTEROGRADE TRACING STUDY. R.J. Vermeulen* and H.W.M. Steinbusch (SPON: ENA). Dept. Pharmacology, Free University, 1081 BT Amsterdam, The Netherlands.

Transplantation of monoaminergic/cholinergic fetal cell suspensions into either the rat caudate-putamen (cp) or the hippocampus has resulted in an increased understanding of the outgrowth arising from these cell suspensions. However most of these studies were focussed either upon the neuromorphological delineation of the outgrowth or behavioral observations. In this study we were interested in two matters. To start with we want to show that serotonergic neurons implanted into the cp of young and middle aged rats receive afferents from the host tissue. In addition we were interested if these afferents only arise from adjacent brain regions, thus i.e. the cp, or also from areas which are more remote like caudally the substantia nigra, pars compacta (snc) or rostrally the prefrontal cortex. The latter two areas are known to project upon the cp. For this reason we injected into the cp of young (3 months old) and middle aged (21 months old) rats a fetal mesencephalic raphe cell suspension in the previously denervated cp. After a survival time of at least four weeks the animals received an injection with PHA-L into either the rostral part of the cp, immediately adjacent to the transplantation sites or a small injection into the prefrontal cortex or in the snc. After 8 days the animals were processed for PHA-L and serotonin-immunocytochemistry using a combined DAB/ DAB-Ni double staining technique. We observed that in particular fibers arising from the snc make contacts with the transplanted serotonergic cells in rats of both ages. Injection into the neighboring cp did not result in an innervation of the transplanted cells. Finally to determine the total outgrowth of a mixed cell suspension in relation to its monoaminergic cell component PHA-l was injected into the area which previously received a cell suspension. Double staining experiments revealed that it was difficult to reach the exact injection site since, due to prolonged survival time, the coordinates have partially changed. Accordingly we used a new approach by mixing PHA-l with the cell suspension. We demonstrated that after a survival time of 4 weeks some of the implanted cells have taken up PHA-l and started to give efferents. Using double staining experiments we demonstrated that some of these cells actually contain serotonin. These studies show that fiber networks in the central nervous are not static elements, but have the capacity to change their localization during their life and adapt to new circumstances. Finally these lightmicroscopical observations give only a first impression about these contacts and they should be followed by detailed electronmicroscopical investigations.

219.11 ULTRASTRUCTURAL ANALYSIS OF NEURONAL AND SYNAPTIC DEVELOPMENT WITHIN NEOSTRIATAL TRANSPLANTS IN AN ANIMAL MODEL OF HUNTINGTON'S DISEASE. Paul D. Walker* and James P. McAllister II (SPON: J. A. Kenning). Depts. of Anatomy and Neurosurgery, Temple University School of Medicine., Philadelphia, PA 19140.

We previously showed that neostriatal (NS) transplants do not establish axonal connections with host NS afferent and efferent regions up to 2 months post-grafting. Instead, grafted neurons project axons to different locations within the transplant and possibly synapse on other grafted neurons (Walker and McAllister, Brain Res., in press). Recently, we analyzed the neuronal and synaptic maturation of NS grafts to determine if transplanted neurons can establish a NS-like connective organization in the absence of normal developmental cues, such as extrinsic connectivity. Five days after intrastriatal kainic acid injections, adult rats received grafts of dissociated E14 NS. Animals containing 1, 3, and 5 week old grafts and age-matched (E21, 2, and 4 week) normal control animals were processed for transmission electron microscopy. Seven days after grafting, microglial cells comprised a large proportion of cells within the transplant. Cells resembling normal NS neuroblast cells were also abundant in the graft. As in the normal prenatal NS, graft neuropil contained much extracellular space. This space was filled with cellular debris which most likely resulted from kainate neurotoxicity and spontaneous death of some grafted neurons. Apposed membranes of cellular processes were seen, but synaptic densities were rare and no synaptic vesicles were present at these contacts. Neurons within the 3 and 5 week grafts were seen individually and in clumps of 3-4 neurons. Cells with ultrastructural characteristics resembling normal spiny neurons were most numerous. In contrast to the normal NS, medium and large neurons with deeply indented nuclei (aspiny neurons) were more frequent in the transplant. However, these cells were less abundant than spiny neurons. Axosomatic synapses were present on all types of transplanted neurons. Neuropil in 3 and 5 week grafts was filled with neural and glial processes and many axospinous and axodendritic synapses. Axo-axonal synapses were also present. When compared with control NS, the transplant neuropil contained enlarged dendrites and fewer synapses. These data indicate that although NS transplants do not establish connections with normal NS afferents and efferents, neurons within the graft develop a complex synaptic organization amongst themselves. Although similar synaptic types as the normal NS were found in the transplant, fewer synapses were present and the morphology of dendrites were altered. These results may reflect differences in developmental cues between grafted and normally maturing NS neurons.

219.12 QUANTITATIVE ANALYSIS OF DENDRITES FROM TRANSPLANTED NEOSTRIATAL NEURONS. James P. McAllister II, Mark C. Zemanick and Paul D. Walker. Depts. of Anatomy and Neurosurgery, Temple University School of Medicine, Philadelphia, PA 19140

Morphologic and biochemical results suggest that grafted embryonic neostriatal neurons have similar characteristics to normal adult neostriatal neurons. Our previous Golgi analysis showed that 4-6 week old neostriatal transplants are populated by neurons qualitatively similar to the neuron-types comprising the normal neostriatum. As in the normal neostriatum, the Spiny I neuron was the type most commonly found in transplants. However, our recent horseradish peroxidase study has indicated that no axonal connections exist between the host and the transplant at 35 days post-transplantation. To determine if transplantation and lack of extrinsic connectivity affect dendritic morphology, the present morphometric study compared the spine density of 35-day old transplanted Spiny I neurons to age-matched controls. Host rats received bilateral neostriatal transplants 5 days after intra-striatal kainic acid lesions. Transplants consisted of cell suspensions of neostriatal tissue taken from embryos on the 14th day of gestation. Hosts were sacrificed at 35 days post-transplantation; control tissue was obtained from 28-day old animals to correlate with the actual age of the transplanted tissue. All tissue was processed using rapid Golgi methods, and well-impregnated neurons were analyzed quantitatively by light microscopy. Control spine densities (0.92 ± 0.25/10 um) were similar to those observed in adult animals by others. The overall spine density of transplant dendrites, however, showed a significant 39.1% reduction when compared to controls ($p < .001$). This reduction was due to a significantly decreased spine density of intermediate and distal branches. Specifically, there was a 38.0% reduction in the spine density of intermediate branches and a 39.1% reduction of distal branches (both $p < .001$). Proximal branches of transplanted neurons, however, demonstrated a significant increase in spine density over controls ($p < .05$). Because of the short length of proximal branches, this increase had little effect on overall spine density. In addition, transplanted neurons were found to have a significant 23.7% reduction ($p < .001$) in the total number of proximal dendrites. This study thus provides evidence that 35 day old transplanted spiny I neurons show quantitative differences in dendritic morphology compared to age-matched controls. These differences may be due to aberrant maturation of grafted neurons as well as a lack of extrinsic input to the transplant.

NEUROTOXICITY I

220.1 BARREL ROTATION AND TOXIC EFFECTS OF NEUROPEPTIDES: ADDITIVE EFFECTS OF INTRACEREBROVENTRICULAR (I.C.V.) ARGININE-VASOPRESSIN (AVP) AND SOMATOSTATIN (SRIF) IN RATS. Carey D. Balaban* and Walter B. Severs. Depts. of Anatomy, Surgery and Pharmacology, Col. Med., Penn State Univ., Hershey, PA 17033

Injections (i.c.v.) of SRIF and AVP can elicit barrel rotation (BR), convulsions and lethal pulmonary edema [Brain Res., 365 (1986) 21-29; Fed. Proc., 46 (1987) 1449 (2 abstracts)]. In addition, i.c.v. SRIF (40 μg) can destroy cerebellar Purkinje cells. This study examined whether these multiple effects are additive. Alert adult SD rats received either (a) 0.5 μg AVP, (b) 20 μg SRIF or (c) 20 μg SRIF + 0.5 μg AVP through a lateral ventricular cannula implanted four days previously (volume: 5 μl; vehicle: artificial CSF). BR incidences of SRIF, AVP and SRIF+AVP groups were 13/16, 6/25 and 17/18, respectively. The AVP incidence was lower ($p<0.01$, Fisher's exact test) than the other groups. The incidence of mortality, preceded by convulsion, was 0/16 for SRIF, 1/25 for AVP and 12/18 for SRIF+AVP; mortality in the latter group was elevated ($p<0.001$, Fisher's exact test vs either peptide alone). Hazard plots of BR latencies were consistent with a two parameter exponential model. Minimum latencies (μ) were 78 s for SRIF, 46 s for AVP and 31 s for SRIF+AVP; fast phase hazard (θ^{-1}) was lower for SRIF (0.62 ± 0.26%/s, slope $\pm$ 95% C.I., r=0.98) than for SRIF+AVP (3.96 ± 0.82%/s, r=0.995; $p<0.05$, t test). For the smaller AVP sample (n=6), $\theta^{-1} = 0.47 \pm 0.32$%/s (r=0.95). The fast phase θ^{-1} for SRIF+AVP was also greater than observed for either SRIF (40 μg) or AVP (1 μg) [*loc. cit.*]; however, the SRIF+AVP value represents the sum of these higher dose θ^{-1} values for single peptides. Similarly, SRIF+AVP mortality represents a sum of mortality observed for SRIF (40 μg) and AVP (1 μg) [*loc. cit.*]. Sample sizes did not permit estimation of slow phase θ^{-1}. BR latencies were longer for SRIF than either AVP or SRIF+AVP rats ($p<0.01$, Mann-Whitney U test); the AVP and SRIF+AVP groups were similar ($p>0.05$). Cupric-silver staining of brains after a 4 day survival period revealed degenerating Purkinje cells in midline cerebellum of SRIF and SRIF+AVP rats. These data imply that i.c.v. SRIF and AVP have additive effects on BR incidence, BR latency (θ^{-1}) and mortality. Since CSF [SRIF] is elevated after metrazole-seizures in rats [Neuropeptides, 9 (1987) 19-24] and both [SRIF] and [AVP] are elevated in CSF from patients with elevated intracranial pressure [Horm. metab. Res., 18 (1986) 555-557; J. Neurol. Neurosurg. Psychiat., 48 (1985) 50-57], we propose that interactions between neuropeptides may be a risk factor for development of multiple motor sequelae, which may be lethal. This motivates simultaneous examination of CSF levels of multiple neuropeptides in both clinical and experimental contexts. (C.D.B. supported by RCDA NS00891).

220.2 CATECHOLAMINES ARE TOXIC TO RAT CEREBRAL CORTEX IN DISSOCIATED CELL CULTURE. P. A. Rosenberg and M. A. Dichter. Departments of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115, and Graduate Hospital and University of Pennsylvania Medical School, Philadelphia, PA, 19146.

We have been interested in understanding the actions of norepinephrine (NE) in cerebral cortex, one of the major projection areas for noradrenergic neurons in the central nervous system. A role for NE in facilitating cortical synaptic plasticity was suggested by reports by Kasamatsu that NE depletion using intracortical 6-hydroxydopamine prevented the ocular dominance shift produced by suturing one eye closed in cats during a critical window of development. These studies interested us in the possibility that a developmental effect of NE on neurons might be demonstrable in tissue culture. To test for an effect on neuronal survival, NE was added to growth medium of cultures plated 24 hours before at a final concentration of 0.25, 2.5, 25 or 250 uM. Control cultures received similar volume of vehicle (100 uM EDTA, 1 mM HCl) only. Cultures were observed 24, 48, and 72 hours later. NE at a concentration of 25 uM was, surprisingly, associated with a large loss of both neurons and nonneuronal cells from the culture. No cells survived exposure to 250 uM NE. Time course experiments comparing cultures in 25 uM NE with control cultures showed a steady decline in cell numbers over at least 48 hours following addition of NE. In other experiments designed to determine the minimal interval of exposure required to demonstrate toxicity it was found that there was no effect of exposure to NE for 1 and 4 hours, but nearly the full toxic effect was manifest following a 24 hour exposure to NE. In order to further define the parameters contributing to toxicity, the effect of cell density on toxicity was examined, and it was found that halving the culture plating density, from 450,000 to 225,000 cells per 35 mm dish, significantly decreased the number of surviving cells. The pharmacology of catecholamine toxicity was characterized, and it was found the effect could be mimicked by any catecholamine, including isoproterenol, but not blocked by beta adrenergic antagonists, suggesting that catecholamine toxicity is not mediated by an adrenergic receptor. On the other hand, toxicity could be blocked by catalase, superoxide dismutase, and tocopherol, suggesting mediation by free radicals generated during oxidative degradation of catecholamines.

220.3 MPP+ UPTAKE STUDIES IN DISSOCIATED DOPAMINERGIC CELL CULTURES. S. Schinelli*, U di Porzio, A. Zuddas and I.J. Kopin, Sect. of Immunopharmacology and Lab. of Neurophysiology, NINCDS, NIH, Bethesda, MD 20892.

The discovery that the administration of the neurotoxin N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to primates and mice can partially reproduce behavioral and biochemical changes observed in idiopathic Parkinson's disease has provided a new tool to study the ethiology of this neurological disorder. Two steps are required for onset of the neurotoxicity: first the bioactivation of MPTP by monoamino oxidase B (MAO-B) into N-methyl-4-phenylpyridine ion (MPP^+) and then the uptake of this active toxin into dopaminergic neurons.

We have studied MPP^+ uptake and its accumulation in DA neurons using dissociated cell cultures from E13 mouse embryonic mesencephalon and compared to that of dopamine (DA). The neurons were grown in serum-free conditions (di Porzio et al., Nature 1980, 288, 370-373). Uptake kinetic parameters were determined in one week old mesencephalic cultures and control cultures from the striatum.

The K_m for DA (0.204 ± 0.079 uM) showed that the affinity was greater than for MPP^+ (1.080 ± 0.227 uM) whereas the V_{max} for MPP^+ (55.25 ± 3.65 pmoles/mg prot/min) was greater than that for DA (24.8 ± 3.44 pmoles/mg prot/min). Under the same conditions, mazindol (a DA uptake inhibitor) showed similar potency in inhibiting both DA and MPP+ uptake. In striatal cell cultures uptake of DA and MPTP was negligible and MPP+ uptake was only about 10% of that in mesencephalic cultures. DA neurons were identified using tyrosine hydroxylase (TH) immunostaining and formaldehyde-induced catecholamine fluorescence. They accounted for about 1% of the total neuronal population in mesencephalic cultures.

Depolarization induced by veratridine (0.1 mM) released comparable proportions of [^{3}H]DA and [^{3}H]MPP^+ from mesencephalic cultures (presumably from DA neurons). These experiments are consistent with uptake of MPP^+ into dopaminergic neurons in vitro by the same system as DA. A small percentage of non-DA neurons may take up small amounts of MPP^+, probably through a low affinity uptake. Furthermore, DA and MPP+ seem to be stored in the same intracellular compartments, at least shortly after entering the cells, and appear to be released by similar mechanism.

220.4 CULTURED SEROTONIN NEURONS ARE SENSITIVE TO MPP+ TOXICITY BUT RESISTANT TO MPTP. L. K. Friedman and C. Mytilineou. Department of Neurology, Mount Sinai School of Medicine, New York, N.Y. 10029.

We have previously shown that the toxic effect of MPTP and its metabolic by-product MPP+ is similar for both dopaminergic (DA) and noradrenergic (NE) neurons in dissociated cell cultures (Friedman and Mytilineou, Soc. Neurosci. Abst. 12:268, 1986). Since the serotonin (5-HT) neurons are resistant to MPTP toxicity in vivo, we examined the effect of the toxins in an in vitro preparation. Varied concentrations of MPTP and MPP+ were added to the feeding medium for 7 days beginning on the 8th day in vitro. Following a 24 hour washing of the cultures were analyzed for toxicity by measuring [3H]NE or [3H]5-HT uptake. MPP+ toxicty increased with increasing concentrations (1 to 10 uM) for both neuronal populations. However, the 5-HT neurons were less affected than the NE neurons at all concentrations of the toxin (65-82% vs. 95-99% inhibition of uptake). In contrast, MPTP toxicity differed markedly in the two neuronal populations. In the NE neurons MPTP at concentrations between 1 and 5 uM resulted in 75% inhibition of NE uptake, while higher concentrations (10 to 100 uM) were less toxic. In the 5-HT neurons MPTP produced no toxic effect at concentrations up to 10 uM. A toxic effect to 5-HT neurons was seen only after 100 uM MPTP (65% inhibition of uptake). The differences in the response of NE and 5-HT neurons to the toxins could be the result of the high inhibitory effect of MPTP on the 5-HT uptake pump. The presence of MAO B within 5-HT neurons could explain the toxicity of MPTP at high concentrations. Supported by NIH grant NS-18979 and American Federation for Aging Research.

220.5 MPTP METABOLISM AND TOXICITY IN DISSOCIATED CELL CULTURES OF EMBRYONIC RAT BRAIN. C. Mytilineou Dept. of Neurology, Mount Sinai School of Medicine, New York, N.Y. 10029.

The metabolic oxidation of MPTP was studied in dissociated cell cultures established from embryonic rat rhombencephalon. The water-soluble metabolite, MPP^+, was separated from MPTP by ether extraction, according to the method of Glover et al. (Neurosci. Lett., 64:216, 1986). Cultures were incubated with 7.5 nanomoles [^{3}H]MPTP and the accumulation of the metabolite was measured in the feeding medium and in the cells, during a 4 day exposure. The metabolism of MPTP increased linearly over time, and 24.1% of the initial concentration of MPTP (1.81 nanomoles) was oxidized in 4 days. The oxidation of MPTP was inhibited by pretreatment with 1 µM deprenyl. The metabolite of MPTP diffused readily into the feeding medium. Less than 1% of the metabolite was retained by the cells. The rate of metabolism of MPTP could be enhanced by increasing the number of cells plated into the tissue culture dish. Thus, adding cortical cells to cultures containing rhombencephalic cells, resulted in an increase of MPTP metabolism, which was proportional to the amount of protein added to the dish. Addition of cortical cells produced a 94% increase of the metabolic oxidation of MPTP, but, when expressed per mg of protein, both sets of cultures metabolized MPTP at the same rate (2.439 vs. 2.425 nanomoles/mg of protein). In the same sets of cultures, MPTP was more toxic to catecholamine neurons in the dishes that had cortical cells added. After exposure to 10 µM MPTP for 7 days, the uptake of [3H]NE was reduced to 50% of control levels in the rhombencephalic cultures; addition of cortical cell accentuated the toxicity and reduced the [^{3}H]NE uptake to 10% of control. In order to examine the involvement of glial cells in MPTP metabolism, glial proliferation was inhibited by treatment of cultures with the mitotic inhibitor fluorodeoxyuridine for 7 days (days 8 to 15 in vitro). Inhibition of glial proliferation resulted in 29.7% reduction of MPTP metabolism by the cultures. Taken together the above results indicate that MPTP is metabolized by rat embryonic brain cells in culture; the MPTP metabolite diffuses readily into the culture medium; an increase in the amount of metabolite accumulated in the feeding medium parallels an increase in the toxicity of MPTP to catecholamine neurons; and reduction in the number of glial cells suppresses the metabolic oxidation of MPTP. Supported by NIH grants NS-11631, NS-18979 and NS-23017.

220.6 MONOAMINE OXIDASE B IS PRESENT IN THE SUBSTANTIA NIGRA PARS RETICULATA OF PRIMATES: AN ENZYME HISTOCHEMICAL STUDY. K.Nakai, Y.Naka*, T.Itakura*, M.Ueno*, T.Okuno*, N.Komai*. Dept. of Neurol. Surg., Wakayama Med. Col., Wakayama 640 Japan.

We have reported that the localized infusion of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) into the substantia nigra (SN) of monkey induced degeneration of dopamine (DA) containing neurons in the unilateral nigrostriatal (SN-ST) system(Nakai et al.Soc.Neurosci.Abst.12:968,1986), in contrast to the result of similar study in rodents which failed to demonstrate the depletion of DA contents in SN-ST system(Bradbury et al.Nature 319:56,1986). Because the oxidative conversion of MPTP into MPP^+ by monoamine oxidase (MAO) B is an important enzymatic reaction for the neurotoxicity of MPTP, we ,as a next step, investigated the precise morphlogical distribution of MAOB in primates and rodents by using the newly modified histochemical procedure (Arai et al.Neurosci. 19:905,1986).

Macaca fascicularis and Sprague-Dawley rats were transcardially perfused with cold 2% glutaraldehyde and 2% paraformaldehyde mixture(PH 7.4, 400ml/kg over 15 min.) under deep anesthesia with Nembutal. Without postfixation the brain blocks were cut into 50-micron-thick coronal sections. After the preincubation period with Clorgyrine(10^{-5},10^{-6},10^{-7}M) for 15 min. at room temperature, the sections were incubated with the mixture of tyramine hydrochloride(5mM),nickel ammonium sulfate(0.6%), diaminobenzidine(0.005%),horseradish peroxidase(0.1%), and sodium azide(20mM) in Tris-HCl buffer (PH 7.6) at 4°C for 12-18 hours. Thus the site of specific MAO activity is demonstrated as a dark blue staining. As reported by the immunohistochemical study (Westlund et al.Science 230:181,1985), we observed strong MAOB activity in the nucleus raphe dorsalis and some of the hypothalamic nuclei in both species. In addition, we observed a prominent histochemical MAOB activity in the substantia nigra pars reticulata(SNPr) of the monkey where proximal axons of DA neurons are running toward the striatum. No significant MAOB activity in SN pars compacta was observed. These MAOB activity in SNPr were dose-dependently blocked by the addition of Deprenyl into the preincubation medium. By examining the rat brain we failed to demonstrate any significant MAOB activity in SNPr.

In conclusion, the observed interspecies difference in the distribution of MAOB activity in SN-ST system may explain the different change in behavior and DA neurons between primates and rodents following MPTP treatment. Furthermore, the present result suggests a possibility ,in combination with the histofluorescence study, that the initial degeneration of DA neurons in SN-ST system following MPTP treatment starts at the proximal axons of DA neurons followed by the retro- and anterograde degeneration toward the cell body and the striatum, respectively.

220.7 FLUNITRAZEPAM CO-TREATMENT ALTERS THE METABOLIC EFFECTS OF MPTP IN THE MOUSE BRAIN. G. Pizzolato*, M. Dam*, U. Freo*, M.R. Leotta* and L. Battistin*. (SPON: S. Squatrito). Dept. of Neurology, Univ. of Padua Sch. of Med., 35100 Padua, Italy.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) produces behavioral, neurochemical, and histopathological changes in several mammalian species, including mice, which closely resemble those of Parkinson's disease. Based on the known mechanisms of MPTP neurotoxicity, a protective action of MAO-B or catecholamine reuptake inhibitors has been demonstrated. Furthermore, CNS depressant drugs, such as phenobarbital, suppress MPTP neurochemical effects and counteract neurotoxicity in other experimental conditions. In order to identify other potentially protective compounds, we investigated whether flunitrazepam (FLU) possesses antidotal effects against MPTP neurotoxicity.

A semiquantitative modification of the (^{14}C)deoxyglucose (DG) method of Sokoloff et al. (J. Neurochem. 28, 897, 1977) has been used. Two groups of six C57 black mice were injected s.c. twice with MPTP (30 mg/kg) or saline, 16 h apart. Other two groups of animals received i.p. FLU (2 mg/kg) 15 min before MPTP or saline administration. DG was injected i.p. 4 h after the last treatment, and the mice were killed 45 min thereafter.

No changes or sligth decreases in DG uptake were observed 4 h after FLU, whereas MPTP alone increased metabolism in regions containing dopamine (substantia nigra and ventral tegmental area), norepinephrine (locus coeruleus), and serotonin (dorsal raphe) cell bodies. When animals were pretreated with FLU, these MPTP-related changes were less but still evident. In addition, MPTP and FLU co-treatment increased DG uptake in several thalamic (midline and intralaminar), hypothalamic (para- and peri-ventricular), and reticular (periacqueductal gray) nuclei.

These results indicate that FLU was unable to block the effects of the neurotoxin on monoaminergic regions. Furthermore, the effects produced by MPTP and FLU co-treatment extend beyond the regional pattern of metabolic changes secondary to MPTP or FLU alone. They give, therefore, anatomo-functional evidence supporting the concept that a drug may cause different effects depending upon the preexisting state of brain neurotrasmission.

220.8 **ULTRASTRUCTURAL ALTERATIONS INDUCED BY 1-METHYL-4-PHENYLPYRIDINE (MMP+) IN ORGANOTYPIC CULTURES OF CANINE SUBSTANTIA NIGRA AND RAT MESENCEPHALON.** B. Christie-Pope*, R.S. Burns*, and W.O. Whetsell, Jr., Vanderbilt University School of Medicine, Nashville, TN 37232.

The mechanism by which MPTP and its metabolite, MPP+, destroy dopaminergic neurons in the substantia nigra is unknown. A free-radical mechanism (Cohen & Mytilineou, Life Sci. 35:237, 1985) and a mechanism of inhibition of mitochondrial oxidation (Nicklas et al., Life Sci. 36:2503, 1985) have been postulated. This study was undertaken to examine the evolution of ultrastructural changes induced by MPP+ in organotypic cultures of canine substantia nigra (SN) neurons and neurons of rat mesencephalon (MES). Canine SN cultures were prepared from newborn mongrel pups (<24 hours old); rat MES cultures, from 14-15 gestational day rat fetuses. All cultures were maintained under identical conditions for at least 21 days in vitro (DIV) prior to exposure to MPP+. The presence of metabolically-active dopaminergic nerve cells in both types of cultures was detected by measuring, with HPLC techniques, levels of homovanilic acid (HVA) in feeding medium bathing each culture after each three-day feeding period. Selected canine SN cultures, at 21 DIV and demonstrated to elaborate HVA, were incubated with 0.1 nM MPP+ (in feeding medium) for 1, 3, 6, 8, 10, 12, and 15 hours. After each of these incubation periods, some cultures were fixed and studied by electron microscopy. The earliest ultrastructural change observed was swelling of mitochondria in large nerve cells by 3 hours of incubation. At 8 hours, extensive mitochondrial swelling as observed in all cells; by 12 hours, swelling of Golgi apparatus was evident; by 15 hours a swelling of mitochondria and cisternal system had become so severe that cell types were indistinguishable. Selected rat MES cultures, at 21 DIV and shown to elaborate HVA, were similarly incubated in MPP+ but at higher levels and for longer periods (see Christie-Pope, Neurosci. Abstr. 12:982, 1986). In contrast to studies in canine SN cultures, only rat MES cultures with pre-MPP+ incubation HVA values greater than 6 pmoles/µl (range:6 to 16 pmoles/µl) exhibited ultrastructural alteration in response to MPP+ treatment. Those changes, including progressive involvement of mitochondria and cisternal system, were seen in large neurons after approximately 72 hours of MPP+ exposure. Different from the canine cultures, a generalized disruption of the rat MES cultures was not observed even after 8 days' MPP+ exposure, however, the general pattern of ultrastructural change within large nerve cells was similar to canine SN. These studies indicate that while there seem to be species differences in susceptibility to MPP+ toxicity (ibid.), the sequence of ultrastructural change occurring in dopaminergic neurons in these two kinds of cultures appear identical. The mitochondrial changes in particular, may reflect an alteration of mitochondrial function. [Supported by USPHS grant NS-10509 and a Pharmaceutical Manufacturers Association Foundation Fellowship (BCP).]

220.9 **AN ULTRASTRUCTURAL STUDY OF MPTP BODIES IN AN AGED SQUIRREL MONKEY.** L.S. Forno, J.W. Langston, L.E. DeLanney, and I. Irwin*. Departments of Pathology, VA Medical Center, Palo Alto, CA 94304 and Stanford University, Stanford, CA 94305, and Institute for Medical Research, San Jose, CA 95128.

Eosinophilic neuronal inclusions, known as Lewy bodies, are characteristically present in Parkinson's disease. We have recently reported eosinophilic inclusion bodies in an experimental model for Parkinson's disease (Forno et al., 1986). The pink bodies were found in nerve cells of three aged MPTP-treated monkeys in the substantia nigra (SN) and other predilection sites for Lewy bodies. The inclusions, here referred to as MPTP bodies, lacked the central core and peripheral halo most often found in Lewy bodies in the SN, but resembled the pale, depigmented foci in nerve cells that may represent an early stage in the formation of these bodies, a pre-Lewy body.

On electron microscopic examination of the MPTP bodies in the SN in one monkey, the inclusions were less well defined than by light microscopy. They were almost completely devoid of Nissl substance, lacked a well formed Golgi apparatus, but contained small numbers of mitochondria and pigment granules, and displayed a striking increase in rather thick filaments. The filaments measured 20 to 25 nm in diameter and resembled neurotubules. They were compared to filaments from Lewy bodies and from Pick bodies, another type of intraneuronal inclusion bodies, present in Pick's disease. The filaments in the MPTP bodies had a larger diameter than filaments in Lewy bodies and Pick bodies, but the Pick body filaments had a smooth contour. In contrast the filaments in the Lewy bodies had fuzzy deposits of electron dense material along their course. Lesser amounts of fuzzy deposits or sidearms were present on the filaments of the MPTP bodies.

At the present time it can not be established whether or not MPTP bodies are also pre-Lewy bodies. Whatever the relation of the MPTP bodies to Lewy bodies and to Parkinson's disease turns out to be, their study promises to yield important insights into the nerve cell degeneration in this form of experimental parkinsonism, and perhaps also into the nerve cell degeneration in Parkinson's disease and in other neurodegenerative disorders. Whether or not the neurotoxin gains access to the nerve cell through uptake by its terminals, or at the level of the cell body and its dendrites remains to be determined.

220.10 SACCADIC EYE MOVEMENT DEFICITS IN MPTP TREATED MONKEYS W.M. King, C. Smith*, K. Bocchiaro*, and D.M. Gash, (Spon: P. Shrager). Depts. of Physiology and Neurobiology and Anatomy, Univ. Rochester Medical Center, Rochester, New York 14642.

MPTP (1-methyl-4-phenyl- 1, 2, 5, 6-tetrahydropyridine) administered systemically to nonhuman primates produces motor deficits and specific morphological lesions virtually identical to those of human Parkinson's disease. In particular, saccadic eye movement deficits such as increased latency, decreased peak velocity, and hypometria were reported in human Parkinson patients (White, O.B., et al., Brain, 106:571, 1983). Similar deficits were reported in a severely ill monkey acutely treated with MPTP (Brooks, B.A., et al., Brain Res., 383:402, 1986). In this study, we have created an animal model of the onset of Parkinson's disease by injecting small doses of MPTP over periods of months. Monkeys were trained to fixate small light emitting diodes arranged in an array. Eye movements were monitered with an accuracy of 0.2 deg using the scleral search coil technique. Monkeys were tested with 4 paradigms designed to examine distractability, and saccades made to predictable, remembered, and visual target locations. To date, 2 monkeys have received MPTP injections: monkey 1 has received a cumulative dose of 12.4 mg/kg over 11 months and monkey 2 has received a cumulative dose of 7.0 mg/kg over 7 weeks.

Both monkeys present occasionally with mild bradykinesthesia and tremor, especially within 2 days of receiving an injection of MPTP. However, these symptoms are not severe, and the monkeys continue to perform the operant tasks, and to groom and feed themselves routinely. Both monkeys do exhibit mild oculomotor deficits. Monkey 1 (with the larger cumulative dose of MPTP) achieves slower peak velocities in all paradigms than does monkey 2. Over the past 8 weeks of testing and dosing, this animal's mean eye movement latency has progressively increased from 171 ms to 270 ms. The mean latency of monkey 2 has not increased in the same paradigm. Eye movement latencies of both monkeys have increased in a predictive tracking paradigm, from 165 to 222 ms in monkey 1 and from 177 ms to 208 ms in monkey 2. Neither monkey shows progressive increases in distractability or in making saccades to remembered target locations. Our data show that the earliest saccadic eye movement deficit associated with the onset of MPTP induced Parkinsonism is an increased latency of visually guided saccades and a modest decrease in peak saccadic velocity. It is notable that these animals usually exhibit more severe deficits within 2 days of receiving MPTP than when tested 1 week later.

220.11 PROBENECID POTENTIATES THE NEUROTOXICITY OF MPTP BY INHIBITING ITS URINARY EXCRETION IN MICE. Y. S. Lau, J. M. Crampton* and J. A. Wilson. Depts. of Pharmacology and Physiology, Creighton University, Omaha, NE 68178.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) has been widely used in developing an animal model for Parkinson's disease. Multiple injections of high doses of MPTP are required to produce a persistent nigrostriatal toxicity in mice. We observed large amounts of radioactivity appear rapidly in the urine of ^{3}H-MPTP-treated mice following subcutaneous injection of the drug in a study of the safety of using MPTP in animal research (FASEB 46: abs.3734, 1987). The radioactive substances excreted are therefore likely to be the source of cross contamination. In this study we examined the rate of excretion and chemical species in the urine of MPTP-treated mice. We further investigated the effects of probenecid on urinary excretion of the drug and on striatal dopamine levels.

Mice (C57 BL) were treated with one dose of MPTP (15 mg/kg containing 1 uCi of ^{3}H-MPTP, s.c.). Spontaneously excreted urine samples were collected for 48 hours. The radioactivity in the urine was counted and the chemical species excreted in the urine were analyzed by using an HPLC. We observed high levels of radioactivity in early (2-4 hours) samples of urine and the excretion of radioactive substances normally reached a nadir about 12 hours after drug injection. The radioactive substances excreted were chromatographically coeluted with MPTP and MPP^{+} in a concentration ratio of 4:1.

When the mice were injected with probenecid (250 mg/kg, i.p.) prior to the MPTP treatment, the volume and rate of urinary output, and the amount of MPTP excreted were all reduced. The striatal dopamine content in control (probenecid-treated), MPTP-treated, and probenecid plus MPTP-treated animals were assayed by using HPLC electrochemical detection. Striatal dopamine levels remained unchanged in these three groups of animals during the first 24 hours after the respective drug treatment. However, significant reduction of dopamine content was detected in MPTP-treated mice 96 hours following the drug treatment. At this time, a potentiation of dopamine depletion was observed in the striatum of probenecid plus MPTP-treated mice.

In summary, within the first few hours large amounts of MPTP are excreted unchanged as the parent drug in the urine. Probenecid reduces the urinary excretion of MPTP, and potentiates the dopamine depleting effect of MPTP in the nigrostriatal region. Thus by permitting the use of smaller doses of MPTP, probenecid improves the safety and efficacy of the rodent model of parkinsonism.

220.12 RETROVIRAL INFECTION IN PC12 PRODUCES MPTP RESISTANT MUTANTS. M.M.S. Lo, C.M. Dersch*, C. Mamalaki. National Institute on Drug Abuse, Addiction Research Center, Baltimore Md 21224.

N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a substance of abuse, is highly toxic and elicits neuropathologic changes in man, often resulting in Parkinson's disease. MPTP is also cytotoxic to pheochromocytoma (PC12) cells. This toxicity is mediated by uptake of MPP+, the active metabolite of MPTP, into the cell via the catecholamine uptake site. Infection of PC12 cells by retroviruses creates mutants which resist MPP+ toxicity. Retrovirus integrates into the chromosomes of infected cells and disrupts certain genes, normally coding for proteins which are involved in MPTP toxicity. Specific biological functions, normally present in PC12 cells, are lost in these mutants.

The number of MPP+ resistant mutants infected with virus is 1 per 10^{5} cells; this being 1000 fold greater than the number of resistant cells obtained by spontaneous mutation. This suggests that MPP+ resistance is caused by viral infection and inactivation of normal cellular genes. Three distinct categories revealed by neurochemical analysis were mutants 1) lacking any dopamine uptake, 2) lacking dopamine uptake specifically inhibited by mazindol or sodium, and 3) with normal dopamine uptake. In most cases, other neurochemical markers such as tyrosine hydroxylase, choline acetyl transferase, glucose uptake, dopamine content and dopamine release appear to be normal or slightly reduced Many of these MPP+ resistant mutants are responsive to NGF.

SDS gel analysis shows specific and distinct differences in the protein composition of the membrane fraction of different mutants. Two proteins were completely absent in some of the mutants

The chromosomal positions of the virus in the MPP+ resistant mutants were mapped by Southern blot analysis using viral probes. Most of the mutants contained only a single copy of the retroviral sequence. Restriction map analysis of 10 different cell lines showed viral integration occuring in three distinct chromosomal regions. This suggests that at least 3 gene targets (any of which) can confer resistance to MPP+. Using DNA recombinant techniques we have isolated flanking genomic sequences from two of these gene targets. Cloning of putative DNA sequences involved in MPP+ toxicity was achieved by insertional mutation of PC12 cells and rescue of flanking genomic sequences. Identification, purification and characterization of proteins, traditionally used in gene cloning, was avoided by this method of isolation of cDNA clones.

MODULATORS I

221.1 SWITCHING OF SECOND MESSENGER AND ELECTROPHYSIOLOGICAL FUNCTION OF CHOLECYSTOKININ RECEPTOR IN XENOPUS OOCYTES. T.M. Moriarty*, B. Gillo*, S. Sealfon*, and E.M. Landau (SPON: R. Zappulla). Dept. of Psychiatry and Fishberg Center in Neurobiology, Mt. Sinai School of Medicine and Bronx V.A. Hospital, New York, N.Y.

Oocytes of the African frog Zenopus laevis are a convenient system for studying receptor modulation. We investigated the role of second messengers in mediating the electrophysiological effect of cholecystokinin (CCK) in native oocytes. Oocytes with the follicular cell layer intact (follicles) and oocytes with the follicular cell layer stripped away by treatment with collagenase (denuded) were studied. Single cells were voltage clamped in a superfusion apparatus in standard fashion.

Application of 2 uM CCK induced a depolarizing inward current which is similar in shape, time course, and reveresal potential to the Cl^{-} current produced by intracellular injection of IP_3 and that which is seen with other transmitters known to act through the phosphatidylinositol pathway. Application of CCK after a five minute pretreatment of follicles with 0.2 uM forskolin or 1 mM 8-Br-cAMP (both in concentrations too low to induce appreciable currents alone) resulted in a reversal of this inward current to an outward hyperpolarizing current. This outward current is similar in shape, time course and reversal potential to the K^{+} current produced by intracellular injection of cAMP and that which is seen with other transmitters known to be linked to cAMP. Pretreatment of denuded oocytes (which cannot generate cAMP dependent K^{+} currents) with forskolin or 8-Br-cAMP resulted in an abolition of the inward current.

The CCK receptor appears to be linked to both the cAMP and the phosphatidylinositol second messenger systems. The cell's electrophysiological response to the transmitter depends on the present intracellular level of cAMP. In the resting state, the cell will respond to CCK through the phosphatidylinositol system and depolarize. If the adenylate cyclase is activated or the intracellular concentration of cAMP is increased, the cell will respond to CCK by switching to the cAMP system and hyperpolarizing. This suggests that the second messenger system activated by a transmitter may depend on the level of phosphorylation of some critical intracellular component.

221.2 INTERACTIONS OF CAPSAICIN AND RELATED COMPOUNDS WITH SECOND MESSENGER PATHWAYS IN A NEURAL CELL LINE. S.I.Patterson*, T.R.Jackson* M.Dreher* and M.R.Hanley, MRC Molecular Neurobiology Unit, University of Cambridge Medical School, Cambridge, CB2 2QH, U.K.

Capsaicin and related pungent agents share a spectrum of biological actions on sensory neurones, including acute stimulation, long lived desensitization to readministration, and neonatal toxicity. The molecular basis of these effects is unknown, but a specific recognition site or "capsaicin receptor" is an attractive possibility. We have examined the ability of capsaicinoids to regulate identified second messenger events in a model system, the NG115-401L hybrid cell line, which exhibits many of the differentiated properties of the physiological target of capsaicin actions, the primary afferent neurone. At a concentration of 1 μM, capsaicin does not stimulate a production of cAMP, inhibit the production of cAMP stimulated by PGE1, mobilise intracellular calcium, or stimulate inositol lipid metabolism. However, 1 μM capsaicin is able to amplify the dose-dependent production of inositol phosphates elicited by bradykinin. This action is the opposite observed upon phorbol diester treatment, which causes an attenuation of the bradykinin response. Thus, capsaicinoids may interact with the signalling pathway modulated by phorbol diesters. Accordingly we have examined several non-invasive indicators of phorbol stimulation for sensitivity to capsaicinoids. Biologically active phorbols and related tumor promoters cause a dose dependent stimulation of phosphatidylcholine breakdown, releasing free extracellular choline. Capsaicin stimulates a similar response directly and moreover, alters the response to phorbol-12, 13-dibutyrate (PDBu). However, capsaicin does not compete for ^{3}H-PDBu binding. Capsaicin also exhibits dose dependent cytostatic and cytotoxic effects on the cell line. The structural requirements and potential relationships between these different effects will be discussed. The results suggest a close relationship between phorbol mediated actions and capsaicinoids, implying that protein kinase C may be a molecular target for the capsaicin family.

221.3 FORSKOLIN PROLONGS CALCIUM ACTION POTENTIALS IN LAMPREY SENSORY NEURONS. M.D. Womble* and W.O. Wickelgren. Dept. of Physiology, Univ. Colorado Health Sci. Ctr., Denver, CO. 80262.

Primary sensory neurons (dorsal cells) of the lamprey spinal cord, in the presence of Na^+ channel (TTX) and K^+ channel (TEA and 3,4 DAP) blockers, produce long-lasting Ca^{+2} action potentials (Ca APs) in response to brief depolarization. The Ca AP is followed by a prolonged afterhyperpolarization produced by a calcium-activated potassium conductance ($G_{K(Ca)}$). Previous work from this laboratory (Leonard and Wickelgren, J. Physiol. 375: 481, 1986) has shown that the application of gamma-aminobutyric acid (GABA) to dorsal cells prolongs the duration of Ca APs by specifically reducing $G_{K(Ca)}$. Here, we report that the action of GABA can be mimicked by the application of forskolin, a specific activator of adenylate cyclase.

Intracellular recordings were made from dorsal cells of isolated lamprey (Lampetra lamottenii) spinal cord segments. In normal saline, injected depolarizing pulses produced brief Na^+ action potentials (Na APs), without a detectable Ca^{+2} component. The addition of 50 uM forskolin to normal saline did not affect Na AP durations, resting potentials, or passive current-voltage characteristics. On the other hand, forskolin increased the duration of both mixed Na-Ca APs, produced by the addition of K^+ channel blockers to normal saline, and pure Ca APs, generated in saline containing both TTX and K^+ channel blockers. However, forskolin did not effect the resting membrane potentials or passive current-voltage characteristics of these cells. The broadening effect of forskolin on Ca APs was shown to be dose-dependent in the range of 25-200 uM, with the highest dose producing approximately a 3-fold increase in AP duration. Since forskolin had no effect on Na APs or on passive membrane properties of dorsal cells, we conclude that it does not act upon either passive membrane channels or voltage-dependent Na^+ or K^+ channels. Rather, forskolin's action appears to require the presence of a detectable Ca^{+2} current. Therefore, forskolin could act to increase the duration Ca APs either by affecting Ca^{+2} channels, to increase Ca^{+2} influx, or by decreasing $G_{K(Ca)}$, a repolarizing conductance change. The latter appears to be the case. The input resistance of dorsal cells during the plateau phase of the Ca AP was increased by forskolin, indicating that during this time a repolarizing current was decreased. Thus, the broadening of the Ca AP produced by forskolin appears to be due to the specific inhibition of $G_{K(Ca)}$, mimicking the membrane effects of GABA on these cells. This suggests that in lamprey dorsal cells, the modulation of $G_{K(Ca)}$ by GABA may be mediated by an increase in intracellular cyclic AMP.

221.4 MULTIPLE ACTIONS OF ATP ON CHICK SKELETAL MUSCLE S.A. Thomas* and R.I. Hume. (SPON: B. Pfingst). Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109.

ATP (1-10μM) has a potent depolarizing effect on chick myotubes in culture and in vivo. In the studies reported here we examined the ATP responsiveness of myotubes in culture exposed to extracellular solutions containing blockers of several voltage dependent channels over a wide range of membrane potentials. These studies indicate that ATP activates at least two distinct currents, and suggest that both are activated by the same ATP receptor.

Intracellular recordings were made in an external solution containing TTX (10^{-7}M), TEA (20mM), and Co^{++} (4mM) to block voltage dependent Na^+, K^+ and Ca^{++} currents respectively. The membrane potential (Vm) of the myotubes could be varied between +20 and -100mV with little if any sign of voltage dependent responses.

At rest (Vm = -40 mV), a brief (1 sec.) application of 10μM ATP elicited a net depolarization, but the waveform was complex. At -10 mV and potentials more positive, ATP produced a large hyperpolarization without any apparent depolarization. At intermediate potentials (for instance -20 mV) ATP produced an initial depolarization followed by a hyperpolarization, then a late depolarization. At all potentials other than -10 mV the latency to response was about 300 msec, but at -10 mV the latency was 1.1 sec. Responses at all potentials can be explained by the superimposition of a slowly activating, hyperpolarizing reponse upon a more rapidly activating, depolarizing response with a reversal potential of -10 mV. In other experiments, ATP-specific conductance was monitored with repetitive current pulses. At early time points, where only depolarization occurs, a conductance increase was seen, and an even greater conductance increase was seen during the interval corresponding to activation of the hyperpolarizing current. Thus both responses are likely due to conductance increases. Substitution of most of the Na^+ in the external solution with choline indicated a partial dependence of the depolarization on Na^+, but there was no effect on the hyperpolarization. Recordings made in an external solution with a high K^+ concentration markedly affected the hyperpolarization. In a third test solution, replacing most of the chloride with bicarbonate had no apparent effect on either current. These results suggest that a nonspecific cation channel and a K^+ channel are responsible for ATP-activated depolarization and hyperpolarization respectively.

The possibility that both of these currents are activated by the same receptor is suggested by several observations. Both currents show profound desensitization to ATP subsequent to ATP activation, with no apparent recovery after 15 minutes at room temperature. In addition, the same concentrations of ATP are required to activate each current. And finally, all the putative ATP receptor agonists which we have tested either evoke both currents or show no activity.

221.5 ACH RELEASE IN THE AVIAN CHOROID COAT IS INHIBITED VIA A G PROTEIN-MEDIATED MECHANISM WHILE RELEASE IN AVIAN IRIS IS NOT. D. Bruce Gray and G. Pilar. Department of Physiology and Neurobiology, The University of Connecticut, Storrs, CT.

It has been shown that morphine delays motoneuron death in the developing chick ciliary ganglion and inhibits ACh release from ciliary ganglion neurons in co-culture with striated muscle (Meriney et al., Science 228: 1451 (1985)).

To determine whether morphine affects transmitter release at intact neuromuscular junctions between the chick ciliary ganglion and its target musculature, ACh release from neuronal terminals in the isolated smooth muscle layer of the choroid coat and the striated iris of the chick eye was measured after stimulation by incubation in high-K+ Tyrode's. At hatching, both tissues exhibit high-affinity sodium-dependent choline uptake-mediated ACh synthesis. To measure transmitter release, excised tissues were preincubated with ^3H choline (specific activity, .5 mCi/mmole; choline concentration, 1 μM) for 1 hr at 37 C and washed repeatedly in zero-Ca++ Tyrode's until release of extrinsic labeled choline declined to insignificant levels. Labeled ACh was separated from choline by high-voltage paper electrophoresis and quantified by scintillation counting. Both tissues exhibit a basal release of labeled ACh that is potentiated severalfold during a 5-minute incubation in high-K+ Tyrode's (55mM KCl). 50% of the basal release and 100% of the stimulated release are calcium dependent.

Co-incubation of the choroid with 1μM morphine sulfate blocks approximately 90% of the stimulated release. The same effect is seen with 100nM somatostatin (1-14). Preincubation of the excised choroid in oxygenated Tyrode's containing pertussis toxin (200 ng/ml) reverses the inhibitory effect of both morphine and somatostatin.

However, ACh release from terminals in the striated iris is not affected by either morphine or somatostatin at μM levels. Thus, earlier results demonstrating morphine sensitivity of ACh release in cultured ciliary ganglion neurons may be explained by selective participation of choroid terminals in the measured ACh release or by acquisition of sensitivity to opiate modulation in vitro by ciliary neurons.

Furthermore, these results suggest that both opiate and somatostatin receptors are present in the choroid target and may act through a final common pathway to modulate ACh release via a G protein. It is unclear at this time whether the appropriate endogenous peptides are present in this system, or what is the nature of the molecular events underlying the modulation.

Supported by NSF grant #BNS 8410581 to G. Pilar.

221.6 **FOLATE INTERACTIONS WITH CEREBRAL G·PROTEINS,** **Dean M. Hartley*and S. Robert Snodgrass, Neurology Division, Childrens Hospital of Los Angeles, and Dept of Neurology, University of Southern California School of Medicine, Los Angeles, CA 90027.**

Large doses of folates produce seizures and excitotoxic brain damage, which is reportedly blocked by NMDA receptor blockers. Various authors have speculated on a possible transmitter or modulator role for folates in the CNS. The slime mold, Dictyostelium discoideum (Devreotes, Dev. Biol. 95: 154, 1983), has a guanine nucleotide binding protein (G proteins) which is stimulated by folic acid, increasing both GTP binding and GTPase activity. We postulated that folates interact directly with one of the cerebral G proteins to increase the excitability of some but not all transmitter receptors. This relationship might resemble that of PCP with NMDA receptors.

We prepared rat brain membranes (20,000xg pellet) by homogenizing with 50 mM Tris-HCl, pH 7.5 and incubating them at 30°C for 45 min in 50 mM Tris-HCl + 50 mM MgCl, pH 7.5. Saturable binding of ^{35}S-guanosine 5-(γ-thio)triphosphate was observed. More than 75% of binding was displaceable with the GTP analog, 5'-guanylylimidodiphosphate. Binding was sensitive to divalent cations and increased by 220% after preincubation of membranes with NaF. A study of 6 brain regions showed significant variations between regions, with greatest GTP binding found in cerebellar membranes. When membranes were preincubated with various folates (20 μM), the binding of ^{35}S-GTP-γ-S was stimulated in some but not all regions. The greatest folate stimulation (45%) was seen in cerebellar membranes, this effect was statistically significant (Bonferroni t-test). Significant folate stimulation (30%) was also observed in hippocampal membranes. Folic acid, dihydrofolate and tetrahydrofolate were all similar in potency as stimulators of GTP binding. Glutamate used at the same concentration as the folates, had no effect on ^{35}S-GTP-γ-S. Other excitotoxins (kainate, quisqualate and quinolinate) failed to duplicate the folate effect.

The effect of pertussis and cholera toxins, known to catalyze the ADP-ribosylation of the inhibitory and stimulatory α-subunit of G proteins, were tested on both hippocampal and cerebellar membranes. Cerebellar membranes were treated with pertussis toxin and preincubated with 20 μM folic acid. Pertussis treatment significantly increased the total GTP bound above the control levels and those values obtained with folic acid treated membranes (non-pertussis treated). This effect was not seen in either cholera treated cerebellar membranes or in hippocampal treated membranes.

221.7 LEUKOTRIENE C_4-BINDING SITES IN THE MOUSE FOREBRAIN. A.M. Goffinet Positron Tomography Lab., Univ. Louvain, B-1348 Louvain-la-Neuve, Belgium.

Leukotriene C_4 (LTC) is a mediator of the inflammatory response for which specific binding sites have been described in various tissues.

Binding sites for $[^3H]LTC_4$ were demonstrated in the mouse brain, by using binding to brain membranes and in vitro autoradiography. Isotherm binding analysis revealed one binding site with a dissociation constant (K_d) of 10.39 ± 1.97 nM (Scatchard) or 10.15 ± 1.00 nM (non linear analysis). The maximal binding capacity (B_{max}) was 49.20 ± 3.80 (Scatchard) or 48.50 ± 2.63 pmols/mg. prot. (non linear). Specific binding represented more than 90% of total binding. Displacement reactions on brain membranes showed that LTC_4 was 100 times more potent than LTD_4, which differs from LTC_4 by the absence of a glutamic acid residue. Glutathione was ten times less potent than LTD_4. Glutamic acid, bilirubin, hematin, azaserine and 6-diazo-5-oxonorleucine were inactive.

On brain sections, the binding of $[^3H]LTC_4$ was inhibited by cold LTC_4, but unaffected by LTD_4. The density of binding sites was minimal on fiber bundles and on choroid plexuses, high in the cerebral cortex, thalamic relay nuclei and caudoputamen, and maximal at the level of granule cell-rich structures such as the dentate gyrus, entorhinal area, indusium griseum.

these results support the hypothesis, first proposed by Lindgren et al. (PNAS 81: 6212; 1984), that leukotrienes may have a modulatory function in the central nervous system.

Supported by grants FRSM 3.4540.81, 3.4540.84 and AFOSR-86-0353.

221.8 AN ENDOGENOUS MODULATOR FOR CA^{2+} CHANNELS IN BRAIN TISSUE: ISOLATION AND CHARACTERIZATION
E. Sanna,* A.G. Wright, Jr. and I. Hanbauer. Hypertension-Endocrine Branch, NHLBI, National Institutes of Health, Bethesda, MD 20892

Several classes of drugs have been shown to increase or decrease the activity of receptor-linked and "voltage-dependent" Ca^{2+} channels. These drugs have as a common feature the ability to bind with high affinity to membrane proteins that are associated with the Ca^{2+} channel. In addition, dihydropyridine binding sites were found up-regulated in sympathetic-denervated rat heart and in brain of morphine-tolerant mice suggesting that these binding sites may play a physiological role as possible recognition sites for an endogenous ligand. Recent work from this laboratory demonstrated the existence in rat brain of a substance that decreases ^3H-nitrendipine binding. In an effort to purify and characterize this endogenous ligand present in brain tissue, we studied the material obtained in various purification steps for its displacement activity of ^3H-nitrendipine binding to hippocampal membranes, and its effect on veratridine- or glutamate-stimulated $^{45}Ca^{2+}$ -uptake in cultured cerebellar granule cells. The purification of the ^3H-nitrendipine-displacing material involved: (1) Precipitation of bulk proteins with TCA (3% final concentration); (2) Methanol-extraction of lyophilized supernatant fraction; (3) Fractionation on Silica-SEPPAK cartridge by a stepwise gradient of chloroform-methanol; and, (4) Fractionation by HPLC on Partisil-10SCX column. The purified, ^3H-nitrendipine-displacing material migrates on TLC plates as one spot that is stained intensively by ninhydrin. The material eluted from Partisil-10SCX decreased reversibly and noncompetitively the specific binding of ^3H-nitrendipine to hippocampal membranes. In addition, it inhibited the veratridine- and glutamate-elicited increase of $^{45}Ca^{2+}$ -uptake as well as the increase of cyclic GMP formation in primary cultures of cerebellar granule cells. Acid hydrolysis of the material eluted from Partisil-10SCX column (5.7 N HCl, 155°C for 30 min.) abolished the ^3H-nitrendipine-displacing and Ca^{2+} uptake-inhibiting activity. The present data suggest that the nitrendipine-displacing material may be an endogenous ligand whose interaction with Ca^{2+} channels is comparable with that of organic Ca^{2+} channel antagonists.

221.9 PURIFICATION OF THE PUTATIVE ENDOGENOUS LIGAND FOR THE HIGH AFFINITY ^3H-IMIPRAMINE RECOGNITION SITE. M.L. Barbaccia and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University School of Medicine, Washington, DC 20007.

Previous reports from our group and other groups have suggested that human plasma and rat brain may contain at least one endogenous substance, different from serotonin, that specifically binds to the high affinity recognition site for ^3H-imipramine and modulates in an inhibitory fashion the ^3H-serotonin (5HT) reuptake by serotonergic axon terminals. Though the complete purification and therefore the identification of the chemical nature of this putative endacoid is still among our goals, we report on the progress achieved in our laboratory towards its purification. The major steps in the latest purification procedure include: 1) homogenization of the whole rat brain in 1 M acetic acid (at 90°C for 10 min); 2) methanol washing of the supernatant after lyophilization; 3) dialysis through a membrane with a m.w. cut-off of 3,500 daltons; 4) application of the small (<3,500 daltons) material to a high voltage electrophoresis on Agarose C; and 5) chromatography of the high voltage electrophoresis fractions that were active in inhibiting ^3H-imipramine specific binding on a strong cation exchange column for HPLC. The HPLC system we used allows to locate the biological activity in a major peak that displaces ^3H-imipramine binding and inhibits ^3H-5HT uptake. These biologically active HPLC fractions were then spotted on a silica gel plate for TLC and allowed to run for 3 hrs in a buffer containing ethanol:acetic acid:water (8:1:1). Three Iodine-sensitive spots were clearly separated. When tested for their activity in inhibiting ^3H-imipramine binding after scraping off each spot from the TLC plate, the major part of the activity was in the spot with the highest R_f value. The compound contained in this spot showed a U.V. absorbance spectrum with a peak at 260 nM and was not sensitive to ninhydrine. This material is now being subjected to mass fragmentographic analysis in order to gain some understanding on its molecular nature. Since its biological activity is not sensitive to proteases pretreatment it seems reasonable to conclude that it may not be peptidergic in nature. It is also interesting that this putative endogenous substance inhibits on a equimolar basis ^3H-imipramine binding and ^3H-5HT uptake into synaptosomes, but appears not to inhibit ^3H paroxetine binding and it is 10 times less potent in blocking ^3H-norepinephrine uptake. We conclude that the putative endogenous ligand effect described above cannot be ascribed to a hyperosmolarity effect as inferred by Lee et al. (Biochemical Pharmacology 36(6): 945-949, 1987).

221.10 PROTEIN PHOSPHORYLATION IN THE BRAIN AND ANTERIOR PITUITARY: EFFECTS OF NEUROPEPTIDES AND STIMULATION BY cAMP-, CALMODULIN-, AND PHOSPHOLIPID-DEPENDENT PROTEIN KINASES. S.T. Cain, M. Abramson*, J.C. Pryor* and C.B. Nemeroff. Departments of Psychiatry and Pharmacology, Duke University Medical Center, Durham, NC 27710.

The cyclic phosphorylation/dephosphorylation of specific protein substrates is likely an integral mechanism in the regulation of synaptic excitability in the central nervous system (Browning et al., 1985, J. Neurochem. 45:11-23). In addition, there is an accumulating body of evidence which suggests that protein phosphorylation changes are involved in the mediation of hormonal secretion from the adenohypophysis (Aguilera et al., 1986, Neuroendocrinology 43:79-88). Our laboratory is interested in the mechanisms of action of brain neuropeptides, in particular the brain-gut tridecapeptide neurotensin (NT) and the hypothalamic hypophysiotropic hormone, corticotropin-releasing factor (CRF). Prior reports have demonstrated that NT receptors in brain are coupled to phosphatidylinositol hydrolysis, and presumably activation of the calcium/phospholipid-dependent protein kinase (protein kinase C, Goedert et al., 1984, Brain Res. 323:193-197). Conversely, a population of CRF receptors in both anterior pituitary and brain is coupled to cAMP formation and activation of cAMP-dependent protein kinases. We have examined specific phosphoprotein substrates which are sensitive to NT and CRF and have begun to identify the types of protein kinases involved in the phosphorylation of these proteins.

Adult, male rats were decapitated and the caudate nucleus or anterior pituitary dissected and homogenized. A lysed synaptosomal fraction was prepared from the caudate nucleus homogenates and used for in vitro phosphorylation. The anterior pituitary homogenate was used for in vitro phosphorylation without further processing. Phosphorylation was accomplished by incubation for 1 minute with 10 μM ATP (containing $[\gamma^{32}P]ATP$) in the presence or absence of various cofactors.

In view of the coupling of CRF receptors to activation of adenylate cyclase, we have compared cAMP-dependent protein phosphorylation in the caudate nucleus and the anterior pituitary. In the caudate nucleus, the primary cAMP-dependent substrates had molecular weights of 74, 72.5, 68.5, 57.5, 51 and 37 Kd. In the pituitary, the cAMP-dependent substrates had molecular weights of 52, 35, 32, 31, 26 and 22 Kd. We are currently in the process of evaluating the effects of CRF on the phosphorylation of cAMP-dependent substrates in brain and pituitary. In contrast, NT stimulated the phosphorylation of a group of caudate nucleus synaptosomal proteins (76, 71 and 49.5 Kd) which appear to be substrates for the calcium/phospholipid-dependent protein kinase.

221.11 PLATELET-ACTIVATING-FACTOR (PAF) INHIBITS LUTEINIZING-HORMONE-RELEASING-HORMONE (LHRH) AND SOMATOSTATIN (SRIF) RELEASE FROM MALE RAT MEDIAN EMINENCE (ME). M.P. Junier*, C. Tiberghien*, V. Fafeur* and F. Dray INSERM U.207, URIA, INSTITUT PASTEUR PARIS

PAF, originally described as a platelet activating factor is effective, among various parameters, on secretory processes. It seemed then interesting to test it on LHRH, SRIF and Growth-Hormone-Releasing-Factor (GRF) release from rat ME,a hypothalamic fragment rich in nerve endings containing these neuropeptides. Additionnally an effect of PAF at the rat Medio-Basal-Hypothalamus lacking the ME (MBH) and at the pituitary level was explored.

Static incubations of ME and MBH (2ME/400 µl Krebs Ringer Bicarbonate Buffer containing 2.2 U/ml Bacitracine and BSA 0.025 %, KRBG, 2MBH/600 µl KRBG)were carried out either 45 min for ME (15 min preincubation, PI, 30 min incubation, I) or 60 min for MBH (30 min PI, 30 min I) at 37°C under an atmosphere of 95 % O_2 5 % CO_2 in the presence of PAF (10^{-17} to 10^{-8} M). LHRH and SRIF release were decreased by PAF (10^{-14} to 10^{-13} M and 10^{-14} to 10^{-11} M respectively) with a maximal inhibition at 10^{-14} M for both neuropeptides (LHRH 78±15 pg/mg protein, n=6 vs control 166±10 pg/mg protein, n=11, SRIF 447±129 pg/mg protein, n=6 vs control 1077±119 pg/mg protein, n=11), whereas GRF release was not affected. [^{3}H]PAF added to the incubation medium containing the ME was extracted and purified on HPLC. It was recovered as authentic PAF in both supernatant and ME where a second compound with a shorter carbonyl chain was present. Stimulated release of LHRH and SRIF by the ionophore A23187 5 µM was decreased by PAF 10^{-14} and 10^{-8} M (at 10^{-14} M 44% and 36% inhibition of A23187-stimulated-LHRH and SRIF release respectively). LHRH and SRIF release from MBH was not altered by PAF (10^{-14} and 10^{-8} M). Dispersed rat antepituitary cells were incubated 3 hours in the presence of PAF (10^{-14} to 10^{-8} M) which did not affect Luteinizing-Hormone neither Growth-Hormone nor Prolactin release.

PAF is the first lipidic compound described as an inhibitor of LHRH and SRIF release from ME while, on the contrary, it is ineffective on GRF release. It acts specifically at the hypothalamic neuronal endings level and counteracts the stimulatory effect of a massive Ca^{++} entry induced by the ionophore A23187 on LHRH and SRIF release. These facts, correlated with the recent finding, in our laboratory, of PAF specific binding sites in rat hypothalamus suggest that PAF is a potential physiological regulator of LHRH and SRIF release.

221.12 CHARACTERIZATION OF PLATELET ACTIVATING FACTOR (PAF) SPECIFIC BINDING IN MALE RAT BRAIN. C. Tiberghien*, M.P. Junier*, M.T. Domingo* and F. Dray (SPON: G. Fillion). INSERM U 207, URIA, INSTITUT PASTEUR, PARIS

Following the recent discovery of a modulatory effect of PAF on neurosecretion, a specific binding of Platelet Activating Factor (PAF) was investigated on male rat brain membrane preparations.

The binding of synthetic [^{3}H]PAF, 1-O[alkyl-1',2'-^{3}H]-alkyl-2-O-acetyl-sn-glycero-3-phosphorylcholine (NEN, England), was achieved in 50 mM Tris buffer containing 0.25% BSA, 10 mM $MgCl_2$, pH 7.4 and at 0°C, with membrane aliquots of about 250 µg in a final volume of 200 µl. The non specific binding was determined by an excess (x1000) of unlabeled PAF or compounds, well known as potent antagonists of PAF on its platelet binding sites (L 652-731 and Kadsurenone, from Merck Sharp and DHOME Research Lab., NJ, USA, BN 52021 from Beaufour, France).

Under these conditions the association kinetic reached equilibrium with a $t_{1/2}$ of about 100 min. Saturation and competition experiments showed a saturable specific binding. Data analysis indicate the presence of two classes of binding sites. The Kd_1 of the high affinity binding component was 0.45 ± 0.16 nM (n_1=10,0 ± 3.5 fmol/mg protein). The Kd_2 of the lower affinity component was 15.5 ± 9 nM (n_2=70 ± 25 fmol/mg protein). The specificity of the binding was investigated in competitive experiments at 1 nM of [^{3}H]PAF. The order of displacement was PAF (ED_{50}=1.0 ± 0.33 nM, n=4) > L652-731 (ED_{50}=46 ± 13 nM, n=2) > Kadsurenone (ED_{50}=132 ± 35 nM, n=2) > BN 52021 (ED_{50}=890 nM, n=1). No competitive effect was observed with two PAF structural derivatives, lyso-PAF and 1-O-hexadecyl-sn-glycerol. Specific binding of [^{3}H]PAF at 1 nM expressed in % of specific binding ((specific bound/total bound)x100) in various brains areas was more important in cortex (33%), quite followed by hypothalamus (20%), lower in cerebellum (12%) and not detectable in pituitary.

These results demonstrate the existence of high affinity and low capacity PAF binding sites in rat brain. The recent finding in our laboratory of an inhibitory effect of PAF on Luteinizing-Hormone-Releasing-Hormone (LHRH) and Somatostatin (SRIF) release, but none on that of Growth-Hormone-Releasing-Factor (GRF), from male rat median eminence suggests that PAF could be a modulator of endocrine function, at the neurosecretory level, through a receptor.

M.P. Junier is the recipient of a fellowship from ROUSSEL-UCLAF France and M.T. Domingo from BEAUFOUR FRANCE.

ACTION POTENTIALS AND ION CHANNELS IX

222.1 ***CONUS* VENOM ALTERS IONIC CURRENTS IN IDENTIFIED *APLYSIA* NEURONS.** Varda Lev-Ram*, Baldomero Olivera* and Irwin B. Levitan (SPON: Herman T. Epstein). Graduate Department of Biochemistry, Brandeis University, Waltham, MA 02254 and Department of Biology, University of Utah, Salt Lake City, UT 84112.

Crude venom extracted from the predator snail *Conus textile* alters membrane excitability in identified *Aplysia* neurons. When venom was applied to the medium bathing an *Aplysia* abdominal ganglion, the electrical activity of the bursting pacemaker neuron R15 changed dramatically. First there was an increase in membrane excitability which resulted in enhancement of bursting, and this was followed by a long lasting hyperpolarization. The hyperpolarization appeared to be a long lasting synaptic inhibition, resulting from an increase in excitability of some unidentified presynaptic cell. The increase in synaptic input to R15 persisted even when cobalt was substituted for calcium in the bathing medium. *Conus* venom also caused an increase in excitability followed by an enhancement of synaptic input in left upper quadrant (LUQ) bursting neurons. Voltage clamp experiments demonstrated that the long lasting synaptic hyperpolarization induced in R15 was due to a decrease in a subthreshold calcium current. Dopamine application also decreases calcium current in R15, and the synaptic component of the venom effect was occluded by dopamine.

The synaptic component was eliminated by axotomizing R15 and LUQ neurons and "puffing" venom from an electrode in the immediate vicinity of the target cell bodies. Under these conditions we observed a decrease in outward current evoked by depolarizing voltage clamp pulses; this could be due either to a decrease in potassium current or an increase in calcium current (or both). In addition the venom caused a decrease in an inwardly rectifying potassium current evoked by hyperpolarizing current pulses. These changes are consistent with the observed increase in membrane excitability, and might also account for increased release of transmitter from the unidentified presynaptic cells. It will be of interest to determine whether individual purified components of the venom specifically affect individual membrane ion currents in these neurons.

222.2 A COMPONENT OF CALCIUM CHANNEL CURRENT IN APLYSIA SENSORY NEURONS IS BLOCKED BY A DIHYDROPYRIDINE. B. W. Edmonds, M. Klein* and E. R. Kandel. Howard Hughes Medical Institute, Center for Neurobiology & Behavior, Columbia University, College of P & S, and NYS Psychiatric Institute, New York, NY 10032.

Recent introduction of pharmacological agents which selectively alter the function of distinct classes of calcium channels has facilitated the examination of multiple types of voltage-sensitive calcium channels in neurons (Nowycky et al., Science, 316, 1985). These channel-specific agents also allow assay of the functional roles of different types of channels. We have begun an investigation of the properties and roles of various calcium channels in the sensory neurons of Aplysia utilizing nifedipine, a dihydropyridine thought to interact with a specific class of calcium channels.

Pleural sensory neurons were voltage-clamped with two micro-electrodes in the presence of (in mM) 460 TEA, 10 KCl, 44 $MgCl_2$, 22 $BaCl_2$ and 10 HEPES, and the effect of nifedipine (1-15 uM in 0.1% ethanol) was examined on inward barium current. Currents were elicited once every 30 sec by 100 ms steps from a holding potential of -60 mV to a test potential of +10 mV, the potential at which the inward current was largest. Nifedipine at concentrations above 2 uM produced a dose-dependent, reversible block of a component of the inward current. Subtraction of currents in the presence of nifedipine from control currents suggests that nifedipine is blocking a non-inactivating inward current similar to the L-type current previously described by Nowycky et al. The observation that a saturating concentration of nifedipine (~ 10 uM) produces only a 50% reduction (SEM 1.7, N = 5) in the peak of the inward current suggests that the barium current in Aplysia sensory neurons comprises at least two components: a dihydropyridine-sensitive and a dihydropyridine-insensitive component. We do not know, however, whether these components are kinetically distinct.

In addition to a more thorough characterization of the currents, we plan to assess the functional roles of the different types of channels by defining the role of these channels in neurotransmitter release and in the modulation of this release.

222.3 Phosphoinositide turnover and modulation of Ca current in dorsal root ganglion neurons are mediated by norepinephrine.

O.E.Harish* K.Dunlap† and L.W.Role. (SPON: D.D. Kelly) Anat. & Cell Biol, Ctr Neurobiol.&Behav., Columbia P&S, NY,NY 10032& †Dept.Physiol., Tufts Med Sch., Boston, Ma 02111.

In dorsal root ganglion neurons, norepinephrine (NE) inhibits the voltage dependent Ca conductance (Dunlap & Fischbach J.Physiol. 317, 1981). Recently, Rane and Dunlap (PNAS 83: 184, 1986) have demonstrated that agents which activate protein kinase C such as 1,2-oleoyl acetylglycerol mimic the effects of norepinephrine (NE) in reducing the voltage activated Ca current in embryonic sensory neurons. Since C kinase has been shown to be activated as the result of phosphoinositide (PI) hydrolysis we examined the possibility that NE might enhance PI metabolism and thereby activate protein kinase C. We have measured the production of inositol phosphates (IP's) in sensory neurons, as an indication of the degree of activation of PI turnover. Dispersed sensory neurons in culture were prelabeled with ^{3}H-inositol and incubated with test agents. The cells were then extracted and the labeled sugars were separated by column chromatography (Downes & Michell, Biochem.J. 198:133, 1981). A significant increase in the production of pooled ^{3}H-IP's was observed at the shortest time that we can measure (~15 sec.). The maximum response (3 fold) was obtained after 1.5 minutes. By 10 minutes the IP's production has returned to the control level. This rapid and transient feature of the NE induced IP's production would predict a similar time course for NE modulation of the Ca current if these two events are *causally* related. Analysis of the time course of the NE modulation of Ca current revealed a steady decline of the response with the continued presence of NE in a manner that matches the time course of inositol phosphates production. Both responses to NE are rapid in onset with significant changes detected immediately. Furthermore, the two responses to NE have similar pharmacology in that they both are inhibited by yohimbine (an α_2 antagonist) and are insensitive to isoproterenol (a β agonist). Finally, Dunlap and collaborators (Holz, Rane & Dunlap Nature 319:20, 1986) have shown that pertussis toxin, which interferes with G-protein activation, decreases the NE modulation of the Ca current. We report here a similar decrease in the NE induced PI hydrolysis after pretreatment with pertussis toxin. This indicates that the two responses are mediated via a G-protein, and further support the idea that these two phenomena are closely linked. We suggest that the production of the inositol phosphates is closely linked to the effect of NE on the modulation of the Ca current in the sensory neurons, and may in fact display the first step in the mechanism for the Ca channel modulation by NE, in the sensory neurons of chick embryos. Supported by awards to LWR from the Klingenstein & Sloan Foundations & by an award to OEH from the Benin Foundation.

222.4 **NOREPINEPHRINE INHIBITION OF SENSORY NEURON CALCIUM CURRENT IS BLOCKED BY A SPECIFIC PROTEIN KINASE C INHIBITOR.**

S.G. Rane, M.P. Walsh* and K. Dunlap. Dept. of Physiology, Tufts Univ. Sch. of Med., Boston, MA 02111 and Dept. of Medical Biochemistry, Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1.

The voltage-dependent, slowly inactivating calcium (Ca) current of chick sensory neurons can be inhibited by norepinephrine (NE) via a mechanism which does not appear to involve either cAMP, cGMP or calmodulin-dependent signal transduction systems. Because phorbol ester and 1,2-oleoylacetyl-glycerol (OAG), compounds which activate the phospholipid/Ca-dependent protein kinase C (PKC), mimic the action of NE, it has been suggested that PKC may mediate this inhibition of Ca current (Rane & Dunlap, 1986, PNAS 83, 184-188). To more directly test this hypothesis, we used the whole cell configuration of the patch clamp technique to introduce into sensory neurons a potent and highly specific 17 kDa protein kinase C inhibitor (PKCI) isolated from bovine brain (McDonald & Walsh, 1985, BBRC 129, 603-610). To promote dialysis of the cell interior, large diameter (3-5 μm ID) borosilicate glass (WPI 1B150F-4) pipettes were used. Cells were dialyzed with an internal solution (containing, in mM, 150 CsCl, 10 HEPES, 5 MgATP, and 5 BAPTA), with or without PKCI, and the responses of the two populations of cells to NE or OAG were compared. Electrophysiological and visual criteria were used to judge that both control and PKCI-treated cells were well dialyzed with patch pipette solution for at least 10 minutes before application of NE (10 μM) or OAG (60 μM). Concentrations of PKCI from 25 to 150 μg/ml were tested and found to attenuate the NE- and OAG-induced inhibition of Ca current in a dose-dependent fashion. At 75 μg/ml PKCI, NE inhibition of Ca current was half of that observed for control cells, and at 150 μg/ml PKCI, NE's effect was reduced by more than 90%. PKCI was somewhat less effective on OAG-mediated responses, producing a 70% attenuation at 150 μg/ml. As a control, a preparation of 150 μg/ml PKCI was exposed to trypsin digestion; dialysis of neurons with this preparation reduced NE's effect by only 30%. Half maximal and maximal inhibition of PKC-dependent phosphorylation in vitro occurred at 37 and 50 μg/ml, respectively (McDonald & Walsh, 1985). Thus, the dose-response curve for PKCI inhibition of NE action on Ca current is right-shifted by a factor of 2 to 3 relative to that describing its inhibition of PKC, in vitro. This discrepancy probably reflects differences between in vivo and in vitro conditions, and the fact that PKCI concentrations in the dialyzed neurons are likely to be less than those in the pipette solution.

The ability of neurotransmitters and PKC activators (OAG and phorbols) to similarly affect certain ion channels has been used as inferential evidence that PKC may be involved in channel modulation. We have used a specific PKCI to show that activation of PKC is an essentail step in the process by which NE down modulates voltage-dependent Ca current in chick sensory neurons. [Supported by NS16482 (KD) and NS07756 (SGR).]

222.5 β-ADRENERGIC AGONISTS INCREASE CALCIUM CHANNEL ACTIVITY IN SECRETORY CELLS OF THE MOUSE ANTERIOR PITUITARY.

Martha C. Nowycky, Dept. Anatomy, Med. Coll. Penn., Philadelphia, PA, 19129.

AtT-20 cells are a clonal line derived from mouse anterior pituitary which secrete adrenocorticotrophic hormone (ACTH) and β-endorphin *in vitro*. β-adrenergic agents, such as isoproterenol, increase secretion via a mechanism which includes an increase in action potential (AP) frequency and consequent increase in Ca^{2+} influx (Surprenant, J. Cell Biol., 95, 559, 1982). Previously, I have shown that β-adrenergic agents act in part by decreasing the activity of a voltage-gated K channel (FK channel) which helps terminate APs (Nowycky, Bphys. J. 51, 57a, 1987).

Using single channel, cell-attached patch clamp techniques, I have studied calcium channel activity in this cell line. The recording pipette contained 110 mM $BaCl_2$ as the charge carrier and 10 mM tetraethylammonium ion to block the FK channel. The cell resting potential was zeroed with isotonic K aspartate solution. Channel activity was elicited by test pulses to +20 or +30 mV from a holding potential of -80 mV, administered at 0.33 Hz.

Under these conditions, the most frequently observed calcium channel generally resembles "L"-type channels of chick dorsal root ganglion (DRG) cells (Nowycky et al., Nature 316, 440, 1985). The single channel conductance is ~23 pS, somewhat smaller than in DRG cells. Channel openings are seen throughout a 70 msec pulse, and the averaged current reconstructed from single channel recordings is flat. In addition, in whole cell recordings with 3 mM Ca^{2+} as the charge carrier, the inward current does not inactivate during a 200 msec pulse. The channels possess dihydropyridine receptors, since the mean open time is greatly increased by the dihydropyridine agonist, Bay K 8644.

Application of isoproterenol (1 μM) to the bath, caused an increase of calcium channel activity in 14 of 21 patches. In responsive cells, the average increase is about 2-fold, while 5 patches exhibit more than a 5-fold increase. The increased activity results from both a decrease in the number of null sweeps and a large increase in the probability of opening in a given sweep. In contrast to the isoproterenol-enhanced increase of calcium current in frog heart cells, which subsided after approximately 10 min.(Bean et al., Nature 307, 371, 1984), the enhanced activity in AtT-20 cells persists for the duration of the experiment (maximum thus far, 30 min.). It is rapidly reversed by addition of propranalol (1 μM).

These results suggest that in AtT-20 cells, β-adrenergic agents modify action potential frequency and secretion by combined effects on calcium and potassium channels. It will be interesting to see if other hormones which regulate ACTH and β-endorphin secretion also interact with these channels, either through second messenger or G protein systems.

222.6 ONE TYPE OF CALCIUM CHANNEL IN NERVE TERMINALS OF THE RAT NEUROHYPOPHYSIS IS SENSITIVE TO DIHYDROPYRIDINES.

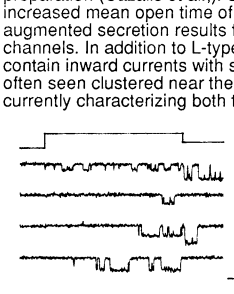
José R. Lemos and Martha C. Nowycky. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545 and Dept. Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129.

Calcium influx through voltage-gated calcium channels is an essential component of transmitter release and hormone secretion. In a variety of neuronal preparations, multiple types of calcium channels have been described, which can be distinguished on the basis of kinetic properties, ionic selectivities, and pharmacology. Thus far, most of the characterizations have been performed at the cell soma. It is not known if the same types of calcium channels are also transported to the nerve terminal and are associated with the site of release.

Using the cell-attached patch clamp technique, we have studied single calcium channel activity in a preparation of freshly dissociated nerve terminals. "Neurosecretosomes" were prepared from the posterior pituitary of adult male rats (Cazalis et al., J. Physiol. 390, 1987). Patch clamp recordings were obtained from isolated terminals of ~ 2 to 5 μ diameter. Patch pipettes were filled with 110 mM $BaCl_2$, 10 mM HEPES, and 0.2 μM TTX. Recordings were performed in either a low Ca^{2+} (3 μM) saline solution or in Ca^{2+}-free isotonic K glutamate.

In the presence of the dihydropyridine calcium channel agonist, Bay K 8644 (1 μM), the predominant inward currents correspond to the L-type calcium channel activity described in dorsal root ganglion cells (Nowycky et al., Nature 316, 440, 1985). Channel openings are characteristically long, often outlasting the pulse and deactivate slowly during repolarizing pulses. The slope conductance is ~28 pS. In the absence of Bay K 8644, channel openings of similar amplitude are brief (~1 msec), as is typical of L-type channels in other preparations.

It has been shown previously that Bay K 8644 potentiates depolarization-induced release of oxytocin and vasopressin in this preparation (Cazalis et al.,). Since this compound causes a dramatically increased mean open time of the L-type Ca channels, it is likely that the augmented secretion results from increased Ca^{2+} influx through these channels. In addition to L-type Ca channels, neurosecretosomes also contain inward currents with smaller conductances. These openings are often seen clustered near the beginning of the test pulse. We are currently characterizing both the large and small conductance channels.



Single sweeps with L-type Ca channel activity in the presence of Bay K 8644, recorded in low Ca^{2+} saline. The holding potential for all sweeps is RP-20 mV, and the patch is repolarized to RP+20 mV. The test potentials are (from top to bottom): RP+70, +60, +50 and +40 mV. Scale bars represent 2 pA and 20 msec.

222.7 LONG TERM STIMULATION OF DOPAMINE RECEPTORS INHIBITS CALCIUM CHANNEL ACTIVITY IN CULTURED PITUITARY CELLS. G. Cota* and C. M. Armstrong* (SPON: B. Ehrlich). Dept. of Physiol., Univ. of Penn., Phila., PA 19104.

The innervation of the pars intermedia (PI) of the rat pituitary gland includes dopaminergic nerve fibres with origin in the hypothalamus. It is well established that dopamine, acting through D-2 dopamine receptors on the PI cells, plays a predominant role in the regulation of the synthesis and release of pro-opiomelanocortin-derived peptides. Previous experiments have shown that the voltage-dependent Ca channel activity of denervated PI cells kept in primary culture increases markedly with time in culture. This may depend on the removal of dopaminergic innervation from the PI cells. We have tested this possibility by culturing the denervated PI cells in the presence of bromocriptine, a potent D-2 agonist. Ca tail currents were recorded in whole-cell mode at the holding potential (-80 mV) after 15-ms activating steps to +60 mV. The tails were fit with two exponentials, thus separating the contribution of SD and FD Ca channels. Individual traces were normalized by cell capacitance. Table I shows the increase in Ca channel activity with time in culture (mean±SEM, n=8-11):

	Time in culture (days) 0.7	2	5	10-11	15-16
FD current (%)	100±14	177±16	321±15	393±40	414±60
SD current (%)	100±9	90±10	115±18	139±18	135±15

Addition of 1 μM bromocriptine to the culture medium prevents or even reverses the increase in Ca channel activity, as illustrated in Table II. All recordings were from 10-11 day cells. Bromocriptine was added 1 hr to 4.5 days before the recordings, but was not present in the recording medium.

	Time of preincubation in bromocriptine 0	1 hr	2 days	4.5 days
FD current (%)	393±40	378±35	190±24	117±17
SD current (%)	139±18	148±24	139±24	103±18

The results indicate that long term stimulation of dopamine receptors reduces the Ca channel activity of PI cells, and raise the possibility that dopaminergic neurons may exert a tonic inhibition on Ca channel expression in PI cells in vivo.

We have also observed acute effects of dopamine on the ionic channel activity of cultured PI cells. Dopamine increases the amplitude of a voltage-dependent, slowly inactivating K current (this effect is blocked by prolonged intracellular dialysis) and speeds the "washout" of FD Ca channels.

222.8 INVOLVEMENT OF C-KINASE AND G PROTEINS IN INHIBITION OF Ca^{2+} CURRENTS BY NEUROPEPTIDE Y IN RAT DORSAL ROOT GANGLION NEURONS D. A. Ewald[1], R. J. Miller[1] and P. C. Sternweis[2]
[1] Dept. of Pharm. & Physiol. Sci., U. of Chicago, Chicago IL 60637
[2] Dept. of Pharm., U. of Texas Health Sci. Cntr., Dallas TX 75234

A variety of modulatory neurotransmitters endogenous to the vertebrate spinal cord can inhibit Ca^{2+} currents in cultured dorsal root ganglion (DRG) neurons. Neuropeptide Y (NPY), the most recently described member of this family of neuromodulators, inhibits both the sustained Ca^{2+} current evoked at 0 mV from a holding potential of -40 mV and the transient Ca^{2+} currents which are additionally evoked at 0 mV from a holding potential of -80 mV. (Whole-cell patch clamp with (in mM) 140 Cs, 10 EGTA, 1 Mg, 2 ATP and an ATP regenerating system in pipette and 10 Ca, 140 TEA and 1 Mg bathing the neurons.) Maximal effect of 10^{-7} M NPY ranged from 40-70% and half-maximally effective dose was 10^{-9} M (n=15). We tested the possibility that activation of C-kinase by the second messenger diacylglycerol (DAG) is a necessary step in this inhibition by "down-regulating" DRG neurons for C-kinase by long-term pretreatment with phorbol esters (Matthies *et al.* J. Neurosci. 7 1198 '87). The inhibitory effect of 10^{-9} M NPY was completely prevented in down-regulated neurons (n=4). At higher concentrations of NPY (e.g. 10^{-7} M) inhibition was not prevented (n=6). It was, however, qualitatively different from inhibition on non-down-regulated neurons being predominantly on the transient Ca^{2+} currents. These results suggest the existence of two types of NPY receptors: a low affinity type which is either directly coupled to Ca^{2+} channels or utilizes a second messenger other that DAG/C-kinase and a higher affinity type which inhibits Ca^{2+} currents via DAG-activated C-kinase.

Inhibition of Ca^{2+} currents by NPY is completely prevented by pretreatment with pertussis toxin (n=10). This implies that G proteins are involved in both the C-kinase mediated and the non-C-kinase mediated inhibitions. We tested the ability of G_o, a pertussis toxin sensitive G protein, to reconstitute the inhibitory effects of NPY by including its alpha subunit (α_o) in the patch pipette along with 1 mM GTP. Reconstitution of NPY-induced inhibition by α_o occured after a time delay of 5 to 15 min. With 10 nM α_o the inhibition ranged from 20-50% (5 neurons, 22 exposures) and was readily reversed after exposure. With 100 nM α_o the inhibition ranged from 50-80% (6 neurons) and was not readily reversed. The effect of NPY in control neurons is larger than that seen with 10 nM α_o and more reversible than that seen with 100 nM α_o. We are pursuing the hypothesis that 10 nM α_o reconstitutes a receptor system coupled directly to the Ca^{2+} channels and that 100 nM α_o additionally reconstitutes a receptor system which requires a second messenger such as DAG to produce inhibition.

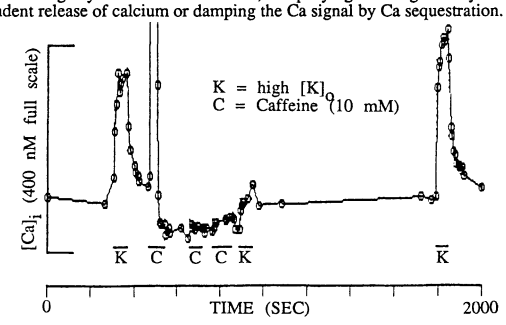
222.9 **FURA-2 IMAGING DEMONSTRATES THE IMPORTANCE OF INTRACELLULAR STORES AND ION CHANNELS IN REGULATING CYTOSOLIC FREE CALCIUM IN SYMPATHETIC NEURONES.** *D.V. Madison, D. Lipscombe*, M. Poenie=*, H. Reuter*, R.W. Tsien, R.Y. Tsien=*, Dept. of Physiology, Yale School of Medicine, New Haven, CT 06510, and =Dept. of Physiology-Anatomy, U.C. Berkeley, CA. 94720.*

We have studied the levels of cytosolic free calcium in dissociated frog sympathetic neurons with the ratio imaging technique using the fluorescent calcium indicator fura-2. The resting cytosolic free calcium level in the neurons was approximately 80 nM. When depolarized with 60 mM extracellular potassium ($[K]_o$), the intracellular calcium concentration ($[Ca]_i$) rose rapidly to an average level of approximately 300 nM and decayed only slightly while the cell remained in high $[K]_o$. $[Ca]_i$ returned to baseline shortly after returning the cell to normal $[K]_o$. Focal extracellular electrical stimulation also caused a similar increase in $[Ca]_i$. High $[K]_o$-induced responses were abolished when $[Ca]_o$ was removed. Application of caffeine (10 mM) caused a very rapid rise in $[Ca]_i$ which decayed very nearly back to baseline levels within a few seconds, even in the continued presence of caffeine. Upon washing caffeine from the extracellular solution, $[Ca]_i$ undershot the baseline level for several seconds. The caffeine response was due to release of calcium from intracellular stores since it was not abolished by removal of $[Ca]_o$. This response was eventually abolished with repeated caffeine applications. Several lines of evidence suggest interactions between voltage-gated Ca entry and Ca release from stores: (1) $[Ca]_i$ continues to rise after electrical stimulation ceases; (2) response to high $[K]_o$ is diminished by prior depletion of stores with caffeine (Figure); (3) Simultaneous application of caffeine and high $[K]_o$ often evoked rhythmic oscillations of $[Ca]_i$. These findings suggest that intracellular Ca stores play a major role in controlling cytosolic Ca transients, amplifying Ca signals by calcium-dependent release of calcium or damping the Ca signal by Ca sequestration.



222.10 **PROPERTIES OF THE CALCIUM CURRENT OF PANCREATIC B-CELLS.** L.S. Satin* and D.L. Cook* (SPON. S. Fatherazi), Departments of Physiol. and Biophys. and of Med., Univ. of Wash., and VA Med. Ctr., Seattle, WA 98108

In pancreatic islet B-cells Ca channel activation leads to Ca uptake and insulin secretion. To characterize these channels we used the whole-cell patch-clamp to measure the Ca current in cultured neonatal rat B-cells. K currents were blocked with internal Cs and ATP and external TEA (10mM) while Na current was blocked with external TTX (3 μM).

Ca current (< 100 pA) activated near -40 mV (from a holding potential of -60 mV), peaked between 0 and + 10 mV, reversed below +100 mV and was abolished by Ca removal or by the addition of 2 mM Co (Satin, L.S. and Cook, D.L., Pflugers Arch 404:385-7, 1985) or very low doses of Cd ($K_D \sim 1$ μM). BAY k 8644 (5 μM) caused a small enhancement of the current.

Several minutes of hyperpolarization increased the amplitude of the Ca current while depolarization reversibly depressed it. The "steady-state" inactivation curve had a $V_{1/2}$ = -60 mV, which is more negative than the activation threshold of the current, suggesting that voltage can affect channel availability independent of Ca influx. However, the decay of the current during a 40 msec command was more marked in Ca than in Ba as expected if inactivation was mediated by a rise in $[Ca]_i$.

Some cells showed evidence of an additional inward current (when holding at -100 mV), which was much less sensitive to Cd and was abolished by removing external Ca.

These data suggest that the major Ca current of B-cells is highly Cd-sensitive and may have an inactivation mechanism that is both voltage and $[Ca]_i$-dependent. Some cells appeared to have a second inward Ca current. More work is necessary to fully isolate and characterize these two Ca conductance mechanisms and to determine their respective roles in the generation of B-cell bursting electrical activity.

222.11 Ca CHANNELS INDUCED IN *XENOPUS* OOCYTES BY RAT BRAIN mRNA:SIZE FRACTIONATION AND PHYSIOLOGICAL STUDIES. J.P. Leonard, T.P. Snutch*, N. Davidson* and H.A. Lester. Divisions of Biology and Chemistry, Caltech, Pasadena CA 91125.

We have continued to study Ca channels induced by injection of rat brain mRNA into Xenopus oocytes and have begun to characterize the mRNA species responsible by size fractionation. RNA was isolated from fresh brains of 15-17 day old rats by a lithium chloride-urea procedure. Oocytes were injected with 70 ng samples of poly A mRNA and membrane currents were recorded under standard 2-microelectrode voltage clamp after allowing 2-7 days for expression. Ba currents through Ca channels exhibited the following properties: relatively slow partial inactivation (τ=650 ms), peak current activation at +15 mV, insensitivity to dihydropyridines, insensitivity to ω-CgTX, 50% inhibition at <10 uM cadmium, insensitivity to forskolin, and enhancement by phorbol esters. Many of these properties are shared by Ca channels involved in neurotransmitter release. Preliminary recordings from excised outside-out patches revealed a single channel conductance of 10-20 pS in 70 mM $BaCl_2$. Reconstruction of macroscopic currents from single channel records shows a current with little inactivation during a 60 ms pulse at +20 or +40 mV.

Size fractionation on a 6-20% sucrose density gradient has provided the initial characterization of the mRNA species encoding the induced Ca channels. Surprisingly, Ca channel activity is found in two peaks: (8.5-10 kb) and (4-7 kb) MW fractions. The I_{Ba} from high MW fractions shares many features with currents from unfractionated mRNA including relatively slow inactivation, peak at +15 mV, high sensitivity to cadmium, and insensitivity to nifedipine. Further physiological characterization of I_{Ba} induced by low and high MW mRNA is underway.

222.12 INDUCTION OF Na CHANNELS AND Na CHANNEL mRNA BY NGF IN PC12 CELLS. B. Kirschenbaum*, T. Snutch*, H. Lester, L. A. Greene, N. Davidson* & B. Rudy (SPON: B.M.Curtis). New York Univ. Med. Ctr., N.Y. N.Y. 10016 and Divs. of Biology and Chemistry, Caltech, Pasadena, CA, 91125.

The PC12 clone is a line of rat pheochromocytoma cells that undergoes neuronal differentiation in the presence of nerve growth factor (NGF). In an effort to elucidate the mechanism by which NGF stimulates these cells to develop neuronal characteristics we have concentrated on the induction of Na action potentials. While PC12 cells grown in the absence of NGF are electrically inexcitable, exposure to NGF for periods of one week or greater results in the appearance of Na action potentials. Previously, we have demonstrated that NGF treatment brings about an increase in Na channel density that is sufficient in magnitude to account for the observed induction of electrical excitability. The mechanism by which NGF brings about this increase remain unknown. Utilizing a cDNA clone for the alpha subunit of the rat brain Na channel to probe PC12 mRNA, we now find an approximately 6 fold induction of Na channel mRNA in NGF stimulated cells. These results indicate that the NGF stimulated appearance of Na channels is a result of either an increased stability of Na channel mRNA or to an enhanced transcription of Na channel gene(s). We find that the observed enhancement of both, Na channel specific Na fluxes and Na channel mRNA levels in NGF stimulated cells occurs rapidly; within hours of NGF application. The discrepancy between the time course of Na channel increase and action potential development suggests that additional factors (e.g. a decrease in K channels), may intervene in the regulation of NGF-induced PC12 excitability. PC12 Na channel mRNA differs slightly in molecular length from that found in rat brain, therefore the possibility exists that the Na channels in PC12 cells are different. This may explain why antibodies against rat brain Na channel do not cross react with PC12 or other peripheral nervous tissue Na channels. CHARACTERIZATION OF CHOLINERGIC RECEPTORS II

223.1 PHENOTYPIC INSTABILITY OF PC12 CELL CULTURES AND APPROACHES TOWARD THE IDENTIFICATION OF NICOTINIC ACETYLCHOLINE RECEPTORS. R. J. Lukas. Division of Neurobiology, Barrow Neurological Institute, 350 West Thomas Road, Phoenix, AZ 85013.

The PC12 rat pheochromocytoma clonal line is a useful model system for the study of sympathetic neuronal differentiation, for the investigation of the mechanism(s) of action of nerve growth factor, and for the study of ganglionic-type nicotinic acetylcholine receptors (nAChR). In this laboratory, where clonal cell lines are routinely maintained in Dulbecco's modified Eagle's medium supplemented with 10% horse serum and 5% fetal bovine serum, PC12 cultures originally obtained from a variety of sources become increasingly adherent and undergo progressive changes in morphological appearance (the ratio of rounded, phase-bright cells to flattened cells decreases) with increasing cell passage.

Four lines of study have been initiated toward elucidation of the relationship(s) between functional nicotinic acetylcholine receptors (nAChR), high-affinity binding sites for ^{3}H-acetylcholine (T-ACh), and ^{125}I-labeled alpha-bungarotoxin (I-Bgt) binding sites on PC12 cells. (1) The expression of functional nAChR (measured by the use of isotopic efflux assays once the cells have achieved a threshold level of adherence to poly-L-lysine-coated substrata), high-affinity binding sites for T-ACh, and I-Bgt binding sites all decrease in parallel with increasing cell passage. (2) The ratio of I-Bgt binding sites to high-affinity T-ACh binding sites on PC12 cells is about 30 regardless of cell passage. (3) Those anti-nAChR antisera that block nAChR function on PC12 cells also block I-Bgt binding to PC12 cell sites with approximately equal efficacy. (4) None of over 100 polypeptide fractions (including kappa-bungarotoxin) purified from the venoms of a variety of snakes (krait, cobra, mamba, seasnake) blocks nAChR function on PC12 cells with an IC_{50} of 1 uM or less.

The data obtained to date are consistent with a variety of interpretations, including (i) that high passage PC12 cell cultures remain monoclonal, but undergo a global loss of neuronal phenotypic markers, (ii) that PC12 cultures of high passage become progressively dominated by non-neuronal PC12 cell mutants, (iii) that functional nAChR and toxin binding sites are distinct elements whose expression is nevertheless co-regulated, and (iv) that PC12 cells express only one class of functional nAChR, which binds neurotoxins in a functionally-impotent configuration and displays low capacity for high-affinity agonist binding. Studies on nerve growth factor effects on high and low passage PC12 cell cultures, attempts to subclone PC12 cell mutants, and nAChR affinity purification protocols are being used to challenge these provisional interpretations.

223.2 **CHARACTERIZATION OF NICOTINIC RECEPTORS IN CHICK RETINA.** R.H. Loring[1], E. Aizenman[2], S.A. Lipton[2] and R.E. Zigmond[1]. Depts. of Pharmacology[1] and Neurology[2], Harvard Med. School and Div. of Neuroscience[2], Children's Hospital, Boston MA 02115.

Toxin F (TXF), but not alpha-bungarotoxin (BGT), from Bungarus multicintus venom blocks nicotinic electrical responses in chick ciliary ganglia (CG; Neurosci. 11:989,1984), cultured neurons from rat superior cervical ganglia (Neurosci., in press) and isolated ganglion cells from rat retina (Aizenman et al., S. Neurosci. Abst., 1987). We also find that TXF (750 nM), but not BGT (10 uM), antagonizes hexamethonium-sensitive depolarizations induced by carbachol in intact chick retina. Since these data suggest that TXF blocks nicotinic receptors in chick retina, we examined the binding of ^{125}I-TXF to this tissue. ^{125}I-TXF binds to two sites in homogenates of retinas from young chicks: one site which is shared with BGT (B_{max}=270 fmol/retina, k_d=5nM) and another site which is not (B_{max}=80 fmol/retina, k_d=3nM). The electrophysiological data suggest that the specific TXF site, and not the site shared with BGT, represents neuronal nicotinic receptors. ^{125}I-TXF dissociates slowly from the TXF specific site with a $T_{1/2}$ of >5h. Nicotinic agonists such as nicotine (k_i=4X10^{-7}M), cytisine (5X10^{-7}M), dimethylphenylpiperazinium (6X10^{-7}M), and carbachol (2X10^{-5}M) inhibit binding to the TXF specific site. Antagonists such as dihydro-B-erythroidine (k_i=1X10^{-6}M) and d-tubocurarine (1X10^{-5}M) but not mecamylamine, hexamethonium or pempidine also inhibit the binding. This pharmacological profile is similar to that reported by others for high affinity nicotine binding in brain. We find by light microscopic autoradiography that ^{125}I-TXF binding localizes to the inner plexiform layer of the chick retina. Preliminary data suggest that Triton-solubilized TXF binding sites are not immunoprecipitated by a monoclonal antibody (Mab 35) that has been shown to recognize putative nicotinic receptors from chick CG (Smith et al., J. Neurosci. 5:2726,1985) and brain (Whiting and Lindstrom, J. Neurosci. 6:3061,1986). If the TXF specific site indeed represents neuronal nicotinic receptors in chick retina, these data suggest that the retinal receptors are immunologically distinct from other putative nicotinic receptors in the chick nervous system. NS22472, NS12651, EY05477.

223.3 THE BINDING OF ANTI-ACETYLCHOLINE RECEPTOR ANTIBODIES TO SYNAPTIC SITES AT INTERNEURONAL SYNAPSES IN THE FROG CARDIAC GANGLION. P. B. Sargent[1] and J. M. Lindstrom[2]. [1]Division of Biomedical Sciences, University of California, Riverside, CA 92521, and [2]Receptor Biology Laboratory, The Salk Institute for Biological Studies, San Diego, CA 92138.

Nicotinic acetylcholine receptors (AChRs) on neurons are poorly characterized in comparison to their muscle and electric organ counterparts. For example, relatively little work has been done to map quantitatively the distribution of neuronal AChRs on the cell surface or to study how receptor distribution might change in response to denervation and reinnervation. We have therefore sought to identify antibodies made against electric organ AChRs which cross-react with receptors on the neuronal surface. Such antibodies would presumably be useful as specific ligands for neuronal AChRs.

Forty-nine rat monoclonal antibodies (mAbs) made against electric organ AChRs were tested for their ability to bind to synaptic sites at interneuronal synapses in the parasympathetic cardiac ganglion of *Rana pipiens*. All the mAbs tested were found previously to cross-react with AChRs in *Rana pipiens* skeletal muscle [Sargent *et al.*, J. Cell Biol. **98**(1984)609-618]. These mAbs included those specific for each of the four electric organ subunits ($\alpha,\beta,\gamma,\delta$) as well as a number of mAbs specific for the main immunogenic region, a highly conserved and highly immunogenic region of overlapping epitopes on the extracellular surface of the α subunit.

Antibodies were tested in protease-treated ganglia (to promote access of reagents to the synaptic cleft) using a double-label fluorescence technique. Rat mAb binding was visualized using a fluorescein-conjugated rabbit anti-rat IgG, and the position of synaptic boutons in the same tissue was revealed by using a mouse anti-synaptic vesicle antibody (kindly provided by Dr. Louis Reichardt) followed by a rhodamine-conjugated horse anti-mouse IgG. Several of the mAbs tested bound to circumscribed regions of the cell surface which co-localized with synaptic boutons. Electron microscopic analysis of antibody binding using immunoperoxidase or immunogold procedures revealed that detectable binding is restricted to that part of the postsynaptic membrane lying beneath the active zone, as found at other autonomic synapses by Marshall [Proc. Natl. Acad. Sci. **78**(1981)1948-1952] and Jacob *et al.* [Proc. Natl. Acad. Sci. USA **81**(1984)3223-3227].

Only 8 of the 49 mAbs which cross-reacted with AChRs in *Rana* skeletal muscle produced detectable binding in the cardiac ganglion. All 8 cross-reacting mAbs were specific for the main immunogenic region (MIR). The likelihood that the cross-reacting mAbs are indeed binding to neuronal AChRs in the cardiac ganglion is increased by the recent finding that mAbs with a similar anti-MIR specificity have been shown to bind to neuronal AChRs in the chick ciliary ganglion [Halvorsen and Berg, J. Neurosci., in press]. These mAbs are presently being used to study the distribution of AChRs on the neuronal surface in normal and denervated cardiac ganglia.

Supported by NIH Grant NS 24207.

223.4 **EXPRESSION OF NEURONAL ACETYLCHOLINE RECEPTOR mRNA IN CHICK CILIARY GANGLIA.** R.T. Boyd[1,*], M.H. Jacob[1], M. Ballivet[2,*], J. Patrick[3], and D.K. Berg[1]. [1]Dept. of Biology, UCSD, La Jolla, CA 92093, [2]Dept. Biochem, Univ. Geneva, Geneva, Switzerland, and [3]The Salk Institute, San Diego, CA 92138,

Previous work has identified 4 distinct genes that encode homologous α-subunits for nicotinic acetylcholine receptors (AChRs) both in chick and in rat. One of these, alpha1, represents the α-subunit of the muscle AChR. The others (alpha2-4) represent AChR α-subunits expressed in parts of the nervous system. Reconstitution experiments in the *Xenopus* oocyte expression system confirm that the rat alpha2-4 genes code for functional α-subunits. We have used the equivalent chick probes to identify homologous mRNAs in chick ciliary ganglion. The ganglion presents a relatively homogeneous population of primary neurons accessible for developmental and regulatory studies of AChR gene expression.

A probe for the alpha3 gene transcript was constructed by subcloning an 800 bp region from an alpha3 genomic clone (300 bp corresponding to amino acids 96-196 of the muscle gene and 500 bp of intron) into the vector pSP65 having an SP6 promoter. Labeled alpha3 RNA probe was then synthesized and used to identify homologous message in embryonic ciliary ganglia. *In situ* hybridization under high stringency conditions revealed homologous message in ciliary ganglion sections when examined with labeled alpha3 probe. The signal was specific since no hybridizing material was apparent when a sense strand probe was used, or when liver or spinal cord sections were examined. The alpha3 probe detected homologous message in ciliary ganglia from 8- and 18-day chick embryos as well as ganglia from adult chickens. The alpha2 and alpha4 probes failed to detect homologous message in ciliary ganglion sections by *in situ* hybridization.

Northern blots of total RNA extracted from 18-day embryonic chick ciliary ganglia also revealed homologous message when hybridized with alpha3 probe at high stringency. A major component of 3.5 kb and a minor component of 2 kb were observed. A component of 3.5 kb was also observed when Northern blots of chick brain poly(A^+) RNA were hybridized with alpha3 probe. The components represented specific hybridization since no bands were obtained with sense strand probe, and since the brain component was much enriched in poly(A^+) vs. total RNA. Again, alpha2 and alpha4 probes failed to reveal homologous components in Northern blots of ciliary ganglion RNA, though they did detect hybridizing message in Northern blots of chick brain poly(A^+) RNA.

Ganglionic levels of AChRs are likely to be regulated by cell-cell interactions: previous work has shown that postganglionic axotomy of ciliary ganglia in newly-hatched chicks causes a 10-fold decline specifically in AChR levels within 5 days. We find that postganglionic axotomy results in a visible diminution of hybridizing signal when ciliary ganglion sections are examined with alpha3 probe by *in situ* hybridization.

These findings indicate that a homologous message likely to represent an AChR subunit can be detected in chick ciliary ganglia and that of the 3 known "neuronal" alpha genes only alpha3 appears to be expressed in the ganglion. The abundance of alpha3 message is sufficient to permit *in vivo* regulatory studies using *in situ* hybridization and Northern analysis. Moreover, the postganglionic axotomy studies suggest that receptor message levels may be regulated by cell-cell interactions. (Supported by NIH grant NS12601, the Muscular Dystrophy Assoc., and the American Heart Assoc.)

223.5 **A DESENSITIZED FORM OF NEURONAL ACETYLCHOLINE RECEPTOR DETECTED BY ^{3}H-NICOTINE BINDING ON BOVINE ADRENAL CHROMAFFIN CELLS.** L.S. Higgins, and D.K. Berg. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

Nicotinic acetylcholine receptors (AChRs) trigger catecholamine release from bovine adrenal chromaffin cells when activated by synaptic input from the splanchnic nerve. Here we report that agonists can induce a high affinity, desensitized form of the AChR on bovine adrenal chromaffin cells that can be detected by ^{3}H-nicotine binding. The receptors have 1:1 stoichiometry for binding ^{3}H-nicotine and ^{125}I-mAb 35, a monoclonal antibody previously shown to recognize the receptor. Chronic treatment of the cells with mAb 35 results in receptor modulation such that all of the high affinity ^{3}H-nicotine binding and all of the functional response to nicotine are lost from the cells.

For these experiments bovine adrenal chromaffin cells were isolated by enzymatic digestion of adrenal tissue and purification on Percoll gradients. ^{3}H-Nicotine binding was examined both with intact cells and with membrane fragments prepared from the cells after 3-9 days in culture. For membrane fragments, rapid filtration over glass fiber filters was used to separate bound and free ligand. Two classes of high affinity ^{3}H-nicotine binding sites were detected. The first class represented the α-bungarotoxin (α-Bgt) binding component in the membrane which previous studies have shown to be distinct from the functional AChR on the cells. The second class of sites had the properties expected for a desensitized, high affinity form of the functional AChR.

Scatchard analysis of the binding (in the presence of 1 μM α-Bgt to block binding to the first class of sites) revealed a single class of high affinity ^{3}H-nicotine binding sites with a K_D of 20 ± 2 nM and B_{max} of 17.3 ± 1.9 fmoles per culture of about $4x10^5$ cells (n=4). Cholinergic antagonists (d-tubocurarine, hexamethonium, decamethonium, mecamylamine, trimethaphan, and the α-neurotoxin Bgt 3.1) blocked the ^{3}H-nicotine binding with the same approximate K_i that they inhibited nicotine-induced catecholamine release from the cells. Agonists (ACh, carbachol, and nicotine), however, inhibited binding with affinities about 2 orders of magnitude greater than the affinities with which they triggered receptor activation. The discrepancy with agonists can be accounted for by an agonist-induced conversion of the AChR to a form having increased affinity for agonist but no change in affinity for antagonists. Thus, preincubation with nicotine in the presence of Substance P desensitizes the receptor (reduces nicotine-induced catecholamine release), and does so with an apparent K_D of 18 ± 5 nM. Preincubation with nM nicotine accelerates the rate of ^{3}H-nicotine binding, and kinetic analysis of this fast association rate together with the dissociation rate yields a K_D of ~20 nM. This value is in good agreement with the equilibrium binding data. Substance P increases the rate but not extent of agonist-induced AChR desensitization and it increases the rate of ^{3}H-nicotine binding. The results indicate that formation of the high affinity, desensitized AChR is rate-limiting in detecting ^{3}H-nicotine binding.

Comparing ^{3}H-nicotine binding to intact cells with that of membrane fragments indicates that about 80% of the sites are on the cell surface. Binding studies with ^{125}I-mAb 35 reveals the same distribution of surface and internal sites, and yields a constant ratio of 1:1 for nicotine and mAb 35 binding sites. Chronic treatment of cultures with mAb 35 results in a specific and complete loss of receptor function as well as loss of ^{3}H-nicotine binding sites from the cell surface, corroborating the ^{3}H-nicotine binding sites as being associated with AChRs. The results indicate that adrenal chromaffin AChRs are similar to muscle AChRs in undergoing an agonist-induced conversion to a desensitized form having increased agonist affinity and unaltered antagonist affinity. (Supported by NS12601, MDA, & AHA.)

223.6 KAPPA-BUNGAROTOXIN BLOCKS NICOTINIC ACETYLCHOLINE RECEPTORS IN BOVINE CHROMAFFIN CELLS AND INSECT CENTRAL NEURONS IN A VOLTAGE-INDEPENDENT MANNER. V.A. Chiappinelli, J.J. Lambert*, J.M. Nooney*, R.D. Pinnock* and D.B. Sattelle*. Dept. Pharmacol., St. Louis Univ. Sch. Med., St. Louis, MO 63104; Dept. Pharmacol. and Clin. Pharmacol., Univ. of Dundee, Dundee DD1 9SY, Great Britain; AFRC Unit, Dept. Zool., Univ. of Cambridge, Cambridge CB2 3EJ, Great Britain.

Kappa-Bungarotoxin (KBgT) and Kappa-Flavitoxin are structurally-related polypeptide neurotoxins isolated from crude venom of the snakes Bungarus multicinctus and B. flaviceps (Chiappinelli, V.A., et al., Brain Res. 402:21, 1987). These Kappa-Neurotoxins bind with high affinity to neuronal nicotinic acetylcholine (ACh) receptors and block nicotinic transmission in avian and murine autonomic ganglia (reviewed in Chiappinelli, V.A., Pharmacol. Therap. 31:1, 1985). Using voltage-clamp techniques, we have now examined the effects of KBgT on bovine chromaffin cells and cockroach neurons.

Bovine chromaffin cells. Whole-cell recordings were made on bovine chromaffin cells maintained in culture for 1-7 days as described (Cottrell, G.A., et al., Brit. J. Pharmac. 90:491, 1987). Local application of ACh (100 µM by pressure ejection) evoked an inward current of 371±20 pA (n=59) on cells voltage-clamped at -60 mV. Application of KBgT produced a dose-dependent blockade of the ACh-induced current. At 600 nM KBgT, the ACh response was 11±4% of control after 10 min of toxin exposure and 7±2% of control after 40 min (n=6). Following prolonged exposure to KBgT, extensive washing (>1 hr) failed to elicit any recovery of the ACh-induced current. The percentage-blockade produced by KBgT was independent of membrane potential over the range of voltages examined (-100 to -20 mV). Perfusion of cells with the competitive antagonist trimethaphan (Durant, N.N., Brit. J. Pharmac. 86:609P, 1985) at 10-30 µM protected against subsequent exposure to 600 nM KBgT.

Cockroach neurons. The cell bodies of the fast coxal depressor motorneurons (D_f) contain nicotinic ACh receptors (David, J.A. and Sattelle, D.B., J. Exp. Biol. 108:119, 1984). KBgT blocked ACh-induced inward currents in voltage-clamped D_f neurons in a dose-dependent manner (IC_{50}=100 nM KBgT). The blockade produced by KBgT was voltage-independent over the range examined (-100 to -30 mV). The pharmacology of cockroach receptors was similar to that of vertebrate autonomic nicotinic receptors. The one striking exception was alpha-bungarotoxin, which was the most potent antagonist at cockroach receptors but failed to recognize functional nicotinic receptors in avian, murine or bovine neurons at 10 µM.

Conclusions. Since Kappa-Neurotoxins bind only weakly to muscle nicotinic receptors, the results provide evidence that the neuronal-type of nicotinic receptor diverged from muscle nicotinic receptors at a very early evolutionary stage. The neuronal nicotinic receptors of species as diverse as cow and cockroach share many pharmacological features. (NIH Grants NS17574 and TW01254 to V.A.C.)

223.7 **Development of ACH and GABA Responses in Embryonic Chick Ciliary Ganglion Neurons.** Engisch,K.*, Yang,J., and Fischbach,G.D., Dept Anat. & Neurobiol., Wash.Univ.Sch.Med., St.Louis, MO, 63110.

Neurons in the chick ciliary ganglion receive cholinergic innervation from cells in the accessory oculomotor nucleus of the midbrain. Preganglionic fibers first arrive in the ganglion between embryonic day 4 and 5 (E4-E5); all ganglionic neurons are innervated by E8. Little is known about the expression of ACH receptors on the target neurons during this period of synapse formation. We have begun to investigate this issue by examining ACH currents in voltage-clamped neurons a few hours after dissociation from E6 to E18 ganglia. We assume that the ACH responses of freshly dissociated neurons are no different from those in vivo. We compared the ACH responses to GABA-induced currents and voltage-gated K+ currents over the same time course.

Neurons were held at -50 mv and ACH or GABA (100 um) was applied via pressure ejection through a micropipette positioned close to the cell soma. We found a dramatic age-dependent increase in ACH responses of neurons isolated between E6 and E10 (E6=94+/-11 pA, E10=500+/-40 pA, n=15), coincident with the establishment of functional transmission in the ganglion. There was a small decrease in ACH responses after E10 followed by a second, 2-fold increase from E14 to E18. GABA responses increased between E6 and E10 but in contrast to ACH responses, continued to increase, reaching a maximum at E12. This was followed by a rapid decline in responses between E12 and E18. Voltage gated K+ currents, on the other hand, showed a gradual but continuous increase during this developmental period.

Innervation plays a major role in regulating ACH receptors on muscle. Our results suggest that innervation may similarly influence the regulation of neuronal ACH receptors. Although the ciliary ganglion receives no known GABAergic innervation, it is interesting that GABA responses roughly follow the early developmental pattern of ACH responses. However, the lack of specific GABAergic input may account for the decrease in GABA responses after E12 and the subsequent divergence from the developmental pattern of ACH responses.

223.8 DIFFERENTIATED CHICK MYOBLASTS THAT EXPRESS ACETYLCHOLINE RECEPTORS CAN PROLIFERATE IN VITRO. M.Morgan* and G.D.Fischbach. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO. 63110

The majority of the mononucleated muscle cells isolated from embryonic day 11 (E11) chick pectoral muscle bind rhodamine-conjugated alpha-bungarotoxin (Rh-BTX) immediately after mechanical dissociation (Morgan and Fischbach 1986 NS Abstract). After 24 hours in vitro, only 45% of the myogenic cells exhibit Rh-BTX binding sites. It is possible that this decline is due to the selective proliferation of undifferentiated cells that do not express acetylcholine receptors (AChRs). However, we have found that those cells expressing AChRs are capable of proliferation in vitro.

Three different experimental approaches were used. First, dissociated mononucleated cells from E11 chick pectoral muscles were plated at clonal densities, and surface AChRs were labelled with Rh-BTX. Individual cells were identified, their location noted, and the presence or absence of AChRs recorded. The cultures were then returned to an incubator (37°, 5% CO_2, 100% humidity) for 24 hours, at which time the identified cells were located again. A total of 136 cells from 50 cultures were unambiguously identified and followed over time in culture. Ninety-one cells divided (67%), and of these, 37 expressed surface AChRs before cell division (41%). Sixteen cells with AChRs did not divide during 48 hours in vitro. These data demonstrate that differentiated cells (those expressing muscle-specific proteins) are capable of dividing in vitro. In a second set of studies, colchicine was added to the cultures in order to accumulate cells in mitosis. The observation of Rh-BTX-labelled cells in colchicine-induced metaphase arrest further demonstrated AChR expression in proliferating cells. Third, cultured muscle cells were exposed to bromodeoxyuridine (BUdR; a thymidine analog) and ^{125}Iodine-BTX. The BUdR was visualized with an anti-BUdR antibody and a fluorescein-conjugated secondary antibody. Because only proliferating cells will incorporate BUdR into their DNA, the double-labelled cells which were observed indicate that AChR-expressing, dividing myoblasts exist in dissociated cell culture.

When nerves first enter the developing chick limb bud (E4), the muscle mass is composed of proliferating, mononucleated muscle cells. The simultaneous presence of neurally-released ACh and of AChRs on proliferating myoblasts could provide an opportunity for neural influence on muscle development via these receptors. In vivo studies are underway to determine whether proliferating presumptive muscle cells express AChRs in the intact animal, and at what developmental stage this becomes evident.

This work was supported by an NSF Predoctoral Fellowship.

223.9 ACETYLCHOLINE RECEPTOR CLUSTERS ARE NOT INVARIABLY ASSOCIATED WITH 43K PROTEIN AT EARLY STAGES Of CHICK MUSCLE DEVELOPMENT. H-C. T. Tsui, C. Carr*, J.B. Cohen, & G.D. Fischbach. Dept. Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Antibodies raised against a 43,000 dalton acetylcholine receptor-associated protein purified from Torpedo electrocytes cross react with determinants at vertebrate endplates. It has been suggested that this protein, which is located on the cytoplasmic surface of the membrane, may be responsible for the formation of acetylcholine receptor (AChR) clusters. We have used cross-reacting antibodies to examine the appearance of 43K immunoreactivity in developing chick myotubes. Cultures were prepared from E11 chick pectoral muscle, labeled with rhodamine-alpha-bungarotoxin (Rd-BTX), permeabilized with 95 % ethanol at -20 degree C, and then labeled with a monoclonal antibody to 43 K followed with a FITC-secondary antibody. Fluorescence images captured with a SIT camera were digitized and analysed with a Trapix image processor-micro-Vax system. Rhodamine and fluorescein images were aligned and the intensities of the fluorochromes were compared and ploted on a pixel by pixel basis.

In mature myotubes, 4 to 6 days in vitro, 43 K was present at all AChR clusters. The correlation coefficient between rhodamine and fluorescein within individual clusters ranged between .73 to .96.(>2000 pixel per cluster) Some mononucleated cells (myoblast) examined immediately after dissociation from E11 muscles exhibited AChR clusters as intense as those of myotubes. However, 32 % (n=59) of these intense myoblast clusters were not associated with 43K. The intensity of 43K fluorescence at those myoblast clusters that did exhibit co-localization was clearly less than that at mature myotube clusters. The mean slope of rhodamine vs. fluorescein linear regression line was only 17 % of the mean slope measured at myotube clusters. It is unlikely that the low level of 43K is due to inadequate membrane permeabilization. Moreover, the same paucity of 43 K fluorescene were observed at some receptor clusters identified in frozen sections of E11 pectoral muscle. Our results suggest that 43K is not essential for receptor cluster formation during early stages of muscle development.

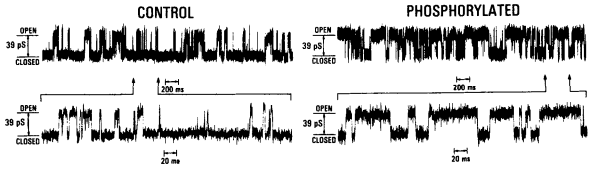
223.10 DETERMINATION OF THE SITES OF cAMP-DEPENDENT PHOSPHORYLATION ON THE γ AND δ SUBUNITS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR. Richard L. Huganir, Elizabeth Moritz* and Gene H. Yee*. The Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, 1230 York Avenue, New York, NY 10021.

The nicotinic acetylcholine receptor is a neurotransmitter-regulated ion channel that mediates the depolarization of the postsynaptic membrane at the neuromuscular junction. The receptor is an integral membrane protein which consists of four subunits in a stoichiometry of $\alpha_2\beta\gamma\delta$. The nicotinic acetylcholine receptor has been shown to be multiply phosphorylated by at least three different protein kinases. cAMP-dependent protein kinase phosphorylates the γ and δ subunits of the receptor, protein kinase C phosphorylates the δ and α subunits, while a tyrosine-specific protein kinase phosphorylates the receptor on the β,γ, and δ subunits.

Recently, it has been demonstrated that phosphorylation of the nicotinic receptor by cAMP-dependent protein kinase increases its rate of rapid desensitization. We now report the identification of the cAMP-dependent phosphorylation sites on the γ and δ subunits. Two-dimensional phosphopeptide mapping of the phosphorylated γ and δ subunits, after limit proteolysis with thermolysin, indicated that each subunit is phosphorylated on a single site. Phosphoamino acid analysis of the ^{32}P-labeled subunits demonstrates that phosphorylation had occurred exclusively on serine residues. Purified phosphorylated subunits were cleaved with cyanogen bromide and the resultant phosphopeptides were purified by reverse-phase high performance liquid chromatography. Shorter phosphopeptides, obtained by secondary digestion with trypsin, were purified and subjected to both automated gas-phase sequencing and manual Edman degradation. The results demonstrate that the γ subunit was phosphorylated at Ser-353, contained within the sequence Arg-Arg-Ser(P)-Ser-Phe-Ile and that the δ subunit was phosphorylated at Ser-361, contained within the sequence Arg-Ser-Ser(P)-Ser-Val-Gly-Tyr-Ile-Ser-Lys. Determination of the sites phosphorylated within the structure of the γ and δ subunits should contribute to the molecular characterization of the regulation of desensitization of the nicotinic acetylcholine receptor by protein phosphorylation.

223.11 PHOSPHORYLATION OF THE NICOTINIC CHOLINERGIC RECEPTOR INCREASES THE PROBABILITY OF CHANNEL OPENING. M.S. Montal*† and M. Montal* (SPON: R. Anholt). Department of Neurosciences, Roche Institute of Molecular Biology, Roche Research Center, Nutley, New Jersey 07110 and †Departments of Biology and Physics, University of California, San Diego, La Jolla, California 92093

To establish the functional modification produced by phosphorylation of the nicotinic acetylcholine receptor (AChR) single channel currents activated by acetylcholine (ACh) from purified *Torpedo californica* ACh receptors reconstituted in lipid bilayers were recorded. Phosphorylation by the purified catalytic subunit of the cyclic AMP dependent protein kinase incorporates phosphate primarily into the ACh receptor γ and δ subunits (Huganir, R.L. and Greengard, P. *Proc. Natl. Acad. Sci. USA*, 80:1130, 1983). Inspection of single channel records show that receptor phosphorylation increases the channel opening probability without affecting the single channel conductance (see Figure top panel). Detailed analysis of the single channel currents indicates that the increment in the opening frequency arises primarily from a shortening of the characteristic long quiescent periods (channel closed times) that separate the bursts of channel openings (note details in expanded records displayed in corresponding lower panels). The results are consistent with the view that ACh receptor phosphorylation modifies the kinetics of its ability to enter into(Huganir, R.L. *et al. Nature*, 321:774, 1986) and exit from the desensitized state. Thus, it is plausible that such covalent modification of a postsynaptic receptor may exert a regulatory role in synaptic plasticity.



Legend: Single AChR channel currents activated by 1 μM ACh and recorded at V = 85 mV (Control) and V = 95 mV (phosphorylated), respectively. The single channel conductances were 40 pS and 41 pS, respectively (in 0.5 M NaCl, 0.5 mM $CaCl_2$, 5 mM tricine, pH 7.4). Lipid bilayers were assembled from AChR vesicles derived monolayers and formed at the tip of patch pipets (*Biochemistry* 22:2319, 1983).

223.12 "DELTALESS" ACETYLCHOLINE RECEPTORS ARE HIGHLY VOLTAGE-DEPENDENT. Michael M. White, Dept. of Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104.

The nicotinic acetylcholine receptor is a multisubunit protein of stoichiometry $\alpha_2\beta\gamma\delta$. The availability of cDNAs for the various subunits makes it possible to apply techniques such as site-directed mutagenesis to the study of the structural features that underlie AChR function. We have chosen to focus our initial efforts some on not-so-subtle (but easily done) "mutations":deletion of whole subunits. Using our in vitro transcription-Xenopus oocyte translation system, we have examined the effects of deletion of various Torpedo subunits. Deletion of the α, β, or γ subunit prevents the appearance of functional AChRs on the oocyte surface. In contrast, when the δ subunit is deleted, one can still record ACh-activated, curare-sensitive currents. Macroscopic currents recorded at -60 mV from oocytes with δ^- receptors are, on the average, ≈10% of those recorded from eggs with "wild-type" receptors. However, when one uses αBTX to "count" the number of receptors on the cell surface, δ^- oocytes have ≈50% of the number of receptors found on the wt oocytes, an indication that the smaller currents are not entirely due to decreased synthesis, but also reflects some difference in intrinsic properties. Both types of receptors have identical affinities for d-tubocurarine(≈50 nM), which rules out a difference in fractional activation by ACh. The I-V relationship of wt AChRs is essentially linear between -160 mV and +50 mV. However, δ^- receptors show a highly non-linear I-V relationship with large inward currents at very negative voltages, and very small outward currents at positive potentials. The current ratio (δ^-/wt) is ≈0.5 at -160 mV (consistent with the toxin-binding data), ≈0.1 at -60 mV, and ≈0 at +50 mV. Current efforts are focussed on high-resolution single-channel recording to determine the microscopic basis of the voltage dependence of the macroscopic currents, and determination of the subunit stoichiometry of δ^- receptors. 223.13 SITE-DIRECTED MUTAGENESIS OF TORPEDO CALIFORNICA ACETYLCHOLINE RECEPTOR. L. PRADIER*, A. S. YEE* and M. G. McNAMEE. Dept. of Biochemistry and Biophysics, University of California, Davis CA 95616.

Purified nicotinic acetylcholine receptor (nAChR) from Torpedo californica was derivitized with N-phenylmaleimide under non-reducing conditions in the presence of cholate detergent (Yee et al., Biochemistry, 25:2110, 1986) and reconstituted into lipid vesicles using dialysis to remove the cholate. The derivitized protein exhibited normal alpha-bungarotoxin binding. In addition, activating ligands such as carbamylcholine underwent the low to high affinity binding transition characteristic of functional receptor. However, inhibition of ion-flux activity, as measured by the carbamylcholine-stimulated influx of rubidium ions into the vesicles, was well-correlated with the level of maleimide labeling. Using tritiated N-phenylmaleimide, the gamma-subunit of the nAChR was shown to be preferentially labelled. Further localization of the label by peptide mapping showed that the label was located primarily on one cyanogen bromide fragment.

In parallel experiments, an expression system using in vitro transcription of the cDNAs coding for the four subunits of T. californica and injection of the transcripts into Xenopus laevis oocytes (Mishina, M. et al., Nature, 313:364, 1985) was set up. The coding sequences for the four subunits were cloned downstrean to the SP6 promoter in the vectors pSP64, pSP65 and pX m (Krieg, P. and Melton, D. A., Nucl. Acid Res., 12:7057, 1984). Preliminary experiments have shown that certain sequences upstream to the initial AUG inhibit in vitro translation and new constructs have been made to increase translation levels. Using site-directed mutagenesis, the cysteine amino acid residues tentatively identified as the N-phenylmaleimide-labeled groups have been altered. The functional properties of these mutants are being assayed in Xenopus oocytes using voltage-clamp methods. (Supported by NIH Grants NS22941 and NS13050).

224.1 SHAKING BEHAVIOR IN THE RAT: INTERACTIONS BETWEEN BENZODIAZEPINE AND SEROTONIN 5-HT-1A AGONISTS. M.R. Pranzatelli. Depart. Neurol., Div. Pediatric Neurology, College of Physicians and Surgeons of Columbia University, New York, NY 10032.

Benzodiazepine (BDZ)-induced excitatory phenomena in rodents, such as wet-dog shakes (WDS), have not been explained pharmacologically. In studying the mechanism of action of BDZ-induced WDS, we found that select BDZ agonists evoked dose-related WDS at low doses in the adult rat with the rank order of potency clonazepam > nitrazepam> flunitrazepam> nimetazepam. WDS appeared within 3-5 minutes of injection and lasted approximately 60 minutes. Lorazepam was the only BDZ agonist without a nitrous-group on the A-ring (diazepam, fludiazepam, oxazepam) at doses up to 60 mg/kg to induce WDS. Non-BDZ agonists (CL 218,872), inverse agonists (B-CCE), peripheral type receptor agonists (Ro 5-4864), BDZ antagonists (Ro 15-1788), and vehicle (ethanol/propylene glycol) were ineffective. Representative putative 5-HT-1 and 5-HT-2 agonists (Ru 24969 and 8-OH-DPAT vs DOI) and antagonists (TVXQ7821 vs ritanserin) were tested as blockers but only the 5-HT-1A agonist 8-OH-DPAT significantly reduced WDS in a dose-dependent manner (ID_{50}= 0.86 mg/kg), whereas Ro 15-1788 increased BDZ-evoked WDS 70% at 20 mg/kg, and diazepam had no blocking effect. Intracisternal injections of 5,7-dihydroxytryptamine which significantly depleted 5-HT in multiple brain regions, did not alter frequency, latency or time course of WDS induced by nitrazepam or flunitrazepam. Only BDZ agonists (not CL 218,872) induced ataxia and sedation, which outlasted WDS and were not blocked by serotonergic drugs. These data suggest a difference in pharmacologic mechanism from 5-HT-2-dependent BDZ-evoked head-twitch in mice, and also indicates a pharmacologic dissociation between BDZ-evoked excitatory (WDS) and inhibitory (sedation, ataxia) behavior in the rat. No simple correlation between BDZ-induced WDS and BDZ radioligand binding, anti-pentylenetetrazol activity, or other BDZ property was found. BDZ-evoked WDS may relate to the unique predominance of BDZ II and 5-HT-1A sites in hippocampus, an apparent locus of WDS, but the role of the 5-HT-1A involvement at the level of the receptor remains to be elucidated. BDZ-induced WDS in the rat may be a useful model of BDZ-serotonin interactions.

224.2 BLOCKADE OF THE ELECTROPHYSIOLOGICAL EFFECT OF 5-HT AND 8-OH-DPAT BY BMY 7378, A PUTATIVE 5-HT_{1A} RECEPTOR ANTAGONIST, IN THE RAT CNS. Y. Chaput* and C. de Montigny. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Canada H3C 3J7.

Electrophysiological and radioligand binding studies suggest that the receptors mediating the inhibitory response to 5-HT in the rat hippocampus and in the nucleus raphe dorsalis are of the 5-HT_{1A} subtype. The buspirone analogue BMY 7378 potently displaces the binding of [^{3}H]8-OH-DPAT, a selective 5-HT_{1A} agonist, from rat hippocampal membranes; furthermore, BMY 7378 blocks the effect of 5-HT and 8-OH-DPAT on forskoline-stimulated cAMP formation while being devoid of intrinsic activity (Yocca et al., 1987). This suggests that BMY 7378 might be a 5-HT_{1A} receptor antagonist. The present study was undertaken to investigate the effect of BMY 7378 on the response of CA_3 dorsal hippocampus pyramidal neurons and of dorsal raphe 5-HT neurons to 5-HT and 8-OH-DPAT.

Male Sprague-Dawley rats (240-300 g) were anesthetized with chloral hydrate (400 mg/kg, i.p.). Extracellular unitary recordings were obtained with five-barrelled glass micropipettes. The following solutions were used for microiontophoresis: 5-HT (0.5 or 2 mM in 200 mM NaCl), 8-OH-DPAT (1 mM in 100 mM NaCl), NE (100 mM in 200 mM NaCl), GABA (10 mM in 50 mM NaCl), and BMY 7378 (50 mM in 200 mM NaCl). Acetylcholine (20 mM in 200 mM NaCl) or glutamic acid (100 mM in 50 mM NaCl) were used to maintain the firing activity of the neuron recorded within its physiological range.

A 50% reduction of the suppressant effect of 5-HT on hippocampus pyramidal neuron firing activity was obtained with an average ejection current of 2 nA of BMY 7378, whereas the same degree of blockade of the effect of 8-OH-DPAT was obtained with an average ejection current of 0.5 nA. The effects of neither NE nor GABA were altered by the microiontophoretic applications of BMY 7378 with currents up to 18 nA. The intravenous administration of BMY 7378 readily antagonized the suppressant effect of microiontophoretically-applied 5-HT on these neurons, with an ED_{50} of approximately 250 g/kg, whereas that of NE was unaffected by doses up to 5 mg/kg. Interestingly, BMY 7378, applied with an average current of 3 nA, did not alter the effect of microiontophoretically-applied 5-HT on dorsal raphe 5-HT neurons whereas it reduced by 30% that of 8-OH-DPAT.

The present results provide in vivo evidence that 5-HT_{1A} receptor blockade by BMY 7378 markedly reduces the inhibitory effect of 5-HT and 8-OH-DPAT in the rat hippocampus. The differential effect of BMY 7378 on 5-HT neuron responses to 5-HT and 8-OH-DPAT might suggest that these agonists act at different receptors. However, given the existing evidence that the somatodendritic 5-HT autoreceptor is of the 5-HT_{1A} subtype, it is more likely that both agonists activate the same receptor via distinct recognition sites.

Supported, in part, by Canadian Medical Research Council (MRC) Grant MA-6444. Y.C. is in receipt of a Fellowship from the Fonds de la Recherche en Santé du Québec and C. de M. of an MRC Scientist Award.

224.3 FAILURE OF SUPRAMAXIMAL ELECTRICAL STIMULATION OF THE DRN TO OVERCOME NERVE TERMINAL SEROTONIN AUTORECEPTOR ACTIVATION. K.F. Martin*, and C.A. Marsden (SPON: C.H. Page). Dept. of Physiol. & Pharmacol., Univ of Nottm. Med. Sch., Nottingham NG7 2UH, U.K.

Neuronal release of serotonin (5HT) is under the control of a 5HT nerve terminal autoreceptor which in the rat suprachiasmatic nucleus (SCN) is of the $5HT_{1B}$ sub-type (Marsden, C.A. & Martin, K.F., Br.J.Pharmac., 85:219P, 1985). Infusion of the $5HT_{1A}$ receptor agonist DPAT into the dorsal raphe (DRN) which inhibits 5HT unit activity (Wilkinson, L.O. et al, Eur.J.Pharmac., in press) does not affect extracellular 5-hydroxyindoleacetic acid (5HIAA) levels in the SCN (Marsden, C.A. & Martin, K.F., Br.J.Pharmac., 86:445P, 1985). These data suggested that 5HIAA levels may not reflect 5HT unit activity. We have therefore examined the possibility that 5HT autoreceptor activity may have a greater influence than 5HT neurone firing rate on 5HT release and metabolism.

Male Wistar rats (295-305 g), anaesthetised with chloral hydrate (600 mg/kg i.p.) had carbon fibre electrodes (0=20 µm) stereotaxically implanted in the left SCN. A 30 g stainless steel injection cannula was implanted into the contralateral SCN so that its tip was 100-150 µm from the working electrode. A bipolar SNE 100 stimulating electrode was implanted into the DRN. Differential pulse voltammograms were obtained every 5 min and the height of the oxidation peak at +300 mV (peak 3) taken as an index of extracellular 5HIAA concentration (Crespi, F. et al, Neurosci.Lett., 43:203, 1983).

Electrical stimulation (square pulses, 0.5 msec duration, constant current) of the DRN for 10 min resulted in a current (50-200 µA) and frequency (5-20 Hz) dependent increase in the height of peak 3 recorded in the SCN. The maximum increase (60±14%, n=4) occurred at 200 µA and 20 Hz approx. 20 min post stimulation. Administration of 0.9% saline (1 µl over 1 min) into the SCN 10 min before stimulation did not affect the response (peak 3 height=150±15%, of control 30 min from start of stimulation, n=5). Infusion of RU 24969 (10 µg in 1 µl over 1 min) into the SCN resulted in a rapid, marked decrease in peak 3 height in the SCN (-80±18% 10 min post infusion, n=5, -95±5%, 40 min post infusion, n=5). Infusion of RU 24969 (10 µg) into the SCN prevented the DRN stimulation induced rise in peak 3 height observed previously. (Peak 3 height 20 min post stimulation and 40 min post RU 24969 = 10±5% of control, n=4.)

These data demonstrate that stimulation of the nerve terminal 5HT autoreceptor in the SCN exerts a more powerful influence over 5HT release and metabolism than 5HT neurone firing rate.

These studies were supported by the Wellcome Trust.

224.4 STIMULATION OF BRAIN SEROTONIN_{1A} RECEPTORS BY THE URAPIDIL ANALOGUE, B695-40, LOWERS ARTERIAL BLOOD PRESSURE. R.A. Gillis*, J.A. Quest*, I.J. Namath*, A.M. Martino-Barrows* and K.J. Kellar (SPON: R. McGee). Dept. Pharmacol., Georgetown Univ., Schools of Medicine and Dentistry, Washington, DC 20007.

We previously demonstrated that the new antihypertensive agent, urapidil, lowers arterial blood pressure by central sympathoinhibition and peripheral blockade of alpha_1-adrenoceptors (Gillis et al., J. Cardiovasc. Pharmacol. 9: 103, 1987). To further investigate the mechanism of the central effect of urapidil, the analogue of urapidil, B695-40, was studied on the ventral surface of the medulla of chloralose-anesthetized cats. Topical application of B695-40 (5 ug/side) produced a marked hypotensive response averaging -64 + 9 mm Hg. This response was much greater in magnitude than that previously described for urapidil on the ventral surface of the medulla. The hypotensive response evoked by B695-40 was mimicked by 8-OH-DPAT, a selective agonist for serotonin_{1A} receptors (Middlemiss and Fozard, Eur. J. Pharmacol. 90: 151, 1983). Pretreatment with WB-4101, an antagonist at the serotonin_{1A} receptor (Norman et al., Mol. Pharmacol. 28: 487, 1985) prevented the hypotension produced by both B695-40 and 8-OH-DPAT. These results suggest that both urapidil and the more potent B695-40 analogue lower blood pressure by stimulating serotonin_{1A} receptors at the ventral surface of the medulla. An action of these drugs at serotonin_{1A} receptors was confirmed by receptor binding studies. Urapidil, B695-40 and WB-4101 were found to be potent competitors for serotonin_{1A} sites labeled by [^{3}H]8-OH-DPAT in rat brain. The affinities of WB-4101 and B695-40 for these sites were 2-10 nM, and the affinity of urapidil was approximately 250 nM.

224.5 IN VIVO RATE OF SEROTONIN SYNTHESIS IN THE DOG BRAIN MEASURED BY POSITRON EMISSION TOMOGRAPHY. M. Diksic*, T.L. Sourkes, H. Nakai*, T. Chaly*, K. Missala* and Y.L. Yamamoto*. Brain Imaging Centre, Montreal Neurological Institute, and Dept. of Psychiatry, McGill Univ., Montreal, Que. H3A 1A1.

Sourkes and associates [Fed Proc 30 (1971) 897] have shown that α-methyl-L-tryptophan (AMTP) follows L-tryptophan (L-Trp) metabolism at least in the 5-hydroxylation metabolic pathway in the brain. Thus, AMTP is a substrate for tryptophan hydroxylase and the product is acted upon by aromatic amino acid decarboxylase, resulting in the formation of α-methylserotonin. Recently, we labelled AMTP with ^{11}C and ^{14}C in the α-methyl position [J Nucl Med 27 (1986) 1047]. After preliminary evaluation of the tracer in the rat brain, the kinetic behaviour was evaluated in the dog brain by means of PET and dynamic scanning. The biological model representing kinetics of AMTP formation in the brain was approximated by considering three compartments. The rate constants for the transfer of AMTP from plasma to brain and back (k_1 and k_2) and the hydroxylation by the rate-limiting enzyme (tryptophan hydroxylase; k_3) were calculated by fitting integral equations representing the radioactivity in brain tissue as a function of time, with rate constants as parameters. Our preliminary data for these rate constants are k_1 = 0.197 ml/g per min (transfer from blood to brain); k_2 = 0.247 min^{-1} (brain-blood transfer) and k_3 = 0.0076 min^{-1} (hydroxylation by tryptophan hydroxylase) in animals with normal plasma tryptophan. Increasing the plasma L-Trp concentration resulted in the decrease of k_1 and increase in k_2; however, k_3 probably does not change. Loading with L-Trp also resulted in the reduction in the volume of distribution. To relate the rate of α-methylserotonin synthesis to the rate of serotonin synthesis, we need constant accounting mainly for the different enzyme affinities for L-Trp and AMTP, because the distribution volume for AMTP and L-Trp are approximately the same. The latter assumption is supported by comparision of our data on AMTP and literature data for L-Trp. The lumped constant (mainly a correction for difference in the hydroxylase activity for two substrates) was estimated to be 0.46 ± 0.12 with values for V_{max} and apparent K_m for AMTP and L-Trp obtained from the literature. From these data the estimate of K_m (apparent) and V_{max} for tryptophan transport through the BBB was 303 ± 54 μM, and 63 ± 10 nmol/g per min, respectively. The average rate of brain serotonin synthesis in the anesthesized dog calculated from these data was 93 pmol/g per min at normal plasma tryptophan concentration (13.2 μM), 1.51 nmol/g per min at total plasma L-Trp of 85.1 μM and 3.1 nmol/g per min at 120.5 μM total plasma L-Trp. This rate of serotonin synthesis measured in dog brain in vivo compares favourably to the rates reported earlier in rat brain.

224.6 CLOZAPINE AS A 5-HT_2 ANTAGONIST IN MAN. Meltzer, H.Y., Bastani, B., Kwon, K., Ramirez, L. and Nash, J.F., Case Western Reserve University School of Medicine

Various preclinical behavioral, endocrine, and temperature studies suggest that clozapine and other atypical neuroleptic drugs are serotonin$_2$ (5-HT) antagonists. We compared the ability of clozapine to block the effect of MK-212, a 5-HT_2 agonist, to increase serum cortisol and prolactin levels with that of typical neuroleptic drugs in schizophrenic patients. MK-212 produced significant increases in cortisol and prolactin levels compared to placebo in 10 unmedicated schizophrenic patients. Clozapine treatment in 8 patients at doses of 400-900 mg/day for 3-6 weeks significantly blocked the MK-212-induced increase in serum cortisol and prolactin whereas administration of typical neuroleptics (e.g. chlorpromazine, trifluperazine, haloperidol) in therapeutic dosages to 10 patients significantly increased the cortisol response to MK-212. The prolactin response to MK-212 was not effected by treatment with the typical neuroleptic drugs. Clozapine treatment inhibited the prolactin response to MK-212. These results are consistent with the hypothesis that clozapine is a 5-HT_2 antagonist. Because of the intricate interaction between dopamine (DA) and 5-HT in the nigrostriatal and limbic systems, this 5-HT antagonism may be important to the unique therapeutic properties of clozapine. Chronic administration of clozapine also decreased basal prolactin levels in patients. This may reflect increased turnover of DA in the tuberoinfundibular DA neurons as previously demonstrated in rats. It might also reflect inhibition of a tonic serotonergic influence on prolactin release which might be mediated through DA or a prolactin releasing factor.

224.7 BLOCKADE OF CONDITIONED AVOIDANCE RESPONDING BY SEROTONERGIC PHENYL PIPERAZINES WITH NO APPARENT AFFINITY FOR DOPAMINE RECEPTORS. G.E. Martin, M.K. Scott*, D.L. DiStefano*, C.L. Fedde*, J.M. Kesslick*, C.B. Davis*, R.P. Shank and W.J. Baldy, Jr*. McNeil Pharmaceutical, Spring House, PA 19477.

The ability to block conditioned avoidance responding (CAR) in animals is a property shared by all clinically effective antipsychotic agents. Potency in blocking CAR has also been shown to be highly correlated with potency in blocking the D-2 dopamine receptor. Hence, block of CAR and D-2 dopamine receptor binding interactions have been used as in vivo and in vitro screening techniques, respectively, for novel antipsychotic agents. We report herein that a series of ortho-substituted phenyl piperazines, with no apparent affinity for the dopamine D-2 binding site, are active in blocking CAR in the rat. In receptor binding studies, these compounds did interact with the serotonin S-1 receptor binding site, but did not markedly inhibit binding of ligands for the α-1, D-1, D-2, or S-2 binding sites.

Male Fisher 344D rats were trained with a discrete trial-lever press CAR paradigm to avoid a 0.7mA footshock. A test session consisted of 60 trials spaced at 1 min. intervals in which the shock was signalled by a tone and a light in the operant chamber. All test agents were given i.p. 30 min. prior to the test session and CAR was compared to that from a control session (no drug) from the previous day. The results were as follows:

	ED50 (mg/kg)	Binding Studies K_i Values (nM)				
R_1	i.p.	D_1	D_2	S_1	S_2	α1
OH	26.2	>1000	>1000	-	>1000	>1000
OCH_3	4.4	>1000	>1000	28	>1000	510
$O(CH_2)_3CH_3$	11.2	NT	>1000	19	>1000	-
$OCH(CH_3)_2$	4.8	NT	64	15	235	84
F	5.0	>1000	>1000	58	>1000	373
CN	5.7	>1000	>1000	26	>1000	214
MCPP	2.4	>1000	>1000	25	40	>100

The CAR block produced by MCPP, which interacts with both the S_1 and S_2 receptor is blocked by the serotonin receptor antagonist metergoline. The block of CAR produced by the S_1 selective agent ortho-methoxyphenylpiperazine, however, was not reduced by metergoline. These are the first S-1 selective agents reported to block CAR in the rat.

224.8 SEROTONERGIC ANTAGONIST PROPERTIES OF ATYPICAL ANTIPSYCHOTICS. Gary Gudelsky, J. Frank Nash* and Herbert Y. Meltzer, Departments of Psychiatry and Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

The use of atypical antipsychotics (e.g., clozapine, melperone, setoperone) appears to be associated with a low incidence of extrapyramidal side effects. Recently, atypical antipsychotics, in contrast to typical antipsychotics, have been demonstrated to possess a relatively higher affinity for 5-HT_2 receptors than for D_2-dopamine receptors. It has been suggested that the 5-HT_2 antagonist property of atypical antipsychotics may contribute to the unique clinical profile of these agents. We have proposed that 5-HT_2 receptors mediate the increase in serum corticosterone concentrations and body temperature produced by the 5-HT agonist MK-212 (6-chloro-2[1-piperazinyl]piperazine), since these effects are antagonized by the 5-HT_2 antagonist ketanserin. In the present study we have assessed the ability of typical and atypical antipsychotics to antagonize the 5-HT_2 receptor-mediated corticosterone secretion and hyperthermia produced by MK-212. MK-212 (2.5 mg/kg, i.p.) produced a marked increase in serum corticosterone concentrations in male, Sprague-Dawley rats. Clozapine (CLZ), melperone (MEL) and setoperone (SET) produced a dose-dependent suppression of MK-212-induced corticosterone secretion. In contrast, neither haloperidol (HAL) nor chlorpromazine (CPZ) affected this response to MK-212. The specific 5-HT_{1A} agonist 8-OH-DPAT (0.1 mg/kg, s.c.) also elevated serum corticosterone concentrations. CLZ, MEL and SET failed to antagonize the 8-OH-DPAT-induced secretion of corticosterone. Similarly, the typical antipsychotics HAL and CPZ also had no effect on corticosterone secretion induced by 8-OH-DPAT. The body temperature of the heat-adapted rats was increased approximately 1°C by MK-212 (1 mg/kg, i.p.). This hyperthermic response was antagonized in a dose-dependent manner by the atypical antipsychotics CLZ, MEL and SET but not by the typical neuroleptics CPZ or HAL. The atypical antipsychotics were essentially equipotent in this regard, and a significant inhibition of MK-212-induced hyperthermia was achieved by 1-3 mg/kg of CLZ, MEL or SET. The administration of 8-OH-DPAT (0.05 mg/kg, s.c.) produced a hypothermic response which was unaffected by CLZ or MEL. These data are supportive of the view that atypical antipsychotic agents, in contrast to typical antipsychotics, possess 5-HT_2 antagonist properties in vivo. Furthermore, these agents appear to act selectively at 5-HT_2 sites, inasmuch as they did not alter 5-HT_{1A} receptor-mediated changes in corticosterone secretion or body temperature.

224.9 EFFECTS OF SEROTONIN RECEPTOR AGONISTS AND ANTAGONISTS ON NEUROENDOCRINE FUNCTION IN RHESUS MONKEYS. G.R. Heninger, D.S. Charney and A. Smith*, Dept. of Psychiatry, Yale Univ. Sch. of Medicine, New Haven, CT 06508.

The 5-HT system plays an important role in modulating neuroendocrine function (i.e, prolactin (PRL) growth hormone (GH) and cortisol (CORT) release), but the subtypes of 5-HT receptors mediating these effects are unknown. Since species differences exist in 5-HT subtypes, the current study was conducted in Rhesus monkeys so the data would be more applicable to humans.

METHODS: Eight male Rhesus monkeys (7-10 kgs) slept in their home cages and were chaired daily. Once weekly at 8 a.m., they had a catheter inserted in the superficial lower leg vein where, following a 90 min. adaptation period, all drugs were administered IV and blood was sampled for PRO, GH and CORT measured using standard RIA methods. The 7 agonists studied (with dose range) included: one nonspecific 5-HT precursor, tryptophan (TRP) (200 mg/kg); three specific 5-HT1a agonists, 8-OH-dipropylaminotetralin (8-OH-DPAT), (0.01 to .3 mg/kg) gepirone (GEP) (.1 to 2 mg/kg) and ipsapirone (IPS) (.2 to 1 mg/kg); one 5-HT1b agonist m-chlorophenylpiperizine (MCPP) (.2 to 2 mg/kg); one mixed 5-HT1a agonist and dopamine antagonist buspirone (BUS) (.1 to 2 mg/kg); and one a 5-HT2 agonist, mescaline (MES) (.2 to 5 mg/kg). The specific 5-HT2 antagonist, ritanserin (RIT) (.1 mg/kg) and the nonspecific 5-HT antagonist metergoline (MET) (.25 mg/kg) were administered prior to agonist infusions.

RESULTS: A dose of .25 mg/kg of GEP (.25 mg/kg = .63 uMole/kg) stimulated an average of 20 ng/ml peak release of prolactin (peak minus base). The average relative rank order of the 7 agonists (in uM/kg - with GEP = to 1) in stimulating an approximate 20 ng/ml peak release of prolactin was: BUS (<.2), 8-OH-DPAT (1), GEP (1), IPS (2), MCPP (4), MES (13), and TRP (>1000). The average per cent inhibition of agonist stimulated PRL response was:

	GEP	MCPP	MES	TRP
RIT	0	50	90	18
MET	90	100	-	97

In comparison to PRL, agonist effects on GH and CORT release were much more variable and they did not follow the same rank order as for PRL. On a uM/kg basis 8-OHDPAT was 3 times more sedative than GEP. Variable amounts of behavioral sedation was observed with the other agonists.

DISCUSSION: The exceptional potency of BUS on PRL release would appear to be due to blockade of dopamine receptors. The relative potency of the other agonists, and the lack of blockade of 5-HT1a agonists by RIT, but the full block of MES by RIT indicates that 5-HT1a receptors are more sensitive in stimulating PRO release than 5-HT2 receptors, although the data also indicates that 5-HT2 receptors are also involved in stimulating PRO release. 224.10 PHYSIOLOGICAL AND PHARMACOLOGICAL CHARACTERIZATION OF THE RESPONSES OF GUINEA PIG NEOCORTICAL NEURONS TO SEROTONIN. M.F. Davies, R.A. Deisz*, D.A. Prince and S.J. Peroutka. Stanford University of Medicine, Dept of Neurology, Stanford, CA, 94305.

The characteristics of the intracellularly recorded responses of cortical pyramidal neurons and interneurons to exogenously applied 5-hydroxytryptamine (5-HT) were investigated in slices of guinea pig somatosensory cortex maintained in vitro by conventional techniques. In 68% of pyramidal neurons, pressure application of 5-HT (10^{-5}-10^{-3} M) caused a slow long-lasting depolarization (0.5-5 mV) which was associated with decreased conductance (20.6 ±1.8%). Current voltage plots suggested that a resting K^+ conductance was reduced by 5-HT and the resistance-voltage plots revealed no voltage dependency. This depolarization was insensitive to tetrodotoxin (TTX) and therefore appeared to be a postsynaptic response. Desensitization was prominent during repeated 5-HT applications. The 5-HT_2 antagonists, ritanserin (10^{-6}M) and cinanserin (10^{-5}M) blocked the depolarization indicating that the 5-HT_2 receptor mediated this response. In 26% of the cells, 5-HT application evoked a slightly faster hyperpolarization (0.5-2.0 mV), secondary to an increased conductance state. This response was also resistant to TTX. The hyperpolarizing response was not secondary to activation of interneurons as it was still observed in the presence of bicuculline or TTX. The 5-HT_{1A} agonist 8-OH-DPAT mimicked and 5-HT_2 antagonists did not block this hyperpolarization. When applied to interneurons, 5-HT always caused a slow depolarization (2-9 mV) which was also associated with a decreased resting conductance.

224.11 CORRELATION OF PSYCHOTROPIC DRUG EFFECTS AT NEUROTRANSMITTER RECEPTORS WITH PHOSPHATIDYLINOSITOL HYDROLYSIS IN RAT CEREBRAL CORTEX P.A. Pierce* and S.J. Peroutka (SPON: S. Hameroff). Departments of Neurology and Pharmacology, Stanford University, Stanford, CA 94305.

The ability of six psychotropic agents to interact with neurotransmitter receptor sites was compared with their ability to stimulate and/or modulate phosphatidylinositol (PI) hydrolysis in rat cerebral cortex. The drugs studied were (±) 3,4 methylenedioxymethamphetamine (MDMA), (±) 3,4 methylenedioxyamphetamine (MDA), 3,4-methylenedioxy-N-ethylamphetamine (MDE), 2,5-dimethoxy-4-iodoamphetamine (DOI), 2,5-dimothoxy-4-bromoamphetamine (DOB), d-lysergic acid diethylamide d-LSD). The neurotransmitter binding sites analyzed included: 5-hydroxytryptamine$_{1A}$ (5-HT_{1A}) sites labeled with ^{3}H-8-OH-DPAT; non-5-HT_{1A} sites labeled with ^{3}H-5-HT; 5-HT_2 sites labeled with ^{3}H-spiperone; putative high affinity 5-HT_2 sites (labeled with ^{3}H-DOB); 5-HT uptake recognition sites labeled with ^{3}H-paroxetine; alpha$_1$-adrenergic sites labeled with ^{3}H-WB 4101; alpha$_2$-adrenergic sites labeled with ^{3}H-rauwolscine; dopamine$_1$ sites labeled with ^{3}H-SCH 23390; dopamine$_2$ sites labeled with ^{3}H-spiperone.

The ring-substituted amphetamines were found to display micromolar affinity for all 5-HT binding site subtypes. By contrast, d-LSD, DOI and DOB display nanomolar potency for 5-HT_2 sites (both those labeled by ^{3}H-spiperone and those labeled by ^{3}H-DOB). In addition, d-LSD displays nanomolar affinity for 5-HT_{1A}, non-5-HT_{1A}, alpha$_2$-adrenergic and dopamine$_2$ sites. The other psychotropic drugs displayed micromolar affinity for all other neurotransmitter binding sites.

The ability of 5-HT to stimulate PI hydrolysis in rat cerebral cortex has been attributed to activation of 5-HT_2 receptors. The rank-order potencies of the above psychotropic agents in modulating PI hydrolysis in rat cerebral cortex was also determined. An attempt will be made to determine if a correlation exists between psychotropic drug effects on PI hydrolysis and a single neurotransmitter receptor.

224.12 ICI 169369 IS AN ANTAGONIST OF 5-HT IN TISSUES CLAIMED TO CONTAIN 5-HT_{1A} AND 5-HT_{1C} RECEPTORS Blackburn, T.P., Cox, B., Grant, T.L. and Growcott, J.W. (SPON: R Pastel). ICI Pharmaceuticals Division, Research Department 2, Mereside, Alderley Park, Macclesfield, Cheshire, SK10 4TG, U.K.

ICI 169369 (2-(2-Dimethylaminoethylthio)-3-phenylquinoline hydrochloride) is a new 5-HT antagonist that is currently undergoing clinical trials in migraine, schizophrenia and anxiety/depression. It is an orally active antagonist in tests designed to measure activity at 5-HT_2 receptors but is devoid of effects at other neurotransmitter receptors (Blackburn et al.,Br.J. Pharmac., 90, 256 and 277P 1987). Some authorities divide 5-HT receptors into 3 separate sub-types; 5-HT_1, 5-HT_2 and 5-HT_3 (Bradley et al., Neuropharmac., 25, 563, 1986) and then divide the 5-HT_1 receptor even further into 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C} and 5-HT_{1D}. This report compares the effects of ICI 169369 with another 5-HT_2 antagonist ketanserin on tissues claimed to contain either the 5-HT_{1A} (the isolated rabbit basilar artery preparation) or the 5-HT_{1C} (the isolated rat stomach fundus preparation) subtype.

5-HT caused dose-related contractions of both the basilar artery and the fundus preparations with EC_{50}'s of 5.9×10^{-8} and 6×10^{-9}M respectively. ICI 169369 caused a dose related inhibition of 5-HT (EC_{50}) on the basilar artery over the concentration range 10^{-8} to 10^{-6}M, with an IC_{50} of 7.4×10^{-8}M. Ketanserin on the other hand was inactive even at concentrations as high as 10^{-6}M. ICI 169369 (10^{-7} to 10^{-5}M) produced a non-competitive inhibition of 5-HT on the rat fundus preparation, but ketanserin was inactive. 8-OHDPAT an agonist claimed to be selective for the 5-HT_{1A} receptor subtype caused dose-related contractions of both tissues, but much higher concentrations were required when compared with 5-HT (EC_{50} values of 10^{-6} to 10^{-5}M). ICI 169369 (10^{-7} to 10^{-6}M) caused a dose related inhibition of 8-OHDPAT on the rat fundus preparation and at 10^{-6}M caused an 86% inhibition of a submaximal response to 8-OHDPAT on the basilar artery. Ketanserin was inactive on both preparations.

These results indicate that the attempts to divide the so called 5-HT_1 receptor into different subtypes based only on the use of agonists is premature and that ICI 169369 can act on receptors that are not currently defined as 5-HT_2 (as classified by the use of ketanserin). These additional properties of ICI 169369 might afford it a wider clinical opportunity since the therapeutic applications of drug interaction with the various 5-HT receptor subtypes remains to be determined.

225.1 THE ROLE OF INFRALIMBIC AND INSULAR CORTEX IN OLFACTORY HEART RATE CONDITIONING IN THE RAT. C. B. Sananes and B. A. Campbell, Dept. Psychology, Princeton Univ., Princeton, NJ 08544

We have recently found that classical conditioning of heart rate to an olfactory stimulus depends on the integrity of the central nucleus of the amygdala (ACE) in the infant rat (Sananes & Campbell, 1986). The aim of the present study was to determine the olfactory pathways to ACE which must be intact for the maturation of this conditioned response.

We examined the role of infralimbic (IL) and insular (INS) cortex on olfactory heart rate conditioning. Both cortical regions receive olfactory input (Krettek & Price, 1977) and project to the central nucleus of the amygdala (Otterson, 1982). Testing was carried out in groups of rat pups with bilateral electrolytic lesions confined to one area (INS; n=6) or the other (IL; n=6). Sham and unoperated control groups were also tested. Three days following surgery, 21-day-old rat pups were tested, using a 10-sec presentation of grape juice odor as the CS, and a 0.5 sec .35-mA subcutaneous shock as the US. A sensitization control with the odor explicitly unpaired with shock was also run. Following testing, the rats were sacrificed and histology performed. In unoperated and sham control groups, the CS elicited a marked conditioned tachycardia, significantly different from their sensitization controls [$F(1,11)=28.14$, $p<.01$) and $F(1,11)=87.61$, $p<.01$)], respectively. Conditioned tachycardia was also seen in the INS group, and differed significantly from the sensitization controls [$F(1,11)=7.75$, $p<.05$)]. In contrast, rat pups that received bilateral lesions of IL showed a severe attenuation of the heart rate CR, which did not differ significantly from the sensitization controls [$F(1,11)=2.89$, p.12)]. None of the lesions interfered with basal heart rate, or unconditioned heart rate changes.

These data demonstrate that infralimbic cortex, and not insular cortex contributes to olfactory heart rate conditioning, and may do so by relaying olfactory information to the central nucleus of the amygdala. We offer a speculative explanation for the slow ontogenetic maturation of olfactory heart rate conditioning in the infant rat.

225.2 APPROPRIATE LESIONS OF THE INTERPOSITUS NUCLEUS COMPLETELY AND PERMANENTLY ABOLISH THE CONDITIONED EYELID/NM RESPONSE IN THE RABBIT. Richard F. Thompson, Joseph Steinmetz and Paul F. Chapman. Department of Psychology, Stanford University, Stanford, CA 94305.

Welsh et al, (Neurosci Abst, 12, 270.12, 1986) reported that following interpositus lesions that abolished the eyelid/NM CR in the CS period, a small amplitude (1.32 mm), infrequent (9-22%), late (within 250 msec of CS offset) "CR" occurred on test trials over the 12 days of post-operative training. In approximately a dozen separate studies, neither we nor other laboratories have observed such responses, other than occasional spontaneous responses of random latency. But we have now repeated the experiment yet again. To date we have run 5 animals. Animals are trained using standard conditions (250 msec tone CS, 100 msec corneal airpuff US, coterminating, CS alone every 9th trial 108 trials per day), to a criterion of 8 CRs in 9 consecutive trials, given 2-4 days of over training and given interpositus lesions. Following 7 days of recovery, animals were trained for up to 24 days and behavioral responses recorded for up to 3 sec following tone CS offset. Two of these animals were given 11-12 days of training on the standard paradigm and 11-12 days of training on the Welsh, et al, idiosyncratic paradigm. None of the animals showed any CRs at all, either early or late. Inspection of the actual data Welsh et al, obtained indicates that their lesions were not completely effective, in that they did not completely abolish the short latency CR in the CS-US onset interval, in contradistinction to their abstract, but in full agreement with previous work on effects of incomplete lesions from our laboratory (Clark et al, Br Res, 291, 125-136, 1984).

225.3 ISCHEMIC INDUCED HIPPOCAMPAL INJURY IN RATS CAUSES DISSOCIATED WORKING MEMORY IMPAIRMENT ON MODIFIED T-MAZE. B.T. Volpe, B. Waczek*, P. Colombo*, H.P. Davis. Cornell University Medical Center, NY, NY, 10021. Burke Center, White Plains, NY, University of Colorado, Colorado Springs, Col.

In order to develop an animal model for the amnesic syndrome that may follow cardiac arrest, and that is characterized by relatively circumscribed CA1 hippocampal injury, we have been examining the behavior of animals that have been exposed to transient forebrain ischemia. Post ischemic (PI) animals demonstrate severe neuron loss in the CA1 hippocampus and dl-striatum. On radial 8 and 12 arm mazes, PI animals demonstrate working memory performance deficits compared to control animals, yet demonstrate normal reference memory performance . Because this dissociation may be a function of task, we employed a split stem T-maze to measure memory for invariant, trial independent information (REFERENCE), and memory for variable trial dependent information (WORKING) using a second, different task. Reference performance required the animals to chose either the rough (r-positive) or smooth (s-positive) surfaced alleyway on the stem. Animals were randomly assigned r-positive or s-positive and remained so for all trials. Surfaces were randomly placed on the right or left alleyway. Working performance required the animals to alternate choice of goal arm for a food reward. A paired run procedure was used, so that an animal received an information run which included a reference judgement in the stem and a forced choice to a goal arm. For the memory run, an animal repeated the reference judgement but was permitted to chose either goal arm. There were ten pairs of runs per trial. Correct working memory performance was scored when the animal alternated goal arm choice. Animals were trained for 20 preoperative trials, exposed to ischemia and returned for 25 postoperative trials. Results showed no difference in preoperative performance ($p > .5$) between PI and sham controls. On post-operative trials there was no difference between groups on REFERENCE memory performance ($p > .1$). However, PI animals performed the WORKING memory task worse than sham controls ($p < .01$). This preliminary data confirms, using another task, the previous observed dissociation of working and reference memory performance, and extends the development of reliable behavioral measures for animal models of human disease. In addition it sets the stage to test whether focal CA1 injury alone or in combination with subiculum or amygdala lesions is sufficient to cause the working memory impairment.

225.4 INCREASED RATE OF FORGETTING OF SPATIAL INFORMATION IN RATS WITH IBOTENATE LESIONS OF HIPPOCAMPUS. L.E. Jarrard, J.M. Ringland*, and L.S. Johnson*. Dept. of Psychology, Washington and Lee Univ., Lexington, VA. 24450.

Hippocampal lesions made with conventional lesion techniques (aspiration, electrolytic) result in rats being impaired in performance of most spatial tasks. However, when the cells in the hippocampus are removed with multiple injections of ibotenic acid (IBO), a procedure that spares fibers of passage and damage to the vasculature and adjacent structures, performance on spatial tasks is less affected. It was found in preliminary research that rats with IBO hippocampal lesions could learn a spatial task that required the animals to return to the same place (match-to-sample (MTS)) on subsequent trials. Thus, the MTS task was used in the present experiment to study forgetting of spatial information in lesioned and control rats.

Animals were divided into 2 control (operated, unoperated) and 2 lesion groups. Multiple injections of small amounts of IBO were used to remove cells in the hippocampus in one lesion group, and in the subiculum in the other group. After recovering from the operations, the animals underwent training on the MTS task using an 8-arm radial maze. Following an information trial, which consisted of raising the door to the arm that was correct on that day and allowing the rat to obtain the food reinforcement, the subjects received 5 trials where only the correct arm was repeatedly baited and the rats allowed to choose from among all 8 arms. On any one day the same arm was correct, while different arms were correct on subsequent days. Following acquisition, forgetting was determined by inserting delays of varying lengths (0, 5, 20, 60 min) between Trials 4 and 5.

Even though rats in the hippocampus group made more errors in acquisition, after 24 days of training their performance did not differ from that of controls. When delays between Trials 4 and 5 were introduced, hippocampals made increasingly more errors as the delays were increased while performance of subiculum and control rats remained the same. Performance of subiculum and control rats did not differ in either acquisition or forgetting.

These findings indicate that removal of the hippocampus results in an increased rate of forgetting of spatial information, thus an impairment similar in many ways to that reported for humans with temporal lobe dysfunction.

(Supported by NSF grant BNS 85-07259.)

225.5 SYNAPTIC PLASTICITY: THE ROLE OF SYNAPTIC CURVATURE. E.J. Markus and T.L. Petit. Div. of Life Sciences, Univ. of Toronto, Scarborough, Ont. M1C 1A4, Canada

One of the plastic aspects of synaptic structure is synaptic shape. Synapes can be divided into four types: smile, flat, frown, and irregular shapes. Smile shaped synapses refer to those contacts in which the presynaptic (axon) element protrudes into the postsynaptic (dendritic) process. These synapses, when oriented such that the presynaptic terminal is above the postsynaptic terminal, resemble smiles. Frown shaped synapses refer to those contacts where the postsynaptic process pushes into the presynaptic terminal. Flat shaped synapses are those which show no curvature, and irregular synapses show no consistent curvature. Recent research has indicated that synaptic curvature is an important plastic feature of the synapse.

There is an increase in the proportion of frown shaped synapses and a decrease in smile shaped synapses with development in the rat neocortex:

Developmental Period	% Smile	% Frown	N
P1-10	37	30	76
P15-30	26	41	438
P60-90	11	49	307

Following repetitive activation with kainic acid in the adult hippocampus (Petit & Markus, in Neuroplasticity, Learning and Memory, Milgram, MacLeod, Petit, eds, A.R. Liss, 1987) or LTP (e.g. Desmond & Levy, J Comp Neurol 253:466-482, 1986) there is an increase in the proportion of smile shaped synapses.

The mechanisms underlying changes in synaptic curvature can be categorized into two types. 1) Passive membrane conformation to the surrounding terminal: changes in curvature could be related to changes in terminal shape or the location of the synapse on the dendritic process. 2) Active local mechanisms: changes in curvature could be related to changes in junction proteins, vesicle release sites, receptors, or internal cytoskeleton.

These mechansims and implications of plasticity in synaptic curvature will be presented.

225.6 MEMORY IMPAIRMENT AND LOSS OF CA1 NEURONS IN THE HIPPOCAMPUS PRODUCED IN THE FOUR VESSEL OCCLUSION (4-VO) ISCHEMIC RAT MODEL OF STROKE. J.M. Ordy, B. Volpe, G. Thomas, and P. Colombo*. Pennwalt Corp., Rochester, NY 14623 & Cornell Medical Center, New York, NY 10021.

Stroke and cardiac arrest represent 2 leading causes of death and in survivors a circumscribed amnesia or memory loss has been reported for events that occur after global ischemia. Neuropathological examinations of patients with cerebral ischemia due to stroke or cardiac arrest have indicated a selective loss of neurons from the CA1 zone of the hippocampus, an area critical for short-term, working, or representational memory. Although clinical evidence for amnesia and CA1 cell loss in cerebral ischemia has been provocative, until recently, animal models of stroke have provided only tenuous evidence for a causal link between hypoxic or ischemic memory impairment and selective vulnerability of CA1 cell loss. More recently, in a four vessel occlusion (4-VO) rat model of stroke, impairments in working but not reference memory in a radial 8-arm maze, with selective cell loss of CA1 neurons, have been demonstrated. Multiple unit maze tests of memory confound working and reference memory as well as motivation and motor performance. The specific aims of this study were to examine the ischemic effects of 4-VO on trial-dependent representational memory of the rat in a T-maze in which ischemic effects on memory can be segregated from effects on motivation and motor performance by separate measurements of start, choice, and goal latencies. Naive and trained male Wistar rats (250-300 g) were subjected to 4-VO by cauterization of vertebral arteries and 30 min. of transient carotid occlusion to reduce cerebral blood flow to less than 3% of control levels in the hippocampus, striatum and cortex. In naive rats tested only after 4-VO, there was a significant decrease in representational memory in the T-maze in eight 4-VO compared to 7 control rats across 4 replications ($F(1,13) = 9.78$, $p = 0.008$), without ischemic effects on start, choice or goal speeds. In rats tested both before and after 4-VO, there was also a significant decrease in memory in nine 4-VO compared to 8 controls at 2 & 4 months post 4-VO ($F(1,15) = 11.12$, $p = 0.004$), without effects on start or choice speeds, but with a significant reduction in goals speeds ($F(1,15) = 4.14$, $p = 0.05$). After memory tests, all 32 rats were perfusion-fixed and paraffin sections (7μM) of anterior dorsal CA1 hippocampus were stained with hematoxylin and eosin, and graded for neuronal damage with light microscopy. In 4-VO rats, there was severe bilateral loss of CA1 neurons in the anterior region with severe to moderate loss in the mid-dorsal and posterior hippocampus. The selective memory deficits and CA1 cell loss in the 4-VO rats of this study provide support for the continued use of this 4-VO rat model for biochemical and pharmacological studies of global cerebral ischemic damage in stroke and cardiac arrest.

225.7 DOUBLE DISSOCIATION OF ITEM AND ORDER (SPATIAL) MEMORY FOLLOWING PARIETAL VS. MEDIAL PREFRONTAL CORTEX LESIONS. R.P. Kesner (Spons: R. Tuckett), Department of Psychology, University of Utah, Salt Lake City, Utah 84112.

Based on Kesner's attribute model of memory, it is assumed that the neocortex represents a critical neural system that subserves knowledge-based memory. More specifically, it is proposed that the medial prefrontal cortex (MPC) mediates temporal cognitive maps, while the parietal cortex (PC) mediates spatial cognitive maps. Furthermore, it is likely that these two neocortical regions can operate independently. In order to provide empirical support for the above assumptions, rats were trained on an eight arm radial maze for Froot Loop reinforcement. After extensive training each animal was allowed on each trial (one per day) to visit four arms in an order that was randomly selected for that trial (study phase). The sequencing of the four arms was accomplished by sequentially opening of Plexiglas doors (one at a time) located at the entrance of each arm. Immediately after the animal had received reinforcement from the last of the four arms, the test phase began. The test for order memory consisted of opening of either the first and second, second and third, or third and fourth door that occurred in the sequence. The rule to be learned leading to an additional reinforcement was to choose the arm that occurred earlier in the sequence. The test for item memory consisted of opening of a door that was previously visited for that trial and a door that was not. The rule to be learned resulting in an additional reinforcement was to choose the arm previously visited during the study phase of the trial (win-stay rule). The order of presentation of the two tests was varied randomly.

Following extensive training, animals performed better than chance for each item position for both tests. The animals then received medial prefrontal cortex or parietal cortex aspiration lesions.

Results indicated that animals with MPC lesions displayed a total deficit for the order memory task, while remembering well the first spatial location within the item memory task. In contrast, animals with PC lesions displayed a total deficit for the item memory task, while remembering well the first choice order of spatial locations within the order memory task. These data suggest that for the first item(s) within a list there is a double dissociation of function between MPC and PC for item and order spatial memory. Thus, the MPC and PC neural regions can probably operate independently and furthermore, item and order (spatial) memory can be coded separately.

225.8 **TACTILE LEARNING IN OCTOPUS IS AFFECTED BY CYTOCHALASIN B.** J. David Robertson., J.Z. Young*, P.H. Lee* and C.B. Bock*, Department of Anatomy, Duke University, Durham, N.C.; Duke University Marine Laboratory, Beaufort, N.C.; Dept. of Experimental Psychology, Oxford, England.

Preliminary electron microscopic study of serial sections of the tactile learning neuropil in the posterior buccal lobe of *Octopus vulgaris* has revealed the presence of numerous complexly related small neuronal processes that resemble filopodia of growth cones. It is postulated that rearrangements of such fine neurites might lie at the basis of learning and memory. Filopodia depend on actin polymerization for activity and this can be blocked reversibly with Cytochalasin B (CB) in vitro. Tactile learning can be nearly abolished by surgical extirpation of the posterior buccal and subfrontal lobes. The present work shows that tactile learning can be significantly decreased by comparision with control animals without affecting visual learning when CB is applied directly to the tactile learning neuropil. In the experiments, animals were positively trained to smooth plastic balls using food rewards and negatively to rough balls using 10VAC shocks.The animals could not distinguish the smooth and rough balls visually but did so readily by touch. 28 animals previously trained positively with smooth balls were anesthetized with $MgCl_2$. Their brains were exposed and the posterior buccal lobes of each were injected bilaterally through a 200 μm beveled Hamilton syringe needle with 0.6-1.0 μl of a solution of artificial sea water containing ~30% horseradish peroxidase as a histological marker, and 2% dimethylsulfoxide with (test) or without (control) 0.6-1.2 % CB. Negative training was begun after the animals were feeding normally (2-3 days). Tactile learning curves from 2 daily sessions of 8 ball presentations each were plotted for 20 sessions and a discrimination index 'I' was calculated according to the formula $I=(x-y)/(x+y)$; where x=takes of positive ball, y=takes of negative ball. The mean index attained by 16 control animals was 0.48 (SE=0.05) and that of 12 CB injected animals was 0.19 (SE=0.05) ($P=0.1$; Wilcoxon). Injection sites were checked histologically in serial sections. Visual learning remained functional in all the injected animals. While they could not discriminate the rough and smooth balls visually, they learned independently from the negative training that the presence of any ball might well lead to shocks, and thus refused to approach the balls as they initially did to obtain food rewards in the positive training. The results support the hypothesis that filopodial activity in the neuropil is necessary for learning and memory. Supported by a gift from RJR/Nabisco Inc.

225.9 **THE HIPPOCAMPAL SYSTEM AND MNEMONIC REPRESENTATION.** H. Eichenbaum, A. Fagan*, P. Mathews*, and N.J. Cohen.
Department of Biological Sciences, Wellesley College, Wellesley, MA 02181

To investigate the role of the hippocampal system in the processing of mnemonic information, the performance of SHAM operated and that of rats with FORNIX lesions were compared on acquisition of different versions of the same two-odor discrimination task that placed different encoding and representational demands on memory. One group of rats was trained using simultaneous presentation of two odor stimuli, and a go-left/go-right response choice, thus encouraging a memory representation based on comparisons both between odor cues and between response choices. FORNIX rats were severly and persistently impaired on this task. A second group of rats was trained with the same response requirement, but the two odors were presented separately and successively across trials, thus hindering odor cue comparison but retaining the same explicit spatial-response choice. FORNIX rats showed a transient learning deficit on this task. A third group was trained with successive odor presentations and a go/no-go response involving only completing or interrupting a single behavioral act. Thus this task both hindered odor comparison and eliminated explicit cues for response choice, and favored a memory representation based on learning the significance of each odor individually. FORNIX rats outperformed SHAM rats on this task. The combined results support an hypothesis that the hippocampal system is critical to a memory representation based on encoding relationships among multiple percepts, and other brain systems support performance adaptations based on encodings of stimuli individually.

To the extent that only the SHAM rats depend on a representation of the relationship between paired S+ and S- odors, one would expect that their performance, and not that of the FORNIX rats, would be disrupted by mismatching the presentation of previously learned odor-pairs. In a separate experiment, we compared response-choice reaction times on "regular" simultaneous-cue trials, composed of previously learned odor-pairs, versus "probe" trials, composed of mismatched S+ and S- stimuli from the same problems. Pairs of FORNIX and SHAM rats were trained on a series of discrimination problems, until the FORNIX rat of each pair reached accurate performance on two different problems. FORNIX rats were severely impaired in learning rate, but each rat eventually acquired two discrimination problems. Then all rats were tested in sessions composed of a mixture of regular trials on both successful problems and on occasional probe trials. Rats of both groups responded correctly on all types of trials. As predicted, SHAM rats had longer response latencies on probes than on regular trials. FORNIX rats had much shorter response latencies on all trials and, in accordance with our prediction, did not evidence a consistent increase in response latency on probe trials. These results support our contention that FORNIX rats fail to process relational information during memory judgements.

225.10 **HIPPOCAMPAL MOSSY FIBERS AND AVOIDANCE LEARNING IN MICE TREATED POSTNATALLY WITH CORTICOSTERONE: CORRELATIONS WITH EXTENT AND LEFT/RIGHT ASYMMETRY.** D.P. Wolfer*, H.-P. Lipp, H. Schwegler*, and M. Brust*. Inst. of Anatomy, Univ. of Zürich, Switzerland, and Inst. of Human Genetics, Univ. of Heidelberg, FRG.

Two-way avoidance learning of mice was found to correlate negatively with the extent of the intra/infrapyramidal mossy fiber (IIP-MF) projection (Schwegler & Lipp, Behav. Brain Res. 7, 1983). Postnatal corticosterone injections impair avoidance learning of adult rats (Olton et al., Dev. Psychobiol. 8, 1977). To test a possible relation between hypercorticism, IIP-MF and two-way avoidance, forty pups of the mouse strain DBA/2 were injected postnatally for 12 days either with total 4.8 micrograms of corticosterone (CORT) or solvent (OIL). The adult mice were tested in an open-field and in a shuttlebox. In 33 mice, the extent of the mossy fiber projections was measured on Timm-stained horizontal sections from the midseptotemporal level. Unexpectedly, CORT- and OIL-mice did not differ in open field and two-way avoidance, but both groups showed fairly poor two-way avoidance, atypical for DBA/2 mice. Hippocampal morphometry revealed no group differences, but considerable variability, anomalies, and asymmetries of the mossy fiber projection in both groups. In the pooled sample of mice, the magnitude of the averaged (left and right) IIP-MF projection was positively correlated with avoidance performance in the early stages of conditioning (day 2, $r=0.48$, $p<0.01$), as well as with various scores of pre- and intertrial locomotor activity, while the averaged extent of the suprapyramidal mossy fiber projection correlated positively with avoidance performance in the later stages (day 6, $r=0.50$, $p<0.01$). Curiously, a (dimension-free) asymmetry-index of the IIP-MF was correlated with the overall avoidance performance, mice having relatively more IIP-MF at left showing superior avoidance ($r=0.58$, $p<0.05$, $n=15$). This was observed in CORT-mice only, in which asymmetry indices of the IIP-MF were also correlated with measures from the open-field, more IIP-MF at left being associated with lower locomotor activity. These results and data from studies in progress indicate that variations of the IIP-MF are not correlated with a specific behavior itself, but appear to modulate the likelihood of behavioral change - the behavior being context-dependent - through stabilizing (more IIP-MF) or de-stabilizing (less IIP-MF) complex patterns of neuronal activity in each hemisphere. Thus, if the initial behavior in the shuttle-box is favorable for learning (e.g., high activity levels), more IIP-MF may lead to positive correlations with avoidance. If the initial behavior is inappropriate (e.g., immobility), more IIP-MF may yield negative correlations. Supported by SNF 3.041 and DFG Schw/252.

225.11 INTRACEREBELLAR LIDOCAINE PRODUCES A REVERSIBLE DECREMENT IN CONDITIONED AND UNCONDITIONED NICTITATING MEMBRANE RESPONSES IN THE RABBIT. J. P. Welsh*, N. Bormann*, P. Iannuzzelli*, and J. A. Harvey. Departments of Psychology and Pharmacology, Univ. of Iowa, Iowa City, IA, 52242.

Destruction of the nucleus interpositus (IP) of the cerebellum has been reported to decrease the frequency and amplitude of a previously acquired conditioned nictitating membrane response (NMR) and to prevent its reacquisition (Clark et al., Brain Res. 291, 1984). In addition, such lesions have been reported to increase the latency of conditioned responses (CRs) (Welsh, Gormezano & Harvey, Neurosci. Abst. 12, 978, 1986). Our recent finding that IP lesions also affect the unconditioned NMR has led us to further investigate the role of the cerebellum in the performance of both the conditioned and unconditioned NMR. Reversible inactivation of the cerebellum has proven to be a valuable method for elucidating the neural bases of motor control (Brooks, Rev. Physiol. Biochem. Pharmacol. 95, 1983). Therefore, we employed intracerebellar infusions of the local anesthetic lidocaine to examine changes in both CRs and unconditioned responses (UCRs). Naive rabbits were implanted with cannulae aimed at the anterior portions of the IP nucleus. Pavlovian conditioning of the nictitating membrane reflex was accomplished by pairing a 300-msec tone or light conditioned stimulus (CS) with a 100-msec unconditioned stimulus (UCS) consisting of a puff of air directed at the right cornea. The offset of the CS coincided with onset of the UCS. Conditioning occurred over 3 or more training sessions until a criterion of 80% CRs was achieved. Each session consisted of 120 pairings of CS and UCS with an intertrial interval of 30-sec (range 25-35 sec). An extension of the NMR of 0.5 mm or greater was scored as a conditioned responses (CRs) if its onset occurred during the 300 msec presentation of the CS and as a UCR if it occurred after UCS onset. Histological examination revealed that five animals had cannula tips located immediately dorsal to the more anterior and lateral portions of IP (n=5). These animals demonstrated a complete loss of CRs within one minute of lidocaine infusion. This effect persisted for 5 to 25 min (mean 15 min) and recovery to preinfusion levels of responding (95% CRs) occurred within 35 minutes of infusion. The elimination of CRs produced by lidocaine was accompanied by a reduction in UCR amplitude with no change in UCR latency. These effects of lidocaine on CR frequency and UCR amplitude could be obtained with repeated injections. Infusion of lidocaine into animals with cannula tips located in regions surrounding the lateral portions of IP had a smaller effect on responding while those even further removed were without effect. The results of this study indicate that the IP is necessary for the normal motoric expression of both conditioned and unconditioned NMRs.

226.1 CHARACTERIZATION OF RAT DOPAMINE β-HYDROXYLASE DEDUCED FROM A cDNA CLONE. Anne McMahon* and Esther L. Sabban, Department of Biochemistry, New York Medical College, Valhalla, N.Y. 10595.

In order to characterize dopamine β-hydroxylase (DBH), the enzyme which catalyzes the formation of norepinephrine, we utilized a cDNA clone for rat DBH which we isolated. This clone of 1131 nucleotides was sequenced and the 211 C-terminal amino acids were deduced followed by 497 nucleotides at the 3'-non-coding region. The amino acid composition deduced was consistent with the overall amino acid composition and acidic properties of DBH. A striking feature is a hexanucleotide (GAGCCG) which is tandemly repeated 10 times and corresponds to part of a 13-fold tandem repeat of the dipeptide glu-pro. The glu-pro dipeptide also occurs 5 additional times in surrounding sequences.

We did not detect any significant homology to the other catecholamine biosynthetic enzymes which have been cloned - rat tyrosine hydroxylase and bovine phenylethanolamine N-methyltransferase.

The mRNA contains a long (at least 500 nucleotide) 3'-non-coding region. There appears to be a single mRNA for DBH in pheochromocytoma cells, of 2100-2200 nucleotides as observed on Northern blot analysis, which leaves at most 1600 nucleotides for the coding region. Therefore, it is likely that the actual molecular weight of DBH is less than the apparent Mr of 67,000 observed by gel electrophoresis of the immunoprecipitated product from translation of the mRNA. Such a discrepancy between actual and apparent molecular weight is not too uncommon for acidic and proline-rich proteins.

DBH in the adrenal and in noradrenergic neurons is present as membrane-bound and soluble forms. It appears that the membrane-bound form contains subunits which are post-translationally processed, possibly by proteolysis, to the soluble form in pheochromocytoma cells and in the locus coeruleus in the brain (Sabban et al, J. Biol Chem., 258:7812, 1983, J. Neurosci, 7:192, 1987). A plot of the average hydrophilicity of the amino acid sequence deduced from the cDNA clone showed that the C-terminal region is quite hydrophilic. Therefore, if there is a polypeptide "anchor" which is proteolytically cleaved during the conversion of the membrane-bound to soluble form of DBH, it is unlikely to reside in the C-terminus of the protein. (Supported by NIH Grant NS 20440).

226.2 EXPRESSION CLONING OF DOPAMINE β-HYDROXYLASE USING LAMBDA gt11. K. P. Decker*, and D. L. Wong. (SPON: R. D. Ciaranello). Department of Psychiatry, Stanford Univ. Sch. of Med. Stanford, CA 94305

We are interested in studying the regulation of dopamine β-hydroxylase [3,4-dihydroxyphenylethylamine, ascorbate:oxygen oxidoreductase (β-hydroxylating)], (DBH), at the transcriptional and genomic levels. For these studies, a cDNA clone for DBH is required. We have isolated such a probe using a lambda gt11 expression cloning system. A rat brain cDNA library (the generous gift of J. Eberwine) was screened with rabbit anti-bovine DBH polyclonal antiserum as primary antibody. To reduce artifactual positive signals, the primary antiserum was pre-absorbed with an E. coli lysate. Iodinated, affinity-purified goat anti-rabbit serum was used as secondary antibody and recombinant clones were identified by autoradiography.

Using the above method for screening the phage library, one plaque out of 180,000 yielded a positive signal. This candidate was plaque-purified until subsequent screens demonstrated positive signals from most plaques. Preliminary experiments showed that the signal produced by the candidate clone could be blocked by preincubation of polyclonal antiserum with purified DBH. DNA was isolated from the recombinant phage, and a 250 bp insert in the Eco R1 site of lambda gt11 was found. This R1 site lies within the structural gene for β-galactosidase, and DNA inserted into this site can therefore be expressed by the phage as a fusion protein composed of β-galactosidase and the protein of interest.

The β-galactosidase portion of the fusion protein thus generated comprises 114.2 kD of molecular weight, as the R1 restriction site interrupts the structural gene 52 bp prior to the transcription termination site. Accounting for the weight of the truncated β- galactosidase, a new polypeptide of apparent molecular weight 10.6 kD is encoded by the insert. Lysogens of the candidate phage were made in another bacterial strain, and the putative fusion protein was also demonstrated in lysates made from this strain. The protein reacted with both anti-β-galactosidase and anti-DBH antiserum in Western blots.

Work is in progress to verify by other methods that the 250 bp insert does, in fact, code for DBH. Once verified, this probe will allow examination of regulatory changes in DBH at the transcriptional and genomic levels, and to isolate a full-length cDNA for the gene.

226.3 BOVINE ADRENAL MEDULLARY DOPAMINE β-HYDROXYLASE SUBUNIT PRIMARY STRUCTURE. D. L. Wong. Dept. of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305.

Soluble bovine adrenal medullary dopamine β-hydroxylase (DBH) consists of three non-identical subunits, α, β and γ, with relative molecular weights of 71, 75 and 78 kD. These are present at a ratio of 1:2:1 and have been purified to homogeneity by sucrose density sedimentation, gel filtration chromatography, affinity chromatography, and preparative SDS-polyacrylamide gel electrophoresis. When the purified subunits are treated with endoglycosidase F, which removes high and complex mannans, a single molecular weight species of 66 kD is generated for each. Intermediate deglycosylation products include species with molecular weights identical to the lower molecular weight subunits and a 68 kD species as well. Lectin blotting shows that concanavalin A (Con A) reacts with the subunits and their partial deglycosylation products confirming that carbohydrate substitution consists primarily of high and complex mannans. Con A reactivity decreases with decreasing molecular weight until the 66 kD product shows no lectin binding. Immunoblotting with a rabbit polyclonal antisera indicates that the subunits and their deglycosylation products are immunoreactive. The antisera must therefore recognize epitopes specific to the primary structure of the enzyme, and the polypeptide backbones of the subunits must be very similar. Amino terminal sequencing of the purified enzyme shows, as suggested by others, that the native protein consists of two non-identical polypeptide chains which are very similar if not identical with the exception that one chain has three additional amino acids at its N-terminus. We have generated three families of polypeptides for the subunits by cyanogen bromide cleavage, formic acid cleavage and proteolytic cleavage with an arginine specific protease. The cyanogen bromide fragments range in molecular weight from 8.8 to 24.5 kD; the formic acid peptides range in size from 16.5 to 68.0 kD; and the arginine cleavage products range in size from 12.0 to 52.5 kD. Immunoreactivity of the cleavage products varies. For the CNBr fragments, only those peptides greater than 11.9 kD are immunoreactive. All of the formic acid peptides are highly immunoreactive although they do not stain well with silver, while none of the arginine cleavage products are immunoreactive. Each set of cleavage products thus appears to generate distinct peptides. Some of these may contain epitopes unique to DBH based on their immunostaining. Furthermore, the various cleavage products may provide us with overlapping peptide fragments. Cyanogen bromide peptides have already been purified preparatively and are currently being sequenced. Sequencing of various overlapping fragments should permit us to piece together the polypeptide backbones for the two nonidentical but very similar polypeptides of DBH.

226.4 **MECHANISM OF ACTIVATION OF TYROSINE HYDROXYLASE.** *C. Abate and T. H. Joh.* Laboratory of Molecular Neurobiology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

Tyrosine hydroxylase (TH), the first and rate limiting enzyme in catecholamine biosynthesis, can be activated by mild proteolysis with trypsin. Trypsin-digested TH (tTH) is a 34 KD fragment that retains catalytic activity and thus can be defined as the catalytic domain of the enzyme. We have previously reported (Abate et al., *Soc. Neurosci. Abst. 12*:601, 1986) that the catalytic domain as represented by tTH extends from amino acid 158 to approximately 454 in the native sequence. This region does not include regulatory phosphorylation sites identified by Campbell et al. (*J. Biol. Chem., 261*:10489, 1985). We sought to characterize the mechanism of activation of TH by comparison of activation by proteolytic removal of the regulatory region with that produced by modification of this region by phosphorylation.

The native form of TH (nTH) was partially purified from rat caudate nuclei as previously described (Joh et al. *PNAS 75*:4744, 1978). tTH was generated by incubation of nTH with 0.2mg/ml of trypsin for 7 min at 30°C; proteolysis was assesed by Western blot analysis. Alternatively, nTH was subjected to phosphorylating conditions in the presence of cAMP-dependent protein kinase. Initial velocity patterns of nTH, tTH and phosphorylated native TH (pTH) were obtained by incubation of enzyme with varying concentrations of cofactor $6MPH_4$ or varying concentrations of substrate tyrosine. Enzyme activity was determined by the method of Coyle (*Biochemical Pharm. 21*:1935, 1972).

As an index of activation, the kinetic parameters of tTH and pTH were assesed. Lineweaver-Burke plots of activity vs. $6MPH_4$ indicate that tTH and pTH share the same K_m for cofactor (1.0×10^{-4} M) and this value is 20 fold lower than that of the native enzyme (2.0×10^{-3} M). In contrast, the K_m of tTH for substrate tyrosine (2.6×10^{-5} M) is 4 fold lower than either the non-phosphorylated or phosphorylated enzyme (9.0×10^{-5} M). In order to determine if digestion to 34 KD is required for activation, nTH was subjected to limited proteolysis in the presence of 10 fold lower conc. of trypsin (0.02mg/ml) for 0 - 30 min. The pattern of proteolysis, identified by Western blot analysis, indicates that under these conditions the enzyme is sequentially digested from 60 KD to 58, 57, and 56 KD; the 56KD band is predominant at 30 minutes. Enzyme activity of TH subsequent to 30 min digestion is 175% of control, non-digested enzyme when assayed in the presence of 1×10^{-3} M $6MPH_4$ and 1×10^{-4} M tyrosine. However, in the presence of 2.5×10^{-5} M tyrosine (1×10^{-3} M $6MPH_4$) activity is 300% of control and in the presence of 1×10^{-4} M $6MPH_4$ (1×10^{-4} M tyrosine) activity is 600% of control. This suggests that proteolysis of to 56 KD results in an increase in affinity for both substrate and cofactor, similiar to the effect produced by more extensive proteolysis to 34 KD.

Thus, proteolysis of TH results in an increase in the affinity of the enzyme for both substrate tyrosine and cofactor $6MPH_4$. This effect corresponds to proteolytic removal of 4000 Daltons which presumably includes N-terminal phosphorylation sites. These data suggest that the mechanism of activation of TH entails modification of a regulatory domain that partially impedes access of substrate and cofactor to the catalytic site. Reversible modification by phosphorylation selectively increases access of cofactor without altering substrate binding.

226.5 **PHOSPHORYLATION SITES ON TYROSINE HYDROXYLASE IN PC12 CELLS.** J.P. Mitchell* and P.R. Vulliet. Department of Physiology, Colorado State University, Fort Collins, CO 80523.

Rat PC12 cells were used to study phosphate incorporation into specific sites on tyrosine hydroxylase (TH) in response to KCl depolarization or nerve growth factor (NGF). PC12 cells were preincubated at 37°C in Krebs-Ringer-HEPES (KRH) buffer containing 0.25 mCi/ml ^{32}P-orthophosphate (carrier-free) to prelabel intracellular ATP stores. After one hour, the ^{32}P-containing KRH buffer was removed and replaced with either KRH buffer alone (control), KRH buffer containing 56 mM KCl (NaCl content reduced to maintain constant tonicity), or KRH buffer containing 50 ng/ml NGF. After 10 minutes, buffers were removed and cells were lysed by adding 200 ul of ice-cold lysis buffer (50 mM tris-acetate, 0.27 M sucrose, 100 mM NaF, 1 mM EDTA, 4 ug/ml leupeptin, 0.2% triton X-100, pH 8.0). Lysates were centrifuged for 5 minutes at 13,000 x g. The TH activity of the supernatants was measured by a coupled decarboxylase procedure. Supernatants were mixed with SDS-sample buffer, heated at 95°C for 5 minutes, and proteins separated on 10% SDS-polyacrylamide gels. Proteins were electrophoretically transferred to nitrocellulose and autoradiographs were made from the nitrocellulose sheets. The major phosphorylated band at 60 kDa, shown previously to be predominantly TH, was cut from the nitrocellulose and digested with trypsin. Over 90% of the radioactivity was released from the nitrocellulose by trypsin. These tryptic phosphopeptides were analysed by isoelectric focusing (pH 2.5-10) and compared to tryptic phosphopeptide standards obtained from purified TH labeled by purified protein kinases (Ca^{++}/calmodulin-dependent and cAMP-dependent kinases).

Both KCl depolarization and NGF treatment increased TH activity in the supernatant; however, these increases in enzyme activity were characterized by different kinetic parameters for each treatment. Total phosphate incorporation into TH increased with both treatments. Both treatments increased phosphorylation of peptide C, previously identified as the serine 19-containing tryptic phosphopeptide. Two additional peptides had increased phosphate incorporation when compared to peptides isolated from control cells. The relative degree of phosphorylation of these three peptides was different for KCl depolarization and NGF treatment, possibly explaining the differences seen in the enzyme kinetics.

Supported by USAF-OSR grant #86-0117.

226.6 THE PHOSPHORYLATION OF TYROSINE HYDROXYLASE IN PC12 CELLS AFTER DOWN REGULATION OF PROTEIN KINASE C. A.L. Cahill and R.L. Perlman, Kennedy Mental Retardation Research Center and Departments of Pediatrics and of Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637

Treatment of the superior cervical ganglion (SCG) or PC12 pheochromocytoma cells with a variety of agonists, including phorbol esters, cAMP analogues, cholinergic agonists, and depolarizing agents, increases the phosphorylation of tyrosine hydroxylase (TH) in these tissues. TH can be phosphorylated in vitro by a number of different protein kinases, including the cAMP- and cGMP-dependent protein kinases, a type II Ca^{2+}/calmodulin-dependent protein kinase, and protein kinase C. We have been interested in determining the roles of these various protein kinases in regulating the phosphorylation of TH in situ. One approach to this problem is to analyze the site-specific phosphorylation of TH in response to various agonists. Six different tryptic phosphopeptides can be isolated from TH from the SCG and from PC12 cells. One of these peptides, known as peptide T3, has been reported to contain a specific protein kinase C phosphorylation site (McTigue et al., J. Biol. Chem. 260, 9047-9056, 1985). In the SCG, phosphorylation of this peptide was increased only by treatment with phorbol dibutyrate (PDBu). In PC12 cells, however, phosphorylation of this peptide was increased not only by phorbol esters, but also by treatment with cAMP analogues, depolarizing agents, and NGF. These results imply that all of these agents may activate protein kinase C in PC12 cells. To investigate the role of protein kinase C in the phosphorylation of TH in PC12 cells, we have depleted cells of protein kinase C and then compared the basal and stimulated phosphorylation of TH in these cells to that in control cells. PC12 cells were depleted of protein kinase C by incubation for 24 h with 1 μM PDBu (Matthies et al., J. Neurosci. 7, 1198-1206, 1987). After 24 h the cells were washed to remove PDBu, labeled with $^{32}P_i$, and then treated with the desired agents. ^{32}P-labeled TH was isolated by SDS-PAGE and subjected to complete tryptic hydrolysis. ^{32}P-labeled phosphopeptides were separated by two-dimensional thin-layer electrophoresis and chromatography and visualized by autoradiography. In protein kinase C-depleted cells, basal phosphorylation of peptide T3 was reduced, and treatment with PDBu did not increase the phosphorylation of peptide T3. Down regulation of protein kinase C appears to provide a useful technique for studying the role of this kinase in the phosphorylation of TH.

226.7 TYROSINE HYDROXYLASE IS AN INTEGRAL COMPONENT OF SECRETORY GRANULES FROM ADRENAL MEDULLA. D.M. Kuhn. Lafayette Clinic, 951 E. Lafayette, Detroit, MI 48207

Intact secretory granules isolated from bovine adrenal medulla express tyrosine hydroxylase (TH) activity. Membrane ghosts prepared from granules retain TH activity while the granule contents are free of hydroxylase activity. When granule membrane proteins are resolved on SDS-polyacrylamide gels and transferred to nitrocellulose, antibodies directed against TH recognize a protein which is slightly lower in molecular weight than TH from PC12 cells but which can be positively identified as TH by various criteria. TH catalytic activity and immunoreactivity can be removed from granule membranes by detergent treatment and by increasing the pH of a ghost preparation but not by increasing ionic strength. TH also remains associated with ghost membranes after treatment with a phosphatidylinositol-specific phospholipase. Trypsin treatment of intact granules or granule membranes releases only small amounts of TH immunoreactivity but causes the total loss of catalytic activity. Biotinylation of intact granules or exposure to the catalytic subunit of cAMP-dependent protein kinase in the presence of (γ-^{32}P)ATP in order to label proteins on the cytoplasmic surface, followed by immunoprecipitation of TH, reveals that TH is apparently labelled by both procedures. These results indicate that TH is an integral component of the granule membrane. Furthermore, TH appears to be imbedded in the cytoplasmic side of the membrane where it is exposed to its substrates and other cytoplasmic and membrane constituents. Plasma membranes were also purified from adrenal medulla and were found to contain both TH immunoreactivity and enzyme activity. Taken together, these results suggest that TH becomes a part of the plasma membrane during exocytosis-induced granule fusion. Furthermore, membrane bound TH may serve as a marker of exocytosis in the adrenal medulla.

226.8 **TUMOR FORMATION AND DOPAMINE PRODUCTION BY PC12 CELLS ON EHS-DERIVED EXTRACELLULAR MATRIX.** C. L. Bethea and T. K. Borg*. Division of Reproductive Biology and Behavior, Oregon Regional Primate Research Center, Beaverton, OR 97006 and Department of Anatomy, Univ. of South Carolina School of Medicine, Columbia, SC 29208.

We previously reported that PC12 cells flatten extensively, increase dopamine secretion, and decrease dopamine storage when cultured on extracellular matrix (ECM) produced by bovine corneal endothelial cells (*Mol. Cell. Endocrinol.* 37:319, 1984). Here, the effect of EH mouse sarcoma-derived (EHS) ECM (Kleinman et al., *Biochem.* 25:312, 1986) on PC12 cell morphology, growth, and dopamine production was examined. PC12 cells (10^5) were plated onto plastic and 4 thicknesses of EHS-ECM. Variable thickness of the ECM was achieved by aliquoting 100, 150, 200 or 250 μl of EHS gel extract into 35 mm dishes. Phase contrast micrographs and scanning electron micrographs obtained on days (D) 2, 4, 6 and 8 after plating showed that cells on plastic grew into a single-layered lawn of cells, whereas cells on 200-250 μl of EHS-ECM grew into large tumors. PC12 cells on 150 μl of ECM first grew into tumors, but by day 8 they appeared to dissolve the ECM and then migrate out from the tumors. One hundred μl of EHS gel did not distribute evenly and intermediate regions of cell piling were observed.

^{3}H-thymidine (THY) incorporation for 30 min, dopamine secretion (ng/ml) and cell content (ng) were then compared between cells cultured on plastic and 250 μl EHS-ECM (thickest). Dopamine (DA) levels were determined with a catechol-o-methyl transferase radioenzymatic assay (2X blank = 40 pg). The results of one experiment are shown below. (n = 3/group)

		D2	D4	D6	D8
^{3}H-THY x 10^3	EHS	4.5	11.0	52.5	164.8
	Plastic	34.6*	46.4*	143.3*	267.6*
DA(ng/ml)	EHS	nd	nd	1.1	3.9
	Plastic	nd	nd	3.1*	7.9*
DA(ng)	EHS	1.5	4.8	20.6	58.1
	Plastic	4.7*	14.1*	55.8*	119.6*

*p<0.05; nd=nondetectable.

Dopamine secretion and content are reduced in EHS-ECM cultures, but this can be attributed to a decrease in cell number. DA/ ^{3}H-THY yields similar ratios for EHS-ECM and plastic on D 4, 6 and 8. Visual examination and ^{3}H-THY incorporation suggest that fewer cells survive plating on EHS-ECM than plastic, but the subsequent doubling times appear comparable. Norepinephrine was undectable in either group with the radioenzymatic assay (2X blank = 83 pg). Therefore, these data suggest that, although EHS-ECM alters plating viability, cell-cell and cell-substratum association, this may not change dopamine production on a per cell basis.

226.9 POSSIBLE ORIGIN OF SULFOCONJUGATED CATECHOLAMINES IN THE PLASMA: THE PERIPHERAL SYMPATHETIC NEURONS. N.T. Buu, W. Debinski*, C. Lussier*, and O. Kuchel*. Lab. of the Autonomic Nervous System, Clinical Research Institute of Montreal, Montreal, Quebec H2W 1R7, Canada.

The origin of plasma sulfoconjugated catecholamines (CA), the predominant (90 percent) fraction of CA in human blood remains unknown. Although sulfoconjugating enzymes which participate in maintaining CA homeostasis, are present in most endocrine tissues (e.g. kidney, heart, adrenal glands) and in blood platelets, recent studies have discounted these tissues as the sources of conjugated CA in the plasma. On the other hand, except for epinephrine, a major portion of plasma CA is derived from the peripheral sympathetic neurons but whether these sympathetic neurons can also be the origins of plasma sulfoconjugated CA remains undetermined.

This study investigates the sulfoconjugation activity in the peripheral sympathetic neurons by measuring the formation of dopamine (DA) sulfate following L-dopa administration in richly innervated tissues of the superior cervical ganglia (SCG), vas deferens and spleen of adult Sprague Dawley control rats and rats pretreated with pargyline, an inhibitor of monoamine oxidase (MAO). Free and sulfoconjugated CA were measured by HPLC with electrochemical detection.

In control rats L-dopa administration led to a significant elevation of DA sulfate in the plasma and tissues. In the SCG the concentrations of DA sulfate became equal to that of free DA (9.9 ± 1.5 ng/pair of ganglia) while in the spleen and vas deferens they accounted for 10 percent of the total DA. In MAO-inhibited rats the same L-dopa treatment caused a two-fold increase in DA sulfate in SCG and a five-fold increase in the other tissues but the concentrations of free DA also doubled.

The results indicated that DA can also undergo sulfoconjugation in the peripheral sympathetic neurons, and this sulfoconjugation, like that in the brain (J. Neurochem. 45:470, 1985), appeared to be regulated by MAO. Thus, the peripheral sympathetic neurons which release the major fraction of free CA into the blood, may also be the major sources of plasma sulfoconjugated CA.

226.10 EXTRANEURONAL SYNTHESIS OF EPINEPHRINE IN BRAIN. I.N. Mefford*, G.M. Foster*and N.K. Garrick (SPON: J.M. Tolliver) Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, Maryland 20892.

Pharmacological evidence supports the view that epinephrine in hypothalamus and perhaps in other brain regions is not synthesized in catecholamine neurons but is formed in some extraneuronal element. The bulk of epinephrine found in rat brain appears to be stored in noradrenergic nerve terminals. Immunohistochemical data suggest that neurons or other cells which contain phenylethanolamine N-methyltransferase (PNMT) in the forebrain do not contain other biosynthetic enzymes, tyrosine hydroxylase and/or dopamine--hydroxylase. Destruction of ascending projections from the A1, A2 and C1, C2 cell body groups or destruction of hypothalamic norepinephrine terminals using 6-hydroxydopamine cause depletion of both norepinephrine and epinephrine, but no decrease in PNMT activity. Stimulation of the C1 area results in marked efflux of epinephrine into extracellular space but no change in extracellular norepinephrine concentration in posterior hypothalamus. This suggests that an N-methyltransferase provides a metabolic barrier to the accumulation of norepinephrine in extracellular space in this brain region.

Two approaches have been taken to address the source and mechanism of this apparent rapid conversion of norepinephrine to epinephrine. Cervical spinal fluid was continuously collected from chair adapted Rhesus monkeys prior to and during infusion of anesthetics and other drugs. Samples were analyzed by microbore HPLC with amperometric detection for epinephrine, norepinephrine and dopamine. Rapid and marked enhancement of epinephrine in cerebrospinal fluid was observed following only a modestly sedating dose of pentobarbital (6 mg/kg i.v.).

The possibility that the extraneuronal synthesis of epinephrine could occur in non-neuronal elements such as glia was examined in astrocyte cultures. The capacity to N-methylate norepinephrine was observed in astrocyte cultures prepared from several brain regions including hypothalamus and cerebral cortex. Using norepinephrine as substrate and S-adenosyl methionine as cofactor, enzyme activity and specificity were compared to adrenal PNMT. Immunocytochemical experiments are presently under way to further characterize this enzyme. The presence of a norepinephrine N-methylating enzyme in astrocytes provides an efficient mechanism for rapid extraneuronal conversion of norepinephrine to epinephrine, perhaps providing a metabolic and diffusional barrier between released norepinephrine and extrajunctional alpha-2 adrenoreceptors at which epinephrine may be the primary agonist.

226.11 ADRENERGIC PROPERTIES OF 2- AND 6-FLUOROEPINEPHRINES. C. Creveling, F. Gusovsky, A. Adejare*, J. Daly, and K. Kirk*. Laboratories of Chemistry and Bioorganic Chemistry, NIDDK, NIH, Bethesda, Maryland 20892.

We have extended our studies on the effects of aromatic fluorine substitution on the chemical and biological properties of catecholamines to epinephrine. 2- and 6-Fluoroepinephrine (2-FEpi, 6-FEpi) were synthesized by a sequence of N-formylation, hydride reduction and hydrogenolysis of previously synthesized fluorinated dibenzyloxyphenethanolamines. Similar to the dramatic change in adrenergic selectivity seen with norepinephrine (Science, 204, 1217, 1979; J. Med. Chem. 22, 1493, 1979), fluorine substitution on the 2- or 6-carbon of the aromatic ring alters the selectivity of epinephrine towards alpha- and beta-adrenergic receptors. Thus, 2-FEpi is a relatively specific beta-adrenergic ligand while 6-FEpi is a relatively specific alpha-adrenergic ligand. However, unlike the effect on norepinephrine but similar to the effect on phenylephrine (J. Med. Chem. 29, 1982, 1986) fluorine substitution can markedly increase the potency of epinephrine as well as induce selectivity. Thus 2-FEpi shows a 3-fold increase in affinity relative to epinephrine for beta-receptors as well as a greatly reduced affinity towards alpha receptors. 6-FEpi, on the other hand, not only has a greatly reduced affinity for beta-receptors, but shows a 3-fold increase in affinity towards alpha-1 receptors. 6-FEpi is equipotent with epinephrine toward alpha-2 receptors. Thus the increase in potency observed with 6-FEpi is specific for alpha-1 receptors. We previously reported that the alpha selective agonist 6-fluorophenylephrine showed a 2-fold increase in potency relative to phenylephrine for both alpha-1 and alpha-2 receptors.

226.12 NEUROTRANSMITTER INDUCED MODIFICATION OF ARACHIDONATE TURNOVER IN CEREBRAL PHOSPHOLIPIDS. L.R. Murthy* and A.I. Barkai*, (spon. W.C. Clark), N.Y.S. Psych. Inst. and Columbia Univ. Coll. P & S., New York, N.Y. 10032.

Arachidonic Acid (AA), the major precursor of eicosanoids, plays an active role in the deacylation-reacylation cycle of membrane phospholipids. This cycle regulates the levels of lysophospholipids, free fatty acids and eicosanoids, which may alter membrane functions and affect neuronal signal transduction. The present study was undertaken to investigate the effects of norepinephrine (NE) and serotonin (5-HT) on AA turnover in cerebral phospholipids. Cross chopped slices of cerebral cortex were incubated for 30 min, with or without varying concentrations of NE, or 5-HT. ^{3}H-AA, ATP, CoA and Mg^{++} were then added and the incubation was continued for additional 5 min. The reaction was stopped by addition of chloroform: methanol (1:2) and lipids were extracted and seperated by HPTLC for radioactive analysis. Incorporation data revealed a dose related increase of ^{3}H-AA in phosphatidylinositol (PI), but a decrease in other phospholipids. The NE effect on PI was attenuated by mepacrine, a phospholipase A_2 inhibitor and also by acyltransferase inhibitors such as indomethacin and tetrahydrocannabinol. The results suggest a phospholipase A_2 activiation by NE with, a concomitant stimulation of a specific lysophosphatidylinositol acyltransferase.

227.1 **CHOLINERGIC VASOPRESSOR MECHANISM IN ROSTRAL VENTROLATERAL MEDULLA IS MEDIATED BY THE M_2 MUSCARINIC RECEPTOR SUBTYPE.** *R. Giuliano, P. Ernsberger, and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

In vitro binding, autoradiographic and functional studies support the existence of subclasses of muscarinic acetylcholine receptors (mAChR) in peripheral tissues and regions of CNS. Recent studies have demonstrated a cholinergic pressor mechanism in the rostral ventrolateral medulla (RVL), a brainstem region containing adrenaline (C1) neurons, which is critically involved in cardiovascular control (*JPET* 231:457, 1984; *Soc. Neurosci. Abstr. 12*:964, 1986). We sought to (1) characterize the binding properties of mAChR in the RVL and (2) define the mAChR subtype which mediates pressor responsiveness to cholinergic activation of the RVL.

Radioligand binding assays were carried out using membranes prepared from ventrolateral medulla of bovine brain and incubated with ^{3}H-quinuclidinyl benzylate (^{3}H-QNB) in Tris buffer (60 min at 25°C). Nonspecific binding was defined by 1μM atropine. ^{3}H-QNB specifically labeled numerous sites (B_{max} = 183 ± 22 fmol/mg protein) with high affinity (K_D = 88 ± 11 pM). In competition experiments against ^{3}H-QNB (70 pM) the following agents were tested: oxotremorine (OXO), the M_1- selective agonist pilocarpine (PILO), scopolamine (SCOP), the novel M_2- selective antagonist AF-DX 116 and the M_1-selective antagonist pirenzepine (PZ). The order of potency for inhibition of ^{3}H-QNB binding was, for agonists: OXO >> PILO, and for antagonists: SCOP > AF-DX 116 = PZ.

In anesthetized, paralyzed and ventilated rats i.v. physostigmine (PS) produced a marked, reproducible rise in AP (44 ± 2 mmHg; n=14). Antagonism of the pressor response to this fixed dose of PS was determined in rats microinjected bilaterally into the C1 area (50 nl) with SCOP (3 pmol to 3 nmol), AF-DX 116 (3 pmol to 3 nmol) or PZ (15 pmol to 3 nmol). Initial resting AP fell after administration of 0.03 nmol AF-DX 116 (23 ± 7 mmHg, n=4). At a dose 100-fold greater (3.0 nmol) SCOP produced a comparable decrease (24 ± 2 mmHg, n=8), but PZ had no effect (1 ± 4 mmHg, n=10). AF-DX 116 inhibited the PS-induced rise in AP in the same dose range as SCOP (% inhibition at 0.3 nmol: 47 ± 12, n=6 vs. 50 ± 10, n=5, respectively, and at 3.0 nmol: 85 ± 10, n=5 vs. 81 ± 3, n=6, respectively) ($p < 0.001$). PZ was ineffective even at 3 nmol (% inhibition: 1 ± 13, n=6). Bilateral microinjection of PILO into the C1 area (10 nmol) had no effect on AP (increase of 7 ± 2 mmHg, n=4), whereas local administration of OXO evoked a dose-related increase (threshold dose, 2 pmol; maximal effect at 25 nmol, 50 ± 3mmHg, n=5). SCOP and AF-DX 116 antagonized the rise in AP elicited by OXO, inhibiting the pressor response to 1 nmol (45 ± 6 mmHg, n=11) approximately 50% at 0.015 nmol SCOP (58 ± 9%, n=5) and 0.15 nmol AF-DX 116 (55 ± 16%, n=4) ($p < 0.001$). PZ exhibited lower potency, antagonizing the OXO pressor effect (59 ± 4%, n=4) at 0.75 nmol, a dose 50 or 5 times higher than that of SCOP or AF-DX 116, respectively.

We conclude that (1) mAChR, predominantly the M_2 subtype, are present in RVL; (2) the muscarinic agonist OXO, but not PILO, binds with high affinity to the M_2 mAChR in RVL; (3) the pressor effect of systemically administered PS or locally-injected OXO is mediated by the M_2 mAChR in RVL; and (4) M_2 mAChR in RVL have an important role in central cardiovascular control.

227.2 **CHOLINERGIC-AUTONOMIC REGULATION: ANATOMICAL SUBSTRATES.** *D.A. Ruggiero, R. Giuliano, R. Stornetta, M. Anwar* and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

While there is ample physiological and pharmacological evidence for cholinergic (Ch) control of arterial pressure (AP) and vasopressin release (e.g., by rostral ventrolateral medulla (RVL) or paraventricular nucleus of hypothalamus (PVN)), the anatomical substrates are poorly understood. The presence of cholinergic or cholinoceptive elements in central autonomic nuclei, or the pathways involved, are either unknown or have not been studied in detail. In this study we sought to define regions in the CNS where cholinergic interactions with central autonomic neurons occur. Rats were anesthetized (Nembutal, 0.4 ml i.p.; 50 mg/ml) and perfused (4% para formaldehyde in 0.1M phosphate buffer, pH 7.4); 25μm sections were processed using antisera against choline acetyltransferase (ChAT), the acetylcholine synthesizing enzyme, by the peroxidase-antiperoxidase technique. The use of a sensitive immunocytochemical procedure combined with darkfield illumination revealed new groups of cholinergic perikarya and terminal fields in several brainstem and spinal autonomic substructures.

In **hypothalamus,** ChAT-positive terminals (but not perikarya) were distributed to discrete autonomic nuclei (zona incerta, dorsal, lateral, posterior and subparafascicular nuclei). No terminals were labeled in PVN. In **pons,** stained cells and terminals occurred in n. Koelliker-Fuse (KF); terminals also occupied dorsal and medial divisions of parabrachial n., periventricular gray (PVG) (excluding locus ceruleus) and raphe. In **medulla,** cells and processes occurred in medial and commissural divisions of n. tractus solitarii. Cells were labeled in raphe obscurus and magnus, PVG and RVL. Cells in RVL lay in proximity to the ventral surface and medial to adrenergic perikarya of the C1 area. In RVL, terminals, of unknown origin, and dendrites of the retrofacial nucleus, were adjacent to or overlapped C1 neurons. In **spinal cord,** ChAT-labeled processes overlapped Ch-sympathetic preganglionic neurons (SPN's) of the intermediomedial and intermediolateral cell columns; processes also occurred in dorsal and ventral horns. Since Ch-perikarya occur in brainstem areas known to project to SPN's, we sought to determine the source(s) of supraspinal Ch-afferents to the cord. WGA-HRP was injected into the thoracic cord and sections reacted with tetramethylbenzidine and processed immunocytochemically for ChAT and phenylethanolamine N-methyltransferase (PNMT, the adrenaline synthesizing enzyme). After thoracic injections, neurons were retrogradely labeled in nuclei containing ChAT- and PNMT-positive cells. No cells were labeled for both ChAT and WGA-HRP; in contrast many cells, concentrated in the RVL, were dually-labeled for PNMT and WGA-HRP.

In conclusion: 1) Ch-cells and terminals or a comingling of both elements occurred differentially in areas known to regulate AP; 2) The absence of Ch-terminals in PVN suggests that Ch-control of vasopressin may be mediated by adjacent cells or by synapses on processes lying external to this nucleus; 3) Newly identified groups of Ch-cells suggest additional substrates for Ch-control of autonomic functions; 4) Ch-afferents on SPN's may be of intrinsic origin. These data, collectively, suggest that Ch-control of cardiovascular functions involves multiple sites throughout the neuraxis.

227.3 **CHOLINE ACETYLTRANSFERASE IN THE RAT ROSTRAL VENTROLATERAL MEDULLA: ULTRASTRUCTURAL LOCALIZATION AND SYNAPTIC INTERACTIONS WITH NEURONS CONTAINING CATECHOLAMINE-SYNTHESIZING ENZYMES.** *T.A. Milner, V.M. Pickel, C. Abate and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Pharmacological and biochemical studies suggest interactions involving cholinergic and catecholaminergic neurons, particularly those of the C1 adrenergic cell group in the rostral ventrolateral medulla (RVL) that have been strongly implicated in cardiovascular control. Ultrastructural localization of choline acetyltransferase (CAT) and its relation to neurons exhibiting immunoreactivity for tyrosine hydroxylase (TH) or phenylethanolamine N-methyltransferase (PNMT) were examined in the RVL using dual immunoautoradiographic and peroxidase anti-peroxidase labeling methods to simultaneously localize antisera from two different species.

By light microscopy, the CAT-immunoreactive cells were located both dorsally (i.e., the nucleus ambiguus) and ventromedially to those labeled with TH or PNMT. A few CAT-labeled processes were dispersed among TH- or PNMT-containing neurons with the majority of overlap immediately ventral to the nucleus ambiguus. By electron microscopy, CAT-immunoreactivity was detected in neuronal perikarya, dendrites and axon terminals and in the vascular endothelial cells of certain blood vessels. The CAT-labeled perikarya were medium sized (15-25μm) and contained abundant cytoplasm and a slightly indented nucleus. Synaptic junctions on CAT-immunoreactive perikarya and dendrites were primarily symmetric with 75% (45 out of 60) of the terminals unlabeled. The remaining terminals were immunoreactive for CAT (18%) or TH/PNMT (7%). Terminals with CAT-immunoreactivity were large (0.8-2.0μm) and contained numerous small clear vesicles and 1-3 dense-core vesicles. Seventy seven percent (112 out of 145) of CAT-labeled terminals formed symmetric synapses with unlabeled perikarya and dendrites; whereas only 8% were with TH- or PNMT-labeled perikarya and dendrites and 15% were with CAT-immunoreactive perikarya and dendrites. Additionally, 60% of the processes immunoreactive for CAT or TH/PNMT, although seen in the same field, were without any apparent synaptic or cellular interrelations. The proportionally small number of observed (symmetric) synapses (in both directions) involving CAT and TH- or PNMT-containing neurons suggests that cholinergic and adrenergic neurons may exert reciprocal inhibition of each other and thus may modulate their response to the more abundant input from unlabeled afferents in the rat RVL. Furthermore, the detection of CAT-immunoreactivity in vascular endothelial cells is analogous to that previously reported in certain cortical and peripheral blood vessels. The results therefore suggest that cholinergic regulation of arterial pressure through the RVL may involve local interneurons. (Supported by NIH grant HL 18974.)

227.4 **GLUTAMATE RECEPTOR ANTAGONIST BLOCKS THE RESPONSES OF SYMPATHETIC PREGANGLIONIC NEURONS (SPN) TO STIMULATION IN THE C1 AREA OF THE ROSTRAL VENTROLATERAL MEDULLA (RVL).** *S. F. Morrison and D. J. Reis,* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

In the rat, the region of the RVL containing the C1 adrenergic cell group (C1 area) is the site of sympathoexcitatory neurons that project to the spinal sympathetic intermediolateral nucleus (IML). The projection is over myelinated and unmyelinated axons with conduction velocities comparable to those estimated for the PNMT containing axons of the lateral funiculus of the spinal cord (Soc. Neurosci. Abstr. 12:1157, 1986). In the present study, we sought to characterize the responses of SPN's to RVL stimulation and to determine if these responses were mediated by activation of glutamate receptors on SPN's. Electrical stimuli (80μA, .8ms, .4Hz) were applied to the RVL of rats anesthetized with urethane, paralyzed, and artificially ventilated. Sympathoexcitatory responses evoked in the preganglionic splanchnic sympathetic nerve consisted of two peaks of excitation with latencies of 61 ± 2 ms and 142 ± 8 ms (n = 8). Both peaks in the sympathetic response to RVL stimulation were abolished by injection of kynurenic acid (25 nmol) into the central canal at the level of the calamus scriptorius, but were unaffected by similar application of the NMDA receptor antagonist, AP5. The SPN's contributing to the splanchnic nerve were antidromically identified in the IML of T7-T9 using stimuli applied to their axons in the splanchnic nerve. The mean antidromic response latency of 42 splanchnic SPN's was 27 ms (range 5 - 51 ms). Individual splanchnic SPN's responded to RVL stimulation in one of three ways: (a) an early activation with a modal response latency of 28 ± 2 ms (n = 12); (b) a late activation with a modal response latency of 112 ± 4 ms (n = 6); or (c) both an early and late excitation with similar latencies to (a) and (b) (n = 5). Both the early and the late excitations of splanchnic SPN's were antagonized in a current-dependent manner by iontophoretically (40-100nA, .2M) applied kynurenic acid. We conclude that both the rapid and slowly conducting sympathoexcitatory pathways from the RVL to the IML produce their effects through activation of glutamate receptors on SPN's which appear to be of the quisqualate or kainate type. These results raise the possibilities (a) that glutamate may be released by the terminals of C1 adrenergic neurons that project from the RVL to the IML or (b) that this sympathetic pathway involves a glutamatergic spinal interneuron.

227.6 CAUDAL VENTROLATERAL MEDULLARY PROJECTIONS TO THE C1 CELL GROUP. L. Jeske and D.O. Nelson, Dept. of Physiology, Northwestern Medical School, Chicago, IL 60611

Noradrenergic projections, arising from the A1 cell group in the caudal ventrolateral medulla (CVLM), are thought to innervate neurons residing in the C1 region of the rostral ventral lateral medulla (RVLM). This projection has been implicated in baroreflex and tonic control of sympathetic activity. In this study we examined the neuroanatomical connections between the CVLM area and the pressor region of the C1 cell column located in the paragigantocellularis area (PGCL) and the paraventricular nucleus (PVN) using a combination of retrograde fluorescent tracers and immunohistofluorescence. Rhodamine (50 nl/25% vol) or fluorogold (100 nl/4% vol) was stereotaxically injected into the PGCL region or the PVN of ketamine-xylazine anesthetized male rats through a glass micropipette (tip diameter 10-50 μm) connected to a custom micropressure injection system. Following a 4 day to 2 week recovery period, brain tissue was processed with fluorescein isothiocyanate (FITC) immunohistofluorescence for dopamine-ß-hydroxylase (DBH) and examined under epifluorescence for double labelling. Labelling was quantitated by carefully counting and mapping the location of retrograde and double labelled neurons in each brain section from 1.5 mm caudal to obex to the level of obex. Less than 5% of the noradrenergic neurons comprising the A1 cell column contained retrograde label after an injection into the PGCL region. The few double labelled neurons were scattered along the length of the A1 column with no apparent rostral-caudal organization. However, intense retrograde staining was evident caudal to obex in a column of cells lying medial and dorsal to DBH reactive cells. Heavy retrograde labelling was also observed at several other medullary and hypothalamus sites, including the PVN. In contrast to the A1 cell group, double labelling of approximately 75% of the A5 and A6 cell groups was observed following retrograde tracer injection into the RVLM. Injection of tracer into the PVN resulted in double labelling of approximately 90% of the CVLM noradrenergic cells in the entire rostral-caudal extent of the A1 cell column. A number of retrograde labelled non-noradrenergic neurons were located dorsal and medial to the A1 cell column in the area where neurons projecting rostral to the PGCL region were found. This region located dorsal-medial to the A1 cell group in the CVLM was found in our previous studies (Fed. Proc, vol 46:1243, 1987) to contain bulbospinal neurons. Thus cells in this region give rise to projections to the PGCL pressor region and to the intermediolateral cell column (IML). In conclusion the noradrenergic projection from the A1 region to the PGCL pressor region of the C1 cell column is minor and as such probably does not play a major role in controlling these cells. CVLM innervation of the PGCL arises primarily from non-noradrenergic neurons located near the A1 cell group. Most noradrenergic innervation of the PGCL region appears to arise from the A5 and A6 cell groups. In contrast, A1 cells do give rise to a heavy projection to the PVN. These data support the work of Guyenet et. al., in questioning the role of A1 to C1 projections in controlling sympathetic outflow and arterial pressure. (Supported by HL29033 and NS23423).

227.7 PNMT NEURONS OF THE C1 CELL GROUP WITH PROJECTIONS TO BOTH LOCUS COERULEUS AND SPINAL CORD. J.R. Haselton* & P.G. Guyenet. (SPON: L. Heimer) Dept. of Pharmacology, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

The locus coeruleus (LC) receives a dense innervation from neurons in the retrofacial portion of the nucleus paragigantocellularis lateralis (PGCL). This projection originates in part from phenylethanolamine N-methyltransferase - immunoreactive (PNMT) cells of the C1 group (Guyenet & Young, Brain Res., 406, 171-184). Since most of the PNMT neurons of this rostral region project to the spinal cord (Ross et al., Neurosci. Lett., 25, 257-262), an attempt was made to identify PNMT neurons which send collaterals to LC and the spinal cord (SC). Rats, anesthetized with sodium pentobarbital (50mg/kg, i.p.), received unilateral injections of the tracers Fluorogold (FG; 1ul, 4% in water) in SC and rhodamine-tagged microbeads (RB; 100nl) in the ipsilateral LC. The animals were perfused 10-14 days later, the brains removed and sliced (40um) on a Vibratome. Coronal tissue slices, taken from the caudal pole of the facial nucleus to 1.8 mm caudally, were processed for the immunohistochemical detection of PNMT using an FITC-conjugated secondary antibody. PNMT neurons which send collaterals to both LC and SC were found scattered throughout the C1 cell group. Because FG fluorescence shone through the FITC filters, a quantitative analysis of triple labeled cells could not be achieved. However, unambiguous examples of triple labeled neurons could be identified in those cases in which the FG label was of adequately low intensity. Two other populations of afferents to LC were also observed in the retrofacial PGCL: one group was PNMT immunoreactive but did not project to SC, and the second group was PNMT negative and also did not project to SC. This latter group contained relatively few cells rostrally, but many such cells were found ≥400um posterior to the caudal pole of the facial nucleus.

In rats anesthetized with urethane (1.1g/kg, i.p.) and sodium pentobarbital (25mg/kg, i.v.) the C1 area was explored with recording microelectrodes while stimulating in LC. Numerous antidromically activated single-units were found. The vast majority (46 of 50) of these neurons were silent, and were characteristically observed as negative potentials. Their mean antidromic latency was 8.1 ±0.6ms, which indicates a mean conduction velocity of 2.1m/s assuming a straight line distance of 3.9mm between the stimulation and recording electrodes; the mean threshold was 197.6 ±35.5uA. All four units tested for responsivity to iontophoretically applied glutamate were excited, indicating that the recordings were from neuronal cell bodies. In several cases a latency shift was observed upon changing the stimulus strength, suggesting that at least some of the antidromically evoked potentials were driven from the terminal field of this projection. None of the reticulo-coeruleal neurons shared any characteristics with the sympathoexcitatory neurons previously reported by this laboratory, although they were recorded in close proximity to the latter. Nor could any of the 20 reticulospinal sympathoexcitatory neurons tested be antidromically driven from LC even when very high stimulus currents (up to 5mA) were used.

Several conclusions are drawn from these data. 1) The projection to LC from the retrofacial PGCL appears to arise in part (36%) from PNMT neurons. 2) At least some PNMT neurons have collaterals which project to both LC and SC. 3) The neurons which project to the LC have different electrophysiological properties than the PGCL sympathoexcitatory neurons previously identified in this laboratory.

227.8 ANATOMICAL RELATIONSHIP BETWEEN RESPIRATORY AND CATECHOLAMINE NEURONS IN VENTROLATERAL MEDULLA OF RAT. H.H. Ellenberger, W.-Z. Zhan* and J.L. Feldman, Systems Neurobiology Laboratory, Kinesiology Department, UCLA, Los Angeles, CA 90024-1568.

The ventrolateral medulla is a probable site of central coordination of respiration and circulation, containing neurons implicated in control of each system. The ventral respiratory group (VRG) and the A_1 and C_1 catecholamine groups form longitudinal cell columns extending the length of the ventrolateral medulla. These populations were simultaneously labeled to determine their local organization. VRG neurons were retrogradely labeled by injection of Fluoro-Gold™ (FG) into the phrenic nucleus and/or by injection of Rhodamine-impregnated latex beads (Rh) into the contralateral VRG. The A_1 and C_1 groups were labeled by the immunohisto-chemical staining of cell bodies containing dopamine-β-hydroxylase (DBH) and phenylethanolamine-N-methyltransferase (PNMT), respectively. FG and/or Rh labeled neurons formed a column extending the entire length of the medulla. These VRG cells congregated in two clusters: a dense ventrolateral cluster of multi-polar, triangular and fusiform cell bodies, and a dorsomedial band of fusiform shaped cell bodies. DBH and PNMT labeled cell bodies also formed a continuous column extending the length of the medulla constituting the A_1 and C_1 groups, respectively. Only DBH cells were labeled in the caudal medulla. DBH and PNMT cells were intermingled at an intermediate level, with PNMT cells concentrated medially and DBH cells concentrated laterally. In the rostral medulla only PNMT labeled cells were present. The VRG and the A_1/C_1 groups formed parallel cell columns in the ventrolateral medulla; the VRG being immediately dorsomedial to the A_1/C_1 groups. Some A_1 and C_1 cells were intermingled with labeled VRG cells, but VRG cells were not double-labeled for either DBH or PNMT. The caudal portion of the A_1 group coincided with the level of the caudal VRG. The level of A_1/C_1 overlap coincided with the level of the rostral VRG, and the level of C_1 coincided with the level of the Bötzinger Complex. The proximal relationship between VRG neurons and the A_1/C_1 neurons, with the overlapping of their dendritic fields suggests that local signal processing and interactions among these cells in the ventrolateral medulla is important for the central coordination of respiratory and cardiovascular control. Supported by NIH Grants HL07363, NS24742 and HL37941.

227.9 TOPICAL APPLICATION OF GLYCINE TO THE ROSTRAL VENTROLATERAL MEDULLA CAUSES UNEQUAL DECREASES IN ACTIVITY OF RENAL AND MESENTERIC SYMPATHETIC NERVES. R.D. STEIN, C.P. YARDLEY*, C.L. FITZSIMONS* AND L.C. WEAVER. John P. Robarts Research Institute and Dept. of Physiol., Univ. Western Ontario, London, Canada, and Dept. of Physiol., Michigan St. Univ., E. Lansing, MI.

Transection of the spinal cord causes a significant decrease in activity of renal sympathetic nerves, but no change in discharge of mesenteric sympathetic nerves. These results suggest that ongoing activity of renal nerves is more dependent upon supraspinal excitatory drive than is activity of mesenteric nerves. Experiments were designed to test this hypothesis further and to determine if decreases in nerve activity seen after blocking of excitatory drive from the rostral ventrolateral medulla (RVLM) can be attributed to the "unmasking" of tonically active sympathoinhibitory systems. Experiments were performed on chloralose-anesthetized cats that were artificially respired. Baroreceptor sensitive multifiber activity of 6 mesenteric and 6 renal nerves was recorded using standard electrophysiological techniques. Neurons in the RVLM were inhibited by bilateral topical application of small cotton pellets soaked with glycine (200 mg/ml, pH 7.37 - 7.43). Application of glycine significantly decreased activity of renal nerves from 42 to 10 μV (pooled SE = 6.8) and activity of mesenteric nerves changed from 35 to 27 μV (SE = 2.6). Activity of renal nerves decreased significantly more than that of mesenteric nerves. The neural responses were accompanied by significant decreases in mean arterial pressure (from 123 to 70 mmHg, SE = 6.8) and heart rate (from 248 to 214 beats/min, SE = 5.2). Application of cotton pellets soaked in physiological saline did not affect nerve activity, blood pressure or heart rate. Responses to glycine began within 20 seconds; mesenteric nerve activity was reduced for 5 minutes, renal nerve discharge was decreased for 20 - 30 minutes and blood pressure returned to control after 15 - 20 minutes. Having established the neural and cardiovascular responses to glycine, this procedure was repeated and the spinal cord was transected at the first cervical segment to eliminate potential descending sympathoinhibitory influences. The second application of glycine decreased renal nerve activity from 53 to 13 μV (SE = 9.5) and changed mesenteric nerve activity from 38 to 32 μV (SE = 4.3). Transection of the spinal cord during the glycine response did not alter renal nerve activity, whereas discharge of mesenteric nerves was significantly increased (32 to 45 μV, SE = 4.3). These findings indicate that tonic excitatory drive from the RVLM affects renal but not mesenteric sympathetic outflow. The small decrease in mesenteric nerve activity seen after blockade of excitatory drive may be attributed to tonically active sympathoinhibitory systems. Supported by NIH, HL21436.

227.10 EVIDENCE THAT TONIC EXCITATORY DRIVE FROM THE ROSTRAL VENTROLATERAL MEDULLA IS NOT UNIFORMLY DISTRIBUTED TO RENAL AND MESENTERIC NERVES. C.P. Yardley,* R.D. Stein, C.L. Fitzsimons* and L.C. Weaver. John P. Robarts Research Inst. and Dept. of Physiol., Univ. West. Ont., London, Canada, and Dept. of Physiol., Mich. St. Univ., E. Lansing, MI.

The rostral ventrolateral medulla (RVLM) is a region crucial for the maintenance of basal levels of arterial blood pressure. Whether the spontaneous activity of neurons in this region is uniformly directed to all sympathetic nerves maintaining vasomotor tone, or preferentially distributed to nerves innervating certain vascular beds, has yet to be elucidated. These alternatives were investigated by microinjecting 0.5-1.0 μl of the inhibitory amino acid glycine, bilaterally into the RVLM of chloralose-anesthetised cats via a cannula electrode while recording blood presure, heart-rate, renal (RNA) and mesenteric nerve activity (MNA). These two sympathetic nerves may not be dependent to the same degree upon supraspinal drive for basal discharge (Stein, Hayner and Weaver, Fed. Proc. 44:1726, 1985). Electrical stimulation of the sites in the RVLM prior to microinjection always elicited increases in blood pressure and activity of both nerves. Five min after the microinjection of glycine blood pressure decreased significantly from 113 to 90 mmHg (pooled SE=2.9) in all 6 cats. Heart-rate was not significantly reduced. Simultaneously, RNA decreased significantly from 42 to 28 μV (SE=2.8). In contrast, the small variation in MNA, 22 to 18 μV (SE=1.3), was not significant. In 4 of 6 cats the depressor response was preceded by an increase in blood pressure from 112 to 174 mmHg, an increase in MNA and variable changes in RNA. Such variable changes in RNA may have been due in part to secondary effects of baroreceptor activation. The early responses lasted 1-4 min and were always followed by a depressor response. The responses to glycine were not due to the volume of injection, as microinjection of 1.0 μl of saline into the same site failed to evoke significant changes in blood pressure or nerve activity. Neither was the glycine acting on neurons in a depressor region near the RVLM as kainic acid microinjected (1.0 μl) into the same region elicited large increases in blood pressure accompanied by increases in MNA and variable changes in RNA. Subsequent histology confirmed that the electrode tips were positioned in the well-defined pressor region of the RVLM. These results demonstrate that vasomotor neurons in the RVLM may be driving sympathetic nerves in a non-uniform manner. Such findings also suggest that the maintenance of blood pressure may depend on the activity of some sympathetic nerves more than others, and that in the past, the role of the mesenteric nerves in maintaining BP may have been overstated. Supported by NIH grant, HL21436.

227.11 STUDIES ON THE CAUDAL VASODEPRESSOR AREA OF THE CAT VENTROLATERAL MEDULLA, P.J. Gatti*, I.J. Namath* and R.A. Gillis* (Spon: V.J. Massari). Depts. of Pharmacology, Howard Univ. College of Medicine and Georgetown Univ. Schls. Med. & Dent., Washington, D.C.

We have recently discovered an area in the caudal ventrolateral medulla of the cat from which profound decreases in arterial blood pressure (BP) and heart rate (HR) can be elicited by microinjecting the gamma aminobutyric acid (GABA) receptor antagonist drug bicuculline (Gatti and Gillis, Soc. Neurosci. Abstr. 12:536, 1986). This area is located from obex to 4 mm rostral to obex, 4 mm lateral to the midline and 1-2 mm beneath the ventral surface of the medulla. From these data, it appears that at this site there is a tonically active GABAergic tone responsible for keeping BP and HR elevated since removal of it (with bicuculline) decreases these indices of cardiovascular function. Since GABA at this site tonically keeps BP and HR elevated, it is presumed that this area is sympathoinhibitory. To test this hypothesis, we microinjected the neuroexcitant amino acid, L-glutamic acid, into this same area while monitoring BP and HR in chloralose-anesthetized artificially respired cats. Unilateral microinjection of L-glutamic acid (10-20 nl of a 100 mM solution) using a picospritzer resulted in a transient fall in BP and HR (n = 4, observations = 7). BP fell by 49 ± 7 mmHg ($p < .05$) and HR by 35 ± 11 bpm ($p < .05$). Injection of an equal volume of the saline vehicle did not affect cardiovascular function. L-glutamic acid lowered BP and HR in an area approximately 2-3 mm rostral to obex 4 mm lateral to the midline and 1-2 mm below the ventral surface of the medulla. This area surrounds the rostral portion of the lateral reticular nucleus and overlaps the bicuculline sensitive site. In an attempt to block neuronal conduction in this area and thus reversibly eliminate this sympathoinhibitory area, the local anesthetic lidocaine was microinjected into this site. Unilateral microinjection of lidocaine (40 nl of a 4% soln) raised BP by 38 mmHg and HR by 10 bpm. These data are therefore consistent with the hypothesis that this area which is under tonic GABAergic inhibition is sympathoinhibitory.

227.12 MONOAMINE RELEASE FROM ROSTRAL VENTROLATERAL MEDULLA IS SYNCHRONOUS WITH CHANGING BLOOD PRESSURE. D. Bhaskaran and C.R. Freed, Depts. of Medicine and Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

Many neurons in the rostral ventrolateral medulla (C1) contain phenylethanolamine-N-methyltransferase (PNMT), the enzyme which converts norepinephrine to epinephrine. The C1 region is known to be involved in the maintenance of arterial pressure and may constitute a vasomotor center (Brain Res. 273: 356, 1983). In our laboratory, we have shown how changes in blood pressure can alter neurotransmitter metabolism in nucleus tractus solitarius, dorsal raphe nucleus (Life Sci. 37: 1783, 1985) and locus coeruleus (Neurosci Abst. 61.19, 1985). We have now studied the neurochemical responses in the C1 nucleus which follow drug induced hypertension and hypotension. Male Sprague-Dawley rats weighing 250-350 g were anesthetized with urethane and had carbon paste in vivo electrochemical electrodes placed in C1. Linear sweep voltammetry at a rate of 5 mV/sec every 5 min was performed using a DCV-5 cyclic voltammetry apparatus (Bioanalytical Systems) with semiderivative signal processing. Phenylephrine was infused i.v. to raise blood pressure by 50 mm Hg and nitroprusside was used to lower blood pressure by 20 mm Hg. Phenylephrine-induced hypertension reduced the catechol peak by -25 + 6% while the indole peak increased by 40 + 8%. Nitroprusside-induced hypotension produced reciprocal results. During hypotension there was an increase in the catechol peak (18 + 5%) and a reduction in the indole peak (-20 + 7%). Interestingly, this is the only nucleus we have examined in which the neurochemical responses to hypotension were the reciprocal of those seen for hypertension. Pharmacological studies with inhibitors of catechol synthesis and catabolism including a-methylparatyrosine (tyrosine hydroxylase), fusaric acid (dopamine-B-hydroxylase), pargyline (monoamine oxidase), and LY134046 (PNMT) showed that the signal measured in that nucleus was likely to be epinephrine with a possible contribution by norepinephrine. The same experimental protocol was used to study the C1 area in Wistar spontaneously hypertensive (SHR) and Wistar-Kyoto normotensive (WKY) rats with findings similar to those observed in Sprague-Dawley animals. These results contrast with our observations in nucleus tractus solitarius (Neurosci. Abst. 114.9, 1986) in which each strain (SHR, WKY, and Sprague-Dawley) showed different changes in neurochemical profiles during changes in blood pressure. The present results show that catechol and indole metabolism in the C1 nucleus is closely related to the direction and magnitude of blood pressure change. Because similar changes are observed across different genetic strains, it is likely that the neurochemical responses reflect basic relationships between blood pressure and neurotransmitter utilization.

227.13 **THE VASODEPRESSOR RESPONSE TO CLONIDINE IS MEDIATED BY IMIDAZOLE AND NOT α_2-ADRENERGIC RECEPTORS IN THE ROSTRAL VENTROLATERAL MEDULLA.** *D.J. Reis, P. Ernsberger, R. Giuliano, R. Willette, and A.R. Granata.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Clonidine, an imidazol(in)e, acts within the ventrolateral medulla (VLM) to lower arterial pressure (AP). It is widely assumed that clonidine acts as an α_2-adrenergic agonist. However, in the VLM clonidine binds not only to α_2-receptors but also to imidazole sites which are distinct from both adrenergic and histaminergic receptors (Ernsberger et al., *Eur. J. Pharmacol.* 134:1, 1987). Furthermore, selective blockade of α_2-receptors in the C1 area of the VLM fails to reverse the hypotensive effect of clonidine applied in the same region (Willette et al, *Fed. Proc.* 46:1460, 1987). We sought to determine whether vasodepressor responses correlate with actions on imidazole or on α_2-receptors in the VLM. A series of compounds structurally-related to clondine were tested: (a) *in vitro* to measure binding affinity at imidazole and α_2 sites, and (b) *in vivo* to establish vasodepressor potency upon microinjection into the C1 area of the rostral VLM. Affinity at imidazole sites was defined as the IC_{50} at binding sites in bovine VLM membranes labeled by the high-affinity clonidine analog ^{3}H-p-aminoclonidine (^{3}H-PAC; 1 nM) in the presence of 10 µM norepinephrine to mask α_2-receptors. Affinity at α_2-receptors was defined as the IC_{50} at ^{3}H-PAC binding sites in bovine frontal cortex membranes, which lack imidazole sites. Vasodepressor potency was defined as the maximum fall in AP elicited by microinjection of the test compound (1 nmol in 50 nl) into the C1 area of the rostral VLM in a male rat anesthetized with urethane (1 g/kg, i.p.), paralyzed, and artificially ventillated.

Clonidine exhibited high affinity at both imidazole and α_2-receptors (IC_{50} = 6 nM for both) and elicited a potent depressor response (40 mmHg). Guanabenz failed to bind to imidazole sites and lowered AP only slightly (10 mmHg), although it had a higher affinity at α_2-receptors than did clonidine (IC_{50} = 3 nM). Norepinephrine and phenylephrine also failed to bind to imidazole sites and elicited little or no change in AP, despite high α_2-affinity (IC_{50} = 122 and 400 nM, respectively). Naphazoline was equipotent with clonidine at α_2-receptors (IC_{50} = 8 nM) but over 40-fold less potent at imidazole sites, and elicited a much smaller fall in AP (6 mmHg). Cimetidine failed to bind to α_2-receptors but exhibited high affinity at imidazole sites (IC_{50} = 30 nM), and elicited a potent depressor response (29 mmHg). Imidazole-4-acetic acid also lacked α_2 binding activity but did bind to imidazole sites with moderate affinity (IC_{50} = 560 nM) and elicited a moderate depressor response (13 mmHg). Vasodepressor potency was strongly correlated with affinity at imidazole sites ($r = 0.937$, $n = 4$) but not with α_2-affinity ($r = 0.002$, $n = 3$). We conclude that stimulation of imidazole and not α_2-receptors mediates depressor activity among clonidine-like compounds. An imidazole receptor in the C1 area of the VLM may participate in the vasodepressor response to clonidine. An endogenous clonidine-displacing substance (CDS), which is the putative natural ligand of these receptors (Ernsberger et al., *J Hypertension* 4(Suppl. 5):S109, 1986), may participate in cardiovascular control.

BRAIN METABOLISM II

228.1 CEREBRAL PERFUSION STUDIES WITH CONTRAST ENHANCED MRI AT 4.7 TESLA. B. Kaplan*, T.A. Kent*, M. Quast*, E. Amparo*, A. Suttle*, H. Eisenberg. Depts. of Neurology, Psychiatry, Pharmacology, Division of Neurosurgery, and Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX.

We have been interested in developing techniques to noninvasively measure cerebral perfusion using paramagnetic contrast agents and magnetic resonance imaging (MRI). Gd-DTPA shortens T1 relaxation times. When conjugated to albumin, Gd-DTPA remains in the intravascular space (Schmiedel, et al, Radiology, 1987) and has promise as an indicator of cerebral blood volume (CBV). Unconjugated, it may be useful as an indicator of blood:brain barrier permeability to moderate sized particles (MW 590) (Kent, et al, JCBF Met, Suppl, in press). In this study, we determined the feasability of measuring regional cerebral ischemia using Gd-DTPA-albumin in anesthetized rats at 4.7 Tesla (GE CSI-II). Cerebral ischemia was produced by bipolar coagulation of both vertebral arteries and then cannulation of a carotid artery. Cerebral blood flow (CBF) was reduced by 30% as determined by radioactive microsphere technique, and CBV was reduced by a similar amount as determined by the ^{51}Cr-EDTA space. There was no histological evidence of infarction. In some cases, both CBF and CBV were increased on the side with carotid occlusion, possibly due to anomalous collaterization. After a baseline MRI to determine T1 (by progressive saturation using a series of five TR's and a 14 msec TE), the Gd-DTPA albumin (.1 ml/kg i.v., 15 Gd-DTPA molecules per ablumin) was injected. In 8 of 11 cases, there was less T1 shortening (approximately 50%) on the occluded side, suggesting reduced CBV, since T1 shortening should be proportional to CBV. In the remainder, there was greater enhancement on the occluded side. In general, these corresponded to the ^{51}Cr-EDTA values. We are attempting to quantitate the CBV by establishing calibration curves of the relationship between T1 shortening and known concentrations of Gd-DTPA-albumin in blood. Preliminary application of these curves to the in-vivo data resulted in calculated CBV of 2-5%. It may also be possible to determine CBF by rapid sequence scanning and determining the rate of enhancement. We are applying these methods to newer superparamagnetic agents and these results will be presented.

228.2 NON-INVASIVE DETERMINATION OF CEREBRAL VENOUS HEMOGLOBIN SATURATION IN THE DOG BY NEAR INFRARED SPECTROSCOPY. M. Ferrari*, J.F. Hartmann*, D.A. Wilson*, D.F. Hanley, and R.J. Traystman. (Spon: K. Kubos). Dept. of Anesthesiology/Critical Care Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Pulse oximetry (PO) provides a non-invasive measure of arterial systemic oxyhemoglobin saturation (SaO_2). However, O_2 dependent organs such as the brain and heart regulate their O_2 delivery independently of changes in arterial O_2 content. Thus, the effects of spontaneous changes in systemic O_2 availability on these organs may not be characterizable by PO. Moreover, PO is restricted to changes occurring in the 80-100% SaO_2 range. Near infrared spectroscopy (NIRS) was developed to monitor changes in tissue hemodynamics and O_2 utilization. However, it is limited to monitoring changes from an uncertain initial state. Derivative NIRS (DNIRS) (Hruschka, W.R. and K.H. Norris, Appl. Spectr. 36:261, 1982) has been extensively applied in agriculture. The technique utilizes the changes in absorption spectra and, potentially, may overcome uncertainties regarding absolute optical density (OD). In this study we evaluated the potential of DNIRS for cerebral venous hemoglobin saturation (SvO_2) measurement using a canine model.

Methods. In 6 barbiturate anesthetized, paralyzed, mechanically ventilated dogs, catheters were placed to collect arterial and superior sagittal sinus (SSS) blood. Two fiber optic bundles from a fast scanning spectrophotometer were affixed firmly to the skull such that the SSS was transilluminated. The breathing mixture was made hypoxic (HH) decrementally and samples of SaO_2 and SvO_2 were determined. A steady state spectrum was recorded at each HH level. The derivatized spectrum was then regressed against the measured SvO_2.

Results. In 4 dogs 40 spectra, with SvO_2 ranging from 1.5-70%, the regression equation $SvO_2 = b_1 + b_2(A_1/A_2) + b_3A_3$ yielded a substantial correlation between the spectral changes and SvO_2 (residuals SD = 3.5; multiple R = .98; $b_1 - b_3$ = regression coefficients; A_1-A_3 = wavelength). In 2 dogs this equation was used to predict SvO_2 in 26 separate spectra of varying HH intensity. The prediction SE was 2.82 and when regressed against sampled SvO_2 yielded an r value of 0.97.

Discussion. The cerebral SvO_2 is directly influenced by the balance between cerebral O_2 delivery and cerebral O_2 uptake. The results of this study indicate that it is possible to build a predictive algorithm for non-invasive SvO_2 measurement in the dog using DNIRS. The small variation encountered in the coefficients describing the relationship suggests that SSS transillumination may also be possible in humans whereby SvO_2 and its changes could be quantified.

228.3 **STRATEGIES FOR THREE-DIMENSIONAL ANALYSIS AND DISPLAY OF HUMAN REGIONAL CEREBRAL BLOOD FLOW.**

D.S. Schlusselberg, W.K. Smith, T.R. Simon*, D.J. Woodward.
Departments of Cell Biology and Radiology, University of Texas Health Science Center at Dallas, Dallas VA Medical Center.

Ongoing studies have been performed to evaluate regional cerebral blood flow (**rCBF**) using the radiopharmaceutical I^{123}-Iodoamphetamine, and Emission Computed Tomography (**ECT**). **ECT** generates images of slices through the brain, with the value of each picture element (*pixel*) corresponding to the relative **rCBF** measured for each volume element (*voxel*). The set of serial contiguous slices are stacked to form a volume consisting of a three-dimensional array of voxels.

The **CARP** system (**C**omputer **A**ided **R**econstruction **P**ackage), developed in the Neuroscience Imaging Laboratory at UTHSCD, includes a volume processor which can manipulate and form images from the three-dimensional array. Objects within the volume can be isolated and compared to other portions of the volume, or to objects extracted from other patient studies. These objects are stored in a hierarchical database, which allows selective transformations to be performed on any defined structure within the volume.

The three-dimensional approach is critical for comparing across studies because of differences in patient positioning, brain size and shape, and amount of total scintigraphic activity. These problems are addressed through the use of three-dimensional translation, rotation, scaling, and non-linear warping of selected objects. The volume processor can generate images which demonstrate local hemispheric activity from any viewing position. Computer generated 3D images of **rCBF** have been found to improve communication to referring physicians in terms of location and extent of abnormal regions, and provide quantitative comparisons which are more precise than subjective evaluation of slice images.

228.4 CEREBRAL BLOOD FLOW AND OXIDATIVE GLYCOLYSIS ARE UNCOUPLED DURING SOMATOSENSORY STIMULATION IN HUMANS. M.E. Raichle, P.T. Fox, and M.A. Mintun*. Departments of Neurology and Radiology and the McDonnell Center for Studies of Higher Brain Function. Washington University School of Medicine, St. Louis, Missouri, USA

Dynamic regional regulation of cerebral blood flow (CBF) by metabolic demand is widely accepted. A recent study (1) reported that physiological increases in neuronal activity (somatosensory stimulation) produced local augmentation of CBF (29%) far in excess of the increase (6%) in cerebral oxygen consumption ($CMRO_2$). As glucose metabolism (CMRGlu) is known to increase with neuronal activity, that study (1) suggested nonoxidative glycolosis as an acute accommodation to increased neuronal work. To test this, we measured CBF and CMRGlu responses to neuronal activation (finger vibration) (1).

Eight paired studies (alternating stimulus side) were performed in four normal volunteers. Each study included 2 CBF scans (resting and stimulated) and 1 CMRGlu scan (stimulated). CBF was measured using an intravenous bolus injection of $H_2{}^{15}O$. CMRGlu was measured using standard ^{18}F-DG methods, with arterial blood samples.

For each study, the zone of maximal activation (parietal cortex) and a control region (frontal cortex) having the same resting CBF were identified from the paried CBF studies. Response magnitudes for CBF and CMRGlu were determined identically, by comparing the parietal and frontal regions in the stimulated state. CBF in the parietal region of interest increased 24% (9 ml/100 gm·min, ± 1 sd; $p < 0.0001$) in agreement with our previous study (1). CMRGlu, however, increased by only 11% (0.8 mg/(100 gm·min), ± 0.2 sd; $p < 0.0025$). This difference in response magnitude was significant ($p < 0.0025$). Comparison of the same regions during stimulation of the ipsilateral hand (the complementary study of each pair) showed no responses for CBF or CMRGlu.

We conclude that neuronal activity increases local blood flow 1 to 3 fold the task-induced local increases in glucose consumption during intense somatosensory stimulation (finger vibration) in humans. Oxygen consumption and glucose consumption, however, are probably coupled both at rest and during acute activation. Whether task-induced increases in local blood flow will exceed local increases in metabolism under other stimulus conditions (e.g. visual) remains to be determined.

228.5 MECHANISTIC PET STUDIES: DEMONSTRATION OF A DEUTERIUM ISOTOPE EFFECT IN THE MAO CATALYZED BINDING OF [^{11}C]L-DEPRENYL IN LIVING BABOON BRAIN. J. S. Fowler*, R. R. MacGregor*, S. L. Dewey, D. J. Schlyer*, J. Logan*, A. P. Wolf* and B. Langstrom* (SPON: P. Brink). Chemistry Department, Brookhaven National Laboratory, Upton, NY 11973 and Institute of Chemistry, University of Uppsala, Box 531, S-751, Uppsala, Sweden

PET is uniquely capable of probing biochemical transformations in the living human and animal body providing that the rate limiting reactions responsible for the concentration of radioactive products in a region of interest can be identifed and characterized.

L-Deprenyl is a suicide inactivator of monoamine oxidase B (MAO B) and is used in the treatment of Parkinson's disease. We have reported the feasibility of using [^{11}C]L-deprenyl to map monoamine oxidase (MAO) in the living human brain (Science 235: 481, 1987). These studies included the demonstration of stereoselectivity and are consistent with the irreversible covalent attachment of the catalytically activated labeled tracer to MAO.

We report here the observation of a significant kinetic isotope effect in the binding of [^{11}C]L-deprenyl to living baboon brain using PET. In these studies, a direct comparison of the brain uptake of [^{11}C]L-deprenyl with [^{11}C]L-deprenyl-α,α-d_2 (N-[^{11}C]methyl-α-methyl-N-2-propynyl-1,1-d_2-benzeneethanamine) was made over the time period 0-90 minutes in three different baboons. For each study a complete arterial plasma curve as well as the amount of unchanged [^{11}C] tracer was measured. Using this information, blood-to-brain influx constants (k_1) were determined for each study (Patlak et al. J. Cereb. Blood Flow Metab. 3:1, 1983). The ratio of k_1(hydrogen):k_1(deuterium) ranged from 1.8 to 2.5 demonstrating that the MAO catalyzed removal of a hydrogen atom from the alpha methylene carbon atom of the propargyl group is rate determining in the mechanism responsible for the retention of L-deprenyl in brain.

Although the deuterium isotope effect has been observed for many substrates and inhibitors of MAO, this is the first example of the in vivo visualization of the deuterium isotope effect with MAO in its native environment demonstrating the power of PET for discriminating kinetic isotope effects in the living body and identifying the specific bond-breaking process which give rise to the PET image.

228.6 LOCAL CEREBRAL GLUCOSE UPTAKE ABNORMALITIES IN PATIENTS WITH MILD CLOSED HEAD INJURY WITH PERSISTING COGNITIVE DEFICITS, DESPITE NORMAL CT AND MRI. M.S. Humayun*, S.K. Presty, N.D. LaFrance*, B. Gordon*, R.F. Dannals*, D. Clough*, J. Links*, H.N. Wagner*, and D.M. Long. Depts. of Neurology, Neurosurgery, and Nuclear Medicine. Johns Hopkins Univ. School of Med., Baltimore, MD 21205

Mild closed head injury (CHI) is often followed by neuropsychologic impairments in recent memory and attention, despite the absence of structural abnormalities shown by CT or MRI. Biomechanical models of CHI (Ommaya et al., Head Injuries: Proc. of the 2nd Chicago Symp. on Neural Trauma 49-75, 1976) predict that the cortical regions in proximity to rough bony protrusions (i.e. temporal and frontal cortices) will suffer greater injury compared to regions covered by smooth surfaces (i.e. occipital cortex). To explore the possibility that CHI may result in glucose metabolism abnormalities, we used the fluorodeoxyglucose (FDG) technique with PET imaging to measure local cerebral glucose uptake (Huang et al., Am. J. Physiol. 238:69-82, 1980) in patients 3-12 months following mild CHI (n=3) and matched controls (n=3). All CHI patients had normal CT, MRI, and EEG and negative drug screens. CHI patients all showed deficits in attention and recent memory on neuropsychologic testing. In order to increase the sensitivity of the PET scan, all subjects were engaged in a computer-based continuous performance task throughout the initial 30 minutes following FDG administration. Local cerebral glucose uptake (LCGU) rates were calculated as ratios of regional activity to mean whole brain activity for each individual. Group comparisons were made using t-tests with $p < .05$ level of significance after Bonferonni correction. Significant differences in LCGU between groups were found in temporal and frontal cortices and the caudate nucleus. The CHI group exhibited decreased LCGU in medial temporal, posterior temporal, and posterior frontal cortices, as well as in the caudate nucleus. LCGU was increased, relative to controls, in the anterior temporal and anterior frontal cortices. There were no significant group differences found in whole brain LCGU. These preliminary results suggest that CHI patients with no structural brain injury show compromised functional activity in neural regions, some of which are consistent with the biomechanical brain injury models. Changes in regional glucose metabolism have been shown to be associated with closed head injury and may contribute to the post-traumatic neuropsychologic deficits.

228.7 **TREATMENT OF INTRACRANIAL ARTERIOVENOUS MALFORMATIONS EVALUATED BY POSITRON EMISSION TOMOGRAPHY**

JL Tyler*, R Leblanc*, J Théron*, A Dagher*, E Meyer*, M Diksic*, AM Hakim*, (Spon: G. Karpati). Montreal Neurological Institute, Montreal, Canada, H3A 2B4.

Positron emission tomography (PET) was performed on 7 patients before and after excision and/or percutaneous embolization of an intracranial arteriovenous malformation (AVM) and the results were compared to data from normal controls. The patient population included 5 males and 2 females with a mean age of 37 years; two AVM's were > 11 cm, three AVM's were 7-11 cm, and two were less than 6 cm in diameter on angiography. Two additional patients with AVM's 6-11 cm in size were each studied on two occasions, one two and one three years apart, without treatment. Parameters measured included cerebral blood flow (CBF), blood volume (CBV), oxygen extraction and utilization (OEF and CMRO2) and glucose utilization (LCMRGl). Five patients underwent attempts at embolization of their AVM, one had surgical resection, and one had both procedures. Initial PET scans showed significant effects of the AVM's on remote cortex when patient data were compared to data from normal controls, with decreased LCMRGl (mean=27µmol/100g/min, S.E.M.=0.3, p<.001), increased CBV (mean=12% brain weight, S.E.M.=0.4, p<.001), and decreased CBF/CBV ratio (mean=5.3, S.E.M.=0.6, p<.005) in remote ipsilateral cortex. Values in the contralateral cortex were at the lower limit of the normal range. These findings imply that the shunting of blood through an AVM has widespread deleterious effects on brain, with oxygen metabolic function being maintained through compensatory mechanisms. Embolization resulting in incomplete long-term obliteration of the AVM did not result in improvement in hemodynamic or metabolic parameters as measured by PET. Surgical treatment resulting in a significant long-term decrease in AVM size was associated with moderate increases in CMRO2 in cortex remote from the AVM. Follow-up of two patients without treatment showed no significant changes in the parameters measured. These data suggest that partial treatment of AVM's may not result in long-term clinical benefit compared to the natural history of the untreated condition.

228.8 FDG/PET SCAN METABOLIC ASYMMETRIES IN ASYMPTOMATIC HIV SEROPOSITIVE SUBJECTS.

R. Duara, L. Resnick*, W.W. Barker*, J.Y. Chang*, J. Herbst*, A. Apicella* and F. Yoshii*. Mount Sinai Medical Center, Miami Beach, FL 33140.

We studied 7 young male homosexual subjects who were completely asymptomatic but HIV seropositive and 10 age-matched male normal volunteers who were HIV seronegative, with resting PET/FDG studies and MRI scans. Mean age and S.D. of the controls was 31.1 ± 9.9 years and of the HIV seropositive subjects was 36.1 ± 6.7 years (p = N.S.).

Mean cerebral metabolic rates for glucose (CMRglc) in the controls was 6.93 ± 2.0 mg/100g/min and in the HIV seropositive subjects was 7.21 ± 1.3 mg/100g/min (p = N.S.). When the regional CMRglc (rCMRglc) values for 24 separate brain lobules were compared no differences between the groups were found. Similarly, the ratio of lobular to mean CMRglc ($r/\bar{x}$) for any lobule was compared and no difference was found between the two groups. However, an index of regional or hemispheric metabolic asymmetry (the unsigned value for [(R-L)/(R+L)/2] showed significant differences between the two groups. For example, the asymmetry index for the whole hemisphere was 0.061 ± 0.035 in HIV seropositives and 0.019 ± 0.018 in the controls ($p < 0.02$); in the prefrontal lobule it was 0.078 ± 0.048 in HIV seropositives and 0.027 ± 0.024 in HIV seronegatives ($p < 0.03$). These results suggested that certain or many regions of the brain in asymptomatic HIV seropositive subjects were significantly asymmetric in either direction (R > L or L > R) when compared to controls. Furthermore, when the asymmetry index in 7 seropositive subjects was individually compared to the mean values for asymmetry in the controls, by the use of Z-scores, it became apparent that the asymmetry was being produced by four of the seven subjects only. The regions showing the major asymmetries in these four subjects were the prefrontal, mid temporal (lateral) and medial temporal regions and the cerebellum (Z scores ranged between 2.24 and 6.5). In conclusion, in HIV seropositive subjects we have studied, no abnormalities in the MRI scans were noted and in the PET scans one half of the subjects had abnormal asymmetry in frontal and temporal regions, indicating probable focal reductions in rCMRglc in these regions on the right or the left sides.

228.9 HUMAN OPIOID ABUSERS SHOW REGIONAL DECREASES IN CEREBRAL GLUCOSE UTILIZATION DURING MORPHINE EUPHORIA.

E.D. London, E. Broussolle, J. Links*, D.F. Wong*, R.F. Dannals*, H.N. Wagner, Jr.*, L.R. Rippetoe*, B. Holicky*, R. Herning*, W.B. Pickworth, F.R. Snyder*, N.G. Cascella*, J.K.T. Toung*, R.A. Margolin*, and J.H. Jaffe*. Neuropharm. Lab., NIDA Addict. Res. Ctr., Baltimore, MD 21224 and Div. Nucl. Med., Johns Hopkins Univ., Baltimore, MD 21205.

The 2-deoxy-D-[1-^{14}C]glucose method allows measurement of the regional cerebral metabolic rate for glucose (rCMRglu), an index of brain function (Sokoloff, L. et al., J. Neurochem., 28: 897, 1977). It has been used to identify brain areas affected by opioids and other abused drugs in rats (London, E. D. et al., Clin. Neuropharmacol., 9, Suppl. 4:208, 1986), and can be applied in human studies, with [^{18}F]fluorodeoxyglucose (FDG) and positron emission tomography (PET) (Phelps, M. E. et al., Ann. Neurol., 6:371, 1979). Due to interest in identifying brain circuits involved in opioid euphoria, we used the PET FDG method in a double-blind, placebo-controlled, crossover study comparing morphine (M) and placebo (P) effects on rCMRglu in men. Subjects were volunteers (21-45 yr) with a history of opioid abuse, but no current drug dependencies except nicotine. In 3 tests before PET, spontaneous EEG was recorded in a 5-min baseline period and for 45 min after M (15 or 30 mg, i.m.) or P. Also recorded were self-reports on a 4-item questionnaire relating to feeling and liking the drug, and a 6-item analogue scale, measuring the strength and quality of the drug effect and the subject's liking for it. Only subjects with positive M responses continued in the study. Positive response criteria included the following: decreased EEG alpha power or frequency or increased theta or delta power, feeling opiate-specific sensations, recognizing M as "dope", and liking it at least slightly. Of the first 13 subjects entering the study, 7 fulfilled the criteria, and underwent 2 PET scans, usually a week apart, with 30 mg M or P given 15 min before FDG (~5 mCi, i.v.), while they were blindfolded and listening to a white noise tape presenting a beep every min. At the sound of each beep, the subject rated his euphoria on a scale of 0-4.

Levels of rCMRglu were measured in 22 areas. M generally decreased rCMRglu, with significant decrements (10-15% P) in 8 brain areas (anterior cingulate cortex, superior & middle frontal gyri, insula, amygdalohippocampal complex, putamen, midbrain, thalamus; Hotelling's $T^2 = 43.234$, $p < .0001$). M did not alter arterial blood gases or pH when FDG was injected, indicating that rCMRglu decreases did not result from hypercapnia. A significant correlation was obtained between temporal pole rCMRglu after M and integrated euphoria scores during the FDG incorporation period ($r = -.80$, $p = .05$). The results indicate that M decreases cerebral oxidative metabolism, and implicate specific neuroanatomical sites as mediators of opioid euphoria.

228.10 PET Study of Frontal Cortical Glucose Metabolic Rate in Schizophrenia

M.S. Buchsbaum*, J. Wu, Psychiatry Dept., Univ. Calif. Irvine, Irvine CA 92717 (Sponsor: R. Wuerker)

Introduction: This study is a preliminary analysis of an ongoing study to replicate the finding of decreased frontal/occipital metabolic activity in schizophrenia. This finding of hypofrontality was first noted in cerebral blood flow studies (Ingvar, 1974) and was subsequently found on PET scan studies by some (Buchsbaum, 1982, 1984) investigators but not by all (Sheppard, 1983). Frontal lobe dysfunction has been hypothesized to play a role in schizophrenic symptomatology.

Methodology: Thirteen patients (11M, 2F age 28 ± 6.7 yrs) who met DSM-III criteria for schizophrenia and eighteen normals (14M, 4F, age 26.2 ± 8.1 yrs) participated. Subjects were given 5 mCi of 18F-2dg and then performed the Continous Performance Test (CPT) for 35 minutes. Subjects were then scanned on CTI Neuroecat IV (FWHM = 7.6 mm). Nine scans parallel to the CM line were obtained. Glucose use was calculated according to the Sokoloff model.

Three slice levels (61%, 41% and 28% of the distance between the canthomeatal line and the vertex of the brain) were chosen for analysis of cortical metabolism. Cortical metabolism was measured by peeling off a 2.2 cm cortical rim from the slice. This rim was divided into four equal quadrants in each hemisphere.

Results: A significant four-way anova [diagnostic group (normals vs schizophrenics) by anteroposterior (4 cortical sectors front to back) by hemisphere (right,left) by level (61%,41%,28%)] was found ($F=2.82$, $p= .04$, d.f. 3,81) which reconfirmed our earlier finding. Exploratory post hoc t-tests showed that schizophrenics had lower relative right frontal lobe, and higher relative occipital lobe and lower right parietal and temporal lobe.

228.11 TEST-RETEST rCMRgl ACTIVITY PATTERNS IN SCHIZOPHRENIC PATIENTS: AN ASSESSMENT OF MEASUREMENT STABILITY. GK THAKER, HH HOLCOMB, CA TAMMINGA, E MATTHEW, H LOATS, B GORDON, J LINKS, R DANNALS and HN WAGNER*. Univ. Md. Psych. Res. Ctr. and Johns Hopkins Hospital, Baltimore, Md. 21205; and Westminster, Md. 21157.

Behavioral dependent changes in regional cerebral metabolic rate of glucose (rCMRgl) can be quantitatively assessed with positron emission tomography (PET). Large inter-individual variations in metabolic activity profiles constitute the principal statistical impediment to PET image analysis. It is, therefore, useful to determine an individual's 'control' rCMRgl profile and the physiological stability of the measurements that determine that profile. Here we describe measurements on four medicated patients with schizophrenia (two women and two men) who were studied with PET twice in similar behavioral conditions. The interscan interval was two days to two weeks. During the initial 30 minute 18F-2DG uptake period, the subjects performed a computer driven visual vigilance task. ROI were measured from the twelve scan planes obtained from each study and plotted. Corresponding images from the two studies were digitally aligned and subtracted from one another. This subtraction method provides a visual representation of pixel-by-pixel differences in rCMRgl. Digital registration with corresponding XCT scans also provided verification of spatial fit between scans. ROI and digital image subtraction analytic methods indicate that medicated, clinically stable patients with schizophrenia appear to have stable, but individually unique, metabolic activity patterns.

228.12 CORTICAL GLUCOSE METABOLIC ASYMMETRIES IN ALZHEIMER'S DISEASE. E.J. Metter, W.H. Riege*, D.E. Kuhl *, D.G. Fujikawa *, G.W. Small (SPON: M.K. Menon). Laboratory of Nuclear Medicine, UCLA School of Medicine, Los Angeles, CA 90024, and Veterans Administration Medical Center, Sepulveda, CA 91343.

Positron emission tomography using (F18)-fluorodeoxyglucose has demonstrated left-right hemispheral and frontal-parietal asymmetries in Alzheimer's disease (AD) patients studied in a resting state. In a previous study of 14 AD patients, we noted that the changes in these two ratios appeared to be independent, and were not found in normal subjects. In this report an additional 30 patients with AD were evaluated (giving a total sample of 44 subjects), to determine whether an association exists between the ratios. A frontal-parietal (F/P) and left right (L/R) ratio were computed for each subject by averaging multiple measures from each region. Normal ranges were determined from 21 age-matched control individuals. For the 44 AD patients, the F/P ratio was larger than normal in 30, while 14 had ratios within the normal range. For the left-right ratio, 14 subjects had higher left than right metabolism, 16 were symmetric and 14 had higher right than left. In this manner six subgroups could be identified. The groups did not differ in the severity of dementia, age, verbal, nonverbal or frontal performance scores. The presence of these prominent asymmetries in AD suggest that major functional changes occur throughout the brain. Previous studies have demonstrated that the left-right differences are associated with differences in visuospatial and language function, but it is unclear what the role of the frontal-parietal asymmetries is in the behavioral changes associated with AD.

INVERTEBRATE LEARNING AND BEHAVIOR III

229.1 DEMONSTRATION OF CLASSICAL CONDITIONING OF EYE WITHDRAWAL IN THE GREEN CRAB. R. D. Feinman and C. I. Abramson*. Department of Biochemistry. SUNY Health Science Center at Brooklyn. Brooklyn, NY 11203.

In the eye withdrawal reflex of the green crab Carcinus maenas aversive stimulation of the anterior portion of the animal causes a rapid reflex retraction of the eye into the carapace. We conditioned eye withdrawal using a 5 s low amplitude vibration to one side of the carapace as a conditioned stimulus (CS). Repeated pairings of this CS with an unconditioned stimulus (US), a 0.5 s puff of air (0.25 psi) to the eye on the same side, resulted in the reliable appearance of the retraction response during CS presentation. We found that there was significantly less responding in control groups subjected to backward conditioning or specifically unpaired presentation of stimuli. We also observed little effect on control animals with presentation of CS alone, US alone or simply time in the apparatus. We subjected 8 experimental animals and 5 control groups of 8 animals each to 100 trials. The number of CS responses of exerimentals reached a plateau after about 60 trials. A summary of total responses:

subject	mean response	SD
paired	48.1	13.2
unpaired	12.3	12.1
backward	11.3	5.4
CS alone	1.1	1.3
US alone	0.4	0.7
blank	0.0	0.0

The paired group was most resistant to extinction as measured by responses to 20 CS alone trials directly following acquisition. We also found some response to the CS in the contralateral eye even though this eye did not respond during training. After 24 hrs rest, the response of paired animals to CS alone presentation was not substantially different from controls, but re-acquisition was dramatically enhanced indicating that there was savings over this period. These results demonstrate that the eye withdrawal reflex can be conditioned in a manner formally identical to classical (Pavlovian) conditioning. The relative simplicity of the underlying neuronal circuit suggests that this may be a useful learning model.

229.2 ASSOCIATIVE AND NON-ASSOCIATIVE LEARNING IN SPINY LOBSTERS: BEHAVIORAL DISCRIMINATION OF ODORANT MIXTURES. J.B. Fine-Levy*, P.C. Daniel*, and C.D. Derby (SPON: D. Edwards). Dept. of Biology, Georgia State University, Atlanta, GA 30303.

We are using the Florida spiny lobster, Panulirus argus, as a behavioral model for the study of quality coding in olfaction, and have developed both a discriminative aversive conditioning paradigm and an habituation paradigm to assay for behavioral discrimination of odorant mixtures. Four artificial mixtures (crab, mullet, oyster, and shrimp) were presented to the animals each at 0.05 mM and 0.5 mM concentrations. These mixtures elicited several types of feeding responses from unconditioned animals. For the aversive conditioning paradigm, twelve lobsters were distributed into four groups of three, each group being trained to avoid both concentrations of one of the mixtures. A total of ten pairings of the aversive stimulus with the conditioned stimulus over five test days was sufficient for associative learning to occur. Following conditioning, changes in responses to the four mixtures were categorized as either active or passive avoidance, and merged to form an index of aversion for each conditioned mixture. Comparisons of these indices indicate that crab mixture and shrimp mixture are perceived as being more similar to each other than to mullet mixture and oyster mixture, while mullet mixture and oyster mixture, though more similar to each other than they are to crab mixture and shrimp mixture, are still perceived to be relatively distinct from each other. Similar results were obtained with the habituation paradigm. A 66-100% decrease in response to the crab mixture was accomplished through 2-min presentations of 5 ml of alternating concentrations (0.05 mM and 0.5 mM) of crab mixture, repeated every five minutes for a total duration of 3 to 3.5 hr. Habituation, measured as relative decrease in response to a stimulus, was greatest to crab mixture (90%), followed by shrimp mixture (65%), oyster mixture (49%), and mullet mixture (47%). The degree of similarities among the mixtures as perceived by the animals is in close parallel with similarities in the overall compositions of the mixtures as indicated by multivariate analyses. Behavioral discriminations of chemical mixtures by these animals, as elucidated by use of these associative and non-associative learning paradigms, may be compared with neurophysiological data (Girardot and Derby, abstract at this meeting) to provide an indication of the type of neural code that allows the animals to perform these discriminations.

(Supported by NINCDS Grant No. NS22225 and a Whitehall Foundation Grant.)

229.3 HABITUATION OF ESCAPE SWIMMING IN TRITONIA APPEARS TO INVOLVE MULTIPLE SITES OF CIRCUIT MODIFICATION. W.N. Frost and P.A. Getting, Dept. of Physiology & Biophysics, Univ. of Iowa, Iowa City, IA 52242.

The neural mechanisms underlying learning and memory are currently being investigated in a number of preparations. Much of this work has concentrated on behaviors such as reflexes. Little is known, however, about the mechanisms underlying modification of certain other types of behaviors, such as rhythmic movements produced by central pattern generators.

In the mollusc Tritonia, noxious epithelial stimuli trigger escape swimming consisting of a series of dorsal/ventral flexions. Abraham and Willows (Com. Behav. Biol., 6:271, 1971) reported that the escape swim undergoes habituation: with repeated stimulation the number of cycles per swim progressively decrements. We are beginning a study of the cellular mechanisms underlying habituation of this behavior.

Our first goal was to characterize the site(s) of plasticity. Habituation was produced by repeated application of a salt solution (150 ul, 4M NaCl, ISI=2 min) to the animal's tail. The number of cycles per swim decremented from an average of 7.3 for the first stimulus to 1.7 by the tenth (n=6). Since this change was a decrement in number of cycles, the habituation was not likely to be due to plasticity in the effector system.

In isolated brain preparations, electrical stimulation of pedal nerves evokes the neural correlate of swimming (a series of coordinated bursts in identified flexion neurons). With repeated electrical stimulation (10 trials, ISI=2 min) the number of burst cycles/swim decreased from an initial level of 5.4 to a final level of 1.9 (n=7). The habituation, therefore, is not likely to be due to receptor adaptation. It appears that a major component of the plasticity underlying habituation was located within the central ganglia.

The synapses made by sensory neurons onto their follower cells show a striking homosynaptic depression (Getting, J. comp. Physiol., 110:271, 1976) and would thus appear to represent one locus of plasticity. Our current studies, however, suggested that at least one additional circuit modification was involved. Behavioral experiments employing stimulation of two body sites with separate receptor populations (head and tail) revealed that habituation showed stimulus site generalization. Animals were made to swim once every 30 min using head stimulation. This interval produced very little habituation. Between two head stimuli a series of 10 stimuli were applied to the tail (ISI=2 min). We found that following habituation to tail stimulation, the response to the next head stimulus was significantly habituated (n=6, $p<0.05$). Experiments with isolated brain preparations, using electrical stimulation of L and R Pedal Nerve 3 in place of different body site stimulation, also led to generalization. A simple explanation for the generalization of habituation was that a second circuit modification had occurred at an interneuronal locus after the convergence of the two sensory pathways.

We conclude that the memory for habituation of the Tritonia swim appears to involve multiple circuit modifications: one involving homosynaptic depression at the first central synapse of the sensory neurons, and a second, interneuronal locus perhaps located within the pattern generator itself. Supported by NS17325 to PAG.

229.4 **CELLULAR ANALYSIS OF THE REINFORCEMENT PATHWAY IN OPERANT CONDITIONING OF HEAD-WAVING IN *APLYSIA*** D.G. Cook & T.J. Carew, Yale University, Department of Psychology, New Haven, CT 06520.

Aplysia can be operantly conditioned to avoid head-waving to one side of their body, if that response is punished by bright light (Cook & Carew, 1986). An important step in the cellular analysis of this operant learning is to identify the neural pathways which mediate reinforcement. In the present study we have examined the role of input from the optic and rhinophore nerves, which are known to be visual pathways in *Aplysia* (Jacklet, 1980).

Using a split-foot preparation, intracellular recordings were made from pedal motor neurons controlling the neck and body wall (Hening et al, 1979). Animals (N=10) received two types of stimuli: Light Trials (30 sec. bright light); and Blank (Control) Trials. Action potentials were recorded 30 sec prior and then during the stimulus period. First, animals received 3 light and 3 blank trials in random order. Then the optic nerve (O.N.) and rhinophore nerve (R.N.) were bilaterally cut and the same procedure was repeated. Prior to nerve cut, light produced a modest increase in firing ($\bar{x}$= 9%). However, following nerve cut, light induced a highly significant increase in firing ($\bar{x}$=40%, $p<.005$). Thus, surprisingly, there was a significant increase in the amount of light-induced excitation of the pedal motor neurons following O.N. and R.N. transection ($p<.01$). This effect was not due to the direct effect of light on the neurons, since subsequent denervation of the CNS abolished the enhancement. These results show: (1) input from the O.N. and R.N. inhibits light-induced excitation of pedal motor neurons; and (2) the excitation unmasked by nerve transection is mediated via extraocular photoreceptors.

In our behavioral experiments light serves as an aversive reinforcer. Our cellular results suggest that input from the eyes and rhinophores actually reduce the effect of light on the head-waving system. Thus, eliminating these pathways should not retard learning; in fact, it may even enhance learning. To test this hypothesis, 3 groups were examined: A Contingent/Cut-Nerve group (N=25); a Contingent/Sham-Operated group (N=25); and a Yoked Control/Sham-Operated group (N=25). Two days after surgery, animals were trained and tested. Contingent/Shams showed significant conditioning ($\bar{x}$[test - baseline]= 26 sec, $p<.05$). Interestingly, the Contingent/Cut-Nerve group also showed significant learning ($p<.01$), with a score ($\bar{x}$=44sec) almost double that of the Contingent/Shams. Yoked/Shams showed no learning.

In summary, our behavioral results confirm cellular observations and suggest that visual input from the eyes and rhinophores is not essential for the operant conditioning, and may in fact retard it. It will now be of interest to assess the functional significance of this suprising result, and to identify the extraocular pathways which mediate reinforcement.

229.5 PSEUDOCONDITIONING, SENSITIZATION AND HABITUATION OF DIRECTIONAL SIPHON RESPONSES IN APLYSIA. M.T. Erickson* and E.T. Walters, Dept.Physiol. & Cell Biol., U.Texas Med.Sch, Houston, TX 77225.

Recently we described qualitatively different defensive siphon responses in Aplysia that aid in directing ink at a site of attack (J.Comp.Physiol.A, 159:339, 1986). Siphon responses to tactile stimulation of the midbody region displayed pseudoconditioning - following strong unconditioned stimuli (US) to the head or tail the responses to midbody test stimulation came to resemble the respective US response. Evidence for some associative specificity with pairing suggested the involvement of pseudoconditioning mechanisms in a form of stimulus-response (S-R) learning (Soc. Neurosci. Abstr. 12:398, 1986).

As a first step in analyzing these forms of learning we have begun a comparative examination of nonassociative plasticity of the directional siphon responses, using an in vitro preparation with a photocell to measure head-type (constricting) and tail-type (flaring) responses, and suction electrodes to stimulate peripheral nerves. In each experiment 20 test stimuli were applied to a peripheral nerve at 60 sec intervals. In some cases a strong US (3 brief trains in 10 sec) was applied to nerves innervating either the head or the tail following the 10th test stimulus. Ten test stimuli were then applied again 1 hr later. Repeated weak test stimuli to head, tail, or midbody nerves caused similar habituation, with the responses falling to about 10% of their initial amplitude by the 20th stimulus, regardless of whether the test response was flaring or constricting. Mean recovery of the habituated responses at 1 hr was only 25% of baseline for tail nerve elicited flaring responses (n=7), 10% for midbody nerve elicited flaring responses (n=5), 70% for midbody nerve constricting responses (n=5), and 25% for head nerve elicited constricting responses (n=6). All test pathways showed short-term sensitization when the US caused the same type of unconditioned response as the test stimulus (n=6,5,6,5, respectively). Under these conditions sensitization at 1 hr was stronger for head or tail test nerves than for midbody test nerves. Pseudoconditioning (defined as the conversion of a constricting response to a flaring response or vice-versa following the tail or head US) was rarely observed using head nerve or tail nerve test pathways. However, midbody nerve elicited constricting responses showed dramatic short-term pseudoconditioning after a tail nerve US, although no pseudoconditioning at 1 hr (n=6). Midbody nerve elicited flaring responses showed weaker short-term pseudoconditioning to a head nerve US, but this pseudoconditioning was still present at 1 hr (n=5). Preliminary data indicate that similar pseudoconditioning can be produced using cutaneous stimuli.

229.6 CENTRAL SUPPRESSION OF DEFENSIVE REFLEXES IN APLYSIA BY NOXIOUS STIMULATION AND BY FACTORS RELEASED FROM BODY WALL. J.K. Krontiris-Litowitz, M.T. Erickson*and E.T. Walters. Dept. of Physiol. & Cell Biol., Univ. Texas Med. Sch., Houston, TX 77225.

Indirect evidence has supported the possibility that noxious stimulation causes suppressive as well as facilitatory effects on defensive reflexes in Aplysia (e.g. Carew, Walters, and Kandel, J. Neurosci. 1:1426, 1981; Goldberg and Lukowiak, J. Neurobiol. 6:395, 1984). To test this possibility further we have examined the effects of conditioning stimulation applied to a contralateral nerve on stable siphon responses elicited by ipsilateral head or tail nerve test stimuli. Whereas moderate intensity conditioning stimuli cause sensitization (Erickson and Walters, this volume), stronger conditioning stimuli (considered noxious because these levels easily exceed the threshold for copious inking) caused clear suppression of the siphon test responses in 9 of 10 preparations. These effects, which in this preparation are probably neurally mediated, display some interesting similarities to reflex suppression described in mammalian models of "stress-induced analgesia".

In the intact animal endocrine signals might also contribute to stress-induced reflex suppression. One set of candidates includes the "trauma factors" which are released into the wash (SBW) collected from noxiously stimulated isolated body wall and into hemolymph from intact stimulated animals. These factors produce body wall contraction and cardioacceleration (Cooper et al. and Krontiris-Litowitz et al., Soc. Neurosci. Abstr., 12:861, 1986). We tested the effects of 10 min bath application of SBW into an isolated well containing the abdominal ganglion on stable gill withdrawal responses elicited by siphon nerve stimulation at 15 min intervals: 23 preparations showed reflex suppression (0-90% of baseline) that recovered at least partially after SBW washout; 6 showed no recovery 30 min after washout; 2 showed no change; and 5 showed weak facilitation (110-140% of baseline). Preliminary evidence suggests that at least some of the suppression is produced by factors with molecular weights between 1000 and 10,000 daltons. Central suppression of the tail withdrawal reflex was also seen in 3 of 6 preparations, but tail withdrawal appeared to be more affected by complicating sensitization (perhaps from the tail pulling against the strain gauge) than gill withdrawal (measured with a photocell). SBW suppression of the gill withdrawal reflex was accompanied by suppression of evoked spike activity in LDG gill motor neurons (6 of 6 cases), in gill motor neuron L7 (5 of 7 cases), and in 6 of 9 unidentified neurons displaying simple excitatory responses to siphon nerve stimulation. We are presently examining effects on LE and VC sensory neurons.

229.7 **ANALYSIS OF THE DEVELOPMENTAL EMERGENCE OF SENSITIZATION IN *APLYSIA* REVEALS AN INHIBITORY EFFECT OF A FACILITATORY STIMULUS.** C.H. Rankin and T.J. Carew, Department of Psychology, Yale Uniersity., New Haven, CT 06520

Previous studies have shown that dishabituation and sensitization, produced by tail shock in the siphon withdrawal reflex in *Aplysia*, emerge as separate processes during development. Moreover, tail shock has been shown to exert an inhibitory effect on the reflex in animals in which sensitization had not yet emerged (Rankin and Carew, 1986, 1987). In these studies a single strong intensity (100 V) tail shock was used. In the present study a range of intensities was used in order to: (1) confirm the developmental separation of dishabituation and sensitization, and (2) to analyze the inhibitory process by examining its interaction with dishabituation.

Animals in early stage 12 were studied. In the first experiment, sensitization was examined in two groups: a Weak Shock group (N=10) received a 3 V tail shock which produced a small contraction and no inking; and a Strong Shock group (N=10) received a 150 V shock, which produced a massive contraction of the entire body and copious inking. To assess sensitization, siphon responses (measured as percent reduction of siphon area) to water-jet stimuli prior to shock were compared to responses following shock. Confirming previous experiments, sensitization was absent in this stage: Weak Shock, $\bar{x}$ pre=40.65, $\bar{x}$ post=37.9; Strong Shock, $\bar{x}$ pre=37.8, $\bar{x}$ post=27.3. In addition, tail shock produced inhibition of the reflex. Interestingly, the inhibition appeared to be greater for strong shock (28% reduction from pre-shock level) compared to weak shock (7% reduction).

We next asked whether inhibition could be revealed by competing it with a facilitatory process (dishabituation) known to exist at this stage. Furthermore, if strong shock produces greater inhibition than weak shock, then dishabituation produced by strong shock should be less than that produced by weak shock. Animals were first habituated (60 stimuli, 3 sec ISI) followed by either the weak (N=10) or the strong (N=10) tail shock. Three more stimuli were then delivered to assess dishabituation. Each group showed significant habituation ($p<.005$). In addition the Weak Shock group exhibited significant dishabituation ($p<.01$). In contrast, the Strong Shock group exhibited no significant dishabituation, consistent with the hypothesis that the strong shock produces sufficient inhibition to block dishabituation.

In conclusion, we have confirmed and extended our previous findings that early in development (1) dishabituation is present, while sensitization is absent; and (2) in the absence of sensitization, an inhibitory process can be revealed. This inhibitory process can be detected both by reflex reduction and by retardation of dishabituation.

229.8 **ANALYSIS OF NON-DECREMENTED EPSPs PRIOR TO THE EMERGENCE OF SENSITIZATION REVEALS AN INHIBITORY PROCESS IN *APLYSIA*.** T.G. Nolen and T.J. Carew. Departments of Psychology and Biology, Yale University, New Haven, CT 06520.

Behavioral studies of the siphon withdrawal reflex of juvenile *Aplysia* have shown that habituation, dishabituation and sensitization emerge according to different developmental timetables, and that prior to the emergence of sensitization, a facilitatory stimulus (tail shock) produces significant reflex inhibition (Rankin and Carew, 1987; and this volume). To explore the cellular basis of this inhibitory process, we have examined the effect of a facilitatory stimulus on afferent input from the siphon, monitored in the identified neuron R2, at different times during development.

Stage 12 of juvenile development was divided into 3 substages: Early, Mid and Late. As an analog of sensitization, we examined heterosynaptic facilitation of non-decremented EPSPs evoked in R2 by brief shocks to the siphon nerve. A brief train of shocks to the right connective (one of the neural paths for the tail input) served as the analog of tail shock. In Late Stage 12, connective stimulation produced significant facilitation of non-decremented EPSPs (N=8, $p<.004$). Likewise, in Mid Stage 12, significant facilitation was observed (N=6, $p<0.031$). However, in Early Stage 12 there was no significant facilitation (N=10, $P>0.4$). Thus there was a significant developmental trend in the emergence of the cellular analog of sensitization ($p<.01$), which paralleled the emergence of behavioral sensitization (Rankin and Carew, 1987).

Since the cellular analog of sensitization emerged between Early and Mid Stage 12, we compared the effects of connective stimulation in these two substages. Whereas the EPSPs in Mid Stage 12 were facilitated above their initial baselines (median= 125%), those in Early Stage 12 were depressed below baseline (median=83%). Thus, there was a significant and opposite effect of connective stimulation in the two substages ($p<.007$), reflecting the transition from inhibition to facilitation.

In conclusion, in Early Stage 12 *Aplysia*, the cellular analog of sensitization was not only absent but, as in the behavior (Rankin and Carew, 1987), significant inhibition was evident. Thus, we have found that tail shock and its analog (connective stimulation) can activate either facilitatory or inhibitory processes in the juvenile CNS, depending upon the stage of development. Because the inhibitory process emerges before the facilitatory process, it can be studied in relative developmental isolation, providing a useful preparation in which to explore the mechanisms underlying these opposite processes, which are known to be triggered in parallel in the adult (Marcus et al, this volume).

229.9 **A QUANTITATIVE ANALYSIS OF THE DEVELOPMENT OF THE CNS IN JUVENILE *APLYSIA*.** D. Cash* and T. J. Carew. Dept. of Psychology, Yale University, New Haven CT, 06520.

Several simple forms of learning emerge during juvenile development in *Aplysia* (Rankin and Carew, 1986, 1987). To analyze the cellular mechanisms underlying this development of learning, it is important to understand basic features of neuronal ontogeny during the juvenile phase. In this study we carried out a systematic analysis of the growth of the CNS by counting all the neurons in all the major central ganglia (buccals, cerebrals, pedals, pleurals, and abdominal) at different stages of juvenile development: Stage 9, 10, 11, Early 12 (12E), Late 12 (12L), and Adult. All ganglia were fixed, sectioned at 10μ, stained with cresyl violet, and scored with a blind procedure.

A striking pattern of neuronal proliferation was observed throughout juvenile development: there was a highly non-linear increase in cell number, with an initial stable phase followed by a dramatic increase during Stage 12. The mean number of neurons in the total CNS per stage was: Stage 9=1058 (N=7); Stage 10=1126 (N=10); Stage 11=1418 (N=10); Stage 12E=2860 (N=10); Stage 12L=7874 (N=2); Adult (50g)=9511 (N=2). Thus there was a highly significant increase in neurons across stages [$F(4,29)=361$, $p<.001$]. However, there were no significant differences between the early stages (9-11,about 40 days) but clear and significant differences among all later stages ($p<.01$ in each case), with the greatest increase in cell number occurring between Stage 12E and 12L(also about 40 days). This same pattern across developmental stages was seen in each of the central ganglia ($p<.001$ in each case). In addition, the relative contribution of each ganglion to the total CNS neurons remained constant throughout the 6 stages, indicating that the basic pattern of non-linear proliferation was reiterated in each of the central ganglia.

In conclusion, our results show that the proliferation of neurons during juvenile development in *Aplysia* is highly non-linear, and that Stage 12 is important for the large-scale addition of neurons in the CNS. The simultaneous increase in each of the CNS ganglia implies the presence of a general developmental signal, and in turn raises the question as to the nature of that signal and the factors which cause it to be triggered. In addition, it is interesting that a specific form of learning, sensitization, also emerges between Early and Late Stage 12 in two independent response systems in *Aplysia*: (1) siphon withdrawal (Rankin and Carew, 1987) and its cellular analog (Nolen and Carew, 1987); and (2) escape locomotion (Stopfer and Carew, 1987). These observations suggest that it may be possible in developing *Aplysia* to relate the emergence of particular forms of learning to the emergence of particular neurons and neural circuits.

229.10 **BEHAVIORAL DISSOCIATION OF DISHABITUATION, SENSITIZATION AND INHIBITION IN THE SIPHON WITHDRAWAL REFLEX OF ADULT *APLYSIA*.** E.A. Marcus, T.G. Nolen, C.H. Rankin and T.J. Carew. Departments of Biology and Psychology, Yale University, New Haven, CT 06520.

Several recent lines of evidence suggest that dishabituation and sensitization in *Aplysia* may be mediated by different mechanisms. Hochner et al (1986) have shown that there are two processes involved in presynaptic facilitation, one acting predominantly at decremented synapses, and the other at non-decremented synapses. In addition, behavioral and cellular developmental studies have shown that dishabituation emerges much earlier than sensitization (Rankin and Carew, 1987; Nolen and Carew, 1987). In the present study we asked whether the behavioral dissociation evident in juvenile *Aplysia* could also be observed in adult animals.

In the first experiment, we varied the intensity of a single shock (1 sec) to the tail. Three groups were run: STRONG (100mA; N=34); INTERMEDIATE (50mA; N=18); and WEAK (2.5mA; N=26). Half the animals in each group received dishabituation training (20 habituating water-jet stimuli to the siphon, followed by shock); the other half received sensitization training (no habituation prior to shock). Animals were tested 1, 10 and 20 min after shock. All shock intensities produced significant dishabituation: WEAK ($p<.025$); INTERMEDIATE ($p<.025$); STRONG ($p<.05$). In contrast, none of the shock intensities produced sensitization; in fact, immediately after shock, reflex depression was observed.

Since sensitization could not be produced by a single shock, we next examined whether it could be produced by repeated shocks. One group (N=10) received a single (50mA) shock; a second group (N=10) received four shocks (2 sec ISI). Sensitization (compared to baseline) was assessed 1, 10 and 20 min later. As before, no sensitization was evident in the single shock group; in fact, significant inhibition was evident (1 and 10 min, $p<.005$). In contrast, the four-shock group first exhibited significant inhibition (1 min, $p<.05$), followed by significant sensitization (20 min, $p<.05$). Thus, whereas a single shock is sufficient to produce dishabituation, multiple shocks of the same intensity are necessary to produce sensitization.

In conclusion, dishabituation, sensitization, and inhibition in the siphon withdrawal reflex can be dissociated in two ways: (1) during development by examining their ontogenetic timetables; and (2) in adults by varying the magnitude of a facilitatory stimulus. In light of the mechanisms known to contribute to the dissociation of dishabituation and sensitization in the adult (Hochner et al, 1986), and the recently described inhibitory processes in this reflex (Belardetti et al, 1987), it will be of interest to examine these and perhaps novel processes as they emerge and are assembled during ontogeny.

229.11 CLASSICAL CONDITIONING OF THE GWR OF APLYSIA AFFECTS THE GILL WITHDRAWAL RESPONSE ELICITED BY DEPOLARIZATION OF CENTRAL MOTOR NEURONS. K.D. Lukowiak and E.Colebrook. Neuroscience Research Group. University of Calgary, Calgary, Alberta Canada T2N 4N1.

The gill withdrawal reflex (GWR) of the in vitro siphon, mantle, gill and abdominal ganglion preparation can be classically conditioned by pairing of a weak tactile stimulus (the conditional stimulus, CS) to the siphon with a strong tactile stimulus (the unconditional stimulus, UCS) to the gill. Initially, the CS does not evoke a GWR but following pairing, the CS comes to elicit a GWR. Conditioning only occurs when the CS is paired with the UCS. Accompanying the behavioral change is a change in the synaptic efficacy between the central siphon sensory neurons and the central gill motor neurons. However, the changes in synaptic efficacy observed at this synapse are not necessary and/or sufficient to explain the observed behavioral changes. Changes must occur at other loci. We hypothesize that such a locus might be distal to the motor neurons. If this hypothesis is correct, then the ability of the gill motor neuron to elicit a gill movement should be altered following classical conditioning. We tested this hypothesis by depolarizing a gill motor neuron (L7 or LDG1) before, during and after classical conditioning training. The cells were depolarized to produce a similar number of action potentials on each test. Two control depolarizations were given at an interstimulus interval of 20 minutes. Following this, each preparation received 10 paired CS-UCS trials (intertrial interval 2 min). The gill motor neuron was then depolarized. The preparations were then rested for 1 hr and then the preparations received 10 more conditioning trials. The motor neuron was again depolarized. This procedure was repeated twice more so that each preparation received 40 paired CS-UCS presentations and was tested on 4 different occasions to determine if the efficacy of the motor neuron to cause a gill movement was altered. We found in initial experiments (n=5) that the gill withdrawal movement produced by depolarization of the motor neuron was significantly increased following classical conditioning in 3 of 5 preparations. In one of the other preparations there was no change and in the fifth preparation the ability of the motor neuron to cause a contraction decreased. In 3 control preparations where the CS and UCS were not paired, the ability of the gill motor neuron to cause a gill movement decreased. Thus, it appears that changes occur distal to the motor neuron during the course of classical conditioning and these changes may play a role in the mediation of associative learning in this preparation.

229.12 OPTICAL MEASUREMENT OF NEURON ACTIVITY DURING THE GILL WITHDRAWAL REFLEX IN APLYSIA. J.-Y. Wu,* D.P. Zecevic, J.A. London, M. Rioult,* and L. B. Cohen. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06510.

Optical measurements were used to obtain an overview of the number and activity of neurons in the Aplysia abdominal ganglion during the gill-withdrawal reflex. The isolated siphon preparation described by Kupfermann et al (1971) was used. The siphon was stimulated with a motor-driven nylon filament. Action potential activity in cell bodies was monitored via a 124 element photodiode array using absorption measurements on ganglia stained with the voltage sensitive dye, NK3041 (nee RH155). Extracellular electrode recordings were made from nerves and connectives and video-tape recordings were made of the gill movements. In recent experiments we used small adults (2 to 5 g) expecting that the reduced light-scattering of ganglia from smaller animals would improve the signal-to-noise ratios of the recordings.

In one preparation we detected activity in 90 neurons during a gill-withdrawal reflex after the preparation had been habituated with 15 mechanical stimuli given at a rate of 1 per minute. When this preparation was sensitized by shocking a connective, we detected activity in 150 neurons during a withdrawal reflex. stimulus.

We do not know how complete this recording was. In an earlier experiment, measurements during gill withdrawals were followed by a stimulation trial where the nerves and connectives were stimulated electrically to try to activate all of the neurons in the ganglion. By counting the number of neurons whose activity could be detected optically in this trial and comparing this with the number of neurons present in the ganglion, 1,100, (Coggeshall, 1967) we obtained a estimate of the completeness of the those recordings (25-40%). With this value we estimated that between 250 and 420 neurons were active during the withdrawal reflex in a sensitized preparation. Thus the neuronal substrate of the Aplysia gill-withdrawal reflex may be very complex. It may be difficult to determine the contribution of any individual neuron or synaptic connection to the total behavior.

229.13 THE CONTRIBUTION OF IDENTIFIED GILL MOTOR NEURONS TO GILL BEHAVIORS IN APLYSIA: MODELS AND NEW DIRECTIONS. J.L. Leonard* and K. Lukowiak (SPON: J.I. Goldberg). Dept. of Zoology, Univ. of Oklahoma, Norman, OK 73019 and Dept. of Medical Physiology, Univ. of Calgary, Calgary, AB T2N 4N1 Canada.

Interest in the response of the gill of Aplysia to tactile stimulation of the siphon (GWR) as a model system for analysis of neuronal mechanisms of learning has been based on the hope that it would be possible to identify the contribution of the CNS neurons to the behavior and to correlate changes in their activity with changes in gill behavior. An early model (Kandel 1979) suggested that PNS neurons make a negligible contribution to the behavior. This implies that CNS neurons are necessary for the GWR and changes in CNS neurons are sufficient to alter behavior. Experimental tests have shown that the CNS is not necessary and the PNS is sufficient for the GWR (Peretz et al. 1976, etc.). CNS pathways may be sufficient to mediate a GWR but this has yet to be demonstrated. Learning studies indicate a poor correspondence between changes in CNS neurons and changes in gill behavior (Lukowiak 1986; Colebrook 1986). Changes in CNS neurons may not be sufficient to alter behavior.

We describe here three alternative models: 1) the Parallel, 2) the Motivational, and 3) the Qualitative model. Under the Parallel model, the CNS and PNS are separate and equal. Either is capable of mediating a complete range of gill behaviors. They interact only at the level of gill muscle and "whoever is talking loudest is boss." This model predicts that the contribution of the CNS can only be identified in the absence of activity in the PNS. In the Motivational model, the CNS acts to alter the probability and/or intensity of gill movement but the type of gill movement made is determined by PNS circuits. The PNS is necessary and sufficient for coordinated gill movements, while CNS neurons may modulate but cannot command coordinated gill movements. The contribution of the CNS will be difficult to identify. The Qualitative model, however, predicts that CNS neurons act to determine the type of gill movement made. That is, a change in the activity of CNS neurons produces a qualitative change in behavior. As part of a test of this last model, we have used a blind procedure to characterize the movements evoked by intracellular stimulation of CNS neurons, in terms of our expanded list of gill Actions (Leonard and Lukowiak 1985). The type of elicited movement is consistent for a particular cell and the addition of Actions with increased stimulation is predictable.

229.14 QUANTITATVE MODELING OF HIGHER-ORDER FEATURES OF CLASSICAL CONDITIONING IN APLYSIA. R.D. Hawkins. Ctr. for Neurobiol. & Behav., Columbia Univ., and NYS Psych. Inst., NY, NY 10032.

Recent studies indicate that a cellular mechanism of classical conditioning of the Aplysia gill- and siphon-withdrawal reflex is an extension of a mechanism underlying sensitization of that reflex (Hawkins et al., 1983; Abrams et al., 1985). This finding suggests that the mechanisms of yet higher forms of learning may similarly be based on the mechanisms of these simple forms of learning. Hawkins and Kandel (1984) illustrated this hypothesis by suggesting how several higher-order features of classical conditioning which are thought to have a cognitive flavor, including second-order conditioning, blocking, and the effect of contingency, could be accounted for by combinations of the cellular processes that underlie habituation, sensitization, and classical conditioning in the basic neural circuit for the gill- and siphon-withdrawal reflex. To test the feasibility of these ideas, I have incorporated them in a quantitative model and performed computer simulations of several of these features of conditioning.

The model is based on known cellular processes and circuitry in Aplysia. The basic circuit includes several sensory neurons (for the CSs and US) which synapse on a facilitator neuron and a motor neuron. The facilitator neuron is assumed to act on all of the terminals of the sensory neurons. Like the single-cell model of Gingrich and Byrne (1987), this model includes several subcellular processes in the sensory neurons: 1) synaptic depression, which I assume is due to long-lasting inactivation of Ca^{2+} channels, 2) presynaptic facilitation, which is thought to be due to cAMP-mediated closure of K^+ channels, leading to spike broadening and enhanced transmitter release (Klein and Kandel, 1980), and 3) activity-dependent presynaptic facilitation, which is thought to be due to priming of the adenylcyclase by Ca^{2+} which enters the sensory cells during spike activity (Hawkins et al., 1983; Walters and Byrne, 1983; Abrams et al., 1985). In addition, firing of the facilitator neuron is assumed to accommodate during prolonged stimulation. Free parameters in the model were adjusted by trial and error so that a single set of parameters would produce a wide range of conditioning phenomena. No attempt has been made to fit empirical data, since some of the behavioral phenomena addressed have not yet been tested in Aplysia.

The model successfully simulates acquisition, extinction, differential conditioning, second-order conditioning, blocking, the effect of contingency (degradation of learning by presentation of unpaired USs or CSs), and latent inhibition. These results demonstrate the feasibility of the ideas incorporated in the model. The validity of those ideas may be tested by recording from the neurons during behavioral conditioning. As a first step in that direction, I have shown that a dissected preparation consisting of the mantle organs and abdominal ganglion undergoes classical conditioning of gill withdrawal (mean increase = 278 $\pm$ 114% following paired training and 45 $\pm$ 36% following unpaired training, $p < .05$). It may now be possible to use this preparation to test the assumptions of the model.

230.1 GENETIC ANALYSIS OF THE ALZHEIMER'S-RELATED AMYLOID BETA PROTEIN GENE. R.E. Tanzi,* E.D. Bird, And R.L. Neve. (Spon: W.F. White) Program in Neuroscience Harvard Medical School; Dept. of Genetics, Children's Hospital; Mailman Res. Ctr., McLean Hospital, Boston and Belmont, MA.

We have isolated multiple cDNAs encoding the Alzheimer's related amyloid beta protein (ABP) gene from fetal brain, fetal eye, and HL60 promyelocytic leukemia cell line cDNA libraries. All three libraries yielded an identical (based on restriction mapping) 1.05 kb EcoRI fragment and an identical 1.6 kb EcoRI piece immediately 5' to the 1.05 kb fragment. In addition, a 1.8 kb EcoRI fragment (also immediately 5' to the 1.05 kb fragment) was isolated from the fetal brain library and was found to have a different restriction map from that of the analogous 1.6 kb piece. The 1.6 kb and 1.8 kb fragments detected identical bands on genomic Southern blots with the exception of an additional 9 kb band picked up with the 1.6 kb fragment and not by the 1.8 kb fragment. This result suggests that the differences in the restriction maps of the two clones may reflect rearrangement, insertion or deletion as opposed to simple base pair differences, perhaps involving differential RNA splicing. This hypothesis is supported by the observation of two RNA bands (3.5 kb and 3.7 kb) revealed by Northern blot analysis with all the ABP cDNAs. Further restriction mapping and sequencing are underway to resolve this possibility.

All of the ABP cDNAs map to chromosome 21, suggesting that amyloid plaques in the brains of elderly Down syndrome (DS, trisomy 21) patients may be due to gene dosage. Northern blot analysis shows a 50% increase in expression of the ABP gene in the DS brains compared to normal controls. To study the possibility of ABP gene duplication in patients with Alzheimer's disease (AD), we identified restriction fragment length polymorphisms (RFLPs) for the ABP cDNAs. Both the 1.6 kb and 1.8 kb clones detect RFLPs with EcoRI, BanI, and RsaI, suggesting that the two fragments reside at the same locus. These RFLPs along with an EcoRI RLFP revealed by the 1.05 kb fragment were used to test brain and lymphocyte DNA samples from normal individuals and patients with AD and DS for 2:1 dosage of ABP gene alleles by Southern blot analysis. A third copy of the ABP gene in an individual heterozygous for an RFLP would double the intensity of one of the two allelic bands comprising the RFLP. Visual inspection of 10 sporadic AD samples tested thus far has revealed no obvious duplication, whereas gene dosage is clearly evident in some DS samples. Further investigation using densitometry to document this result is underway.

230.2 ANALYSIS OF BETA AMYLOID mRNA IN ALZHEIMER'S DISEASE BY *IN SITU* HYBRIDIZATION. M.L. Cohen, T.E. Golde, M.F. Usiak, L.H. Younkin, and S.G. Younkin. Depts. of Pathology and Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

We have employed *in situ* hybridization to determine (1) which cells in the CNS express the beta amyloid (bA) gene and (2) if bA genes are overexpressed in Alzheimer's disease (AD). We focussed our analysis on the nucleus basalis of Meynert (nbM) which is composed of large cholinergic neurons known to degenerate in AD. We hybridized with an antisense bA oligonucleotide (bases 1895-1918 in the A4 region of the bA sequence published by Kang et al., Nature 325:733-736, 1987), an antisense human beta tubulin (bT) oligonucleotide (positive control), and a random sequence oligonucleotide (control for non-specific binding). The 3 probes were 24 bases long with G-C contents of 62-67%. In our initial experiments, probes were tailed with ^{35}S-dATP using terminal deoxynucleotidyl transferase. These probes produced erratic high background signals that were particularly severe in white matter. We circumvented this problem by tailing with ^{125}I-dCTP to activities of over 10^8 cpm/ug. Hybridizations were performed on thaw mounted 12 um cryostat sections cut from tissue blocks that had been rapidly frozen by immersion in isopentane cooled with liquid nitrogen. In each experiment, sections from AD and control cases were processed in parallel and the 3 probes were hybridized to 3 serial sections from each block. Sections were fixed 5 min in paraformaldehyde, treated with acetic anhydride, delipidated, and hybridized overnight at 50 C in 1X SSC, 1 mg/ml salmon sperm DNA, 1 mg/ml tRNA, 10% polyethylene glycol, and 1 nM probe. They were then washed 15 min in 0.2X SSC at 37 C X4, 60 min in 0.2X SSC at room T X2, and dipped twice in water. Sections were air dried, dipped in Kodak NTB-2 emulsion, and grains evaluated after a 4-8 day exposure. Tubulin and bA mRNA were present in large neurons of the cerebral cortex and nbM. Tubulin mRNA was readily detected in glial and endothelial cells, but we have so far been unable to detect bA mRNA in these cell types. Hybridization of the bA probe to nbM sections from 5 control and 5 AD cases well matched for age and postmortem interval yielded an average of 385% more specific grains (grains with bA probe - grains with non-specific probe) over cholinergic somata in AD ($p<0.01$). Parallel hybridization of the bT probe to nbM sections from these same cases yielded an average of 23% fewer specific grains over cholinergic somata in AD. Our finding of increased bA mRNA in a neuronal population degenerating in AD is particularly significant because it has recently been reported that a segment of chromosome 21 bearing the bA gene is duplicated in AD. (Supported by AG-06656 and the AFAR).

230.3 A REGIONAL AND LAMINAR ANALYSIS OF THE AMYLOID-β-PROTEIN mRNA IN THE NEOCORTEX OF NORMAL HUMAN, MONKEY AND ALZHEIMER'S DISEASE BRAINS BY IN SITU HYBRIDIZATION. J.H. Morrison*, D.A. Lewis*, G.A. Higgins*, W.G. Young*, D. Goldgaber**, D.C. Gajdusek**, and M.C. Wilson*. *Research Institute of Scripps Clinic, La Jolla CA 92037 and **NINCDS, Bethesda, Maryland 20892.

Using ^{35}S-labeled RNA probes we have determined that significant regional and laminar specificity exists for the distribution of the amyloid-β-protein mRNA and presumably the amyloid-β-protein that has been strongly implicated in the cellular pathology of Alzheimers' Disease (AD). In situ hybridization results demonstrate that in the prefrontal cortex of normal human the majority of large neurons in II, III, and V express an abundant level of amyloid-β-protein mRNA. Fewer neurons exhibit hybridization to amyloid-β-protein mRNA probes in the primary motor and somatosensory areas, and the signal is particularly low in layers IV and VI in these areas. Primary visual cortex is striking for its very high density of labeled cells in III and V and paucity of cells in the sublaminae of IV. The regional and laminar patterns in monkey are similar to normal human with two exceptions: 1) there is a notable heightened density of labeled cells in deep III and superficial V in monkey whereas the labeled cells are more evenly distributed throughout III and V of normal human and 2) primary visual cortex of monkey has a much lower density of labeled cells than human, particularly in layer III. In addition, extensive regional heterogeneity exists in the monkey temporal lobe. Most regions have a relatively high abundance, except for entorhinal cortex, which appears to have the lowest signal intensity of any temporal region. The AD cases studied thus far are highly variable, but in one well-studied case with a high density of plaques and tangles there is a marked decrease in both cell number and amyloid-β-protein mRNA content per labeled cell in prefrontal cortex as compared to the same region of normal human cortex. This decrease is particularly striking in layer III. We interpret the loss of cells and possibly decreased signal per cell in this case to be a reflection of the degeneration or low viability of the large cells prone to degeneration or tangle formation in layer III of prefrontal cortex in AD.

Some of the regional and laminar distribution patterns of amyloid-β-protein mRNA correlate well with the distribution of plaques and tangles in AD. However, exceptions such as the high density of labeled cells in layers III and V of human primary visual cortex, an area of relatively low density of plaques and tangles in AD, suggest that the presence of high intracellular levels of amyloid-β-protein may be necessary but not sufficient to confer vulnerability on a given cell class in AD.

230.4 QUANTITATIVE IN SITU HYBRIDIZATION SHOWS DIFFERENTIAL EXPRESSION OF AMYLOID-β PROTEIN mRNA WITHIN NEURONS OF THE HIPPOCAMPAL FORMATION IN ALZHEIMER'S DISEASE. G.A. Higgins *[1], D.A. Lewis [1], W.G. Young [1], S. Bahmanyar [2], D. Goldgaber [2], D.C. Gajdusek [2], J.H. Morrison [1] and M.C. Wilson *[1] (SPON: W.C. Weiderholt). [1] Research Institute of Scripps Clinic, La Jolla, CA 92037 and [2] NINCDS, Bethesda, MD 20892.

The hippocampal formation is a primary site for the neuropathological deposition of senile plaques (SP) and neurofibrillary tangles (NFT) in Alzheimer's Disease (AD). Recently, cDNA clones have been isolated to β-amyloid mRNA, whose product forms a major component of SP and possibly NFT. Additionally, the locus encoding β-amyloid protein has been genetically linked to inheritance of familial forms of AD and may be duplicated in sporadic AD.

We have mapped the neuroanatomical distribution of amyloid mRNA in the hippocampal formation of monkey, normal human, and in AD to determine which cells express β-amyloid, and whether this distribution correlates with the pathological desposition of amyloid in AD. In situ hybridization was performed on paraformaldehyde-fixed tissue sections treated with proteinase K and hybridized with an 35S-labelled RNA probe homologous to human β-amyloid mRNA.

Our results show that amyloid mRNA is expressed by neurons at high abundance in both normal and AD hippocampal formation and neocortex, but not in the cerebellum. In the hippocampus proper, β-amyloid transcripts are present at high abundance in pyramidal neurons of CA1, CA2, CA3 and the hilus, and in granule cells of the dentate gyrus. In contrast, expression at lower abundance was observed in neurons of the subicular complex and entorhinal cortex of normal human and monkey hippocampus. Quantitative analysis of cellular optical density showed that these entorhinal and subicular neurons exhibit less than half the hybridization signal of CA3 pyramidal neurons (eg. 48+11.75 versus 126+18.62). However, comparison of these same cell populations in AD suggests that entorhinal and subicular neurons have similar abundance of β-amyloid transcripts as CA pyramidal neurons.

Thus, amyloid β-protein mRNA is expressed widely in divergent neuronal populations of the hippocampal formation, including regions such as CA2 and CA3 which are relatively spared from AD neuropathology. However, the elevated abundance of amyloid mRNA in the subiculum and entorhinal cortex of surviving neurons in AD versus normal brain suggests the possibility that overexpression of the β-amyloid gene in these regions may lead to cell death and pathology in AD. 230.5 STRUCTURE AND EXPRESSION OF AMYLOIDOGENIC GLYCOPROTEIN IN RAT BRAIN: IMPLICATION FOR ALZHEIMER'S DISEASE, B. Shivers, C. Hilbich*, K. Beyreuther*, and P.H. Seeburg*. Center for Molecular Biology, University of Heidelberg, D-6900 Heidelberg, F.R.G.

Amyloid is deposited at characteristic locations in human brains from aged individuals and those with Alzheimer's disease or Down's syndrome. These deposits contain amyloid A4 polypeptide (M_r 4,500) which is derived from a larger glycoprotein (1-3) with the structural characteristics of a cell-surface receptor (1). We have cloned and sequenced the cDNA for the rat amyloidogenic glycoprotein and found it to encode a 695 amino acid glycoprotein sharing a 97% identity with its human homologue. Inspection of the 3 amino acid differences between the region encoding rat and human A4 amyloid polypeptide did not reveal why the human protein is more susceptible than the rat protein to proteolytic events which generate the A4 polypeptide. To examine the expression of this glycoprotein in rat brain, we incubated fixed, frozen sections of adult male rat brain with either amyloidogenic glycoprotein cRNA, or with antisera made against 3 peptide sequences found in the glycoprotein. We discovered that rat amyloidogenic glycoprotein is an abundant and ubiquitious brain protein appearing as patches on neuronal cell membranes. Its highest expression in rat brain occurs in regions (e.g. neocortex, hippocampus, olfactory tubercle) which contain amyloid deposits in humans as well as in some other regions which do not contain amyloid deposits in humans (e.g. cerebellar cortex, thalamus). Since aged rat brains rarely contain amyloid deposits, it appears that elevated levels of expression of this highly conserved glycoprotein alone do not invariably lead to amyloid deposition, focussing our attention on local factors which foster aberrant catabolism of this normally-expressed brain protein. The high abundance and wide distribution of amyloidogenic glycoprotein protein in rat brain as well as its patch-like appearance on neuronal membrane surfaces support a role for this protein in cell-cell contact.

230.6 ANALYSIS OF GENE DOSAGE FOR THE β-AMYLOID PRECURSOR PROTEIN IN NORMAL AGED HUMANS AND PATIENTS WITH ALZHEIMER'S DISEASE. M.B. Podlisny, G. Lee and D.J. Selkoe* (SPON: S. Khoshbin). Center for Neurologic Diseases, Harvard Medical School, Brigham and Women's Hospital, Boston, MA 02115.

The deposition of extracellular amyloid filaments in cortical and meningeal microvessels and in the centers of neuritic plaques is an invariable accompaniment of Alzheimer's disease (AD). Protein chemical and immunochemical analyses of partially purified vascular or plaque core amyloid have shown that a major proteinaceous component of these filaments is a 4.5 kDa hydrophobic protein designated the β-protein. The recent isolation of cloned cDNAs for the β-protein precursor in several laboratories has revealed that the gene is localized to the midportion of the long arm of chromosome 21. This finding provides an explanation for the almost constant development of AD-type amyloid deposits in patients with trisomy 21 on the basis of increased gene dosage. Two studies reporting duplication of a small segment of the long arm of chromosome 21 containing the amyloid β-protein in patients with sporadic AD have recently appeared. It is important to confirm these data in a larger number of patients.

We screened a human brain cDNA library with an oligonucleotide encloding the amyloid β-protein residues 20-29 (phe→gly). Of 7 clones detected, the largest clone (designated β-6) contained a 1.6 kb insert containing bases 849 - 2451 of the full-length β-protein precursor cDNA reported by Kang et al.[1] A 0.95 kb Eco R1 fragment of this insert (encoding amino acids 284 - 600 of the precursor) was used to probe Eco R1 digests of human genomic DNA purified from fresh lymphocytes of 11 normal aged individuals (ages 64-89), 4 patients with trisomy 21 (ages 27-54) and 15 patients with clinically typical AD (ages 62-89). On each Southern blot, β-6 plasmid standards representing 0.5, 1, 2, 4 or 8 gene copies/haploid genome were included to establish gene copy number and to verify linearity of the hybridization signals. Each blot was also probed with a cDNA for human MAP2 (chromosome 2; kindly provided by K. Kosik) which served to control for sample uniformity from lane to lane and whose signal was compared to those from the β-6 probe for a relative assessment of gene dosage. The ratio of β-6/MAP2 hybridization signal in Down's samples was ~1.5 times that in normal individuals. Results of the initial 15 AD samples as well as additional cases will be presented. Ascertaining the frequency at which increased β-protein gene dosage occurs in familial and sporadic AD will determine whether alternative mechanisms for the increased deposition of amyloid proteins in AD need to be invoked.

230.7 α-1-ANTICHYMOTRYPSIN, A SERINE PROTEASE INHIBITOR, IS A COMPONENT OF AMYLOID DEPOSITS IN ALZHEIMER'S DISEASE BRAIN. C. R. Abraham*, D. J. Selkoe and H. Potter, Dept. of Neurobiology, Harvard Med. Sch., and Brigham and Women's Hospital, Boston, MA 02115.

Neuropathological analysis of Alzheimer's disease brains reveals three main characteristic lesions: neurofibrillary tangles, senile plaques and fibrous deposits in cerebral and meningeal blood vessels. The senile plaques contain a rim of degenerating or regenerating neurites and an amyloid core. Similar amyloid is also deposited in the blood vessel walls. The amyloid is ultrastructurally and antigenically different from the filaments that comprise the intracellular neurofibrillary tangles, the former having a 6-10 nm width while the latter are two helical filaments with a periodicity of 160 nm and a width of ~ 20 nm. Senile plaques and vascular deposits are present only in normal aged individuals (humans and other mammals), in Alzheimer's disease, and Down's syndrome, whereas neurofibrillary tangles are found in several other conditions. Thus amyloid deposits are a more specific marker of normal aging and Alzheimer's disease.

We used two approaches — molecular cloning and immunochemical analysis — to identify one of the components of Alzheimer's disease amyloid deposits as the serine protease inhibitor α-1-antichymotrypsin. Antibodies produced against isolated amyloid filaments from postmortem human brain which label amyloid cores in senile plaques and amyloid deposits in blood vessels were used to identify normal liver as expressing large amounts of certain amyloid components. The antiserum was then used to screen a liver λgt11 c-DNA expression library, which yielded three related clones. The 1.5 Kb insert was subcloned in pGEM 4 for sequencing and production of labelled probes. Northern blot analysis revealed a 1.5 Kb message which proved that we have a full-length c-DNA. The largest expression was seen in the liver, but some is also present in normal brain, and perhaps in a higher amount in Alzheimer's disease brain. DNA sequence analysis of these clones showed them to contain the c-DNA coding for α-1-antichymotrypsin, a potent protease inhibitor produced in the liver and present at high concentration in the serum. Antibodies to purified α-1-antichymotrypsin stained the amyloid deposits in Alzheimer's brain, confirming the presence of this protein in the lesions. Models in which the protease inhibitor α-1-antichymotrypsin could play an active role in the development of amyloid deposits in Alzheimer's disease, together with the other known component of the amyloid, the β-protein, will be discussed.

230.8 LOSS OF ALKALINE RIBONUCLEASE INHIBITOR PROTEIN ASSOCIATED WITH ALZHEIMER NEURONAL DEGENERATION. R.E. Majocha, E.M. Sajdel-Sulkowska, A. Rodenrys*, M. Ventosa-Michelman* and C.A. Marotta (SPON: A. Pope). Program in Neuroscience and Department of Psychiatry, Harvard Medical School, McLean Hospital and Massachusetts General Hospital, Boston, MA 02114.

In early studies we first demonstrated that postmortem (pm) control and Alzheimer's Disease (AD) brains yield intact RNA in amounts suitable for in vitro translation and for the preparation of recombinant cDNA libraries that contain cDNAs of identified proteins (see Zain et al, these Proceedings, 1987). We and others observed, however, that the yield of AD RNA is often diminished and the decrease is not solely a result of antemortem hypoxia or pm storage since biopsied cortex from living AD patients also contains reduced neuronal RNA (J. Neurol. Neurosurg. Psych. 44:97 and 49:229). Both transcriptional and degradative factors are under investigation. We have observed that the activity of AD lysosomal acid RNase is increased, total alkaline ribonuclease is unchanged and that the activity regulated by the ribonuclease inhibitor protein (rip) is increased in many cases even in the presence of a reducing agent. We prepared a monoclonal antibody (mab) to human rip to examine whether or not the distribution of the protein bears a relation to the neuronal degeneration seen in AD. In frontal cortex of controls, in addition to some glial staining, a dark reaction product in layer III neurons was localized to dendrites and the cell body. In AD cases there were decreased numbers of darkly stained pyramidal cell bodies, and dendrites were often weakly stained. The mab reacted strongly with astrocytes, which is consistent with the high levels of AD GFAP mRNA we routinely obtain (Zain et al, these Proceedings, 1987). Double staining with the mab and with thioflavin S or with antibodies to paired helical filaments demonstrated the progressive loss of neuronal rip that was replaced by neurofibrillary tangles. The immunocytochemical results indicate that the loss of rip activity previously noted in AD is not entirely related to the oxidation state of the protein. Model studies of others support the concept that the normal in vivo metabolism of RNA involves the combined action of acid and alkaline RNases. Cataldo et al (these Proceedings, 1987), using antibodies to lysosomal markers, demonstrated increased immunoreactivity in layer III neurons. The combined action of lysosomal and non-lysosomal enzymes may act to reduce RNA levels in AD neurons. However, the occasional instability observed for pm AD RNA, as assessed by Northern blots, may result from factors unrelated to the normal degradative pathway. Supported by AG04522.

230.9 ELEVATED PHOSPHORYLATION OF THE M_R 60,000 PROTEIN (P60) IN ALZHEIMER'S DISEASE. T. Saitoh, L.A. Hansen*, G. Cole*, R.D. Terry*, and K.R. Dobkins*. Univ. of California, San Diego, Sch. of Med., Neuroscience Dept., M-024, La Jolla, CA 92093.

M_r 60,000 protein (P60) phosphorylation is elevated in cytosol from Alzheimer brain as compared to control brain (T. Saitoh and K. R. Dobkins, Proc. Natl. Acad. Sci. USA, 83:9764-9767, 1986).

Because reactive fibrous gliosis accompanies neuronal degeneration, any increased level of a biochemical marker in Alzheimer's disease might derive from this gliosis. Accordingly, we studied P60 phosphorylation in brain tissue from Pick's disease and multi-infarct dementia where the degree of gliosis is substantial, but P60 phosphorylation in these diseases was not significantly different from the control. Thus, P60 phosphorylation seems to be specifically elevated in Alzheimer tissue.

We tried to correlate P60 phosphorylation with numbers of neurofibrillary tangles and numbers of neuritic plaques, two indices of the severity of Alzheimer's disease. The more tangles observed, the more P60 phosphorylation. The plot of tangle numbers against P60 phosphorylation gave a linear correlation ($r=0.85$; $P<0.001$). Interestingly, the number of plaques, however, did not have a significant correlation with the degree of P60 phosphorylation suggesting that P60 phosphorylation may be involved in the formation of neurofibrillary tangles. Overphosphorylation is a characteristic of neurofibrillary tangle constituents and, as described below, P60 may be a protein kinase.

We asked if P60 is a component of protein kinase. All protein kinases autophosphate. If P60 is a protein kinase or makes a complex with a kinase, increasing the viscosity of reaction medium should not affect the degree of P60 phosphorylation, although this manipulation decreases P60 phosphorylation if P60 kinase is physically apart from P60. Increasing the reaction viscosity by high sucrose decreased the total phosphorylation, but not P60 phosphorylation, supporting autophosphorylation. Another way to test the association of protein kinase and its substrate is to change the protein concentration in the reaction. If protein kinase is associated with substrate (or part of it), reducing the protein concentration does not affect the relative degree of P60 phosphorylation. The result showed that relative P60 phosphorylation does not depend on the protein concentration of the reaction mix, although total protein phosphorylation decreased as proteins get diluted. Both the viscosity experiment and protein concentration experiment are consistent with P60 being either a kinase or associated with a kinase.

We then tested the metal requirement for P60 phosphorylation and found it to be stimulated two-fold by Mn^{2+}. Tyrosine phosphorylation is known to be stimulated Mn^{2+} and, in fact, P60 is phosphorylated at a tyrosine residue.

230.10 THE TAU1 EPITOPE IS NOT IN THE CARBOXY TERMINUS OF A TAU cDNA FUSION PROTEIN K.S. Kosik,* R. Neve, G. Lee* and L.I. Binder.* (Sponsor: M. Yamamoto). Brigham and Women's Hosp. and Harvard Medical School, Boston, MA 02115 and University of Alabama, Birmingham, AL 35294

The microtubule-associated protein, tau, is the most strongly implicated component of the Alzheimer neurofibrillary tangles. Tau-immunoreactivity is also present in the dystrophic neurites observed in wide regions of the Alzheimer cortical neuropil. Recently, we have isolated a cDNA clone for the human tau gene from a human fetal brain expression library (Neve et al., Mol Brain Res, 1986) and confirmed its identity by sequence homology with a mouse tau cDNA. This tau clone obtained by screening the library with a mouse tau cDNA contains the entire coding region of tau as well as some 3' untranslated message. A second human tau clone was obtained from the same library by screening the library with an affinity-purified tau antibody (Drubin et al., J Cell Biol, 1984). The antibody-selected clone hybridized to the original human tau clone. When the restriction map of the expression clone was compared to that of the full-length clone, it was found that only the carboxy one-third of the tau coding region was contained in the expression clone. The resulting fusion protein was tested on Western blots for its reactivity with a number of different tau antibodies. The antibody designated tau1 (Binder et al., J Cell Biol, 1985) is reactive with all the heterogeneous forms of tau in a number of species including human. However, it reacts with Alzheimer neurofibrillary tangles only after treatment with alkaline phosphatase and is thus considered directed at a phosphatase-sensitive site (Grundke-Iqbal, PNAS, 1986). Tau1 did not react with the fusion protein containing the carboxy one-third of tau. It is therefore unlikely that the tau1 epitope is within this carboxy terminal region. It is, however, possible that the epitope is obscured by the presence of the beta-galactosidase fused to the tau fragment. A polyclonal antibody raised against Alzheimer neurofibrillary tangles did react with the fusion protein, as well as anti-beta-galactosidase, both of which demonstrated a fusion protein of approximately 20 kDa. Two other antibodies did not react with the fusion protein. They were 5E2, a monoclonal antibody raised against fetal tau, and a second polyclonal antibody raised against Alzheimer neurofibrillary tangles with apparent specificity for tau on immunoblots. It is likely that Alzheimer paired helical filaments contain more than a single tau epitope. (Supported by NIH grants AG06601 and NS00835)

230.11 THE EVOLUTION, DISTRIBUTION AND MORPHOLOGY OF TAU IMMUNOREACTIVITY SUGGEST A CEREBROVASCULAR ORIGIN OF DEMENTIA OF THE ALZHEIMER TYPE. STRAIGHT OR TWISTED TUBULE IS A MORE APPROPRIATE NAME THAN PAIRED HELICAL FILAMENT. S. Ch. Papasozomenos. Dept. of Path. and Lab. Med., Univ. of Texas Med. Sch., Houston, TX 77225.

In a prospective study, autopsy and biopsy formalin-fixed tissues were taken from throughout the CNS of 4 patients with Alzheimer's disease (AD), 10 patients with senile dementia of the Alzheimer type (SDAT), 3 demented patients with Down's syndrome (DS) and controls. Two monoclonal antibodies against tau, Tau-1 and Tau-2, an antiserum against GFA protein and the peroxidase-antiperoxidase technique at the light and EM levels were used. Both Tau-1 and Tau-2 stained the neurofibrillary tangles (NFTs), the neurites but not the amyloid in senile plaques (SPs), and swollen neurites scattered in the neuropil. Tau-1 required dephosphorylation of sections prior to immunostaining. Tau-2 stained also astrocytes. The distribution and morphology of tau immunoreactivity was similar in all 3 forms of dementia of the Alzheimer type (DAT), but the rapidity of evolution and the amount were most severe in DS and least severe in SDAT. Tau immunoreactivity was first noted in astrocytes in the amygdala, subiculum, Sommer's sector, the neocortical layer V, basal ganglia, brainstem, pontine nuclei, medulla and cerebellum. Tau-2-positive astrocytes participated in the formation of SPs but GFA-positive reactive astrocytes associated with SPs and in other regions were Tau-2-negative. In neuronal perikarya, tau immunoreactivity first appeared as excessive granules representing stained ribosomes and later as NFTs. In full-blown cases, the most prominent patterns of selective neuronal vulnerability were: a) a horizontal laminating cortical pattern, with layer V containing most of the NFTs and swollen neurites, layers II and III containing most of the SPs, layer I being the least affected, and the depths of sulci being more severely involved than the crests of gyri; b) the primary sensory areas were the least affected neocortical regions; c) the subiculum, CA1 and CA2 were the most and the CA3, CA4 and presubiculum were the least involved regions of the hippocampus; d) SPs were frequently associated with vessels; e) the basomedial region of the amygdala contained the most and the lateral region the least number of SPs; f) cholinergic, noradrenergic, serotonergic and dopaminergic neurons were equally affected; and g) efferent-afferent associations did not correlate with the patterns of vulnerability. Controls were negative.

These findings are best explained by a hypothesis which includes: 1) a diffusible factor that originates from blood vessels and damages both vulnerable neurons and astrocytes, and 2) known patterns of regional brain vascular densities and angio-architecture.

EM immunostaining of formalin-fixed tissues showed that NFTs and swollen neurites were made of mostly straight tubular structures with intensely stained walls, unstained lumens and occasionally a visible protofilamentous substructure with helical arrangement of protofilaments. The relationship between fixation in glutaraldehyde and the number of paired helical filaments is under further investigation. These findings suggest that straight or twisted tubules are a more appropriate name for the filamentous structures that comprise the NFTs than paired helical filaments.

230.12 UBIQUITIN CONJUGATES: A NEW COMPONENT OF ABNORMAL NEURONAL FILAMENTS IN NEURODEGENERATIVE DISEASES. V. Manetto*, P. Gambetti, M. Tabaton*, P. Mulvihill*, V. Fried*, H. Smith*, L. Autilio-Gambetti, G. Perry. Institute of Pathology, Case Western University, Cleveland, OH 44106 and St. Jude Children's Research Hospital, Memphis, TN 38101

A distinctive feature of several neurodegenerative diseases is the presence of neuronal cytoplasmic inclusions. Neurofibrillary tangles (NFT) of Alzheimer disease, Pick bodies (PB) of Pick disease, Lewy bodies (LB) of Parkinson disease and neurofibrillary tangles of Progressive Supranuclear Palsy (NFTPSP) are all inclusions composed primarily of filamentous structures. Although the chemical nature of these inclusions has not yet been established, immunocytochemical studies have shown that all share epitopes with phosphorylated neurofilaments and, except for LB, with tau proteins.

Recently, it has been reported that ubiquitin, a protein involved in non-lysosomal proteolysis and other cell functions, forms stable conjugates with NFT of AD. An alteration in the ubiquitin dependent proteolytic system has been postulated in this condition. In order to test if stable ubiquitin conjugates are unique to AD, we investigated the presence of such conjugates in inclusions characteristic of other neurodegenerative diseases, known to share epitopes and insolubility properties with NFT of AD. Using eight monoclonal antibodies (Mab) directed against different ubiquitin conjugates, we carried out an immunocytochemical study at the light and electromicroscopic level. We found that five of the eight Mabs immunostained all these inclusion and that the filamentous constituents of these inclusions, i.e. the paired helical filaments in NFT of AD, straight filaments in PB and in NFT of PSP, as well as filaments radiating from the core of LB in Parkinson disease, were decorated at the ultrastructural level. No other intracytoplasmic organelles were immunodecorated, indicating that ubiquitin is conjugated with the filamentous components of these inclusions. These findings suggest that the ubiquitin system is involved not only in AD, but also in Parkinson disease and other neurodegenerative diseases. Ubiquitin's role in the formation of these inclusions remains to be elucidated.

Supported by NIH Grants NS14503 and AG 00795.

231.1 **REAL-TIME VIDEO IMAGING OF ELECTRICAL EVENTS IN THE OLFACTORY BULB USING A POTENTIOMETRIC DYE.** J. S. Kauer. Depts. of Neurosurgery and Anatomy and Cell Biology, Tufts-N.E.M.C. Boston. MA. 02111.

Optical recording methods offer the opportunity to observe global responses from neural circuits after a variety of experimental manipulations. The use of diode arrays has permitted analysis of rapidly changing dye-related activity at as many as 144 simultaneous sites. An improvement in spatial resolution was achieved by Blasdel and Salama (Nature 321:579-585, 1986), who used averages of many video frames to image static dye absorption changes related to ocular dominance and orientation columns in monkey striate cortex. In the present paper sequences of real-time video images of changes in a fluorescent voltage-sensitive dye have been generated after a shock to the olfactory nerve (ON). The frame sequences may be displayed as short, animated 'movies' and can thus describe the temporal progression of ensemble activity in identifiable bulbar layers.

Series of 16 sequential, real-time (30 frames/sec) video images (128 x 128 pixels x 8 bits) of fluorescence changes in dye RH414 (kindly provided by Dr. A. Grinwald) were generated after stimulation of the ON. Images were acquired using a Dage Newvicon TV camera, and were digitized and enhanced using computerized processing. The time course of the fluorescence changes correlated well with simultaneously recorded field potentials. Signals were not seen in unstained tissue nor in the absence of electrical stimulation, and were abolished after treatment of the bulb with 10 um. tetrodotoxin. Stimulation of the entire ON elicited widely distributed fluorescence changes, first in the glomerular layer, then within the deeper bulbar layers, and subsequently in the medial olfactory tract. Signals were observed in the contralateral bulb with delays appropriate for activation via centrifugal fibres stimulated by the ipsilateral bulb. Stimulation of widely separated medial and lateral ON fascicles also elicited widespread fluorescence changes in the bulbar layers, suggesting that small ON fascicles have influence over broad regions of the bulbar ciruitry. The onset latency of the fluorescence signals was increased after stimulation of the peripheral fascicles, reflecting the increase in propagation delay.

This study has provided the first global view of the temporal and spatial characteristics of olfactory bulb activity after electrical stimulation. The method holds promise for permitting high resolution analysis of the distribution of potentials generated by physiological, odor stimulation as well as for allowing investigation of global processes in other CNS regions.

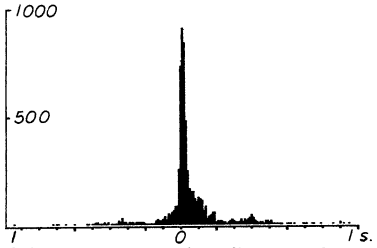
231.2 **THE ALL-INTERVAL PARADIGM AND ANALYSIS OF THE STRUCTURE OF NEURONAL SPIKE TRAINS.** R. Lestienne* and B.L. Strehler* (Sponsor: S.W. Bottger), CNRS, Paris (France) and Molecular Biology, ACBR, U.S.C., Los Angeles, CA., 90089

It has recently been demonstrated that large numbers of precisely replicating patterns of discharge (<1/7000th s. difference between copies) are imbedded in neuronal pulse trains (PNAS, 83,(1986), 9812) and that the capacity to produce such replicas decays is a direct function of the number of pulses present in each copy of the replica (to be published, Brain Res.) The above suggested to us that the generation of such specific patterns results from the facilitation of specific synaptic pathways to a common output neuron and that the decay rate is determined by the probability that a given involved synapse loses its ability to generate one or another pulse in a complex pattern. This in turn implies that the occurence of a given complex and replicating pattern (e.g a triplet of pulses) should be followed by copies of less complex patterns (e.g. doublets) whose intervals correspond to those present in the more complex associated pattern. As shown in the accompanying figure, we found that indeed there is a close association in time between the occurence of replicating triplets and the separate emission of component doublets as seen in outputs from neurons of the monkey visual cortex in response to Heubel and Wiesel stimuli. Doublets are emitted in the immediate vicinity (+/- 20 ms) of both the first and the second copy of the triplet. An interpretation of these findings is as follows: When an appropriate input is presented, specific (coded) patterns of output in time are generated that are decodable by receiving cells that possess appropriate delay line networks for decoding such inputs; and that a temporary record of the decoding of such patterns is stored in specific patterns of synapses of the responding cells, perhaps through Hebb-like selective postsynaptic facilitation. The use of the All-Interval Paradigm makes the detection of such patterns of events possible and capable of being evaluated through appropriate computer analysis.



Histogram of time between onset of the first copy of a replicating triplet and separate doublets identical to those present in such triplets. Abscissa: Time between occurence of triplet and related doublet; Ordinate: Number of doublets/0.01 s. Only triplets whose copies are < 0.5 sec apart are included. (# of triplets: 1482)

231.3 **SEROTONERGIC PRIMARY SENSORY NEURONS FEED BACK TO MOTOR NEURONS IN THE CRAB STOMATOGASTRIC GANGLION.** P.S. Katz and R.M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

We have previously reported that serotonergic muscle receptor cells innervate the gastro-pyloric region of the stomach in crabs (Katz and Harris-Warrick, Neuroscience Abstr., 12:1207, 1986). These Gastro-Pyloric Receptor cells (GPR cells) are the sole source of serotonergic fibers to the stomatogastric ganglion (STG) in the crabs *Cancer irroratus* and *Cancer borealis*. In these crabs there are 2 bilaterally symmetric pairs of GPR cells that innervate stomach muscles and project centrally to the STG and higher ganglia. One cell (GPR1) innervates a muscle (gm8b) that is responsible for closing the lateral teeth of the gastric mill. This muscle is controlled by two motor neurons (MG and LG). The other GPR cell (GPR2) innervates two different muscles (gm9a and cpv3a) that in turn receive motor input from 2 different motor neurons (MG and LP) that are members of the gastric and pyloric Central Pattern Generators (CPGs), respectively.

In this study, we examined the response properties of the GPR cells as well as their effects on the motor neurons. Both cells fire increasing numbers of action potentials in response to increases in muscle tension generated either by imposed stretch of the muscle or by motor neuron stimulation (isometric tension); however their response properties are different. GPR1 responds phasically to increased tension and adapts to repeated muscle stretches. GPR2 responds more tonically, generating continuous spiking at a constant rate if the muscle remains stretched for long periods of time.

Both cells have effects on motor neurons in the STG. GPR1 causes one-for-one EPSPs in the LG motor neuron, but inhibits the MG. We have not yet determined whether these are direct effects or are mediated through other cells. Exciting GPR2, by stretching gm9a, can have modulatory effects, including prolonged activation of the pyloric rhythm. Bath applied serotonin can mimic the activation of the pyloric CPG.

The different response properties of the 2 GPR cells may be related to the cells' different sensory feedback roles. We have shown that GPR1 is phasically active and excites the LG motor neuron in what may be an example of a classical resistance reflex feedback loop. In contrast to a classical reflex, the tonic excitation of GPR2 may function to activate or modulate the pyloric CPG under certain conditions of food entering the pylorus. The two muscles innervated by GPR2 are located at the border between the gastric mill and the pylorus and thus may be in a position to sense the passage of food between the two stomach regions.

In conclusion, we have demonstrated that: 1) Serotonergic input to motor systems can arise from peripheral sensory cells and therefore need not be considered only to descend from higher control centers in motor systems. 2) Proprioceptive feedback can be modulatory in addition to having direct excitatory or inhibitory effects.

231.4 SENSORY INPUT OR SPONTANEOUS CENTRAL RHYTHMICITY CAN "SWITCH" A NEURON FROM ONE NEURAL NETWORK TO ANOTHER. S.L. Hooper and M. Moulins, Lab. de Neuro. et Physiol. Comp., 33120 Arcachon, France

The pyloric (cycle period 1-2 s) and the cardiac sac (CS, period 30-90s) are two different central pattern generators (CPGs) of the stomatogastric nervous system (SNS) of the lobster, Palinurus vulgaris. Brief electrical stimulation of the pln, a SNS sensory nerve, or stretch of the stomach region innervated by the pln, induces 1) a CS CPG burst; 2) excitation of the ventricular dilator neuron (VD) of the pyloric CPG during the CS burst, followed by a long lasting (av. 36s) silence in which the VD no longer fires with pyloric activity; and 3) inhibition during the CS burst of another pyloric neuron, the inferior cardiac (IC), followed by a long lasting phase shift of the IC activity in the pyloric pattern. The same changes in VD and IC activities occur during spontaneous CS activity, and thus the VD functionally "switches" from the pyloric to the cardiac sac CPG when the latter is rhythmically active.

To characterize the cellular bases of these changes we used pharmacological agents and Lucifer Yellow photoinactivation (Miller & Selverston, Science, 1979) to isolate the VD and IC from pyloric synaptic input. Isolated VDs still respond to pln stimulation or CS activity as noted above. The VD is excited during a CS burst by known cardiac sac CPG elements, the IV neurons, but its ensuing silence is due to the long lasting effects of as yet unidentified modulatory neuron(s) that likely act by suppressing the VD's regenerative membrane properties. The effects of pln stimulation or spontaneous CS activity on the IC in the intact pyloric CPG, however, are indirect; isolated ICs are unaffected by pln stimulation or spontaneous CS activity. These effects instead result from an inhibitory synapse from the VD to the IC. During a CS burst (either spontaneous or triggered by pln stimulation), the IC is inhibited because of the VD excitation during CS bursts. After the CS burst, the VD is silent and so no longer inhibits the IC; thus the IC phase changes from that observed during normal pyloric activity, in which the VD participates. This conclusion is supported by photoinactivating only the VD, which results in IC phase shifts similar to those caused by pln stimulation or spontaneous CS activity.

We conclude: 1) Both sensory and rhythmic neural activity can induce a long lasting quiescence in the VD, and since the VD normally participates in the generation of the pyloric pattern, its absence results in a functional rewiring of the pyloric CPG. 2) When thus removed from the pyloric CPG, the VD can express the activity of another CPG, and then uses its synapses to pyloric CPG neurons to modify the pyloric output during cardiac sac CPG bursts. Supported by a NSF/CNRS exchange fellowship to S.L.H.

231.5 POTASSIUM CHANNEL BLOCKADE INDUCES RHYTHMIC ACTIVITY IN A CONDITIONAL BURSTER NEURON IN THE LOBSTER STOMATOGASTRIC GANGLION. R.M. Harris-Warrick and B.R.Johnson , Sect. Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853

The anterior burster (AB) neuron is a conditional burster in the stomatogastric ganglion of the spiny lobster, Panulirus interruptus . When isolated from all synaptic input, it loses its burst-generating abilities. However, unpatterned neuromodulatory input reinitiates rhythmic bursting. This induction of bursting could occur by two general classes of mechanisms: 1) activation of the conductances that support bursting, or 2) removal of inhibitory conductances that prevent the cell from bursting. We have found that several treatments which inhibit potassium currents can uncover bursting in quiescent AB cells, supporting the second mechanism.

The AB cell was isolated in situ from all detectable synaptic input by a sucrose/TTX block of descending inputs from other ganglia and by 6-carboxyfluorescein photoinactivation of the three cells within the STG that synapse on the AB. Addition of 1-2mM 4-aminopyridine (4-AP), which selectively blocks a current similar to IA in STG cells (Hartline et al, Neurosci. Abst. 12 :358,1986), induced regular and rhythmic bursting in quiescent AB cells. Tetraethylammonium chloride (TEA:5-10 mM), which blocks several other potassium channels (but not IA) in STG neurons, also induced bursting; these bursts were of larger amplitude than those seen with 4-AP.

Rhythmic bursting can also be induced by a reduction of calcium entry into quiescent AB cells. This was accomplished by superfusion with 0-Ca2+-high Mg2+ saline or addition of 0.1-0.5 mM Cd2+ or 10 mM Co2+ to the normal saline. With all three treatments, bursting began within 2 min. and was stable for several minutes. However, the bursting mechanism itself depends on calcium entry (Gola and Selverston,J.Comp.Physiol., 145 :191,1981), and with time the cell stopped rhythmic activity. One possible explanation for this induction of bursting by reduced calcium entry is that a tonic calcium-activated potassium conductance contributes to the inhibiton of bursting in the quiescent AB cell. Supporting this hypothesis, we found that apamin, a polypeptide toxin from bee venom which blocks one class of calcium-activated potassium channel, can also induce slow bursting in quiescent AB neurons.

These results suggest that in the non-bursting state of the AB cell, the conductances that underlie bursting are present but their expression is actively blocked by the simultaneous presence of several potassium conductances. Thus, in this cell, the induction of bursting may be more properly described as a disinhibition. Supported by NIH NS17323 and NRSA NS 07859.

231.6 NEURAL CONTROL OF FEEDING IN BASOMMATOPHORAN SNAILS. A.D. Murphy and M.M. Lu.* Department of Biological Sciences, University of Illinois at Chicago, Chicago, IL 60680.

The neural control of feeding has been studied extensively in the basommatophoran snails, Helisoma and Lymnaea. Though feeding behavior in the two snails appears very similar, reports suggest that the neural organization of feeding is fundamentally different (e.g. Benjamin, P.R. in Neural Origin of Rhythmic Movements; Roberts A., & Roberts B., eds., Cambridge Univ. Press, 1983). Comparative studies in our laboratory suggest that some reported differences are more apparent than real, though real differences exist. We have shown in Helisoma that the pattern generator is composed of three subunits, S1,S2, and S3. Each subunit is comprised of a group of interneurons which can generate bursts of action potentials (APs) that evoke characteristic post-sunaptic potentials on identified motoneurons. Bursts of APs can occur sporadically or rhythmically. Subunits can be either phase-linked or independently active, and the relative timing of activity of subunits within a "feeding cycle"is variable, i.e. they can be phase-linked with different temporal relationships. These characteristics allow a variety of qualitatively different motor patterns to be produced.

Morphological and physiological studies suggest that the S1 subunit of Helisoma includes homologs of the N1 interneurons described in Lymnaea by Benjamin. It also includes an apparent homolog of the slow oscillator neuron of Lymnaea and several additional interneurons for which no counterpart in Lymnaea has been described. The S2 subunit corresponds to the "cyberchron network" described by S.B. Kater (Am. Zool. 14, 1017-1036, 1974) and appears to be homologous with the N2 interneurons of Lymnaea. The S3 subunit in Helisoma includes a pair of interneurons located on the dorsal surfaces of the buccal ganglia (BG) adjacent to the commissure. It also includes the VB1 cluster of neurons with small cardioactive peptide B (SCP_B)-like immunoreactivity located on the ventral surfaces of the BG. The S3 subunit is totally different from the N3 interneurons described in Lymnaea. S3 inputs are excitatory to motoneuron B19 and inhibitory to neuron B5 in Helisoma. No comparable inputs have been described onto the apparent homologs, B4 and B2, in Lymnaea. However, immunocytochemical staining with a monoclonal antibody to SCP_B (from A.O.D. Willows) shows a cluster of neurons with SCP_B-like immunoreactivity on the ventral surface of the BG of Lymnaea. They have similar axonal projections to those of the VB1 cluster of Helisoma. This suggests that the missing S3 components that impart tremendous flexibility to Helisoma may exist in Lymnaea and account for variability in its motor patterns that has not previously been addressed. Direct comparisons and new findings in both systems may show that the neural organization of feeding may be fundamentally very similar in the basommatophoran snails.

231.7 EVOLUTION OF BEHAVIOR: AN HOMOLOGOUS PEPTIDERGIC ESCAPE SWIM INTERNEURON IN SWIMMING GASTROPOD NUDIBRANCHS (TRITONIA, HERMISSENDA) AND A RELATED NON-SWIMMING SPECIES (AEOLIDIA). R. D. Longley* and A. J. Longley. Pacific Sciences Institute, P.O. Box 835, Friday Harbor, WA 98250 and Friday Harbor Laboratories, Friday Harbor, WA 98250.

Electrophysiological mechanisms responsible for behavioral change during the evolution of neurons have not been described, in part because of the small number of known neuron homologues with a clearly defined function. We have searched for homologues to an interneuron, C2 in Tritonia diomedea, which is necessary for escape swimming in the semi-intact animal (Taghert, P.H., Willows, A.O.D., J. Comp. Physiol., 123:253, 1978) and for the neural correlates of escape swimming in the isolated ganglia of this species (Lennard, P.R., Getting, P.A., Hume, R.I., J. Neurophysiol., 44:165, 1980).

Using lucifer yellow fills of visually similar cells and immunohistochemical staining of these cells (Longley, R.D., Longley, A.J., Soc. Neurosci. Abstr., 11:943, 1985), we have identified presumptive homologues to C2 in Hermissenda crassicornis and Aeolidia papillosa. We found, in their somata, a unique dual immunoreactivity to an antibody to SCP_B (from Boris Masinovsky and Steve Kempf, Univ. Wash.) and an antibody to FMRFamide (AB-232 from John Bishop, NIH). This homologue, in all three species, belongs to a class of cells with FMRFamide-like immunoreactive axons that enter the pedal commissure contralaterally, an axon pathway not previously reported for C2 (Getting, P.A., Lennard, P.R., Hume, R.I., J. Neurophysiol., 44:151, 1980; Snow, R.W., J. Neurobiol., 13:251, 1982).

Intracellular recording from these cells shows short-latency excitatory monosynaptic input on pedal nerve stimulation, as described for C2 in T. diomedea (ibid.). Both T. diomedea and H. crassicornis also receive long lasting excitatory input and tend to burst, but in A. papillosa, which does not do escape swimming, these inputs do not occur after nerve stimulation. Instead, in A. papillosa we usually see long lasting inhibition.

In the interneuron homologues described here, we find no evidence for a change in neurotransmitter or general morphology, but rather an electrophysiological change in the character (excitatory or inhibitory) of their synaptic input. This could result from a change in synapse number or type and/or a loss or gain of presynaptic neurons. The former possibility, where synaptic contacts vary but neuron number and axon morphology remain similar to an ancestral nervous system, could be a more labile evolutionary mechanism, occurring late in development, that alters a specific behavior without gross modification of a developmental program.

231.8 PROPRIOCEPTIVE INPUT DETERMINES THE TIMING OF ELEVATOR ACTIVITY IN INTACT FLYING LOCUSTS. H. Wolf* and K.G. Pearson, Department of Physiology, University of Alberta, Edmonton, Canada.

In intact, tethered flying locusts intracellular recordings were obtained from flight motoneurons and interneurons. The depolarizations occurring in elevator motoneurons at high wingbeat frequencies were qualitatively different from those generated in deafferented preparations. The main difference was that deafferentation slowed the rising phase of the depolarizations and thus delayed the onset of elevator activity relative to the preceding depressor activity. This resulted in a phase shift of elevator activity in the depressor cycle. The following observations demonstrated that the initial rapid depolarizations in elevator motoneurons of intact animals are produced by phasic input from a group of wing proprioceptors, the hingwing tegulae: 1) hindwing tegula afferents are excited during the wing downstroke and the onset of their activity precedes the onset of depolarizations in elevator motoneurons by a few milliseconds, 2) hindwing tegula afferents make monosynaptic excitatory connections to hindwing elevator motoneurons and strong disynaptic excitatory connections to forewing elevators, 3) removal of the hindwing tegulae slows the rate of depolarization in elevator motoneurons, and 4) electrical stimulation of tegula afferents in animals with tegulae surgically removed restores the initial rapid depolarizations in elevator motoneurons. From these observations we conclude that the timing of the onset of elevator activity depends on phasic input from the hindwing tegulae.

In animals flying with low wingbeat frequencies the depolarizations occurring in elevator motoneurons were characterised by two distinct components. The rapid depolarizations typical of intact flight at high wingbeat frequencies were prolonged by the addition of discrete, late depolarizations resembling the depolarizations occurring in elevator motoneurons of deafferented preparations. We investigated the effect of stimulating the wing stretch receptors on these two distinct depolarizations. Stretch receptor stimulation suppressed the late depolarizations but had no effect on the rapid early depolarizations. These observations demonstrate that in intact flying animals stretch receptor input functions to limit the duration of the depolarizations in elevator motoneurons. The results further indicate that the centrally generated depolarizations produced in deafferented preparations are suppressed by stretch receptor input. Thus at high wingbeat frequencies elevator depolarizations may be generated entirely by phasic input from the tegulae.

231.9 LOCAL INTERACTIONS AMONG INTERNEURONS IN THE LOCUST FLIGHT SYSTEM
R.M. Robertson, Department of Biology, McGill University, 1205 Ave. Dr. Penfield, Montreal, Quebec, H3A 1B1, Canada.

Interneurons in the flight system of the locust are located in the three thoracic ganglia (prothoracic, mesothoracic and metathoracic). The circuit of interconnections between flight interneurons which has been described as contributing to burst generation in the system spans the meso- and metathoracic ganglia, but it has been reported that each of these two ganglia is capable of generating rhythmical motor activity in isolation. Furthermore, a delayed excitatory connection has major importance in the operation of the central circuit and has been modelled as disynaptic disinhibition with tonic and graded release of transmitter at the second synapse (i.e. incorporating a local interaction). Recently I have investigated the synaptic interactions among flight interneurons within single ganglia to determine the extent to which local interactions contribute to rhythmicity. I used a deafferented preparation of *Locusta migratoria* which is capable of expressing the centrally generated flight rhythm. Simultaneous recordings from different flight interneurons were made by penetrating their processes in the neuropil with glass microelectrodes containing Lucifer Yellow.

Delayed excitatory connections were found to have a widespread occurrence. In all cases the properties of the connections were consistent with the idea that each was produced by a similar disinhibitory process. Spikes in some interneurons were followed by short latency ipsps as well as delayed epsps in the same follower neuron to produce inhibitory/excitatory potentials. The relative sizes of the two components were variable and depended on the level of polarization of the follower neuron and other undetermined factors (possibly the level of polarization of the intercalated interneuron). A subthreshold depolarization of interneuron 301 induced a plateau-like potential which outlasted the stimulus. Evidence indicates that this did not result from an intrinsic property of the neuronal membrane but resulted from feedback *via* a local synaptic interaction, thus demonstrating subthreshold graded release of transmitter from the dendritic region of 301. Such a mechanism may contribute to the rapid depolarizing phase of the membrane potential oscillation of 301 during expression of the flight rhythm. The results show that local and graded interactions have a greater role in the operation of the central circuit underlying locust flight than previously suspected.

231.10 **INTERACTIONS BETWEEN CUTANEOUS FLEXION REFLEX PATHWAYS AND SCRATCH CENTRAL PATTERN GENERATORS IN THE TURTLE.**
Scott Currie and Paul S.G. Stein, Department of Biology, Washington University, St. Louis, MO 63130.

An immobilized, low-spinal turtle displays a fictive scratch reflex in response to mechanical stimulation of specific regions of the shell (J. Neurophysiol. 53: 1501-34, 1985). Turtles exhibit three forms of the scratch reflex: the rostral, pocket and caudal scratches. Each form exhibits a rhythmic alternation between hip protractor (flexor) activity and hip retractor (extensor) activity. Cutaneous stimulation of parts of the hindlimb elicits a fictive flexion reflex, characterized by a robust activation of hip protractor nerves (J. Comp. Physiol. 146: 401-9, 1982). In the present study, we elicited fictive flexion reflexes by mechanical or electrical stimulation of the dorsal surface of the foot.

Stimulation of the contralateral foot during a flexion reflex caused a strong crossed inhibition of hip protractor nerve activity and often a weak crossed excitation of the hip retractor nerve. Intracellular recordings from hip protractor motor neurons exhibit a long-lasting depolarization during a flexion reflex (ibid.). We found that contralateral foot stimulation during a flexion reflex caused a transient repolarization of hip protractor motor neurons. This repolarization may be a direct inhibition of motor neurons via the crossed inhibitory pathway, an inhibition of pre-motor interneurons (removed excitation), or a combination of both effects.

Foot stimulation perturbed on-going scratch motor patterns in a phase-dependent manner. Stimulation of the ipsilateral foot during the hip protraction phase of a fictive rostral, pocket or caudal scratch lengthened the duration of hip protractor activity; stimulation during the hip retraction phase shortened the duration of hip retractor activity. Stimulation of the contralateral foot during the hip protraction phase of a rostral or pocket scratch shortened the duration of hip protractor activity; stimulation during the hip retraction phase lengthened the duration of hip retractor activity. Cutaneous stimulation of the ipsi- or contra-lateral foot could cause permanent resets of fictive scratch motor rhythms. These results demonstrate strong central interactions and suggest shared circuitry between cutaneous flexion reflex pathways and scratch central pattern generators. We are currently developing criteria for interneuron identification based on activity during (1) flexion, (2) crossed inhibition of flexion and (3) scratch reflexes.

231.11 SPINAL INTERNEURONS THAT MAY MEDIATE THE CROSSED INHIBITION DURING A MAUTHNER-INITIATED ESCAPE BEHAVIOR IN GOLDFISH.
J.R. Fetcho and D.S. Faber. Dept. Physiol. SUNY at Buffalo, NY 14214.

During the relatively simple motor behavior initiated by the Mauthner cell (M-cell) in goldfish, the M-axon monosynaptically excites ipsilateral motoneurons and descending spinal interneurons, producing an abrupt, forceful bend toward the side of the active M-axon. While the ipsilateral neurons are excited, contralateral motoneurons and descending interneurons are chemically inhibited. Earlier studies, in conjunction with our recent data, provide several predictions about how the inhibition is accomplished: 1) Neither the M-axons nor the inhibited contralateral motoneurons and descending interneurons have crossing processes; therefore the inhibition must be mediated by interneurons that cross the spinal cord; 2) The short latency of the inhibition indicates that the M-axon-inhibitory interneuron connections are probably electrical; and 3) The IPSPs in motoneurons and descending interneurons are most easily inverted by chloride injection near the location of the excitatory inputs from the ipsilateral M-axon, suggesting that the inhibitory contacts are located near the excitatory ones.

We have identified neurons with these expected features in the spinal cord of goldfish. We recorded intracellularly, simultaneously from both M-axons and spinal neurons in anaesthetized, paralyzed goldfish, and found neurons that were excited by the M-axon at very short latency (m=.11 msec, s.d.=.02, N=8) with excitatory postsynaptic potentials that were resistant to fatigue by high frequency stimulation (50 Hz). These neurons received a longer latency (m=.56 msec, s.d.=.16, N=4), Cl^--dependent inhibition from the M-axon contralateral to the one that excited them. Intracellular HRP injections (N=4) show that they have a relatively small cell body located dorsally, above the central canal, and ipsilateral to the excitatory M-axon. A thin process from the cell body runs ventrally to the ipsilateral M-axon where it enlarges, passes dorsal to the M-axon and crosses the spinal cord between the two M-axons. After crossing, it runs longitudinally, parallel to the contralateral M-axon for approximately one segment. Terminal branches of this contralateral process show a striking correspondence with the collaterals of the M-axon that form the excitatory contacts with motoneurons and descending interneurons. Each branch arising from the longitudinal process ramifies distal to the end of a single M-axon collateral, with as many as ten branches from one interneuron associated with an equal number of collaterals. Thus, as predicted, these neurons are electrically coupled to one M-axon, cross the spinal cord, and have terminals in the regions where contralateral neurons receive their excitatory input from the other M-axon. Supported by an NIH Postdoctoral Fellowship (JRF) and NIH Grant NS-15335.

231.12 SELF ORGANIZED PATTERN FORMATION IN COORDINATED MOVEMENT BEHAVIOR: THE SYNERGETIC APPROACH.
J.A.S. Kelso*, G. Schöner* and H. Haken* (SPON: Allan J. Nash). Center for Complex Systems, Florida Atlantic University, Boca Raton, FL 33432 and Institute for Theoretical Physics and Synergetics, University of Stuttgart, FRG.

Synchronization, entrainment, frequency- and phase-locking are commonly observed features of neuronal patterns generated by many species [e.g., A. I. Selverston, (1985) Ed. Model neural networks and behavior. Plenum, New York]. Their relation to macroscopic behavioral patterns, however, is less clear. We report the results of joint experimental and theoretical work showing that similar intrinsic patterns can arise also in human multilimb coordination tasks, in a purely self-organized fashion. Such pattern formation may be understood as follows [Kelso, Schöner, Scholz & Haken, (1987) Physica Scripta, 35, 79-87]: 1) movement patterns are characterized by a collective variable, relative phase, which serves as an order parameter [H. Haken (1983) Synergetics: An Introduction, 3rd Edition, Springer, Heidelberg]; 2) stable patterns are modelled as attractors for the collective variable; 3) the stability and stationarity of the patterns is measured and interpreted in terms of the stochastic dynamics of relative phase with certain time scales relations; 4) switching among patterns is due to loss of stability of the attractor (a nonequilibrium phase transition); 5) the switching process is governed by the stochastic dynamics of relative phase; 6) the dynamics of the collective variable are derived from a cooperative (nonlinear) coupling among the individual components, thus linking levels of observation. Schoner and Kelso [Biol. Cybernetics, submitted] have elaborated this approach to include recent observations on environmentally elicited and learned movement patterns. Again, these patterns can be derived from the component level, analytically and computationally. We conjecture that our approach has the potential to relate macroscopic behavioral levels to more microscopic physiological levels (e.g., neural networks), by linking functionally specific dynamics at different scales of analysis.

231.13 SYNERGETIC THEORY OF MOVEMENT COORDINATION: RECOGNITION AND LEARNING OF ENVIRONMENTALLY ELICITED PATTERNS. G. Schöner* and J.A.S. Kelso* (SPON: R. K. Berntson). Center for Complex Systems, Florida Atlantic University, Boca Raton, FL 33432.

The synergetic approach to the study of coordination [Kelso & Schöner, In Graham, R. and Wunderlin, A. (Eds.) Lasers and Synergetics, Springer, 1987] is applied to the coordinated rhythmic patterns formed: a) in the continuous presence of environmental information (periodic stimuli specifying a required relative phase); and b) when the periodic stimuli are removed after the patterns have been learned. Using the collective variable, relative phase, the dynamics of these patterns are modelled as arising from the competition between external (environmentally specified) and intrinsic dynamics. The intrinsic dynamics have been derived in earlier work based on observations of phase transitions in movement coordination [Haken, Kelso & Bunz, Biol. Cybern., 51, 347 (1985)]. Recent experimental results on human movement coordination by two groups of investigators are explained and new predictions are presented. The well-documented learning of environmentally specified movement patterns is modelled as a dynamic transformation of external into intrinsic dynamics. The formulation includes the process of pattern recognition as a learned pattern is elicited. Learning and pattern recognition processes are driven by: (1) a match between the learned patterns (as attractive states) and the environment; and (2) a competition among learned patterns. The solutions of the learning model and experimental implications, including a possible phase transition in learning, are presented. The relation of our theory, which is formally related to theories of nonlinear reaction networks by M. Eigen and P. Schuster, [The Hypercycle, Springer-Verlag, Berlin, 1979] to recent neural network models of learning and pattern recognition is discussed.

[Work supported by ONR, AFOSR and NINCDS. G.S. is supported by a Forschungsstipendium of the Deutsche Forschungsgemeinschaft, Bonn, FRG.]

231.14 THE PHASE TRANSITION CHARACTER OF SWITCHING BETWEEN RHYTHMIC PATTERNS OF HUMAN BIMANUAL COORDINATION: TEST OF A DYNAMICAL MODEL. J.P. Scholz*, J.A.S. Kelso* and G. Schoner* (SPON: N. F. Capra). Dept. of Physical Therapy, Georgia State Univ., Atlanta, GA 30303; Center for Complex Systems and Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL 33431

Transitions among patterns of intra- and interlimb coordination are a common feature of animal behavior. Yet little is known about the processes underlying such transitions. Recent work of Kelso and colleagues has addressed this issue in human movement. Principles from the interdisciplinary field of synergetics (Haken, H., Synergetics: An Introduction, Springer, Berlin, 1983) have been employed to develop a detailed stochastic model (Soc. Neurosci Abstr. 385.18, 1986; Schoner, G., Haken, H. & Kelso, J.A.S., Biol. Cybern., 53:247, 1986) of switching between patterns of bimanual coordination. This model provides an analogy between movement transitions and the spontaneous formation of patterns in non-equilibrium systems treated by synergetics, in which stability considerations and self-organizing processes play a decisive role. The research presented here attempted to test specific predictions about the bimanual system's behavior that derive directly from the model, specifically, critical slowing down (CSD) and switching time. Another important prediction of the stochastic model, critical fluctuations, has been addressed elsewhere (Kelso, J.A.S., Scholz, J.P. & Schoner, G., Physics Letters A, 118:279, 1986).

In the present experiment, subjects (N = 5) rhythmically flexed and extended their index fingers in synchrony with a metronome while producing either an in-phase (ϕ = 0 deg) or an out-of-phase (ϕ = 180 deg) pattern of finger coordination. Metronome frequency was increased in 0.2 Hz steps every 10s, 9 times/trial (N = 70). CSD was evaluated by measuring the time taken for the fingers to return to their previous coordinative state (i.e., relaxation time) after a perturbation was administered to the right finger. In all cases, a transition from the out-of-phase to the in-phase pattern (but never in the opposite direction) occurred at a critical value of oscillation frequency. The time taken for the switch to occur was measured from the onset of the transition frequency until attainment of the first stable cycle in the new state (ϕ = 0 deg).

The mean and distribution of the experimental switching times were remarkably similar to those estimated from the stochastic model. Relaxation times increased significantly with frequency (CSD) in the out-of-phase but not the in-phase pattern of finger coordination. Thus, the model and results were self-consistent suggesting that movement transitions can be understood as non-equilibrium phase transitions, and providing supportive evidence for the self-organizational nature of motor pattern generation.

SPINAL CORD AND BRAINSTEM II

232.1 SPINAL NETWORK DEVELOPMENT AND ITS RELATION TO HINDLIMB MOVEMENT: AN *IN VITRO* ELECTROPHYSIOLOGICAL STUDY IN NEONATAL RAT. R. Navarrete, K. Walton and R. Llinas. Dept. Physiol. & Biophys., New York Univ. Med. Sch., 550 First Ave., New York, NY 10016.

Unraveling the factors relevant in governing the development of the nervous system is an essential step toward understanding CNS function. We have approached this problem by focusing on the role of electrical neuronal activity studying the spinal cord (SC) of neonatal rat (P0-P10) using *in vitro* techniques. Previously, we studied motoneuron membrane properties (Fulton & Walton, 1986, J. Physiol. 370,651) and spontaneous oscillations, the latter using a SC brainstem-cerebellum preparation (Walton & Llinas, 1986, IUPS. 16:118). Recently we have investigated the development of lumbar circuits in the contex of motor activity using a hemisected SC-hindlimb preparation. Electromyograms (emg's) and the electrical activity in ventral roots (L4 or L5) and motor nerves were used as measures of motor output. This preparation has allowed intracellular recordings from flexor and extensor motoneurons [identified by their antidromic invasion from common peroneal (c.p.) or tibial (tib.) nerves, respectively]. Some cells were further identified as innervating predominantly slow (soleus) or fast (EDL-TA) muscles. Spontaneous rhythmic activity is present in this preparation as indicated by emg's and corroborated by extracellular ventral root and intracellular motoneuron recordings. These oscillations were readily triggered by dorsal root or by peripheral nerve stimulation. Synaptic potentials were evoked by muscle nerve stimulation. For example, EPSP's were recorded from extensor motoneurons after tib., soleus and c.p. nerve stimulation. Differences in the time-to-peak of compound EPSP's evoked by agonist (tib.) or antagonist (c.p.) nerve stimulation (16.4 $\pm$ 6.9ms, n=3) and (45.5 $\pm$ 5.1ms, n=6), respectively (P7-10, room temp.) are consistent with their identification as extensor motoneurons. Emg and intracellular recordings show that, in contrast to the adult, the latency for activation of extensor motoneurons was similar for stimulation of agonist and antagonist nerves. The latency for EPSP's was 11.7 $\pm$ 1.0 ms, (n=7) for tib. and 16.9 $\pm$ 2.2ms, (n=7) for c.p. stimulation. Recurrent and reciprocal inhibition was also present. IPSP's were evoked in soleus motoneurons by tib., soleus and by c.p. nerve stimulation. Thus, intracellular recordings have demonstrated that all elements of synaptic integration are present, but immature, in *in vitro* neonatal SC. Further, their molding into mature spinal circuits is amenable to study *in vitro*. Supported by NS22975, NS13742 from NINCDS and The Irma T. Hirschl Trust.

232.2 REFLEX ORGANIZATION IN A LONG TERM *IN VITRO* TURTLE PREPARATION. K.A.S. Shirley, V. Boss, and P.R. Lennard. Dept. of Biology, Emory Univ., Atlanta, GA 30322.

An *in vitro* spinal cord-nerve-muscle preparation provides numerous advantages for the study of reflex organization and modulation. The advantages are accessibility for recording and stimulating, stability for intracellular penetrations, and ease of application of pharmacological agents by rapid perfusion. We have developed a preparation which remains viable for 4-5 days so that neuroanatomical tracing methods can be used in conjunction with physiological and pharmacological procedures.

The limb enlargement of the spinal cord along with various combinations of muscles and their respective peripheral nerves were dissected from an euthanized turtle *(Pseudemys scripta)*. Following gross dissection, the preparation was transferred to Hepes-buffered reptilian Ringer's solution where the dissection was completed over a 3-5 hour time period using sterile technique. The limb enlargement and 5-8 spinal segments were exposed except for a small strip of vertebral bone immediately surrounding the spinal roots ipsilateral to the chosen muscles. The preparation was pinned out over nylon mesh above wells formed in a sylgard-coated chamber which held a volume of 15-20 ml. The preparation was perfused continuously with culture medium at a rate which turned over the chamber volume at least twice per hour. The medium was Dulbecco's modified Eagle (GIBCO 430-1600), to which 44 mM bicarbonate and 15 ml/l of antibiotic-antimycotic (GIBCO 600-5240AE) were added. Sterile 95% O_2, 5% CO_2 was bubbled constantly into the medium. The whole system was placed on a vibration isolation table in a laminar flow hood. Bipolar hook electrodes for recording and/or stimulating were placed around the spinal cord and each muscle nerve. Two sets of bipolar EMG electrodes were implanted in each muscle. Intra- and extracellular electrodes were positioned in the spinal cord using hydraulically driven remote-controlled micromanipulators.

A typical preparation consisted of the hindlimb enlargement plus 2 rostral and 1 caudal spinal segments, appropriate peripheral nerves, and the muscles iliofibularis and ambiens. Viability of the preparation was assessed by EMG activity evoked either by spinal cord or peripheral nerve stimulation, or by stretch reflexes induced with a muscle vibrator. The EMG response declined only slightly over three days, and to a greater extent during the fourth and fifth days. This *in vitro* system is being used to determine the organization of reflexes in various combinations of synergistic and antagonistic muscles. The effects of descending monoaminergic and serotonergic pathways thought to be involved in modulating spinal reflexes and locomotion are being examined using bath applied pharmacological agents and electrical stimulation of spinal tracts. (Supported by USPHS grant NS17732).

232.3 NEURAL CONTROL SYSTEM FOR MAMMALIAN LOCOMOTION *IN VITRO*. J. C. Smith and J. L. Feldman. Systems Neurobiology Lab, Dept. of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Motor patterns for locomotion are generated by *in vitro* preparations of neonatal rat brainstem and spinal cord (Smith et al., Soc. Neurosci. Abs. 12: 386, 1986; J. Neurosci. Methods, 1987, in press). We have now established that these preparations retain functional neural circuitry for major components of the mammalian locomotor control system, including brainstem locomotor command generating networks, spinal motor pattern generating circuitry, and spinal sensory afferent input pathways. Activation of any of these components *in vitro* generates rhythmic locomotor activity. We developed methods for selective stimulation of each of these components and the locomotor output patterns were analyzed. The neuraxis was isolated from neonatal rats and maintained *in vitro* as previously described (*ibid.*). Motor patterns were characterized from recordings of cervical and lumbar spinal ventral root discharge and recordings of limb muscle (flexor, extensor) EMG in preparations retaining innervated hindlimbs. Brainstem and spinal networks were selectively activated by specific neurochemicals (*ibid.*). Excitatory amino acids [L-aspartic acid or L-glutamic acid (0.1-0.5 mM) with amino acid uptake inhibitor dihydrokainic acid (0.2 mM)] were typically used to activate the spinal circuitry; substance P (1-10 μM) was typically used to active brainstem networks. Sensory pathways were activated by dorsal root stimulation/ exteroceptive stimuli (e.g. tail pinch) in preparations with hindlimbs and tail. Similar patterns of nerve and muscle activity during the locomotor cycle were generated in all cases. Characteristics of the motor output patterns include: (1) multi-joint, stepping-like movements of limbs; (2) alternating flexor-extensor activity during the step cycle characteristic of quadruped locomotion; (3) interlimb coordination (all four limbs) resembling quadruped walking. Using selective pharmacological antagonists and uptake inhibitors for candidate neurotransmitters (*ibid.*), we established that the generation of the locomotor activity critically depends on synaptic release of endogenous excitatory amino acids in spinal networks. Excitatory amino acids activating N-methyl-D-aspartic acid (NMDA) receptors play a central role as previously established (*ibid.*); NMDA receptor block with 2-amino-5-phosphonovaleric acid (AP5) suppresses the locomotor activity in all cases. The data suggest that the descending locomotor command and sensory input pathways converge on a common set of spinal locomotor rhythm generating neurons activated by the endogenous excitatory amino acids. These results indicate that key networks of the locomotor control system can be selectively activated *in vitro* to produce appropriate motor behavior. The *in vitro* brainstem-spinal cord preparations offer the opportunity for investigation of several major neural networks of the mammalian locomotor control system. 232.4 **REGENERATION OF DESCENDING COMMAND PATHWAYS FOR LOCOMOTION IN AN IN VITRO PREPARATION OF THE LAMPREY CNS.** A.D. McClellan, Dept. of Physiol., Univ. of Iowa, Iowa City, IA

Larval lampreys that have received a complete spinal cord transection regain voluntary control of locomotion within about 8 weeks (@ 25°C). An unresolved issue, however, is whether locomotor activity below the healed transection site is due to regeneration of descending command pathways for locomotion or to other mechanisms, such as mechanosensory coupling, that bypass the transection site. Therefore, the role of regenerated descending command pathways for locomotion was tested in an in vitro brainstem/spinal cord preparation (McClellan, 1984), in which mechanical factors and sensory feedback were eliminated.

Control animals: EMG activity obtained during episodes of locomotion in larval lampreys indicated that cycle times (0.24 - 1.39 s), burst proportions (0.1 - 0.4), and segmental phase-lags (0.003 - 0.012) were similar to those described in adult lampreys (McClellan, 1984). In curarized in vitro brainstem/spinal cord preparations, electrical stimulation of brainstem "locomotor command regions" (McClellan and Grillner, 1984) could elicit well-coordinated locomotor patterns in spinal ventral roots similar to the muscle patterns observed in intact larval animals.

Acute spinal-transected animals: Larval lampreys with an acute mid-body transection could still locomote, but muscle activity was not usually present below the transection site. Presumably the undulatory locomotor movements in the rostral half of the body are passively conducted along the body caudal to the acute transection site.

Spinal-regenerated animals: In spinal-regenerated animals locomotor activity in body muscles could be recorded along the entire body above and below the healed transection site. These patterns were similar to those observed in control animals. In curarized in vitro preparations, stimulation of brainstem "locomotor regions" and sometimes sensory stimulation of the head could elicit well-coordinated locomotor patterns in ventral roots above and below the transection site. Moreover, with a low-calcium Ringer's solution bathing only the spinal cord above the transection site, locomotor activity could still be elicited caudal to the transection suggesting that descending command pathways had regenerated across the transection site and made connections with motor networks. This is the first demonstration of coordinated locomotor activity elicited below a healed transection site by regenerated descending command pathways in an in vitro preparation in which nonspecific factors, such as sensory feedback, have been eliminated. However, locomotor activity was only present up to 3.0 cm caudal to the transection site in animals that had recovered for 8-20 weeks. Thus, regenerated descending command pathways alone appear capable of initiating locomotor activity just below the transection site, but the muscle activity patterns and movements which occur over more caudal parts of the body may depend on a combination of factors. These results set the stage for a cellular analysis of the role of regeneration of descending locomotor command pathways in behavioral recovery.

232.5 **REPETITIVE FIRING PROPERTIES OF NEURONS WITHIN THE NUCLEUS AMBIGUUS OF ADULT GUINEA PIGS USING THE *IN VITRO* SLICE TECHNIQUE.** S.M. Johnson* and P.A. Getting, Dept. of Physiol. Biophys., Univ. of Iowa, Iowa City, IA 52242.

Our goal is to understand how neurons within the medulla shape the form and timing of the rhythmic respiratory motor pattern in mammals. The purpose of this study was to determine the repetitive firing properties of neurons in the region of the Nucleus Ambiguus (NA), a heterogenous nucleus which contains neurons belonging to the Ventral Respiratory Group (VRG). The *in vitro* slice technique was used to obtain stable intracellular recordings (n=48) in the current clamp mode from transverse brainstem slices (400-500 microns thick, 0.0-1.5 mm rostral to the obex) of adult guinea pigs.

Approximately 13% of the cells displayed delayed excitation (DE). DE is a prolonged delay in the onset of firing following a hyperpolarizing prepulse. The maximum delay that could be elicited from cells within the NA was 200-250 msec. These findings differed from those found in the Dorsal Respiratory Group (DRG), a group of respiratory neurons found in the region of the ventral Nucleus Tractus Solitarius. In the DRG, 40% of the cells display DE with a delay ranging from 380-760 msec (Dekin and Getting, *Brain Res.*, 324:180-184, 1984).

All cells displayed spike frequency adaptation (SFA) which was quantified as the ratio of the steady state frequency to the peak firing frequency during a two second depolarizing stimulus. Cells which displayed DE had a broad range of SFA ratios from 0.4-0.8. In contrast, the cells which did not display DE could be separated into two major groups based upon the degree of SFA. Cells with SFA ratios of 0.6-0.8 were considered to have mild SFA and cells with SFA ratios of 0.0-0.4 were considered to have strong SFA. Using this criteria, 56% of the cells exhibited mild SFA and 44% of the cells exhibited strong SFA.

Post-inhibitory rebound (PIR) was found in 13% of the cells in which DE was not expressed. PIR was never found in a cell which exhibited DE and there was no obvious correlation between PIR and either mild SFA or strong SFA. PIR is present in NA cells but not in DRG neurons (Dekin *et al., J. Neurophysiol.*, in press).

232.6 RESPIRATORY INTERNEURON LOCATIONS AND PHOTOINACTIVATION IN LAMPREY. D.F. Russell. Dept. of Anesthesiology, Box 8054, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The study of the lamprey, a simple stem vertebrate, may clarify basic mechanisms of neural control of respiration. The first aim of this work was to localize the somata of neurons that generate the respiratory rhythm. HRP was applied to sites in the medulla that are known to contain the axons of respiratory interneurons, in both adults and larvae. (1) Premotor interneurons were localized by making small HRP injections into the respiratory motor nuclei (nuc.X; as in other fish, respiratory motorneurons are in the medulla). An ipsilateral and ventral axon tract passed rostrally near cranial nerves VIII and V. In adults, an ipsilateral ventral cell group was labelled near the exit zone of n.V. In larvae, an ipsilateral and dorsal group of ca. 50 neurons with ca. 5 μ somata was labelled rostral to nuc.V. (2) Since the respiratory generator is duplicated bilaterally, a search was made for coordinating neurons that synchronize the two sides, by making local injections of HRP at the midline at the level of rostral nuc.V, the site of a respiratory commissure in adults. This gave bilateral labelling of dorsal populations of neurons located rostral and lateral to nuc.V, extending dorsal of the sulcus limitans, although some cells were more ventral.

The second aim was to dissect the respiratory generator using the photosensitizing dyes sulforhodamine and rose bengal and 546 nm illumination from a compound fluorescence microscope. Intracellular injection of dye into Muller cells and illumination caused loss of the input resistance and of resting, action, and synaptic potentials, as in other systems. Two new methods were developed: photoinactivation after axonal backfilling with dye, and local illumination after bath application of dye. The first method was tested on the Müller (reticulospinal) neurons by backfilling their axons with dye applied to the rostral spinal cord, while monitoring the reflex excitation of these cells by vestibular inputs; illumination of backfilled cells was effective in abolishing most of the vestibular-evoked descending volleys. The second method was used to test whether neurons rostral to nuc.V are needed for respiratory pattern generation in larvae. Illumination with 200 μ spots of light abolished the respiratory rhythm, supporting Homma's (J. Comp. Physiol. 104:175) conclusion and the HRP results above that certain respiratory interneurons are located in this region.

Supported by NIH grant NS23028.

232.7 LOCALIZATION OF LAST-ORDER SPINAL INTERNEURONS PARTICIPATING IN THE PRODUCTION OF LOCOMOTION IN THE CAT. B.R. Noga, S.J. Shefchyk, and L.M. Jordan. Dept. Physiol., Univ. Manitoba, Winnipeg, CANADA, R3E 0W3.

The wheat germ agglutinin-horseradish peroxidase (WGA-HRP) transneuronal labelling technique (Jankowska, Brain Res., 341: 403, 1985) was used to localize last order spinal interneurons which participate in the production of hindlimb locomotion in intact cats. Wheat germ agglutinin conjugated HRP was unilaterally injected in the proximal part of the cut nerve branch to the anterior biceps muscle. After injection, the cats were walked on a treadmill (belt speed 0.3 m/sec) or overground for periods of 1.5 to 2 hours/day for 3 days.

Anterior biceps motoneurons located in the motor nuclei of lumbar (L) and sacral (S) segments (L7-S1) were heavily labelled. In addition to spinal motoneurons, interneurons were transneuronally labelled with this technique. Labelled interneurons were localized throughout L5-L7 but were not found in the S1 segment or caudal to the motor nuclei. Ipsilateral to the injection, the interneurons were primarily localized to Rexed's lamina VII (L7 > L6 > L5), although some labelled cells were also found in lamina V-VI (L6). Contralateral labelled interneurons were restricted to lamina VIII (L5-L7). The cells located in ipsilateral lamina VII also overlap those areas in which Renshaw cells and Ia inhibitory interneurons have been localized (Jankowska and Lindstrom, Acta physiol. scand., 81: 428, 1971; J. Physiol., (Lond.), 226: 805, 1972). Previous work has demonstrated that these cells are rhythmically active during locomotion induced by stimulation of the mesencephalic locomotor region (Noga, et al, Exp. Brain Res., 66: 99, 1987). It is expected that some of these lamina VII cells belong to a different functional group which participate in the production of the rhythmic excitatory drive to motoneurons during locomotion (Shefchyk and Jordan, J. Neurophysiol., 53: 1345, 1985). Previous work (Harrison, et al, J. Physiol. (Lond.), 371: 147) has demonstrated that contralateral lamina VIII interneurons may be involved in crossed reflex interactions. The present results indicate that these cells are also active during overground locomotion. It is suggested that these cells may comprise at least part of the crossed spinal module for walking movements revealed in fictive locomotion experiments (Jordan, et al, Soc. Neurosci. Abstr. 12, p. 877). Transneuronal labelling experiments in paralyzed cats induced to walk by stimulation of the mesencephalic locomotor region are presently underway.

232.8 ACTIVITY OF L4 INTERNEURONS WITH GROUP II INPUT DURING FICTIVE LOCOMOTION IN THE MESENCEPHALIC CAT S. J. Shefchyk, D. A. McCrea, D. J. Kreillaars*, B. R. Noga and L. M. Jordan. Dept. Physiol, Univ. of Manitoba, Winnipeg, CANADA R3E 0W3.

Experiments were performed to determine the activity during fictive locomotion of the population of interneurons in the midlumbar spinal cord previously described by Jankowska and coworkers (Edgley and Jankowska, J. Physiol. 385:393-414, 1987). These interneurons receive input from cutaneous, joint and muscle afferents as well as several descending pathways (Edgley, Jankowska and Shefchyk, unpublished), but their most striking features are a strong group II input from quadriceps, sartorius and deep peroneal nerves and the observation that they project monosynaptically to motoneurons in the lower lumbar segments where they can have either excitatory or inhibitory actions (Jankowska and coworkers, unpublished). It was suggested that these interneurons may play a role in determining hip position, and perhaps influence the production of the step cycle. This is supported by the fact that stimuli applied to the cuneiform nucleus, or mesencephalic locomotor region (MLR) could activate the L4 group II interneurons in the anesthetized preparation (Edgley et al., unpublished).

We have conducted experiments using extracellular recordings from L4 interneurons to examine the activity of these cells during fictive stepping induced by electrical stimulation of the MLR in decerebrate cats. The interneurons were identified using the following criteria: they received group II afferent input from the quadriceps nerve, they were not ascending tract cells, and they were antidromically activated by stimulation in the posterior biceps-semitendinosis or gastrocnemius motor nuclei.

None of the interneurons meeting these criteria were rhythmically active during fictive stepping. In addition, the responses evoked from peripheral nerve stimulation (at group II strengths and greater) in these neurons were inhibited during fictive stepping. These evoked responses returned immediately upon cessation of the fictive locomotor activity. These findings are consistent with the fact that these cells are inhibited in animals treated with l-DOPA (Edgley, et al. unpublished). We suggest that these cells form a component of the short latency flexor reflex afferent pathway shown by Lundberg and collaborators (Jankowska, et al, Acta physiol. scand. 70:369-388, 1967) to be depressed in spinal animals following treatment with L-DOPA.

Supported by the Medical Research Council of Canada.

232.9 MODULATION OF SHORT LATENCY CUTANEOUS EXCITATATION IN FLEXOR AND EXTENSOR MOTONEURONS DURING FICTIVE LOCOMOTION IN THE CAT. B.J.Schmidt, D.E.R.Meyers, M.Tokuriki*, J.W.Fleshman and R.E.Burke
Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20892

We previously showed that low threshold afferents in the cutaneous superficial peroneal (SP) nerve produce short-latency (minimally disynaptic) EPSPs in flexor digitorum longus (FDL) motoneurons (MNs) that are markedly facilitated during the early flexion phase of fictive stepping, when FDL is normally active (Neurosci. Abstr. 12:242.9 1986). This suggests that interneurons in this pathway receive convergent excitation from the central pattern generator (CPG) for locomotion and could mediate some fraction of the excitatory CPG locomotor drive to FDL MNs. The present study was designed to examine whether the same general pattern of modulation might hold true for excitatory effects from distal skin regions (nerves: SP, sural, saphenous, and plantar) in other hindlimb flexor and extensor alpha-MNs.

Fictive stepping was induced in 19 decerebrate, unanesthetized cats, either by administration of nialamide and l-DOPA in acutely spinalized (T13) cats (n=17), or by electrical stimulation of the mesencephalic locomotor region (n=2). Each cutaneous nerve was stimulated repetitively (2 x thr; 10 Hz) while recording intracellularly from lumbar MNs during fictive stepping. MNs were identified either by antidromic activation from hindlimb muscle nerves or by phase of activity during stepping. Current pulses (CP; 15-25 ms duration, up to 15 nA) were injected intracellularly between the recurring PSPs to monitor fluctuations in background input conductance. PSPs and CP responses were averaged during the early, mid and late phases of extension or flexion during fictive stepping (3 to 30 steps), limiting attention to cases with initial excitatory components. All EPSP amplitudes in a given stepping sequence were evaluated at the same reference latency.

Input conductance systematically increased in extensor MNs during the phase of flexor activity, and vice versa in flexor cells. Evoked EPSP amplitudes were therefore normalized with respect to input conductance in order to estimate the contribution of premotoneuronal mechanisms to EPSP modulation. In extensor MNs, the earliest EPSP component (n=35; normalized for input conductance) was consistently increased (mean 2-fold) during the flexion phase, irrespective of skin nerve stimulated. In flexor MNs, SP (n=16) and saphenous (n=5) EPSPs exhibited inconsistent phasic modulation, while all sural (n=4) and plantar (n=4) EPSPs were increased (mean 1.4-fold) during the extension phase. The patterns of facilitation do not support the generalization that last-order excitatory interneurons in these cutaneous reflex pathways also mediate CPG excitatory drive to hindlimb motor nuclei. Rather, phasic modulation of these excitatory pathways may simply control specific reflexes during the step cycle.

232.10 ACTIVATION OF LOCOMOTION BY MICROINJECTION OF NEUROTRANSMITTER AGONISTS AND ANTAGONISTS INTO THE AVIAN BRAINSTEM. G.N. Sholomenko and J.D. Steeves. Dept. of Zoology, University of British Columbia (UBC), Vancouver, B.C., V6T 2A9.

The bulbospinal pathways subserving the initiation of locomotion in birds strongly resemble those found in lower vertebrates and mammals (Steeves et al., 1987. Brain Res. **401**:205-212; Sholomenko & Steeves, 1987. Exp. Neurol. **95**:403-418). Electrical microstimulation (25-50uA at 30-60Hz) of several areas within the avian brainstem, including the ventromedial gigantocellular reticular formation (Rgc) and a mesencephalic region near the lateral spiriform nucleus (SpL), activate walking and runnning, as well as flying (at slightly higher stimulating current strengths). Since electrical stimulation activates both neuronal cell bodies and fibers of passage within the region of effective current spread, a more specific means of activating only neuronal cell bodies was sought.

Neurotransmitter agonists and antagonists were infused into the brainstem of acute decerebrate adult birds (Canada geese or White Pekin ducks) via multi-barrel glass micropipettes. Injection of the GABA antagonist, picrotoxin (0.3M,1.5ul), near the SpL produced bouts of locomotor activity (treadmill walking and wing flapping) in animals that did not spontaneously locomote in response to peripheral afferent input from a moving treadmill belt. Injection of smaller amounts of picrotoxin decreased the threshold for activating locomotion via electrical stimulation. Microinjections of GABA blocked both electrically activated and picrotoxin induced locomotion.

Direct injection of the ACh agonist, carbachol (20-100mM,2.0ul), into the Rgc produced prolonged periods of walking. The carbachol induced locomotion was blocked by infusion of an ACh antagonist, atropine (20mM,1.0ul), from another barrel of the micropipette.

Our results in the bird agree with similar findings in rats and cats and indicate that GABAergic and cholinergic components modulate the excitability of brainstem locomotor regions involved in the activation of locomotion.

Supported by NSERC of Canada and B.C. Health Care Research Foundation (BCHCRF).

232.11 INVOLVEMENT OF SUPRASPINAL REGIONS IN THE PHRENIC-TO-PHRENIC INHIBITORY REFLEX. Dexter F. Speck, Department of Physiology and Biophysics, University of Kentucky, Lexington, KY 40536-0084.

Previous experiments (Brain Res., in press) suggest a role for supraspinal involvement in the production of a phrenic-to-phrenic inhibitory reflex (PIR). A plausible hypothesis is that phrenic nerve afferents project to a brainstem interneuron which has a descending inhibitory effect on phrenic motoneurons. Since expiratory neurons in the Botzinger Complex (BotC) have been demonstrated to have an inhibitory effect on phrenic motoneurons, electrolytic and chemical lesion studies were used to examine the BotC involvement in the phrenic-to-phrenic inhibitory reflex.

All experiments were conducted in decerebrate, paralyzed, artificially ventilated, thoracotomized and vagotomized cats. After routine surgery the brainstem was exposed to permit insertion of microelectrodes into the BotC. Phrenic nerves were isolated bilaterally for recording and/or stimulation. In the first study, tungsten recording microelectrodes were inserted into the region of the BotC. After mapping the expiratory-modulated population, the microelectrode was positioned in the middle of the BotC. The right phrenic nerve was stimulated (3 Hz, 0.2 msec, 0.01 - 15 mA) and the threshold current for eliciting the bilateral PIR was determined. Phrenic neurogram responses to threshold and supramaximal (15 mA) stimulation were recorded before lesioning the BotC (20uA for 2 min) through the recording electrode. After lesioning, the PIR was examined for changes in threshold, duration and efficacy. The microelectrode was then moved to the contralateral BotC and the protocol was repeated. After each experiment, brainstems were removed and the lesions were histologically verified. In most animals the inhibitory reflex was attenuated by bilateral BotC lesions suggesting that the lesioned areas played a role in the reflex.

Six experiments involving chemical lesions (kainic acid - KA) were performed to determine if BotC neurons were important in the PIR. Micropipettes filled with KA (1 ug/ul) and a dye were inserted into the BotC. While recording expiratory-modulated activity, 30-50 nl of KA was ejected. Unilateral KA injections caused transient, severe hypertension and 1-2 hours of apnea and/or apneusis. Once normal rhythmicity resumed, the PIR was compared to control values before making a contralateral injection. This second injection usually disturbed respiratory rhythm for 3-12 hours. When normal rhythmicity returned, the response to phrenic nerve afferent stimulation was unaltered. These results suggest that axons important in producing the phrenic-to-phrenic reflex pass through the region of the BotC, but that BotC neurons are not necessary for this reflex. (Supported by HL 34568)

232.12 EFFECTS OF RETICULAR FORMATION ACTIVATION ON RHYTHMICAL TRIGEMINAL BEHAVIOR IN THE GUINEA PIG. S.M. Gurahian, L.J. Goldberg and S.H. Chandler. Depts. of Oral Biology, Kinesiology, Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024

It has been shown that rhythmical jaw movements (RJMs) evoked by 40 Hz stimulation of the masticatory area of the cortex in anesthesized guinea pigs are produced by the potentiation and depotentiation of a short-latency, cortico-trigeminal pathway. This pathway terminates on motoneurons innervating jaw closer and opener muscles. Stimulation of the pontis nucleus caudalis (PnC) of the reticular formation was shown to completely suppress the cortically induced RJM behavior. We hypothesized that this suppression was not due to a direct effect of PnC stimulation on the motoneurons themselves. In order to test this hypothesis, the effect of PnC stimulation on the excitability of trigeminal motoneurons was investigated.

In ketamine anesthesized guinea pigs, bipolar electromyographic (EMG) electrodes were placed in the left anterior belly of the digastric muscle and in the left deep masseter muscle. Jaw movements were monitored utilizing a photoelectric position sensor which tracked a tungsten light source fixed to the mandible. Jaw opener and closer motoneuron field potentials were activated by stimulation of reflex pathways. Repetitive stimulation (40 Hz) of the masticatory area of the cortex was used to evoke RJMs. Stimulation of the same cortical area at 2 Hz (3 pulses, 500 pps) was used to activate the short-latency, cortico-trigeminal pathway (2 Hz stimulation does not evoked RJMs). The PnC was stimulated at 100 Hz, at a current sufficient to abolish cortically evoked RJMs. Recordings of jaw opener and closer motoneuron field potentials and intracellular recordings of closer motoneurons were obtained during stimulation of the PnC alone or in conjuction with cortical stimulation.

It was found that PnC stimulation had no observable effect on the reflex evoked opener or closer motoneuron field potentials. The activation of trigeminal motoneurons by short train pulses to the masticatory area of the cortex was also not affected by PnC stimulation. This same PnC stimulation, however, completely blocked cortically evoked RJMs. In this case the inhibitory postsynaptic potentials produced in jaw closer motoneurons during cortically evoked RJMs were significantly reduced as were the digastric motoneuron field potentials. PnC stimulation itself did not affect the resting membrane potential of jaw closer motoneurons. These findings suggest that PnC stimulation exhibits no direct effect on trigeminal motoneurons and that the suppression of cortically evoked RJMs by PnC stimulation must result from the PnC effect on brainstem networks responsible for the rhythmic potentiation and depotentiation of the cortico-trigeminal pathway. Supported by NIH grants DE4166 and DE06193

NEUROENDOCRINE CONTROLS: PITUITARY V

233.1 VOLTAGE DEPENDENT POTASSIUM CHANNELS IN TELEOST FISH PITUITARY CELLS. C. R. Fourtner and C. A. Loretz* , Department of Biological Sciences, State University of New York at Buffalo, Buffalo, New York, 14260.

Hormone-secreting paraneuronal cells of the goby (Gillichthys mirabilis: Teleostei) pituitary gland were studied using the cell-attached and excised-patch variants of the patch clamp technique to investigate the regulation of membrane ion channels in relation to changes in membrane potential. Cells of the rostral pars distalis (RPD) were dissociated using hyaluronidase (0.1 mg/ml) and plated in normal Ringer solution onto plastic petri dishes. Isolated cells of the RPD exhibited spontaneous action potentials of slow duration (ca. 20ms) in cell-attached recordings, resembling the Ca^{2+}-based action potentials described for prolactin-secreting GH3 clonal rat pituitary cells (Dufy, B., et al. Nature 282:855, 1979.) and prolacting-secreting cells of the teleost RPD (Teraskevich, P.S., and Douglas, W. W. Nature 276:832, 1978.); the spontaneous rate of firing was about 2 Hz. In excised, inside-out membrane patches bathed on both sides with defined solutions, two channels have been identified. One is a voltage-dependent K^+ channel with a single-channel conductance of ca. 20-40 pS. Channel activity (as the open probability, P_+) is inversely related to membrane polarization, i.e., depolarization increases P_+ over the range, roughly, of -80 mV to 0 mV. The other is a slow-inactivating K^+ channel of conductance 25-30 pS. Depolarizing voltage steps induce channel opening followed by channel inactivation over the course of a few seconds. Inactivation occurs even after substantial depolarization to membrane potentials in excess of +50mV. The rate of inactivation is proportional to the magnitude of the voltage step. This slow-inactivating channel may be part of a pacemaker mechanism for the rhythmic action potentials.

Aided by Biomedical Research Support Grant BRSG-SO-RR-07066.

233.2 STIMULATION OF DOPAMINE D-2 RECEPTORS ACTIVATES POTASSIUM CHANNELS IN MAMMOTROPHS: EVIDENCE FOR A FUNCTIONAL TARGET OF DOPAMINE ACTION. M. Memo, C. Missale, L. Castelletti*, A. Valerio* and P.F. Spano. Inst. Pharm. Exp. Ther., School of Medicine, University of Brescia, Italy.

The effect of dopamine (DA) and some DAergic agonists (RU 24213, bromocriptine and SKF 82526) were examined for their ability to modify potassium permeability in enriched population of rat prolactin-secreting cells.

Measurement of fluxes of Rb was used to study the properties of voltage-regulated potassium channels. Enriched population of mammotrophs was achieved by discontinous density gradient of Percoll.

We found that DA dose-dependently increased potassium efflux from pituitary cells. The calculated EC-50 was about 3 nM. The maximal effect was achieved by 50 nM DA. This effect was mimicked by different DA D-2 receptor agonists, such as RU 24213 and bromocriptine. On the contrary, the selective DA D-1 agonist SKF 82526 (1 μM) was unable to change potassium permeability. DA-stimulated potassium efflux was antagonized by DA D-2 antagonists such as (-) sulpiride (1 μM) or haloperidol (1 μM). Both (+)sulpiride (the pharmacologically inactive isomer) and SCH 23390 (the DA D-1 antagonist) were inactive in blocking DA-induced potassium efflux.

The increase of potassium permeability was significantly evident after a very short period (30 sec) of exposure of the cells to 10 nM DA.

We previously found that DA, by a D-2 receptor interaction, inhibits calcium entry into pituitary cells. In order to establish whether the reduced calcium channel activity was responsable for an enhanced potassium efflux, cells were exposed to an inorganic calcium entry blocker (500 nM Cadmium) and then DA was tested for its ability to modify potessium channel permeability. The results showed that in this experimental conditions DA was still capable to increase potassium efflux.

Taken together, these data suggest that the primary site of action of DA which may be determinant in cousing iperpolarization is an opening of potassium channel.

233.3 SECONDARY REGULATION OF POLYPHOSPHOINOSITIDE METABOLISM: DOPAMINERGIC ATTENUATION OF PHOSPHOINOSITIDE PHOSPHORYLATION. W.D. Jarvis[1], A.M. Judd*, P.C. Stock*, and R.M. MacLeod[1]. Departments of Internal Medicine and Neuroscience[1], University of Virginia, Charlottesville, VA 22908.

Prolactin release by the anterior pituitary lactotroph is regulated primarily by the inhibitory action of dopamine (DA). Previously, we reported that DA and the D-2 receptor agonist bromocriptine (Br) also produce substantial inhibitions of both basal and stimulated [^{32}P]orthophosphate incorporation into anterior pituitary membranal phosphoinositides; however, receptor-mediated increases in inositol phosphate formation persist unimpaired in the presence of DA or Br, demonstrating that phospholipase C (PhLC) activity is insensitive to dopaminergic influence.

We therefore have examined the influence of D-2 DA receptor activity on the basal turnover rates of phosphatidylinositol (PtdIns), phosphatidylinositol-4-phosphate (PtdIns(4)P), and phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P_2). Briefly, primary cultures of normal female rat anterior pituitary cells were labeled with [^{3}H]inositol ([^{3}H]Ins) for varying times in the absence or presence of Br (50 nM). Extracted radiolabeled phosphoinositides were deacylated under alkaline conditions and then assayed by conventional anion-exchange resin chromatography.

Incorporation of [^{3}H]Ins into cellular phosphoinositide was linear, reaching isotopic equilibrium; exposure to Br resulted in a continuous (6-36 hr) and significant ($P < .01$) reduction in the rate of [^{3}H]Ins incorporation into all phosphoinositides. Disparate attenuations in the respective rates of radiolabeling of individual phosphoinositide species were also observed. The relative proportions obtained at 36 hr were as follows:

	% total cellular phosphoinositide		
	Control	50 nM Br	
PtdIns	76	87	$p < .01$ vs. control
PtdIns(4)P	19	13	$P < .01$ vs. control
PtdIns(4,5)P_2	4	1	$P < .01$ vs. control

Consistent with our earlier findings, these data indicate that activation of the D-2 DA receptor attenuates the activity of those systems associated with the tandem phosphorylations of PtdIns and PtdIns(4)P processes that give rise to PtdIns(4)P and PtdIns(4,5)P_2, respectively. We therefore propose that DA exerts an inhibitory influence on the phosphorylation, rather than the hydrolysis, of anterior pituitary membranal phosphoinositides, as one of the component mechanisms of the dopaminergic inhibition of prolactin release. [Supported by NIH Research Grant CA-07535 and grants from the American Parkingson Disease Association.]

233.4 DOPAMINE WITHDRAWAL: AN IMPORTANT SIGNAL FOR PHOSPHOINOSITIDE HYDROLYSIS IN LACTOTROPHS. G. Martinez de la Escalera*, T.F.J. Martin* and R.I. Weiner. Reprod. Endo. Center, UCSF, San Francisco, CA and University of Wisconsin, Madison, WI.

Prolactin (PRL) release is tonically inhibited by dopamine (DA). Extensive evidence indicates that withdrawal of the inhibitory influence of dopamine is an important physiological trigger for the stimulation of PRL secretion. Increased activity of adenylate cyclase and intracellular Ca^{++} have been implicated as post receptor mechanisms involved in mediating the action of DA. However, the acute administration of DA has yielded conflicting results regarding the hydrolisis of phosphoinositides, as an early event in the activation of the Ca^{++} pathway. We have tested the effect of withdrawal of tonic DA inhibition on the concentration of phosphoinositides and inositol phosphates. Dispersed anterior pituitary cells from estrogen-treated rats, composed of 70 - 80% lactotrophs, were plated on Matrigel-coated 35 mm dishes. Cells were labeled with (^{3}H)-myoinositol for 36 hs, in the presence or absence of DA (500 nM). The effect of removing or adding DA (500 nM) to the incubation medium for 5 min were tested in the presence of 10 mM LiCl. Labeled inositol phosphate metabolites (IPx) were extracted from the cells and quantitated by anion exchange chromatography. Phosphoinositides (PIx) were quantitated after KOH deacylation. The concentration of IPx was moderately but significantly ($p<0.05$) lower in cells incubated with DA for 36 hs vs untreated cells. The removal of DA for 5 min induced a 77% stimulation of IPx (19,114 ± 981 vs 10,800 ± 388 dpm/1.5X 10^6 cells, n = 3) and a reciprocal 27% decrease in PIx concentrations (11,526 ± 524 vs 15,818 ± 617 dpm/1.5 X 10^6 cells, n = 3). On the other hand, the acute administration of DA to cells incubated without DA for 36 hs, induced no change in the concentration of IPx, although the concentration of PIx was 50% higher than in the controls. These results confirm previous observations showing no decrease in the concentration of IPx in response to the acute administration of DA to cultured anterior pituitary cells. However, the withdrawal of DA was an effective stimulus of phospholipase C mediated hydrolisis of phosphoinositides, consistent with the involvement of this pathway in mediating the action of DA. Furthermore, these results suggest that the important biological signal for PRL secretion is the removal of DA inhibition, which is in fact the normal physiological occurrence.

233.5 EFFECTS OF TRH AND THE CALCIUM CHANNEL AGONIST BAY K 8644 ON IP_4 AND OTHER INOSITOL PHOSPHATES AND ON PROLACTIN RELEASE. J.A. Pachter*, G.J. Law* and P.S. Dannies* (SPON: S.F. Basinger). Dept. of Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510.

TRH (thyrotropin-releasing hormone) stimulates prolactin release from anterior pituitary lactotrophs by a mechanism which is thought to involve stimulation of phosphoinositide metabolism and opening of membrane Ca^{2+} channels, both of which elevate cytosolic free calcium levels ($[Ca^{2+}]_c$). Both 1 uM TRH and the calcium channel agonist BAY K 8644 (1 uM) stimulated prolactin release from perifused GH_4C_1 anterior pituitary tumor cells. When added simultaneously, these agents were synergistic. To investigate the mechanism of this synergism, we measured the effects of TRH and BAY K 8644 on $[Ca^{2+}]_c$ levels, $^{45}Ca^{2+}$ uptake, and inositol phosphate production. Measurements with the fluorescent Ca^{2+} indicator indo-1 in a perifusion system as previously described (Law et al., 1987, Endocrine Soc. Abstract) showed that each agent was capable of elevating $[Ca^{2+}]_c$ above the level stimulated by the other agent. This enhancement of $[Ca^{2+}]_c$ does not result from the collective actions of TRH and BAY K 8644 on measurable Ca^{2+} influx, since the net stimulation of $^{45}Ca^{2+}$ uptake by BAY K 8644 was inhibited by 60%, rather than facilitated by TRH. Although these $^{45}Ca^{2+}$ data do not rule out the possibility that synergistic effects of TRH and BAY K 8644 on Ca^{2+} influx might be masked by a simultaneous increase in the rate of Ca^{2+} efflux, they suggest that the collective effects of TRH and BAY K 8644 on $[Ca^{2+}]_c$ may result, at least partly, from intracellular Ca^{2+} mobilization. Thus, we predicted that BAY K 8644 and TRH might cooperatively stimulate the production of inositol trisphosphate (IP_3) which is known to mobilize intracellular Ca^{2+}.

To measure inositol phosphate production, GH_4C_1 cells were preincubated in monolayers for 48 hours with media containing [^{3}H]-myoinositol. The dishes were treated with 1 uM TRH or 1 uM BAY K 8644 in the presence of 10 mM LiCl, followed by acid extraction, neutralization and separation of inositol phosphates on dowex columns. TRH induced 1.9-, 3.3-, 4.8- and 1.6-fold rises in IP_1, IP_2, IP_3 and IP_4, respectively within the first 15 seconds. BAY K 8644 had no effect. When given together, however, BAY K 8644 enhanced the effect of TRH on IP_3 and IP_4 by 62% and 45%, respectively over a 20 minute period, with lesser enhancements of TRH-stimulated IP_1 and IP_2 levels. These results suggest that the synergistic effects of TRH and BAY K 8644 on prolactin release may be mediated, at least partly, by enhancement of TRH-stimulated inositol polyphosphate production by the Ca^{2+} channel agonist. Whether this effect of BAY K 8644 is a consequence of its action on Ca^{2+} channels remains to be determined.

233.6 EFFECTS OF SRIF AND DA ON BAY K 8644-INDUCED PROLACTIN AND GH RELEASE FROM PITUITARY CELLS IN VITRO ; MODULATORY ACTION OF 17 β-ESTRADIOL. S.V. Drouva, C. Berthelier*, E. Rérat*, E. Laplante*, H. Clauser*, C. Kordon U. 159 INSERM, 2 ter rue d'Alésia, 75014 Paris, France.

Dopamine (DA) as well as SRIF are both effective inhibitors of prolactin (PRL) and the latter of Growth hormone (GH) release from rat anterior pituitary ; their potency is however modulated by sex steroids. Different cellular mechanisms have been proposed to mediate their inhibitory action. In the present study we attempted to investigate their possible interactions with the pituitary Ca2+ voltage dependent channels and evaluate sex differences or modifications after 17 β-estradiol (E2) treatment. BAYK8644 (BK) a calcium voltage dependent channel agonist, stimulated in a dose (10^{-9}-10^{-7} M) and time (15-120 min) dependent manner PRL and GH release in primary cultures of pituitary cells obtained from male or female rats. The effect on PRL secretion was however more pronounced than that on GH release with any dose, time and experimental model tested and both were blocked by nifedipine, a calcium channel antagonist. DA (10^{-7} M) inhibited BK-induced PRL release from male or female pituitary cells treated or not with E2 (10^{-9} M for 72 hours). SRIF (S-14, 10^{-9}-10^{-8} M) although without effect on BK-induced PRL release, inhibited significantly the GH responses to BK from male as well as female pituitary cells cultured in the absence of E2. Administration of E2 to female pituitary cells not only enhanced the stimulatory action of BK on PRL and GH release, but revealed the inhibitory effect of SRIF on BK-induced PRL secretion and increased SRIF inhibition of BK-induced GH release, effects which may be related to the E2-induction of SRIF receptors. Interestingly, BK was unable to stimulate LH release from male pituitary cells ; however, it was effective after long incubations with female pituitary cell cultures and became more potent in cultures receiving E2. BK stimulation of pituitary hormones secretion does not implicate inositol phospholipids hydrolysis, since inositol phosphates estimation by anion-exchange chromatography showed no significant difference between control and BK-treated cells at any time and experimental model tested. In addition, involvement of phospholipase A2 in BK effect, can be excluded since 5, 8, 11, 14-eicosatetraynoic acid (ETYA) was unable to counteract the BK-induced hormones secretion. These data indicate that the distribution as well as the activity of calcium voltage dependent channels are different in different pituitary cell populations and might be modulated by sex steroids. In addition, they suggest that a possible site of the inhibitory effect of SRIF and DA may be the calcium channel, gating calcium entry into pituitary cells.

233.7 EFFECTS OF GENDER ON FORSKOLIN-ASSOCIATED LUTEINIZING HORMONE RELEASE BY PERIFUSED RAT ANTERIOR PITUITARY FRAGMENTS. M.J.Sollenberger*, L.Rajan* and W.S. Evans* (SPON: C.Desjardins). Department of Internal Medicine, University of Virginia, School of Medicine, Charlottesville, VA 22908.

We have previously shown that forskolin (FORSK), a compound which increases intracellular cyclic AMP (cAMP), causes a concentration-dependent release of luteinizing hormone (LH) by continuously perifused anterior pituitary cells from female rats (AJP 12:E392,1985). We have also observed that cAMP causes a gradual rather than acute release of LH and have postulated that cAMP mediates the process whereby non-immediately-releasable LH becomes available for release. We have further hypothesized that the non-immediately-releasable LH pool is estrogen dependent and that the amount of LH accessable by cAMP is greater in female vs. male pituitary tissue. To investigate this thesis we have extended our original studies to compare the concentration-response relationships between tissue from female (at random stages of the estrous cycle) and male rats. Anterior pituitary fragments were perifused for 4 h with medium (Medium 199) alone and then exposed to medium or various concentrations of FORSK for 4 h. LH in the eluate was measured by radioimmunoassay. Mean (±SEM) LH secretory rates (pg/min/mg pituitary tissue), expressed as change from baseline, were as follows:

	Concentration of Forskolin (uM)						
	0.01	0.03	0.1	0.3	1.0	3.0	10.0
Male (n=4)	1.4 ±1.4	1.8 ±1.2	5.3 ±5.3	5.0 ±2.3	8.7 ±3.9	8.1 ±6.0	10.2 ± 3.8
Female (n=3)	3.1 ±1.5	9.9 ±3.1	4.9 ±2.6	21.3 ± 6.0	25.0 ± 5.4	27.5 ± 4.8	26.3 ± 3.2

The concentration of FORSK necessary to elicit a half-maximal response (EC_{50}) was approximately the same in tissue from female vs. male rats (0.15 vs. 0.13 uM). However, the maximal secretory rate achieved using tissue from female rats was 3-fold higher than that obtained with tissue from male rats (28.1 vs. 9.3 pg/min/mg pituitary tissue). This gender related difference in the ability of FORSK to release LH is particularly interesting since it is well described that pituitaries from female rats contain less total LH than those from male rats. These results are consistent with the above hypothesis that increased LH secreted by female glands may be the result of increased cAMP activation and/or increased amounts of hormone which can be accessed by cAMP. Supported by HD19170 and HD00711.

233.8 HUMAN RELAXIN STIMULATES CYCLIC AMP ACCUMULATION IN CULTURED RAT ANTERIOR PITUITARY. M.J. Cronin and C. Bakhit. Genentech, Inc., Pharmacological Sciences, South San Francisco, California 94080.

Relaxin is a hormone of human pregnancy that promotes restructuring of connective tissue, induces a quiescent myometrium until late gestation, and facilitates cervical ripening at term. Recently, it has been shown with native porcine relaxin that oxytocin and vasopressin neurons in the hypothalamus may be functional targets of relaxin (Nature 309:372, 1986 & 325:813, 1987). Following the structural identification and synthesis of pure human relaxin, the scope of its action and the response of second messenger system(s) activated or inhibited by the relaxin receptor can be ascertained. We studied anterior pituitary cells to determine if there was a change in cyclic AMP levels that would suggest both an important target for relaxin and a potential intracellular mediator for the relaxin receptor. Primary cultures of anterior pituitary cells from randomly cycling female rats were utilized. Intracellular cyclic AMP was measured by radioimmunoassay. We found that human synthetic relaxin stimulated cyclic AMP accumulation in a graded manner (Table). In cells treated with a phosphodiesterase inhibitor (i.e., isobutylmethylxanthine, 1 mM), the half-maximal concentration of relaxin required for stimulation was 100-300 pM, and maximal stimulation was 8.3 ± 2.2-fold above baseline at 15 min (4 independent experiments). It was of interest that somatostatin inhibited by about 90% relaxin-stimulated cyclic AMP levels, indicating that a somatostatin-sensitive endocrine cell(s) responds to relaxin. These data imply that anterior pituitary cells express relaxin-like receptors that can directly or indirectly stimulate adenylate cyclase activity. With the necessary involvement of the pituitary in reproduction, we suggest that this gland is a component of a relaxin endocrine axis.

Treatment	Concentration (nM)	Cellular Cyclic AMP* (pmoles/well/15 min)

233.9 WHOLE-CELL PATCH PIPETTE RECORDINGS OF MEMBRANE CAPACITANCE CHANGES IN GH3 PITUITARY CELLS EXPOSED TO SECRETAGOGUES. B. Dufy and J.L. Barker, Lab. Neurophysiologie, CNRS UA 1200, University of Bordeaux II, France and Lab. Neurophysiology, NINCDS, Bethesda, MD.

Clonal "GH3" pituitary cells that secrete prolactin and growth hormone express chemically and electrically regulated forms of membrane excitability. We have attempted to resolve the relationship between membrane excitability and exocytotic secretion by utilizing the patch pipette recording technique in the whole-cell recording (WCR) mode in conjunction with a lock-in amplifier system similar to that described by Neher and Marty (PNAS, 79 (1982) 6712). The coupling of secretagogue stimulation at the membrane with exocytosis of cytoplasmic granule hormone contents is thought to involve fusion of granules with plasma membrane followed by an increase in surface area and, in consequence, membrane capacitance (C_m). When WCRs were made from 64 15-25 micron GH3B6 cells with a simple intracellular electrolyte in the pipette (140mM Kgluconate, 2mM $MgCl_2$, 5mM HEPES (pH7.3) and 1.1mM EGTA (estimated intracellular Ca^{2+}-about 10nM)), the resting properties were -45 (±8)mV membrane potential, 2 Gohms input resistance and 19(±5) pF C_m. Under these conditions C_m fluctuated over a 0.3pF range with smaller excursions superimposed on the larger fluctuations. Applications of 30mM K^+ sufficient to depolarize cells by about 40mV for 30 seconds had typically modest effects on C_m, usually involving 10-20-second increases of about 0.2-0.3pF. Invariably, these disappeared after 15-20 minutes of WCR. When WCRs were made with pipettes containing an electrolyte formulated using an aqueous lysate of the GH3B6 clone as the diluent (Dufy, et al BBRC 137 (1986) 388), resting properties were ostensibly similar. However, pulses of K^+ now evoked C_m increases of 0.6-0.8pF that often lasted over 120 seconds. If such K^+ pulses were repeatedly applied the increase and duration of the C_m response decreased and eventually disappeared. In cells dialyzed with lysate C_m did not detectably change in response to depolarizing current injections sufficient to generate 60-second trains of Ca^{2+}-dependent action potentials at -30mV. Applications of thyrotropin releasing hormone (TRH), which induces prolactin secretion from GH3B6 cells, evoked changes in membrane excitability and C_m that rapidly disappeared when simple electrolyte was used, but could be sustained if lysate was included. When present, C_m often increased during the period of TRH-induced hyperpolarization. The results indicate that soluble components in the cytoplasm are essential for secretagogue-mediated changes in C_m and that C_m responses induced by TRH can start without activation of voltage-dependent Ca^{2+} conductance mechanisms.

234.1 ADRENERGIC INFLUENCES ON APOMORPHINE-INDUCED STEROTYPED MOVEMENTS IN PIGEONS. D. C. Fisher* & I. J. Goodman
Department of Psychology, West Virginia University, Morgantown, WV 26506

A variety of sterotyped responses may be induced in birds by apomorphine (APO), a dopamine (DA) agonist, with dosage affecting the type, frequency and duration of these responses (Goodman, 1981). Agents affecting other brain transmitter systems (e.g. cholinergic, serotonergic) interact with the DA system to alter APO-induced repetive pecking rates, for example; whereas, adrenergic agents are reported as ineffective (Cheng & Long, 1974). Because the latter report is based on limited testing and because norepinephrine (NE) is implicated in repetitive pecking induced by a feeding intervention (FIBS) (Goodman et al, 1983), the present study attempted to further test the possible influence of adrenergic systems on APO sterotypy.

Observations of adult male pigeon behavior were made by raters via a video monitor. The procedure of visual-hand counting has the disadvantage of requiring vigilant viewing, but permits measurement of non-wall or -floor pecks (e.g. air and body pecks) and non-pecking sterotypies (e.g. headshakes, mandibulating, and swallowing), which an automated sensing system might misinterpret or ignore. Birds were tested with a fixed dose (1.5 mg/kg, im) of APO alone during one session and with the systemic administration of adrenergic test drugs preceding that of APO in another session.

Clonidine, an alpha agonist acting at pre- and postsynaptic receptors, slightly increased pecking rates at low doses (below .03 mg/kg), but markedly decreased pecking at higher doses, as did yohimbine, a presynaptic alpha antagonist, (.1 - 1.0 mg/kg). Prazosin, a postsynaptic alpha antagonist, on the other hand, increased pecking (.1 - .5 mg/kg). The beta antagonist, propranolol, reduced pecking slightly at 3 mg/kg and below, and markedly above this dosage. Isoproterenol, a beta agonist, markedly increased pecking at .05 mg/kg.

Future work should more directly test the effects of centrally administered adrenergic agents to separate out peripheral contributions and localize their central site(s) of action.

234.2 ACCUMBENS DOPAMINE MODULATES AMYGDALA SUPPRESSION OF SPONTANEOUS EXPLORATORY ACTIVITY IN RATS. C.Y. Yim and G.J. Mogenson. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada. N6A 5C1

Previous electrophysiological experiments showed that stimulation of the basolateral nucleus of the amygdala (AMY) inhibits ventral pallidal (VP) neurons and that the inhibition was modulated by accumbens (NAcc) dopamine (DA) (J. Neurophysiol. 50(1983)-148). VP neurons, on the other hand, project to the midbrain mesencephalic locomotor region and it has been shown that GABAergic inhibition of neuronal activity in the VP suppresses locomotor activity. These observations suggest that AMY may have an inhibitory influence on ambulatory activity mediated by way of the projection to the NAcc and subsequently to the VP. Furthermore, as suggested by the electrophysiological findings, the influence of AMY on locomotor activity may be modulated by NAcc DA. To investigate these possibilities, the effects and interactions of injections of NMDA into the AMY and DA into the NAcc on the spontaneous ambulatory activity of rats were tested in a series of behavioral experiments. Male Wistar rats implanted with injection guide cannulae into the AMY, NAcc and/or VP were placed in an experimental cage partitioned into 3 chambers with communicating holes between the chambers. Animals remained spontaneously active in the experimental cage for over 30 min even for repeated trials. It was found that NMDA injection into the AMY produced a 35%-72% (n=48) reduction in this spontaneous exploratory activity. The suppression of the exploratory behavior was enhanced by an injection of nipecotic acid (.5-1.0 ug), a GABA uptake inhibitor, into the VP but was attenuated by injection of GDEE (5 ug), a glutamatergic receptor blocker, or DA (5 ug) into the NAcc. None of these injections by themselves produced any significant change in locomotor activity. These findings indicate that the AMY to NAcc to VP projection has an inhibitory role in the behaving animal, a hypothesis which is consistent with electrophysiological findings and earlier reports in the literature that stimulation of AMY produces "arrest" and "attentive" responses in animals. Furthermore, these results also illustrate that dopamine released in the accumbens, perhaps by other competing behavioral processes, can indirectly activate the motor system by suppressing the inhibition from the amygdala by a presynaptic modulatory action shown in previous electrophysiological experiments.

234.3 DIFFERENTIAL EFFECTS OF DOPAMINE D_1 AND D_2 AGONISTS (SKF 38393 AND QUINPIROLE - LY 171555) AND ANTAGONISTS (SCH 23390 AND SULPIRIDE) ON THE ACOUSTIC STARTLE REFLEX: INTERACTIONS WITH APOMORPHINE AND COCAINE. M. Davis, Dept. Psychiat., Yale Univ. Sch. Med., 34 Park St. New Haven, Ct 06508

The acoustic startle reflex is known to be increased by drugs that increase dopamine transmission such as d-amphetamine, apomorphine, and cocaine. The present study evaluated the effects of more selective D_1 and D_2 agonists on this behavior.

Groups of 10 rats each were injected subcutaneously with a selective agonist or its vehicle and startle was elicited with a 105-dB burst of white noise presented once every 20 sec for a 30-60 min period immediately after injection. The D_2 agonist quinpirole markedly and potently (ED_{50} = 0.30 mg/kg) depressed acoustic startle monotonically over a dose range of 0.07 to 10 mg/kg. This effect was blocked by the D_2 antagonist sulpiride (20 mg/kg), which at this dose did not alter startle. In contrast, the D_1 antagonist SCH 23390 (0.25 mg/kg) depressed startle baseline but still did not block the inhibitory effect of quinpirole. On the other hand, the D_1 agonist SKF 38395 (5 - 40 mg/kg) increased acoustic startle. The excitatory effect of 40 mg/kg was blocked by the D_1 antagonist SCH 23390 (0.25 mg/kg). Similarly, excitatory effects of cocaine (10 mg/kg) were blocked by SCH 23390. In contrast, this same dose of SCH 23390 did not block excitatory effects of other drugs such as strychnine (1.0 mg/kg) or 8-OH-DPAT (1.25 mg/kg) which increase startle by non-dopaminergic mechanisms.

These data suggest that D_2 agonists depress acoustic startle whereas D_1 agonists increase acoustic startle. Given this antagonist relationship between D_1 and D_2 selective drugs, the effects of mixed D_1,D_2 agonists like apomorphine on acoustic startle may result from a balance between D_2 mediated inhibition and D_1 mediated excitation. Consistent with this hypothesis, a dose of 0.4 mg/kg of apomorphine, which increases acoustic startle in vehicle-pretreated rats, actually depresses startle after pretreatment with the D_1 antagonist, SCH 23390. Conversely, the excitatory effect of 0.2 mg/kg of apomorphine was augmented by pretreatment with sulpiride (20 mg/kg).

These data suggest that activation of D_1 and D_2 receptors can have opposite effects on a simple reflex. Moreover, acoustic startle provides the advantage that the same behavioral measure could be used to evaluate functional changes in D_1 vs. D_2 receptor sensitivity following denervation or chronic treatment with dopamine antagonists, a subject currently being investigated.

234.4 **A COMPARISON OF INTRASTRIATAL AND PERIPHERAL AMPHETAMINE STEREOTYPY.** J.M. Wallace* and P. Winn* (SPON: P. Dean). Dept. Psychol., Univ. St. Andrews, St. Andrews, Fife, Scotland KY16 9JU.

Lesion studies suggest that (d-) amphetamine (AMP) stereotypy is mediated by dopamine (DA) in the dorsal striatum (DS) while AMP-induced locomotion is mediated by the DA in the ventral striatum (VS) (Kelly P., Seviour P.W. and Iversen S.D., Brain Res., 94: 507-522, 1975). However, attempts to induce stereotypy by injection of AMP into DS have not been wholly successful. It might be suggested that to produce stereotypy equivalent to that induced by i.p. AMP one needs to stimulate both DS and VS. If this is the case, simultaneous injection of AMP into DS and VS should produce responses similar to i.p. AMP; but if stereotypy can be produced by stimulation of DS alone, and locomotion by VS, it would suggest striatal dissociation. Twelve male rats were implanted with 2 pairs of bilateral guide cannulae, one aimed at DS the other at VS. Rats were given 3 habituation sessions of 1 hr each. After this i.p. injection of 5mg/kg AMP and saline were given in a randomised order, followed by 4 intracerebral AMP conditions: VS 160ug AMP, DS saline; VS saline, DS 160ug; VS 80ug, DS 80ug; VS saline, DS saline. Each injection was of 2ul, infused over 4min and cannulae were left for a further 2min to allow for diffusion. A minimum of 48hr was allowed between treatments. Behaviour was categorised using a checklist and a modified Creese-Iversen stereotypy rating scale, observations being made in a 10sec window every 2min for 40min. Infusion of AMP into DS, VS or DS/VS produced stereotypy no different to that of 5mg/kg i.p.. Chekclist data revealed some AMP-saline differences: infusion into VS produced more sniffing, rearing and locomotion than control; infusion into DS produced no increase in rearing or locomotion but did increase head down movements and sniffing; simultaneous infusion into DS and VS increased locomotion and sniffing but not rearing. Rating scale data suggests that infusion into VS or DS/VS produces a stereotypy with locomotion but that infusion into DS produces stereotypy in a fixed position. These data suggest that it is possible to elicit stereotypy from infusion of AMP into the striatum indistinguishable from that produced by 5mg/kg i.p., but that the dissociation of DS and VS is not as clear as has been thought.

234.5 IN VIVO DIALYSIS MEASUREMENTS OF STRIATAL DOPAMINE AND DOPAC IN THE TRAINED CIRCLING RAT. K.E. Sabol and C.R. Freed, Univ. of Colo. Health Sciences Center, Denver, CO 80262.

Previous reports from our laboratory have shown that trained circling rats have increased dopamine (DA) and DOPAC levels in striatum contralateral (contra) to the direction of the circling. (Yamamoto and Freed, Nature 298: 467, 1982; Freed and Yamamoto, Science 229: 62, 1985). These results were obtained using direct tissue assay and in vivo electrochemistry. We have now used the technique of in vivo dialysis to directly measure release of striatal DA and DOPAC during movement. Male Sprague-Dawley rats 300-350 gm were trained to run in place on a circular treadmill. The treadmill apparatus was made of 2 concentric plexiglass tubes, the outer 8" and the inner 2" in diameter. The rats ran in the circular path between the 2 cylinders. One quarter of the chamber was closed off to the rat and contained a tail holding device. The floor was detached from the rest of the chamber and was free to rotate. A liquid feeder was attached to the inner cylinder. Rats were water deprived and placed in the chamber with the tail clamped. As the animal walked in place with its anchored tail, the floor moved under him. The animal received a drop of water for each 360 degree turn of the floor disk. The circular shape of the chamber and running path led to an asymmetric arc posture. The apparatus was designed so that the rat could circle both to the right and left and turning was monitored by a VIC-20 microcomputer. When stable performance was achieved in both directions, rats were implanted with 17 gauge guide cannulae which extended 3 mm below dura overlying striatum. After one week of surgical recovery and additional training, animals were tested with an in vivo dialysis probe lowered into medial anterior striatum (A 2.4 mm anterior to bregma, L 2.0 mm, H 7.5 mm below dura; nosebar set at +5). The concentric design dialysis probe was made of 300 μ diameter dialysis tubing (ENKA). Ringer's solution was perfused through the cannula at 0.52 μl/min and the effluent was directly injected into an on-line HPLC system. Every 10 min, a 5 μl sample was automatically injected onto a 100 x 1 mm microbore column (Keystone Scientific: 3 μ C18 Spherisorb packing) by a pneumatically activated valve under the control of a VIC-20 microcomputer. An ISCO uLC-500 HPLC syringe pump and BAS LC-4B EC detector were used. Mobile phase consisted of 0.05 M trichloroacetic acid, 0.2 M H_3PO_4, 0.1 mM EDTA, 3% MeOH, 0.22 mM octyl sodium sulfate, and pH = 4.4. Under these chromatographic conditions, DOPAC and DA retention times were 3.0 and 5.8 min respectively. Three hours after the cannulae were lowered into the brain baseline DOPAC values were 14.4 ± 1.8 pmole/5 ul/10 min; and dopamine values were 30.5 ± 4.4 fmole/5 ul/10 min. The effects of inplace circling on dopamine and DOPAC values will be discussed.

234.6 MEASUREMENT OF SEROTONIN RELEASE BY IN VIVO DIALYSIS IN HYPOTHALAMUS OF FREELY-MOVING RATS. M. Minzenberg* and S. Auerbach. Biological Sciences, Rutgers Univ., Piscataway, N. J. 08855.

A controversy exists concerning the role of serotonin (5-HT) in physiology. Pharmacological studies indicate that increased 5-HT release in the CNS mediates sleep onset. In opposition is evidence from single-unit studies that the discharge rate of 5-HT- neurons declines during the transition from waking to slow-wave sleep. An important factor to consider when interpreting single-unit studies is that release of 5-HT at terminal areas may be locally altered independent of changes in neuronal discharge. We are using in vivo dialysis to determine if there are significant dissociations between neuronal activity and 5-HT release that could account for the disparate conclusions.

Rats were stereotaxically implanted with guide cannulae aimed at the lateral hypothalamus. Two weeks later, a concentric-model dialysis probe was inserted into the hypothalamus through a guide cannula. The probe was perfused with artificial CSF through a fluid swivel. Rats were free to move within the experimental chamber. Analysis of 5-HT in the perfusate was accomplished via HPLC-EC.

Initial experiments were carried out to determine if 5-HT release reflects predicted effects of drugs that alter monoamine release. Fenfluramine is a 5-HT releasing agent that produces an acute behavioral "5-HT syndrome". Fenfluramine (10 mg/kg ip) stimulated 5-HT release to 2.1 ± 0.8 times the mean baseline value (at 1.5 h post drug; mean ± s.e.; n=5). Duration of the elevated 5-HT release closely paralleled the 2.5 h time course of the 5-HT syndrome. Local injection of fenfluramine (1 ug in 1 ul saline) into the hypothalamus had no apparent behavioral effects but produced a 2050% (mean; n=3) increase in 5-HT release. Peak release was obtained at 15 min post-drug.

We next examined 5-HT release across the light-dark cycle. Levels of 5-HT in the perfusate collected during the dark period was 260.5 ± 25.4% (mean ± s.e.; n=10) of 5-HT baseline levels before lights-off. Since rats are inactive for a significant portion of the light hours and very active in the dark, these results support previous electrophysiological studies in freely-moving cats that suggest decreased 5-HT activity at sleep onset. (supported by NSF grant BNS-8708014)

234.7 METAPHIT PREVENTS LOCOMOTOR ACTIVATION BY DOPAMINE UPTAKE BLOCKERS AND INCREASES HOMOVANILLIC ACID. M.E.A. Reith, P. Berger*, A.E. Jacobson*, K.C. Rice* and H. Sershen*. Ctr. for Neurochemistry, N.S. Kline Inst., Ward's Island, NY 10035, Clinical Neuroscience Research Unit, Yale Univ. Sch. of Med., New Haven, CT 06508, and NIADDK, NIH, Bethesda, MD 20892.

Metaphit (1-(1-(3-isothiocyanathophenyl)-cyclohexyl)-piperidine), a phencyclidine (PCP) analog and a proposed PCP receptor acylator, inactivates the carrier involved in the neuronal uptake of dopamine in in vitro experiments with mouse striatal preparations (Berger et al., Neuropharmacol. 25: 931, 1986; Schweri et al., J. Neurochem. 48: 102, 1987). The present experiments were carried out to assess whether in vivo administered metaphit (20 mg/kg i.v.) 1) produces a long-term blockade of dopamine uptake sites, 2) antagonizes the hyperactivity induced by various psychostimulant drugs, and 3) affects the concentrations of dopamine metabolites in the striatum and olfactory tubercle of young adult male BALB/cBy mice.

In ex vivo experiments 2 h and 24 h after i.v. metaphit-pretreatment, no changes were observed either in [^{3}H]cocaine binding to striatal membranes or in [^{3}H]dopamine uptake into synaptosomes or slices. In in vivo experiments 24 h after metaphit-pretreatment, selective labeling of dopamine uptake sites in the mouse striatum with [^{3}H]GBR (1-(2-(diphenylmethoxy)-ethyl)-4-(3-phenylpropyl)-piperazine) was unaffected.

Metaphit-pretreatment 24 h prior to locomotor testing, antagonized the hyperactivity induced by i.p. administration of dopamine uptake blockers (methylphenidate 20 mg/kg, mazindol 12 mg/kg, cocaine 25 mg/kg, GBR 20 mg/kg) but not that induced by drugs that affect locomotion by different mechanisms (amphetamine 6 mg/kg, phencyclidine 5 mg/kg). Metaphit did not affect the baselines of locomotor activity. No differences were observed between the pretreatment groups in the distribution of postinjection activities over 10-min blocks during the 30-min period after injection of methylphenidate, mazindol, or cocaine.

Twenty-four h after treatment with metaphit there was an increase in homovanillic acid in the striatum and olfactory tubercle. There was no effect of metaphit on the disappearance rate of 3,4-dihydroxyphenylacetic acid (half-life 8 min) and homovanillic acid from the striatum during monoamine oxidase inhibition with pargyline (100 mg/kg i.p.). If the increase in homovanillic acid reflects a higher rate of dopamine catabolism in metaphit-pretreated animals, it could explain the lack of locomotor stimulating effect of dopamine uptake blockers in these animals resulting from a rapid breakdown of extracellularly accumulated dopamine.

234.8 **SPARING FROM SENSORIMOTOR IMPAIRMENTS IN RATS DEPLETED OF BRAIN DOPAMINE DURING DEVELOPMENT.** **F.B. Weihmuller* and J.P. Bruno. Psychobiology Program, Dept. of Psychology, Ohio State University, Columbus, OH 43210.**

We have reported that rats given near-total depletions of brain DA on Day 3 do not exhibit the severe deficits in ingestion seen in comparably lesioned adults. The present experiments compared sensorimotor integration in rats depleted of striatal DA as neonates, weanlings, or adults, and determined whether exposure to stress can undermine these functions. Animals were injected with 6-HDA (150-250 ug, ivt) on Day 3, Day 15, or as adults 30 min after treatment with the NE uptake blocker desmethylimipramine (25 mg/kg, ip). Weanlings and adults were also given the MAO inhibitor pargyline (40 mg/kg, ip) to potentiate the actions of 6-HDA. Sensorimotor function was assessed using a comprehensive battery of tests in each group of animals soon after the lesion and once the pups reached adulthood. Rats sustaining ≥ 90% depletions of striatal DA as adults (n=6) exhibited akinesia, catalepsy, and tremor for up to 49 days after the lesion. These animals also exhibited sensory neglect, particularly of the hindlimbs and flanks, as 3-8 times more force was required to elicit orientation to a Von Frey hair than was needed in controls. Three aspects of the behavior of adult-treated animals were noteworthy. First, while the sensorimotor deficits in rats with ≥ 90% depletions persisted for up to 7 weeks postlesion, the initial ingestive deficits were only apparent for 7-9 days; thus the appearance of ingestive and sensorimotor deficits can be temporally dissociated. Second, deficits in sensorimotor integration were obvious even in rats with depletions as small as 50-80% (n=6), although they recovered more quickly. Third, even after these sensorimotor impairments had disappeared they could easily be reinstated by forcing the animals to swim in cold (13°C) water for 25 sec. In marked contrast, rats sustaining ≥ 90% depletions on Day 3 (n=4) or Day 15 (n=6) did not exhibit any signs of akinesia, catalepsy, tremor, or sensory neglect either soon after the lesion or once they reached adulthood. Moreover, the stress of a cold-water swim revealed no deficits. These results extend our original observations by demonstrating that the behavioral sparing seen in rats depleted of DA as neonates is also seen when lesions are made during weaning and that the nature of this sparing includes sensorimotor functions as well as ingestive behavior.

234.9 MAPPING OF DOPAMINE LEVELS IN THE MESO-CORTICAL DOPAMINE TERMINAL FIELD: AN IN VIVO ELECTROCHEMICAL STUDY. G. Gerhardt, M. Parrish* and A. Gratton, Depts. of Psychiat. & Pharmacol., U. of Colorado Hlth. Sci. Ctr., Denver, CO 80262.

There is increasing evidence that the meso-cortical dopamine (DA) system may be an important substrate for the euphoretic properties of psychomotor stimulants. While the anatomy of the DA cortical terminal field has been characterized with various histochemical techniques, there is little data describing, in vivo, the anatomical distribution and temporal dynamics of DA release in cortex. In the present study we measured, with in vivo high speed chronoamperometry, the release of cortical DA following local applications of potassium (K^+).

Male Sprague-Dawley rats were anesthetized with urethane and placed in a stereotaxic apparatus. A glass capillary filled with 123 mM K^+ and a Nafion-coated graphite/epoxy capillary (GEC) electrode were fastened together and lowered into the brain. The cortical region explored extended from 1.5 to 4.0 mm anterior to bregma and from 0.8 to 2.5 mm from the midline. Chronoamperometric measurements were performed by applying square-wave pulses (from -0.2 to +0.45 V) to the GEC at a rate of 5 Hz. The current flow resulting from the oxidation and subsequent reduction of electroactive species at the GEC tip was digitized and integrated over the last 60% of the positive and negative going pulses. The ratio of the recorded oxidation to reduction currents was used as an index for the identification of the released electroactive species. Figure A is an example of a K^+-evoked release of DA in the medial prefrontal cortex and Figure B shows variations in the magnitude of evoked releases as a function of the cortical sites tested. The anatomical distribution of K^+-evoked releases as well as the ratio of the recorded oxidation to reduction currents suggest that DA is the predominant monoamine in the area of cortex we studied. Interestingly, the magnitude and temporal dynamics of K^+-evoked releases of cortical DA appear to be similar to those previously reported in nucleus accumbens.

234.10 PHARMACOLOGICAL AND BEHAVIORAL STIMULATION PRODUCE CHANGES IN STRIATAL DOPAMINE ACTIVITY MEASURED BY IN VIVO DIALYSIS. J.D. Salamone*, E.D. Abercrombie, R.W. Keller, M.J. Zigmond, E.M. Stricker. (SPON: Shang Yao). Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

In order to monitor central dopamine-(DA)-related activity in behaving animals, rats were chronically implanted with dialysis cannulae in the neostriatum. The cannulae consisted of a 4.5 mm loop of dialysis tubing (pore size, 15000 Daltons) that was supported by stainless steel wire and glued to polyethylene tubing. Striatal dialysis perfusates were collected for several days after implantation, with the rats allowed free movement in the test chamber by the use of a fluid commutator. Artificial CSF was pushed through the cannulae at a flow rate of 2.0 ul/min, and samples were collected at 15-30 min intervals. All samples were analyzed by high performance liquid chromatography with electrochemical detection, under conditions that permitted the measurement of DA and its metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA).

In baseline samples, DA was present in much lower concentrations than DOPAC and HVA. Systemic administration of 5.0 mg/kg amphetamine produced stereotyped behavior in parallel with increases in DA of 300% or greater. Perfusion with a medium that contained the DA uptake blocker nomifensine (10^{-5} M) increased extracellular DA by more than 400%. In contast, food-deprived rats that were feeding or lever-pressing for food reinforcement in 30-min sessions showed no consistent changes in DA. Feeding increased DOPAC and HVA by 8-15% relative to the baseline values. Responding on schedules of reinforcement also increased DOPAC and HVA, with HVA showing consistent and stable increases that reached a peak of 15-50% above baseline 30-120 min after the cessation of the behavioral session.

The increases in HVA demonstrate that behavioral activation can cause modest enhancement of DA turnover. However, it is possible that the high-affinity uptake of DA prevents the detection of small but behaviorally relevant increases in extracellular DA. These results suggest that the use of dialysis perfusion in behaving animals will allow for comparisons between DA activity and behavior across a broad range of conditions.

234.11 CATECHOLAMINE MEDIATION OF ROOTING AND PROBING IN NEONATAL RATS. L.M. Terry and W.G. Hall. Department of Psychology, Duke University, Durham, NC 27706.

When placed in contact with a dam, infant rats show vigorous rooting and probing into the maternal fur as they search for a nipple. Similar appetitive responding can reliably be elicited experimentally by placing pups on synthetic fur. Our work indicates that such responding is increased by deprivation of nutrition and maternal care (Bornstein et al., 1987). Because appetitive behavior in adult rats is modulated by catecholamine functioning, this study was carried out to assess the role of catecholamine synthesis in the early appetitive responding of rats and, in particular, the enhanced responding of deprived pups.

Six-day-old infant rats were placed in one of three deprivation conditions 22 hr prior to testing: maternally and nutritionally deprived (M&N), nutritionally deprived (N; pups received maternal stimulation from a nonlactating dam), or nondeprived (ND). Four hr before testing 1 pup from each deprivation condition received a s.c. injection of either saline, 100 mg/kg alpha-methyl-p-tyrosine (AMPT), or 150 mg/kg AMPT to inhibit catecholamine synthesis. Baseline activity and behavioral measures were taken just prior to testing. All pups were placed on synthetic fur for 30 min while in a warm incubator. Detailed behavioral observations were made every 5 min.

Baseline activity scores did not vary between drug groups, though, pups in the M&N deprivation group showed more rooting and probing than ND pups or N pups. Probing and activity scores of M&N pups when placed on fur were significantly affected by AMPT. During the first 10 min of fur stimulation all M&N pups showed high levels of locomotion, rooting and probing. Thereafter, pups treated with AMPT showed significant decreases in rooting, probing and locomotion. Untreated pups' activity remained at high levels for the entire 30 min period. Pups in both the N and the ND deprivation groups were unaffected by AMPT throughout the testing period.

Inhibition of catecholamine synthesis significantly inhibits rooting and probing in deprived infant rats, and this effect occurs after an initial bout of high activity. This finding, based on acute manipulations, suggests that the catecholamine system may play a role in mediating nipple search behavior in young rats.

234.12 SPONTANEOUS ACTIVITY OF STRIATAL NEURONS IS INCREASED IN ADULT RATS GIVEN DOPAMINE-DEPLETING BRAIN LESIONS AS NEONATES. S-P. Onn, J.R. Balzer*, E.M. Stricker, M.J. Zigmond, T.W. Berger. Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Near-total depletions of striatal dopamine (DA), produced by 6-hydroxydopamine (6-HDA)-induced brain lesions in adult rats, cause profound behavioral dysfunctions. In contrast, few such impairments are observed after the same large lesions are made in neonatal rats. We have shown that the spontaneous activity of two types of striatal neurons (Type I and Type II) increases in rats given the lesions as adults (Orr et al., Soc. Neurosci. Abstr. 1986), but returns to normal with recovery of behavioral function (Nisenbaum et al., Brain Res. 1986). The present work examined the spontaneous activity of Type II striatal neurons in adult rats behaving normally despite having received near-total DA-depleting brain lesions as neonates.

Three-day-old rat pups were injected with 6-HDA (150 ug, in 0.9% NaCl and 0.1% ascorbic acid) bilaterally into the lateral cerebroventricles. Three or four months later, the spontaneous activity of single striatal neurons (n = 47) was recorded extracellularly in these rats, using 8% chloral hydrate as anesthesia. Type I and II striatal neurons were identified by their different waveforms and different responses to paired impulse stimulation of the corticostriate pathway. Similar observations in rats not given 6-HDA were used for purposes of comparison. After electrophysiological recording, DA levels in striatal tissue were determined by high performance liquid chromatography with electrochemical detection.

The spontaneous activity of Type II striatal neurons in 6-HDA-treated rats was increased significantly in comparison with control animals. Neurochemical analyses indicated at least 90-95% depletions of striatal DA. These results indicate that the sparing of behavioral function in rats given large DA-depleting brain lesions as neonates is not associated with normal electrophysiological activity in Type II striatal neurons. The elevated activity of these cells instead resembles that seen in Type II striatal neurons of rats given the lesions as adults, in association with profound behavioral impairments.

We conclude that the appearance of normal behavior in rats despite large DA-depleting brain lesions is not invariably linked to normal activity in Type II striatal neurons. The effects of neonatal lesions on the activity of Type I striatal neurons is under investigation.

234.13 THE ROLE OF MESOLIMBIC DOPAMINE IN THE STIMULANT ACTION OF MDMA. L.H. Gold, C.B. Hubner and G.F. Koob. Div. of Preclinical Neuroscience and Endocrinology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

Substituted amphetamines combine hallucinogenic activity with the classical stimulant actions of amphetamine. When administered acutely, methylenedioxymethamphetamine (MDMA) causes a decrease in brain concentrations of tryptophan hydroxylase, serotonin (5-HT) and 5-hydroxyindoleacetic acid. In vitro, MDMA releases ^{3}H[5-HT] from whole brain synaptosomes and striatal slices. Evidence from various laboratories suggests that MDMA may also act on the dopamine system. MDMA has a dose response curve parallel to apomorphine in a drug discrimination test and demonstrates sensitization, like that seen with amphetamine, in a DRL (differential reinforcement of low rate of responding) procedure. Moreover, using in vivo voltammetry, MDMA causes an initial transient dopamine decrease concomitantly with a more long-lasting decrease in 5-HT efflux measured in the nucleus accumbens (N. Acc.). Long term high level use of the parent compounds, methamphetamine and amphetamine, has been found to be toxic to dopamine and 5-HT neurons. Similarly there have been several recent reports which suggest a profound and relatively selective 5-HT terminal degeneration for both MDA and MDMA. Thus, although MDMA does not seem to be toxic to dopamine neurons, alterations in dopaminergic systems may be responsible for some of its acute behavioral effects.

The purpose of the present studies was to investigate the neural substrates for the stimulant properties of the amphetamine analog MDMA by examining the effects of neurotoxin specific lesions to the mesolimbic dopamine system on locomotor activity produced by MDMA. Rats received 6-OHDA or sham lesions of the N. Acc. and were probed on day 10 post-lesion with an injection of amphetamine (0.5 mg/kg subcutaneously) and tested in photocell cages for a two hour session. The number of photocell beam interruptions and crossovers were measured as an index of locomotor activity. On day 14 post-lesion all rats were injected with MDMA (10 mg/kg sc) and tested for a four hour session. MDMA produced an increase in locomotor activity in the sham operated animals that lasted for more than four hours, but this response was significantly attenuated in rats with lesions. Results suggest that like amphetamine, the locomotor activation associated with MDMA may involve the presynaptic release of dopamine in the region of the N. Acc. Determination of whether this depends on a serotonin interaction or serotonin neurotoxicity will require further study. (Supported in part by NIDA Grant DA 04043 and Parkinson's Disease Foundation Summer Fellowship)

234.14 AUTOMATED MEASUREMENT OF BEHAVIOR: TURNING AND WALL-FACING ASYMMETRIES AFTER 6-OHDA INJECTION INTO THE SUBSTANTIA NIGRA. A.E. Bonatz*, H. Steiner*, R.K.W. Schwarting and J.P. Huston. Institute of Physiological Psychology, University of Düsseldorf, 4000 Düsseldorf, Federal Republic of Germany.

Unilateral lesions of the nigrostriatal dopamine system induce sensorimotor asymmetries, usually measured as turning or lateralized sensory responsiveness ("neglect"). The tendency of a rat to move along the perimeter of an open field (called "wall-facing" or "peritaxis") can also be used as a behavioral measure of sensorimotor asymmetries (Steiner, et al., Behav. Brain Res., 22: 283, 1986).

We developed a video image analyzing system (VIAS) for automated measurement of behavior by digitized video images and microcomputer evaluation. This system records the rat's behavior by tracing not only its center point, but also its longitudinal axis. This provides acurate information about the rat's orientation. The VIAS simultaneously measures: (a) locomotion in meters, (b) turning by the number of 1/4, 1/2, 3/4 and complete turns, each classified in different diameter classes, and (c) peritaxis by the time spent facing the wall with either side of the body.

The VIAS was used to measure these three behaviors in rats after unilateral 6-OHDA lesions in the substantia nigra. The results show that: (1) VIAS measures with high validity (correlation with rater recorded data was r=.92 to .98 for the different behaviors). (2) Behavioral recovery from a SN lesion was indicated by decreasing number of narrow ipsiversive turns and an increasing number of turns with wider diameter. (3) Apomorphine- and amphetamine-induced turns differed in diameter. (4) Wall-facing (or peritaxis) was lateralized to the side ipsilateral to the 6-OHDA lesion and was sensitive to apomorphine and amphetamine effects: after amphetamine, wall-facing was predominantly with the side ipsilateral to the lesion and was reversed after apomorphine. (5) Recovery from peritaxis asymmetries was indicated by increased wall-facing with the side contralateral to the lesion.

It is concluded that VIAS provides a useful tool for a detailed measurement of turning behavior and lateralized wall-facing, and these can be used as behavioral indices of sensorimotor deficits after lesions in the basal ganglia.

234.15 A COMPARISON OF THE EFFECTS OF TYPICAL AND ATYPICAL NEUROLEPTICS ON SEXUAL BEHAVIOR IN MALE RATS. J.G. Pfaus* and A.G. Phillips, Department of Psychology, University of British Columbia, Vancouver, BC, Canada, V6T 1Y7.

Neuroleptic drugs induce a variety of sexual dysfunctions in both animals and humans. In male rats, typical neuroleptics such as chlorpromazine, haloperidol, or pimozide delay or inhibit the initiation of copulation, reduce the number of vaginal intromissions that precede ejaculation, and under some conditions reduce the ejaculation latency and increase the latency to reinitiate copulation after ejaculation. In contrast, atypical neuroleptics such as thioridazine delay the initiation of copulation but increase, rather than decrease, the latency to ejaculate. Other atypical neuroleptics such as sulperide, or peripheral dopamine (DA) antagonists such as domperidone, have no effect on copulation even at high doses. However, differences in methodology, especially concerning the degree of baseline sexual performance among subjects, make it difficult to compare the results of these studies.

In the present experiments, the dose-response effects of haloperidol, pimozide, clozapine, or metoclopramide were assessed on patterns of sexual behavior in intact, sexually active rats with a high level of sexual performance and experience. Following baseline testing for sexual behavior, sexually active rats were randomly assigned to receive a specific neuroleptic drug and received either 0, 0.1, 0.5, 1.0, or 5.0 mg/kg, sc of the drug in a latinized fashion at 4-day intervals. Sexual behavior was assessed following drug administration by placing the male with a sexually receptive female in a testing arena for 30 min. Testing times for each drug were chosen on the basis of previous studies.

Haloperidol and pimozide both significantly delayed the initiation of copulation in a dose-dependent fashion and reduced the number of intromissions that preceded ejaculation. High doses of haloperidol (1, 5 mg/kg) inhibited the initiation of copulation altogether. Clozapine, an atypical neuroleptic that preferentially blocks mesolimbic DA receptors, dose-dependently delayed, and at higher doses inhibited, the initiation of copulation but had no effect on copulatory behavior once it was initiated. In contrast, metoclopramide, an atypical neuroleptic that preferentially blocks mesostriatal DA receptors, dose-dependently reduced the number of intromissions that preceded ejaculation but had no effect on the ability of rats to initiate copulation.

The present experiments suggest that aspects of copulatory behavior are affected differently by neuroleptics depending upon their site of action in the brain. Blockade of mesolimbic DA receptors appears to delay the initiation of copulation whereas blockade of mesostriatal DA receptors decreases the ejaculatory threshold.

Supported by a grant from the Medical Research Council of Canada (PG-23).

234.16 **DIFFERENTIAL EFFECTS OF DOPAMINE ANTAGONISTS ON AMPHETAMINE-INDUCED LOCOMOTOR STIMULATION AND REWARD.** **G.D. Carr and A.G. Phillips. Department of Psychology, University of British Columbia, Vancouver, BC, Canada, V6T 1Y7.**

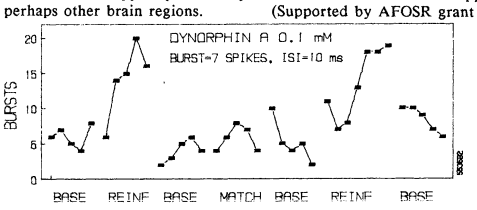
Two well-established behavioral effects of amphetamine are its locomotor stimulation and rewarding properties. Converging evidence has suggested that both of these effects are dependent, to a large extent, on the capacity of amphetamine to increase the release of dopamine in the nucleus accumbens. Both effects can be produced by intra-accumbens micro-injections of amphetamine and the effects of systemic injection are antagonized by lesions of the accumbens.

Previous studies have also reported that dopamine receptor antagonists (neuroleptics) block both the locomotor stimulation and reward. The present study investigated the effects of three atypical neuroleptics on these amphetamine effects in rats. To date, data has been obtained with one dose of each drug; metoclopramide (5mg/kg), clozapine (10mg/kg) or sulperide (20mg/kg) were injected prior to treatment with d-amphetamine (2mg/kg) (all injections s.c.). The animals were tested for the rewarding effects of the drug combinations using the conditioned place preference (CPP) paradigm. Rats received the drugs paired with one of two distinctive compartments and saline was paired with the other. Following six drug and saline pairings over 12 days, a partition separating the compartments was removed and the rats were given a free choice between the compartments. A preference for the drug-paired compartment was taken as evidence of a rewarding effect of the treatment. The pairing compartments were equiped with photocell beam detectors which served to measure the locomotor activity during the drug treatments. Amphetamine alone produced robust locomotor stimulation and CPP as previously reported. However, at the doses tested, the neuroleptics were differentially effective at blocking these effects. Metoclopramide and clozapine compietely blocked the locomotor stimulation but had no effect on the CPP. In contrast, sulperide blocked the CPP but had no effect on the locomotor stimulation.

In contrast to previous findings, this double dissociation of the rewarding and locomotor stimulant effects of amphetamine suggests that they may be mediated by separable dopaminergic substrates. A compiete dose-response curve will be needed to confirm and clarify this possibility.

235.1 **DYNORPHIN A: A NEW REINFORCEMENT TRANSMITTER?** L. Stein and J.D. Belluzzi. Department of Pharmacology, College of Medicine, University of California at Irvine, Irvine, CA 92717.

Recent mapping of the distribution of dynorphins in the rat brain (Fallon & Leslie, 1986) has revealed rich concentrations of dynorphin cell bodies and fibers in sites known to support very high rates of self-stimulation. For example, it is now possible to speculate that high rates of self-stimulation in the bed nucleus of the stria terminalis (Olds, 1962), ansa lenticularis (Stein *et al.*, 1973), ventrolateral central gray (Liebman *et al.*, 1973), and particularly in the region surrounding the superior cerebellar peduncle immediately lateral to locus coeruleus (Ritter & Stein, 1973) may be associated with their rich dynorphin innervation. In the latter two sites, self-stimulation is blocked by naloxone (Kelsey *et al* 1984; Loughlin *et al* 1983). In brain slice experiments, we have reported apparent reinforcement of individual CA1 cellular activity by pairing bursts of firing with local applications of dopamine, cocaine, or the selective dopamine D2 receptor agonist N0437 (Belluzzi & Stein, 1983; Stein & Belluzzi, 1987). However, the same dopaminergic drugs failed to reinforce the activity of hippocampal CA3 cells. Because there is a rich enkephalin and dynorphin projection from dentate granule cells to CA3 dendrites, we have attempted to reinforce CA3 activity with leucine-enkephalin and dynorphin A(1-17). Previous attempts to reinforce CA1 activity with these peptides were unsuccessful. In the present experiments, bursts of CA3 activity were recorded extracellularly; pressure microinjections were delivered through the same pipette. The number of spikes required to define a reinforceable burst were set individually for each neuron studied so that bursts occurred, on baseline, at the rate of 2-6/min. The Figure shows a representative positive experiment with dynorphin A (10^{-4}M in pipette) as reinforcement. The frequency of bursts was rapidly increased in two separate periods of operant conditioning (REINF), but not in a control period (MATCH) during which a matched number of dynorphin injections were presented independently of cellular activity. The relatively selective kappa agonist U50488H (10^{-4}M) also reinforced CA3 activity, but leucine-enkephalin (10^{-4} to 10^{-3}M) was ineffective. The results raise the intriguing possibility that dynorphin A may function as a reinforcement transmitter by activation of kappa opiate receptors in the CA3 field of hippocampus and perhaps other brain regions. (Supported by AFOSR grant 84-0325)



235.2 **OPERANT CONDITIONING OF HIPPOCAMPAL CA1 NEURONS REQUIRES IMMEDIATELY-CONTINGENT ACTIVATION OF DOPAMINE D2 RECEPTORS.** J.D. Belluzzi and L. Stein. Department of Pharmacology, College of Medicine, University of California at Irvine, Irvine, CA 92717.

Operant conditioning of individual CA1 cellular activity in slices of hippocampus with local applications of dopamine as reinforcement has been reported (Belluzzi & Stein, *Neurosci. Abst.*, 1983). More recently, we found that dopamine's reinforcing effects are exerted at dopamine D2 receptors (Belluzzi & Stein, *Neurosci. Abst.*, 1986). Here we report (1) that highly reliable neuronal operant conditioning is obtained with the specific dopamine D2 receptor agonist N0437 as reinforcement, and (2) that such operant conditioning is abolished when the reinforcing injection is delayed for 500ms after the neuronal response. A single-barrelled glass micropipette for simultaneous recording and pressure injection was filled with N0437 (10mM in 165mM saline) and aimed at spontaneously active pyramidal cells in the CA1 layer of hippocampal slices. The neuronal response for reinforcement was a "burst" of relatively fast activity. To be eligible for reinforcement, such bursts had to contain a minimum number of spikes; this minimum number was individually established for each neuron studied during a baseline period so that, prior to operant conditioning, reinforceable bursts occurred at a rate of approximately 5/min. In the reinforcement period, a pressure injector was activated for 10-80ms immediately after each burst to deliver a 10 μ-diameter droplet of drug to the vicinity of the cell body. The efficacy of operant conditioning associated with reinforcement delays of 0, 100, 200, or 500 ms was determined in an experiment involving 32 CA1 cells; each cell received operant conditioning at a single reinforcement delay. A delay-of-reinforcement gradient was generated by averaging the peak bursting rates associated with each delay (Figure). The curve indicates that reinforcement delays exceeding 200ms largely eliminate the effectiveness of N-0437 reinforcement in CA1 operant conditioning. The steep gradient of effectiveness of delayed reinforcement makes it unlikely that non-specific stimulation or some artifact of the injection procedure accounts for the increase in neuronal firing. Rather, the stringent requirement for contingency supports the idea that we have identified a neuronal conditioning process that may be closely related to behavioral operant conditioning. 235.3 EFFECTS OF PHLORIZIN ON INHIBITORY AVOIDANCE BEHAVIOR IN RATS AND MICE. J.L. Hall, K.L. Cottrill* and P.E. Gold. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.

Recent evidence indicates that peripheral and central glucose administration enhances memory in several tasks and in a variety of species including rats, mice, and humans. Additionally, circulating glucose levels measured soon after training predict later retention performance, suggesting that circulating glucose levels may regulate memory storage. Glucose gains access to the brain via a carrier-mediated transport mechanism. Phlorizin competes with glucose for binding to this carrier and thus inhibits glucose transport into the brain (Pardridge & Oldendorf, 1975, Biochim Biophys Acta, 382: 377-92). Believing that phlorizin might therefore impair memory, we tested the drug's effects on inhibitory avoidance training in mice and rats.

Mice were trained in a one-trial inhibitory (passive) avoidance task (200 uA escapable footshock). Thirty min prior to training, the animals received an injection of phlorizin (0.3-3.0 mg/kg, IP) or saline. On the test trial 48 hr later, animals which received phlorizin (0.3 or 3.0 mg/kg) had retention scores significantly higher than those of saline-injected animals. Thus, in contrast with our expectations, phlorizin actually enhanced memory storage.

Rats were also trained in a one-trial inhibitory avoidance task (0.5 mA, 0.5 sec). Thirty min prior to training animals received phlorizin (0.0003 - 0.3 mg/kg, IP) or saline. Animals were tested 24 hr later. The dose-response curve was inverted-U in shape. Phlorizin-injected animals (0.03 or 0.003 mg/kg) again had retention scores significantly higher than those of controls.

Since the brain is highly dependent on circulating glucose for its fuel, it is possible that the organism responds to insufficient glucose transport in a compensatory manner by increasing circulating glucose levels. Preliminary studies indicate that this is, in fact, the case. Animals injected with phlorizin (0.03 mg/kg IP) demonstrated elevations in circulating glucose levels of 26 $\pm$ 7 mg/dl near the time at which training would have occurred. Importantly, these increases in plasma glucose levels are comparable to those which predict good retention performance under other conditions as well. Additionally, the blood-brain barrier to glucose is a dynamic system. Thus with insufficient brain glucose, transport of glucose from blood to brain may increase. Future studies will address the issue of the extent to which the increases in plasma glucose effectively compensate for the loss in glucose transport in the presence of phlorizin. 235.4 FOURTH VENTRICLE ADMINISTRATION OF AN OPIOID ANALOGUE CAN BLOCK THE DEVELOPMENT OF CONDITIONED HEART RATE RESPONSES. G.C. Harris and R.D. Fitzgerald*. Department of Medical Psychology, Oregon Health Sciences University, Portland, OR, 97201.

Previous research has shown that administration of the opioid analogue [N-MePhe^3,D-Pro^4] morphiceptin into the rostral fourth ventricle abolished a previously learned heart rate (HR) conditioned response (CR) (Lavond, Mauk, Madden, IV, Barchas, & Thompson, Pharmacol Biochem Behav, 19: 379-382, 1983). The current study was designed to look at the effects of opioid administration in the rostral fourth ventricle on the development of HR CRs. Classical conditioning training consisted of a discrimination paradigm in which one (6-sec) tone conditioned stimulus (CS+) was paired with a 0.5 sec chest shock unconditioned stimulus (UCS), while a second tone (CS-) was not paired with shock. Three groups of rats were infused with either 0.9% saline (SAL), 10 µgs of D-ala^2-met-enkephalinamide (DALA), or 10 µgs of DALA + 5 µgs of the opioid antagonist naltrexone (DALA-NAL) in the rostral fourth ventricle. A fourth group (DALA-BR.ST.) was infused with 10 µgs of DALA in the brain stem ventral to the fourth ventricle infusion site. Drug infusions were made prior to the conditioning session on two consecutive days. All groups were then left in their home cages for two days after which time they were brought back and tested in a non-drugged state. The results showed that the DALA-NAL and DALA-BR.ST. groups showed the development of a normal HR CR, comparable to that seen in the SAL group. The DALA group, however, failed to develop a HR CR. The absence of a CR in this group was evident even when the rats were tested 48 hrs later in a non-drugged state. A significant reduction in the HR orienting reflex (OR) was seen in the DALA group only on the first CS presentation. No significant effects were seen on the HR UCR in the DALA group when compared to the SAL group. These results suggest that the decremental effects of DALA on the CR were due to the activation of opioid receptors located in the rostral fourth ventricle, possibly in the region of the locus coeruleus or in the periaqueductal/periventricular gray regions. It is thought that DALA may have prevented the development of a learned association by decreasing emotional awareness of stimuli. (Supported by NHLBI #T32-HL07332 and the N.L. Tartar Research Fund)

235.5 EFFECTS OF PHYSOSTIGMINE ON OPERANT SERIAL REVERSAL LEARNING. D.B. Clissold* and G.A. Heise*. (Spon: M.J. Pontecorvo). Nova Pharmaceutical Corporation, and Department of Psychology, Indiana University, Bloomington, Indiana 47401.

The effects of the anticholinesterase physostigmine on performance of repeated acquisition/reversal learning paradigms were examined. In Experiment 1, rats (n = 6/group) were trained to criterion on a series of three stimulus (bright, dim and flashing lights) reversal problems. Subjects remained on the same problem until criterion was met. The stimulus-response relationship was then reversed for two stimuli with the third stimulus constant over two problems. In different groups of rats, physostigmine (or an equal volume of vehicle) was injected either immediately prior to each session (0.03 mg/kg) or immediately following each session (0.5 mg/kg). After 50 sessions, the total number of discrimination problems solved was compared among the four groups. Animals injected with physostigmine either pre- or post-session solved more discrimination reversal problems than did control animals. Experiment 2 utilized a two-stimulus (bright vs dim light) reversal learning paradigm. Animals that were injected with physostigmine in Experiment 1 were injected with vehicle in Experiment 2. Animals injected with vehicle in Experiment 1 were injected with physostigmine in Experiment 2. The time of injection was held constant. Although no between-group differences were found in Experiment 2, a comparison of performance across Experiments 1 and 2 determined that individual animals learned significantly more reversal problems when injected with physostigmine, independent of stimulus condition (experiment). In Experiment 3, animals were trained to perform daily reversals of a light vs tone Go: No Go discrimination. This baseline of performance (trials to criterion) was the dependent variable for contrasting the effects of acute post-session injections of physostigmine (0.5 mg/kg) or vehicle. In this experiment, physostigmine resulted in a decrement in the next session's performance. Results are discussed in terms of cholinergic involvement in learning and memory.

235.6 RATS PERFORM WIN-STAY BETTER THAN WIN-SHIFT IN A TWO-CHOICE WATER ESCAPE SITUATION. L. W. Means. Psych. Dept., East Carolina Univ., Greenville, NC 27858-4353.

In both the T- and radial arm mazes rodents spontaneously make and readily acquire win-shift responses for positive reinforcement. On the other hand, shocking mice in the T-maze results in the development of a perseverative (win-stay) response (D. Mitchell, et al., Learn. & Mot., 1984, 15). In the circular water maze, rats acquire either a win-stay task when the escape platform location is held constant or a win-shift task when the platform is randomly placed in one of 4 positions (C.F. Mactutus & D.L. Murray, Soc. Neurosci. Abstr., 1986).

Three experiments were conducted to compare groups of Sprague-Dawley rats on win-stay and win-shift performance in a 1.4 m circular water maze. Fishline strung above divided the maze into 3 equal pie-wedge sections, a starting section and 2 choice sections. In all 3 experiments, subjects began each trial from the same location and escaped from the water (24+2°C) onto a platform hidden 1.0 cm below the surface. Trials were given in couplets: (1) a reference trial, during which the escape platform was randomly placed in the center of one of the choice sections, and (2) a test trial given 10 m later. For the win-stay task, the platform was placed at the same location on both trials of a couplet. For the win-shift task, the platform was placed in the opposite choice section on a test trial from that of the reference trial. In the first experiment, each group received 20 couplets. In the second experiment, each group received 55 couplets, and the platform was lowered to the bottom of the maze for 60 s following an incorrect first choice on any trial. In the third experiment, each group received 20 couplets, and a barrier separated the 2 choice sections of the maze. Also, the escape platform was lowered for 60 s following incorrect choices.

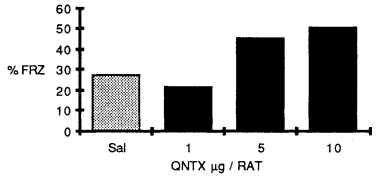
All 3 experiments produced the same results. Animals made significantly more correct test trial choices (entered section containing platform first) on the win-stay task than on the win-shift task. Animals that failed to learn on either task developed a position bias, going to the same section first on a series of consecutive trials. Thus, it appears that it is most natural for a rodent to perform win-stay responses in an aversive situation and win-shift responses in an appetitive situation.

235.7 SELECTIVE DOPAMINE D1 AND D2 RECEPTOR AGONISTS PRODUCE CONDITIONED TASTE AVERSIONS. D.C. Hoffman & R.J. Beninger. Dept. of Psychol., Queen's University, Kingston, Canada K7L 3N6.

Dopamine (DA) receptor agonists (e.g., apomorphine, cocaine and (+)-amphetamine) produce both rewarding and aversive effects in the conditioned place preference and conditioned taste aversion (CTA) paradigms, respectively. With the discovery of DA receptor subtypes, research has focused on determining the possible contributions of D1 and D2 receptors to these DA-mediated effects. Recently, we discovered that selective stimulation of D2 receptors with quinpirole in rats produced a significant place preference, however, treatment with a selective D1 agonist, SKF 38393, resulted in a significant place aversion. These data suggested that the rewarding and aversive properties of DA agonists may be mediated through two different receptor subtypes. If this is true, one might expect SKF 38393, but not quinpirole, to produce a CTA. This hypothesis was tested in the present experiment. The protocol consisted of 3 phases. During the 4-day pre-exposure phase, water-deprived male Wistar rats were presented with 2 flavored solutions for 30 min. The amount consumed was recorded. Conditioning occurred over the following 4 days; on days 1 and 3, rats were treated with drug and presented with one flavored solution. Doses of quinpirole (1.0 mg/kg IP) and SKF 38393 (10.0 mg/kg IP) which were effective in place conditioning were compared to the effects of (+)-amphetamine (2.0 mg/kg IP) and a saline control group. On days 2 and 4, all rats received saline and were given access to the alternate flavored solution. Test days occurred over the next 4 days during which untreated animals were presented with the 2 flavored solutions for 30 min. In contrast to the saline control group, rats treated with (+)-amphetamine, quinpirole or SKF 38393 demonstrated a significant decrease in percent intake of the conditioned flavor from pre-exposure to test indicating the establishment of a CTA. Thus, the hypothesis that the D1 receptor is exclusively involved in mediating the aversive qualities of DA agonists was not supported; both receptor subtypes appear to be involved in taste aversion learning. (Funded by the National Sciences and Engineering Research Council of Canada.)

235.8 CENTRAL BUT NOT PERIPHERAL ADMINISTRATION OF QUATERNARY NALTREXONE ENHANCES FREEZING. F.J. Helmstetter, D.J. Calcagnetti*, and M.S. Fanselow*. Department of Psychology, Dartmouth College, Hanover, N.H. 03755.

Administration of opioid antagonists prior to training in an aversive conditioning preparation using footshock tends to enhance acquisition of conditional defensive responding. We have previously demonstrated that i.p. administration of the tertiary form of naltrexone, which may act at both central and peripheral opioid binding sites, produces an enhancement of freezing at doses that block the analgesia conditioned with this procedure (Physiol Behav,39:501). Two experiments using naltrexone methobromide (QNTX), a quaternary compound that normally does not penetrate the "blood-brain barrier", were conducted to determine the relative contribution of central and peripheral opioid receptors to this effect. In the first experiment 20 female rats were given 1, 10, or 20 mg/ml/kg of QNTX or saline before being placed in a conditioning chamber. Four min later each rat received three 1ma/.75s footshocks spaced 20s apart. Subjects were returned to the chambers 24 h later and the amount of time spent engaged in de- fensive freezing was measured. QNTX administered i.p. had no reliable effect on conditional responding, $F(3,16) = 1.36$, $p > .20$. In the second experiment, 42 rats were prepared with cannula implanted into the right lateral ventricle. The procedure of the first experiment was followed except that now QNTX was administered i.c.v. (4µl/40s) at doses of 0, 1, 5 and 10 µg/rat. As indicated in the figure, QNTX given i.c.v. produced a reliable enhancement of freezing, $F(3,34) = 3.61$, $p < .03$. These results suggest that opioid modulation of aversive conditioning depends on a population of receptor sites within the central nervous system.



235.9 CHOLINERGIC MUSCARINIC BLOCKADE IN THE RAT IMPAIRS STRATEGY SELECTION BUT NOT LEARNING AND RETENTION OF NONSPATIAL VISUAL DISCRIMINATIONS IN A SWIMMING POOL. I.Q. Whishaw and B.F. Petrie*. Dept. of Psychology, Univ. of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

A puzzling feature of the research on cholinergic systems is its apparent bifurcated focus. Although it is known that cholinergic muscarinic receptor blocking agents such as atropine and scopolamine impair a wide range of physiological and behavioral functions, little attention has been directed toward the relationships between the abnormalities in unconditioned behaviors and conditioned behaviors. Ethologists have argued that an animal's ability to perform well on learning tasks is dependent on the existence of innate mechanisms that can be usefully applied to the task. Early learning theorists also suggested that animals experiment with "attempted solutions" or "hypotheses" from which the appropriate behavior pattern is eventually selected. The present study examined whether learning impairments following cholinergic blockade are due to impairments of systems that are in some way necessary precursors of learning or whether they are due to interference with processes of memory storage.

A procedure was developed to study black vs white and horizontal vs vertical pattern visual discriminations in a swimming pool. The effects of central cholinergic muscarinic receptor blockade by atropine sulfate was then evaluated. The drug treatment impaired acquisition but not retention. Behavioral observations showed that the control rats used a number of strategies during the process of problem solving that facilitated acquisition of the discrimination. Through modifications of training procedures, the processes of strategy selection and discrimination learning were dissociated. Cholinergic blockade was found to impair strategy selection but not discrimination learning. The results question the widely held view that cholinergic systems are involved in learning and memory and suggest instead that cholinergic systems are involved in the selection of the movements or strategies that are prerequisite for learning.

235.10 MODULATION OF MEMORY RETENTION BY GUT PEPTIDES IN MICE. J.E. Morley and J.F. Flood, GRECC, VA Medical Center, Sepulveda, CA 91343

Recently, we showed that feeding immediately after learning enhanced retention for footshock avoidance training (Flood et al., Science, 1987). CCK also enhanced memory on this task but its effect could be abolished by vagotomy. The effect of feeding on memory is not blocked by vagotomy. We, therefore, reasoned that other gastrointestinal peptides may also enhance memory by a vagally independent mechanism.

To test this, mice were partially trained on a t-maze footshock avoidance task. Immediately after training mice received an intraperitoneal (IP) or intracerebroventricular (ICV) injection of bombesin, gastrin releasing peptide (GRP) or saline. Retention was tested one week later.

The results indicate that bombesin at 1 ug/kg IP (73% recall score) or GRP at 10 ug/kg IP (80% recall score) enhanced retention relative to a saline control group (13% recall score). Optimal improvement of retention with ICV administration required higher doses than were administered IP; bombesin significantly improving retention at 0.5 ug (as compared to 0.035 ug/mouse IP) and GRP at 2.5 ug (as compared to 0.35 ug/mouse IP). The higher doses needed to improve retention by the central route of administration suggests that bombesin and GRP act through a peripheral mechanism or that the site of action in the central nervous system is not readily penetrated by the ICV administration.

These data indicate that a number of gastrointestinal peptides that inhibit feeding will also enhance memory by a peripheral mechanism. The teleological advantage of memory being enhanced after ingesting a meal is obvious.

235.11 INTRASEPTAL INJECTION OF GABA-A, BUT NOT GABA-B, RECEPTOR AGONISTS PRODUCES DOSE-RELATED WORKING MEMORY IMPAIRMENTS IN THE RAT. J. J. Chrobak, D. F. Emerich, F. Safir-Temple, G. M. Spindler *and T. J. Walsh. Department of Psychology, Rutgers University, New Brunswick, NJ, 08903, USA.

The septohippocampal cholinergic system appears to be a critical neural substrate for memory processes. Alterations of this system induced by drugs, cholinotoxins such as ethylcholine aziridinium ion (AF64A), or neurodegenerative diseases produce impairments in working memory tasks. Manipulation of GABAergic receptors within the medial septum decreases the turnover of acetylcholine in the hippocampus. The following experiments examined whether intraseptal injection of GABA-A (muscimol) or GABA-B (baclofen) agonists would produce working memory impairments similar to those observed following compromise of the septohippocampal cholinergic system.

Twelve male Sprague-Dawley rats were trained to perform a radial-arm-maze task with a one hour delay imposed between the fourth and fifth maze choice. In this task rats have access to 4 out of 8 maze arms during a pre-delay session; the pattern of arms varying daily. After choosing these 4 arms, the animals are returned to their home cages for one hour. Following the delay, they are returned to the maze and allowed to freely chose among all 8 arms. Arms not previously chosen are baited, and entry into arms chosen during the pre-delay session constitutes an error. Following acquisition, a single indwelling canulae was implanted into the medial septal region and animals were allowed one week to recover from the surgery before behavioral testing resumed. A within-subjects design was utilized to examine the effects of intraseptal administration of muscimol (0, 0.75, 1.5 or 3.0 nanomoles) and baclofen (3.0 nanomoles), on RAM performance. All drugs or artificial CSF were administered immediately following the pre-delay session in a volume of 1 ul.

The GABA-A agonist, muscimol, produced a dose-dependent impairment in RAM performance when administered immediately following the pre-delay session. The GABA-B agonist, baclofen, which has been shown not to alter ACh turnover, did not alter performance of this task. Muscimol did not alter motor behavior; following intraseptal injection rats chose arms, consumed food pellets and completed the task with latencies comparable to those observed on control days. Similar muscimol-induced impairments were observed when delays of four hours were imposed between training and testing suggesting that the behavioral deficits represented an inability to store or retain spatial working memories rather than a general performance deficit. These studies demonstrate that pharmacological manipulation of GABA-A receptors in the medial septum modifies working memory processes in the rat. Studies are in progress to determine whether these cognitive deficits are related to an alteration in septohippocampal cholinergic activity.

235.12 STIMULATION OF BRAIN NICOTINIC RECEPTORS ENHANCES MEMORY IN A DELAYED MATCHING TASK BY MONKEYS. K. Elrod, W.J. Jackson and J.J. Buccafusco. Dept. of Pharmacology and Toxicology, and Physiology and Endocrinology, Medical College of Georgia and Veterans Administration Medical Center, Augusta, GA 30912.

Brain cholinergic neurons are known to play an important role in the processes of learning and memory. A selective loss of cholinergic neurons in pathways important for such processes may at least in part underly the symptoms associated with Alzheimer's disease. Such a cholinergic deficiency is readily apparent when measuring enzyme markers selective for cholinergic neurons in autopsy tissue samples. In contrast, the receptive field of muscarinic receptors does not usually exhibit a loss in affinity or number. Several recent reports have, however, confirmed a loss of nicotinic binding sites in relevant brain structures. The role of these nicotinic receptors is not well understood; however, nicotine is known to facilitate acetylcholine release. The purpose of this study was to determine whether nicotine could enhance memory performance, and whether the centrally-acting nicotinic antagonist mecamylamine, could produce the reverse effect. Four young adult macaque monkeys were well-trained in a matching-to-sample paradigm over a period of several months. During the course of this study, the monkeys were maintained at 85% body weight and received food reinforcement pellets for correct responses in the task. Just prior to each set of matching problems a monkey was given an i.m. injection of one of several doses of nicotine. Three of four monkeys exhibited enhanced performance following administration of at least one of the doses of nicotine. The optimal dose, reflected by the most facilitation, was 2.5 or 5 ug/kg. Overall, we observed an approximate 13% improvement in performance at the longer delay periods in monkeys receiving benefit from nicotine. While the dose-response relationship was highly individualized for each animal, the maximal degree of improvement following nicotine occurred at the longer delay intervals. The beneficial effect of nicotine could be repeated in each animal on several occasions. The ability of nicotine to enhance performance in these animals depended upon the dose administered as well as the degree of difficulty of the task presented. In contrast to the facilitating effects of nicotine, administration of 0.25 - 2 mg/kg mecamylamine produced a dose-related impairment in performance. The selective peripheral nicotinic antagonist, hexamethonium, 2 mg/kg, was not as effective in inhibiting matching performance. These results indicate that nicotinic receptors may be exploited pharmacologically to enhance memory processes. If these results have application to humans, patients with cognitive deficits involving learning and memory might receive more benefit than normal individuals from drugs which stimulate brain cholinergic nicotinic receptors. Supported by BRSG 5-07-RR05635-25 and the Veterans Admin.

235.13 REPEATED ACQUISITION OF RADIAL MAZE PERFORMANCE: A NOVEL PROCEDURE FOR ASSESSING CHEMICALLY INDUCED DISRUPTION OF ASSOCIATIVE LEARNING. D.B. Peele and S.P. Baron*, Northrop Services, Inc.- Environmental Sciences, Research Triangle Park, NC 27709.

Deficits in learning, memory and other cognitive processes are commonly reported in humans following exposure to a diverse range of industrial and agricultural chemicals. Despite the existence of a vast number of environmental chemicals whose neurotoxic potential has yet to be assessed, there are virtually no acceptable techniques to rapidly screen for potential chemically induced learning deficits. Further, few tests exist that are capable of longitudinal learning assessments; typically, learning is assessed only once in individual animal subjects. The present experiment was designed to address these problems by examining a repeated acquisition (learning) paradigm with rats performing in a radial-arm maze.

Adult male Long-Evans rats were trained on a radial maze task in which 45-mg food pellets were available in only four of the eight arms of the maze; the particular arms containing food were assigned randomly at the start of each daily session. The automated maze consisted of a covered, eight-arm Plexiglas maze with pellet dispensers located at the distal end of each arm. Access to the arms was permitted by raising or lowering pneumatically controlled guillotine doors, located at the entrance of each arm. Experimental conditions and data collection were arranged by a minicomputer. A trial terminated when the rat obtained all four pellets, or following 300 sec. During each 14-trial daily session, the number of errors (selecting non-baited arms or repeated arm selections) showed a within-session decline and choice accuracy for the first four arm selections showed a positive acceleration across trials for all subjects. Scopolamine (0.03 to 0.3 mg/kg, ip), but not methylscopolamine (0.3 mg/kg, ip), reduced the accuracy of the first four arm selections and increased total errors in a dosage-dependent manner. Session times were also increased by the highest dosages of scopolamine. An examination of within-session error reduction showed only slight signs of improvement (i.e., learning) at the higher dosages of scopolamine. The ease and rapidity with which rats acquired the baseline and the sensitivity of performance to disruption by scopolamine suggests that repeated acquisition of radial-arm maze performance holds promise as a convenient procedure for detecting learning deficits induced by chemical exposure.

235.14 SPATIAL NAVIGATION: DISRUPTION BY MOTOR IMPAIRMENTS? C.F. MACTUTUS, C.R. GUTMAN*, and R.M. BOOZE, Dept. of Medicine (Toxicol.), Jefferson Medical College, Philadelphia, PA 19107 and Dept. of Medicine (Neurol.), Duke University, Durham, NC 27705.

The water maze paradigm, as elegantly demonstrated (Morris, 1981), utilizes place and cue tasks to dissociate treatment effects on spatial localization from motivational or motor performance factors. Similar careful studies have been performed with hippocampal lesions (Morris et al., 1982) and cholinergic agents (Whishaw, 1985). We explored the boundary conditions regarding the susceptibility of spatial localization to disruption by motor impairments induced by a well-characterized tremorogen--harmine.

Adult Fischer-344 rats, bred in our laboratory, had received previous training to find a hidden platform (10 cm^2), positioned 2.5 cm below the milky white, opaque, water surface, in a 1.2 m circular water maze. The animal's prior experience included a total of 40 training trials (with a fixed or random platform location), a probe test, and a transfer test. Presently, all animals received 4 training trials, with a fixed or randomly located platform (ns=24), and were then administered saline or harmine (10 mg/kg). After a delay of 10 or 30 min the animals received 4 additional training trials followed by a probe test trial. Consistent with their extensive experience the animals' training latencies were quite rapid, but asymptotic performance values were significantly shorter for the fixed (7.5 sec) relative to the random (11.3 sec) group ($p < 0.005$). Harmine severely disrupted swimming behavior as observed by the marked and similar increase in response latencies for both the fixed (3.9 vs 26.8 sec) and random (11.6 vs 25.2 sec) platform groups. Post-injection delay did not alter the magnitude of this disruption. Quadrant preference scores during the probe trial suggested the performance of harmine treated rats in the 10-min delay condition was indistinguishable from saline-injected controls; the performance of animals in the random platform groups was similarly unaffected. In contrast, harmine-treated rats in the 30-min delay condition displayed little if any spatial bias for the prior platform location, i.e., their preference scores were indistinguishable from those of both random platform groups but were significantly impaired relative to the saline-injected fixed platform group ($p < 0.005$). A quantitative assessment of whole body tremor indicated that although marked tremor was present in both delay groups, the disruption of spatial localization was associated only with a more intense tremor. In sum, despite the frank motor disturbance and impairment of swimming performance induced by harmine, spatial localization may not be impaired. Such relative resistance to disruption suggests this task may be particularly appropriate for investigating potential cognitive dysfunction produced by toxicants or other chemical agents of unknown action.

235.15 SINGLE AND REPEATED ADMINISTRATIONS OF AF102B, A NOVEL MUSCARINIC AGONIST, IMPROVE COGNITIVE DYSFUNCTIONS IN AF64A-TREATED RATS. N.Nakahara*, Y.Iga*, S.Samuraizono*, T.Sawai*, S.Katayama*, and F.Mizobe, Res.Inst.of Life Sci., Snow Brand Milk Products Co., Tochigi 329-05, Japan

Senile dementia of the Alzheimer type (SDAT) is characterized behaviorally by a general decline in cognitive function. A marked presynaptic hypofunction in cholinergic system is observed in certain brain regions involved in cognitive processes, whereas postsynaptic muscarinic receptors seem to be relatively intact. These findings suggest the possibility to develop a novel treatment approach for SDAT ,i.e., when cholinergic nerve terminals are diminished, a muscarinic agonist directly acting on postsynaptic M1 receptors compensates for loss of ACh and alleviates cognitive dysfunctions. AF64A treatment of rat has been reported to result in a selective and irreversible reduction of presynaptic markers in cholinergic system, and suggested to provide a potential animal model for SDAT. We have investigated the effects of AF102B on performance of AF64A-treated rats (AF64A-rats) in a step-through passive avoidance task and a delayed nonmatching to sample task in T-maze. Electrophysiological and biochemical studies in rabbit SCG and the CNS synaptosomes have suggested that AF102B is a muscarinic M1-type agonist.

Male Sprague-Dawley rats were treated with AF64A (3 nmole/2 ul/side, ICV). We have observed damages in septum, but not in fimbria-fornix, by light microscopic examination of tissues taken 30 days after AF64A treatment. ChAT activity was reduced in hippocampus, but not in frontal cortex and striatum. No significant difference between AF64A-rats and control-rats was found in sensitivity to electric shock and in spontaneous motor activity. AF64A-rats exhibited impairments of performance both in passive avoidance and in T-maze.

A single administration of AF102B to AF64A-rats resulted in a significant improvement in a passive avoidance task at doses of 1.0 mg/kg,i.p. and 1.0 mg/kg,p.o. The performance in a T-maze task was examined to evaluate the effects of chronic administrations of AF102B for 5 weeks. AF102B (5.0 mg/kg,i.p.) significantly improved the performance of AF64A-rats in a T-maze task at the fourth and fifth week. Any side-effects in behavior were not observed in the rats during 5-week periods for chronic administration of AF102B.

In conclusion, AF102B can be considered as a potential candidate for SDAT treatment.

235.16 BEHAVIORAL EFFECTS OF TETRAHYDROAMINOACRIDINE FOLLOWING SCOPOLAMINE PRETREATMENT AND NUCLEUS BASALIS MAGNOCELLULARIS LESIONS IN RATS. C.P.J. Dokla[1], P. Gabos*[1], J.C. Babrowicz*[1], L. Rydelek*[1], D. Pereira*[1], R. Patrignelli*[1], and L.J. Thal [2]. [1]Dept. of Psychology, Fairfield Univ., Fairfield, CT 06430 and [2]Dept. of Neurology, San Diego VA Medical Center, La Jolla, CA 92161.

1,2,3,4-tetrahydro-9-aminoacridine (THA), a potent, reversible, and long lasting anticholinesterase has recently been reported to be efficacious in the long-term treatment of Alzheimer's disease (Summers, W.K. et al. N. Engl. J. Med., 315: 1241, 1986). The behavioral and memory-enhancing effects of THA were examined in a series of experiments following treatment with the cholinergic muscarinic antagonist, scopolamine, and also after lesions of the rat nucleus basalis magnocellularis (NBM).

In Experiment 1, the ability of THA to reverse perseverative peripheral pool swimming induced by scopolamine was assessed. Male Long-Evans rats were given a single 5-min spontaneous swim test (Symons, J.P. et al. Soc. Neurosci. Abstr., 12: 897, 1986) using a black 1.5 m Morris water tank (without escape platform) filled to a depth of 41 cm with clear water. The distance and pattern of swimming was analyzed from videotaped data. Both physostigmine salicylate (1.0 mg/kg,ip) and THA (10 mg/kg, but not 2 mg/kg) reduced total swim distance following scopolamine hydrochloride (0.32 mg/kg) pretreatment but only physostigmine significantly enhanced exploration of central areas of the pool ($p < .01$). In Experiment 2, Morris water-task learning was examined on five consecutive testing days following NBM lesions (6 µg/1 µl, ibotenic acid; bilateral lesions) or scopolamine pretreatment (0.32 and 1.0 mg/kg groups). Both NBM lesions and scopolamine blockade impaired Morris water-task acquisition and induced perseverative peripheral pool swimming. Neither 2 nor 10 mg/kg of THA significantly improved escape latencies when given daily pretesting to the NBM groups; however, spatial search on a probe trial (day 5) was enhanced by 10 mg/kg of THA. THA (2 mg/kg) failed to improve escape latencies after daily scopolamine pretreatment (1.0 mg/kg) but did significantly enhance escape latency on a single test session (day 3) in a group pretreated with 0.32 mg/kg of scopolamine ($p < .001$). In Experiment 3, NBM-lesioned rats were tested on a multiple trial passive-avoidance task which used an ultrasonic tone (30-62 Khz, 120 dB, 3.0 sec) in place of footshock. Sham and unilateral NBM-lesioned Sprague-Dawley rats acquired the task rapidly during the first week, but the bilateral NBM group was severely impaired in acquisition and retention of the task during the first 14 days ($p < .001$). THA (2 mg/kg) given daily immediately after training trials on days 15-19 significantly enhanced retention ($p < .05$), but the deficit re-emerged following the termination of drug treatments (days 20-24).

235.17 EFFECTS OF ORAL SCOPOLAMINE ON MEMORY AND ATTENTION IN MAN. G. C. Preston*, P. Broks*, M. Traub*, C. Ward*, P. Poppleton* and S. Stahl. Merck Sharp & Dohme, Terlings Park, Harlow, U.K.

In the context of the anticholinergic model of dementia, most studies of the effects of scopolamine have emphasised its amnestic properties. Generally, such investigations have employed relatively high drug doses (> 0.4mg subcutaneously or intramuscularly) and a limited range of cognitive tests. Under such conditions it is conceivable that memory loss represents a non-specific consequence of the drug's sedative effects. In a series of studies we investigated the effects of low doses of scopolamine (0.3, 0.6 & 1.2mg p.o.), methylscopolamine (0.6mg p.o.) and placebo on the performance of young, healthy volunteers on a battery of tests of memory and attention. The highest dose of scopolamine impaired performance on a verbal free recall task (Buschke selective reminding procedure), which could be attributed to an effect of the drug on secondary memory. This dose also produced an increase in reaction time using an unsignalled simple and choice reaction time procedure. Performance on a number of tasks was unaffected by these doses of the drug. These included tests of visual selective attention, simple reaction time in which a warning cue was provided (alerting function), tests of semantic memory (letter / category fluency and reaction time to categorize words), verbal and visuo-spatial primary memory (digit span and spatial span) and a visuo-spatial analog of verbal selective reminding. Two tests showed monotonic dose-dependent effects of scopolamine. These were a test of sustained vigilance (Wilkins, Shallice & McCarthy, Neuropsychol., in press) which requires the subject to count low-frequency trains of beeps, and tests of visual contrast sensitivity. Visual acuity was not concomitantly affected by the drug.

In the above studies we reproduced the amnestic effects of scopolamine. However, the tests which were most sensitive to muscarinic blockade were simple tests of attention rather than of memory. At higher effective doses using subcutaneous administration (e.g. 0.4mg s.c.) there is less selectivity in the drug's action: performance on both memory and attentional tests is profoundly impaired. The possibility that attentional tests such as the sustained vigilance test might be useful in the study of dementia itself is now being tested. In addition we are examining the pharmacological specificity of the pattern of results by comparison with the effects of anticholinergics with those of other classes of drug.

235.18 EFFECTS OF PARATHION EXPOSURE ON ACQUISITION OF A FREE-OPERANT AVOIDANCE TASK. F.O. Risinger and W.M. Bourn. School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209-0470.

Parathion is an organophosphate insecticide having anticholinesterase properties. In this study the time course of behavioral effects and cholinesterase inhibition was determined following oral exposure to parathion. Within the time intervals for the greatest behavioral effects and cholinesterase inhibition, the influence of oral parathion exposure on acquisition of a 2-way free operant avoidance task was examined.

Female Sprague-Dawley rats were dosed orally with either parathion (1.5 mg/kg) or a vehicle control. They were tested at 0, 30, 60, 120, or 240 minutes after dosing. Behavioral testing consisted of a 5 minute period in an enclosed activity monitoring device (activity cage) in which two types of motor movement were recorded (whole body movement and head/limb movement). Additionally, the animals were observed in an open field chamber (ambulation and rearing recorded) for a 5 minute period. After the behavioral measures were recorded brain AChE, red blood cell AChE, and plasma ChE activity was determined by a radiometric assay. Significant behavioral changes were seen only 120 minutes after dosing. Activity cage whole body movement, open field ambulation, and open field rearing were significantly ($p<.01$) reduced in parathion exposed subjects. These behavioral effects corresponded with the greatest inhibition of cholinesterase activity.

In the avoidance acquisition experiment female Sprague-Dawley rats were tested from 90 to 150 minutes after receiving various doses of parathion (0, 0.5, 1.0, and 1.5 mg/kg, po). Animals were placed in a shuttle box and subjected to a 2-way shock avoidance conditioning procedure which consisted of non-signaled shock occuring every 20 seconds. Avoidance responses were recorded for 100 trials. Parathion exposed animals at all doses demonstrated lower frequencies of avoidance responding ($p<.01$) with the greatest effect seen with the 1.5 mg/kg dose. Cholinesterase activity paralleled dose levels and behavioral values. The results suggest that free-operant avoidance procedures may be sensitive indicators of parathion exposure.

235.19 INTRA-AMYGDALA INJECTIONS OF β-ADRENERGIC ANTAGONISTS BLOCK THE MEMORY-ENHANCING EFFECT OF PERIPHERALLY-ADMINISTERED NALOXONE. I.B. Introini-Collison, A.H. Nagahara* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

Recent findings have suggested that the memory-enhancing effects of naloxone are blocked by treatments interfering with central noradrenergic systems (Gallagher, 1985; Introini-Collison & Baratti, 1986; Izquierdo & Graudenz, 1980). These findings are consistent with evidence that naloxone blocks the inhibitory effect of opioid peptides on the release of norepinephrine. In view of evidence that retention can be modulated by intra-amygdala injections of norepinephrine, the present experiments were undertaken to determine whether the memory enhancing effects of naloxone are blocked by intra-amygdala administration of adrenoceptor antagonists. Sprague Dawley rats (220-250g) were bilaterally implanted with amygdala cannulae. They were then trained on an inhibitory avoidance response and then, two weeks later, on a Y-maze discrimination response. Immediately following the training on each task, they were injected (intraperitoneally, IP, and in the amygdala). Retention was tested one week following the training on each task. Naloxone administered ip (3.0 mg/kg) significantly facilitated retention of both tasks. This effect of naloxone was observed both in unoperated and cannulae-implanted control rats. The memory-enhancing effect of naloxone IP was blocked by propranolol (0.3 or 1.0 μg) injected in the amygdala, but not when this β-noradrenergic blocker (0.3 μg) was injected into either the caudate or the cortex dorsal to the amygdala. Further, when injected into the amygdala, both the β_1-adrenoceptor blocker atenolol (0.3 or 1.0 μg) and the β_2-adrenoceptor blocker zinterol (0.3 or 1.0 μg), in doses which did not affect memory when administered alone, completely blocked naloxone-induced (3.0 mg/kg; ip) enhancement of memory. In contrast, posttraining intra-amygdala administration of α-antagonists prazosin (α_1) and yohimbine (α_2) (1.0 μg) did not attenuate the memory-enhancing effects of systemically-administered naloxone.

These findings support the view that naloxone-induced memory facilitation is mediated by the activation of β- but not α-noradrenergic receptors which are located in the amygdaloid complex.

235.20 MEMORY-ENHANCEMENT WITH INTRA-AMYGDALA POSTTRAINING OF ADMINISTRATION OF NALOXONE IS BLOCKED BY CONCURRENT ADMINISTRATION OF PROPRANOLOL. A.H. Nagahara*, I.B. Introini-Collison and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717

Previous results from our laboratory indicate that the memory-enhancing effects of posttraining systemic (IP) administration of naloxone on memory are blocked by intra-amygdala injections of β-noradrenergic antagonists. If, as these findings suggest, naloxone affects memory through influences involving β-noradrenergic receptors within the amygdala then the memory-enhancing effect of intra-amygdally administered naloxone should be blocked by concurrent administration of a β-noradrenergic antagonist. The present experiment examined this implication. Sprague Dawley rats (220-250g) were bilaterally implanted with amygdala cannulae. They were first trained on an inhibitory avoidance task (IA) and then, two weeks later, on a Y-maze discrimination task (YMD). Bilateral intra-amygdala injections (1.0 μl) were administered immediately posttraining. Retention was evaluated one week following training on each task. Naloxone (0.1, 0.3 or 1.0 μg) facilitated retention in both tasks. The most effective doses were 0.1 μg for the IA task and 0.3 μg for the YMD task. Naloxone (0.1 μg) did not affect retention when administered via cannulae implanted in either the caudate-putamen or cortex dorsal to amygdala. Thus, the effects of intra-amygdala naloxone does not appear to be due to diffusion of the drug to these brain regions. These results strongly support the view that opioid peptidergic systems in the amygdala are involved in memory modulation. Further, as we observed previously with systemic injections of naloxone, intra-amygdala injections of the $\beta_{1,2}$-adrenoceptor blocker propranolol (0.3 μg) blocked the memory enhancing effects of intra-amygdally injected naloxone (administered concurrently)(IA: 0.1 μg; YMD: 0.3 μg).

We interpret these findings as indicating that the enhancing effects of intra-amygdala naloxone are mediated by the activation of β-noradrenergic receptors within the amygdala. Such effects are presumably due to blocking of inhibitory effects of opioid peptides on the release of norepinephrine.

236.1 **MODIFICATION OF RUBRAL CELL ACTIVITY UNDERLIES ASSOCIATIVE CONDITIONING INDUCED BY PAIRED STIMULATION OF CORTICORUBRAL FIBERS AND LOCUS COERULEUS.** Y.ODA, H.KISHIDA*, M.ITO* and I.NAGATSU# Dept. Biophysical Engineering, Fac. Engineering Science, Osaka Univ., Toyonaka 560, and #Dept. Anatomy, Fujita-Gakuen Health Univ., School of Medicine, Toyoake 470-11, Japan.

Classical conditioning of forelimb flexion in cat is produced by pairing a stimulus (conditioned stimulus, CS) to the corticofugal fibers with an electric shock (unconditioned stimulus, US) to the forelimb skin (Tsukahara et al.,1981). The pathway mediating the conditioned response is suggested to be the cortico-rubrospinal pathway, since the corticofugal fibers were eliminated just caudal to the red nucleus (RN)(Tsukahara et al.,1981). However, little is known of the US pathway. We consider that the locus coeruleus nucleus (LC) is a candidate mediating the US, since the LC neurons can be activated by noxious stimulus such as skin shock and they are the origin of the central noradrenergic system which may play an important role in synaptic plasticity. In the previous study, noradrenergic innervation of the RN in cat was demonstrated immunohistochemically by using an antiserum against dopamine-β-hydroxylase (Oda et al., 1986). Here, we tested whether paired stimulation of the corticorubral fibers and the LC would induce associative conditioning of forelimb flexion and modification of RN cell activity.

The CS applied to the cerebral peduncle (CP) and the stimulus to the LC were a train of five electric pulses with an interval of *2* msec. The intensity of the CS was adjusted to produce forelimb flexion (flexion angle> *0.06°*) at the probability of *20%* during the pretraining period. Three types of training were employed. In the paired conditioning, the CS was followed by the LC stimulus *120* msec later and *50* trials were applied daily. The probability of forelimb flexion induced by the CS increased during the training period of *8* days ($\overline{X}$ = *72.8%*, on the last day, *n= 10*). Applying the CS or the LC stimuli alone for the same period did not significantly increase the probabilities of the forelimb flexion in response to the CS. The scores on the *8*th day were $\overline{X}$ = *28.6%* (*n= 7*) in the LC-alone group and $\overline{X}$ = *24.0%* (*n= 6*) in the CS-alone group.

We compared the firing responses of single RN cells to the CS among the paired, LC-alone, CS-alone and naive groups. The firing rate of the response was highest in the paired group. The firing rate within *3* msec after a single-pulse stimulus to the CP was higher in the paired group than in others (*p< 0.01*). The response during this period was considered to be monosynaptic, because polysynaptic responses through the cerebellum or the cerebrum do not occur within this period. Neither spontaneous discharge rate nor the monosynaptic responses to stimulation of another excitatory input from the interpositus nucleus were different among the four preparations.

In conclusion, associative conditioning is produced by pairing stimuli to the CP and the LC and its establishment can be explained by the increase of monosynaptic transmission through the corticorubral synapses.

236.2 ELECTROPHYSIOLOGICAL CHARACTERISTICS OF MAGNOCELLULAR MEDIAL GENICULATE NUCLEUS NEURONS DURING PAVLOVIAN DIFFERENTIAL HEART RATE CONDITIONING IN THE RABBIT. W.F. Supple, Jr. & B.S. Kapp, Dept of Psychology, University of Vermont, Burlington, VT 05405

Considerable evidence suggests that a forebrain system involving the amygdaloid central nucleus (ACE) contributes importantly in the rabbit to bradycardia elicited by a conditioned fear-arousing acoustic stimulus (Kapp & Pascoe, 1986). Consistent with this notion are data demonstrating that ACE neurons respond differentially to acoustic CS+ and CS- presentations during differential fear conditioning and that these neuronal responses correlate significantly with CS induced bradycardiac responses (Pascoe & Kapp, 1985). Since the magnocellular medial geniculate nucleus (mMGN) projects to the ACE and contributes to a variety of aversively conditioned responses (Gabriel et al., 1976; Jarrell et al., 1986; LeDoux et al., 1984; Weinberger, 1982), the present study examined the responses of mMGN neurons during differential fear conditioning to determine if they resemble those observed in the ACE and to further understand the contribution of this system to fear-conditioned bradycardia.

Twelve New Zealand rabbits received differential Pavlovian heart rate conditioning trials in which one tone (CS+) was paired with an aversive shock (UCS) and a second tone (CS-) of differing frequency was not. Extracellular single unit recordings were obtained from 60 histologically verified mMGN neurons in response to the CS+ and CS- during subsequent retention testing. The majority of these units demonstrated differential responding to the two stimuli. In 10 neurons with spontaneous rates between 1.4 - 20.0 Hz both the CS+ and CS- elicited an increase in activity. However, as assessed by standard scores the response to the CS+ was greater and of shorter onset latency (22.2 ms ± 4.0 ms) than that to the CS- (71.1 ms ± 9.0 ms). A second group of neurons with spontaneous rates between 4.1 - 18.0 Hz demonstrated a greater increase in activity with shorter onset latency (28.8 ± 8.3 ms) to the CS- compared to the CS+ (48.5 ± 11.1 ms). A third group of neurons demonstrated a differential decrease in activity; some cells showed a greater decrease to the CS+ compared to the CS- while others showed greater decreases to the CS- than to the CS+.

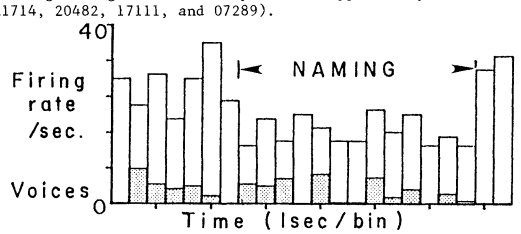
In further support of the contention that the differential mMGN unit responses reflect associative processes are additional unit data recorded in response to unreinforced presentations of the CS+ and CS- tones in naive, unconditioned rabbits. Increased activity in response to both tones was observed in each of six neurons recorded from six rabbits. However, no differential responses were observed and both tones elicited similar increases in activity.

These results suggest that (1) mMGN units do not respond differentially to the CS+ and CS- frequencies in the naive rabbit and (2) the differential mMGN unit responses observed in the conditioned rabbit reflect acquired associative processes. Moreover, unit responses of the mMGN are similar to those recorded in the ACE in response to fear-conditioned acoustic stimuli under similar conditioning and retention procedures. These data suggest that the mMGN and ACE are components of a forebrain system involved in the mediation of fear-conditioned bradycardiac responses to acoustic stimuli in the rabbit. Supported by a Grant-in-Aid from the American Heart Association.

236.3 HUMAN TEMPORAL LOBE NEURONAL ACTIVITY: INHIBITION DURING NAMING IN ONLY ONE OF TWO LANGUAGES. D.F. Cawthon,* E. Lettich,* and G.A. Ojemann. Dept. of Neurol.Surg., Univ. Washington, Seattle,WA 98195.

We recorded extracellular multiunit neuronal activity with tungsten microelectrodes from left anterior middle temporal gyrus dominant for speech (by Wada test) in a bilingual patient, according to institutional human subject standards. The recording site showed no surface epileptic activity and the sampled cell population showed no bursting activity, but at the margin of resection for epilepsy surgery. The patient had a college degree in Spanish but her native language was American English. In naming and reading tasks, she saw 6 slides of objects or words respectively, which she was asked to name or read silently or overtly for each batch of 6 trials either in English or in Spanish, using the identical series of slides.

Multiunit activity in the English naming tasks showed prolonged inhibition compared to Spanish especially in overt naming, as illustrated by a sharp transition to higher firing rates when the task changed from overt naming in English to overt naming in Spanish. In English but not in Spanish, neuronal activity during naming was lower than during reading. Inhibition during naming in English was confirmed in a related task where a prolonged drop in firing coincided with the patient's efforts to retrieve names of animals starting with "d" (Fig.), and higher activity promptly resumed at the end of the task or at interruptions by other voiced instructions. These activity changes in neuronal populations represent independent data to confirm the data from lesions (Stud.Neuroling. 3:65, 1977) and cortical stimulation studies from our surgical author's experience (Arch.Neurol. 35:409, 1978; Behav.Br.Sci. 6:189, 1983) which have demonstrated separation of areas essential for different languages in dominant temporal lobe. Stimulation necessary at surgery in this patient showed no changes at or near the recording site, and the patient had no language changes postoperatively. Therefore, the cell population sampled was not part of a critical area for language processing but may represent activity in an inhibitory surround zone for naming in English but not Spanish. (Supported by NIH Grants NS 21714, 20482, 17111, and 07289).



236.4 AUTO- AND CROSS-CORRELATIONAL ANALYSIS OF THE SEPTO-HIPPOCAMPAL SYSTEM DURING JAW MOVEMENT CONDITIONING IN THE RABBIT. R.A. Swain*, C.G. Oliver* and S.D. Berry. Dept. of Psychology, Miami Univ., Oxford, OH 45056 and SRL, Inc., Dayton, OH 45440.

The temporal parameters of conditioned and unconditioned neural responses in the medial septal nucleus (MSN) and hippocampus were examined in 8 New Zealand White rabbits. Each animal had chronic stainless steel recording electrodes implanted in the MSN and in area CA1 of the dorsal hippocampus under general anesthesia (Ketamine, 50 mg/kg and Xylazine, 10 mg/kg). After 1 week recovery, each rabbit was adapted to restraint and standard classical conditioning apparatus, and was placed on a 22 Hr water deprivation schedule. Classical jaw movement conditioning (CJM) was established using a 350 msec, 85 dB, 1 KHz tone as the conditioned stimulus (CS), and a 1 cc, 100 msec duration, .022% saccharin solution in water as the unconditioned stimulus (UCS). The interstimulus interval was 250 msec, and the intertrial interval averaged 1 min. Six blocks of trials were given in each daily session. Half of the animals were in a control condition, with trials consisting of explicitly unpaired tone or saccharin presentations. Permanent records of the transduced jaw movement, neural activity, and marker pulses denoting stimulus onset times were taken during each trial. In each brain structure, field potential (slow wave or EEG) responses and multiple unit spike activity were recorded from the same microelectrode. Unit activity was band passed filtered (500-5K Hz) and a window discriminator selected the largest spikes (3:1) for computer averaging into 10 msec bins. Slow waves were filtered from 0.5 to 25 Hz, and sampled at 10 msec intervals. Statistical analyses were performed on the responses averaged over the 48 paired trials in a session, or (for the control group) over the 48 tone or 48 saccharin trials. Averages of time-locked unit activity showed the development of conditioned responses to the CS in both MSN and CA1, but responses to the UCS only in CA1. Controls did not display evoked unit responses. Averaged slow wave activity showed significantly larger CS- and UCS-evoked responses in trained rabbits than in controls. In addition, the latency of the CA1 evoked response to the UCS was shorter in trained subjects. Auto and cross correlations of the slow wave, unit, and behavioral averages demonstrated that all CA1 and behavioral responses were periodic, with hippocampal activity occurring prior to behavioral movements. MSN responses, however, were not periodic but occurred at latencies that were consistent with this region being an important source of input in the development of hippocampal conditioned neural responses.

236.5 REFLEX FACILITATION OF THE NICTITATING MEMBRANE RESPONSE AND THE ACQUISITION OF CONDITIONED RESPONSES AS A FUNCTION OF INTERSTIMULUS INTERVAL. T. Scott, C. Walts*, and D. J. Weisz. Dept. of Psychology, Yale University, New Haven, CT 06520

Using the nictitating membrane (NM) preparation in rabbit, Ison and Leonard (1971) demonstrated that the presentation of an auditory stimulus from 160 to 1280 msec prior to the elicitation of an unconditioned NM response could enhance the amplitude of the elicited reflex. Subsequent research has demonstrated that interstimulus intervals (ISIs) that produce the most robust facilitation of the unconditioned NM response support the most rapid acquisition of conditioned responses (CRs) (Young et al., JCPP, 1976; Harvey et al., J. Neurosci., 1985). These findings have led to the hypothesis that there may be an interaction between the circuits that mediate these two behavioral phenomena. The correlation between reflex facilitation and CR acquisition has not been tested, however, at ISIs longer than 1280 msec. Therefore, we examined both reflex facilitation and CR acquisition rate at five ISIs--500, 1000, 2000, 4000, and 8000 msec. The intervals include two (500 and 1000 msec) that support rapid acquisition of CRs and one (8000 msec) that produces relatively few CRs.

All animals (n-25) were trained in two phases. During the first phase, animals received a total of 72 trials consisting of 12 US-alone presentations and 12 CS-US presentations at each of the five ISIs in order to determine the amount of reflex facilitation present at each of the intervals. The CS was a 1 kHz tone (85 db) that ended at the onset of an airpuff US (2.0 psi). During the second phase, animals were randomly assigned to one of five conditioning groups. Each group was then trained at one of the ISIs for eight days (54 CS-US trials/day).

The mean UR amplitudes were 8.2 mm on US-alone trials, and 11.3 mm (500 msec), 11.0 mm (1000 msec), 10.3 mm (2000 msec), 9.8 mm (4000 msec), and 9.7 mm (8000 msec) on the CS-US trials. A one-way ANOVA (randomized block design) revealed a significant effect of trial type ($F(5,120)=17.9$, $p<.01$). Post hoc tests revealed significant reflex facilitation at each of the five ISIs (all p's$<.01$), and significantly greater facilitation at the 500 and 1000 msec ISIs than at 4000 and 8000 msec. In addition, a significant correlation ($r=.9$, $p<.01$) was found between the amount of facilitation and the number of CRs elicited during phase two of training. These results provide further support for the finding that the amount of reflex facilitation is an excellent predictor of CR acquisition rate. Furthermore, they indicate that the physiological events that mediate reflex facilitation should be maximal at relatively short intervals after tone onset (e.g. 500 msec), although their effects may still be present at 8000 msec.

236.6 AN ASSOCIATIVE PROCESS IS INVOLVED IN THE MAINTENANCE OF REFLEX FACILITATION OF THE UNCONDITIONED NICTITATING MEMBRANE (NM) RESPONSE. D. J. Weisz and J. McInerney*. Dept. of Psychology, Yale University, New Haven, CT 06520

Facilitation of the amplitude of the unconditioned NM response by the prior presentation of a neutral stimulus occurs on the very first trial, and, therefore, its initial appearance is considered to involve non-associative processes. We have shown, however, that the ability of an auditory stimulus to maintain its facilitation across trials can be modified by experience with the stimulus (Weisz & LoTurco, Behav. Neurosci., in press). Specifically, non-reinforced presentations of an auditory CS can significantly reduce or eliminate the ability of the CS to facilitate the NM response. On the other hand, repeated pairing of the CS with an airpuff US results in the maintenance of facilitation until animals begin to acquire conditioned responses. Although dishabituation by the US cannot be excluded, we hypothesized that the maintenance of facilitation is due to an associative process by which the neutral stimulus acquires significance during CS-US pairings.

Two experiments were conducted to test this hypothesis. The experiments were identical except for the conditioned stimuli (1 kHz tone and vibrotactile stimulus, counterbalanced, in Expt. 1; and 1 and 4 kHz tones, counterbalanced, in Expt. 2). In each experiment, the experimental group received six blocks of training over two days, with each block consisting of five reinforced trials with the target CS (CS1) intermingled with 25 non-reinforced CS1 presentations. The ability of CS1 to facilitate the NM response was tested at the end of each block by measuring the difference between the amplitudes of unconditioned responses on US-alone and CS1-US trials. The control group in each experiment had identical training except that the conditioned stimulus for the five reinforced trials was CS2.

The results of both experiments showed that there was no amplitude facilitation by CS1 in the control groups. This replicated our earlier finding that non-reinforced presentations of a CS reduces the ability of the CS to facilitate the NM response. On the other hand, facilitation by CS1 in the experimental groups was robust (2.4 mm or 25% in Expt. 1; and 2.7 mm or 23% in Expt. 2), and differed significantly from that in the control groups (Expt. 1, $F(1,18)=9.31$, $p<.01$; Expt. 2, $F(1,11)=6.10$, $p<.05$). Therefore, the presentation of only five reinforced CS1 trials protected CS1 from habituation when it was presented 25 times in isolation. These data indicate that an associative process is involved in the maintenance of reflex facilitation of the unconditioned NM response, and that this associative process occurs with relatively few CS-US pairings.

236.7 PREFRONTAL REPRESENTATION OF SPATIAL AND NON-SPATIAL INFORMATION DURING VISUAL DELAY TASKS. J. Quintana*, J. Yajeya* and J.M. Fuster. Department of Psychiatry and Brain Research Institute. UCLA School of Medicine, Los Angeles, CA 90024.

The extracellular activity of 306 single units was recorded from the dorsolateral prefrontal cortex (PC) of two monkeys performing two visual discrimination tasks with delayed response. One of the tasks, delayed matching-to-sample (DMS), required matching the color of one of two stimuli presented simultaneously for choice to the color of the stimulus presented as a sample 18 seconds before. The other task, delayed conditional position discrimination (DCPD), required the choice of one of two identical (white) side-by-side stimuli (right or left) depending on the color of the cue presented 18 seconds before. At the beginning of task trials, differential unit reactions to the two DCPD colored cues were more common than those to the two DMS samples. During the delay period, 15% of all units showed differential discharge related to the two colors of either task, but only two units (0.6%) showed such differential delay discharge in both tasks. In the DCPD task, a large proportion of the units showing direction-related activity at the time of choice also reacted with a firing frequency change to one or both--spatially identical-- trial-initiating cues. The results indicate that, during visual delay tasks, neurons in the dorsolateral prefrontal cortex (superior convexity and sulcus principalis), may process both spatial and non-spatial information. Because of their protracted differential discharge between cue and response (i.e., during the delay), some units seem involved in the transfer of sensory information (spatial or non-spatial) across time. These findings support the idea of the participation of PC neurons in the representation of multiple attributes of sensory stimuli in a behavioral context and the overlap of the cortical representations of different attributes. They are also consistent with the role of the PC in the cross-temporal mediation of sensory-motor contingencies and, therefore, in the temporal organization of behavior.

236.8 NEURAL CORRELATES OF CLASSICALLY CONDITIONED BRADYCARDIA IN THE RABBIT: STUDIES OF THE FRONTAL CORTEX. C.M. Gibbs, L.B. Prescott* and D.A. Powell. Neuroscience Lab., WJB Dorn Veterans' Hospital & Dept. of Psychology, Univ. of South Carolina, Columbia, SC 29201.

Repeated pairings of a pure tonal conditioned stimulus (CS) with eye-shock, under appropriate temporal parameters, lead to the rapid development of a bradycardiac conditioned response (CR) in the rabbit that has been shown to be mediated by a rather complex, limbic forebrain system. In this regard, we previously reported (Soc Neurosci Abstr 12:516) that within the cardioactive anterior midline cortex of the rabbit, corresponding to the precentral agranular and anterior limbic regions of Rose and Woolsey, CS-evoked multiple-unit activity (MUA) undergoes associative training-induced changes in a manner consistent with the concomitant development of this heart rate (HR) CR. We now report that such training-induced changes in anteromedial cortical MUA are, in fact, correlated with learned HR changes, a finding that contrasts markedly with the preliminary results of our ongoing studies of the similarly cardioactive insular cortex.

The studies involved experimentally naive, male and female New Zealand albino rabbits, each chronically prepared for recording MUA in either the anteromedial or the insular cortex. Following postoperative convalescence, the animal was adapted to handling/restraint and then received 10 presentations of a 4-sec, 1216-Hz, 75-db tone (pretraining), followed by either 40 classical conditioning trials (tones paired with 0.25-sec, 3-mA eye-shocks) or nonassociative training (unpaired tones and eye-shocks).

We have now confirmed that presentation of a novel tone stimulus elicits reliable increases in MUA at most sites in the anteromedial cortex and that classical conditioning results in a rapid enhancement (<5-10 trials) of this evoked MUA. Moreover, the training-induced changes in the shortest-latency (20-200 msec) component of the CS-evoked MUA are reliably correlated with conditioned decreases in HR ($r=-.51$, $p<.02$). In contrast, pretraining tone presentations appear to have more variable effects on MUA in the insular cortex, since unit subpopulations showing either increased discharge, decreased discharge, or no change in discharge at tone onset have been encountered. Further, conditioning effects on CS-evoked MUA in the insular cortex have been relatively inconsistent, and training-induced changes in MUA, when observed, have shown little or no relationship to conditioned HR changes. We would suggest that the present results are entirely consistent with previous findings in our laboratory, which have indicated that bilateral destruction of the anteromedial cortex profoundly disrupts the development of a discriminative HR CR in the rabbit (J comp physiol Psychol 96:755), whereas insular lesions have more modest decremental effects on this learned response (Behav Brain Res 17:125).

236.9 SOMATOSTATIN AND CHOLINERGIC TRAITS IN THE BASAL FOREBRAIN-HIPPOCAMPAL SYSTEM: DEVELOPMENT AND BEHAVIORAL FUNCTION. D.R. Kornack and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

One goal of contemporary neuroscience research is to understand how communication within neural systems generates specific behaviors. In the mammalian brain, the basal forebrain-hippocampal (BF-HP) system is a particularly useful model, having well-defined anatomic interconnections and expressing a variety of known transmitters. However, most attempts to integrate BF-HP behaviors with transmitter functions have focused exclusively on acetylcholine, and ignored the potential roles of other known transmitters in this system. We are beginning to explore two related questions using the BF-HP system in the rat. How do different transmitters interact in the genesis of behavior? How is expression of different transmitter traits regulated in the BF-HP, and how does this regulation relate to organismal behavior? To begin approaching these questions, we have examined the expression of cholinergic and peptidergic transmitter traits during development and after surgical disruption of the BF-HP that alters a specific behavior.

From birth to 8 weeks of age, the activity of choline acetyltransferase (CAT), the acetylcholine biosynthetic enzyme, increased 15-fold in BF and 35-fold in HP. Simultaneously, somatostatin (SS) increased 20-fold in both BF and dorsal HP, and 100-fold in ventral HP, suggesting that very different transmitter traits exhibit similar developmental profiles. SS and CAT are of particular interest, since both are deficient in Alzheimer's Disease, characterized, in part, by disordered memory, and since the BF-HP is critical for normal memory function. To determine whether SS, as well as acetylcholine, is important in BF-HP function, the neural system was disrupted in adult animals. The fimbria were transected bilaterally in rats trained to perform to criterion in a continuous trial, rewarded alternation discrimination T-maze task, a spatial memory behavior. Lesions markedly impaired choice accuracy compared to pre-operative performance and to that of sham-operated controls. HP CAT activity of lesioned rats decreased 50%, while activity in the BF was unchanged. In contrast to the marked cholinergic response, fimbria lesions did not alter SS levels in either BF or HP.

Our observations suggest that SS, which is implicated in degenerative brain disease, and which parallels cholinergic development in the BF-HP, does not play a role in the spatial memory behavior generated by this neural system. 236.10 HIPPOCAMPAL LESIONS CAN IMPAIR MEMORY OF A SHORT-DELAY EYEBLINK CONDITIONED RESPONSE IN RABBIT. E. Akase* and J. F. Disterhoft. Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Multiple and single neuron recording studies have demonstrated a substantial involvement of hippocampal neurons during and after learning Pavlovian tasks in cat, rabbit and rat. Biophysical analyses of hippocampal brain slices made from eyeblink conditioned rabbits have demonstrated postsynaptic reductions in a calcium-mediated potassium current which is conditioning-specific and local to the hippocampus (Disterhoft, Coulter and Alkon, PNAS, 83: 2733-2737, 1986). However, several studies have demonstrated no effect of hippocampal lesions, at least on short-delay blink conditioning (e.g., Schmaltz and Theios, J. Comp. Physiol. Psychol., 79: 328-333, 1972). We reexamined this question during the early stage of acquisition. We reasoned that, if the hippocampus is particularly involved in transferring information from the short- to long-term memory store, hippocampal lesions should have maximal effect on retention at this time during learning.

Subjects were 20 young adult male albino rabbits weighing 1.5-2 Kg. Lesion animals (N=11) were anesthetized with i.m. injections of Ketamine (75 mg/Kg) and Xylazine (5mg/Kg). Suction lesions, done in sterile surgical conditions, removed overlying neocortex and at least the dorsal hippocampus bilaterally. Rabbits were habituated and then trained in a short-delay eyeblink conditioning paradigm. A 400 msec, 85 db, 6 KHz tone CS overlapped and coterminated with a 150 msec corneal air puff UCS. All rabbits were trained in daily 80 trial sessions to a behavioral criterion of two successive 10-trial blocks with 80% or more CRs. After 24 hours, two extinction sessions in which the tone CS was presented alone were begun. Four intact and 5 lesioned rabbits were extinguished in the sound attenuated training chamber, 5 intact and 6 lesioned rabbits were extinguished in the laboratory, where the stimulus context was different from that experienced during training.

Differences among the conditions were maximally present in the first 40 extinction trials (values reported here). **Retention effect:** hippocampal lesioned rabbits showed fewer CRs during extinction than did controls (20% vs. 49%, $p<.025$). **Stimulus context effect:** the intact rabbits showed more CRs during extinction in the training chamber than in the changed stimulus context (77% vs. 27.5%, $p<.01$); the hippocampal lesioned animals showed less differentiation between stimulus contexts (31% vs. 12%, n.s.).

Lesioned rabbits extinguish faster than intact rabbits and are not as effected by a change in stimulus context during extinction. Previous studies may not have observed the retention effect because the lesioned rabbits in those studies were more completely trained before extinction commenced. Testing retention of a learned response which is still in the process of consolidation is apparently a more sensitive evaluation of the hippocampal contribution. The stimulus context effect has not previously been tested in eyeblink conditioning. Experiments are continuing to increase the sample size in all groups and to test neocortical lesion control animals.

236.11 LONG-TERM POTENTIATION IN THE DENTATE GYRUS IS INDUCED PREFERENTIALLY ON THE POSITIVE PHASE OF THETHA RHYTHM. J. WINSON, C. PAVLIDES*, AND Y. GREENSTEIN, Rockefeller University, N.Y., N.Y. 10021 and CUNY.

Hippocampal long-term potentiation (LTP) is considered a model for learning and memory. The physiological conditions under which LTP may occur are poorly understood. Theta rhythm in the hippocampus was hypothesized to be involved in LTP induction. The present experiment was undertaken to test this hypothesis.

In urethane anesthetized rats, a stimulating electrode was positioned in the medial perforant path (PP) to elicit the granule cell field potential and in the midbrain to activate theta rhythm. An electrode was positioned in the dentate gyrus granule cell layer to concurrently record field potentials and hippocampal EEG.

Having reliably produced theta rhythm with midbrain stimulation, the peak-to-peak time interval of the theta rhythm was determined for each individual animal. Baseline for both the initial slope and population (POP) spike of a field response following a PP stimulus were determined. Two control conditions followed: C1- the application of ten, 5-pulse bursts (interspike interval 2.5 ms; pulse width 150 usec) with an interpulse interval equal to the peak-to-peak time interval of the theta rhythm; C2- the application of midbrain stimulation for the generation of 10 cycles of theta rhythm, with no tetanic stimulation. Following C1 and C2, the same tetanic stimulation as in C1 was applied either at the peak (C3) or trough (C4) of ten cycles of theta rhythm. Subthreshold LTP stimulation was used in all conditions. If no LTP was detected, the intensity was increased by small increments and the protocol was repeated.

In the 7 rats in which tetanic stimulation was applied at the peak of theta rhythm there was a significant increase in both the slope ($9.0\%\pm1.6$ SEM, $p<.003$) and POP. spike ($47\%\pm11.0$ SEM, $p<.03$), during C3 relatively to the previous C2. In the 7 rats in which tetanic stimulation was applied at the trough of theta rhythm a significant increase in both slope and POP. spike occurred in C1 before it occurred in C4. In 3 of these rats there was a significant decrease of the slope in C4 ($-8.7\%\pm1.5$ SEM, $p<.02$); in the remaining four, no further change occurred during C4. The POP. spike did not change significantly in C4 in the 7 rats taken as a group. In none of these cases had LTP saturation been reached.

The induction of LTP during theta rhythm and the possible association of LTP with memory suggest that theta rhythm may be involved in mnemonic processes.

236.12 RED NUCLEUS SINGLE-UNIT ACTIVITY DURING THE CLASSICALLY CONDITIONED RABBIT NICTITATING MEMBRANE RESPONSE. John E. Desmond & John W. Moore. Dept. of Psychology, Univ. of Mass., Amherst, MA 01003.

This study examined the firing patterns of single neurons in the red nucleus (RN) of the awake rabbit during classical conditioning training. The RN has been implicated in the control of the conditioned nictitating membrane (NM) response by the following lines of evidence: (1) HRP administration to the accessory abducens nucleus, the nucleus that controls NM movement, resulted in labeling of cells in the contralateral RN (Desmond et al., *Brain Res Bull*, 10:747, 1983). (2) Lesions of RN disrupted contralateral, but not ipsilateral, NM CRs without affecting URs (Rosenfield & Moore, *Behav Brain Res*, 17:77, 1985). (3) Nucleus interpositus, which is implicated in CR control (McCormick & Thompson, *Science*, 223:296, 1984; Yeo et al., *Exp Brain Res*, 60:87, 1985), sends efferents to contralateral RN.

New Zealand albino rabbits were trained to discriminate between a reinforced CS+ and a nonreinforced CS- (tones of 1200 or 600 Hz, 75 db SPL). This procedure results in both CR and non-CR trial types and thus, helps determine whether changes in neuronal activity are CR-related (Desmond & Moore, *Exp Brain Res*, 65:59, 1985). The UCS was electrostimulation to the periorbital region of the right eye. Rabbits were anesthetized and prepared for subsequent recording. A recording chamber was cemented in place over a small hole on the left side of the skull.

To date, 85 cells have been recorded from the midbrain and 50 of these were located in RN. A total of 26 of these cells displayed CR-related increases in firing. Thus far, there is little evidence of CR-related inhibition of firing. The CR-related cells fell into 2 categories: (1) Cells with very low baseline (pre-CS) firing rates (i.e., < 10 Hz) that increased substantially before and during the CR. These cells were located mostly in dorsal regions of parvocellular RN throughout the rostral-caudal extent of RN. The increase in firing preceded CR onset typically by 50 ms, although some of these cells appeared to lead by ≥ 100 ms. (2) Cells with baseline firing rates of 15-30 Hz or more. Most of these were associated with the dorsal magnocellular division of RN, and were found throughout the rostral-caudal extent of the nucleus. The increase in firing of these cells preceded the CR by 20-100 ms. Many of these cells displayed a characteristic UCS response consisting of excitation followed by 10-60 ms of inhibition.

These results support a role for RN in controlling the CR. The lead times of neuronal activity over the behavior are consistent with causal involvement.

236.13 HIPPOCAMPAL COMPLEX SPIKE CELL ACTIVITY DURING WAKING AND SLEEPING BEHAVIORS.
C. Pavlides* and J. Winson (SPON: H. ASANUMA). Rockefeller University, NY, NY 10021 and CUNY.

Hippocampal (CA1) complex spike (place) cells of freely behaving rats (8-arm maze) were recorded in pairs over an extended period of time, spanning a number of waking (exploration and still-alert) and sleeping behaviors, including quiet-awake, slow-wave sleep, pre-rapid-eye movement sleep and rapid-eye-movement sleep. Pairs of units were chosen that did not have overlapping place fields. The rats were restricted from entering the place fields of both cells on the night before testing and on the day of recording they were exposed to their diverse place fields independently and in a counterbalanced design. Following exposure of each cell to its place field, recording was made in the succeeding sleeping episodes and the following firing characteristics of both cells were analyzed: rate of firing, rate of bursting, number of spikes within a burst, interspike interval (for spikes within a burst) and the interburst intervals.

Following exposure of each of the place cells to its place field, significant increases in the spiking activity of the exposed cell were observed in the subsequent sleeping states, while the cell that was not exposed to its place field continued to fire at its baseline rate. Similarly, when the second cell was exposed to its place field, its firing was observed to increase in the sleeping states that followed while the first cell's firing subsided to its baseline level. The increased activity was observed in the following parameters: rate of firing (spikes/sec., including all spikes within a burst), the number of spikes within a burst, as well as the number of bursts displaying short interspike intervals (2-4 msec., approximately 400 Hz).

The findings suggest that neuronal activity of hippocampal place cells in the awake states may influence the firing characteristics of these cells in subsequent sleep episodes. The increase in the firing rates along with the greater number of spikes and the shorter interspike intervals within the burst, following exposure to a cell's place field, may speak for possible information processing occurring during sleep.

236.14 PRIMING AT THETA RHYTHM PERIODICITY FACILITATES THE INDUCTION OF LONG-TERM POTENTIATION IN DENTATE GYRUS. Y. GREENSTEIN, C. PAVLIDES* AND J. WINSON, ROCKEFELLER UNIVERSITY, N.Y., N.Y. 10021 and CUNY.

Long-term potentiation (LTP) in the hippocampus is a long-term enhancement of synaptic efficacy which may be involved in learning and memory . Recent studies have reported that in the CA1 field in hippocampal slices LTP is preferentially induced if a priming stimulus is followed by a tetanic train at an interval of 200 ms., which corresponds to the periodicity of naturally occurring theta rhythm (5 Hz). Theta rhythm is prominent in the hippocampus and one of its generators is located in the dentate gyrus (DG) granule cells. The following study was undertaken to determine if priming at theta rhythm frequency in the IN VIVO preparation could preferentially induce LTP.

In urethane anesthetized rats, a stimulating electrode was placed in the medial perforant pathway (PP). A recording electrode was placed in the granule cell body layer of the DG to record the evoked field potential. The initial slope and population spike were measured. A single pulse (.25 msec width) was delivered to the PP every 30 sec. to evaluate LTP. For LTP induction a priming stimulus was followed by a tetanic train (6 pulses, 100 Hz, .20 msec pulse width) at varying time intervals (100, 200, 350, 500 ms). The order of the time intervals was randomized for each animal. The intensities of both priming pulse and train were subthreshold for LTP induction. If no LTP was induced, the current was increased by a small increment and the sequence of stimulation at different priming intervals was repeated.

The average potentiation (in percent of previous condition) for each of the priming intervals was as follows (n=7):

Priming interval	Spike		Slope	
100	1.20		0.00	
200	28.97	p<.003	3.74	p<.03
350	0.50		0.00	
500	1.47		2.27	n.s.

The findings indicate that LTP in the dentate gyrus in the IN VIVO preparation is preferentially induced at 200 msec, corresponding to 5 Hz. This finding corroborates previous studies done on hippocampal slices in the CA1 field and further supports the possible contribution of theta rhythm to LTP.

(Supported by NIMH RSDA 5-KO2-MH00232 and H.F. Guggenheim Foundation grants to J. Winson).

236.15 **A CEREBELLAR CORTICAL CIRCUIT IMPLEMENTATION OF THE SUTTON-BARTO-DESMOND MODEL OF THE CLASSICALLY CONDITIONED RABBIT NICTITATING MEMBRANE RESPONSE.**
Diana E.J. Blazis* & John W. Moore. Dept. of Psychology, Univ. of Mass., Amhers MA 01003.

The Sutton-Barto-Desmond (SBD) model describes many features of rabbit nictitating membrane response (NMR) conditioning, including blocking, higher-order conditioning, interstimulus interval effects, conditioned response (CR) topography and neuronal firing (Moore et al, *Behav Brain Res* 21:143, 1986). Several laboratories have demonstrated that learning and generation of conditioned NMRs may involve cerebellar Purkinje cells (PCs) located in hemispheral lobule VI (HVI) (e.g., Berthier & Moore, *Exp Brain Res*, 63:341, 1986). We considered various schemes by which the cerebellar cortical circuits might be aligned with the computation of synaptic weights as specified by the SBD model. In the SBD model, weights of conditioned stimuli (CSs) are continually altered on the basis of the magnitude and sign of the difference between the model's output and the trace of preceding outputs, $s - \bar{s}$. The relationship between s and $\bar{s}$ can be approximated by an exponential function with a time constant of about 30 ms, thus imposing a constraint on circuit models which might describe how $s - \bar{s}$ is computed.

Observations of CR-related neuronal firing by PCs in HVI suggested that several PC types are involved in NMR production (Berthier & Moore, 1986). These included "lead" and "lag" cells, the firing of which mirrored and preceded or lagged, respectively, the temporal occurrence of the CR, as well as "on" and "off" cells, the firing rates of which increased above or decreased below baseline, respectively, on trials containing CRs. A circuit model which implements the SBD model incorporates these PC types. The SBD model's output, s, is fed back to HVI by mossy fibers (MFs) and climbing fibers which impinge on granule and Golgi cells. A second set of granule cells computes $\bar{s}$. The term $s - \bar{s}$ is computed by Golgi cells, which act as differential amplifiers influencing a third set of granule cells carrying CS inputs to PCs assumed to generate CRs. Learning, defined as changes in synaptic weight, occurs at synapses between MFs carrying CS inputs and the third class of granule cells, to the extent that those synapses are eligible for change.

Time constants of the various components of the SBD model and its circuit implementation are consistent with the empirical literature; for example, the time constant of Golgi cell inhibition is about 30 ms (Eccles et al, *Exp Brain Res*, 3:81, 1967), thereby approximating the relationship between s and $\bar{s}$. The wide range of firing rates observed in Golgi cells (Miles et al, *J Neurophysiol*,43:1437,1980; Schulman & Bloom, *Brain Res*, 210:350, 1981) is consistent with the requirement of a continuum of possible values for $s - \bar{s}$. Furthermore, the circuit model can account for the ratio of on to off cells observed by Berthier and Moore. The alignment of the SBD model with cerebellar cortical circuitry supports the role of cerebellar cortex in learning and performance of the conditioned NMR.

236.16 SPINAL CONDITIONING EFFECTS ON SPINAL MOTONEURONS. Alvin L. Beggs, Ph.D. and Michael M. Patterson, Ph.D. Ohio University College of Osteopathic Medicine, Athens, Ohio 45701.

Deep peroneal motor nerve responses in spinalized cats show increases when superficial peroneal nerve stimulation (CS) is paired with an ankle skin shock (US). The present experiments were conducted to examine motoneuron activity during acquisition and extinction procedures. In the first experiment, a microelectrode was lowered into the ventral horn motoneuron pools of spinalized cats. Cats then received either paired or explicitly unpaired CS-US presentations followed by CS-alone extinction trials. Responses to single pulse test trials delivered through the microelectrode were recorded. The data indicated that paired trials produced significant acquisition and extinction effects, with no significant changes in the test trial responses. In the second experiment, microelectrode placement and conditioning procedures were the same as in Experiment 1. Multiple unit activity (MUA) was recorded during test trials from the ventral horn. A test trial consisted of a single 1-ms pulse delivered to the sensory nerve. MUA recordings were made for a period of 750 ms on each test trial which represented 250 ms pre-CS, 250 ms beginning with CS onset, and an additional 250 ms which would correspond to US period on a paired trial. Standard scores based on pre-CS spike counts were computed for the remaining two time periods for base-line, acquisition and extinction periods. The conditioning data again showed both acquisition and extinction effects, which were also showed in the standard scores of ventral horn MUA. The first experiment indicated that no motoneuron excitability change occured during conditioning procedures. However, the results of Experiment 2 indicate increased firing rates of spinal motoneurons during stimulus pairing which decreased during extinction trials. These data may suggest that the cells are firing more frequently due to stimulus contiguity effects or that recruitment of more cells occurs due to stimulus pairing.

This research was supported by NIH grant 14545 to M.M. Patterson.

236.17 NEURON RESPONSES ELICITED IN MONKEY AMYGDALA BY COMPLEX SENSORY STIMULI AND DELAYED COMPARISON TEST. H. NISHIJO*, T. ONO AND R. TAMURA* Dept. of Physiol., Fac. of Med., Toyama Med. and Pharmaceu. Univ., Toyama 930-01, Japan.

It is suggested that hypoemotionality and some cognitive deficits produced by amygdalar lesion arise from the same underlying dysfunction of sensory processing. In this study, single neuron activity in the monkey amygdala (AM) was recorded during discrimination of various positive and negative stimuli presented in four kinds of operant bar press tasks, and in delayed comparison of pairs (DPC) among four colored lamps. The neuronal responses were analyzed in terms of responsiveness to visual, auditory, somesthetic and oral stimulation. Of 585 neurons tested for sensory responses, 107 responded primarily to a single modality (40 vision, 26 audition and 41 ingestion), 117 responded transiently or tonically to all four modalities, and 14 responded selectively to only one stimulus item. All of these neurons responded to certain rewarding or aversive stimuli. Of the 585 neurons, 423 were also tested in DPC, and 124 responded in one or more phases: 1) 17/30 vision related responded to 1st and/or 2nd cue lamps, and 4/30 responded throughout the 1st and 2nd cue and delay periods; 2) 0/21 audition related responded in DPC; 3) 4/30 ingestion related responded to 1st and/or 2nd cue lamps, and 30/30 responded in the ingestion phase; 4) 21/70 multimodal responded transiently and 47/70 responded tonically to the 1st and/or 2nd cue lamps (9/47 responded also in the delay period); 5) 4/14 selective neurons responded in ingestion phase in DPC only when a specific item was the reward. In summary: No amygdalar neurons, such as those reported in the inferotemporal cortex, responded differentially to color in the delay period. This suggests that the AM is not involved in short term memory in DPC for familiar color matching. However AM neurons that responded in the delay period indicate some involvement of the AM in certain memory processes, possibly internal rehearsal of the stimulus.

236.18 PAIRED-PULSE FACILITATION IS DIFFERENTIALLY AFFECTED BY LTP AND EXTRACELLULAR CALCIUM CONCENTRATIONS. D. Muller* and G. Lynch. Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717, U.S.A.

These experiments explored the possibility that increases in pre-synaptic calcium fluxes are involved in the hippocampal long-term potentiation (LTP) effect. We reasoned that if this were so, then the induction of LTP should affect various aspects of synaptic transmission in a manner similar to that found after manipulations thought to increase calcium influx into terminals. Studies at the neuromuscular junction have shown that the extent of calcium influx during depolarization is determined in part by the extracellular concentration of the cation and we assumed that this holds for hippocampus. We therefore first assessed the effects of increasing extracellular calcium on one measure of pre-synaptic physiology--paired pulse facilitation--and then tested if the induction of LTP reproduced these effects.

Hippocampal slices were first maintained at 1 mM Ca for one hour and then extra-cellular calcium was increased by steps up to 6 mM. The slope and amplitude of the field EPSP generated in the apical dendrites of field CA1 by stimulation of the Schaffer-commissural system was tested at each concentration as was the degree of paired pulse facilitation using an interpulse interval of 40 msec. As expected the size of the evoked response was a negatively accelerating function of calcium concentration with the shape of the curve closely resembling that described for the neuromuscular junction. Paired-pulse facilitation, expressed as a ratio of the second response to the first, decreased with increasing calcium levels; thus it appears that the degree of facilitation is negatively related to size of the calcium influx occurring on the first pulse.

LTP was tested in different slices at different calcium concentrations. In all cases, the strength of the potentiating stimulation was adjusted to produce a one millivolt population spike. Robust potentiation was obtained in most slices at 2 mM but not at lower concentrations of calcium. Slices incubated at the higher calcium concentrations did not exhibit a greater degree of LTP but the potentiation effect was, if anything, more reliably produced. This suggests, in contrast to earlier reports, that prolonged incubation in elevated calcium by itself does not trigger LTP. The induction of LTP at all levels of calcium did not reduce paired pulse facilitation; i.e., the ratio of the second response to the first was the same in potentiated as "naive" synapses. Thus increasing the amplitude of a given response via LTP does not have the same effect on paired pulse facilitation as does increasing the response by raising extracellular calcium. This discrepancy indicates that LTP is not likely to be due to an increased flux of calcium into pre-synaptic endings.

LEARNING AND MEMORY: PHARMACOLOGY III

237.1 INHIBITORY AVOIDANCE LEARNING IN DEVELOPING RATS IS IMPAIRED BY NEONATAL 6-HYDROXYDOPA, BUT NOT DSP4. C.A. Cornwell-Jones, J. W. Chang*, B. Cole*, K. Goltz* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

Previous evidence suggests that central norepinephrine (NE) may be particularly important for some forms of early learning. For example, although the noradrenergic neurotoxin DSP4 does not impair inhibitory avoidance learning in adult rats, it impairs the ability of early experience to enhance adult learning (McGaugh et al., Neurosci. Abst. 12, 1986). The present experiment compared the effects of two noradrenergic neurotoxins, 6-hydroxydopa (6-OHDOPA) and N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP4) on inhibitory avoidance learning in juvenile rats 35-40 days old.

On the day of birth Sprague-Dawley male rat pups assigned to the DSP4 experiment were injected s.c. with 50 μg/g of DSP4 and littermates received water. Rats in the remaining litters were injected with 60 μg/g of 6-OHDOPA on postnatal Days 0 and 2. Control littermates received vehicle. Half the rats in each group were trained in a one-trial inhibitory avoidance task, and tested for retention the following day. Shock threshold values were determined for remaining animals. The frontal cortex (FC), hippocampus (HP), and brainstem (BS) were subsequently assayed for NE, dopamine (DA) and serotonin (5-HT), and their metabolites including 5-hydroxyindole-3-acetic acid (5-HIAA), using high pressure liquid chromatography with electrochemical detection.

Neurotoxin effects on forebrain NE levels were similar: FC NE concentrations were reduced to 35% and 26% of control values by DSP4 and 6-OHDOPA respectively. HP NE concentrations were reduced to 15% and 13% of control values by DSP4 and 6-OHDOPA respectively. Neurotoxin effects on some other values differed however. DSP4 reduced HP 5-HIAA and 5-HT by 30% and 48% respectively, while 6-OHDOPA did not significantly affect such values. The largest differences were seen in the brainstem where 6-OHDOPA elevated 5-HT and 5-HIAA by 54% and 70% respectively, and where NE levels were elevated to 129% and 256% of control values by DSP4 and 6-OHDOPA respectively.

Retention of the inhibitory avoidance task was significantly impaired by 6-OHDOPA, but not DSP4. The deficit did not reflect increased resistance to pain since shock threshold values for controls and 6-OHDOPA-treated animals were not statistically different. The difference in the behavioral effects of these neurotoxins cannot be attributed to differences in forebrain NE. The finding of large differences in brainstem NE strongly suggests that brainstem mechanisms may underlie these behavioral differences.

237.2 THE ROLE OF ADRENERGIC RECEPTORS IN THE BEHAVIORAL EFFECTS OF HIPPOCAMPAL SYMPATHETIC INGROWTH. A. Peagler* and L.E. Harrell. (Spon: E. Faught) Dept. Neurology and Psychology, VAMC and Univ. Alabama Med. Ctr., Birmingham, AL 35294.

Peripheral noradrenergic fibers, originating from the superior cervical ganglia, grow into the hippocampus following cholinergic denervation. Behavioral studies have suggested that hippocampal sympathetic ingrowth (HSI) is detrimental to the recovery of a spatial/memory task. In order to determine if this effect was mediated through adrenergic activity, we studied the effect of and B adrenergic blockaid on the reacquisition of a spatial/memory task following HSI.

Adult male Sprague-Dawley rats were assigned to one of two groups: Group 1 ultimately treated with the α -blocking agent,regitine (20 mg/kg); Group 2 treated with the B-blocking agent propranolol (20 mg/kg). Initially all animals were reduced to 85% of their body weight and underwent training on a modified version of a radial-8-arm maze task in which 4 of the arms were baited. Training continued until all animals reached a specific learning criterion (visiting 4 baited arms out of the first 5 selections on 4 out of 5 consecutive days). Following this animals in each group were randomly assigned to one surgical/treatment condition: CONV (sham medial septal lesion (MSL), sham superior cervical ganglionectomy (SGx) + vehicle (V)); COND (sham surgeries + Drug (D)); MSLV (MSL + SGx + V); MSLD (MSL + SGx + D); MSLGxV (MSL + ganglionectomy (Gx) + V); MSLGxD (MSL + Gx + D). Two days following surgery, animals underwent reacquisition trainng. This was performed in a similar manner to initial acquisition with the exception that either D or V was administered IP 30 minutes prior to testing. Training was continued until learning criterion was reachieved.

Preliminary examination of our results revealed that attainment of initial learning criterion was similar among animals assigned to both groups and various treatment conditions. As expected MSL produced a deterioration in task performance. In the vehicle treated groups animals without HSI appeared to recover faster than those with HSI. Drug treatment, however, interacted with the lesion effect and the presence or absence of HSI. Propranolol treatment caused a deterioration of learning in lesioned animals without HSI (MSLGx), while producing no changes in behavior of CON or MSL groups. Regitine treatment caused learning to deteriorate in the CON group, had no effect in the MSLGx group and enhanced learning in the MSL animals.

Although preliminary, our results suggest that maintenance of performance of this spatial/learning task in normal animals requires the integrity of α -adrenergic activity and that the detrimental effects of HSI may be mediate through activity within α -adrenergic systems.

237.3 NORDRENERGIC LESIONS BLOCK PHYSOSTIGMINE ENHANCEMENT OF N.BASALIS LESION INDUCED MEMORY DEFICITS: CLONIDINE REINSTATES PHYSOSTIGMINE ENHANCEMENT. V. Haroutunian, G. Tsuboyama, P.D. Kanof, and K.L. Davis. The Mount Sinai Sch. of Med., New York, NY 10029.

Alzheimer's disease(AD) is characterized by forebrain cholinergic deficits,and in some cases dramatic noradrenergic (NE) deficits. Cholinomimetic therapy offers clinically significant symptomatic relief in only a subpopulation of AD victims. Results of recent animal studies suggest that NE lesions can block cholinomimetic enhancement of memory in n. basalis (nbM) lesioned rats and may provided one of the bases for poor response in aproportion of AD patients. Rats received sham lesions, ibotenic acid lesions of the nbM (5ug/ul leading to 32% depletion of cortical CAT), 6-OHDA lesions of the ascending noradrenergic (NE) system (8ug/2ul resulting in 92% depletion of cortical NE), or lesions of both systems. After a two week recovery period each rat was trained in a one trial passive avoidance paradigm. Immediately after training each rat received sc injections of saline or one of several doses of physostigmine. The physostigmine dose was varied between 0.015-0.24 mg/kg. Retention of passive avoidance was assessed 72 hours later and showed that 0.06 and 0.12 mg/kg doses of physostigmine enhanced retention test performance in nbM lesioned rats ($ps<0.01$), but failed to affect the retention test deficits of the nbM + NE lesioned rats ($ps>0.1$). In a second study, sham operated rats and nbM + NE lesioned rats were trained on one trial passive avoidance.and received either a 0.06mg/kg dose of physostigmine alone, or physostigmine plus clonidine. The dose of clonidine was varied between 0.005-0.5 mg/kg in different groups of rats ($Ns=8-10$). Retention test performance was enhanced ($ps<0.01$) in nbM+NE lesioned rats which had received either the 0.5mg/kg dose of physostigmine alone, or in lesioned rats which had received 0.06mg/kg physostigmine plus 0.01 mg/kg clonidine. These results indicate that a)the failure of cholinomimetics to enhance cognition in some AD patients may be due to NE deficits superimposed upon the cholinergic deficit and, b) that the combined administration of cholinomimetics and clonidine may prove to be more efficacious than cholinergic therapy alone.

237.4 THE EFFECTS OF HUPERZINE A, AN ACETYLCHOLINESTERASE INHIBITOR, ON THE ENHANCEMENT OF MEMORY IN MICE, RATS AND MONKEYS[1].
G.P. Vincent, L. Rumennik, R. Cumin*, J. Martin*, and J. Sepinwall. Departments of Neurobiology and Obesity Research and PF/CNS, Hoffmann-La Roche Inc., Nutley, N.J. 07110 and Basle, Switzerland.

Huperzine A (Hup-A) is an alkaloid extracted from Huperzia serrata that is a potent and reversible inhibitor of acetylcholinesterase, with greater selectivity and 3 times the potency of physostigmine (Wang et al., Acta Pharmacol. Sin. 7:110-113, 1986). We have studied Hup-A in three species in various tests to assess its activity as a potential cognitive performance enhancing (CPE) agent.

In CF1 mice, Hup-A protected against electro-brain-shock (EBS) disruption in retrieval of an active avoidance response. Hup-A was active at doses of 0.001-0.01 mg/kg, i.p. and exhibited an inverted U-shaped dose-response curve. Physostigmine was active at a single dose of 0.1 mg/kg, i.p. with an equivalent magnitude of effect to that of Hup-A. The duration of action of Hup-A in this procedure was limited to 20 - 30 minutes after intraperitoneal injection. Hup-A was also active after oral administration but only at the single dose of 0.003 mg/kg and only at a 60 minute pretreatment time.

Hup-A was tested in C57BL/10 mice in the Morris water maze, a test which requires an animal to attend to spatial cues to locate the position of a hidden platform. Hup-A significantly decreased the latency to find the hidden platform by these mice at doses ranging from 0.001-0.1 mg/kg i.p. In contrast, physostigmine (0.003-0.1) was inactive in this procedure.

In albino rats, Hup-A was tested for its ability to reverse scopolamine (1 mg/kg) induced amnesia for the retention of a passive avoidance response. Hup-A was active from 0.00003-0.001 mg/kg s.c., whereas the "therapeutic window" of physostigmine was narrow and extended only from 0.005-0.01 mg/kg s.c. Hup-A was also active when administered orally from 0.1-1 mg/kg.

Hup-A also improved the accuracy of retention by 5-13% at doses of 0.003-0.03 mg/kg i.m. in squirrel monkeys on a delayed match-to-sample procedure. At 0.1 mg/kg, Hup-A resulted in a slowing of the animals' performance while accuracy remained high. This decrease in the speed of performance was antagonized by administration of scopolamine methylbromide and thus was the result of a peripheral cholinergic action of Hup-A.

These results demonstrate that Hup-A is a potent CPE agent, with a broad range of activity, especially after parenteral administration.

[1]. Appreciation is extended to Shanghai Institute of Material Medica, Shanghai, China for supplying Huperzine A; these studies are part of a collaborative effort with the Shanghai Institute.

237.5 CONTEXT-CONDITIONED FREEZING IS BLOCKED BY MORPHINE.
J. CRANNEY AND S. GRAUDINS School of Psychology, University of New South Wales, P.O.Box 1, Kensington, NSW 2033, Australia.

The freezing response, which can be elicited experimentally by electric footshock, is one of the rat's species-specific defence reactions (Bolles,Psych.Review,71:32,1980). Fanselow (Behav.Neurosci,98:269,1984) demonstrated that freezing could be conditioned to contextual stimuli, and that this context-conditioned freezing was enhanced by naloxone administration. Borszcz, Cranney and Leaton (Proc.Eastern Psych.Assoc.,1985) showed that startle stimuli could support context-conditioned freezing, and Cranney (Pav.J.Bio.Sci, in press, 1987) reported that this effect may be mediated by endogenous opioid systems. This study investigated the effects of naloxone and morphine administration on freezing and startle amplitude.

Thirty-six male Wistar rats were matched by weight across four groups. On Day 1, the MOR group was administered morphine sulphate (10 mg/Kg)20 min, and saline (1 ml/Kg)1 min, prior to testing. The MOR-NAL group were administered morphine sulphate 20 min, and naloxone (4 mg/Kg)1 min, prior to testing. The SAL group were administered saline 1 min prior to testing. Testing consisted of ten 110-dB noise bursts with an ITI of 60s. Activity (freezing/no freezing) during the 10s prior to the first startle stimulus of the session was recorded. On Day 2,there was no drug administration but the same startle test was employed.

On Day 1, there were no differences amongst groups in both the prior freezing response and the startle amplitude of the first startle stimulus. No rats froze prior to the first stimulus except for 3 of the 9 MOR rats. On Day 2, the SAL group froze 53 per cent of the 10s prior to the first startle stimulus, and the NAL group froze 42 per cent. This finding does not replicate previous reports of naloxone-enhanced context-conditioning. However, the MOR-SAL Group did not show any context-conditioned freezing. This effect was attenuated by naloxone administration, with the MOR-NAL Group showing 53 per cent freezing to the context. Thus, morphine eliminated context-conditioned freezing. This suggests that either (1) morphine reduced the nociceptive properties of the startle stimulus, and so reduced the capacity of the stimulus to support context-conditioned freezing, (2) morphine interacts with an endogenous opioid system that is activated by startle stimulus presentation, or (3) context-conditioned opiate hyperactivity masked freezing behaviour. The relevance of these findings to theories of fear conditioning and startle modulation are discussed.

237.6 INFLUENCE OF OPIOID PEPTIDES IN MEMORY FORMATION IN THE CHICK. T.A. Patterson, G. Schulteis, J.L. Martinez, Jr., V.J. Hruby*, E.L. Bennett, & M.R. Rosenzweig. Dept. of Psych., Univ. of Calif., Berkeley, CA. 94720 and Dept. of Chem., Univ. of Ariz., Tucson, AZ 85721.

Several studies examined the effects of opioid peptides on memory formation in the chick. Two-day-old male Dekalb-Warren chicks were trained in a one-trial taste-avoidance task. Injections (10.0 µl/hemisphere) of saline or drug were made into the medial hyperstriatum ventrale (MHV) 5 min pretraining and chicks were tested 24 hr posttraining.

Experiment 1 determined that bilateral injection of 0.001-1.0 nmole/hemisphere β-endorphin (β-END) produced amnesia. Bilateral injection of naloxone (50.0 nmole/hemisphere) reversed amnesia produced by the highest dose of β-END. These results suggest that amnesia produced by β-END is an opioid effect.

Experiment 2 showed that bilateral injection of 1.0 nmole/hemisphere [leu]enkephalin (LEU) was amnestic. The dose response curve was U-shaped: 0.001-0.3 and 3.0-10.0 nmole/hemisphere doses were not amnestic. The highly selective delta agonist D-Pen^2-L-Pen^5-enkephalin (DPLPE) was 30 times more potent than LEU in producing amnesia. The dose response curve was again U-shaped: bilateral injection of 0.03 nmole/hemisphere produced amnesia, whereas doses of 0.003-0.01 and 0.1-1.0 nmole/hemisphere were not amnestic. Bilateral injection of the delta selective antagonist, ICI 174,864 (10.0 nmole/hemisphere), reversed amnesia produced by either 1.0 nmole/hemisphere LEU or 0.03 nmole/hemisphere DPLPE. These results indicate that amnesia produced by LEU is mediated through delta opioid receptors and suggest that delta receptors play a role in formation of memory in the chick.

Patterson et al. (1986) showed that memory formation in the chick is lateralized. Experiment 3 compared the effects of bilateral and unilateral injections into MHV of LEU or β-END (1.0 nmole/hemisphere). Only bilateral injections of LEU produced amnesia. Bilateral injection of β-END was amnestic, as was unilateral injection into the right, but not left MHV. These results suggest that the effects of β-END are centrally-mediated, whereas the effects of LEU may be peripherally-mediated or localized to other brain regions. The possible roles of lateralization of opioid effects will be presented.

237.7 INVOLVEMENT OF OPIOID DELTA RECEPTORS IN ACTIVE AVOIDANCE CONDITIONING IN MICE. G. Schulteis, V.J. Hruby*, and J.L. Martinez, Jr. Psych. Dept., Univ. of Calif., Berkeley, CA 94720, and Chem. Dept., Univ. of Ariz., Tuscon, AZ 85721.

[Leu]enkephalin (LE) impairs acquisition of one-way active avoidance conditioning (1985, Life Sci. , 37:2345). As LE exhibits greater affinity for delta, than for mu or kappa, receptors (1983, Br. Med. Bull. , 39:25), we compared the behavioral effects of the endogenous ligand LE with those of [D-Pen^{2}-D-Pen^{5}]enkephalin, a highly selective delta agonist, and ICI 154,129 (ICI), a delta-selective antagonist.

Male Swiss-Webster mice were tested in a one-way active avoidance task (330 μA shock) 2 min after i.p. injection of drug or saline (SAL). Fourteen training trials were given, with a 20 sec intertrial interval. As compared to SAL, LE mice made significantly fewer avoidances at the 30 μg/kg (t[2,42)]= 2.66, p<.011) and 100 μg/kg (t[2,41] = 3.79, p<.0008) doses. DPDPE (11.62 μg/kg, equimolar to 10 μg/kg LE) also impaired learning (t[2,39] = 4.72, p<.0002), whereas ICI enhanced acquisition at the 30 mg/kg (t[2,27] = 2.59, p<.015) and 100 mg/kg (t[2,28] = 2.22, p<.034) doses.

We also examined the effects of LE and DPDPE on shock-induced locomotor activity levels and analgesia. The low potency and high cost of ICI precluded its inclusion. Activity was measured 2 min after injection of drug or SAL, by giving mice a 2 sec footshock (330 μA) immediately prior to placing them in an open field chamber divided into 16, 3-inch squares. Avoidance-impairing doses of LE and DPDPE had no effect on the number of lines crossed during a 10 min observation period. Analgesia was measured by jump thresholds in a flinch-jump paradigm. Four series of ten, 150 msec shocks, ranging from 75-480 μA in 45 μA steps, were delivered in alternating ascending and descending order. Neither DPDPE (11.62 μg/kg) nor LE (100 μg/kg), given 2 min prior to testing, induced analgesia.

In conclusion, stimulation of delta receptors with the selective agonist DPDPE mimics the impairment of acquisition observed with the endogenous ligand LE, at 3-10 times the LE potency. These effects of LE and DPDPE appear to involve direct modulation of learning, as neither drug alters shock-induced activity or analgesia thresholds. Finally, preventing endogenous ligands from binding to delta receptors with ICI enhances learning, an effect opposite that seen with LE and DPDPE. Taken together, these results suggest that delta receptor activation is normally involved in the modulation of avoidance learning, and that the effects of LE may be mediated by this receptor.

237.8 TWO ENKEPHALIN METABOLITES, TYR-GLY-GLY-PHE AND TYR-GLY, IMPAIR ACQUISITION OF AN ACTIVE AVOIDANCE RESPONSE IN MICE. P.H. Janak*, A. Valedon*, G. Schulteis, B.E. Derrick,*K. Fett*, S.B. Weinberger, J.L. Martinez, Jr. Department of Psychology, University of California, Berkeley, CA 94720.

We previously reported that an enkephalin metabolite, tyr-gly-gly (TGG), impairs acquisition of an active avoidance response in mice (Neurosci. Abs.,1986,12,706). In the present study, we examined the avoidance conditioning effects of the metabolites, tyr-gly-gly-phe (TGGP) and tyr-gly (TG).

Male Swiss-Webster mice were tested in a one-way active avoidance task 2 min following i.p. injection of peptide or saline, as described by Schulteis et al. (Neurosci. Abs.,1987,13). [Leu]enkephalin (LE) (100 μg/kg), TGGP (80 μg/kg), and TG (43 μg/kg) all significantly impaired acquisition of the avoidance response, as compared to saline treatment. The effective dose of both TGGP and TG was equimolar to the effective dose of LE.

We also observed shock-induced locomotor activity in an open field. LE has no effect in this test (Schulteis, et al., Neurosci. Abs.,1987,13). TGGP (80 μg/kg), but not TG (43 μg/kg), significantly decreased activity levels. This effect may contribute to TGGP's, but not TG's, impairing action on avoidance conditioning.

There are several ways to interpret these data: 1) TGGP, TGG, and TG all have low opioid potency as compared to LE (Dewey, In Endorphins: Chemistry, Physiology, Pharmacology, and Clinical Relevance. Malick & Bell (eds), Marcel Dekker, Inc., 1982). It is possible, therefore, that LE and its metabolites act at separate receptor populations, LE acting at opioid receptors, and metabolites acting at non-opioid receptors. 2) The LE metabolite des-tyr-LE has no effect on avoidance conditioning in mice (Neurosci. Abs., 1985,10,383), suggesting that the tyr-gly sequence is necessary for the avoidance impairing effects of LE and its metabolites. With this interpretation, LE and its active metabolites could influence conditioning through a single, although not necessarily an opioid, receptor. 3) Although LE, TGGP, and TG all produce the same action on avoidance conditioning, their spectra of behavioral activity differ, since only TGGP decreases locomotor activity. These peptides may therefore produce similar active avoidance impairments through different receptor mechanisms.

237.9 **REVERSAL OF LESION-INDUCED SWIM MAZE DEFICITS WITH A CENTRAL ACETYLCHOLINESTERASE (AChE) INHIBITOR.** **J.E. Sweeney, C.F. Höhmann, J.A. Bowersox*, T.H. Moran and J. T. Coyle, Depts. of Environ. Health and Neuroscience. The Johns Hopkins University Schools of Public Health and Hygiene and Medicine, Baltimore, MD 21205.**

Destruction of cholinergic neurons of the basal forebrain (BF) which project to neocortex in rodents results in impaired performance on tasks involving working memory. In this study, we examined whether lesions to and pharmacologic manipulation of the central cholinergic system in mice impair performance on a swim maze task. Further, we examined whether this deficit could be reversed by a centrally-acting reversible acetylcholinesterase (AChE) inhibitor, galanthamine hydrobromide (GHB). GHB has an *in vivo* half life of approximately 6 hours, making its effects longer than most previously tested AChE inhibitors.

Adult male Balb/C mice received bilateral ibotenate lesions to BF and were allowed to recover for two weeks. Working memory was assessed in lesioned animals and age-matched controls on a water maze task. The swim tank (72-cm diameter) contained a platform submerged 1 cm below the surface of the opacified water. Mice were placed into each quadrant of the tank, and latency to find the platform was measured. Following acquisition, the position of the platform was changed daily and the new position demonstrated to the animal before latency was measured. After reaching criteria (< 100 sec), mice received saline injections (0.33 ml / kg, i.p.), and on the following day GHB (5 mg/kg, i.p.) one half hour before testing. Another group of mice were trained to criteria and tested with scopolamine (0.8 mg/kg,i.p.), a centrally-acting muscarinic antagonist, or N-methyl scopolamine (0.8 mg/kg), a peripheral antagonist.

Even though no significant differences were noted for acquisition of the task (either days to acquire or latency when the platform remained in one position), a clear distinction could be noted when the platform was moved on consecutive days; mean latency for lesioned animals was 200± 63 sec, and mean latency for control animals was 60±6 sec. GHB reduced latency in lesioned animals to 100±17 sec, while latency in control animals increased to 169±20 sec. Within 2 days of the drug treatment, performance in both groups returned to pre-injection levels. Scopolamine injections clearly impaired the animals' performance (latency was 206±44 sec), whereas N-methyl scopolamine, the peripheral muscarinic antagonist did not affect latency (51± 3 sec).

We have developed a working memory task for mice which is sensitive to cholinergic interuption, by either lesions to BF or administration of a central muscarinic antagonist. Results suggest that galanthamine can temporarily reverse impaired performance in BF lesioned animals. Further, it appears that optimum levels of acetylcholine (ACh) are necessary for accurate performance of this task; and that either too little or too much ACh is associated with impaired performance. Since galanthamine has a longer half life than many centrally-acting cholinergic drugs, it could be of possible clinical use in patients suffering from central cholinergic losses, for examples, in Alzheimer's Disease.

237.10 **DOPAMINERGIC MODULATION OF COGNITIVE FUNCTIONS. BEHAVIOURAL AND NEUROCHEMICAL EVIDENCE.** G.Schettini,T.Florio*,E.Landolfi*,O.Meucci*, M.Grimaldi*,G.Magri* and A.Marino*. Department of Pharmacology, II School of Medicine, University of Naples, Via S.Pansini 5, 80131 Naples, ITALY.

Brain dopaminergic transmission is involved in modulating cognitive functions.

In the present study we evaluated the effect of co-dergocrine, a compound used in brain aging, on different behavioural tests and neurochemical parameters related to the dopaminergic transmission, both in young and aged animals.

Co-dergocrine (1-3-10mg/kg ip, 1h before trial, daily for 20 days) improved the acquisition of a conditioned avoidance response (CAR), being more effective at 3mg/kg dose. This latter dose slightly increased the CARs in old animals. The same treatment caused in young rats an increase of NE and DA stimulated adenylate cyclase (AC) activity in the frontal cortex. Co-dergocrine inhibited locomotor activity in old animals in a dose dependent manner, while showed a triphasic pattern of response in young rats: inhibition for low dose (0.03mg/kg), stimulation for middle dose (0.3mg/kg), again inhibition for high dose (10mg/kg). Striatal DA-sensitive AC activity was inhibited in co-dergocrine 3mg/kg 20days treated rats.

Co-dergocrine directly added to membrane preparations of different brain areas did not modify in young animals basal striatal AC activity, while the presence of SCH-23390 (100nM), a D_1 receptor antagonist, it inhibited striatal AC activity. In old rats co-dergocrine dose dependentlystimulated striatal AC activity, while in presence of SCH-23390 the enzyme activity was inhibited. Co-dergocrine reduced the frontal cortex AC activity at high concentrations and in the hippocampus a biphasic pattern of response was present. Thus co-dergocrine inproves cognitive functions in rat, likely acting on dopaminergic transmission. A different response between young and old animals to co-dergocrine is also shown, probably due to the changes in sensitivity and number of the two types of DA receptors during aging.

237.11 ANXIOGENIC EFFECT OF ACTH IN DISCRIMINATION AVOIDANCE LEARNING IN RATS. C. Hara, N. Ogawa* and M. Ishikawa*. Dept. of Pharmacol.,Ehime Univ. Sch. of Med., Ehime-ken 791-02, Japan.

ACTH is known to affect avoidance learning behavior of rats. The behavioral effect of ACTH is based on its extra-adrenal action (Miller, R.E. and Ogawa, N., 1962), and can be attributed to facilitation of consolidation of memory (de Weid, D. and Bohus, B., 1966) or anxiogenic effect (Weiss, J.M. et al., 1970; File, S.E. and Vellucci, S.V., 1978). In order to study the central action of ACTH, the present study examined influences of ACTH4-10 and ACTH4-9 without adrenocortical activity in the acquisition process of discrimination avoidance conditioning, which can be assessed anxiety level of rats (Gomita, Y. et al., 1985).

Male Wistar strain rats with a cannula for intraventricular (i.c.v.) injection were used. The rats were individually housed in the air-conditioned room (23±1°C) with lighting schedule of a 12:12 LD cycle (lights on 7:00-19:00) throughout the experiment. Food and water were supplied ad lib. ACTH4-10 and ACTH4-9 (0.2, 1.0 µg) were injected i.c.v. with 5 µl injection volume 10 min before beginning the discrimination avoidance conditioning. Chlordiazepoxide (CDP; 1.5 mg/kg) as an anxiolytic drug was administered i.p. 30 min before beginning the conditioning. The rats were divided into 4 groups as follows; saline(S; i.c.v.)x S (i.p.), S (i.c.v.)x CDP, ACTH fragments x S (i.p.), and ACTH fragments x CDP. The discrimination conditioned avoidance response was measured in the two-compartment shuttle box. The rats were trained to discriminate between positive and negative conditioned stimuli (CS). Two pure tones with a frequency of 400 Hz for positive CS and that of 800 Hz for negative CS, and visa versa, were used. The positive CS for 6 sec was followed by foot shock (0.7-1.2 mA) as unconditioned stimulus. Transfer of the rat to the opposite compartment in response to the negative CS was regarded to be an incorrect response. Transfer between compartments in the shuttle box during the intertrial period was also recorded as a spontaneous response.

In the results, there was no difference among 4 groups in the acquisition of avoidance learning. However, SxS and SxCDP groups showed significant difference between the acquisition of avoidance learning and the number of incorrect response within 10 days after beginning the conditioning. That is, both groups accomplished the discrimination avoidance learning. On the other hand, ACTH4-10 and ACTH4-9 treatments did not accomplished the discrimination learning, since the incorrect response to negative CS increased. CDP improved the impairment by ACTH fragments. There was no difference among 4 groups in spontaneous response.

Therefore, the results of the present study seem to suggest that ACTH is implicated in anxiety.

237.12 A VASOPRESSIN FRAGMENT MODULATES SELECTIVE ATTENTION. J. RAABE M.D. BUNSEY‡ B. STRUPP‡ D. LEVITSKY‡ and M. KESLER* Dept. of Psychol. and Div. Nut. Sci., Cornell U., Ithaca, N.Y. 14853.

Vasopressin's (VP) putative mnemonic role has recieved a great deal of attention. In contrast, very little research has examined the influence of this neuropeptide on attentional processes. Specifically, several lines of indirect evidence (electrophysiological, neuroanatomical, and behavioral) suggest that VP might narrow the focus of attention. However, only one study has directly addressed this hypothesis (Jennings, et.al.,]986), and it yielded inconclusive results.

The present study further examined this attentional hypothesis. Eighty hooded rats were administered either the VP fragment, AVP 4-9 (1.0, 3.0, or 10.0 ug/kg) or the vehicle solution one hour prior to behavioral testing. The behavioral test assessed the animal's ability to (1) determine which of two sets of tactile cues were predictive of reward and which were irrelevant, and (2) selectively attend to the predictive set of cues and filter out the irrelevant stimuli. On each trial, the animals were presented with two covered boxes, one containing a piece of Froot Loop cereal. For one fourth of the animals, the tactile cues on the boxes predicted reward and the lid cues were non-predictive. For another fourth of the animals, the reverse was true. These two subgroups comprised the distracting condition. The remaining half of the subjects were presented with either box or lid cues, but not both (i.e., the non-distracting condition). The animals were tested in their homecages in a non-deprived state in order to minimize arousal. Analysis of the number of trials to criterion indicated that there was no effect of the peptide treatment in the non-distracting condition. However, in the distracting condition, there was a significant interaction between dose and relevant dimension (i.e., whether boxes or lids were relevant). Specifically, performance of those rats for whom box cues were predictive improved with increasing dose of the peptide, while performance of rats for whom lid cues were relevant deteriorated as the dose increased.

These findings indicate that the AVP 4-9 treatment caused the rats to selectively focus on one aspect of their environment (the box cues). When this focus of attention contained information that was predictive of reward, performance improved. In contrast, when this information was irrelevant, learning rate was impaired. Possible implications for psychiatric disorders characterized by abnormal VP release are discussed.

237.13 INDIVIDUAL DIFFERENCES IN MEMORY FUNCTION PREDICT VASOPRESSIN'S MNEMONIC EFFECT. B.J. Strupp* (SPON: N. Spear). Div. Nutr. Sci., Cornell Univ., Ithaca, NY 14853.

Although many investigators have reported that administration of vasopressin or analogues improves memory function in animals, two features of these experiments limit their implications for the role of the endogenous neuropeptide. First, the majority of these studies employed systemic administration of arginine vasopressin, the results of which may be artifactual, due to the aversiveness of this treatment. Second, all of the studies that have demonstrated memory facilitation with analogues or routes of administration that are not aversive have utilized aversively-motivated paradigms, rendering the generalizability of such findings questionable (see Strupp and Levitsky 1985). The three studies presented here were designed to determine if memory function could be improved in an appetitively-motivated paradigm by the administration of AVP_{4-9}, a vasopressin fragment that is virtually devoid of pressor effects (and therefore, presumably, aversive effects).

All three experiments assessed memory function in elevated radial arm mazes (8-, 12-, and 16-arm mazes respectively). After each rat had entered half of the arms (selected by the experimenter and hence termed forced choices), it was returned to its homecage. Following an interval of 9-14 hours (depending on the experiment) the rat was placed back into the maze. Only those arms which the rat did not traverse earlier that day were baited. The number of errors committed in retrieving the remaining food was used as the index of memory. In Experiment 1, AVP_{4-9} (0, .2, .67, 2.0, 6.67 µg/kg) was administered 30 minutes prior to the forced choices; all 4 active doses of the peptide significantly prevented the forgetting seen in the control condition. In Experiment 2, AVP_{4-9} (0, .02, .2, 2.0 µg/kg) administered immediately after the forced choice session was ineffective. However inspection of the data suggested (a) that different doses may have been beneficial to different rats, and (b) that the performance of one third of the rats may have been at a ceiling. Therefore in Experiment 3, each rat was tested in a 16-arm maze with the vehicle and the one dose of AVP_{4-9} that had most improved its performance in Experiment 2. Post-trial AVP_{4-9} significantly reduced forgetting. In addition, a significant inverse relationship was found between the rats' baseline performance and the degree of improvement caused by the peptide relative to the vehicle treatment. The most proficient rats were impaired by the peptide treatment, whereas memory of the least proficient animals was improved.

These results support a mnemonic role for vasopressin. Moreover they illustrate the importance of considering individual differences in studying the biology of cognition and in predicting therapeutic utility.

237.14 ENVIRONMENT-SPECIFIC CONDITIONED ACTIVITY BASED ON SCOPOLAMINE IS NOT BLOCKED BY PIMOZIDE. E.J. Mazurski and R.J. Beninger. Department of Psychology, Queen's University, Kingston, Canada, K7L 3N6.

Environment-specific conditioned locomotor activity has been demonstrated using a number of dopamine agonists. The present study used a classical conditioning paradigm to determine if the stimulant effects of the anticholinergic scopolamine could also be conditioned to specific environmental cues. Two groups (n = 12 and 9) of rats had 12 60-min pairings of a distinctive environment (activity monitors that automatically assess horizontal and vertical activity) with scopolamine (1.0 or 8.0 mg/kg, IP, 30 min prior to each session). Corresponding control (unpaired) groups received saline. After each session all rats received a second injection; the paired groups received saline, and the unpaired groups received the appropriate dose of scopolamine. After every fourth pairing session a test, where all rats received saline 30 min before the session, was conducted to assess conditioning. Both doses of scopolamine produced an unconditioned enhancement of horizontal activity, although conditioned horizontal activity was seen only with 8.0 mg/kg. The low dose increased unconditioned vertical activity during the latter part of the session whereas an initial decrease was observed with the high dose. However, conditioned increases in vertical activity were seen with both doses. The possibility that this conditioned effect was mediated by dopamine was tested in a further experiment. Two groups of rats were treated similarly to the 8.0 mg/kg groups except both received the dopamine antagonist pimozide (0.4 mg/kg IP) 4 h prior to each pairing session. This dose has been reported to block conditioning based on amphetamine or cocaine. As pimozide did not alter the unconditioned or conditioned response, it was concluded that environment-specific conditioning based on scopolamine may not be mediated by dopamine. Possibly, conditioning was a direct result of learned changes within the cholinergic system.

237.15 AMNESIA PRODUCTION BY SODIUM NITRITE. M.E. Judge, R.P. Wiard* and B.R. Cooper. Department of Pharmacology, Burroughs Wellcome Company, Research Triangle Park, North Carolina 27709.

The effects of sodium nitrite ($NaNO_2$) on the memory of approach/avoidance conditioning were examined to assess the possibility of using $NaNO_2$ induced hypoxia in pharmacological screening for cognitive enhancing compounds. Thirsty mice were trained to inhibit drinking in a small test chamber by using a one-trial approach/avoidance procedure ("lick-suppression test"). Mice were water deprived for 48 hours before the learning trial. Individual mice were placed in a 6 x 6 x 6 in. chamber with water available through a stainless steel drinking tube protruding through one wall. After 5 seconds of drinking, each subsequent contact with the water tube resulted in the delivery of a 1mA shock through the tube. The trial was terminated when contact with the tube was suppressed for 60 seconds. The memory test consisted of an identical session the following day with no shock available. Memory was defined as inhibition of contact with the water tube.

In the first experiment $NaNO_2$ was administered (i.p.) 30 min. before training in a wide range of doses (0.001 to 150 mg/kg). The number of mice discarded for failing to drink within 2 min. was under 10% until the dose of $NaNO_2$ reached 70 mg/kg, then increased through 50% at 120 mg/kg, to 100% at 150 mg/kg. $NaNO_2$ produced amnesia for the training, but only at a high dose (120 mg/kg). Above this dose to few mice completed training for memory to be assessed. The behavior of control groups of mice indicated that the amnesia was genuine, and not due to some non-specific side-effect of the $NaNO_2$ treatment. In the second experiment, 120 mg/kg of $NaNO_2$ was injected at three times: 60 or 30 min. before, or immediately after training. A significant amnesia was produced only with 30 min pretreatment. Studies are in progress to compare $NaNO_2$ and scopolamine induced amnesia , in particular to determine if the $NaNO_2$ induced amnesia is reversible.

237.16 REINFORCING AND MEMORY PROMOTING PROPERTIES OF SUBSTANCE P IN THE REGION OF THE NUCLEUS BASALIS MAGNOCELLULARIS. J.P. Huston, M.S. Holzhauer*, E. Kafetzopoulos* and J.A. Nagel*. Institute of Physiological Psychology, University of Düsseldorf, 4000 Düsseldorf Federal Republic of Germany.

Results from anatomical and cell culture studies suggest that SP provides an input into the nucleus basalis magnocellularis (NBM), an area which may play an important role in learning. To test whether SP in the region of the NBM has mnemonic and reinforcing properties, rats were injected with SP into this region and tested on a passive avoidance task and a place preference task.

Male Wistar rats were unilaterally injected with SP dissolved in a 0.9 % saline vehicle containing .01 M acetic acid. SP or vehicle was applied in a volume of 0.5 µl over 30 sec.

For the step-down task, the rat was placed on a small wooden pedestal in the middle of a plexiglass box having a grid floor. Latency to descend from the pedestal was measured for two baseline trials spaced 24 hrs apart. Immediately after the animal stepped down on the second baseline trial, it received a 1 mA shock for one second. The rat was removed from the box and injected with SP (100 or 10 ng) or the vehicle. Control groups included a 5 hr-delayed injection group, a SP-no footshock group, and a sham-operated group. Retention was tested 24 hours later. Rats injected with 100 ng of SP had significantly longer step-down latencies on the retention test than did vehicle controls, whereas the 5 hr-delay group did not differ from the vehicle group.

For the place preference task, animals were allowed to explore a box consisting of a white and a black chamber for 10 minutes on three consecutive days. About 90 % of the animals showed a preference for the black chamber. On the fourth day, rats received an injection of SP (1 or 100 ng) or vehicle and were than placed into the non-preferred compartment for 10 min. On day 5, the amount of time spent in each compartment was recorded. Rats treated with 1 ng SP changed their place preference as indicated by a significant decrease in time spent in the previously preferred compartment, whereas rats injected with the vehicle or 100 ng of SP retained their previously established place preference.

These results indicate that SP injected into the region of the NBM showed mnemonic and reinforcing properties. SP facilitated the performance of an inhibitory avoidance task in a time- and dose-dependent fashion. SP acted as a positive reinforcer in a conditioned place preference paradigm.

237.17 EFFECTS OF SCOPOLAMINE AND PRENATAL EXPOSURE TO DIAZEPAM ON RETENTION OF PASSIVE AVOIDANCE. Amalia Márquez-Orozco*, María Cristina Márquez-Orozco* and Roberto A. Prado-Alcalá. (SPON: R. Tapia) Embryol. Dept. and Physiol. Dept., Sch. of Med., Natl. Univ. of México, P.O.B. 70-250, México, D.F., México 04510.

We have reported that prenatal exposure to diazepam does not interfere with learning of active and passive avoidance in 30-day old mice. Since this treatment produces important morphological alterations in structures known to be essential for the retention of passive avoidance, and scopolamine (SCOP) injections produce significant deficits in this process, we decided to test the effects of subthreshold doses of SCOP, injected to mice prenatally-exposed to diazepam. It was predicted that the interaction of treatments would induce a memory deficit. We tested the effects of the i.p. application of a low dose of SCOP (6 mg/kg), which in our conditions of training does not produce memory impairments, or of isotonic saline (SAL) to the offspring of pregnant CD-1 mice that had been treated with 2.7 mg/kg of diazepam (one daily injection from the 6th to the 17th day of gestation); these mice were kept under a 12/12 h light-dark cycle which was initiated at 7:00 a.m., with food and water always available. Right after birth the pups were separated from their mothers, and up to the age of 21 days, half of each litter (that was reduced to n=6) was nursed together with other three newborns by non-treated mice. Behavioral testing was started at 180 days of age. There were four groups of prenatal-diazepam animals: SCOP-treated males, SCOP-treated females, SAL-treated males and SAL-treated females (n = 10/group). All animals were trained to avoid a footshock that was given in the larger compartment of a two-compartment box (one-trial passive avoidance); the i.p. injections were applied 1 minute after training. Retention of the task was tested 6 days later. There were no significant differences in retention between the groups of males nor between the groups of females, although the males performed better than the females, regardless of treatment (P's < 0.05) These results suggest that low doses of SCOP do not interact with the effects of diazepam to produce memory deficits, and that the impairment that was seen in the female mice was due to the effects of prenatal diazepam.

237.18 MEMORY ENHANCEMENT WITH TENILSETAM: ANTAGONISM OF SCOPOLAMINE AND CYCLOHEXIMIDE INDUCED AMNESIA OF PASSIVE AVOIDANCE IN MICE. D. K. Rush and K. Streit*. Cassella AG, CNS Pharmacology, Frankfurt, FRG.

The novel nootropic compound tenilsetam (3-(2-thienyl)-piperazinone, CAS 997) has been shown to improve memory impaired by cholinergic blockade with scopolamine, acute forebrain ischemia resulting from carotid occlusion, and sodium nitrite induced anemic hypoxia in passive avoidance and 1-trial reward tasks in various species (Drug Dev Res, 4:567, 1984). The studies with sodium nitrite, administered post-training to induce an amnesia, suggest that tenilsetam may exert a beneficial influence on memory consolidation. The present experiments were conducted to further characterize the effects of this nootropic compound on memory processes.

Tenilsetam (10, 30, and 100 mg/kg p.o.), administered 60 min prior to training of a step-through dark avoidance response, dose dependently reversed a scopolamine (3 mg/kg i.p., 5 min prior to training) induced amnesia in mice as measured by both latency and duration parameters. Administered immediately after training, tenilsetam (10, 30, and 100 mg/kg i.p.) showed a moderate effect only at the highest dose. This differential effect of pre- and post-training tenilsetam parallels the ability of scopolamine (0.3 and 3 mg/kg i.p.) to induce an amnesia; a much stronger impairment is seen when this anticholinergic is administered prior to rather than after training.

To explore the influence of tenilsetam on memory consolidation processes, the protein synthesis inhibitor cycloheximide (150 mg/kg i.p.) administered either 20 min prior to or immediately following training was found to induce an amnesia, suggesting that the impaired memory resulted from an influence on post-training memory processing. Tenilsetam (10, 30, and 100 mg/kg), administered either 60 min prior to (p.o.) or immediately after training (i.p.), dose dependently antagonized the amnesia induced by pre-training cycloheximide administration. Post-training administration of tenilsetam (10, 30, and 100 mg/kg i.p.) also antagonized an amnesia induced by post-training cycloheximide. These results indicate that, in addition to its ability to counteract the effects of scopolamine, tenilsetam beneficially influences post-training memory processes thought to be dependent on protein synthesis.

Taken together, these findings suggest that tenilsetam may prove clinically useful in treating memory disorders.

237.19 DIFFERENTIAL EFFECTS OF PHYSOSTIGMINE AND 3,4-DIAMINOPYRIDINE ON RETENTION OF A SPATIAL MEMORY TASK FOLLOWING NUCLEUS BASALIS LESIONS IN RATS. B. A. Wirsching, R. J. Beninger*, K. Jhamandas, R. J. Boegman and M. Bialik+. Depts. of Psychology* and Pharmacology and Toxicology+, Queen's Univ., Kingston, Canada, K7L 3N6.

Recent studies have demonstrated that injections of quinolinic acid (QUIN) into the nucleus basalis magnocellularis (nbm) produce significant decreases in cortical choline acetyltransferase (CAT) and impairments of memory (Beninger et al., Neurosci let, 68:317, 1986). Furthermore, pharmacological manipulations of the central cholinergic system have been reported to attenuate the lesion-induced memory deficit. The present study further investigated the effects of QUIN lesions of the nbm on 8-arm radial maze performance and determined the extent to which physostigmine, an anticholinesterase, and 3,4-diaminopyridine (3,4-DAP), a drug that enhances acetylcholine release, can improve the memory impairment. Nineteen experimentally naive food-deprived Sprague-Dawley rats were pretrained on an 8-arm radial maze with 4 arms baited, until choice accuracy stabilized over 4 days to a criterion of $\geq$87% correct. All rats then underwent unilateral infusions of 120 nmoles of QUIN in 1 ul into the nbm. Following recovery, 10 rats received physostigmine (0.0, .01, .05, .10, .20, or .50 mg/kg, ip, 30 mins prior to a session); 9 rats received 3,4 DAP (0.0, .00000001, .000001, .0001, .01, 1.0 mg/kg, ip, 15 mins prior to a session). Drugs were given daily for 4 consecutive days followed by 4 non-drug days. In each drug condition each animal received every dose in a counterbalanced order. Analysis of covariance performed on error scores summed over four days, revealed that physostigmine led to a significant dose-dependent decrease in working memory errors (re-entries into baited arms). Reference memory errors (entries into never baited arms) were not significantly affected. In contrast, 3,4-DAP did not produce a reliable dose-dependent improvement of either type of memory. At completion of behavioural testing rats were decapitated and a section of their parietal-frontal cortex removed and assayed for CAT. Lesioned animals showed a significant decrease (mean$\pm$sem = 41.2%$\pm$2.55) in CAT activity on the injected side compared to the non-injected side. Results confirm that QUIN lesions of the nbm produce memory deficits in the radial maze and suggest that the cholinesterase inhibitor, physostigmine, but not 3,4-DAP attenuates these memory deficits. (Funded by the Ontario Mental Health Foundation.)

HUMAN BEHAVIORAL NEUROBIOLOGY II

238.1 EVENT-RELATED SLOW POTENTIALS: TOPOGRAPHIC DISTRIBUTION DURING PRIMARY MEMORY. C.Berka*,V.P.Clark and E.Halgren, Brain Research Institute, UCLA; VA Medical Center - Southwest Regional Epilepsy Center, West Los Angeles, CA 90024.

In an attempt to probe the neural correlates of Primary Memory (PM), event-related slow potentials were recorded at the scalp in healthy right-handed males performing delayed and immediate matching tasks. Slow negative potentials occurring in the S1-S2 interval (six seconds duration in the delay task) were similar to those reported previously in humans (Butler, S.R., Biol Psychol, 13:157, 1981) and primates (Fuster, J.M., J Neurophysiol, 36:61, 1973). Increases in single-unit activity in prefrontal cortical neurons during the delay between S1 and S2 have also been observed (Fuster, 1973), and may contribute to the generation of the scalp-recorded potentials. In addition, magnetoencephalography suggests at least two possible slow potential generators, both anterior to the central sulcus (Weinberg, H., Il Nuovo Cimento, 2:495, 1983). If the slow potentials reflect the continued firing of neurons encoding S1, then an understanding of the parameters which influence them may provide insight into the role of the frontal cortex in PM. In the present paradigm, maximal load was placed on PM by using complex, nonverbalizable stimuli and three-syllable nonsense words presented briefly (500msec). In both immediate and delay conditions, a two-choice key press response (match/mismatch) was required. Three classes of stimuli were presented: abstract pictures, abstract sounds, and nonsense words. Behavioral performance revealed that the tasks were of equivalent difficulty. DC recordings (at FCz, POz, F3, and F4 all referenced to linked mastoids) evidenced slow negative shifts in the S1-S2 interval for all stimuli in the delay task; consistent negative shifts were not observed in the immediate matching task. The potentials were maximally negative at the anterior midline site for all conditions, but a comparison of the abstract pictures and sounds revealed increased negativity for pictures, particularly at the anterior sites. This may simply imply that visual images require more complex encoding, or could actually reflect differential contributions to frontal cortex from modality-specific sensory regions. The anterior-posterior distribution of the slow potentials recorded during nonsense words resembled that of pictures, but a laterality was observed (F3 more negative than F4) which was not evident in the other conditions. Greater left hemisphere negativity could reflect a general preparation of the left frontal lobe to engage in language processing or could be evidence of a lateralized constellation of neurons involved in PM for verbal material.

238.2 NEUROMAGNETIC STUDIES OF VISUAL EVOKED RESPONSES: EFFECTS OF SELECTIVE ATTENTION. C. J. Aine, J. S. George* and E. R. Flynn, Neuromagnetism Lab, M/S M882, Los Alamos National Laboratory, Los Alamos, New Mexico 87545

We have employed neuromagnetometry, a noninvasive technique capable of high spatial resolution, to study the effects of selective attention in a visual evoked response paradigm. Two right handed males and two females participated in the study. In all subjects magnetic recordings were obtained from 14 sensor locations over the left (contralateral) occipital cortex using a 7 channel neuromagnetometer, and from 3 scalp electrode locations. In two subjects, a more extensive mapping was undertaken including 37 magnetic sensor locations and 12 electrode placements. Subjects were shown a random sequence of sinusoidal gratings (1 or 5 cycles per degree, each subtending 2 degrees of visual angle) presented in the central visual field, or 7 degrees into the right visual field. Subjects were required to respond to one of the four stimulus conditions by pressing a fiberoptic-coupled mechanical switch within .5 sec of target simulus onset. At least five components could be reliably identified based on neuromagnetic waveforms and correlations with ERP records: the P1, N1,P2, N2 and P3. As in previous studies, we noted large differences in magnetic field distribution as a function of field of stimulation, and smaller but consistent differences in amplitude and distribution as a function of spatial frequency. The addition of the response task generally enhanced response component amplitude, particularly in peripheral field stimulation. The distribution of attention related differences was similar but not identical to the distribution of the primary components. In most records a significant difference was observed between responses to attended and unattended stimuli at 300 -600 msec poststimulus. Extensive mapping of two subjects suggests that at least two components contribute to the P3 complex. In one subject the early component (~340 msec) has a focal distribution consistent with a parietal-occipital source. Both subjects show a later broad component with a less focal distribution suggesting a deeper source.

238.3 **NEUROMAGNETIC STUDY OF SELECTIVE AUDITORY ATTENTION EFFECTS IN THE HUMAN BRAIN.** Deborah L. Arthur and Edward R. Flynn. Neuromagnetism Laboratory, MS D-434, Los Alamos National Laboratory, Los Alamos, NM,87545.

Controversy persists about whether selective attention enhances the amplitude of the exogenous N1 component or whether it results in the addition of an endogenous process ("Nd")stemming from a different physiological source. We are evaluating these alternatives by the method of neuromagnetism to determine whether the same regions of auditory cortex that are active during the time of the N1m are also responsible for the generation of the subsequent magnetic Nd counterpart (Ndm).

A dichotic listening paradigm was employed in which the standard tone bursts were presented at a constant rate of 800 msec and with overall probabilities of 40% each. The subject's task was to respond to occasional target tones in the attended ear (probability 10%) that were identical in frequency to the standard tones in that ear, but longer (150 msec) in duration. Neuromagnetic data was collected from four right handed subjects using a 7-channel neuromagnetometer. In 2 subjects, simultaneous ERP data was collected from Fz, Cz and Pz. The magnetic field was measured at either 14 or 21 points over temporal regions of both sides of the head. Subsequently, these data were used to construct maps of isofield contours and the underlying dipoles were then fit to equivalent current dipoles using a least squares code. A goodness of fit of the model with the data was calculated to characterize how much of the variance of the measured field pattern could be explained by the dipole model.

Selective attention resulted in a consistent modulation of the response (the Ndm) which began about 150 msec after stimulus onset and lasted throughout most of the remaining epoch. The Ndm component did not typically overlap the N1m component due to the slow rate of stimulation, although in one subject there was also a significant effect of attention on the N1m component. Left hemisphere analyses completed for this subject indicated that the source of N1m activity evoked by an attended tone was indistinguishable from activity evoked by the same tone when it was ignored. The goodness of fit using the N1m source as a model for Ndm data never exceeded 75%, supporting the hypothesis that selective attention invokes additional endogenous activity during the occurrence of the Ndm.

238.4 **TOPOGRAPHIC ELECTROENCEPHALOGRAPH CORRELATES OF THE PERCEPTION OF RHYTHM.** R.G. Niederhoffer,*[1] J.D.E. Gabrieli,[1] and R. Coppola,[2] [1]Department of Psychology, Harvard University, Cambridge, MA 02139 and [2]NIMH, Bethesda, MD 20892

Brain electrical activity during the perception of music has been studied previously by several investigators, but separable activity related to components of music, such as rhythm and pitch, has received less attention. Clinical reports and dichotic-listening studies with normal subjects suggest that although the right hemisphere may be dominant for some aspects of musical perception, the perception of rhythm may be associated with left-hemisphere functions. In order to address this issue, topographic electroencephalography (EEG) was used to measure regional changes in neuroelectric activity associated with four auditory tasks. The subjects were right-handed, young males without familial sinistrality. They performed, with their eyes closed, four 80-second auditory tasks: memorizing musical passages (transformed Bach chorales) and verbal passages (syntactically-reversible embedded-clause sentences) and counting changes in rhythmic patterns and tone frequencies. Recordings made during the tasks were compared to an active 80-second baseline condition (counting randomly spaced clicks) that occurred before and after each task. The recording montage consisted of 16 electrodes, placed at frontal, temporal, parietal, and occipital sites in the standard 10-20 system, but without midline electrodes. Electrodes in each hemisphere were referenced to the ipsilateral ear. Extra-cerebral artifacts were rejected visually, and ten artifact-free 2.56-second epochs were selected for further analysis. Subjects who did not have 10 such records in all 12 conditions (4 tasks, 8 baselines), or whose recognition memory or counting scores indicated that they had not performed the task throughout the recording (i.e. whose scores were more than 1.5 standard deviations below the group mean) were eliminated from further analysis.

Subjects showed regional task-related reversible changes in total alpha-band power. This was most consistent across subjects for the rhythm task, with decreased relative left-hemisphere alpha-band power occurring at posterior sites. To the extent that such a decrease may be interpreted as increased regional activity, these results suggest that different brain regions play separable roles in the normal perception of music and that the posterior left-hemisphere may be critical to the perception of rhythm. Topographic EEG studies may be useful in the development of neurally plausible models of normal human perception and cognition.

238.5 EVOKED POTENTIAL AND REACTION TIME MEASURES OF SEMANTIC PRIMING IN A PICTURE NAMING TASK. D.S. O'Leary, L. Varholick and M. Seidenberg. Psychology Dept. Univ. Health Sciences/Chicago Med. Sch., N. Chicago, IL 60064

Semantic priming involves facilitation of access to items stored in memory due to prior processing of a conceptually-similar item. We studied semantic priming effects in a picture naming task in 8 normal adult human subjects using both vocal reaction time (RT) and evoked potentials (EPs). Ninety pictures of common objects served as targets. There were three conditions of prime-target pairings: (1) Related Condition: the target was preceded by the presentation of a semantically related picture (e.g. "pear" - "apple") which served as a prime, (2) Unrelated Condition: the prime and target pictures were unrelated (e.g. "hammer" - "apple") and (3) Neutral Condition: a blank slide preceded the target picture. Thirty trials of each condition were randomly intermixed. Duration of both primes and targets was 250 msecs and there was a 1 sec inter-stimulus interval. EEG was recorded from C3 and C4 referenced to tip of nose, and eye EMG was recorded for off-line artifacting and averaging. Subjects named both pictures 2 secs after stimulus offset. Vocal RT's to the pictures were recorded in a second session. Vocal RTs were significantly faster when the preceding picture was semantically related than when it was unrelated. With the exception of one subject, neutral trials were faster than either related or unrelated trials. This replicates previous behavioral findings reflecting a semantic priming facilitation effect. In the EP data, five components could be reliably identified. Repeated measures ANOVAs revealed no differences across conditions or hemispheres in a negative component (N1) peaking at about 130 msecs after picture onset. A positive component with a latency of about 210 msecs (P2) showed a significant difference across conditions, being later in the related condition than in the unrelated or neutral conditions. This pattern was reversed in a following negative component (N2) which had a significantly shorter latency in the related condition than in the unrealted or neutral conditions. Neither P1 nor N2 showed evidence of a hemispheric difference. A late positive wave showed a marginally significant ($p < .08$) interaction between condition and hemisphere. The late positivity peaked significantly earlier over the left hemisphere in the related condition than in the unrelated or neutral conditions. This was not the case for the right hemisphere waveforms. A late negative wave showed a similar pattern. Neither baseline to peak, nor peak to peak amplitude measures showed significant condition or hemisphere effects for these waveforms. These data will be discussed in terms of the value of EP techniques in determining the processing stage at which the semantic priming facilitation effect occurs.

238.6 VISUAL EVENT RELATED POTENTIALS IN VERBAL AND SEMANTIC DISCRIMINATIONS. R. Simson* H.G. Vaughan and W. Ritter*

To examine the differential effects on ERPs of discriminative processes during verbal identification, semantic categorization and target selection, we presented 3-5 letter words at 1.5 sec intervals on a video monitor in 3 discriminative conditions in which an unpredictable change in the stimulus characteristics occured on 20% of the trials. In the semantic condition, an average of 5 words within the same semantic category were sequentially presented and on 20% of the trials the category was unpredictably shifted. In 1 verbal condition, the same word was presented in sequences averaging 5 in length, with an unpredictable shift to another word sequence on 20% of the trials. In the other verbal condition, the same word was repeated and on 20% of the trials 1 of 20 different words was randomly inserted in the sequence. Reaction time (RT) was recorded to each 20% stimulus (target). A simple reaction time (SRT) condition required a rapid response to the same word on all trials.

ERPs were recorded from frontal, central, parietal, occipital and inferotemporal (mastoid) electrodes, referred to the nose. Average ERPs were obtained to the targets (T) and non-targets (NT) in each condition, and to all stimuli in the SRT condition.

Difference waveforms, derived by subtracting the SRT from the NT ERPs in the verbal conditions, revealed negative potentials that began about 200 msec after stimulus onset and terminated about 150 msec later. NT-SRT difference potentials in the semantic task had the same onset but lasted for 300 msec. Comparison of the semantic and verbal NT ERPs revealed a divergence beginning at 280 msec that lasted about 200 msec.

T-NT difference waveforms in the verbal conditions contained a negative wave beginning about 250 msec that was terminated by a large positive wave at 380 msec in the T response. In the semantic condition, T-NT differences were most prominent in a later negative wave, beginning about 300 msec and lasting at least 300 msec. The negative potentials seen in the verbal conditions were equally present in the T and NT ERPs of the semantic condition, and thus did not appear in the difference waveforms. RT to semantic targets was 200 msec longer than to verbal targets. Thus, 3 sequential but overlapping negative potentials appear to be related to processing physical and semantic features and to target selection.

238.7 THE SPATIAL GRADIENT OF VISUAL SELECTIVE ATTENTION: RELATIONSHIPS BETWEEN EVENT-RELATED BRAIN POTENTIALS AND TARGET DETECTIONS. G.R. Mangun* & S.A. Hillyard. Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093.

The effect of spatial selective attention upon visual processing has been likened in some cases to a small discrete "spotlight", and in others to a more widely distributed "gradient" of facilitated processing that surrounds an attended point in the visual field. Recently, using event-related brain potentials (ERPs) as indices of sensory processing, we reported that the attention-sensitive P135 and N185 waves showed systematic decrements in amplitude as the focus of attention was shifted progressively farther away from the evoking stimulus (Mangun & Hillyard, Human Factors, in press); these findings implied that a rather broad gradient of spatial attention could modify early visual processing. The study reported here obtained behavioral measures of information processing that were correlated with these ERP measures of attentional gradients.

Stimuli were vertically oriented bars flashed one at a time at locations five degrees to the left or right of the vertical meridian or at the midline, all in the upper visual field. Subjects were required to maintain eye fixation upon a central point while focusing their attention upon one of the three visual field locations during an experimental run. They indicated detection of shorter "target" stimuli that occurred 10% of the time at the attended location by making speeded button presses with one hand. In addition, subjects were given a secondary task wherein they responded with the opposite hand if they "happened to notice" any of the shorter target bars at either of the two unattended stimulus locations. ERPs and stimulus detectability measures (d prime) were compared for lateral stimuli when attention was focused upon them, as opposed to when attention was directed to the midline or opposite field stimuli.

The occipitally recorded P135 and N185 waves evoked by lateral stimuli demonstrated systematic amplitude decrements as the focus of attention was shifted to locations increasingly distant from the evoking stimulus location. The longer latency N280 wave did not display such a graded decrement but was instead specifically elicited by the attended stimulus. The behavioral measures of target detection performance (d prime) were also found to decrease systematically as the focus of attention was shifted to locations at increasing distances from the unattended lateral location at which stimuli were incidentally detected.

The parallel changes observed in ERP amplitudes and d prime scores suggest that the decrements seen in the P135 and N185 waves during spatial shifts of attention reflect actual losses in sensory information transmission.

238.8 SIGNAL AVERAGING APPLIED TO POSITRON EMISSION TOMOGRAPHY. M.A. Mintun*, P.T. Fox, and M.E. Raichle (SPON: J. McCasland) Depts of Neurology and Neurosurgery (Neurology) and Radiology and the McDonnell Center for Studies of Higher Brain Function, Washington University Medical School, St. Louis, Missouri 63110

Signal averaging is a powerful, widely employed means of suppressing measurement noise and, thereby, enhancing the detection of state-dependent changes in brain activity. We have applied signal averaging to positron emission tomography (PET) for functional brain mapping.

With PET, task-related regional changes are most effectively detected by direct subtraction of intrasubject pairs of PET CBF images. Image-pair subtraction displays the entire population of regional differences between the parent images while preserving their spatial organization. This population includes noise as well as signal (i.e., task-related regional changes). While robust regional changes can be distinguished from image noise by intensity alone, more subtle activations will be beneath noise levels. Thus the need for improving Signal:Noise ratio.

Task-induced CBF changes are regionally specific, occuring within the brain structures participating in the studied behavior; noise is spatially random. Spatial-domain averaging, then, should increase signal:noise. Spatial-domain averaging was implemented by translating all PET images into a standardized stereotactic coordinate space (Fox et al 1985, J Comput Assist Tomogr 9:141-153) to allow averaging across subjects. Noise suppression due to averaging was tested using same-state subtraction pairs (i.e., control minus control). Noise (computed as the standard deviation of the population of regional differences) fell as the square root of the number of subjects pooled, as tested for averaged-image n's from 1 to 20. Signal strength was tested using vibrotactile finger stimulation, as the primary cortical response is readily detected in all subjects. Signal:noise ratio improved steadily with n from 1.2 (n = 1) to 8.3 (n = 25).

We conclude that inter-subject averaging markedly improves the sensitivity of PET for detecting task-induced regional brain activation.

238.9 A COMPUTATIONAL ANALYSIS OF THE RELATION BETWEEN MEMORY FOR OBJECTS AND THEIR LOCATIONS IN NORMAL AND DEMENTED SUBJECTS. M. Snow*, J.D.E. Gabrieli, C.M. Darnell*, M.M. Kjelgaard*, M.M. Keane*, S. Baylog*, J.H. Growdon and S. Corkin. (SPON: D. Claman). Department of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139

We examined the relationship between memory for an object (what) and for its spatial location (where) in groups with intact or impaired fact-learning capacities: 11 normal subjects, 23 mildly or moderately demented patients with Alzheimer's disease (AD), and 6 patients with Parkinson's disease (PD) who were nondemented. In this experiment (adapted from Smith & Milner, 1981), each subject was presented with 20 toy versions of familiar objects placed on a 30-inch square piece of paper. First the subject was asked to name each object. The examiner then removed the objects and asked the subject to recall them and to replace the objects in their original locations. Three scores were calculated: percentage of objects named correctly, percentage of objects recalled correctly, and a series of scores for recall of spatial location. Relocation accuracy was assessed by calculating the mean displacement per object after transforming each subject's array of locations in the following ways: translating so that the array's center of gravity coincided with the original array; scaling so that the overall dispersion matched that of the original array; rotating to give a minimum-displacement matching with the original array; relabeling the individual locations to give a minimum displacement correspondence with the original array. Analyses of object displacement after those transformations provided measures of location memory independent of several possible distortions; calculating the severity of the four types of displacement errors could be used to characterize computationally the nature of replacement errors. For each subject, analyses were performed for objects recalled or not recalled and objects named or unnamed. The AD patients were impaired in object naming, object recall, and location recall by all measures of location error. The PD patients were unimpaired. For the normal subjects and PD patients, location memory was not significantly different for recalled versus unrecalled objects. For the AD patients, location memory was not significantly different for named versus unnamed objects. Thus, episodic memory for objects in normal subjects and PD patients and semantic memory (names) for objects in AD patients were dissociable from memory for spatial location. These results provide further evidence for the functional separtion of memory for "what" versus "where" and for the idea that different neural systems mediate these two forms of memory.

238.10 PERCEPTUAL DISORGANIZATION IN PATIENTS WITH PARIETAL-TEMPORAL LESIONS. L. C. Robertson* & M. R. Lamb* (SPON: M. Remler) Depts. of Psychiatry & Neurology, University of California, Davis, & VAMC, 150 Muir Road, Martinez, CA 94553

When normal subjects look at a scene they see objects within other objects. Brain damage often disrupts this type of perceptual organization in different ways depending on the side of lesion. For instance, larger (global) objects are more likely to be misperceived with damage to the right hemisphere and smaller (local) objects are more likely to be misperceived with damage to the left hemisphere. We do not know, however, what specific cognitive mechanism(s) underly the overall performance in these patients. Several mechanisms are involved in normal perceptual organization (e.g., vision, attention, long and short term memory, etc), and damage to any one of these could result in global or local deficits.

In the present work we examined the role of divided attention on perceptual organization in patients with damage to the right or left parietal-temporal junction (PT). There is converging evidence from research using single unit and behavioral measures that subregions of this area are associated with spatial attention. Therefore, it was possible that PT damage also disrupted attention such that attention could not be distributed normally between global and local levels of a stimulus.

Stimuli composed of several local letters arranged to form a global letter were presented to a group of 6 right PT damaged patients (RPT), 10 left PT damaged patients (LPT), and 9 matched controls. Between blocks of trials the probability of a designated target appearing at the global or local level was varied, and reaction times and errors were recorded. Controls allocated more attentional resources to the global level when targets were more frequent at the global level and more attention to the local level when targets were more frequent at the local level. The LPT group was able to allocate attention in a similar manner. However, overall their response times to local targets differed from controls in that reaction times were slower to local targets than to global targets. The RPT group was only able to allocate attention normally when the targets were more frequent at the local level but were unable to do so when the targets were more frequent at the global level. These data will be discussed in terms of attentional and sensory mechanisms as the source of global and local deficits observed in patients with parietal damage.

238.11 LOCALIZATION OF METABOLIC AND ELECTROPHYSIOLOGIC ACTIVATION DURING VERBAL TASKS. V.I.Nenov, C.Berka, S.Kamath*, E.Halgren, M.Smith, M.Mandelkern*, J.Ropchan* and W.Blahd*, Brain Res Inst UCLA; VA Medical Center -- Southwest Regional Epilepsy Center & Nuclear Medicine Service, Los Angeles, CA 90024.

PET studies allow us to obtain physiologic images of the entire brain. Mapping of local cerebral metabolic rates for glucose (LCMRGlc) with FDG has been used to study the response of the human brain to sensory and cognitive stimulation [Mazziotta JC, etal., Human Neurobio 1983]. Regional cerebral blood flow (rCBF) has been used to study gray matter activation during memorizing and reasoning [Riesberg J, etal. Brain 1973]. Electrophysiological studies have found a series of potentials (termed N4/P3) that are evoked by meaningful complex stimuli. The N4/P3 are generated in the Medial Temporal Lobe (MTL) as well as in other cerebral structures. Furthermore, the N4 to words is larger in the left MTL [Smith ME, etal. EEG Clin Neurophys 1986]. Aphasia is nearly always due to a left brain lesion. However, the isolated right hemisphere has substantial language abilities and rCBF & PET studies have usually indicated that activation in verbal tasks is bilateral and symmetrical or only slightly lateralized. These observations suggest a number of questions: 1) Will the MTL be activated metabolically in a task where it is known to be activated electrophysiologically? 2) What other structures will be activated in this task? 3) To what degree will these activations be lateralized?

Normal right handed males were subjected to three PET studies -- one resting and two stimulations. The lexical decision task was performed during the FDG uptake period when words and nonwords were flashed on a TV monitor and subjects pressed a key when a real word was detected. A number of transaxial PET images covering the whole brain, 11mm apart with 22 mm collimator aperture were obtained. MRI scans in planes corresponding to the PET planes were obtained for each subject prior to the study and were used for structural localization. Structural identification was based on a standardized proportional system [Talairach J, etal. 1967] which uses the anterior comissure - posterior comissure (AC-PC) line as a basis. Data analysis included image subtraction (stimulation minus resting) of corresponding planes; drawing of regions of interest (ROIs) around standard structures; calculation of the percentage change of LCMRGlc; and statistical evaluation of the significance of the observations.

Performing a lexical decision task with nonrepeated words increased LCMRGlc in the macular part of the striate cortex, left MTL (especially the parahippocampal gyrus), anterior cingulate gyrus, and inferior frontal cortex (including orbito-frontal cortex and gyrus rectus). The task related changes in activation were confined to limbic and specific neocortical structures, rather than the moer widespread regions thought to be involved in langauge processing. More sophisticated experiments are required in order to reveal the temporal sequence of activation during memory tasks.

238.12 COMPARISON OF MANIA VERSUS DEPRESSION FOLLOWING BRAIN INJURY: CAUSAL FACTORS. J.D. Boston*, R.G. Robinson, T.R.Price*. (SPON: G.D. Pearlson) Dept. of Psychiatry and Neuroscience, Johns Hopkins Univ. Sch. of Med., & Univ. of Maryland Sch. of Med., Baltimore, Md. 21205

A consecutive series of patients with either major depression (n=31), mania (n=15) or no affective disturbance as determined by DSMIII symptom criteria (n=28) following brain injury were examined.

Examination of lesion location (based on CT-scan findings or neurological examination) revealed that 10 of 15 patients with mania had exclusive right hemisphere involvement while 4 had bilateral or midline lesions and only 1 had a left hemisphere lesion. In contrast, 19 of 31 depressed patients had left hemisphere lesions, 7 had right hemisphere lesions and 5 had bilateral or brainstem lesions. Among the non-depressed patients, 9 had left hemisphere lesions, 10 had right hemisphere lesions and 9 had bilateral brainstem lesions ($X2=15.2, p<.004$ for lesion location by mood diagnosis). Mania was significantly more frequently associated with right hemisphere injury while depression was significantly more frequently associated with left hemisphere lesions.

Statistical analysis of demographic data indicated no statistically significant differences between groups in mean sex, age and education. Single or double informant family histories revealed that 7 of 15 mania patients (46%) had a family history of affective disorder (4 definite and 3 possible). In the major depressed group 3 (9%) had a family history of affective disturbance (2 definite and 1 possible). One patient (4%) in the no affective disturbance group had a possible family history of affective disturbance ($X2=15.5$, $df=2$, $p<.001$). This unequal distribution of family history of affective disorder remained significant when only definite family history was analyzed ($X=9.52$, $df=2$, $p<.01$). Results of this study indicate that mania following brain injury may be rare because two factors, a genetic loading and a specific right hemisphere lesion, are necessary for its expression. Depression does not appear to require a genetic predisposition and is associated with left frontal injury. Mania and depression associated with brain injury appear to have different etiological mechanisms.

238.13 **SINISTRALITY IN MALE AND FEMALE HOMOSEXUALITY: NEUROBIOLOGICAL IMPLICATIONS.** C.M. McCormick*, S.F. Witelson and E. Kingstone* (SPON: J. Cleghorn). Departments of Psychiatry and Psychology, McMaster University, Hamilton, Ont., Canada, L8N 3Z5.

No reliable evidence of any physical differences between homosexuals and heterosexuals has been found (e.g., circulating sex hormones, body build). However, there is some evidence for biological factors in sexual orientation. For example, the incidence of homosexuality is relatively stable across cultures and through the ages (Whitam, F., Arch. Sex. Beh., 12:207, 1983), and there is a higher concordance for sexual orientation in MZ than DZ twins (Pillard, R. et al., Arch. Sex. Beh., 10:465, 1981).

Given that sexual preference must have some perceptual component and is thus related to brain function, we probed for a possible neurobiological difference between heterosexuals and homosexuals via a neuropsychological route. We report here findings on hand preference, used as an index of hemisphere specialization, in a group of 70 homosexuals recruited through a local homophile organization (males: n=38, median age=30 yr, min/max= 19/60; females: n=32, median age=26 yr, min/max=19/45). The criterion for inclusion was clear homosexual preference on two standardized sexual orientation questionnaires. The hand preference of each subject was classified as either consistent-right-preference (CRP) or non consistent-right-preference (NCRP) based on their responses to a 12-item hand-preference questionnaire (Annett, M., Br. J. Psychol., 61:303, 1970). In large studies of the general population, approximately 65% show CRP and 35% show NCRP, with no difference between males and females (Annett, 1970).

In the present study, the proportion of homosexual females showing NCRP (63%) was significantly greater than that in the general population ($z=3.32$, $p<.001$). The proportion of homosexual males showing NCRP (37%) was not significantly different than that in the general population ($z=0.26$). These results, buttressed with a review of the literature demonstrating (1) a higher incidence of NCRP and (2) increased homosexual behavior in groups of females exposed prenatally to abnormal levels of sex hormones (e.g., congenital adrenal hyperplasia, Nass, R. et al., Annals of Neurol., 18:416, 1985; diethylstilbestrol, Ehrhardt, A. et al., Arch. Sex. Beh., 14:57, 1985) lead us to hypothesize that female homosexuality may have an atypical neurobiological base related to increased prenatal levels of sex hormones. The results also suggest that homosexuality may be different in the sexes. Overall, such results raise the possibility of interrelations among the factors of brain lateralization, sexual orientation, hormone levels, medical disorders (e.g., autoimmune disorders) and cognitive ability (e.g., the higher incidence of left handedness among mathematically gifted individuals). Supported by NIH grant NS 18954 to SFW and by the Dept. of Psychiatry.

238.14 RELATIONSHIP OF POST-STROKE DEPRESSION TO PET SCAN ASYMMETRY IN CORTICAL SEROTONIN RECEPTORS. R.G. Robinson, H.S. Mayberg, D.F. Wong, R.M. Parikh*, P.L. Bolduc*, T.R. Price*, R.F. Dannals*, J.A. Links*, A.A. Wilson*, H.T. Rayvert*, H.N. Wagner,Jr. Dept. of Radiology Psychiatry and Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Stroke patients who had a single lesion of either the right or left hemisphere and no other neurologic or medical disorder were examined using C-11 N Methyl Spiperone positron emission tomography (PET). Patient with left (n=8) or right (n=9) hemisphere strokes were not significantly different in background demographic characteristics, medications taken at the time of PET scanning or time since stroke. In addition, the two groups were comparable in motor, sensory or visual symptoms and anterior-posterior lesion location or lesion volume. Four patients met diagnostic criteria for major depressive disorder but the frequency of major or minor depression and mean depression scores were not significantly different between groups. Spiperone binding was analysed in cortical, temporal and parietal regions on symmetrical brain areas excluding the lesion site. Patients with right hemisphere strokes had significantly greater ipsilateral to contralateral binding of spiperone than did patients with left hemisphere strokes or normals. This increased ipsilateral to contralateral binding ratio in patients with right hemisphere strokes was the result of increased binding in the right hemisphere as opposed to decreased binding in the left hemisphere. In addition, the ipsilateral to contralateral binding ratio in the temporal cortex was significantly negatively correlated with depression rating scales (eg. r=-.93 between negatively Zung Depression Score and PET binding) but not to either intellectual impairment or activities of daily living.

Based on previous study (Robinson et al. Brain, 187, 81 1984), patients with left frontal brain injury are significantly more likely to develop depression than patients with any other lesion location. Findings from the present study suggest that depression is most severe among patients who had the lowest amount of spiperone binding. The failure of the left hemisphere to increase serotonin S2 receptor binding may play a role in the development of depression following stroke and increased binding in the right hemisphere may protect against the development of post stroke depression.

238.15 VISUAL SELECTIVE ATTENTION TO MEANINGFUL TEXT: AN ANALYSIS OF EVENT-RELATED POTENTIALS A.C. Nobre and G. McCarthy VA Medical Center, West Haven, CT and Departments of Neurology and Psychology, Yale University, New Haven, CT 06516

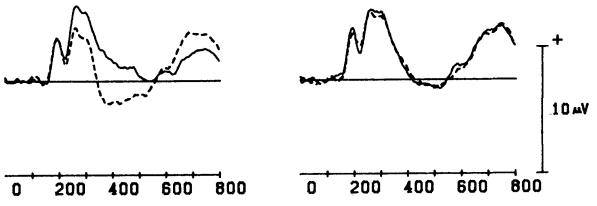
We report a study of focused and divided attention to visually presented stories using event-related potentials (ERPs) recorded from the scalp. The words comprising two stories were randomly intermixed and displayed one word at a time in the center of a computer display. Each word was presented for 50 msec and successive words were presented every 350–500 msec. The words from one story were displayed in red letters while the words from the other story were displayed in green letters. Subjects were asked to read silently either the green or red story (focused attention), or to read both stories (divided attention). Comprehension was tested immediately after each of the 9 runs.

ERPs elicited by each word was acquired from a 12-channel scalp montage referenced to a balanced sterno-vertebral electrode. Additional electrodes were used to record the vertical and horizontal electro-oculogram. The ERPs were sorted by story and attention condition.

ERPs (from Cz) elicited by words from the attended (solid) and unattended (dashed) stories from the focused attention condition are shown at bottom left. These ERPs represent the average of the 8 subjects tested. The ERPs to attended story words diverged from unattended words in a positive direction beginning at about 250 msec and lasting until 600 msec. This difference was related to attentional instruction only and was not affected by the specific color of the attended and unattended stories. The positive difference was largest at midline centro-parietal electrode sites and was larger over the left than right temporal scalp.

ERPs to red (solid) and green (dashed) stories from the divided attention condition are shown at bottom right. No differences were obtained when both stories were attended — ERPs to both colors were of approximate equal amplitude to the attended story of the focused condition. Our data suggest that differential neural processing of attended and unattended stories is evident by at least 250 msec. They further suggest that ERPs may provide a useful probe of attentional resources in word processing tasks.

Supported by the Veterans Administration and by NIMH Grant MH-05286.



238.16 AUTOMATIC SHIFTS OF AUDITORY ATTENTION ARE IMPAIRED BY PARIETAL/TEMPORAL LESIONS D. L. Woods, R. T. Knight, D. Scabini* and C. C. Clayworth* Clinical Electrophysiology Laboratory, Dept. of Neurology, U.C. Davis, VA Medical Center, Martinez, CA, 94553

We examined the effects of various non-target stimuli on reaction times to target tonebursts in a "cocktail party" experiment. Subjects selectively attended to one sequence of tonebursts while ignoring a similar sequence in the opposite ear. Stimuli were presented dichotically through headphones at a rapid rate (2.5-4/sec), with high pitched tonebursts (1300 Hz) in one ear and low pitched tonebursts (700 Hz) in the other. 90% of the stimuli were tonebursts of short duration (25 msec, "standards"), and 3% were novel sounds (computer-generated FM sweeps and digitized environmental sounds). The remaining 7% of the stimuli were "target" tonebursts identical to the standards except for duration (75 msec). The subjects' task was to respond to targets in the attended ear.

Reaction times (RTs) to targets averaged 789 msec. Although novel sounds rarely elicited false alarms, RTs to targets were markedly delayed when the target was immediately preceded by a novel sound (by 302 msec, $p < 0.001$). A greater delay was evident when targets were preceded by novels in the attended ear than when preceded by novels in the non-attended ear (347 vs 253 msec, $p < 0.001$). In comparison with targets that followed attended standards, RTs were delayed when targets followed standards in the non-attended ear (by 27 msec, $p < 0.05$). The results suggest that all auditory stimuli attract attention, but the attention-attracting properties of task-irrelevant stimuli can be inhibited when they are presented frequently.

In comparison with controls, reaction times were prolonged in a group of 16 patients with unilateral parietal-temporal lesions (by 80 msec, $p < 0.001$). RTs were comparable in subgroups of patients with left and right sided lesions, and there was a trend toward slower RTs contralateral to the lesion (lesion side x ear, $p < 0.09$). However, novel stimuli produced a smaller increase in RTs to subsequent targets in patients than in controls (237 vs 302 msec, $p < 0.005$). This suggests that the automatic attention-attracting properties of novel stimuli are reduced by parietal-temporal lesions. Supported by the VA Research Service and NIH Grant 21135 to RTK.

SPINAL CORD AND BRAINSTEM III

239.1 **DOUBLE LABELING OF RED NUCLEUS NEURONS FROM DYE INJECTIONS INTO THE INFERIOR OLIVARY NUCLEUS AND DORSO-LATERAL FUNICULUS OF THE SPINAL CORD IN RAT.** P.R. Kennedy. Biomedical Research Division, Georgia Tech Research Institute, Atlanta, GA 30332.

Despite previous negative findings (Brown et al, J. Comp. Neurol. 176:1, 1977; Carlton et al., Neuroscience Letters, 30:191, 1982; Rutherford et al., J. Comp. Neurol. 229:285, 1984), recent data suggested that a connection exists between the red nucleus (RN) and the inferior olivary nucleus (ION) in the rat (Kennedy, Soc Neuroscience Abstr., 12(1):353, 1986; Kennedy, Neuroscience Letters, 74:262, 1987). This connection was demonstrated using highly concentrated WGA-HRP injections adjacent to the ION that resulted in retrograde transport into neuronal somata where it was visualized as grains of reaction product. The present report extends this observation using Flouro-Gold (FG) dye instead of WGA-HRP. These injections were combined with True (or Fast) Blue dye placements in the Dorso-lateral Funiculus (DLF) of the spinal cord to label the Rubro-spinal Tract (RST) and assess the possibility that the rubro-olivary connection is a collateral of the RST.

In 6 Long Evans rats, the pyramidal tract adjacent to ION was injected with 1.25% FG in volumes of typically 10 to 20 nanoliters. With higher concentrations (2.5, 5 and 10%) of FG in 7 rats, toxic effects on the respiratory center led to gradual onset of fatal apnea within about an hour of injection. After 4 to 7 days survival, perfusion with normal saline and 10% formalin was followed by frozen sectioning at 40 microns, air drying, Xylene immersion and cover slipping with DPX. Visualization with epi-flourescent light at UV wavelengths revealed grains of FG throughout the cytoplasm of RN neurons best seen after the longer survival times. Numerous labeled neurons were seen through the full rostro-caudal extent of RN, similar in number and distribution to the previously reported WGA-HRP labeled neurons (Kennedy, Neuroscience Letters, 74:262, 1987), thus confirming the connection between RN and ION.

Three to 5 days after recovery from the ION injection in three rats, True Blue (TB) or Fast Blue (FB) was soaked in gelfoam plegets and placed against the cut ends of RST axons within the transected DLF of the spinal cord at the C3 to C4 segmental level. Very few neurons were labeled with TB or FB alone: Virtually all were doubly labeled with FG. As expected from known somatotopy, neurons dorsally and rostrally were singly labeled with FG while the doubly labeled neurons were seen ventrally and caudally and extended as far rostral as the fasciculus retroflexus.

This suggests that in the rat, RN neurons have both rubro-spinal and rubro-olivary outputs. It is likely that the rubro-olivary output is a collateral of the rubro-spinal tract.

239.2 CODING OF TARGET AND RESPONSE VARIABLES IN CAT RED NUCLEUS. J.H.Martin, E.Sybirska*, J.Brennan*, and C.Ghez. Ctr. for Neurobiol.& Behav., Columbia Univ. and NYS Psych. Inst., New York, NY 10032

Reversible inactivation of the red nucleus (RN) and the corticospinal tract prolongs reaction time and impairs trajectory control (Neurosci. Abst. 12,1986). The present study examines the role of the RN in the initiation and execution of rapid limb responses by recording the activity of single neurons during performance of a series of skilled tracking tasks in cats.

Animals were trained to make adjustments in isometric forearm force or position to match shifts in a target. A feeder moving to the right or the left displayed force or position errors. Shifts of opposite direction evoked forelimb extension and flexion, as well as right and left neck responses toward the moving display. To dissociate the coding of target stimulus and response variables in task-related neuronal activity, forelimb responses of a given direction were evoked by stimuli in either of the two directions by inverting display polarity. To dissociate the coding of forearm and neck responses, animals were trained to make adjustments in neck torque applied to the head fixation frame in isolation.

Task-related neurons were recorded from forelimb regions of RN (threshold microstimulation effects in contralateral forelimb muscles at currents <15 uA) in two cats. Neurons had receptive fields on the contralateral forelimb and some also showed convergence of afferent input from other body sites. RN neurons whose activity was modulated in advance of a change in forelimb force (lead cells, N=57) were the focus of this study, however, cells whose activity lagged the response were also observed. Lead cells were modulated during spontaneous reaching movements. The activity of some lead cells was better synchronized with the onset of the forearm response, whereas others were better synchronized with the stimulus. Three classes of lead cells were identified. The first (33%, n=14) showed reciprocal changes in activity correlated with a single direction of forearm force production. These cells were better timed to the response than to the stimulus and could participate in specifying response direction. The activity of the second class (18%, n=8) showed a consistent relation to changes in neck torque, either in isolation or associated with forearm responses and this activity was better timed to the stimulus. These cells may serve to coordinate synergic coupling between distal and proximal muscles during task performance. The third class (49%, n=21) had non-reciprocal discharge patterns which varied in the different task conditions. Their activity could be timed to the stimulus in one condition but to the response in another, or modulated before responses of one direction while lagging in another. The function of these more complex lead cells remains unclear.

Motor cortex lead cells specifically related to the direction of forearm force production are timed to the stimulus (Exp Brain Res 57, 1985). The more consistent lead time of RN neurons related to forearm force suggests that the red nucleus may have a more direct role in response initiation than motor cortex. (Supported by NS 19205)

239.3 RED NUCLEUS IN THE NON-HUMAN PRIMATE: THE FINE STRUCTURE OF PROJECTIONS FROM THE DEEP CEREBELLAR NUCLEI DEMONSTRATED BY THE AXON TRANSPORT OF WHEAT GERM AGGLUTININ-HORSERADISH PEROXIDASE.

D.D. Ralston, A.M. Milroy* and H.J. Ralston, III. The Department of Anatomy, University of California, San Francisco, California 94143.

The red nucleus of the non-human primate, located in the midbrain, is divided into a rostral 2/3 composed of small (10-15u) and medium (20-30u) sized cells, and a caudal 1/3 composed of small (10-15u), medium (20-30u) and large (40-90u) sized cells. These two anatomical components are set apart, not only for the morphological differences at the light and electron microscopic level, ie. cell size and distribution, but also for the division of labor between the two regions of the nucleus, as well as the afferent and efferent projections to each region.

The fine structure of the synaptic populations within the magnocellularis and the parvocellularis portions of the nucleus have been described and categorized into several groups in a previous study (Ralston, et al; Neurosci: Abstr. 12: 418.2, 1986). The present study attempts to define the morphological nature of the synapses which mediate excitatory input from the deep cerebellar nuclei to both the parvocellularis and magnocellularis regions of the nucleus. Given the data derived from physiological experiments which have demonstrated that the input from the cerebellum is a powerful one and exerts a major influence on the rubral neurons, it is anticipated that the cerebellar input would be composed of the large round pale population of terminals, because of their synaptic input to the soma and proximal dendrites.

Macaque fascicularis were used in this study to determine the nature of the afferents. The animals were immobilized with ketamine hydrochloride (10mg./kg.) I.M. and anaesthetized with I.V. pentobarbital (28 mg./kg.). All surgical procedures were carried out using sterile technique. Wheat germ agglutinin-horseradish peroxidase was injected into selected regions of the deep cerebellar nuclei using stereotaxic coordinates. After 3-4 days survival time the monkey was reanaesthetized and perfused intracardially with an aldehyde solution. Serial vibratome sections of midbrain were processed for LM using TMB as a chromogen (Mesulam) and for EM using the ammonium molybdate technique of Olucha, 1985, and the slow osmication procedure of Henry, 1985. Results demonstrate that the terminals of the deep cerebellar nuclei constitute a portion of the population of the pale round vesicle terminals ending on cell bodies and proximal dendrites. The majority of the labeled structures are composed of myelinated axons suggesting that some of the labeled terminals may be collaterals of myelinated fibers en route to the thalamus, as these axons are known to course through the red nucleus. There were no other labeled terminal profiles observed within the nucleus. (Supported by NS-23347 from N.I.H.)

239.4 THE EFFECT OF TEMPORAL PATTERNS OF NATURAL STIMULATION ON DSCT ACTIVITY IN CAT.

C.E.Osborn, R.E.Poppele and Liming Shen*. Lab. of Neurophysiol.,Dept. of Physiol.,U. of Minnesota, Minneapolis, MN

DSCT units are preferentially activated by stimulation of muscle nerves when the interval between stimuli is either $<$ 20ms or $>$ 60ms (Osborn and Poppele, Neurosci. Abs. 12:249, 1986). We have extended these investigations to include the more natural stimuli of muscle stretch and contraction. Spike activity of 211 DSCT units was recorded during randomly applied stretches or contractions of Gastrocnemius-soleus (GS). Single stretches ($<$1mm) reached a peak in 40 ms; single contractions were either maximal twitches elicited by direct stimulation of cut ventral roots, or were produced through the crossed-extensor reflex. Regardless of the type of stimulus used, the probability that a stimulus produced an excitatory response depended on the time since the preceding stimulus (see figure below). Interstimulus intervals of 20-50 ms (dotted line) were much less effective in producing a spike than either longer (solid line) or shorter intervals (not shown). The effect of interstimulus interval was therefore similar to that observed during direct stimulation of afferent fibers. However, the underlying mechanisms may not be the same. Our preliminary experiments on muscle spindles in GS suggest that long stimulus intervals produce a more synchronous and therefore more potent afferent fiber discharge to the DSCT than do intermediate stimulus intervals. Using electrical stimulation of nerves, however, each afferent fiber volley is synchronous and of equal size, and the sensitivity of DSCT units to stimulus intervals emerges from properties intrinsic to the cells and the interneuronal circuitry. Thus, the ability of DSCT to encode temporal patterns in natural stimuli may be a cascaded effect of stimulus history on afferent fiber discharge and the behavior of the intrinsic spinal cord circuitry. 239.5 **ELECTROPHYSIOLOGICAL PROPERTIES OF GUINEA-PIG FACIAL MOTONEURONS:A COMBINED STUDY IN THE ACUTE PREPARATION AND THE IN VITRO WHOLE BRAIN.**

M.MUHLETHALER*,M.SERAFIN* AND P.P.VIDAL
DEPARTEMENT DE PHYSIOLOGIE CMU 1211 GENEVA 4 SWITZERLAND
LAB.DE PHYSIOLOGIE NEUROSENSORIELLE CNRS 75006 PARIS FRANCE

Cranial motoneurons innervating somatic musculature have not yet been studied as far as their ionic conductances are concerned . In order to do so we considered facial motoneurons , in an isolated whole brain,to be an adequate preparation . A prerequisite for that work , was the comparison of their membrane properties in vitro and in vivo (acute preparation) .

Electrical stimulation of either the facial nerve trunk(in vitro) or its branches (in vivo) evoked similar triphasic field potentials , although conduction velocity was slower in vitro . Intracellular recordings indicated that antidromically elicited action potentials were comparable in both preparations as far as amplitude , rise time and duration were concerned.When present , depolarizing and hyperpolarizing after-potentials were of the same order of magnitude . As already observed in other in vitro preparations,membrane input resistance was consistantly higher in vitro than in vivo . Membrane time constants were similar . In view of these results it was concluded that facial motoneurons in the isolated whole brain were suitable for pharmacological experiments.

Using ionic channel blockers(TTX,TEA,4-AP,Cs++, Co++ and Cd++) it was found that FN neurons exhibited the usual fast Na and K conductances. Our experiments suggest the additional presence of an anomalous rectification , a calcium dependant potassium conductance and more interestingly, high threshold calcium spikes of presumed dendritic origin. Moreover in presence of TEA we were able to reveal the existence of fast rising spiklets , which were presumably dendritic sodium spikes.

In conclusion the facial motoneurons appeared to be equiped with a set of conductances which make them capable of actively processing the incoming flow of afferent informations . Understanding the roles of these conductances will require the study of facial motoneurons in the alert preparation. (Supported by Swiss NSF no 3.288-0.85)

239.6 **ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF RETICULAR NEURONS IN NUCLEUS GIGANTOCELLULARIS : A STUDY IN BRAINSTEM SLICES AND ISOLATED WHOLE BRAIN OF GUINEA-PIG.**

M.SERAFIN*, P.P.VIDAL and M.MUHLETHALER* (SPON: C.R.BADER)
DEPT. DE PHYSIOLOGIE CMU 1211 GENEVE 4 SWITZERLAND
LAB. DE PHYSIOL. NEUROSENS. CNRS 75006 PARIS FRANCE

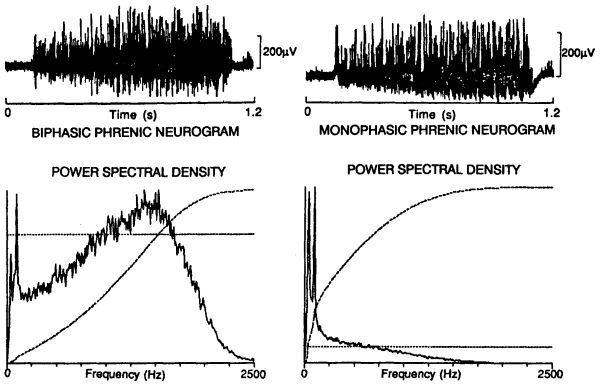
Ponto-medullary reticular neurons belong to networks subserving very different functions. Whether such heterogeneity is reflected at the level of the ionic conductances of these neurons is yet unknown. As a first step we have recorded intracellularly from a restricted pool of cells located above the inferior olive and known to contain a large number of reticulo-spinal neurons. Membrane properties and pharmacology allowed to divide the neurons in three classes.

Neurons of the first class were characterized by a thin (M±SEM:.29 ± .02 ms,n=15) action potential (AP) followed by an early fast and a delayed slower after-hyperpolarization (AHP). Moreover these cells displayed strong anomalous rectifications (AR) and rebound responses. Application of TTX in conjunction with potassium channel blockers (TEA and 4-AP) revealed both high threshold calcium spikes (Ca-HTS) as well as large and prolonged calcium plateau potentials. Neurons of the second class had wider AP (.46 ± .03 ms,n=31) followed by a single AHP. In presence of ionic channel blockers they displayed only Ca-HTS. Although more or less prevalent from one cell to another, rebound responses, AR and a delayed return to baseline following hyperpolarizing pulses were found in these neurons. This latter response (possibly due to an A-current) was large and prolonged in a minority of cells (up to 600 ms). Neurons of the third class were characterized by a broad AP having a pronounced shoulder on its repolarizing phase. In presence of TTX, the major part of the AP could be ascribed to a calcium spike probably initiated at somatic level. The shape of the AP and the slow oscillatory behaviour at rest were reminiscent of raphe neurons.

In conclusion, it remains to be determined whether one or more of these cell groups represent reticulospinal neurons. At present this can only be tested in vivo with antidromic stimulation from the spinal cord. (Supported by Swiss NSF no 3.288-0.85)

239.7 **MONOPHASIC NEUROGRAM REQUIRED FOR DETECTION OF HIGH-FREQUENCY SYNCHRONY (*HFS*) IN INSPIRATORY ACTIVITY.** *Charles A. Richardson.* Cardiovascular Research Institute, Departments of Anesthesia and Physiology, University of California, San Francisco, CA 94143-0542

Although high-frequency synchrony (*HFS*) in the phrenic neurogram of cats is a common phenomenon first reported in 1912 and observed by many investigators since, some researchers have reported low or variable incidence of *HFS* and discounted its importance in central respiratory pattern generation. To investigate the possibility that nerve recording technique might play a role in the low incidence of detectable *HFS* in some experiments, I recorded the biphasic and monophasic neurogram simultaneously in the right phrenic nerve in four decerebrate, paralyzed, artificially ventilated cats. About 2-3 cm of the right phrenic nerve was desheathed. A proximal bipolar electrode yielded the biphasic signal; a distal bipolar electrode with the nerve crushed between its pair of wires yielded the monophasic signal. In the example below, each power spectral density plot is normalized to its maximum spectral line, that of the monophasic signal being 8.9 times greater than that of the biphasic signal. In every case, I found that action potentials summed and **interfered** with each other at the biphasic electrode resulting in a broad band of noise with only 7% of the power below 200Hz. At the monophasic electrode, action potentials summed and **reinforced** at the frequency of *HFS* resulting in sharp spectral peaks with 52% of the power below 200Hz. The average fraction of total power in a frequency band 20Hz wide, centered at the frequency of *HFS* was only 2.5% in the biphasic signals, compared to 14.1% in the monophasic signals. Clearly, any signal processing technique designed to detect *HFS* in the phrenic neurogram is at a marked disadvantage if applied to the biphasic neurogram instead of the monophasic neurogram. (Supported by NIH HL-26176)



239.8 Specific responses to a passive movement in the cerebellar and olivary projecting neurons in the main cuneatus nucleus (MCN) in cats.

Domich.L,F.J.Rubia* and R.Alvarez-Caceres.* Centro Ramón y Cajal. Ctra.del Colmenar Km 9.Madrid.28034.Spain.

It is well accepted that two afferent systems to the Purkinje cell,the mossy and climbing fibers have an interdependent behaviour with a parallel or reciprocal activity and that both systems transmit an accurate information about the dynamic and statics parameters of the movement.One would expect that this precise and complex information is already present at a precerebellar level.

In cats lightly anesthetized with Nembutal,we have analized the responses of the cells of the main cuneatus nucleus provoked by a passive movement of the paw at wrist level.A ramp at 40°/s and the displacement angle between +20° and -20° according to the horizontal plane was used as stimulus.

Two populations of cells were recorded,those of cerebellar projection located in the rostrolateral part of the MCN and the cells projecting to the inferior olive situated on the basal-caudal part of the MCN.Specific responses to dynamic and static parameters are observed within both populations.

In agreement with our expectations,similar responses to those observed at the cerebellar level have been detected.Three types of responses are present:type A a phasic discharge at the onset and the offset of the ramp,type B a phasic -tonic discharge appear at the onset and during the steady high position and type C similar to type B but inversed phase.The proportion of each type of response (A:47%,B:34% and C:19%)is very closed to the values reported at cerebellar level at least for the cuneocerebellar cells,because for the cuneolivary projecting neurons a striking difference is observed.The majority of these cells exibit a type A response,86% over 47% of the cerebellar projecting cells.

The results show that at this precerebellar level there exist almost the same specific responses to the parameters of the passive movement suggesting that the information is processed at this site. The significant quantitative differences between the cells of cuneocerebellar projection which represent one of the mossy fibers sources and the cells projecting to the inferior olive and indirectly related to the climbing fibers would suggest a different role about the specific information coming out from both neuronal populations.

239.9 CHARACTERISTICS OF MEDULLARY NEURONS THAT PROJECT TO THE FACIAL OR TRIGEMINAL MOTOR NUCLEI IN THE RAT.

L. Evey, J. Travers,*and R. Norgren. Dept. Behavioral Science, College of Medicine, Pennsylvania State Univ., Hershey, PA 17033, and Dept. of Oral Biology, School of Dentistry,*Ohio State Univ., Columbus, OH 43210

Anatomical evidence indicates that interneurons that synapse in either the facial (VII) or trigeminal motor (mV) nuclei are scattered in the medullary reticular formation (mRF). Axons arising from the nucleus of the solitary tract (NST) pass through this area of mRF providing a potential basis for sensorimotor integration of ingestion and rejection (Grill, & Norgren, Br. Res., 143:281-297, 1978). Rats were prepared with two chronically implanted bipolar stimulating electrodes, one positioned in VII and the other in contralateral mV. After a week of recovery, animals were reanesthetized with a combination of barbiturate and chloralose or urethane and secured in an atraumatic head mount with the nose tilted down. Microelectrode penetrations were made from 1.5 mm rostral to 1.0 mm caudal to obex and from 2.0 mm lateral toward the midline. Search stimuli (0.1 ms, 150 uA, 1 Hz) were applied concurrently to mV and VII. Selected recording sites and stimulus electrode locations were marked with microlesions. Due to a lack of spontaneous activity, the criterion for antidromic invasion was that elicited action potentials must follow each of five stimulus pulses at 500 Hz. Antidromically driven units were tested for responses to jaw stretch, light touch, and pressure (pinch with forceps) applied to oral-facial regions. Taste responses were checked by washing midrange concentrations of NaCl, sucrose, quinine, and HCl over the anterior tongue. A total of 32 antidromically driven neurons, representing approximately 5 % of all units isolated in the mRF, were recorded from 8 rats during 116 electrode penetrations. Antidromic thresholds ranged from 20 to 150 uA. There were 23 neurons driven from VII. Of these, 11 were activated from the contralateral nucleus (mean latency = 1.0 ms, Sd = .46) and 12 from the ipsilateral nucleus (mean latency = 0.7 ms, Sd = .28). Eight neurons were driven from mV, all from the contralateral nucleus (mean latency = 0.8 ms, Sd = .38). Spontaneous activity was never present and, with one exception, no responses occurred to somatosensory or taste stimulation. One neuron antidromically driven from mV responded to light touch of the gingiva near the ipsilateral lower incisor. Based upon background neural activity, antidromically driven cells were located near neurons that responded to pinching of the tongue, lips, or ears, or to neurons that were synchronized with respiratory rhythms. Gustatory responses were not observed in any cells tested. Neurons were distributed ventrolateral to the hypoglossal nucleus in the mRF between the roots of the hypoglossal nerve medially, and the efferent vagal fascicles, laterally. These findings are consistent with previous experiments using neuroanatomical tracers. Supported by NIH NS07686, NS20397, NS24889, and NIMH Research Scientist Award, MH00653, to R.N.

239.10 DISTRIBUTION OF HIGH AND LOW FREQUENCY OSCILLATIONS (HFO, LFO) AMONG PHRENIC (PHR) MOTONEURONS AND DORSAL MEDULLARY INSPIRATORY (I) NEURONS OF NEWBORN PIGS.

A.L. Sica, M.R. Gandhi*, D.F. Donnelly*, N. Prasad*and A.M. Steele*. Research Center, Schneider Children's Hospital, SUNY, Stony Brook, New Hyde Park, N.Y. 11042.

To obtain information about the development, distribution and origin of central I activity in newborn pigs, we have compared: a) auto power spectra (APS) of PHR discharges in pigs at two different ages (4-6 d and 10-15 d); b) APS of discharges in different PHR nerve roots in 4-6 d pigs; c) APS of PHR nerve and dorsal medullary I neuron discharges in 5-15 d pigs. Pigs were anesthetized with Saffan, paralyzed with decamethonium bromide and artificially ventilated with 100% O_2. End-tidal CO_2, rectal temperature and abdominal aortic blood pressure were within normal limits. Signals were processed as follows: a) PHR signals were successively high pass filtered (10 Hz), low pass filtered (200 Hz) and acquired at 512 Hz; b) for neuronal activity, each action potential in a spike train was converted to a 100 microsec pulse, low pass filtered (200 Hz) and acquired along with PHR signal. APS were estimated with a Fast Fourier Transform routine synchronized to the onset of I; final APS were obtained by averaging of spectral estimates in each I phase and included at least 30 central I phases. Examination of PHR spectra in younger pigs showed that major peaks occurred with equal likelihood in 90-150 Hz band (HFO) and in 20-50 Hz band (LFO). However, PHR spectra of older pigs had major peaks only in HFO band, which is similar to PHR spectra of cats (this confirms the results of others). Comparison of APS in PHR roots showed that peak power was in HFO band in some roots and in LFO band in other roots. Squared coherence estimates between PHR roots were usually >0.5. For I neurons, there was good correspondence between discharge pattern and location of major spectral peaks; neurons with augmenting patterns had peaks in HFO band, those with decrementing patterns had peaks in LFO band. Squared coherence estimates between neurons and PHR were usually <0.2. In conclusion, these data suggest that the rate of maturation in PHR motoneuron pools is uneven, some have mature HFO in their APS, other APS have immature LFO. This difference is also observed in APS of I neurons, which are probably part of the neural network for I pattern generation. (ALS and DFD are Parker B. Francis Fellows. This work was supported by a grant from Long Island Jewish Medical Center, LIJMC #3-818.)

239.11 THE FINAL COMMON PATHWAY IN VOCALIZATION IN THE CAT
Gert Holstege, Dept. Anat. Univ. Calif. San Fransisco CA 94143

The neuronal framework of vocalization in mammals has been intensively investigated, but their precize pathways have not been elucidated. Vocalization is a coordinated pattern of motor activities of 1: abdominal, 2: laryngeal, 3: pharyngeal, 4: peri-oral, 5: mouth opening and 6: tongue musculature. These muscles are respectively innervated by 1: motoneurons located in the ventral horn of the mid- and low thoracic and upper lumbar spinal cord, 2: the caudal half of the nucleus ambiguus, 3: the dorsal group of the nucleus ambiguus, 4: the ventrolateral facial subnucleus, 5: the ventro-medial motor trigeminal nucleus and 6: the hypoglossal nucleus. Vocalization can be elicited by stimulation in different parts of the limbic system, but most easily in the periaqueductal grey (PAG). However, direct projections to vocalization involved motoneurons have not been demonstrated, which suggests that interneurons play an essential role. A specific interneuronal cell group projecting to all the vocalization involved motoneuronal cell groups has not been found. In this report we will demonstrate that the nucleus retro-ambiguus (NRA) in the lateral part of the caudal medulla projects to the vocalization motoneurons and that the NRA receives strong afferent projections from the PAG.
In 6 cases 0,5µL containing 50µCi ^{3}H-leucine was injected in the caudal brain stem and in 15 cases in the PAG. In the 6 caudal brain stem injected cases labeled fibers crossed the midline just caudal to the obex and descended in the ventral funiculus of the contralateral half of the spinal cord. Labeled fibers were distributed to the abdominal muscle motoneuronal cell group and in the more rostrally located injections also to the phrenic nucleus. These projections were bilateral but with a contralateral preponderance. HRP-injections at the T1 level of the spinal cord indicated that these contralaterally descending fibers were derived from neurons in the NRA.
Ascending fibers were distributed to the nucleus ambiguus, the ventrolateral facial subnucleus and the ventromedial motor trigeminal nucleus. All these projections were mainly contralateral.
In the cases with ^{3}H-leucine injections in the PAG, labeled fibers descended laterally through the caudal mesencephalic and pontine reticular formation and medially through the medullary reticular formation. Many fibers terminated diffusely in these same areas including the nucleus raphe magnus and in some cases the nucleus raphe pallidus. However, especially in those cases in which the ventrolateral part of the caudal PAG was involved in the injection site, a very specific distribution of labeled fibers was observed in the NRA. No labeled fibers were found in the motoneuronal cell groups, with the exception of the dorsal vagal nucleus. These results suggest that the NRA plays a vital role in the neuronal framework of vocalization.

239.12 **EFFECTS OF PAG STIMULATION ON LARYNGEAL EMG AND VOCALIZATION IN THE AWAKE MONKEY.**
E. A. DeRosier*, J. D. Ortega*, S. Park* and C. R. Larson. Dept. of Communication Sciences and Disorders. Northwestern University, Evanston, IL 60201

Previous studies have demonstrated that single PAG neurons change their firing rates prior to vocalization in monkeys trained to vocalize. Vocalization-related neurons were located in the dorsolateral and ventrolateral PAG. Clear functional relations were not demonstrated for many neurons, which prompted the present study.

Three macaque monkeys were reinforced for sitting quietly in a restraining chair. Monkeys were surgically prepared for recording from laryngeal muscles with chronically implanted EMG electrodes, and a recording chamber was attached to the skull. A tungsten microelectrode was used for microstimulation of the PAG. The PAG was explored by moving the electrode vertically in steps of 0.5 mm. Each day the electrode was moved horizontally in steps of 0.5 mm by means of an X-Y stage on the recording chamber. Twenty trains of stimuli (20 ms train, 0.1 ms biphasic pulses, 200 pps, 20-150 µA) were delivered at each location and rectified EMGs were averaged for the 20 trains. Trains of pulses (200 pps) lasting 500 ms also were delivered to elicit vocalization. Vocal and EMG signals were recorded on magnetic tape for later analysis.

Short-train stimulation typically excited thyroarytenoid (TA) and cricothyroid (CT) muscles and suppressed posterior cricoarytenoid (PCA) muscles. The latencies from onset of the train to beginning of the responses was 12-20 ms, and durations of responses were 20-30 ms. Responses could be elicited from widespread stimulation in the PAG, but most were obtained from ear bar zero anterior 3 mm. Most responses were obtained by stimulation of the dorsal anterior PAG.

Long-train stimulation only elicited vocalization from areas in which laryngeal muscles were also excited by stimulation. Clear calls such as "coos" were elicited predominantly from the dorsal anterior PAG, whereas, rough sounding calls such as "barks" were elicited more posteriorly. During each type of vocalization the elicited muscle patterns were similar to the short-train stimulation patterns. During the barks, the CT and TA muscles gave bursts of activity that corresponded to bursts of sound.

These data indicate a rough organization of the PAG. The dorsal anterior PAG seems more related to the laryngeal system than other areas. Analysis of the patterns of EMG responses suggests that the PAG may be organized into small groups of cells, which when stimulated, produce coordinated muscle responses. That different types of vocalizations are elicited from different locations, suggests the PAG may also be organized on the basis of qualitative aspects of vocalization. The vocalizations we elicited by stimulation in different regions may be related to a variety of other behaviors, e.g. aggression, that are also elicited by PAG stimulation.

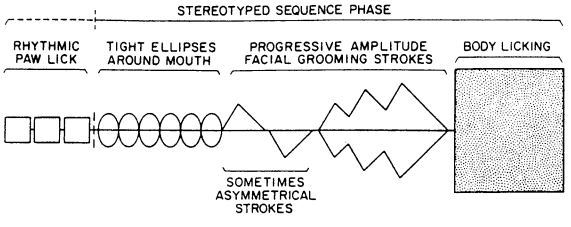
239.13 BRAINSTEM GENERATION OF ACTION ORDER AFTER DESCENDING DECEREBRATION
K.C. Berridge Department of Psychology, University of Michigan, Ann Arbor, MI 48109.

Descending levels of decerebration were employed in rats to examine the capacity of the caudal brainstem to order actions into complex sequences. We have described 'action syntax' rules that order acts into predictable sequences (Berridge, Fentress, & Parr, Behav. Brain. Res., 23:59, 1987). The focus of this study was upon a chaining rule that generates highly stereotyped and recognizable sequences from combinations of up to 15 coordinated actions. We reported last year that this rule can be generated without somatosensory feedback. We also reported that chain completion is partially disrupted by lesions of the neostriatum & globus pallidus.

The ability of various chronic decerebrate preparations to produce sequentially ordered grooming chains in response to fur wetting was examined after complete spatula transection either rostral to the midbrain (MESENCEPHALIC Decerebrate), or at the midbrain/pons junction (METENCEPHALIC Decerebrate), or at the pons/medulla junction (MYELENCEPHALIC Decerebrate). Behavioral testing began 10 days after decerebration.

Complete and structurally coordinated chains were produced by mesencephalic decerebrates, although not as frequently as by intact rats. Complete but prolonged and partially degraded chains were occasionally produced by metencephalic decerebrates. No perfect chains were produced by myelencephalic decerebrates. However, extremely degraded chain 'skeletons' were sometimes generated by myelencephalic rats.

These results suggest that a) Rostral brain (e.g., striatal) lesions that impair sequential chaining may do so by disrupting syntax implementation rather than generation per se, b) the basic generation of this chaining rule can be carried out by brainstem circuitry, and c) this sequencing circuit may not be localized at a particular level within the brainstem, but rather is distributed as a degenerate and partially redundant network that is only reduced incrementally by descending transections.



240.1 FLUORESCENCE ACTIVATED CELL SORTER ANALYSIS OF INCREASED DIHYDROFOLATE REDUCTASE ENZYME LEVELS INDUCED BY METHOTREXATE IN PRIMARY CULTURES DERIVED FROM MOUSE BRAIN. E.E. Serrano* and R.T. Schimke*. Dept. of Biological Sciences, Stanford University, Stanford, CA 94305. (SPON: C. Gundersen)

Methotrexate (MTX) is a 4-amino analog of folic acid and a commonly used antineoplastic drug which acts by competitive inhibition of the enzyme dihydrofolate reductase (DHFR). Stepwise selection of cultured mouse, hamster and human cell lines with MTX has been shown to result in the emergence of resistant populations of cells. MTX resistance can be imparted by a variety of mechanisms such as altered MTX transport, reduced DHFR affinity for MTX or increased levels of DHFR. The resistance conferred by overproduction of DHFR is a consequence of amplification of the DHFR gene and has been well documented in a variety somatic cell lines (Schimke, Cell 37: 705-713 1984).

In order to examine the effects of MTX treatment on cells whose origin approximated the in vivo condition more closely, we chose to develop a primary culture system using the brains from 16-18 day old Swiss Webster mouse embryos. Following enzymatic and mechanical dissociation, cells were plated on T25 flasks at a concentration of 1.5 X 10^6 cells/flask in control medium and allowed to grow for a week. The first passage eliminated neurons and left a glial culture comprised primarily of astrocytes which could be stained with GFAP. Healthy dividing cultures could be easily maintained up to five months. At the first passage cells were divided into control and MTX groups and subjected to a two or three step selection procedure where cells were split and placed in higher concentrations of MTX at each passage. Cultures received nanomolar concentrations of MTX over a three to four month period.

The Fluorescence Activated Cell Sorter (FACS) at the Shared Cell Sorter Facility at Stanford was used to analyze the characteristics of the cell population following MTX treatment. DHFR levels were assayed with fluoresceinated MTX (F-MTX). Cultures were examined on the FACS with regard to: a)autofluorescence b)viability (propidium iodide) c)size (forward scatter) d)cell division (Hoechst) e)DHFR (F-MTX).

Cultures exposed to stepwise selection of 30/60/90 or 60/120 nM MTX showed a significant two to three fold increase in fluorescence (and hence DHFR levels) relative to controls. When DHFR from the 30/60/90 culture was probed with ^{32}P labelled DHFR cDNA and mouse alpha fetoprotein cDNA using the slot hybridization technique, there was a twofold increase in gene copy number.

Thus, while the magnitude of the response in the primary cultures was smaller, our findings were consistent with the results obtained with somatic cell lines.

240.2 STRUCTURAL ANALYSIS AND ISOLATION OF THE HUMAN S-ANTIGEN GENE. C.M. Craft, and T. Shinohara*. Dept. of Psychiatry, University of Texas Health Science Center at Dallas, Dallas, TX 75235, LDN, NICHD, and LMDB, NEI, NIH, Bethesda, MD 20892.

S-Antigen (48K protein) is a tissue-specific, soluble protein in the retina and pineal gland. In visual transduction, S-antigen binds to photolyzed, phosphorylated rhodopsin in retinal rods. This binding prevents rhodopsin from interacting with transducin and turns off the photon induced signal. The functional role of pineal S-antigen in neural transduction is not known. In disease, this highly antigenic protein induces an inflammatory response in retinas and pineal glands (experimental autoimmune uveitus). To better understand the physiological function of S-antigen in normal and disease states, we first analyzed the molecular structure of this protein.

We have previously characterized bovine retinal S-antigen cDNAs, the primary and secondary structure, immunogenicity, and its mRNA (Craft et al., 1985, Society for Neurosci., 339.2; Wistow et al., 1986, FEBS, 196:23-28). We now present the gene analysis of bovine and human genomic DNA. Total genomic DNA was digested with restriction enzymes, electrophoresed, blotted and hybridized with bovine S-antigen cDNA probes (BSC-440 and BSC-880). The results suggest a single gene per haploid genome and indicate that the S-antigen of retina and pineal gland is the same gene product. However, from other experiments we found S-antigen from bovine retina and pineal gland show different isoelectic points and glycosylation patterns, which suggest alternate post-translational modification.

We constructed a lambda EMBL human genomic library of DNA enriched 50-fold for human S-antigen gene fragments isolated by large scale electrophoresis. We isolated 8 clones containing a 9.4 kilobase fragment from this library. Cross-hybridizations of Southern blots with a bovine S-antigen cDNA (BSC-880) probe verified the 9.4 kilobase fragment was analogous to the human S-antigen genomic fragment. This fragment was subcloned into plasmid vectors for restriction analysis and M13 for dideoxy sequencing. Deduced polypeptide sequence of the human S-antigen from DNA sequence revealed extensive homology with the bovine sequence. Although the 5' end of the S-antigen gene is absent in this fragment, a 3' exon of this human gene with a 90% homology to the bovine cDNA sequence and a 100% homology to a bovine tryptic peptide sequence was verified. Splice junctions were highly conserved and long stretches of introns surrounded this exon. Currently, we are isolating the 5' end of the gene from a human cosmid library and determining the human chromosome localization of S-antigen with CHO/human chromosome hybrids.

240.3 ISOLATION AND CHARACTERIZATION OF THE HUMAN TYROSINE HYDROXYLASE GENE. K.L. O'Malley,* L. Vinnedge, B.M. Martin, J.R. Kelsoe,* A.L. Winfield and E.I. Ginns. Molecular Neurogenetics Unit, NIMH, and Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

We are studying the structural organization and regulation of the human tyrosine hydroxylase (TH) gene in order to investigate whether mutations in this gene occur in bipolar affective illness or other neuropsychiatric disorders. A human brain genomic DNA library constructed in EMBL3 was screened using a full length rat tyrosine hydroxylase cDNA as a probe (Brown et al., Biochem., in press). Out of one million recombinant phage we identified one clone which hybridized to probes derived from the 5' and 3' ends of the rat cDNA. Using restriction endonuclease mapping, Southern blotting and DNA sequencing, we have determined the organization of the human tyrosine hydroxylase gene. Like its rodent counterpart, the human gene is single-copy and spans approximately 8 kb. Comparison of the rat and human gene 5' flanking regions suggests that these sequences may be conserved because of their importance for transcriptional regulation. A cAMP enhancer element is located upstream of the transcriptional start sites in both the rat and human genes. However, unlike the rat gene, the human gene undergoes alternative splicing to generate several exon 1 sequences (see abstract E.I. Ginns et al.). Evidence will be presented that the proteins encoded using these alternative splice sites can be expressed.

It has been previously shown that tyrosine hydroxylase and phenylalanine hydroxylase (PH) evolved from a common ancestral gene. The human PH gene spans over 90 kb with introns as large as 23 kb (DiLella et al., Biochem. 25: 749, 1986). Our characterization of both rat and human tyrosine hydroxylase genes demonstrates that this size difference between TH and PH is primarily a result of changes in intervening sequences. Major changes in noncoding regions have occurred since the divergence of these genes.

240.4 Cloning and Expression of Multiple cDNA's For Human Tyrosine Hydroxylase. E.I. Ginns*, J.R. Kelsoe, B.M. Martin*, S.L. Winfield*, M.E. LaMarca*, M.D. Luu*, S.M. Paul* and K.L. O'Malley [2], (Spon: F.K. Goodwin) Molecular Neurogenetics Unit, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892, [2]Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO.

In order to study the possible involvement of tyrosine hydroxylase (EC 1.14.16.2) in the pathogenesis of bipolar affective illness and other neuropsychiatric disorders, cDNA clones for human tyrosine hydroxylase have been isolated from a lambda GT10 library constructed from a neuroblastoma. Four clones were isolated by hybridization using a unique 5' fragment from the human tyrosine hydroxylase gene (see abstract O'Malley et al.). These cDNA clones contained the full coding region as well as both 5' and 3' untranslated sequences. In contrast to the previously reported rodent tyrosine hydroxylase cDNAs, the human cDNAs were heterogeneous in their 5' coding sequences. These differences correspond to alternative splice sites observed by us in the human tyrosine hydroxylase gene (see abstract O'Malley et al.).

In order to explore the significance of these multiple forms of tyrosine hydroxylase, baculovirus expression vectors (Summers and Smith, 1986) containing tyrosine hydroxylase cDNAs having the different human 5' sequences are being used to produce enzymatically active protein. The availability of large quantities of the different forms of purified tyrosine hydroxylase will permit comparative kinetic and structural analyses, as well as production of specific antiserum for immunocytochemical and pulse-chase studies. These approaches should clarify the physiologic significance of the various forms of tyrosine hydroxylase, including possible differences in their subcellular distribution (bound versus soluble), cofactor activation, and phosphorylation.

240.5 SEQUENCE COMPARISON OF BOVINE ADRENAL PHENYLETHANOLAMINE N-METHYLTRANSFERASE AND ITS GENOMIC DNA CLONE E.P. Weisberg*, D.K. Batter, W.E. Brown*#, and B.B. Kaplan (SPON: James Byrd, III, M.D.) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, 15213, and #Department of Biological Sciences, Carnegie-Mellon University, Pittsburgh, PA 15213

A cDNA clone for bovine adrenal PNMT was used to screen a Charon 28 bovine genomic library. One clone, designated λP1, was identified which putatively contained the entire PNMT gene. The structure and complete nucleotide sequence of this genomic clone was subsequently delineated by restriction endonuclease mapping and dideoxy sequence analysis (Batter, et al., submitted for publication). In order to unambiguously establish the identity of this clone, the nucleotide sequence was compared to partial amino acid sequence data derived from the purified protein.

PNMT was purified to apparent homogeneity by a modification of the procedure of Pohorecky and Baliga (Arch. Biochem. Biophys., 156:703-711, 1973). A bovine adrenomedullary tissue homogenate was fractionated by ammonium sulfate precipitation, gel filtration and ion exchange chromatography. The specific activity of the purified protein was 610 nmole/mg-hr. PNMT has an apparent molecular mass of 31,000, as judged by SDS-PAGE. Results of an amino acid analysis of the purified protein is consistent with the amino acid composition deduced from the genomic sequence.

The purified protein was subjected to specific chemical cleavage by both cyanogen bromide and formic acid. These procedures cleaved the protein at a Met residue near the C-terminus, and an acid labile Asp-Pro bond near the N-terminus. N-terminal amino acid sequence analysis of the CNBr cleavage product identified 13 amino acid residues. Nine additional residues were obtained from the formic acid cleavage product. Our results also suggest that the N-terminus of the protein is blocked since it is not labile to the sequencing reagents.

The purified protein was also subjected to enzymatic digestion by trypsin. The products of complete digestion were fractionated by reverse-phase HPLC, and four well-defined fractions subjected to sequence analysis. Amino acid sequence analysis identified 3, 10, 11, and 15 amino acids in the four tryptic peptides.

In total, six peptides were sequenced, accounting for approximately 20% of the entire PNMT protein. The amino acid sequence of all peptides isolated was identified within the protein sequence deduced from the nucleotide sequence of the gene. This work provides an independent and unambiguous verification that the genomic clone, λP1, contains the entire coding region for adrenomedullary PNMT. (This work was supported by USPHS grant NS19608, MH29670 and MH18273).

240.6 HUMANS AND RATS CONTAIN A SINGLE GENE ENCODING BRAIN GLUTAMIC ACID DECARBOXYLASE. M.G. Erlander, N.J.K. Tillakaratne*, R.M. Goldstein*, S. Gonzalez*, D.L. Kaufman*, Y. Kobayashi* and A.J. Tobin. Department of Biology, Molecular Biology Institute, and Brain Research Institute, University of California, Los Angeles, CA 90024.

The fusion protein produced by bacteria infected with lambda-GAD catalyzes the stoichiometric conversion of glutamate into CO_2 and GABA (Kaufman et al, Science, 232, 1138-1140). We have compared the K_m for glutamate and the K_i for two GAD inhibitors (aminooxyacetic acid and 2-mercaptopropionic acid) of this fusion protein with that of partially purified brain extracts. These data support the identification of this cDNA as that encoding the major species of brain GAD.

Lambda-GAD, constructed in lambda gt-11, contains a 2.3 kb feline cDNA, whose sequence we have recently reported (Kobayashi, et al., J. Neurosci., in press). We have isolated several dozen human GAD cDNAs by plaque hybridization to a cDNA library from human fetal brain (obtained from R. Neve). One of these cDNAs, 3.3 kb long, contains extensive homology with 2 kb of the 2.3 kb feline cDNA.

We have used feline cDNA to isolate eight overlapping lambda and cosmid clones from human genomic libraries (obtained from T. Maniatis and H. Lehrach). These clones extend over 75 kb of human DNA. All the restriction fragments revealed by Southern blotting of human DNA are contained within this contiguous region. This result indicates that the human genome contains only a single gene homologous to our cloned GAD cDNA.

We have similarly analyzed 20 clones from a rat genomic library obtained from J. Bonner. These clones, and the corresponding rat Southern blots, span only 30 kb of rat DNA. The structure of the rat GAD gene thus appears to differ from that in the human genome.

This work was supported by a grant to AJT from NINCDS (#NS 22256) and a program project grant to Dr. A.V. Delgado-Escueta (#NS 21908). DLK has been supported by a USPHS Training Grant in Cell and Molecular Biology (#GM 07185), MGE by the ARCS Foundation, SG by the UCLA Summer Research Program for Minority Undergraduate Students, and NJKT by the American Association for University Women, Phi Beta Kappa, and the Ursula Mandel Fellowship.

240.7 **TISSUE-SPECIFIC EXPRESSION OF THE RAT GALANIN GENE: ISOLATION AND CHARACTERIZATION OF CLONED cDNAs.** Lee M. Kaplan*, Eliot R. Spindel, Kurt J. Isselbacher*, & William W. Chin*. Laboratory of Molecular Genetics, Brigham & Women's Hospital, Boston, MA 02115, and Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA 02114.

Galanin is a 29-amino acid peptide localized in central and peripheral neurons of several vertebrate species. In the CNS, galanin-like immunoreactivity is found in cholinergic neurons of several nuclei which have been shown to undergo specific degeneration in Alzheimer's disease. Galanin is also widely distributed in the myenteric and submucous plexuses of the GI tract, where it has been shown to have a variety of direct and neurally-mediated effects on smooth muscle contractility.

In order to permit study of the regulation of galanin gene expression in an easily manipulated animal model, we cloned cDNAs encoding rat galanin (rGal). Mixed synthetic oligonucleotide probes were used to isolate several rGal clones from a cDNA library prepared from rat hypothalamic tissue. Sequence analysis of three such clones revealed rGal to be synthesized initially as a 124-amino acid precursor. The deduced amino acid sequence of the precursor includes a signal peptide, galanin, and a 60-amino acid carboxy-terminal peptide (galanin mRNA-associated peptide; rGal-MAP). The galanin portion is flanked on each side by Lys-Arg tryptic cleavage sites. The predicted amino acid sequence of rGal is 90% homologous with porcine galanin, with all 3 amino acid differences in the C-terminal heptapeptide. However, the amidated C-terminal amino acid of rGal is threonine rather than alanine. These data confirm the phylogenetic conservation of the N-terminal region of galanin predicted from immunological studies. Although rGal-MAP shows only 58% overall homology with its porcine counterpart, its amino acid sequence includes a large region of near identity (>90% homology). The high interspecies conservation suggests the existence of and a biological role for this galanin mRNA-associated peptide.

Northern blot analysis using a ^{32}P-labeled anti-sense cRNA probe reveals a single band of hybridizing mRNA which is approximately 900 nucleotides long. Rat galanin mRNA is localized predominantly in the CNS and GI tract. Highest CNS concentrations are found in the hypothalamus, with lower levels in the cerebral cortex and brainstem. In the GI tract, highest levels are in the duodenum with progressively lower concentrations in the small intestine, stomach, and colon. In contrast to its relative abundance in porcine adrenal medulla, galanin mRNA is barely detectable in rat adrenal tissue. The cloning of rat galanin will facilitate further examination of tissue-specific and developmental expression of the galanin gene.

240.8 REGULATION OF MYELIN BASIC PROTEIN PRODUCTION IN MICE HETEROTIC FOR MYELINATION. Robin Miskimins* and Robert K. Yu. Dept. of Neurology, Yale University School of Medicine, New Haven, CT 06510, USA

We have recently shown that there is some form of transcriptional or post-transcriptional control operating in the regulation of myelin basic protein (MBP) production in the CNS (Miskimins et al., Proc. Natl. Acad. Sci. USA, 83:1532, 1986) using mice heterotic for myelin production during the most active phase of synthesis. These mice are the F_1 generation of a cross between C57Bl/6J and DBA/2J. We were interested in determining how this control might be exerted, whether the effects we have seen are also present in the PNS, and whether the reciprocal cross offspring (DBA/2J X C57Bl/6J) also show heterosis for MBP production. We have quantitated several markers for myelin in the sciatic nerve of 16 day old mice. No heterosis for myelin content in the PNS has been observed. In addition we have performed Northern blot analysis of MBP RNA from the reciprocal cross mice. We have seen that these mice also show increased levels of MBP mRNA production at 16 days of age. Our approach to understanding how transcription of the MBP gene might be regulated has been to use low ionic strength polyacrylamide gels to identify the regions of the 5' end of the MBP gene that specifically interact with DNA binding proteins. We have mapped several fragments of DNA in the 5' end of the MBP gene that interact with these proteins. One includes the first exon, part of the first intron and about 200 bases of 5' flanking sequence. We are also using these gels to isolate the fragments that bind the proteins and footprint the binding sites. Our data indicate that there are several protein binding sites in the 5' end of the MBP gene, some of which may be for the specific regulation of transcriptional activation of the gene during myelinogenesis. In addition we have obtained a glioma cell line (courtesy of Dr. S. Pfeiffer) in which we have observed low levels of MBP mRNA production. We are hopeful these cells will prove useful in identifying regulatory proteins involved in transcriptional control of myelin genes. (Supported by USPHS grant NS-23102)

240.9 MOLECULAR BASIS FOR THE DIFFERENTIAL REGULATION OF NEURON-SPECIFIC AND NON-NEURONAL ENOLASE GENE EXPRESSION IN THE BRAIN. S.M. Forss-Petter* and J.G. Sutcliffe, Research Institute of Scripps Clinic, La Jolla, CA 92037.

To illuminate the features of lineage-specific and developmentally regulated gene expression in the rat brain, we are analyzing the regulatory signals required for transcription of the enolase isozyme genes. We have previously cloned the rat neuron-specific enolase (NSE) mRNA, determined its complete nucleotide sequence (2222 bases excluding polyA), and analyzed its pattern of expression (Forss-Petter et al., J.Neurosci.Res.16:141, 1986). In the adult, NSE is one of the most abundant (0.5%) neuron-specific mRNAs. The first NSE transcripts can be detected in the 14-day rat embryo. A major increase in expression takes place during the second postnatal week, correlating with the appearance of NSE protein but accumulating faster to adult level.

Primer extension and S1 nuclease protection show that transcription of NSE initiates at 8 or more sites spanning 60 nucleotides, whereas transcription of non-neuronal enolase (NNE) initiates at a single site. Southern blot analyses indicate a single NSE gene and at least ten copies of the NNE gene (some of which are probably pseudogenes) in the rat genome. NSE cDNA probes were used to isolate genomic clones of NSE and NNE (which cross-hybridize at low stringency) from a lambda phage library, and oligonucleotides were used to confirm the assignments and indicate fragments proximal to the promoter regions. Analysis of the nucleotide sequence of the NSE promoter region reveals no canonical TATA/CAAT motifs but a very GC-rich (potential S1-binding) sequence, similar to other genes using multiple sites for transcription initiation. We have analyzed three different genes for NNE, two of which contain no TATA or CAAT boxes within 250 nucleotides upstream from the cap site. We cannot yet tell whether one single gene or many genes with identical regulatory signals are actually transcribed. Multiple copies of the rat ID sequence are present within and surrounding the NSE gene, whereas none could be detected in any of the three NNE genes analyzed.

NSE mRNA is expressed in rat C6 (glioma) and PC12 (pheochromocytoma) cells and in mouse neuroblastoma lines; NNE mRNA is abundant in every line we tested. In the adrenergic mouse neuroblastoma line NIE-115, DMSO induction stimulates differentiation to a neuronal phenotype and also NSE mRNA expression (roughly ten-fold). The extent of the cis-acting signals required for proper transcription initiation, investigated in transfection assay with NSE/NNE promoter-driven expression of a reporter gene will be discussed.

240.10 **NEURON SPECIFIC OLFACTORY MARKER PROTEIN: GENE STRUCTURE STUDIES.** **K. E. Rogers and F. L. Margolis.** Department of Neurosciences, Roche Institute of Molecular Biology, Nutley, New Jersey, 07110.

Olfactory marker protein (OMP) is a 19kd cytoplasmic protein which is expressed by mature olfactory receptor neurons. Although the biochemical properties of this developmentally regulated macromolecule have been extensively characterized, its function remains unknown. We have previously cloned and characterized rat OMP-cDNA and subsequently used that cDNA as a probe to investigate OMP-mRNA regulation. In the study presented here, we used random-primed labeled OMP-cDNA restriction fragments as probes to identify and isolate genomic DNA encoding rat OMP from a Charon 4A lambda phage library. After screening 9 x 10^5 pfu, three recombinant phages were isolated (λ-OMP1, λ-OMP2, λ-OMP3). Each isolate was shown to contain approximately 16.5 kb of rat genomic DNA. A restriction map was constructed for λ-OMP1, and exon-containing fragments were identified by Southern blot hybridization to OMP-cDNA. Various regions from the cDNA, containing either non-coding or coding information, were used as probes to select genomic fragments which contained information primarily upstream to the coding region. These fragments were sub-cloned into M13mp10 vectors and sequenced by the Sanger dideoxy method. Sequence analysis of a 900 base-pair Pst I fragment demonstrated that the fragment included 198 nucleotides of coding information as well as 700 additional nucleotides upstream from the ATG start site. However, the Pst I fragment did not contain intron sequences within the coding region. A TATA-like sequence was noted 53 nucleotides 5' to the ATG start codon, but no apparent CAAT box was detected in the appropriate region. Additional characterization of λ-OMP1 is now underway. Furthermore, we are now engaged in determining whether the Pst 1 fragment contains actual OMP promoter activity or other features which confer tissue-restricted expression.

240.11 GENETIC TRANSFORMATION WITH DNA OF MEC-3, A GENE REQUIRED FOR DEVELOPMENT OF A SINGLE NEURONAL TYPE IN C. ELEGANS Jeffrey C. Way* and Martin Chalfie, Dept. of Biological Sciences, Columbia University, New York, NY 10027

The nematode C. elegans has six mechanosensory neurons for the sensation of gentle touch. Many mutations which abolish touch-sensitivity have been isolated (mec mutations); most of these are in genes which appear to affect the functioning of the touch receptors, and which abolish at most one of the special features of these cells.

In mec-3 mutants of C. elegans, the six touch receptor neurons possess none of their distinctive features, such as 15-protofilament microtubules and associated extracellular material. The cell division pattern which produces these cells is normal and no other cell type appears to be altered. Thus, unlike other mec genes, mec-3 appears to be involved in the specification of the touch receptors, and not their function.

Previously, (Way and Chalfie, Neurosci. Abst. 52:10 [1986]) we showed that in mec-3 mutants, the altered touch receptor still retains neuronal characteristics. We also described cloning the gene by transposon tagging.

We have rescued a mec-3 mutant by microinjection of cloned DNA, using the procedure of A. Fire (EMBO J. 5, 2673 [1986]). In each transformant, the DNA behaves genetically as a free duplication. This duplication can be lost during mitosis to generate mosaic animals, which may be touch sensitive in the head or tail only, or which may have no transformed progeny. As determined by Southern blotting, there are between 50 and 250 copies of the transforming DNA per haploid genome. By injection of deleted DNAs, we have delimited the mec-3 gene to at most 8,000 bases.

In dominant mec-4(d) mutants, the touch receptors degenerate, presumably because a toxic mec-4(d) product is expressed in the touch cells. In mec-3;mec-4(d) double mutants, the cells do not degenerate, but appear as they do in mec-3 mutants. This suggests that mec-3 is necessary for the expression of the normal mec-4 gene. Intriguingly, in one particular mec-3;mec-4(d) strain carrying the mec-3(+) transforming DNA, additional cells degenerate. The precise mechanism for this phenomenon is unknown.

This research was supported by NIH Grant GM30997 and a Post-doctoral Fellowship from the Damon Runyon-Walter Winchell Cancer Fund.

240.12 EXPRESSION OF THE NERVE GROWTH FACTOR GENE: CELL-SPECIFIC REGULATION. P.J.Alvarez, S.A.Quarless*, E.C. Azmitia and G.Heinrich. Lab for Mol. Endo., Howard Hughes Med. Inst., Dept. Med., Mass.Gen.Hosp., Boston, MA 02114

Nerve Growth Factor (NGF) is produced by targets of specific neurons in the CNS and PNS. In these targets NGF production is correlated with the density of innervation and differs markedly among targets, suggesting that regionally specialized cells express the NGF gene in quantitatively and qualitatively different ways. The specific cells that secrete NGF in the CNS and the molecular mechanisms that restrict NGF gene expressions to and regulate it within these cells are still unknown. We are using several approaches to address these questions.

In order to identify the cis elements in and around the NGF gene that determine cell-specificity we created a fusion gene from the mouse NGF gene promoter region and a reporter gene encoding human growth hormone (hGH). This construct was transfected into the L929, C6, HL60, PC12, and NIE115 cell lines and assayed for hGH with a two-site radioimmunoassay (RIA) as a measure of transcription of the fusion gene. Expression of the fusion gene was then correlated with the cell's intrinsic ability to transcribe the NGF gene into NGF mRNA by Northern blot and S1 protection hybridization assays. We are now using deletion mutants of the fusion gene to further characterize the cis-acting elements that are responsible for cell-specificity and will transfect fusion genes containing the cell-specifier(s) into primary hippocampal neurons and glia to determine whether these cells are permissive for NGF gene expression.

Our second approach is to identify by primary culture the cells that express the NGF gene, and its mode of regulation. Brains of newborn rats were dissociated with trypsin, and cultured in DMEM/20% fetal calf serum. After 5 weeks and at least one passage the cultures contained predominantly fibroblasts by immunostaining and immunoprecipitation analysis. The cultures produced hybridizable NGF mRNA. 1 mM Na-butyrate in the medium for 24h increased NGF mRNA 2.5-fold, and decreased beta-actin mRNA 10-fold. These data demonstrate that fibroblasts derived from brain synthesize NGF mRNA in primary culture in a regulatable fashion.

240.13 RAT GROWTH HORMONE (rGH) GENE 5' FLANKING SEQUENCES TARGET THE EXPRESSION OF A MARKER GENE TO THE PITUITARY OF TRANSGENIC MICE. S.A. Lira*, E.B. Crenshaw III*, L.W. Swanson and M.G. Rosenfeld*. (SPON: R. Emeson). Howard Hughes Medical Institute, La Jolla, CA, 92093.

Growth hormone (GH) is a polypeptide hormone produced by the somatotrophs of the anterior pituitary. In the rat it is coded by a single gene which is under transcriptional control of growth hormone releasing factor, glucocorticoids and thyroid hormone. Rat pituitary cells in culture produce at least 10^8 more GH than liver cells in the same conditions. To address questions concerning the tissue-specific expression of the rGH gene we performed gene transfer experiments in pituitary and non-pituitary cell lines using the chloramphenicol acetyltransferase (CAT) gene as a reporter (Nature 322:557, 1986).These experiments provided the identification of a 5' flanking region (from -47 to -235bp) that conferred pituitary cell-line expression when fused to a heterologous gene. This region was shown to act in a position and orientation independent fashion and on a heterologous promoter, resembling an enhancer element. We decided to examine further the nature of the signals present on the 5' flanking region by fusing three different segments with the human growth hormone gene (hGH) and injecting them into fertilized mouse oocytes. The fragments encompassed respectively 1.7kb, 320bp and 180bp of the rGH gene upstream region. Fragments were excised from the vectors, purified and injected according standard techniques. At 3 weeks of age a segment of the mouse tails was excised, DNA extracted and blotted on nitrocellulose filter. Blots were hybridized with a PvuII probe from the hGH gene . Positive animals were selected and mated to generate transgenic lines. We generated 5 founders for the 320bp-hGH series,9 founders for the 180bp-hGH series and 13 founders for the 1.7kb-hGH series. When analyzed around 45 days of age none of the animals showed signs of gigantism when compared to their littermates.
Immunohistochemical analysis of the pituitary gland of at least two different integration events for each series revealed the expression of hGH in the anterior lobe of the transgenic animals but not in their control littermates. Double labeling studies using antibodies against LH, ACTH, TSH, PRL and mGH revealed the expression of the transgene in the somatotrophs of all three series and in a sub-population of TSH producing cells. No expression of the hGH was detected in gonadotrophs, corticotrophs, or lactotrophs in the 320-GH or 180-GH animals analyzed, but co-labeling with hGH was sometimes detected in the lactotrophs of the 1.7-GH animals. Work is presently being conducted to determine if the transgene is being expressed in sites other than the pituitary.
The findings described above are suggestive of the presence of genetic information located on the 180bp upstream of the rGH gene that allows for expression of a marker gene in the somatotrophs.
Sergio Lira is partially supported by the Brazilian Research Council (CNPq).

240.14 RAT CALCITONIN (rCal) GENE 5' FLANKING SEQUENCES TARGET THE EXPRESSION OF A MARKER GENE TO THYROID C-CELLS IN TRANSGENIC MICE. S.E. Leff, L. Stolarsky*, S.A. Lira*, E.B. Crenshaw III*, L.W. Swanson and M.G. Rosenfeld*. Howard Hughes Medical Institute, La Jolla, CA 92093.

We have been studying the cell-type specific expression of the rCal gene, a gene that produces primarily calcitonin mRNA in thyroid C-cells and calcitonin gene-related peptide (CGRP) mRNA in some peripheral sensory neurons also derived from the neural crest. In addition, CGRP and its mRNA are found in several central nervous system nuclei. Transfections of fusion genes comprised of the 5' flanking DNA and promoter of rCal, and the reporter gene chloramphenicol acetyl transferase (CAT) identify a segment of 5' flanking DNA between -810 to -1350 bp from the promoter that specifically enhances the expression of genes directed from the rCal promoter in medullary thyroid carcinoma derived cell lines. However, the promoter segment alone from -155 to +30 bp is competent to direct expression of reporter genes at moderate to high levels in a number of heterologous cell lines in this transient transfection paradigm (L.Stolarsky et al, in preparation). To test whether 5'flanking DNA from the rCal gene that includes this segment contains developmental information to direct expression of a marker gene, human growth hormone (hGH), to thyroid C-cells and the appropriate neuronal cell types, we introduced fusion genes comprised of hGH or a modified "midi" hGH gene under the control of the rCal promoter and 5' flanking DNA to -1350 bp into newly fertilized mouse embryos.

Northern blot hybridization analysis detected high levels of hGH mRNA in thyroids, moderate levels in lung, and low to moderate levels in the brainstem. In situ hybridization analyses using ^{35}S-hGH antisense riboprobes identified high levels of hGH mRNA in thyroid C-cells, and low levels of hybridization in the trigeminal ganglion. These data indicate that rCal 5' flanking DNA can direct its cell-specific expression to thyroid C-cells. Expression of this fusion gene in the nervous system is under investigation.

240.15 COMPLEMENTARY DNA CLONING OF A NERVOUS SYSTEM SPECIFIC INTERMEDIATE FILAMENT FROM *XENOPUS LAEVIS* WITH HOMOLOGY TO MAMMALIAN NEUROFILAMENT. L. Charnas, K. Richter*, T. Sargent*, and I. Dawid*. Hum. Gen. Branch and Lab. of Mol. Gen., NICHD, NIH, Bethesda, MD 20892

Neurofilaments are a neuron specific class (Type IV) of the intermediate filament gene family. They are expressed after neurite outgrowth begins and are a useful marker of neuronal differentiation. We were interested in developing nucleic acid probes to be used as markers of early neuronal differentiation. We screened 5 X 10^4 plaques from a *X. laevis* brain cDNA λgt11 library with NF68, a cDNA probe for mouse NF-L (Lewis, S. and Cowan, N., J. Cell Bio. 1985, 100:843-850). Four distinct clones were isolated and partially sequenced. The derived amino acid sequence of each clone was homologous to regions within the rod domain of mouse neurofilament.

The complete nucleotide sequence of a 1.9 kB clone, XNK3, demonstrated a 1.07 kB coding region and an 0.86 kB 3' noncoding region. The derived amino acid sequence coded for 357 amino acids, 286 amino acids within the rod domain and 71 amino acids in the carboxy terminus. The rod domain showed some homology to nonepithelial intermediate filaments but had the highest homology to mammalian neurofilament, with identity in the final 29 amino acids of the 2B portion of the rod domain. The carboxy terminus began with the sequence -**TSVG**-, distinctive for NF-L proteins, and in the middle, had a single -**KEEKE**- sequence, characteristic of mammalian NF-M's. The remainder of the C-domain was rich in glycine and serine and had limited homology to other known intermediate filament

Northern blot analysis probing with XNK3 demonstrated a 2.4 kB band present in brain, but absent in liver, ovary, skin, and muscle. This corresponds to a maximum size of 58kDa for the protein encoded by XNK3. We speculate that XNK3 is a novel, low molecular weight neurofilament in *X. laevis*. Developmental expression profiles and cell localization experiments with *in situ* hybridization analysis are in progress.

241.1 IMMUNOHISTOCHEMICAL LOCALIZATION OF GABA, CHOLINE ACETYLTRANSFERASE, GLUTAMATE AND ASPARTATE IN THE VISUAL SYSTEMS OF GOLDFISH AND MICE. G.H. Kageyama and R.L. Meyer. Dev. Biol. Center, University of California, Irvine, CA 92717.

The immunohistochemical localization of GABA, choline acetyltransferase (ChAT), glutamate (GLU) and aspartate (ASP) was examined in the visual systems of normal and monocularly enculceated (or optic nerve crushed) goldfish and in normal mice.

GABA (Immuno Nuclear). In the goldfish optic tectum GABA was found in Type III cells in stratum opticum (SO), sparsely distributed neurons in the stratus griseum centrale (SGC) and neurons in stratum periventriculare (SPV). Large GABA+ puncta were localized sparsely distributed in stratum marginale (SM) and SGC, and densely distributed within sublamina b of SO, throughout the stratum fibrosum et griseum superficialis (SFGS), sublamina a of the SGC and neuropil of the stratum album centrale (SAC). In the primary optic innervation layer (SFGS) neither optic nerve crush or enucleation resulted in any notable changes in GABA labeling. At the E.M. level GABA was localized within predominantly large non-optic vesicle-containing profiles. In the retina of goldfish and mice GABA was found as previously reported within certain classes of amacrine cells and their processes stratified within the inner plexiform layer (IPL). GABA was also found within small neurons located sparsely distributed within the mouse LGN and superior colliculus.

ChAT (Immuno Nuclear). In goldfish ChAT was localized within a class of small type XIV tectal periventricular neuron and retinal amacrine cells and processes as previously reported. ChAT labeling was not notably affected by either optic nerve crush or long-term enucleation. At the E.M. level ChAT was localized within non-optic vesicle-containing profiles within the SFGS.

GLU (Bob Wenthold, NIH). In goldfish optic tectum GLU was localized within the Type I pyramidal neurons in the SFGS and their dendrites in SM, as well as neurons sparsely distributed throughout the SGC, large neurons (presumed Type XIII) in the SAC and in the smaller Type XIV periventricular neurons in the SPV. Fibers in the SO and fibers and terminals in the SFGS were also labeled and disappeared 3 days after optic nerve crush without notably affecting the labeling of Type I neurons. In the retina of both goldfish and mice GLU labeled some retinal ganglion cells, cone pedicles, cells in the inner nuclear layer and processes in the inner plexiform layer. In the mouse large cells in the LGN and large and small cells in superior colliculus were labeled. GLU labeling was blocked by 0.05M L-glutamate, but not aspartate.

ASP (Chemicon and Bob Wenthold, NIH). In both goldfish and mice ASP was localized in the same cells and processes as described for GLU I and GLU II but differed in staining intensity. ASP labeling was blocked by 0.05M L-aspartate but not glutamate.

(Support: NIH Grants EY06746 and HD-07029.)

241.2 IDENTIFICATION OF N-ACETYL-ASPARTYLGLUTAMATE-LIKE IMMUNOREACTIVITY IN THE ANTERIOR HYPOTHALAMUS OF THE RAT. J.R. Moffett, M.A.A. Namboodiri and J.H., Neale. Dept. of Biology, Georgetown Univ., Wash. D.C. 20057.

Several lines of evidence developed in recent years suggest that the acetylated dipeptide, N-acetyl-aspartylglutamate (NAAG), might serve in some capacity as a neuroactive agent. Support for this idea has come from studies utilizing anti-NAAG sera, which demonstrate specific NAAG-immunoreactivity (IR) in numerous cell types in the CNS, including retinal ganglion cells, and the projection zones of the primary and accessory optic tracts in rat, cat and primate. In order to investigate the role of this dipeptide in the retino-hypothalamic axis, the distribution of NAAG IR was mapped in the retinohypothalamic pathways and anterior hypothalamic areas of the rat following optic nerve transections.

At the anterior margin of the third ventricle, the anterior periventricular nucleus exhibited NAAG-IR which was both intracellular, and diffuse within the neuropil. Additionally, many NAAG positive neurons were visible throughout the preoptic area. More caudally, densely staining NAAG positive neurons were observed in the hypothalamic periventricular nucleus, and in a dorsal crescent of cells in the suprachiasmatic nucleus. Both of these nuclei contained a high degree of diffuse staining in the neuropil as well. Laterally, immunoreactive cell groups and diffuse staining neuropil were visible throughout the extent of the lateral hypothalamus, encompassing several nuclear groups. NAAG positive axonal cross sections were seen scattered throughout the optic chiasm proper, with the greatest density of such fibers occurring in the dorsal half of the chiasm. Notably, diffuse NAAG-IR was present in several presumptive ganglion cell projection zones, including, the suprachiasmatic nuclei, supraoptic nuclei, and the lateral hypothalamus. Unilateral optic nerve transection in albino rats resulted in loss of reactivity in corresponding optic nerve axonal crossections, and reductions in the diffuse neuropil reactivity in the ventral suprachiasmatic nucleus, the supraoptic nucleus, and lateral hypothalamus.

These data expand the number of visual pathways in which neurons utilizing NAAG are likely to participate, and suggest that this dipeptide may be involved in some form of direct retinal regulation of hypothalamic function. (Supported by NIDA grant DA 02297).

241.3 CHOLINERGIC MODULATION OF GLUTAMATE IN THE THALAMIC RETICULAR NUCLEUS. G.A. Marks, Andrew Hoelscher* and H.P. Roffwarg. Dept. of Psychiatry, Univ. of Texas Health Science Ctr. at Dallas, Dallas, TX 75235.

Evidence supports a central role for cells of the thalamic reticular nucleus (TRN) in the control of the transfer of sensory information through the thalamus. The TRN exerts a GABAergic inhibitory influence upon specific thalamic relay nuclei. It, in turn, receives input from collaterals of relay cells in the respective nuclei, putatively glutaminergic-facilitating influences from cortex and ascending influences from the brain-stem. Work in several laboratories, utilizing the anesthetized cat preparation, indicates that at least one brainstem input to TRN is cholinergic and that cholinergic agonists, mediated through muscarinic receptors, inhibit TRN cells. Recently, Kayama et. al., working with the anesthetized rat, concluded that the brainstem cholinergic influence on TRN neurons is excitatory. To investigate this controversy, we have microiontophoretically applied cholinergic agonists to TRN cells in anesthetized rats. We found responses that are too complex to characterize as solely inhibitory or excitatory.

Male Long-Evans hooded rats were anesthetized under chloral hydrate (IP). Four-barrel micropipets were used to apply drugs iontophoretically. Three barrels contained active drug solutions and a fourth contained 3M Nacl for current balance and current testing. An insulated etched-tungsten electrode was cemented to the micropipette (tip to tip $< 20\mu m$) and used to record the activity of single cells extracellularly.

The TRN cells studied were responsive to either visual or somatosensory stimulation and were physiologically identified by a spike-burst response to single shocks of the OT (visual) and ML (somatosensory). With the vast majority of cells, carbachol (carb) ejection elicited a quick-onset inhibition followed by facilitation. Low currents of carb, which in itself had little effect on activity, caused marked increases in the facilitatory response to glutamate (glu). This effect took several minutes to develop and several minutes to recover. In rarely encountered cells capable of very regular tonic discharge, carb only elicited inhibitory responses, and no interaction with glu was observed.

Our conclusion, based on these preliminary data, is that the influence of cholinergic agonists on the vast majority of TRN cells is twofold: (1) a short-acting, mode-dependent inhibition and (2) a long-lasting neuromodulatory effect, potentiating the putatively glutaminergic cortical influence. Responses may be mediated by two different muscarinic receptor subtypes.

241.4 MODULATORY ACTION OF THE RETICULAR TRANSMITTERS NOREPINEPHRINE AND 5-HYDROXYTRYPTAMINE (SEROTONIN) IN THE CAT'S VISUAL THALAMUS. H.-Ch. Pape* and U.Th. Eysel Institute of Physiology, University of Essen, D-4300 Essen 1, West Germany.

Acetylcholine (ACh), norepinephrine (NE) and 5-hydroxytryptamine (5HT; serotonin) are regarded as transmitters of reticular influences in the geniculate nuclei (recent review by Sherman, S.M. and Koch, C. Exp.Brain Res.,63: 1, 1986). While a range of specific ACh effects on visual thalamic function is well documented, NE and 5HT have so far been reported to act more globally in terms of depression or facilitation of geniculate activity. We applied NE and 5HT locally by microiontophoresis during single cell recording in the perigeniculate (PGN) and dorsal lateral geniculate (dLGN) nuclei of the cat. Effects were compared with those of ACh and the excitatory transmitter L-glutamate. In the dLGN, visually and glutamate evoked activities were depressed by NE in 91% of the cells (n=34), and in 89% (n=18) by 5HT. Facilitation was not observed. Possible influences of the monoamines on inhibitory processes in the dLGN were investigated during continuous 5HT and NE ejection, with simultaneous application of glutamate compensating monoamine induced depression. In roughly one-third of the cells, long-range lateral inhibition was reduced by NE (n=21) or 5HT (n=10). Effects ranged from weak disinhibitory modulation to complete disinhibition. Binocular and center/surround inhibition were not affected by NE nor 5HT. For comparison, ACh elicited increased firing rates in 79% of the cells (n=29), disinhibited long-range inhibition in 77% (n=13) and enhanced center/surround antagonism. In the perigeniculate nucleus, NE, 5HT and ACh depressed neuronal activity, with ACh being most effective.

In conclusion, differential reticular influences on dLGN activity (depressant action of NE and 5HT, facilitation with ACh) and modulation of inhibitory mechanisms in the geniculate nuclei (disinhibition of global inhibition by all reticular transmitters, enhanced specific inhibition only with ACh) might reflect gating of geniculate transmission in relation to various states of sleep and arousal.

241.5 DISTRIBUTION AND MORPHOLOGY OF CHOLINERGIC AXONS IN THE LATERAL GENICULATE NUCLEUS AND OTHER THALAMIC NUCLEI IN THE CAT.
D. Fitzpatrick and D. Raczkowski. Department of Anatomy, Duke University Medical Center, Durham, NC 27710.

We examined the distribution and morphology of putative cholinergic axons in the cat's thalamus using a monoclonal antibody to choline acetyltransferase (ChAT). Fine ChAT-immunoreactive (ChAT+) fibers with small varicosities are visible throughout the thalamus, but there are conspicuous regional differences in their density. ChAT+ fibers are particularly dense in the dorsal lateral geniculate nucleus (LGNd) and this density stands in sharp contrast to the sparse distribution of ChAT+ fibers in other principal sensory (GMv and VP) and motor (VA and VL) nuclei. Within laminae A, A1, C and the MIN of the LGNd, ChAT+ varicosities are grouped together into clusters. In contrast, ChAT+ axon terminals in laminae C1-C3, appear less dense and have a uniform distribution. In the A laminae, ChAT+ profiles contain pleomorphic vesicles and make synaptic contacts with the dendritic processes of projection and local circuit neurons as previously reported by deLima et al. (1985).

ChAT+ varicose fibers are also numerous within the pulvinar nucleus (Pul), the ventral lateral geniculate nucleus (LGNv), the intermediate nucleus of the lateral group, the lateral medial - suprageniculate complex (Graybiel and Berson, 1980) and the paracentral and central-lateral components of the intralaminar nuclei. With the exception of the LGNv, these nuclei are not direct targets of the retina. Nevertheless, they all receive projections from the visual midbrain and have been implicated in visual sensory or motor functions. In general, the distribution of ChAT+ fibers is similar to the pattern of acetylcholinesterase (AChE) staining in the thalamus, but there are exceptions: the tecto-recipient portion of the lateral posterior nucleus and the centre median-parafascicular complex, both rich in AChE activity, are only sparsely innervated by ChAT+ fibers.

Finally, ChAT+ fibers outline the cell bodies and proximal dendrites of neurons throughout the reticular nucleus (Ret) of the ventral thalamus, including the perigeniculate nucleus. Since most nuclei of the dorsal thalamus receive projections from the Ret, this may be the main route by which cholinergic neurons in the midbrain and pontine reticular formation exert a global influence over thalamic function. However, the differential distribution of ChAT+ fibers within the dorsal thalamus suggests that the cholinergic system has an additional, more specialized role in influencing cellular activity in thalamic nuclei linked to the visual system. 241.6 THE CELLULAR MECHANISMS OF THALAMIC PGO WAVES. B. Hu*., M. Deschênes and M. Steriade. Lab. Neurophysiology, Sch. of Med., Laval University, Quebec, Canada, G1K 7P4.

This study investigated the effect of peribrachial (PB) stimulation on neurons of the lateral geniculate nucleus (LGN) in the cat. Intracellular and field potential events were recorded simultaneously in normal or reserpinized cats under a variety of anesthetic conditions. In all animals, the visual cortical areas were removed and, in most preparations, both retina were also lesioned. In LGN relay neurons, PB stimulation triggered an all-or-none IPSP superimposed on a slow depolarization. The IPSP occurred at a latency of ~80 msec, lasted for ~50 msec, and was reversed by intracellular Cl injection. This IPSP was observed in all LGN neurons. The slow depolarization started at a latency of ~20 msec and lasted for 200-300 msec. Its amplitude was very variable, being barely detectable in some neurons. This depolarization grew with hyperpolarization of the cell and was accompanied by an increased conductance. The all-or-none IPSP appearing on the plateau of the slow depolarization had an intrageniculate origin since perigeniculate neurons were always inhibited by PB stimulation. Results obtained after reserpine treatment were identical to those just described, showing that these responses did not originate from stimulation of NE or 5-HT fibers. In addition, in reserpinized cats, spontaneous PGO waves were recorded in the LGN. These PGO could also be triggered by auditory or somatic stimuli that usually evoked orienting reactions in behaving animals. The intracellular events associated with these field potentials were identical to those triggered by PB stimulation. It is then concluded that LGN-PGO waves are the thalamic correlates of orienting reactions and that the PB nucleus is the final common path transmitting these corollary discharges toward the diencephalon. Supported by MRC grants MT-5877 and MT-3689.

241.7 EFFECT OF RETINAL IMPULSE BLOCKAGE ON THE ACTIVITY AND AMOUNT OF CYTOCHROME OXIDASE IN THE ADULT CAT LATERAL GENICULATE NUCLEUS: a HISTOCHEMICAL AND IMMUNOCYTOCHEMICAL STUDY. T. M. Cheng* and M. Wong-Riley (SPON. D. A. Riley). Dept. of Anat. & Cellular Biology, Med. Coll. of Wis., Milwaukee, WI 53226.

At the light and EM levels, histochemically-localized cytochrome oxidase (C.O.) activity has been shown to vary between different neuronal types in relationship to functional neuronal activity (Brain Res.,171:11,'79;J.Comp.Neurol.,222:1,'84). In addition, we have shown that the relative amount of C.O. immunolabeled with our specific antisera at the light and EM levels vary between neuronal profiles in the normal adult cerebellum, in direct correlation with the relative level of histochemical C.O. activity (Soc.Neurosci. Abstr.,12:695,'86). The present study investigated the influence of monocular tetrodotoxin (TTX)-induced blockage of retinal action potentials on both the amount and activity of C.O. in neurons of the lateral geniculate nucleus (LGN), and also served as an extension of previous light microscopic observations of the effect of TTX on C.O. activity in the cat visual system (Brain Res., 261:185,'83). Quantitative analysis of cellular immunolabeling at the light microscopic level and histochemical C.O. activity at the light and EM levels revealed functionally-related enzymatic changes in both the amount and the activity of C.O.. A relative decrease in histochemically-detected C.O. activity correlated with a relative decrease in immunocytochemically-labeled C.O.. In addition, not only were neurons in the normal CNS not all alike, but not all neurons responded alike to the blockage of afferent impulse activity. For example, in the cat LGN, the large cells normally are physiologically more active (Physiol.Rev.,62:738,'82), have a higher level of histochemical C.O. activity (J.Comp. Neurol.,242:338,'85), have a higher amount of C.O., and have more mitochondria per unit of cytoplasmic area. These metabolically more active large neurons were also more affected by the inhibition of afferent input than the smaller, less active neurons. At the EM level, the overall decrease in cellular activity and amount of C.O. observed at the light microscopic level appeared to be mainly due to changes in mitochondrial distribution. These alterations were consequences of blocking retinogeniculate impulses which normally maintain the "driving force" or presynaptic input to the LGN neurons. These neurons may, in turn, reduce their output to the striate cortex, thereby decreasing their oxidative demand for energy. The large cells being metabolically more active normally, were more affected than the smaller, less active ones. In summary, the maintenance of the functional and enzymatic integrity of post-synaptic geniculate neurons in the adult cat, as demonstrated by decreases in both the amount and activity of C.O., appears to be dependent upon presynaptic input. (Supp. by NIH NS18122 and EY05439).

241.8 ULTRASTRUCTURAL STUDIES OF THE PRIMATE LATERAL GENICULATE NUCLEUS: RETINAL, SUPERIOR COLLICULAR AND PARABIGEMINAL INPUTS TO THE SMALL-CELLED LAYERS. S. Feig*, D. Van Lieshout* and J.K. Harting* (SPON: A. Berman). Dept. of Anatomy, Univ. of Wis., Madison, WI 53706.

We have used electron microscopic anterograde autoradiography to analyze the synaptic relationships of retinal (RT), superior collicular (SC) and parabigeminal (PB) axon terminals within the small-cell, koniocellular layers of the Galago lateral geniculate nucleus (LGN). These koniocellular layers are quite large in Galago and are an important component of the small-cell retino-cortical channel. Thus, they receive predominantly W-cell input from the retina and project to the supragranular layers of area 17. They also receive substantial projections from the superficial layers of the superior colliculus and from the parabigeminal nucleus [Harting et al., Brain Res. 366(1986) 358-363].

At the ultrastructural level, koniocellular RT's have a very distinctive appearance. They are very closely clustered and are small in comparison to RT's in the parvocellular and magnocellular layers. Koniocellular RT's are almost equally presynaptic to pleomorphic vesicle-containing elements (f2) and small-diameter dendritic shafts and spines. Many of the postsynaptic targets of RT's in the koniocellular layers are targets of other RT and f2 terminals. However, we have never observed an f1-type terminal (another profile with pleomorphic vesicles) presynaptic to one of these retinal targets, even though f1-type endings are present in the koniocellular layers.

A preliminary analysis of the interlaminar zones reveals many of the ultrastructural features described above for the koniocellular layers. Available data regarding SC and PB inputs indicate that these terminals contain round vesicles and dark mitochondria and make asymetrical contacts.

RETINAL TERMINAL	%RT CONTACTING POSTSYNAPTIC TARGET			χTERMINAL
	DENDRITIC SHAFT	DENDRITIC SPINE	F2	DIAM.(μm)
magno	96%	12%	44%	2.37±.48
parvo	84%	36%	21%	1.64±.48

241.9 LATERAL PULVINAR RESPONSES RELATED TO REWARD AND STIMULUS SIGNIFICANCE. D. Burman and L.A. Benevento. Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60680.

Single-cell recording was undertaken in the lateral pulvinar (PL) of a behaving monkey (Macaca fascicularis). Prior to recording, the monkey had been trained on a series of visuomotor tasks. In a form discrimination task, the monkey was required to discriminate between a circular and a square spot in order to anticipate the direction and timing of a saccade required later in the task. The monkey had to anticipate the direction and timing of the saccade in order to consistently perform the task correctly, due to limitations on the time allowed for completion of the saccade. In the original discrimination task, the discriminandum (S1) appeared two seconds after the appearance of the initial fixation spot (i.e., S1 appeared at t=2), then remained onscreen until completion of the task. Another spot (S2) appeared at t=4, and the monkey had to decide whether to saccade to S1 at t=4 or to S2 at t=6 based upon whether S1 was circular or a square. As reported earlier (Burman and Benevento, Soc. Neurosci. Abstr. 11: 234, 1985), some PL cells responded preferentially to the S1 circular spot. These cells also responded to other cues that signified the monkey should prepare to saccade within two seconds (such as the S2 circle and the reward); the responses to these cues may be termed time-dependent. Other PL cells have been found which had direction-dependent responses. The response of these cells to S1 depended on the direction of the saccade which would follow, as signified by the combination of the location and form of S1. In addition, PL responses during performance of a modified form discrimination task have been analyzed. In the modified task, S1 appeared at t=2 for only 30 ms, reappeared at t=4, and remained onscreen once the monkey was cued to saccade promptly. A tonic response to S1 could not be a purely visual response, since it did not depend on the presence of a visual stimulus or its offset; such a response would be related to the significance of S1. Some PL cells did indeed have a tonic response to S1 in the modified task, and many of these cells also responded during the reward period. The reward also served as a cue for a saccade, since the monkey consistently moved its eyes shortly after the reward period ended; this saccade was typically in the direction opposite that required by the task. (Thus, if the monkey moved its eyes to the right during the task, it would move its eyes back to the left after the reward.) Although the reward-associated responses of many PL cells could be related to the direction or timing of the saccade which would follow, a few cells responded more vigorously to the reward than to any visual stimulus or to any saccade. A hypothesis of PL function is expounded, which suggests that PL is involved in the analysis of stimulus significance and increasing the efficiency of cortical mechanisms involved in the selection of saccade targets.

241.10 VISUAL RESPONSES OF NEURONS IN THE PULVINAR OF THE MACAQUE. John W. McClurkin, Caroline Kertzman, and David Lee Robinson. Lab. of Sensorimotor Res., National Eye Inst., Bethesda, MD 20892, USA.

Most neurons in the two retinotopically organized areas of the pulvinar are visually responsive. However, many have weak and/or inconsistent responses to identical presentations of a stimulus. We have observed that brief and rapidly flashing stimuli are very effective in locating and delineating visual receptive fields. Here we have studied the responses of pulvinar neurons to stroboscopic stimuli presented at frequencies from 1 to 8 pulses per second and compared the results with those found for the same cells to oscillating stimuli. We also tested the responses of cells in the superficial layers of the superior colliculus and parvocellular layers of the lateral geniculate nucleus to stroboscopic and oscillating stimuli.

All neurons were studied in awake, trained rhesus monkeys while they fixated a spot of light throughout the periods of stimulation of the visual receptive fields. We found a subset of pulvinar cells which responded weakly, if at all, to a stationary stimulus presented in the visual receptive field for over one second. When a similar stimulus was flashed briefly (10 microsec) at rates of one or two per second, there was still only a weak response. When the same stimulus was flashed at rates of from 4 to 6 per second, there was a dramatic and consistent response entrainment from the cell. This response consisted of a brief burst of spikes following each flash of the stimulus. We never observed a tonic or prolonged elevation in activity associated with our stroboscopic stimuli. The responses of these cells declined markedly to presentation rates of over 6 pulses per second. Thus the rate at which the strobe entrained the cell was very finely tuned. Furthermore, there was an augmentation of the response to the optimum presentation rate. The first and second stimuli in any individual train of pulses evoked much weaker discharges than later ones. When the same cell was tested with a comparable stimulus which oscillated back-and-forth across the visual receptive field, there was no similar frequency selectivity or discharge augmentation. When these same tests were conducted on visually responsive cells in the superior colliculus and lateral geniculate nucleus, we did not observe the selectivity for stimulation frequency. Furthermore, we did not find neurons which showed response augmentation with repetitive stimulation. In fact, most cells had a response decrement.

It is clear from these studies that there is a population of cells in the pulvinar which is very responsive to repetitive stimulation at about four per second. Although the frequency selectivity probably depends on synaptic processes in the pulvinar, its unique presence in this area may reflect the function of this part of the visual system.

241.11 THE MACAQUE PULVINAR: INCREASES IN VISUAL SENSITIVITY FOLLOWING SACCADIC EYE MOVEMENTS. David Lee Robinson, Caroline Kertzman, and John W. McClurkin. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, USA.

Previously we have shown that the activity of many cells in the pulvinar is altered in association with saccadic eye movements. This can be either an excitatory or inhibitory pattern. Furthermore, the activity change also follows saccades to remembered locations in the dark, thus ruling out visual signals as its source. In this study, we sought to determine whether the sensitivity of pulvinar cells to visual stimuli changes following saccadic eye movements.

Monkeys were trained to fixate a spot of light and to make saccadic eye movements to peripheral targets. Eye position was monitored by computer with a scleral search coil. Stimuli were positioned with a pair of mirror galvanometers controlled by the computer and could be stabilized on any part of the retina. Stimulus onset was triggered from the start of the eye movement in saccade trials or at least 500 msec after the monkey achieved fixation on the standard fixation trials. The responses of cells to a receptive field stimulus during fixation were compared to their responses to comparable stimuli presented at varying delays after saccadic eye movements. We found an increase in visual sensitivity following eye movements in about one third of the cells sampled in the two retinotopically organized areas of the pulvinar. There was considerable variability in the time course of the increase in sensitivity. For some cells, visual responsivity was at a maximum immediately after the eye movement and declined to fixation levels over 500 milliseconds. For others, maximum sensitivity was not reached until 250 to 500 msec after the saccade. Finally, in some cells, there was a complex interaction between the post-saccadic changes in spontaneous activity and the increase in visual sensitivity.

New information is processed by the visual system following saccadic eye movements. The function of increased visual sensitivity in the pulvinar, therefore, may be to alert the cortex to the presence of new stimuli.

241.12 CORTICAL PROJECTIONS TO THE CAUDAL SUBDIVISION OF THE LATERAL POSTERIOR-PULVINAR THALAMIC COMPLEX IN THE CAT. M.L. Rodrigo-Angulo and F. Reinoso-Suárez. Dpto. Morfología. Fac. Medicina. Universidad Autónoma de Madrid. 28029 Madrid. Spain.

In the cat thalamus, the most caudal part of the lateral posterior-pulvinar thalamic complex (LP-Pu) has been defined by Graybiel and Berson (Neurosci.,5:1175-1238, 1980) as the LP-Pu extrageniculate visual subdivision. It is formed by the following nuclei:caudal part of the pulvinar (Pu), lateralis posterior lateralis (LPL), lateralis posterior medialis (LPM) and lateralis medialis-suprageniculate complex (LM-Sg). Based on cytoarchitectonical and histochemical data we have delimited these nuclei, have separated LM from Sg and excluded the latter. The aim of this study was to elucidate the organization of the cortical afferent connections to each one of those nuclei using the retrograde HRP transport method. By means of glass micropipettes, stereotaxically guided injections of an aqueous solution of HRP (20%) were made in the various nuclei in 10 adult cats. Our results demonstrate that caudal LP-Pu receives abundant cortical projections which amount of an average of 79.05% with respect to the total number of afferents from the telencephalon, diencephalon and brainstem. In the case of LPL, the percentage of cortical afferents reached 93.0% of the total. However, no one or just a few of these projections come from the contralateral hemisphere. We did not find any specific projection from given cortical areas to cytoarchitectonically defined nuclei, although preferences could be observed. The Pu receives projections mainly from visual cortical areas 17,18,19,20, and 21. The lateral suprasylvian visual areas (LS), the visual splenial area (AVS) and the retrosplenial area (Rs) also project to the Pu. Visual areas also represent the main source of projections to LPL. Area 17 projects most heavily upon LPL, which also receives projections from areas 18,19,20,21,and the posteromedial (PmLS), posterolateral (PlLS), dorsal (DLS) and ventral (VLS) subdivisions of the LS. Sparse projections were also detected from area 36, Rs, and posterior suprasylvian area (Ps). The LPM receives a rather uniform projection from cortical areas 17,18, 19,20,21,DLS,PlLS,Ps, and Rs. Different sectors of LM exhibit specific projection patterns. The dorsolateral sector receives its main projection from the insular granular and agranular areas, the visual area of the anterior ectosylvian sulcus, caudal part of the sylvian sulcus, cortical areas 5 and 7, AVS, and cingulate area (Cg). Less abundant projections arise from 18,19,20,21,4,6, anterior limbic (LA) and prelimbic (Pl) areas, and from prefrontal cortex (Pf). The ventromedial sector of LM receives projections from the insular agranular cortex, PF, LA, Cg, Pl and area 5, while projections from visual cortical areas were absent. Overall, we observed a shift of cortical labeled neurons, from caudal to rostral areas, corresponding to a sequence, from lateral to medial, on the caudal LP-Pu. Supported by Grant CAYCT 512/84.

241.13 RETINOHYPOTHALAMIC PATHWAY REVISITED IN MAMMALS: AN UNUSUAL IPSILATERAL ASYMMETRY IN PRIMATES. H.M. Cooper*, G. Mick*, M. Magnin* (SPON: H. Kennedy), INSERM-Unité 94, 69500 Bron, France.

In mammals the proportion of decussating and non-decussating retinal axons within the optic chiasm varies according to the degree of frontal orientation of the optical axes of the eyes. In animals with laterally placed eyes, the majority of retinal axons cross in the chiasm, whereas in animals with frontally directed eyes such as primates, the number of crossed and uncrossed fibers is approximately equal. However, the bilateral distribution of retinal efferents terminating within a given primary visual nucleus is not strictly related to the degree of decussation and, in the case of the primate retinohypothalamic projection we find that the density of retinal terminals is greater ipsilaterally.

We studied retinal projections in both strepsirhine (Microcebus murinus, Galago alleni) and haplorhine (Callithrix jacchus, Macaca fascicularis, Hylobates concolor) primates as well as in non-primate species from 7 other orders of mammals using anterograde transport of tritiated amino acids or HRP injected into the vitreous of one eye. The density and spatial distribution of label was quantified using computerized image density analysis. The pattern of distribution of anterograde label in various visual nuclei agreed with classical descriptions of retinal projections in each species, indicating that the tracers were transported normally from all areas of the retina. However, in primates the amount of label (silver grains or HRP granules) throughout the suprachiasmatic nucleus (SCN) was greater ipsilateral to the injected eye. This was particularly striking in the gibbon and in the macaque where the ipsilateral density of label was 6 to 9 times greater than contralateral label. By contrast retinal input to the SCN in rodents, carnivores and marsupials was predominantly contralateral. In megachiropteran bats, edentates and pholidotes label was equally distributed on both sides of the SCN.

The results demonstrate that, in contrast to other primary visual nuclei, the retinohypothalamic projection in primates is the only visual sub-system with a distinct ipsilateral bias. Whether this reflects a higher proportion of ganglion cells in the ipsilateral retina or a difference in the densities of ganglion cell terminal arborizations in the SCN requires further investigation.

241.14 NONRETINAL AFFERENTS TO THE MEDIAL TERMINAL ACCESSORY OPTIC NUCLEUS IN THE RABBIT. R.A. Giolli, R.H.I. Blanks and Y. Torigoe. Dept. of Anatomy and Neurobiology, Coll. Med., Univ. Calif. Irvine, CA 92717.

The distribution and density of nonretinal afferents to the rabbit medial terminal accessory optic nucleus (MTN) have been determined after injections of horseradish peroxidase (HRP) into the MTN in seven rabbits, and verification of certain of these projections has been made in rabbit and rat utilizing anterograde transport of tritiated leucine or leucine/proline from appropriate injections into cerebral cortical areas and brain stem nuclei.

Horseradish peroxidase labeled neurons have been identified: (A) In four visual and/or oculomotor nuclei in which available autoradiographic brain series have confirmed the presence of afferent projections to the MTN: (1) The nucleus of the optic tract/dorsal terminal accessory optic nucleus, (2) the interstitial nucleus of the superior fasciculus (posterior fibers), (3) the periaqueductal gray (including its supraoculomotor portion), and (4) the pars medialis, deep mesencephalic nucleus. (B) In the ventral lateral geniculate nucleus, in which a projection to the MTN has been confirmed autoradiographically in the rat by others. (C) In brain stem nuclei and cortical areas in which available autoradiographic brain series fail to confirm the presence of MTN afferents: (1) The nucleus reticularis pontis, pars oralis and pars caudalis, (2) intermediate intersitial nucleus of the medial longitudinal fasciculus, (3) nucleus raphe pontis, and (4) five cortical areas (area retrosplenialis granularis dorsalis, striate area, parietal area 3, subicular cortex and regio praecentralis granularis). (D) In other nuclei, in which autoradiographic brain series are unavailable for study, but others have failed to confirm the presence of these afferents to the MTN suggesting a false-positive interpretation with neuronal labeling probably resulting from spread of HRP into ventral tegmental nuclei adjacent to the MTN. Thus in the medulla and pons, labeled neurons are found in the medial, lateral and superior vestibular nuclei, medullary reticular formation including nucleus reticularis gigantocellularis, lateral reticular nucleus, raphe magnus, spinal nucleus of V, nucleus gracilis/cuneatus, dorsal and ventral division of the parabrachial nucleus, central pontine gray, nucleus K of Meessen and Olszewski, and dorsal nucleus of the lateral lemniscus. In the midbrain labeled cells are present in the intersitital nucleus of Cajal and strata griseum intermedium and profundus of the superior colliculus. In the diencephalon, labeled neurons are found in the posterior and medial pretectal nuclei, zona incerta, and ventral lateral geniculate nucleus. Labeled somata also are observed in the caudate-putamen, fundus striati, lateral preoptic area and lateral hypothalamic nucleus of the telencephalon. These nonretinal afferents to the MTN probably function in the fine tuning of visual-oculomotor information. (Supported by NIH grant EY03642 and NSF grant BNS 8612919).

241.15 VISUAL CORTICAL PROJECTIONS TO THE CAUDATE NUCLEUS IN MACAQUE MONKEY. W. Fries* and A.-M. Lehmann* (Spon. U. Buettner). Dept. of Neurology and Institute for Medical Psychology, Ludwig-Maximilians-University,Munich (FRG).

The cerebral cortex has been recognized as a major source of input to the caudate nucleus. The precise mode of corticostriatal connectivity is still an issue of debate; concepts of both rostrocaudal as well as mediolateral arrangements have been proposed (Kemp and Powell, Brain 93, 1970; Selemon and Goldman- Rakic, J. Neurosci. 5, 1985). We have studied the termination of efferent fibers from striate and prestriate visual areas in the caudate nucleus using anterograde axonal transport of HRP or WGA-HRP after cortical injections and subsequent TMB-histochemistry. Terminal fields of visual corticostriatal fibers were located in the rostrocaudal part of the caudate, confirming previous reports. However, depending on the injection site, major differences in their topographical arrangement were found with respect to their rostrocaudal extent. Striate cortex injections into central visual field representation resulted in none or little labelling, whereas injections into far periphery yielded terminal fields of moderate rostrocaudal extent suggesting a gradient of strength in the projection from central to peripheral similar to that of corticopontine projections (Fries, Neurosci. Abstr. 7, 1981). When area V4 was injected, the terminal fields were restricted to a small region of caudal caudate. Yet, injections into neighbouring area V5 yielded substantial labelling extending from dorsal to ventral caudate. Thus, neighbouring areas of visual cortex do not project to neighbouring parts of caudate, as one would expect following the topographical concept, but overlap with respect to their rostrocaudal extent. In contrast, the visual area in the posterior bank of intraparietal sulcus (POa) and the frontal eye fields were found to project throughout almost the entire rostrocaudal extent of the caudate. Hence, both topographical as well as nontopographical principles govern the mode of termination of efferents from visual and visually dominated cortical areas. These findings are relevant in view of recent findings of visually and eye movement triggered responses of caudate neurons in the awake monkey (Hikosaka and Sakamoto, Exp. Brain Res. 63, 1986).

241.16 SIZE-DIFFERENCE THRESHOLDS AFTER LESIONS OF VISUAL THALAMIC NUCLEI IN PIGEONS. C. Kertzman and W. Hodos. Dept. of Psychology, Univ. of Maryland, College Park, MD 20742.

Nucleus rotundus (Rt) and nucleus dorsolateralis posterior (DLP) are the thalamic components of two parallel ascending pathways within the tectofugal division of the pigeon visual system. An earlier study (Hodos, Weiss, & Bessette, 1986) had shown that lesions of the telencephalic components of these pathways produced postoperative elevations in size-difference thresholds only if the lesion included both structures. What was not revealed by their study was whether the integrity of the thalamic components is necessary for pigeons to discriminate small differences in the size of stimuli or whether the birds could still make the discrimination with only one of the two nuclei intact. Moreover, no prior behavioral evidence existed to indicate that DLP plays a role in visual information processing.

Fourteen pigeons were tested preoperatively using a variant of the method of constant stimuli to determine the smallest difference between the size of two annuli that the subjects could discern. The comparison stimuli ranged from 3.5 mm to 15 mm in diameter. After surgery, in which lesions were placed bilaterally in Rt, DLP, or both structures, subjects' size-difference thresholds were again determined. Combined lesions of Rt and DLP resulted in impaired psychophysical performance, which was characterized by initial elevations in threshold followed by a gradual improvement in performance. Some birds eventually returned to their preoperative level. In contrast, subjects with lesions in Rt or DLP alone showed an immediate return to their preoperative sensitivity levels.

These results indicate that both nuclei can process information about the size of visual stimuli. Moreover, the processing that occurs within either nucleus is sufficient for the pigeon to discriminate size differences. These data provide the first behavioral evidence that DLP participates in visual information processing and suggest that DLP may be specialized for the visuomotor control of feeding.

241.17 VISUAL RESPONSE CHARACTERISTICS OF CELLS IN NUCLEUS ISTHMI OF PIGEONS. Wang, Yong-Chang* and Frost, B.J., Departments of Physiology and Psychology, Queen's University, Kingston, Ontario K7L 3N6.

In the parvocellular division of the avian nucleus isthmi (Ipc) neurons receive an input from the optic tectum, and in turn project back to that structure (Hunt, Streit, Kunzle and Cuenod, 1977). We have employed standard extracellular recording techniques and computer generated stimuli to study the visual response properties and retinotopic organization of Ipc in urethane anesthetised pigeons.

From sequential penetrations in stereotaxic coordinates it was determined that the rostral regions of Ipc receive projections from the nasal areas of the visual field, while the temporal visual field is mapped onto the caudal pole. Also, the upper visual field is mapped onto the more dorsal aspects of the nucleus and the lower visual fields onto the more ventral aspects of the structure. The receptive fields of Ipc units are quite large ranging from 15 degrees in diameter to over 90 degrees, with more frontally located RFs exhibiting an oval shape where the long axis is oriented approximately vertical. In spite of their large size all RFs contained a "hotspot" where they responded vigorously.

All Ipc cells were driven optimally by moving black or white stimuli; direction of contrast being unimportant. Directional tuning curves were quite broad, and like tectal neurons, characterised by a distinct null for nasal to temporal directions of motion in the visual field. Within the receptive fields there were often small subregions which responded to the off-set, or onset and off-set of light spots, although these responses were relatively weak. Size tuning curves revealed that most units preferred stimuli about 2° diameter. Ipc neurons did not respond to whole-field motion or diffuse changes in illumination. Ipc units also respond well to kinematograms and some responded only to the leading edge of kinematographic bars moved in the direction of their long axes. Most Ipc cells appear to have inhibitory regions surounding their ERFs where additional moving stimuli totally inhibit responses. In some instances these zones do not extend completely around the ERFs.

241.18 EFFERENT CONNECTIONS OF THE LENTIFORM NUCLEUS OF THE MESENCEPHALON IN CHICKEN. Stefan R. Bodnarenko and Olivia C. McKenna. Biology Dept., City College, N.Y., N.Y. 10031 and Biopsychology Program, Hunter College, N.Y., N.Y. 10021.

The avian lentiform nucleus of the mesencephalon (LM) and the mammalian nucleus of the optic tract (NOT) are two pretectal retinorecipient areas known to receive large field retinal slip signals and to play a role in the generation of horizontal optokinetic eye movements. The notion that the LM and NOT are homologous structures is based on their similar embryological derivation and their position at the mesodiencephalic border. Further evidence for their homology is based on the similarity of their afferents which originate from the retina, visual telencephalon, and accessory optic system (AOS). In this study we have explored the efferent projections of the LM in 6 week old chickens using anterograde tract tracing techniques to determine whether the homology of the LM to the NOT extends to their efferent projections. After iontophoretic injections of HRP or tritiated amino acids into the LM, three groups of axons were seen leaving the injection site traveling caudally, but each in separate directions. One group of axons which exited from the lateral LM, directly entered the adjacent optic tectum and coursed through the inner layers to terminate in lamina 6. Another group of axons which exited from the dorsal LM, moved medially and coursed around the dorsal and ventral surfaces of the lateral spiriform nucleus, to reach the dorsal pretectal nuclei---the pretectal nucleus, principal precommissural nucleus, and pretectal area. Some fibers from this group crossed to contralateral dorsomesencephalic areas via the posterior commisure. Other fibers from this group terminated in the nucleus of Darkschewitsch. The third group of axons, which exited from the ventral LM, projected caudally and terminated in the three subdivisions of the nucleus of the basal optic root (nBOR) of the AOS. Caudal to the nBOR, fibers were followed ipsilaterally to their terminations in the ventral portion of the nucleus of the deep mesencephalon, the medial pontine nucleus and the inferior olive. In addition, axons were seen entering the cerebellum bilaterally in the brachium conjunctivum.

The targets of the avian LM are remarkably similar to those of the mammalian NOT. Both provide projections to the cerebellum indirectly via the medial pontine and inferior olivary nuclei; the LM also contributes a direct projection. Both the LM and NOT project to the nucleus of Darkschewitsch providing an indirect pathway to the vestibular nuclei. In addition, both project to other visual areas---pretectal nuclei, optic tectum and AOS. The similarity of these efferent targets further strengthens the idea that the LM is homologous to the NOT. BIOLOGICAL RHYTHMS V

242.1 PRENATAL ENTRAINMENT BY MELATONIN: THE PREDICTED PHASE RELATIONSHIP BETWEEN HAMSTER MOTHER AND FETUS. F.C. Davis. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Evidence of the last 10 years indicates that the rodent suprachiasmatic nucleus (SCN) is entrained by maternal rhythmicity before birth. Although the mechanism for fetal entrainment is not known, there is evidence that a rhythm in melatonin can mediate prenatal entrainment in Syrian hamsters; daily injections of melatonin during gestation can set the phase of activity rhythms measured after birth (Davis and Mannion, 1986). This result has now been repeated with a dose of melatonin smaller than those used in initial experiments (10 vs 50 or 100 ug/day), and results now show that the phase established by melatonin injections is the same phase that would be predicted to be established by the mother's endogenous melatonin rhythm if it caused entrainment. As in earlier studies, pregnant Syrian hamsters (Mesocricetus auratus) were maintained in constant dim light and received SCN lesions on day 7 of gestation. On days 8 to 15 they were given subcutaneous injections of sesame oil every 12 hours (1100 and 2300 hours). One group received melatonin at 1100 hrs and the other at 2300 hrs. Pups remained in dim LL after weaning (PN 20) and were placed in individual running-wheel cages to measure the phase of their activity rhythms (activity onset as phase reference). With 10 ug/day, the average phase of 6 litters (31 pups) exposed at 2300 was 18.41 hrs, and 2 litters (9 pups) exposed at 11.00 was 5.79 hrs, for an average difference of 11.38 hrs. The average phase of all litters exposed at 2300 (10, all doses) was 18.84 hrs and that of all litters exposed at 1100 (9) was 6.77 hrs. The average postweaning freerunning periods were the same for both groups of pups, 24.20 hrs. The average freerunning period and the average phases at weaning were used to determine the hypothetical phases of the pups on the last day of melatonin injections (day 15 of gestation). The phases were 14.84 for the 2300 group and 2.77 for the 11.00 group so that activity onset preceeds the melatonin injection by 8.16 hrs and 8.23 hrs, respectively. This is the approximate phase relationship between activity onset and the peak of the endogenous pineal melatonin rhythm in Syrian hamsters (Elliott and Tamarkin). Because the activity onsets of mothers and pups are approximately in phase at weaning (Davis and Gorski, 1985), this phase relationship may also exist for the mother and fetus. If so, the relationship between the activity onset phase of the fetal pacemaker and the mother's melatonin rhythm is predicted to be approximately 8 hrs. Evidence that the phase relationship between exogenous melatonin and the fetal pacemaker is also 8 hrs, supports the hypothesis that melatonin is a physiologically important signal for fetal entrainment. Supported by NIH grant HD-18686 to F.C.D.

242.2 PRECOCIOUS SPINY MICE AS A MODEL TO ASSESS THE POTENTIAL FOR RETINA-MEDIATED LIGHT PERCEPTION IN UTERO. S.L. Jacques*, D.R. Weaver, and S.M. Reppert. (SPON: E.J. Hunnicutt, Jr.). Department of Dermatology and Children's Service, Massachusetts General Hospital & Harvard Medical School, Boston, MA 02114.

The mammalian fetus is generally considered to be isolated from environmental lighting. The light-dark cycle during the prenatal period does influence physiology and behavior of the developing animal, however. This occurs by indirect mechanisms, in which the dam senses the lighting cycle and communicates relevant aspects of the cycle (e.g., phase, day length) to the fetus. Direct perception of environmental lighting by the fetus in utero has not been extensively investigated.

In a recent paper, we studied the penetration of light into the uterine lumen in pregnant albino rats and guinea pigs with a surgically implanted optical fiber (Photochem Photobiol 1987 45: 637). Transmission was greatest for wavelengths > 600 nm because of lower attenuation by tissue absorbance. Interestingly, there was also a band of increased transmission at around 500 nm, with approximately 2% of incident light reaching the lumen of the uterus. This wavelength corresponds to the wavelength of maximum sensitivity to light in rodents, and the peak in the action spectrum of rhodopsin. It thus appears that light of biologically relevant wavelengths does reach the fetus within the uterus, and it may be sufficiently intense to be perceived.

Perception of light depends not only on light being present, but also on the presence of sufficiently developed receptive tissues. We are studying the development of the circadian timing system and its responsiveness to light in a precocious rodent, the spiny mouse (Acomys cahirinus). The retinohypothalamic tract, the primary pathway for entrainment of circadian rhythms, is clearly present within the suprachiasmatic nuclei (SCN) of spiny mouse pups on the day of birth. Pups were injected with horseradish peroxidase (30%, 4 ul per eye, bilaterally, under anesthesia) within 24 h of birth; survival time was 24 h. Thus the anatomical substrate for detection of light by the circadian timing system is present at birth, and may be present earlier.

To determine whether the retinohypothalamic tract is functional on the day of birth, we used 2-deoxyglucose to study the metabolic activity of the SCN. In both adult and fetal spiny mice, metabolic activity of the SCN is higher during subjective day than at night. On the day of birth, exposure to light at night increased the metabolic activity of the pup SCN compared to siblings not exposed to light. This indicates that environmental lighting is perceived by the circadian system of the pup on the day of birth. The stage is thus set to examine whether light reaching the fetal spiny mouse is perceived, and whether prenatal light perception is physiologically important. Supported by AM25395 and HD14427.

242.3 VOLUNTARY EXERCISE (EX) PREVENTS THE ANESTRUS INDUCED BY EXOGENOUS MELATONIN (MEL) IN PINEALECTOMIZED (PX) FEMALE GOLDEN HAMSTERS. D.R. Pieper, C.A. Lobocki*, D. Samuels* and K.T. Borer. Providence Hospital, Department of Physiology, Southfield, MI 48037 and The University of Michigan, Department of Kinesiology, Ann Arbor, MI 48109.

Female golden hamsters become anestrus after about 10-15 weeks in a short photoperiod. This anestrous state is a result of altered MEL secretion from the pineal, and a similar cessation of estrous cyclicity results from twice daily MEL injections into PX hamsters on long photoperiod. A recent study has indicated that access to a running wheel reverses the anestrus associated with short photoperiod in golden hamsters. The present study tested whether EX would also prevent the anestrus induced by exogenous MEL injection in PX hamsters on long photoperiod.

Forty 50 day old golden hamsters were PX and allowed to recover for 2 weeks. Twenty of the animals were then placed in running wheel cages (EX) while the other 20 were left in suspended cages without wheels (sedentary, SED). One week later, one half of each group began receiving 15 ug MEL s.c. at 10 a.m. and 4 p.m. daily, while the other half was injected with vehicle (VEH). Estrous cyclicity was followed for 7 weeks, and all animals were then sequentially bled through atrial catheters for determination of serum LH levels.

Sixty-70% of the SED MEL group became anestrus after 4 wks of MEL injections and remained acyclic for the remainder of the experiment. On the other hand, at least 90% of the hamsters in all of the other 3 groups (including the EX MEL group) continued having normal estrous cycles throughout the experiment. The SED MEL hamsters that became acyclic had daily surges in serum LH peaking at 8-11 hrs after lights on, but all other animals in all groups had LH surges only on the afternoon of proestrus.

These results indicate that the effect of exercise on short photoperiod induced anestrus are not due to an influence of exercise on the secretion of MEL from the pineal. Rather, EX somehow influences the site of action of MEL. Supported by NSF Grant #DCB 8509689 to DRP and #DCB 8502902 to KTB.

242.4 EVIDENCE FOR A SEX DIFFERENCE IN THE FUNCTIONAL ANATOMY OF HYPOTHALAMIC CIRCUITS INVOLVED IN SEASONAL REPRODUCTION IN HAMSTERS. L.L. Badura*, C.L. Sisk, and A.A. Nunez, Psychology Dept./ Neuroscience Prog., Michigan State University, E. Lansing, MI, 48824.

In hamsters of both sexes, exposure to a nonstimulatory photoperiod (<12.5 hr light/24 hr day) results in gonadal regression and reproductive quiescence (Science, 158: 925-928, 1967; Biol. Reprod., 12: 223-231, 1974; Science, 191: 197-199, 1976). The suppression of reproductive functions in nonstimulatory photoperiods involves the pineal product melatonin (Biol. Reprod., 20: 32-50, 1979). The current model of the pathway by which photic information reaches the pineal gland includes the suprachiasmatic (SCN) and paraventricular (PVN) nuclei of the hypothalamus (Science, 227: 714-720, 1985). In male hamsters, horizontal knife cuts that either interrupt connections between the SCN and the PVN or projections travelling dorsal from the PVN prevent testicular regression in short days (Brain Res. Bull., 15: 149-153, 1985; Neurosci. Lett., 61: 261-266, 1985; Brain Res., 370: 102-107, 1986). In the present study, we employed similar knife cuts to investigate the role of hypothalamic pathways in the photoperiodic control of female reproductive physiology.

Cycling female hamsters were initially housed in a long-day (16L:8D) photoperiod. One group of females received a horizontal knife cut aimed either ventral or dorsal to the PVN; another group received sham surgery. After a one week recovery period, half of the animals in each group were transferred to a short-day (6L:18D) photoperiod. Vaginal discharge was monitored daily until all sham-operated animals in 6L:18D showed discharges characteristic of anestrus. The animals were then laparotomized, the uteri bilaterally exposed, and photographed with a Polaroid land camera for determination of uterine width.

Animals with knife cuts located ventral to or through the ventral half of the PVN continued to show regular 4-day estrous cycles in both long- and short-days. Thus, similar to findings for the male, these cuts prevented photoperiod-induced gonadal regression, suggesting that projections from the SCN to the PVN are a component of the neural mechanism modulating pineal responses to photoperiod and thus seasonal reproductive cycles. In contrast, animals with cuts dorsal to or through the most dorsal portions of the PVN and sham-operated animals in 6L:18D ceased to show estrous cycles after 8-10 weeks of exposure to short days, and had uteri significantly smaller than all other groups. Animals with cuts dorsal to the PVN in 16L:8D continued to show estrous cycles and maintained stimulated uteri, indicating the projections interrupted by these cuts are not themselves necessary for the expression of estrous cyclicity. These findings differ from those obtained with males in which knife cuts dorsal to the PVN prevented testicular regression in short-days. Therefore, a sex difference may exist in the functional anatomy of the hypothalamic circuits involved in the control of hamster seasonal reproduction.

242.5 COMPARISON OF THE EFFECTIVENESS OF SINGLE VS. PAIRED WEEKLY LIGHT PULSES FOR MAINTAINING TESTES IN SYRIAN HAMSTERS. (MESOCRICETUS AURATUS) C.E. McCormack Dept. of Physiology. The Chicago Med. Sch., N. Chicago, IL 60064

It has been proposed that in Syrian hamsters, the photoinducible zone (PIZ) for maintenance of gonadal function coincides with the time interval during which light exposure causes phase-shifts in the circadian rhythm of locomotion (J. Elliott in "Biological Clocks in Seasonal Reproductive Cycles," ed. by B.K. & D.E. Follett, 1981) i.e., the PIZ is within the PRC (phase-response-curve). The following experiment was performed to quantitate the capacity of light pulses given during the PRC to maintain gonadal function. Male, 70 day-old hamsters (LVG-Charles River), housed in individual isolated activity wheels, were exposed for 2 wk to daily 14h photoperiods (400 lux, cool white fluorescent), and then were placed in continuous darkness (DD) and given weekly light pulses until autopsy 9 wk later. Six experimental groups were given either 1 min (1') or 15' light pulses (400 lux) each week at a circadian times (ct) which elicited phase-delays ($-d\emptyset$) (1300-1600 ct), phase-advances ($+d\emptyset$) (1700-2000 ct), or no change in phase (0600 ct) of the locomotor rhythm. A 7th experimental group was given a weekly 0.5' pulse at the onset of spontaneous locomotion (1200 ct) and another 0.5' pulse 10h later (ct 2200). One control group remained in DD, and one in continuous light (LL). Given in the table are mean paired weights of testes (TW)(g/100g body wt±SEM), the % of hamsters with TW > 2.0g, and the mean $d\emptyset$ of the locomotor rhythm in hours. Of the 6 groups given single weekly light pulses, those given 15' pulses at times which produced a $-d\emptyset$ (15' at 1300-1600) or a $+d\emptyset$ (15' at 1700-2000) had larger TW than DD controls or hamsters showing no $d\emptyset$ (0600)($P < .01$). Regardless of when given, 1' pulses produced small $d\emptyset$ and failed to maintain testes. However, 1' of light per week did maintain testes if given as paired 0.5' pulses at times which entrained the locomotor rhythm (1200+2200 ct)($P < .01$ vs DD). These results indicate that while a PIZ does exist within the PRC, the hamster is more sensitive to paired light pulses given at opposite ends of the PRC than to single pulses during the PRC. (Supported by 1-R01-HD-13131 and BRSG-S07-RR05366-24)

242.6 **THE EFFECTS OF FEEDBACK LIGHTING ON THE PHOTOPERIODIC RESPONSE IN THE MATURE DJUNGARIAN HAMSTER.** F.M. Sulzman*[1], H.N. Krum*[2] and J.S. Ferraro[2] (SPON: R. Zec). [2]Dept. of Biol. Sci., SUNY-Binghamton, Binghamton, NY 13901; [1]Div. of Life Sci., NASA, Washington, DC 20546.

Mature male Djungarian hamsters (*Phodopus sungorus*) were housed in cages where the animals had free access to food, water and an activity wheel. These cages were placed in individual light-tight sound-attenuated chambers. The animals were exposed to one of the five following lighting conditions for 43 days: a light-dark cycle of 16 hours of light followed by 8 hours of dark (LD16:8), constant light (LL, 45-75 lux), constant dark (DD, 0 lux), feedback lighting (LD_{FB}, a condition which illuminates the cage in response to locomotor activity) or a feedback lighting neighbor control ($LD_{FB\ NC}$, the animal receives the same light pattern as a paired animal in LD_{FB}, but has no control over it). Locomotor activity was continuously monitored. At the end of the experimental exposure, animals were autopsied. Testicular and sex accessory glands weights were determined. The reproductive and circadian period results are shown in Figure 1 (mean±SEM); weights are in mg/10g total body weight and period lengths are presented in hours.

Figure 1

Means with similar superscripts are not significantly different. Unlike previous results observed in mature Syrian hamsters or immature Djungarian hamsters, LD_{FB} was photostimulatory and thus maintained reproductive function. Furthermore, it is apparent that LD_{FB} not only mimics LL in its ability to maintain reproductive function in the mature Djungarian hamster, but LD_{FB} is also capable of mimicking the period lengthening effects of LL, similar to previous studies in other species. Part of the explanation of why LD_{FB} is more stimulating in the mature than the immature Djungarian hamster, may be that Djungarian hamsters become less responsive to nonstimulatory photoperiods with age (K. Hoffmann, BOR, 32 Suppl. 1:57, 1985). However, this explanation does not account for the differences between mature Djungarian and mature Syrian hamsters. Another difference arises from the fact that $LD_{FB\ NC}$ is photostimulatory in the mature Syrian hamster while it is only submaximally stimulating in mature Djungarian hamsters. It is quite obvious that further work is necessary to determine how these organisms interpret light signals. Supported by NIH grant 1 R01 NS23128-01 (JSF).

242.7 PHOTOPERIODIC HISTORY CONTROLS THE NEUROENDOCRINE INTERPRETATION OF THE PINEAL MELATONIN SIGNAL IN THE MALE SYRIAN HAMSTER.
M.H.Hastings*, J.Herbert*, J.Hutchison, J.B.Powers, E.A.Steel*, & A.P.Walker* (SPON: E.Smith). Dept. of Anatomy and MRC Unit on Development of Behaviour, University of Cambridge, U.K., and Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Although it is well established that the pineal gland mediates photoperiodic control of neuroendocrine activity through the actions of its hormone melatonin (MEL), the factors which influence interpretation of this nocturnal signal are poorly understood. This study tests the hypothesis that photoperiodic history may control the central response to pineal MEL. Male Syrian hamsters were held on long days (LD, 16L:8D) for 4 weeks and then half of them were transferred to short days (SD, 8L:16D). Seven weeks later, half of the animals in both LD and SD were transferred to 12L:12D (groups LM and SM, respectively) while the rest remained on LD or SD (groups LL and SS). After an additional 7 weeks, animals were sacrificed at intervals through the night, and trunk blood and pineal glands retained.

In all groups, pineal MEL content was low (<100 pg) for the first 4 hr of darkness and then rose rapidly (>250 pg). The duration of the nocturnal peak was directly proportional to the length of the dark phase (LL 4.5 h, LM 8 h, SM 8 h and SS 11 h). There was no significant difference in the MEL rhythms of groups SM and LM. Exposure to SD for 14 weeks caused a marked decline in serum LH (LL 1.49 ± 0.25, SS 0.58 ± 0.09 ng/ml). However, the effect of 12L:12D upon serum LH levels was dependent upon photoperiodic history. Animals entering 12L:12D from LD (LM) showed a decline (0.32 ± 0.09) whereas in animals previously held on SD, 12L:12D stimulated LH release (SM, 2.63 ± 0.50 ng/ml). Serum prolactin (PRL) was also sensitive to photoperiod. After 14 weeks of exposure, animals in LD had higher levels than those in SD (LL 10.68 ± 1.39, SS 0.72 ± 0.05 ng/ml). However, photoperiodic history did not have a significant effect upon serum PRL levels of animals exposed to 12L:12D. In both groups, levels were not significantly different from SD controls (LM 0.98 ± 0.16, SM 1.69 ± 0.24 ng/ml).

This study demonstrates: (a) The duration of the pineal MEL signial is a high-fidelity representation of the length of the dark phase in any photoschedule. (b) At an intermediate daylength, the interpretation of the MEL signal by neuroendocrine systems regulating LH secretion is controlled by photoperiodic history. (c) This effect of photoperiodic history is not apparent in the control of PRL secretion, implying that MEL may be read in several ways and possibly at several sites within the brain.

242.8 PHOTOPERIODIC INFLUENCES ON SEXUAL BEHAVIOR IN MALE SYRIAN HAMSTERS
J.B.Powers, E.A.Steel,* J.B.Hutchison, M.H.Hastings,* J. Herbert* and A.P.Walker.* Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240, Dept. Anatomy, and MRC Unit on the Development & Integration of Behaviour, Univ. of Cambridge, U.K.

Photoperiod history affects the neuroendocrine response to altered daylength. Male Syrian hamsters interpret an LD 12:12 photoperiod as inhibitory or stimulatory, depending on whether they have been previously exposed to long or short days. This differential response is reflected in the secretion of both androgens and gonadotrophins, and in the activity of brain aromatase (see Hastings et al; Hutchison et al; Neurosci. Abstr. 1987). Here the effects of photoperiod history (PPH) on masculine sexual behavior were determined.

Male hamsters remained gonadally intact (I) or were castrated and given subphysiological doses of testosterone (CT) chronically; they were placed in long (LD 16:8) or short (LD 8:16) days for 16 weeks. Sociosexual behaviors were assessed during wks 7 and 15. On wk 8, half the males in long and short days were transferred to medium days (LD 12:12) generating LL, LM, SS,and SM groups; I and CT conditions were equally represented in each of the 4 PP's.

PP treatment affected sociosexual performance on both wk 7 and wk 15 tests, but only among I males; CT hamsters did not differ significantly on any behavioral measure in either test. Among I males, PP did not affect the initiation of copulation; mount latencies were not significantly different between groups. However, on both wk 7 and 15 tests, intromission and ejaculation latencies of LL males were shorter than those of any other PP group ($p < .05$). The proportions intromitting and ejaculating were 9/10, 3/10, 5/9, 7/10 and 8/10, 1/10, 0/9, 2/10 for LL, LM, SS and SM groups, respectively. Anogenital investigation rates were lower among LM and SS, compared to LL males ($p < .05$); LL and SM groups were not significantly different. These findings indicate that short days impaired sociosexual responsiveness, and that LM and SM males behaved differently on some measures even though they experienced the same PP for 8 wks.

PP affected endogenous levels of T among I males. Mean values at sacrifice on wk 16 were 1.01, 0.12, 0.44 and 0.69 ng/ml for LL, LM, SS and SM groups, respectively. T levels were significantly higher among LL than among LM or SS males ($p < .05$). Interestingly, levels of T among the CT hamsters (0.30, 0.41, 0.53 and 0.46 ng/ml) were not significantly different from intact SS levels, yet behavioral performance among the latter group was remarkably impaired. This suggests that T may be much less effective behaviorally among gonadally regressed males, compared to castrates receiving equivalent levels of T. Factors that might account for this difference (T availability patterns; specific testis secretions) are now being investigated.

Supported by HD 14535 (JBP) and MRC (MH; JH).

242.9 DJUNGARIAN HAMSTERS UNDERGO CHANGES IN REPRODUCTIVE FUNCTION WHEN EXPOSED TO CHANGES IN DAYLENGTH AT PHOTOPERIOD EXTREMES.
D.A. Hall*, S.A. Rivkees*, D.R. Weaver, S.M. Reppert. (SPON: G.C. Crosby). Radiology and Children's Services, Massachusetts Gen. Hosp. and Harvard Medical School, Boston, MA 02114.

For long-day breeders such as the Djungarian hamster (Phodopus sungorus), long photoperiods (>14L/day) are characterized as stimulatory, while short days (<14L/day) are considered to inhibit reproductive function. More recent evidence suggests that reproductive activity in this species is also a function of an animal's photoperiodic history. However, it is unknown whether changes in photoperiod can induce reproductive changes when the change occurs at extreme photoperiods. We addressed this issue by examining the reproductive response of animals maintained in either (1) extremely long photoperiods and then shifted to a shorter, but "stimulatory," photoperiod, or (2) extremely short photoperiods and then exposed to a longer, but "inhibitory," photoperiod. To determine the extent and temporal sequence of reproductive responses, ultrasonography was employed to determine serial changes in testis size in individual animals.

60-day-old male Djungarian hamsters were assigned to two groups: Group I (n=5) was maintained in 6L:18D for 8 weeks and then changed to 10L:14D for 8 weeks. Group II (n=5) was maintained in 20L:4D and then transferred to 16L:8D for 16 weeks. Using ultrasonography, serial measurements of testis size of individual animals were performed every two weeks by the same observer using a Diasonics Real-Time Scanner with a 10 MHz transducer. Testis size was calculated from ultrasonographic length and width measurements using the equation $\pi/6 \times L \times W^2$. Ultrasonographic estimation of testis size had a coefficient of variation of 8% and closely matched actual testis size (n=22, Y=1.01X + 0.2, R=.98, p<.01).

Both groups responded to changes in photoperiod. Within two weeks of transfer from 6L:18D to 10L:14D, testes of males in Group I increased in size, but complete recrudescence did not occur: individual testes measured 16±0.8 mg (M±SEM) after 8 weeks in 6L:18D, and 106±13 mg after 8 weeks in 10L:14D. Animals in Group II transferred from 20L:4D to 16L:8D experienced a 50% decrease in testis size, with testes decreasing from 254±15 mg in 20L:4D to 132±10 mg after 8 weeks in 16L:8D. Testicular recrudescence subsequently occurred with testes increasing to 411±70 mg after an additional 8 weeks in 16L:8D.

These findings suggest that the reproductive axis of Djungarian hamsters can respond to changes in photoperiod at extreme daylengths that have previously been considered to be either purely stimulatory or inhibitory. Supported by NIH grant HD14427.

242.10 LONG DAY LENGTHS INCREASE BRAIN WEIGHT IN THE SIBERIAN HAMSTER, PHODOPUS SUNGORUS.
N. Spears*, J. Dark & I. Zucker. (SPON: M. Breedlove). Dept Psych., Univ of California, Berkeley, CA 94720.

Male meadow voles reared in long day lengths have heavier brains with greater total DNA content than males reared in short day lengths (Dark et al, Brain Res., 1987). Meadow voles and Siberian hamsters both undergo similar seasonal changes in their anatomy and physiology, many of which can be simulated in the laboratory by varying photoperiod. Here, we investigated whether Siberian hamsters also showed photoperiod-induced inhibition of brain development.

Female hamsters were mated and maintained in long day lengths (16L:8D). Offspring were weaned at 18 days of age, and randomly assigned to a long or short (8L:16D) photoperiod. Autopsies were performed at 60 days of age (42 days after weaning), and testes and uteri weighed. The brains were dissected, weighed and frozen for later determination of DNA content.

Male hamsters reared in long day lengths had greater body weights, testicular weights and brain weights than those reared in short day lengths ($P<0.05$ in each case). Females reared in long day lengths had greater body weights and uterus weights than those reared in short day lengths ($P<0.05$ in each case). Photoperiod did not affect brain weight of females. In long days, males had greater body and brain weights than did females ($P<0.05$ for each comparison). In the short day lengths, there was no sexual dimorphism in body weight, but males had greater brain weights than females ($P<0.05$). The findings will be discussed in terms of changes in cell number, as revealed by DNA analysis.

Male,but not female, Siberian hamsters undergo photoperiod-induced brain changes similar to those described for male meadow voles. However, Siberian hamsters differ from meadow voles in that short day lengths do not eliminate the sexual dimorphism in brain size.

Supported by NIH Grant HD 02982.

242.11 ANDROGENS AFFECT BRAIN WEIGHT AND DNA CONTENT IN THE MEADOW VOLE. C.S. Whaling* J. Dark and I. Zucker. Group in Endocrinology and Psychology Department, Univ. of Calif., Berkeley, CA 94720.

Microtus pennsylvanicus exhibit seasonal variation in total brain weight and total brain DNA content; male voles maintained during development in short day lengths (10 h light/day) have smaller brains with less DNA than counterparts kept in long days (14 h light/day) at 70 days of age (Dark et al., Brain Res., 1987). Because testicular activity is also inhibited in short day lengths, we tested the hypothesis that androgens mediate these differences in brain weight and cell number. At 19 days of age male voles were either gonadectomized or sham-operated and intact 19 day old females were implanted subcutaneously with Silastic capsules (Dow Corning #602-305, length of 4 mm) filled with testosterone propionate (Tp) or left empty. At 70 days of age brains were removed and weighed and blood was collected for assay of T. In each experiment voles with reduced plasma T concentrations had significantly heavier brains.

		Plasma T (ng/ml)	Brain Weight(mg)
Male voles:	Controls (N=20)	3.5±1.2	680.0±7.8
	Castrates (N=21)	0.3±.04	708.7±5.9*
Female voles:	Controls (N=20)	0.5±.05	672.3±9.3
	Tp (N=20)	6.8±0.9	647.4±7.0*

*indicates $p<0.05$, two-tailed t-test

Body weight did not differ significantly between treatment groups. Increased brain weight in long day male voles cannot be attributed to increased androgen secretion, which acts to restrain rather than stimulate brain growth.

Supported by NIH Grant HD 02982.

242.12 LONG PHOTOPERIODS REVERSE PRIOR SHORT DAY LENGTH-INDUCED RETARDED BRAIN DEVELOPMENT IN MEADOW VOLES. J. Dark, C.S. Whaling* and I. Zucker. Dept. of Psychology and Group in Endocrinology, Univ. of California, Berkeley, CA 94720.

Meadow voles (Microtus pennsylvanicus) reared in short day lengths are smaller and show retarded reproductive development, compared with controls kept in long day lengths. In addition, their brains are lower in weight with fewer cells (Dark et al, Brain Res., 1987). The effects of short day lengths on body size and reproductive apparatus can be reversed by switching voles to long-days. The purpose of this investigation was to determine whether transferring voles from short to long photoperiods would reverse the previously retarded brain development of male meadow voles.

On the day of birth, dams and their litters were assigned to either remain in the maternal photoperiod (LD 14:10) or were moved to a short photoperiod (LD 10:14). At 70 days of age, half of the voles in each photoperiod were transferred to the opposing photoperiod, thus forming 4 groups: LL-voles in long-days throughout testing, LS-voles initially in long then switched to short-days, SS-voles remaining in short-days throughout testing, and SL-voles switched from short to long-days. All animals were autopsied at 140 days of age: brains were dissected, weighed and frozen for determination of DNA content.

Final photoperiod significantly affected brain mass of male meadow voles: animals kept in long day lengths during the final 70 days of testing possessed significantly heavier brains than those in short day lengths. Voles maintained in short days and then switched to long photoperiods(SL) had heavier brains than animals remaining in short day lengths (SS). Initial photoperiod did not significantly affect brain mass.

Short photoperiod-induced retardation of brain development can be successfully reversed by exposing voles to long day lengths, even at a chronological age when brain growth is ordinarily assumed to be complete.

Supported by NIH Grant HD 02982.

242.13 INTERACTIONS BETWEEN CIRCADIAN BODY TEMPERATURE AND WHEEL RUNNING RHYTHMS OVER THE ESTROUS CYCLE IN ALBINO RATS. S.Kent*, D. Freedman* and E.Satinoff (SPON: J.Malpeli). Dept. of Psychology, University of Illinois, Champaign, IL 61820.

We examined the relationship between body temperature (Tb) and activity in cycling female rats of the Sherman strain. The rats were housed in activity wheels in a room kept at 23 ± 1°C. Tb's were recorded with telemetry and activity counts cumulated and recorded every 10m. Analyses from 5 rats with regular 4-day cycles are reported here. Data were collected for 7-8 cycles in a 12:12 LD photoperiod, and then for 8-9 cycles in 10:14 LD.

In LD 12:12, mean daily Tb was 37.8 ± 0.1°C (± sem) and did not vary more than 0.1°C over the cycle. Highest hourly mean Tb was 39.2 ± 0.2°C and lowest hourly mean Tb was 36.9 ± 0.1°C. Highest mean Tb occurred on the day of proestrus (P). Peak Tb was 0.2-.3°C higher and trough Tb from 0-.1°C lower on P than on any other day in the cycle. In 4/5 rats the acrophase of the Tb rhythm on P was advanced 57 ± 13m compared to the other 3 days. In the fifth rat there was no change. Activity increased a mean of 48 ± 10% on the night of P and an advanced phase (41m) was seen in 4/5 rats. The rat that showed no change in activity phase was different from the one that showed no change in Tb phase.

In LD 10:14, mean daily Tb declined 0.3°C and mean activity declined 24%. The highest hourly mean Tb was 39.0 ± 0.1°C and the lowest was 36.6 ± 0.1°C. Tb and activity phases advanced on P in 4/5 and 2/5 rats, respectively. Mean Tb and mean peaks and troughs were similar to those seen in LD 12:12.

The wheels of 4 rats were then shut for 28 days. Mean Tb declined 0.4°C but differences over the estrous cycle remained, with peak Tb staying 0.2°C higher on the night of P. The most striking change was the decline in Tb amplitude, to a mean peak of 38.0 ± 0.1°C and a mean trough of 36.1 ± 0.1°C. Changes within the estrous cycle remained constant.

These results indicate that 1. Tb and activity increased on the night of P. 2. Tb and activity rhythms phase-advanced on the night of P, but not necessarily together. 3. When the rats had access to the wheel, trough Tb's during the day were significantly higher than when the wheels were shut, even though over 95% of the activity occurred at night.

242.14 PHOTOPERIOD INFLUENCES ANDROGEN-INDUCED AROMATASE ACTIVITY IN THE BRAIN OF THE MALE SYRIAN HAMSTER. J. Hutchison, R.E. Hutchison*, T.H. Steimer*, M.H. Hastings*, J. Herbert*, J.B. Powers, L. Steel*, and A.P. Walker*. M.R.C. Unit on the Development and Integration of Behaviour and Department of Anatomy, University of Cambridge, U.K., Division of Biology of Growth & Reproduction, University Hospital, Geneva, Switzerland, Department of Psychology, Vanderbilt University, Nashville, U.S.A.

Estrogens, formed locally in the brain by aromatization of androgens, are important in the activation of male behavior. In the male hamster, estradiol-17β (E_2) acts with testosterone to influence mating behavior. Exposure to short photoperiod reduces male behavioral responsiveness to androgen (Powers et al, Soc. Neurosci. Abstr., 1987). Our study examines whether (a) short photoperiod affects aromatization of testosterone (T) in the brain, (b) aromatase activity is related to photoperiodic effects on plasma levels of T, LH, prolactin, (PRO) and pineal melatonin (MEL). The latter provides a representation of the length of the dark phase (Hastings et al, Neurosci. Abstr., 1987).

Estrogen formation in individual brain samples was assayed in vitro using the stereospecific production of ^3H_2O from (1β-^{3}H)T as a measurement of aromatase activity. Male hamsters, either castrated or intact, were maintained on long days (LD, 16L:8D) for 4 weeks and then half were transferred to short days (SD, 8L:16D) for 16 weeks. The other half remained on long days. At the time of castration, a group of SD and LD castrates received subcutaneous silastic implants of T.

Formation of estrogen from T was higher in the preoptic area (POA) than other areas. Despite negligible plasma T levels in LD castrates, POA aromatase activity was in the same range as intact LD males. Aromatase activity did not differ significantly between SD and LD intact or castrated males, indicating that photoperiod does not directly influence basal levels of enzyme activity. There were no correlations between T, LH, PRO, MEL and aromatase activity. However, POA aromatase activity was increased by T in SD castrates. There was no comparable increase in LD castrates. This photoperiodic effect appears to be limited to the aromatization pathway, since production of androgenic metabolites was similar in SD and LD males.

We conclude that (a) aromatization of T is localised in POA, (b) preoptic aromatase activity is not related directly to plasma T in LD males, (c) activity of the enzyme is increased by T in short day conditions. Sensitivity of the aromatase to the inductive effects of T appears to be increased by short photoperiod.

242.15 GONADAL, THYROID AND PINEAL NYCTOHEMERAL RHYTHMS IN THE HYPERPROLACTINEMIC MALE RAT. M.K. Vaughan, D.C. Herbert, G.M. Vaughan*, F.J. Weaker*, A.I. Esquifino*, J.A.F. Tresguerres & R.J. Reiter, Dept. of Cellular & Structural Biology, Univ. Texas Health Science Center, San Antonio, TX 78284 & Institute of Surgical Research, Ft. Sam Houston, TX 78234.

Young, male Sprague-Dawley rats were separated into 2 groups: controls and transplanted. Males in the transplanted group received a pituitary under a kidney capsule from an adult female donor. All transplanted and control rats were kept in a 14:10 LD room (lights on 0600 h) for 3 weeks at which time groups of 8-9 rats were decapitated at 1200, 1600, 2200, 0200, 0400 or 0800 h. Pineal glands, pituitaries (pit) from the eutopic position and sera were collected. Grafted animals had elevated serum prolactin (PRL) concentrations that exhibited a rhythm with the highest values in the light phase. Serum PRL in control animals did not exhibit a significant 24-h rhythm. Eutopic pit PRL content, manifesting a biphasic (12-h) rhythm with crests during the day and night in controls, exhibited a similar pattern in grafted rats though an overall reduction in pit PRL content was seen in the grafted animals. Neither the normal biphasic serum testosterone rhythm nor the normal 24-h rhythm (nocturnal surge) of pineal N-acetyltransferase activity and melatonin content was altered in the hyperprolactinemic rats. Serum thyroxine (T_4) and triiodothyronine (T_3) and their free indices (FT_4I, FT_3I) were highest during the day in control and grafted rats. The overall serum T_4 and FT_4I levels were lower in grafted rats though overall T_3 and FT_3I levels did not differ between grafted and controls. Grafted animals showed an additional nocturnal peak in T_4, FT_4I, T_3, and FT_3I. T_3 uptake (T_3U) values were similar between controls and grafted rats, in both cases exhibiting a fall during the night. Changes in serum thyronines were not explainable by changes in serum binding as assessed by the T_3U, and thus may represent changes in thyroidal secretion of T_4. The rhythms in serum PRL suggest the presence of rhythmic circulating factor(s) capable of influencing ectopic lactotrophs and the reduced eutopic pit PRL content suggests a role for PRL in influencing eutopic lactotrophs in the hyperprolactinemic male rat model. Though circulating testosterone and pineal melatonin synthesis were not altered in this model, thyroid function appeared to be altered (Supported by NSF grant PCM 8118487 and North American-Spanish Joint Committee Grant #CCA 8309108).

242.16 NEUROTRANSMITTER CHANGES ASSOCIATED WITH SEASONAL REPRODUCTIVE ACTIVITY IN THE EUROPEAN STARLING. G.F. Ball, D.L. Allen, and V.N. Luine, Rockefeller University, New York, N.Y. 10021.

European starlings (Sturnus vulgaris), like many songbird species, show dramatic seasonal changes in their response to long photoperiods that stimulate vernal gonadal recrudescence. These changes in responsivity are thought to be mediated in part by variations in hypothalamic neurochemistry. For example, Dawson et al. (1985 J. Endo. 105:71-77) have demonstrated that hypothalamic levels of gonadotropin-releasing hormone (GnRH) are low in starlings refractory to the effects of long days but that GnRH levels increase sharply when the birds have experienced a sufficient number of short days to regain photosensitivity. In order to identify other neurochemical systems that may be involved in the mediation of this differential response to photoperiod, we examined differences in neurotransmitter activity in captive male starlings in different seasonal states. These states consist of birds that are photorefractory, photosensitive, or photosensitive and photostimulated (i.e. with fully developed gonads).

Epinephrine (E), norepinephrine, dopamine, 5-hydroxyindole acetic acid (5-HIAA) and serotonin (5HT) levels were measured in discrete brain areas. Catecholamine turnover rates were estimated following injection of the tyrosine-hydroxylase inhibitor, α-methyl-para-tyrosine. Areas selected for microdissection include regions implicated in the control of reproduction such as the pre-optic area (POA), which contains GnRH cell bodies that regulate pituitary secretion, as well as a number of nuclei that are a part of the sexually dimorphic song control complex, such as Area X.

In the POA and Area X, no differences in monoamine levels were noted between photosensitive and photostimulated birds, so the data were combined. Striking differences were found in serotonin activity in the POA. Levels of 5-HIAA and the ratio of 5-HIAA to 5-HT were higher in refractory birds. This suggests that serotonin may inhibit gonadal recrudescence. In Area X, a highly sexually dimorphic nucleus that has been implicated in the control of song, levels of epinephrine were increased in photorefractory birds. Thus, seasonal variation in brain neurochemistry appears to occur in both hypothalamic and extra-hypothalamic areas implicated in the regulation of hormonal and behavioral changes associated with reproduction. (Supported by HD-12011, Revson Foundation Fellowship, BRSG-S07RR07065, and NIH Training Grant).

NEUROETHOLOGY III

243.1 A REIDENTIFIABLE MOLLUSCAN NEURON RESPONSIVE TO MAGNETIC STIMULI. K. J. Lohmann and A. O. D. Willows. Dept. of Zoology NJ-15, University of Washington, Seattle, WA 98195 and Friday Harbor Laboratories, 620 University Road, Friday Harbor, WA 98250.

Behavioral experiments have indicated that the marine mollusc Tritonia diomedea can derive directional information from the magnetic field of the earth (Lohmann, K. J., and Willows, A. O. D. Science, 235: 331, 1987). We have initiated electrophysiological experiments designed to isolate neurons involved in the detection of the geomagnetic field.

Using a whole animal preparation (Willows, A. O. D., Dorsett, D. A., and Hoyle, G., J. Neurobiol., 4: 207, 1973) surrounded by a Helmholtz coil system, intracellular recordings were made from neurons in the pedal, pleural, and cerebral ganglia while animals were subjected to the geomagnetic field and to imposed earth-strength fields generated by the coil. The results indicate that one large, reidentifiable neuron (left pedal neuron 5) consistently shows enhanced electrical activity in response to changes in ambient earth-strength magnetic fields. Although responses are often subtle, the effect is repeatable and has been elicited in more than 30 animals. Similar increases in electrical activity have not been observed in other pedal neurons exposed to identical magnetic stimuli.

The magnetically sensitive neuron does not have any apparent motor function, fails to respond to conventional chemical or tactile stimuli, and is inhibited during escape swimming. In addition, the whitish pigmentation of left pedal neuron 5 is characteristic of cells that contain neuroactive peptides and function in modulating behavioral state (Masinovsky, B. P., Lloyd, P. E., and Willows, A. O. D., J. Neurobiol., 16: 27, 1985).

243.2 COMPARATIVE SURVEY OF A SMALL-AXON TRACT IN THE CERVICAL CONNECTIVE OF FLIES (DIPTERA). D. G. King, Dept. of Zoology and Dept. of Anatomy, Southern Illinois Univ., Carbondale, IL 62901.

The cervical connective of flies encompasses several thousand axons whose cross-sectional areas can range across more than three orders of magnitude within a single specimen. These axons display a consistent spatial arrangement which suggests homology from species to species among diverse families. Most larger axons are located in a dorsomedial motor quadrant, with smaller ascending axons ventrally and laterally. In many species a few bilaterally paired axons and axon tracts are individually identifiable on the basis of position and relative size (King, Soc. Neurosci. Abstr. 9:834, 10:51; Benson & King, Soc. Neurosci. Abstr. 11:626). One such identifiable tract contains several hundred very small axons (diameter < 0.5μm) grouped into a coherent ventro-medial bundle. In transverse section this tract appears as an irregular region located beside the midline near the ventral margin of the connective. With toluidine blue, this tract stains deeply and thus contrasts with the larger axons in surrounding regions.

The ventromedial small-axon tract is conspicuous in some species from each of the three dipteran suborders, suggesting that it forms part of the basic (ancestral) structural pattern for flies. The tract is especially prominent in some tipulids, syrphids, muscids and calliphorids. Nevertheless, a similar tract is not apparent in all species. Particularly in small flies, a clearly-defined ventromedial tract may not be distinguishable because most other cervical connective axons are also similarly small. However, no ventromedial tract appears even in some larger flies whose cervical connectives contain mostly larger axons. In these flies--including some asilids, rhagionids, bombyliids, conopids, and glossinids--a homologous tract either does not occur or consists of many fewer axons. (Alternatively, homologous axons could be larger or could be diffusely arranged rather than coherently grouped.)

The ventromedial small-axon tract corresponds in position and axon size to the tarsal chemoreceptor projection reported in Phormia regina (Calliphoridae) by Edgecomb (1986 Ph.D. Dissertation, Dept. of Entomol., Purdue Univ.) and by Edgecomb & Murdock (Soc. Neurosci. Abstr. 12:863), although the functional identity of this tract has not yet been explored in other species. Obviously, tarsal chemoreception might be less important to robber flies, which are visually-guided aerial predators, than to house flies, which identify their food by walking in it. However, evolutionary change is constrained not only by adaptive utility but also by ontogenetic potential, so comparative study reveals not only patterns of functional specialization but also degrees of freedom available for genetic determination of neural organization.

(Supported in part by NIH grant NS18542 and by SIU School of Medicine. Ray Venezia provided skillful technical assistance.)

243.3 MICROGEOGRAPHIC VARIATION IN THE ACOUSTIC COMMUNICATION SYSTEM OF THE CRICKET FROG. W. Wilczynski and M. J. Ryan*. Dept. of Psych. and Dept. of Zool., Univ. of Texas, Austin, TX, 78712.

Nevo and Capranica (Evol. Biol., 19: 147, 1985) previously demonstrated large-scale geographic variation in call characteristics within two subspecies of cricket frogs, Acris crepitans crepitans and A. c. blanchardi. We have begun an investigation of the microgeographic variation in both the calls and the physiological properties of the peripheral auditory system of these subspecies to assess the coevolution of signal production and reception and its impact on individuals' behavioral selectivity for subspecific calls. Males of both subspecies produce a pulsatile call in which all energy lies above 2.0 kHz. The calls are grouped into subspecies-specific temporal patterns that differ mainly in the call pattern at the end of each call group. However, this part of the call group seems mainly important in intermale aggressive displays (W. Wagner, unpublished). The largest and most consistent difference between subspecies calls is the dominant frequency: the overall mean for A. c. crepitans is 3.91 kHz, while for A. c. blanchardi the mean is 3.54 kHz. The spectral composition changes abruptly in a zone of parapatry in East Texas where the eastern (crepitans) and western (blanchardi) subspecies meet near the Trinity River. In addition, a population of cricket frogs in a relic, East Texas-like habitat in Central Texas near Bastrop, Texas, surrounded by A. c. blanchardi populations has a call with spectral characteristics similar to those of the East Texas A. c. crepitans (mean dominant frequency for this population is 3.77 kHz). Regression analysis shows that call frequency is negatively correlated with male size within each subspecies (for head width regressed on dominant frequency, $r^2 = .335$). However, residual analysis shows that body size alone does not account for subspecific differences in dominant frequency. Furthermore, there is no evidence that character displacement has exaggerated spectral or temporal differences in the parapatric zone. Single unit recordings in the eighth cranial nerve show that in a Central Texas population of A. c. blanchardi auditory fibers innervating the basilar papilla have best frequencies ($\bar{X}$ = 3.50 kHz) that match the dominant frequency of calls from the same population ($\bar{X}$ = 3.56 kHz). Studies are now underway to determine whether a similar match occurs in A. c. crepitans or in the anomalous population near Bastrop, TX, and whether differential peripheral tuning of the basilar papilla contributes to phonotaxis selectivity by individuals for calls from their own subspecies and geographic location.

We thank W. Wagner for assistance during this study. Supported by NSF grant BNS 8606289.

243.4 AUDITORY SENSITIVITY OF HYPOTHALAMIC NEURONS IN RANA PIPIENS. J. D. Allison and W. Wilczynski. Dept. of Psychology, Univ. of Texas, Austin, TX. 78712.

Recent anatomical evidence has suggested the existence of several pathways from auditory centers in this genus to the ventral hypothalamus, an area known to be involved in sex steroid secretion (Neary and Wilczynski, Neurosci. Letters, 71:142-146, 1986). We investigated the physiological response properties of cells in this area to broadband noise bursts or mating calls, played at 77dB SPL. Single units were isolated using standard techniques and the spontaneous firing rate for each was determined using a gated electronic counter. Auditory sensitivity was defined as a 20% or more change in firing rate from the spontaneous firing rate (Urano and Gorbman, J. Comp. Physiol., 141:163-171, 1981). Recording sites were confirmed by application of HRP.

Results indicate that a number of cells in the ventral hypothalamus are sensitive to auditory stimuli. The mean spontaneous firing rate for these sensitive cells was 10.45 spikes/s. Thirty-nine percent of the hypothalamic units isolated changed their firing rate when stimulated with a mating call; 25% showed an excitatory response while 14% were inhibited by the stimulus. The average firing rate change for active units was 2.9 spikes/s (a 27% change). Noise bursts altered the response of 46% of the isolated units; 29.8% were excited by the stimulus and 17% were inhibited. The average change in firing rate for these units was 4.57 spikes/s (a 43.8% change). The difference in mean change of firing rate between the two stimuli was not significant ($t=1.32; p>.05$). However, the variance in firing rate change for the populations was found to be significantly smaller for those cells stimulated with the mating call ($F=6.07; p<.01$). Treatment with human chorionic gonadotropin in intact and castrated animals by injection for 3 successive days prior to recording did not affect spontaneous firing rate or acoustic sensitivity, even though the ventral hypothalamus is a known testosterone binding site (Kelley et al., Brain Res., 140:287-305, 1978). The evidence presented suggests the ventral hypothalamus to be a possible site of sensory-endocrine interactions involved with reproductive behavior in the genus Rana.

We thank J. H. Fox and B. E. McClelland for assistance with this study. Supported by NSF grants BNS 8406221 and NSF BNS 8606289.

243.5 ACOUSTICAL AND NEURAL ASPECTS OF HEARING IN THE BROWN LONG-EARED BAT PLECOTUS AURITUS. R.B. Coles, A. Guppy, M.B. Anderson* & P. Schlegel*. Zoologisches Institut, Universitat Munchen, West Germany & Dept. Zoology, University of Aberdeen, Scotland, U.K.

The frequency sensitivity of hearing in Plecotus auritus was determined by recording averaged evoked potentials and auditory neurones in the inferior colliculus. Using free-field stimuli, the neural audiogram shows good threshold sensitivity in the range 7-50 kHz; above this range there is a steep loss of sensitivity (100dB/octave) with an upper hearing limit near 65 kHz. Auditory sensitivity decreases at 55dB/octave below 7kHz, with a low frequency limit near 2kHz. A remarkable feature of the audiogram of P. auritus is extremely high sensitivity to sound in the range 8-18kHz where thresholds reach -20dB SPL (re.20μPa). Tuning curves and spatial receptive field properties were also examined in midbrain neurones.

The acoustical properties of the external ear show that pressure gain at the eardrum reaches 20dB between 8-20kHz. The gain of the pinna increases rapidly above 6kHz, to a peak of 16dB between 8-12kHz, then decreasing to an average of 8dB up to 80kHz. The gain of the pinna is comparable to a finite-length acoustic horn. The directional properties of the external ear are determined by sound diffraction at the pinna mouth (average radius 12mm). In elevation, the acoustic axis of the pinna moves upwards by 30° between 9-20kHz resulting from asymmetry of the pinna. In azimuth, the acoustic axis is 25° from the midline up to 35-40kHz, and tends to move towards the midline at higher frequencies. Acoustically, the tragus influences the depth and location of nulls below the horizon.

The upper frequency region of good hearing sensitivity is correlated with the main sonar band between 35-45kHz, whereas the more sensitive lower frequency region corresponds to social signals such as a loud long-sweep call used in the field, with energy in the audio range down to 12kHz.

The highly sensitive low frequency hearing of P. auritus is also found in Megadermatid bats and suitable for prey detection by passive listening and location, without the use of echolocation. An important adaptation for this type of foraging behaviour is a large pinna which amplifies sound and provides directionality at low frequencies.

243.6 RANGE JITTER DISCRIMINATION OF FILTERED ECHOES BY ECHOLOCATING BATS. C. F. Moss and H.-U. Schnitzler*. Department of Biology, University of Tübingen, D-7400 Tübingen, F. R. Germany.

Echolocating bats use the time delay between emitted sounds and returning echoes to determine the distance to an object. The big brown brown bat, Eptesicus fuscus, can measure the time delay of sonar echoes with an accuracy of less than 1 μsec, corresponding to a distance discrimination of less than a mm (Simmons, Science, 204: 1336-1338, 1979). Exactly how the bat achieves this remarkable degree of precision is not yet well understood, and therefore, we aimed at evaluating what information in the returning echo is important to the bat's performance in a timing accuracy task.

Six big brown bats were trained in a yes-no procedure to discriminate between two phantom targets, one that simulated a stationary target that returned at a fixed delay and another that simulated a jittering target that underwent small step changes in delay. Bats emitted sonar sounds into a microphone and listened to simulated echoes played through a loudspeaker located at a distance of 1 m. When presented with sounds returned at a variable delay, bats learned to indicate a "yes" (jitter present) response by approaching a platform to the left, and when presented with sounds returned at a fixed delay, they learned to indicate a "no" (jitter absent) response by approaching a platform to the right. The magnitude of the jitter was reduced from 100 μsec to zero in small steps to estimate the smallest jitter the bat can reliably detect. Percentage hits (yes response, jitter present) and false alarms (yes response, jitter absent) were calculated for individual animals at each jitter magnitude tested.

Eptesicus fuscus emits a frequency modulated sonar sound whose 1st harmonic sweeps from approximately 55 to 25 kHz in 2 ms. Sound energy is also present in the 2nd and 3rd harmonics, contributing to a broadband signal which is well suited to transmit information in the time domain. In this study, range jitter discrimination was estimated under conditions in which the echo information available to the bat was manipulated. Baseline performance with natural echoes was compared to that with filtered echoes. The results indicate that the low frequency portion (40-25 kHz) of the 1st harmonic alone is sufficient for the bat to discriminate temporal jitter of less than 0.5 μsec. These findings will be discussed in terms of receiver models that can best account for the behavioral data.

243.7 ECHOLOCATION IN BATS: ECHO DELAY AND ECHO SPECTRUM BOTH CONVERGE ONTO THE TARGET RANGE AXIS IN PERCEPTION. J.A. Simmons, E.G. Freedman, S.B. Stevenson, and L. Chen. Hunter Laboratory of Psychology, Brown University, Providence, RI 02912.

Echolocating bats (Eptesicus fuscus) can perceive the distance to individual sonar targets with an acuity of a fraction of a millimeter from the time-delay of echoes. In terms of delay, this acuity is in the region of half a microsecond. To successfully capture a flying insect at the end of a pursuit maneuver, the required target-range acuity is only 1 to 2 cm, however, so it appears as though bats have considerably more target-ranging acuity than is strictly necessary for intercepting prey. What is the significance of this "excess" acuity?

Bats also can perceive the difference in distance to the different parts of a complex target that extends along the range axis, again, with an acuity of a fraction of a millimeter. Flying insects have dimensions of several centimeters and might subtend a horizontal or vertical angle of a few degrees at the distances of 0.5 to 1 m relevant to pursuit. Because the minimum perceived image-width is about 3 degrees horizontally and 6 degrees vertically, insects probably do not have "shape" in these dimensions. The fine acuity for the range distribution of a complex target must constitute the primary basis for perceiving the shape of objects as small as insects.

The echoes from two parts of a small, complex target overlap in time by an amount dependent on the separation of the target elements along the range axis. Physiological data from several laboratories, a model of peripheral auditory encoding of echo waveforms, and behavioral data all indicate that the distance between two target elements is represented by the spectrum of echoes if the time separation of the corresponding echo components is smaller than 100 to 200 microsec. Nevertheless, the bat perceives complex targets as being extended along the range axis, with each target component referred to its correct absolute range from the bat. The auditory system's spectral code for the time separation of echo components from complex targets must converge onto the same display as the delay of echoes for target range. This could be accomplished by neural computation of the time separation from the location and spacing of spectral notches along the frequency axis, followed by a mapping of this computed time separation onto the echo delay representation of target range. It could also occur more directly in the creation of the echo delay representation itself if the spectrum of echoes can contribute to the spectrogram correlation process that appears to underlie target ranging. To support fine range perception from echo spectra, the bat has the capacity to perceive echo delay with a correspondingly fine acuity, even though time delay as such might not have to be perceived with this acuity under natural conditions.

243.8 RUFF TREATMENT AND SOUND LOCALIZATION. T.A. Haresign* and A. Moiseff. Dept. of Physiology and Neurobiology, Univ. of Conn., Storrs, CT 06268.

The barn owl, Tyto alba, uses a bicoordinate system for localizing sounds in space. Interaural time difference is used mainly to determine the azimuth of a sound in space and the interaural intensity difference is used to determine elevation. Time differences are proportional to the interaural distance and the angle of the sound relative to the aural axis. Interaural intensity difference is the result of bilateral asymmetries that exist in the ear openings and the facial ruff. The owl processes these binaural cues to construct a map of auditory space in the nervous system. To confirm the importance of the facial ruff in sound localization the feathers comprising the ruff were trimmed during their initial outgrowth. The cutting was done so that the feather length never exceeded one quarter of the adult size. These birds were tested in free field conditions as adults.

Individual birds showed varying degrees of localization ability. All of the birds could localize azimuth correctly, but vertical localization was incorrect. The effects varied from random elevation errors to systematic errors where the owls consistently localized above the actual target.

This data is interesting in light of monaural occlusion studies (Knudsen, E. I. et al., J. Neurosci. 4:1001 1984). In those experiments owls whose auditory experience was altered during development by monaural ear plugging adapted to the altered cues as evidenced by their ability to accurately localize sounds in spite of the altered cues. In our study, the birds were unable to adapt to the ruff treatment.

Currently, experiments are underway using earphones to present auditory stimuli to the owls. Preliminary results indicate that treated owls don't respond correctly to earphone stimuli known to elicit accurate behavior in untreated birds. This may reflect a limitation in the adaptive capabilities of the owl's auditory system.

243.10 AUDITORY SELECTIVITY IN THE SONG-CONTROL NUCLEUS HVc APPEARS WITH THE ONSET OF PLASTIC SONG. Susan F. Volman and Masakazu Konishi. Division of Biology 216-76, Caltech, Pasadena, CA 91125.

In adult white-crowned sparrows, auditory responses in the song-control nucleus HVc are selective for an individual bird's own song (Margoliash, J. Neurosci., 1986). Juvenile birds (4-8 months old) that have been exposed to an appropriate song model ("tutor song"), but have not yet sung, show no evidence of neuronal selectivity (Volman and Konishi, Soc. Neurosci. Absts., 1986). We have now quantified song selectivity in HVc neurons of 10 birds, 8-10 months old, during the plastic-song phase of song development. Plastic song has many of the phrase elements of full adult song, but is more variable and often lacks some of the fine structure. We recorded the vocalizations of these birds every 2-4 days and recorded electrophysiologically from HVc as soon after development of plastic song as possible (approximately 2-10 days).

The responses of multi-unit clusters and single units were recorded at 50 sites in these birds. Auditory stimuli were tutor song, 2-4 examples of the birds' own plastic songs, other birds' songs, and tone bursts and other synthetic sounds. Song selectivity was clearly apparent by at least 2 criteria: 1) forward song elicited a greater neuronal response than reverse song at 95% of the recording sites when a bird's plastic song was played, and at 93% of the sites to the tutor song. 2) Alien song, from another subspecies of white-crown, was a poorer stimulus than plastic song at 97% of the sites and than tutor song at 76%. Although tutor song was usually a good stimulus, there was a slight but significant preference for the plastic songs. This preference was most likely to be seen in birds whose plastic song was least similar to the tutor song, including 3 birds in which glass beads, inserted between the two internal tympaniform membranes of the syrinx, successfully frequency shifted the song.

In adult birds a small proportion of neurons in HVc can be classified as "song specific" in that they respond almost exclusively to particular combinations of phrases present in a bird's song (Margoliash, J. Neurosci., 1983). In pre-singing birds we had encountered a few neurons with similar spectral/temporal stimulus specificities. Song-specific units, tuned to the plastic song and/or the tutor song, were also present in birds singing plastic song, and with apparently greater frequency than in pre-singing birds, although these proportions are difficult to quantify. In adult and plastic-song birds, clear auditory responses can be recorded in almost any electrode penetration through HVc. In juvenile birds, by contrast, particularly in the lateral part of the nucleus, auditory responses are more likely to be inhibitory or weak and inconsistent. Thus onset of singing is coincident with an increase in responsiveness as well as with the appearance of selectivity in HVC.

243.11 CHANGES IN FIRING RATE ASSOCIATED WITH HORMONE ADMINISTRATION IN DOVE MIDBRAIN NEURONS. M. Havens and M.-F. Cheng. Rutgers University, Institute of Animal Behavior, Newark, NJ 07102

The distribution of cells which concentrate estrogen in the female ring dove has been described (J. Comp. Neurol. 167:83-104, 1976). There are nuclei which contain a relatively large number of estrogen concentrating neurons. One of these nuclei, the midbrain nucleus intercollicularis (ICo), plays a major role in the control of estrogen dependent female nest coo display. This display is a critical behavior for successful breeding in ring doves. Previous work in our laboratory has demonstrated that ICo lesions disrupt nest coo display and that estrodiol implants in ICo reinstate the behavior in ovariectomized birds.

We have begun to investigate the functional effects of hormones on midbrain neurons in and around ICo. Extracellular field potentials were recorded from single midbrain neurons in ovariectomized doves until a well-isolated, stable cell was encountered in ICo. The electrode was then cemented in place and a second electrode lowered into the brain. After two to four electrodes had been cemented in place, the bird received an im injection of estradiol (50 µg). The spontaneous firing rate and responses to auditory stimulation were then recorded at 10 min intervals for 1 hr. The next day the bird was again anesthetized, given a second 50 µg injection of estradiol and recordings were made as on the first day. On the third day the recording procedure was repeated after which recordings were made from the opposite side of the brain using movable electrodes. In this way recordings were made before hormone exposure, during exposure to a hormone regime which would normally facilitate nest coo display in an ovariectomized bird and after hormone exposure.

Most isolated cells were not present after the first day of recording, however, several have been followed for two days and some for three days. Profound increases and decreases in spontaneous firing rate was observed in many of the neurons after hormone exposure. Approximately half of the cells increased their spontaneous firing rate while half decreased. However, increases in firing rate were more transitory than decreases in that increases typically lasted for 10 to 20 min of a recording hour while suppressions in firing rate typically lasted for longer than 30 min and in the case of several neurons have lasted up to 72 hr. One of the most consistent observations has been that the firing rate of these neurons is affected in less than 20 min after hormone injection on the first day and in many cases in less than 10 min. This observation raises the question of the mechanism of action of estradiol on these neurons.

243.12 AUDITORY LOCALIZATION BEHAVIOR IN CATS DEPRIVED OF VISION. J.P. Rauschecker* and U. Kniepert* (SPON: V. Braitenberg). Max-Planck-Institut für biologische Kybernetik, D-7400 Tübingen, West Germany.

Prolonged binocular deprivation of pattern vision leads to an increase of auditory responsiveness in superior colliculus (SC) of rats and cats (Vidyasagar, Nature, 275: 140-141, 1978; Rauschecker and Harris, Exp. Brain Res., 50: 69-83, 1983). We have asked whether the higher incidence of auditory-responsive neurons in SC has actual consequences on the behavioral performance of cats that were deprived of vision either from birth or later in life. Since the superior colliculus is known to participate in localization behavior, we have used an experimental paradigm that tested the animals for their ability to localize a sound source in space.

Three normal cats and five cats that were deprived of vision from birth by binocular lid suture were studied. All animals were over 3 months of age. Using operant techniques the cats were trained to run from a startbox in the center of a circular arena (3 m diameter) straight towards one of 8 loudspeakers. All speakers were at zero elevation with respect to the animals' head and in equally spaced azimuthal positions behind the wall of the arena. For testing they were addressed in random order. Acoustic stimuli consisted of tone pips (40 msec, 10 kHz, 75 dB SPL). The experiments were performed in a sound-attenuated chamber and were surveyed and evaluated using a video camera system equipped with a fish-eye lens. Sound localization was measured with a resolution of 5 deg.

In general, both groups showed better performance for straight-ahead positions of the auditory target than for lateral or rear positions. However, for all 8 positions the deprived cats were consistently better in localizing the sound source than the controls. Sound localization errors were up to twice as large in normal as in visually deprived cats. Two of the normal controls were additionally tested in the dark using an infrared-sensitive camera, and no difference was found. The same animals were then lid-sutured and retested after 3 months. A slight improvement in sound localization accuracy was found after this late deprivation, which was however much less pronounced than in the early deprived animals.

243.13 SUPERIOR COLLICULUS FUNCTION IN VISUALLY ELICITED "FEAR" AND IN SCANNING MOVEMENTS IN SYRIAN HAMSTERS. G.E. Schneider, L.S. Carman*, and S. Ayres*. (SPON: W. Rosenblith) Dept. of Brain and Cognitive Sciences,M.I.T., Cambridge, MA 02139.

Most studies of behavioral functions of the superior colliculus (SC) have focused on its role in orienting toward visual stimuli. However, recent studies of hamsters using ablation and electrical stimulation indicate that the SC may be important for visually elicited fear responses. In the present study, 20 adult Syrian hamsters with adult or neonatal bilateral lesions were examined in a battery of visual tasks. Adult lesions included (i) transection of the brachium of SC (BSC), (ii) ibotenic acid lesions of pretectum (PT), (iii) ablation of visual cortex (VC), and (iv) control lesions (EXP) involving exposure of the midbrain but with damage limited to the caudomedial hemisphere (such exposures were used in making BSC and PT lesions). Neonatal lesions of the SC were inflicted with heat on the day after birth.

The most reliable deficit in animals with tectal damage was seen when the task involved visually elicited "fear". Thus, normal hamsters, and animals with VC, PT, and EXP lesions, responded to a visual "loom" stimulus by running or freezing, while those with BSC or neonatal SC lesions exhibited few, if any, such responsess. These "fear" deficits occured even in hamsters which showed some orienting abilities when presented with seeds.

"Scanning time"--the amount of time a hamster spent making scanning movements as he emerged from a tunnel into an open arena with baited visual targets--was also highly correlated with SC damage. Animals with BSC or neonatal SC lesions did not scan before entering the arena, while all other lesion groups showed extensive scanning. Other authors have suggested that scanning may be critical for detecting or orienting toward stimuli, but the hamsters in this task showed no correlation between amount of scanning and accuracy of target approach. Similarly, hamsters presented with seeds showed no scanning before turning to take a seed. These observations suggest to us that scanning in the open arena is not used to locate the food, but rather to survey the environment for novel and potentially dangerous visual stimuli. Ablation of the SC eliminates this visual fear response.

Using the data from all of the animals, amount of scanning and intensity of response to a threatening stimulus were positively correlated ($p<.01$, $r_s = .76$). It is relevant to note that, in normals, scanning and response to a threatening visual stimulus are both robust during initial testing, then both quickly habituate. The other animals with intact SC showed little or no habituation of scanning behavior. It is possible that habituation in these cases was impaired because of hippocampal lesions inflicted during the exposure of the midbrain. 244.1 THE EFFECTS OF ELETROMYOGRAPHIC BIOFEEDBACK ON REACTION TIME AND MOVEMENT TIME. R.B. Schultz*, B.R. Etnyre, and J.M. MacArthur*. Rice University, Houston, TX 77030

The effects of electromyographic (EMG) biofeedback on Reaction Time (RT) and Movement Time (MT) were investigated utilizing 45 male subjects from a university population. All subjects performed RT and MT tasks. Both experimental groups were exposed to EMG biofeedback, one experimental group received written information explaining the purpose of the EMG biofeedback. Significant differences in the mean RT's in the first block of 25 trials compared with the subsequent three blocks of trials supported a learning effect. No other effects for RT were significant. A significant difference between MT's for the EMG-Only group and the Control group were revealed with no difference between the Control and EMG-Biofeedback groups. The differences between experimental groups may have been due to strategy alteration, anxiety and motivation.

244.2 FORCE FEEDBACK DYNAMICS DURING HUMAN MUSCLE FATIGUE. R.F. Kirsch* and W.Z. Rymer Northwestern University Medical School and Rehab. Instit. of Chicago, Chicago, IL 60611.

We have begun to examine the actions of force-sensitive reflex pathways in man under dynamic conditions. As in a previous study (Kirsch and Rymer, J. Neurophysiol. 57: 1987), muscle fatigue is being used to reduce contractile force of the elbow joint musculature, a disturbance which should be compensated by a force regulator. In our present study, a random (bandlimited Gaussian white noise) angular perturbation is being used for two primary reasons. First, the random perturbation is quite unpredictable, greatly reducing the contamination of results by voluntary intervention. Secondly, efficient mathematical algorithms can be employed to characterize the dynamic behavior of the system.

Subjects are seated and secured in a chair such that the elbow of their dominant arm rotates about the same axis as a large torque motor, which is used to apply a controlled angular perturbation. Joint angle and torque are sampled via computer, as are surface EMG signals from each of the two heads of biceps, brachioradialis, and triceps. The subject is asked to achieve a certain background torque level (ranging from 10 to 35% of max) and to maintain this mean level during application of the 8 sec random perturbation of ±2 deg about a mean elbow angle of 90 deg. A set of such trials are performed before and after a set of repeated fatiguing contractions. Post-fatigue trials began 10 minutes after completion of the fatiguing exercise to minimize the metabolic effects of fatigue on the EMG signal.

Our results are based on comparisons of pre- and post-fatigue torque and EMG responses. We reasoned that a force regulator would act to maintain the force response of a weakened muscle to an applied perturbation by removing inhibition and thus generating a larger EMG response. In 3 subjects studied to date, substantial fatigue, as evidenced by large shifts in the slope of the isometric torque-EMG relationship (mean shift across all subjects of 150.3%) was induced, but dynamic variations in torque during the perturbation were virtually identical before and after fatigue for matched mean torque levels. Stiffness frequency responses identified as the transfer function between angle and torque (which was modified to remove actuator dynamics) were likewise quite similar. This is in agreement with past work (Hunter and Kearney, J. Biomech. 16:985-991, 1983). On the other hand, incremental EMG, calculated as the root-mean-square (RMS) value of the EMG signal during the perturbation minus the isometric RMS value, increased significantly for matched isometric EMG levels in both lateral biceps and brachioradialis of all three subjects (average shifts of 42.4 and 40.9%, respectively). Interestingly, the incremental EMG signal of medial biceps remained constant or decreased slightly in 2 of the 3 subjects (it was contaminated with noise in the third subject).

In summary, the dynamic character of elbow joint torque was essentially unmodified by fatigue, while the size of the reflex EMG response to the perturbation was increased significantly. This behavior is consistent with the actions of a force regulatory system. Work continues on detailing the dynamics of this system and determining its role in normal motor control.

244.3 CAVEATS OF TREMOR RESEARCH: A COMPUTER MODEL. R.J. Elble. Dept. of Medicine, Southern Ill. Univ. Sch. of Med., Springfield, IL 62708.

We have shown that physiologic tremor is composed of two distinct oscillations, mechanical-reflex and 8- to 12-Hz. The mechanical-reflex oscillation may assume a wide range of frequencies, determined by limb mechanics and reflex loop dynamics. By contrast, the 8- to 12-Hz oscillation has a mean frequency that is largely independent of limb inertia and stiffness. Similarly, the sine qua non of essential tremor is an oscillation in the range of 5 to 12 Hz which has a mean frequency that is independent of limb mechanics and reflex latencies. This pathologic oscillation is distinct from the normal mechanical-reflex oscillation exhibited by controls and patients alike. These properties suggest that the 8- to 12-Hz physiologic and essential tremors are produced by nonlinear central oscillators coupled to the stretch reflex. To conceptualize the complexities of this hypothesis, we developed a computer model containing the following elements: 1) a nonlinear (Van der Pol) central oscillator, 2) a second-order critically damped skeletal muscle model, 3) second-order lightly damped limb mechanics, and 4) first-order spindle and golgi tendon organ feedback. To construct this model, differential equations were written for each component, based on previous laboratory studies by other authors. These equations were then integrated into a classic feedback loop arrangement and solved on a personal computer using the Euler method. Components of this model were studied individually and together in a closed loop arrangement whereby the strength of feedback to the central oscillator could be varied. This model illustrates the following important caveats of tremor research: 1) Torque or displacement perturbations to the mechanical-reflex system produce phase resetting at a fixed latency determined by the reflex loop time, but similar perturbations to the nonlinear central oscillator produce resetting at a variable latency determined by the strength of the perturbation. 2) The nonlinear central oscillator has an inherent preferred frequency that is independent of reflex loop dynamics, but strong sensory feedback to the cental oscillator can produce frequency entrainment at the mechanical-reflex frequency. We (J. Neurol. Neurosurg. Psychiat. 1987, in press) and other authors have utilized brief torque perturbations to the wrist and time-locked computer averaging of EMG and wrist angle data to examine reflex involvement in physiologic and essential tremor. However, such analysis assumes a linear behavior for the various components of tremor. Our laboratory data indicate that this assumption is incorrect for the 8- to 12-Hz physiologic and essential tremors, and our computer model illustrates the complex phase resetting and frequency entrainment produced by system nonlinearities. (Supported by NINCDS grant RO1-NS20973)

244.4 A MUSCULOSKELETAL MODEL OF THE HUMAN LOWER EXTREMITY FOR PREDICTING MUSCULOTENDON TORQUES IN THE SAGITTAL PLANE. M.G. Hoy, M.E. Gordon, and F.E. Zajac. Mech. Eng. Dept., Stanford Univ. and Rehab. Res. & Dev. Ctr., VA Med. Ctr., Palo Alto, CA 94304.

Musculotendon actuators control human movement by generating torques which act on the body segments. How actuators are coordinated in control of a specific movement may depend on the ability of each actuator to generate torque at certain joint angles. To understand the torque-producing ability of each actuator, the geometry of the musculoskeletal system and the length-dependence of musculotendon force must be considered. Musculoskeletal geometry determines moment arm, and therefore the torque generated by a given musculotendon force. How musculotendon force varies with musculotendon length, however, depends on the relative length of tendon in series with muscle (Zajac *et al.*, Proc. 8th Conf. IEEE Eng. Med. Biol. Soc., 1986). Effective human tendon lengths, which include the length of tendon both internal and external to the muscle, and their effect on human musculotendon force and torque have not been previously reported.

To determine the isometric torque-producing capacity of lower extremity actuators, we modeled the trunk, thigh, shank, and foot as planar segments articulated at the hip, knee, and ankle. Eighteen actuators were each represented by one or more straight line segments. We used coordinate data reported by Brand *et al.* (J. Biomech. Eng. 104: 304, 1982) to describe the attachment sites of actuators on the skeletal segments, and to calculate musculotendon length and moment arm for each actuator. Musculotendon force was calculated using a dimensionless actuator model that is scaled to individual actuators by four parameters: maximum muscle strength, optimal muscle fiber length (l^M_o), pinnation angle at l^M_o, and tendon slack length (l^T_s) (Zajac *et al.*, 1986). Tendon slack lengths were chosen by assuming that passive force is developed in muscle only at fiber lengths greater than l^M_o, then selecting l^T_s so that the joint angle at which l^M_o occurred coincided with the onset of *in vivo* passive torque at the joint.

With our model, we show that musculotendon torque depends on actuator-specific musculoskeletal geometry and musculotendon parameters, and that tendon slack length has a profound influence on isometric musculotendon torque. We found that the joint angle of peak isometric torque and the range of joint angles over which each actuator produced torque were unique, even among actuators generating torque in the same direction at a joint. Neglecting the effect of tendon in analyses of musculotendon torque may lead to erroneous predictions of musculotendon function not only in static situations but during movement as well.

244.5 ABOUT THE KINEMATICS IN THE CONTROL OF STEPPING. A. Beuter, H. Flashner*, and A. Arabyan*. Kinanthropologie, Université du Québec à Montréal, C.P. 8888, Succ. "A", P.Q., H3C 3P8 and Mechanical Engineering, University of Southern California, OHE 430, Los Angeles, CA 90089.

It has been suggested that movement planning is done in terms of endpoint coordinates (Flash, 1983) and that inverse Kinematics is used to transform the endpoint positions into the corresponding time sequence of joint angles (Hollerbach, 1985). Although efforts have been made to model endpoint coordinates in planar, multijointed limb movements, no direct evidence of an inverse kinematics process has been offered sofar. Beuter et al., (1986) and Flashner et al., (1987) have suggested that the speed of operation and the variability observed in stepping prevented the implementation of a full inverse kinematics solution. They showed that in stepping only a small number of cartesian space parameters were necessary to specify the foot path (i.e., step length, height and duration), and suggested that the trajectory required to perform the task would be better analyzed in joint space. Therefore the goal of this investigation was to express joint trajectories in terms of simple functions and small numbers of undetermined parameters. Experimental data were collected on six subjects stepping repeatedly at a natural cadence over a low obstacle. Subjects' performances were videotaped in the sagittal plane at 60 pfs and digitized using a motion analysis system. The trajectories of the hip and knee joints of a typical subject were modeled using different classes of functions including polynomials, cosine, harmonics, even polynoms and cycloids by the means of least squares approximation. Results show that the qualitative characteristics of the trajectories are preserved by all approximations with a small number of basis functions. Deviations from the experimental data in low order approximations usually occurred at the end of the swing phase when extensor muscles are activated in anticipation for landing. Results indicate that under normal operation, free-swinging leg movements in stepping are performed in an open loop mode and that only a limited amount of information stored in the nervous system is required for completing the motion. In other words, it appears that the nervous system does not need to implement a full inverse kinematics solution in the control of stepping.

244.6 ABSENCE OF DIRECTION-SPECIFIC RATE CODING AMONG LOW THRESHOLD MOTOR UNITS OF FIRST DORSAL INTEROSSEUS. R.M. Enoka, G.A. Robinson and A.R. Kossev*. Dept. of Exercise & Sport Sciences, Univ. of Arizona, Tucson, AZ 85721.

There has been an interest in the differential behavior of single motor units in multifunctional muscles, such as when a muscle contributes to one action or another. We have addressed this issue by examining motor-unit rate coding in the first dorsal interosseus muscle (FDI) of human subjects during isometric, ramp increases in force. It is known that the force exerted by FDI is modulated significantly by rate coding. We were interested in the patterns of rate coding when FDI acted as a prime mover (abduction force) and as a synergist (flexion force).

Motor-unit potentials were measured with a branched, bipolar electrode (Gydikov et al., Electromyogr. Clin. Neurophysiol., 26:273, 1986) made of 2 stainless steel, insulated wires, each 50 μm in diameter. The electrode contained 3 leading-off areas (~ 500 μm each); 2 on one wire, 2-3 mm apart, and 1 on the other wire. The electrode, about 25 cm in length, was inserted subcutaneously so that both ends of the electrode emerged from the skin with the leading-off areas in close proximity to the surface of the muscle. The leading-off areas could, therefore, be positioned to maximize the selectivity of the measurement. The index finger of each subject was placed in a splint, and the hand was positioned so that the force exerted by FDI in the abduction and flexion directions was sensed by separate transducers located at the first interphalangeal joint.

Target forces were displayed on an oscilloscope, and in response to verbal commands, subjects performed slow (2-4 s) ramp increases in force ($\bar{X} \pm SD$ = 4.11 $\pm$ 3.26 N/s, range = 0.94 - 13.88 N/s) to the target levels. The target forces ($\bar{X} \pm SD$ = 13.8 $\pm$ 8.5%, range = 5.4 - 32.8% of maximum) were set at a value that was just above threshold ($\bar{X} \pm SD$ = 8.7 $\pm$ 5.6%, range = 2.6 - 21.6%), but sufficient to sustain a low, steady motor-unit discharge. There were no marked differences in the recruitment thresholds of individual motor units in the flexion and abduction directions. In all instances, interimpulse intervals were initially long and declined as the target force was approached. This reliance on rate coding is similar to that reported previously for FDI (Milner-Brown et al., J. Physiol. (Lond.), 230: 371, 1973) but not for other muscles, such as biceps brachii (Kukulka & Clamann, Brain Res., 219: 45, 1981). For each motor unit, qualitatively similar discharge patterns were observed in both the abduction and flexion directions. These data confirm other reports on the absence of a direction effect on motor unit behavior, at least among low threshold, FDI motor units.

244.7 FATIGUE-INDUCED CHANGES IN THE THRESHOLD FORCES OF RECRUITMENT AND DERECRUITMENT FOR LOW THRESHOLD MOTOR UNITS OF FIRST DORSAL INTEROSSEUS. A.R. Kossev*, G.A. Robinson and R.M. Enoka (SPON: A. Kaszniak). Dept. of Exercise and Sport Sciences, Univ. of Arizona, Tucson, AZ 85721.

Fatigue modulates motor-unit behavior in human subjects, such as reducing discharge rate during maximal efforts. However, recruitment thresholds of motor units during isometric, ramp increases in force, which are known to depend on activation history, are not thought to be affected by fatigue, at least that associated with a 120-s sustained contraction (Denier van der Gon et al., J. Physiol. (Lond.), 359: 107, 1985). Since this conclusion was based on submaximal efforts, we examined the effects of more substantial fatigue on the recruitment (F_r) and derecruitment (F_d) threshold forces of motor units.

The experimental techniques are described in the accompanying poster (Enoka et al.). The protocol involved three sequences (n ~ 12) of a ramp increase, plateau, and ramp decrease in isometric force. The first and third sequences were used to determine F_r and F_d in both the abduction and flexion directions. Each phase of the task (ramp, plateau, and ramp) lasted 2-3 s, and there was a 5-s rest between each performance. The oscilloscope-displayed target force (plateau) was just above threshold (see preceding poster). The second sequence comprised the fatigue test; the ramps took 2 s each, the plateau lasted 10 s, the target force was 50% of maximum, and there was no rest period between each performance. The subjects repeated this sequence until they could no longer attain the target values.

The protocol was designed to compare F_r and F_d of single motor units during and after the fatigue test to those obtained before the test (control). The data revealed: (1) F_r declined over the course of the fatigue test. The relative change seemed inversely related to initial F_r; (2) despite attempts to maintain smooth ramp profiles, there was marked variability in F_r and F_d during the fatigue test; (3) although the fatigue test was performed only in the abduction direction, postfatigue-test F_r and F_d values in both directions were greater than control values. The fatigue test induced a similar degree of fatigue in FDI whether the muscle acted as a prime mover (abduction) or as a synergist (flexion); (4) the typical reliance of FDI motor units on rate coding to modulate force was less apparent after the fatigue test in that some units did display the traditional discharge rate profiles while others did not. These data provide further evidence of a fatigue-related effect on motor-unit behavior in conscious human subjects; specifically, fatigue caused an increase in F_r and F_d of low-threshold motor units in FDI during slow, ramp changes in isometric force.

244.8 DISSOCIATION OF H-REFLEX AND ELECTROMYOGRAPHIC CHANGES PRIOR TO VOLUNTARY MOVEMENT. K.C. Hayes and J.A. Hendry*. Dept. of Physiology, Univ. Western Ontario, London, Ontario, Canada N6A 5C1.

This study was designed to test the hypothesis that post synaptic inhibition of the alpha motoneuron pool is the primary mechanism underlying the electromyographic "premovement silent period" (PSP) that precedes phasic activation of a tonically contracted muscle. Hoffmann (H) reflexes were evoked from the soleus muscle of nine healthy adult subjects as they maintained tonic contraction of triceps surae prior to a rapid plantar flexion reaction time (RT) task. PSPs were observed in all subjects, with an overall frequency of 78% of the RT trials. PSPs preceded the voluntary plantar flexion response by 60-80 ms and had an average duration of 54±22 ms. The amplitude of H-reflexes evoked during the PSP was not diminished, indicating that postsynaptic inhibition of the alpha motoneuron pool is unlikely to contribute to the PSP. The normalized mean amplitude of H-reflexes evoked during the PSP was, in fact, significantly ($p \leq .05$) greater ($\bar{x}$=44%) than the mean of H-reflexes evoked during background contraction ($\bar{x}$=35%). These results support the alternate hypothesis of a reduced output from supraspinal centers underlying the PSP. A reduction in descending excitatory input to the motoneuron pool may be coupled with reduced presynaptic inhibition of Ia afferent terminals that, in turn, contributes to increased peripheral reflex excitability. The functional significance of these mechanisms would be their potential for clearing the spinal centers to allow synchronous motor unit recruitment and at the same time allowing for an elevated gain or reduced threshold of the segmental stretch reflex.

244.9 EXCITATION FROM THE SURAL NERVE IS PREFERENTIALLY DISTRIBUTED TO THE MEDIAL GASTROCNEMIUS PORTION OF THE TRICEPS SURAE MOTONEURON POOL. L. LaBella, J. Kehler*, and D.A. McCrea. Department of Physiology, University of Manitoba, Winnipeg, Canada, R3E 0W3.

Postsynaptic potentials (PSPs) were recorded intracellularly in 115 triceps surae motoneurons of 10 chloralose-anaesthetized adult cats with intact spinal cords, upon electrical stimulation of the ipsilateral sural and perforant hindlimb nerves.

With twice threshold (2T) stimulation of the sural nerve, excitatory PSPs (EPSPs) with latencies typically between 2.0 and 2.5 ms, were the predominant effect in 95% of all medial gastrocnemius (MG) motoneurons tested. These EPSPs occurred with a minimum central latency of 1.8 ms suggesting a trisynaptic linkage of a minimum of two interneurons. Only in a few MG cells was the EPSP followed by an inhibitory potential (IPSP), and in only one cell was an IPSP the sole effect. Unlike these effects recorded in MG motoneurons, 2T stimulation of sural led to either inhibition or no potential change in most lateral gastrocnemius (LG) and soleus (SOL) cells tested. Thus, EPSPs were the predominant effect in only 15 and 30% of LG and SOL cells respectively. The minimum central latency for excitation was 2.5 ms, suggesting the presence of at least three interneurons. In contrast to the apparently pure excitation normally produced in MG cells, EPSPs in LG and SOL rarely occurred without subsequent inhibition. The results indicate that sural excitation occurs preferentially in the MG portion of the triceps surae motoneuronal pool, and at a preferentially shorter latency. In addition, it appears that this distribution is independent of motoneuron "type" as assessed by consideration of a variety of motoneuron membrane electrical properties. Insofar as membrane properties reflect motoneurons of different motor unit type, this data contradicts reports that the incidence of sural EPSPs is greater in those cells belonging to faster units. Stimulation of the perforant nerve at 5T produced predominant inhibition in 71% of all triceps surae motoneurons studied. Thus, the effects were consistent with an "FRA-like" synaptic input from this nerve. However, of the small number of cells which did receive excitation from this nerve, the majority were MG (7 of 8). These EPSPs occurred more frequently at 5T than at lower stimulation strengths and once again, the polarity of PSPs appears to be independent of motoneuron type.

Taken together, these findings suggest that at least some peripheral excitation may be differentially distributed among motoneurons belonging to the same functional pool. Whether or not this represents an organizing principle in the regulation of muscle synergy requires further investigation, but it appears that the ordering of cutaneous effects in ankle extensor motoneurons is not necessarily according to motoneuron "type", as has been previously reported.

244.10 COMPARISON OF PHYSIOLOGICAL AND HISTOCHEMICAL PROPERTIES OF MOTOR UNITS FOLLOWING CROSS-REINNERVATION OF ANTAGONISTIC MUSCLES IN THE CAT HINDLIMB. C.K. Thomas, T. Gordon, R.B. Stein and S. Erdebil*. (SPON: M. Warenycia), Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alberta, T6G 2H7.

We have shown that the normal size relationships between muscle unit force and axon size returns after self- and cross-reinnervation of triceps surae muscles (Gordon & Stein, J. Neurophysiol., 48: 1175, 1982; Gordon et al., J. Physiol., 374: 443, 1987). This re-ordering of motor units involves considerable reorganization since nerves supply muscle fibers which formerly belonged to several different motor units. In this correlative physiological and histochemical study of reinnervated lateral (LG), medial (MG) gastrocnemius and soleus muscles after cross- reinnervation by flexor motoneurons, we have examined the basis for the return of the size principle. Eighteen to 24 months after cross-union of the tibial and common peroneal nerves of 2-6 month old cats, motor units were classified into types, FF, FR, and S and muscle fibers classified as the corresponding FG, FOG and SO fiber types on the basis of histochemical staining.

As previously shown, motor unit force was well correlated with the size of the innervating motor axon but the force of different unit types overlapped considerably more than normal. The reinnervated motor units also showed a higher degree of fatiguability with muscles containing a high proportion of motor units which were intermediate between FR and FF units in fatiguability. Motor units with fatigue indexes below 0.5 were included with FF units and those with indexes above 0.5 were included with the FR units for comparison with histochemical fiber types.

SO and FOG muscle fibers were found in all reinnervated muscles but FG fibers were only found in reinnervated MG and LG muscles, consistent with previous findings of resistance of soleus muscles to complete conversion. Type grouping of muscle fibers was characteristic of the reinnervated muscles. Reinnervated SO fiber size increased significantly to become similar to FOG and FG fibers and calculation of the relative innervation ratio by the relative proportion of muscle fiber types to corresponding motor unit types indicated that the muscle unit size increased in S units. Nonetheless, the force generated by S motor units remained smaller relative to FR with the gradation of mean force in the reinnervated muscles consistent with the normal S<FR<FF despite overlap between groups. Since mean force varies over a 10-fold range and mean fiber area and relative innervation ratio vary over less than a 2-fold range, these data suggest that force per cross-sectional area (specific force) of the muscle fibers is respecified after reinnervation.

244.11 MOTOR UNIT FORCE, INNERVATION RATIO AND MUSCLE FIBER SIZE IN NORMAL AND REINNERVATED MUSCLE. J.E. Totosy de Zepetnek*, H.V. Zung*, and T. Gordon. (SPON. P. Bawa). Dept. of Pharmacology. University of Alberta, Edmonton, Alberta, Canada. T6G 2H7.

Motor units in reinnervated muscle develop force in the normal range and force is well correlated with axon size (Gordon and Stein, J. Neurophysiol. 48:1175, 1982). Since axons reinnervate muscle fibers that formerly belonged to several different motor units, this return of the size principle requires extensive readjustment of motor unit force to match axon size. We have examined 1) the basis for the recovery of the normal force range and for the return of the normal size relationship between force and axon size and 2) whether reinnervated motor unit force is better predicted by type or by the size of the innervating motoneuron.

Four to six months after section and resuture of the common peroneal nerve, isolated single motor units from the rat tibialis anterior muscle were classified physiologically as per Burke et al. (J. Physiol. 234: 749, 1973) then histochemically following repetitive fatiguing stimulation to glycogen deplete the muscle unit. Glycogen-depleted fibres were detected using periodic acid-Schiff (PAS) stained sections from which we could directly measure the number of fibers (innervation ratio) and total muscle fiber cross-sectional area for each unit.

Examination of reinnervated motor units revealed that although the range of maximum force development was normal (10-250 mN) there was greater overlap between motor unit types in both force and fatigability. On the other hand, in both normal and reinnervated motor units fully analysed to date (1 FF, 3 FI and 4 FR), force was well correlated with muscle fiber cross-sectional area and innervation ratio such that force varied directly as a function of total unit area (slope (m) from a log-log plot =1.02±0.13, r=0.95, n=8). In contrast, there was no correlation between intrinsic force (motor unit force per muscle unit area) and tetanic force (m=0.06±0.11, r=0.20, n=8). Thus for any reinnervated fast motor unit, subtype is a poor predictor of motor unit force. These data suggest that motor units form a continuum with force depending on total cross-sectional area.

244.12 ORGANIZATION OF MOTOR UNIT PROPERTIES IN THE CAT TRICEPS SURAE MUSCLES AFTER PARTIAL DENERVATION. T. Gordon, and R. Orozco. Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alta., Canada T6G 2H7.

Axonal sprouting is a well recognised compensatory response of undamaged neurons to injury or loss of neighbouring motoneurons, but the degree to which this sprouting enlarges muscle units is unclear. In partially denervated rat hindlimb muscles, a condition in which terminal sprouting predominates, a 5-fold expansion of unit size has been described. Because this corresponds with the size of neonatal motor units, Brown et al. (Ann. Rev. Neurosci. 4:17, 1981) suggested that the neonatal muscle unit reflects the maximum capacity of a motoneuron. However, larger expansions in the cat flexor digitorum longus muscles (Hatcher et al. Exp. Brain Res. 60:590, 1985) indicate that this may not be a general prediction.

In this study, we eliminated 7%-94% of the innervation of triceps surae muscles by section of one of the 2 contributing ventral roots, L7 or S1. Since proportions of nerves which exit in either root vary widely between animals but not bilaterally within animals, measurement of charge delivered to each root in response to stimulation of the peripheral nerves, and the force developed in the muscles in response to stimulation of the L7 and S1 roots, provided direct measures of the extent of partial denervation and of the compensatory response.

Two to twelve months after section of one ventral root, force in the medial and lateral gastrocnemius muscles had recovered so that the intact root had fully compensated for the partial denervation. Force elicited in the intact root on the experimental side was altered in direct proportion to the loss of innervation, while root charge was unchanged. Soleus muscles, in contrast, failed to recover contralateral levels of force.

1) Complete compensatory enlargement of muscle units in the MG and LG muscles without alteration in axonal size and 2) incomplete force compensation in soleus was confirmed by isolation and characterization of single motor unit. (n=322 and 127 for experimental & control units from 5 and 16 cats respectively). Unit force was normally correlated with axonal size, and graded according to type with S < FR < FI=FF, but there was a greater overlap between types in force and fatiguability.

We suggest that nodal sprouting, which is more common in fast-twitch muscles, allows effective reinnervation of partially denervated muscles and that the limited sprouting described previously could be due to the limitations of terminal sprouting rather than due to limited motoneuron capacity.

244.13 CONTRACTILE PROPERTIES OF THENAR MOTOR UNITS IN NORMAL AND QUADRIPLEGIC SUBJECTS. B. Calancie, T. Gordon, R.B. Stein, L.A. Davis* and B. Dolphin*, Depts. of Physiology, Pharmacology and Surgery, University of Alberta, Edmonton, Alberta, Canada.

Microstimulation of motor axons was used to obtain the mechanical characteristics (twitch tension, contraction time, and half-relaxation time) of single motor units in the opponens pollicis muscle of normal (n=3) and quadriplegic (n=3) subjects. The quadriplegic subjects are being studied to assess the effect of chronic electrical stimulation on muscle properties.

A bipolar needle electrode was placed in the opponens pollicis at a point approximately mid-way along and ventral to the first metacarpal. EMG was measured with 2 surface disc electrodes 8 mm in diameter placed over the thenar muscles and separated by about 3 cm. The thumb contacted a force transducer at the distal end of the first phalange. Threshold stimulation via the bipolar needle of a single motor unit caused an all-or-none increment in surface EMG which, along with the force record, was averaged on an LSI 11/23 computer.

To our surprise, motor unit twitch amplitudes in one quadriplegic subject were larger on average than units in control subjects. The range, mean and standard deviations were 5 to 69.1 mN, 30.5 $\pm$ 14.5 mN for the quadriplegic units (n=40), and 2.4 to 76.8 mN, 18.0 $\pm$ 14.7 mN for the control units (n=61). Contraction times were similar in range and mean value (51.7 to 127.3 ms, 71.0 $\pm$ 12.5 ms; 51.7 to 113 ms, 74.4 $\pm$ 14.0 ms), as were half-relaxation times (36.0 to 121.2 ms, 66.9 $\pm$ 21.2 ms; 32.5 to 95 ms, 59.5 $\pm$ 16.5 ms).

One possible explanation for the large twitch tensions is that some motoneurons to opponens pollicis in the quadriplegic subject may have been destroyed by the spinal lesion, and that surviving motoneurons sprouted to innervate a larger number of muscle fibers than seen in normal subjects. The frequent spasms occurring in the subject appear to have been sufficient to prevent substantial fiber atrophy, but not sufficient to maintain the fatigue resistance of these motor units, which is low.

244.14 **QUANTITATIVE ANALYSIS OF THE TEMPORAL RELATIONSHIPS AMONG HINDLIMB MOTONEURONS DURING FICTIVE LOCOMOTION IN THE CAT.** D.J. Kriellaars*, R.M. Brownstone, B.R. Noga and L.M. Jordan. Dept. of Physiology, University of Manitoba, Winnipeg, Canada, R3E OW3.

The nature of the central neuronal organization for mammalian locomotion is not well established. Controversy remains on whether or not a strict alternation of activity exists between flexors and extensors as predicted by a half-centre organization. Some researchers have suggested that the neuronal organization for locomotion has a multipartite nature (Stein, pp.245-253, in Comparative Neurobiology: Modes of Communications in the Nervous System, Ed: Cohen & Strumwasser, 1985.) from the observation that motoneuron populations for pluriarticular muscles (posterior biceps, semitendinosus, flexor digitorum longus) exhibit activity in both flexion and extension (i.e. are double bursting) or have activity which is "sandwiched" between extension and flexion. In paralyzed precollicular-postmammillary decerebrate cats, fictive locomotion was elicited by electrical stimulation of the mesencephalic locomotor region. Intracellular records of two lumbar motoneurons and bilateral electroneurograms (ENGs) from a variety of hindlimb peripheral nerves were simultaneously digitized. Dual intracellular records allow direct observation of the relationship of central pattern generator-related synaptic events in contrasting species of motoneurons. During locomotion, motoneurons exhibited membrane potential oscillations with locomotor periodicity called locomotor drive potentials (LDPs). The relationships among flexor and extensor LDPs and ENGs were statistically and quantitatively assessed by plotting the start time of flexor activity against the stop time of extensor activity and vice versa. We utilized the first derivative of the LDPs which proved to be a sensitive technique to detect coincident inflexion points in the simultaneously recorded motoneurons and their relationship to ENGs. The data indicate that the motoneuronal activity could be accounted for on the basis of a strict alternating output from the spinal central pattern generator. Observations from dual motoneuron records indicate that the excitatory drive creating a flexor LDP directly covaries with the inhibition of an extensor LDP. Comparison of double burst motoneurons with pure flexors or extensors demonstrates that these motoneuron pools receive both extensor and flexor excitatory drives and indicate that the extensor inhibitory drive may terminate the brief burst of activity during the flexion phase. These observations support the spinal module system for locomotion (Jordan et al, Soc. Neurosci. Abstr., Vol. 12, Part 2, p.877, 1986).

244.15 **EVIDENCE FOR A SPINAL MECHANISM REGULATING THE AFTERHYPERPOLARIZATION AMPLITUDE IN LUMBAR MOTONEURONES DURING FICTIVE LOCOMOTION IN THE CAT.** R.M. Brownstone, L.M. Jordan, D.J. Kriellaars *, B.R. Noga. Dept. Physiol., Univ. Manitoba, Winnipeg, Canada, R3E OW3.

It has previously been shown (Brownstone et al, Soc. Neurosci. Abstr., Vol. 12, Part 2, p.877, 1986) that the afterhyperpolarization (AHP) is reduced or eliminated during repetitive firing of cat alpha-motoneurones during fictive locomotion. It is now shown that this reduction in the AHP is not an all-or-none effect. At high firing rates, the AHP is completely abolished. The frequency-current (f-I) relation is then eliminated; i.e. there is no relation between current injected into the cell and the rate at which it fires. However, at lower firing rates, the AHP is reduced in amplitude rather than eliminated completely. At this time, the f-I relation is not abolished, but rather attains an increased gain as compared with the control, indicating that the AHP conductance is reduced rather than shunted. In some cells, the AHP may be modulated within each step cycle, producing a consistent change in firing pattern within each burst.

The reduction in the AHP is associated with locomotor-related spiking in the motoneurone. In a cell that is rhythmically active during locomotion but not firing, the AHP witnessed following short pulse current-evoked spikes is larger in amplitude during the depolarized phase of the locomotor drive potential (LDP) and smaller during the hyperpolarized phase. However, when the cell exhibits rhythmic spiking during the LDP, the AHP is reduced in amplitude.

The reduction in the AHP is related to the depolarized phase of the LDP. In the majority of cells into which short current pulses were injected to produce action potentials throughout the step cycle, there was a reduction in the AHP only during the depolarized phase. Also, when sustained depolarizing current was injected into the cell such that repetitive firing occurred during both the depolarized and hyperpolarized phases, there was a marked reduction in the AHP amplitude during the depolarized phase. The AHPs in the hyperpolarized phase were similar in amplitude to those elicited before the locomotor trial.

These data lead us to suggest that the mechanism responsible for reducing the amplitude of the AHP is intimately related to the central pattern generator for locomotion, and therefore likely resides within the spinal cord.

244.16 LOCUSTS LOAD COMPENSATE USING SEVERAL DISCRETE MOTOR STRATEGIES THAT CAN BE ELICITED, IN PART, BY STIMULATION OF A SINGLE SENSE ORGAN. S.N. Zill and K.A. Jepson*. Dept. of Cellular and Structural Biology, Univ. of Colo. Med. Sch., Denver, CO 80262.

Many animals show patterns of coordinated motor responses to load compensate and maintain postural stability when the substrate upon which they are standing is displaced. Human subjects, for example, respond with several discrete types of strategies when standing upon a moveable platform (Horak and Nashner, J. Neurophysiol. 55:1369, 1986): small and intermediate movements of the platform produce swaying at the ankle or hip joints, while large displacements produce 'steps', that is, movements of a whole leg to shift the base of support under the center of body mass. The particular leg sense organs that can mediate these different responses have not been identified in vertebrates. We have applied a similar paradigm to examine load compensatory responses of an invertebrate, the locust. Our results suggest that locusts use either joint swaying or leg 'stepping' strategies in load compensation and that a single identified joint receptor, the femoral chordotonal organ, may contribute to the mediation of both responses.

Locusts were restrained and myogram wires placed in the extensor and flexor tibiae muscles of both hindlegs. Animals were then released into a cage which was mounted on a swivel joint and driven by a motor. The motor produced repetitive displacements (rotations through a 45° arc at 0.7 Hz) of the cage and the substrate upon which the animal stood. Freely standing animals actively using the hindleg in postural support showed two general patterns of muscle activity in response to displacements of the cage. In one pattern, termed the resistance mode, tibial motoneurons fired repetitively at fixed phases in cycles of displacement. In another pattern, termed the flexion mode, animals moved the femoro-tibial joint to complete flexion and tonically fired the flexor muscle. The latter strategy apparently places the joint in a position to maximize stability of body support.

Both general types of responses can also be elicited by stimulating a single joint receptor of the hindleg, the femoral chordotonal organ, in both restrained and freely moving preparations. The present study has demonstrated that insects can load compensate and that a single proprioceptive sense organ can mediate load compensatory postural adaptations in several different modes of reflex action. We are currently examining the interneurons of the central nervous system that can mediate and modulate these reflex actions.

Supported by NIH Grant NS22682 and a Whitehall Foundation grant.

244.17 **KINEMATIC STRATEGIES OF WIPING IN SPINAL FROGS.** S. F. Giszter* and J. McIntyre* (SPON: E. Bizzi). Dept. Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Previous workers have shown that spinal frogs are able to wipe irritations from the body surface in a coordinated way. Because frogs adjust movements based on differing body configurations and stimulus positions, the spinal frog may be a model system to study the physiological mechanisms underlying coordinate transformations and trajectory formation. We have performed a detailed examination of wiping behaviors to answer the following questions about the kinematic strategies and control used to accomplish the wiping task: 1) How repeatable is performance for movements with similar target location and initial postures? 2) Are wiping trajectories continuously or discretely adjusted in response to variations in target location over the body and variations in body position? 3) What kind of adjustments are made in response to perturbations?

Bullfrogs (rana catesbaiana) were transected at the level of the fourth ventricle, while in leopard frogs (rana pipiens) the CNS anterior to the fourth ventricle was removed. Wipes were elicited with a vibrating stylus or glassfibre patches soaked in 5% sulphuric acid. Wiping in the two species were qualitatively similar. Movements were measured by digitizing limb positions in videotapes (30Hz sample rate), and using a Watsmart infrared camera system to obtain orientations of reference LED arrays attached to the frogs (100Hz sample rate).

1) To assess performance for similar targets we recorded wiping by one hindlimb to a stimulus applied to the contralateral hindlimb. In this behavior both legs move to an aiming position from which the effector limb moves to wipe the target limb. The unperturbed spinal frog reproduces these endpoint aiming positions in successive wipes within a range of several millimetres (body length ~15cm).

2) To evaluate aiming adjustments the aiming positions of the hindlimb for wiping to locations distributed over the back and forelimb were examined for continuous variations of target location and body configuration. A small discrete set of stereotyped endpoint locations and wipe directions were used by the wiping limb as opposed to a continuously varying adjustment to the continuously varied target location.

3) We also examined hindlimb to hindlimb wiping for evidence of adjustment to disturbances. Small unimposed variations of limb locations about the average aiming position showed no interlimb correlations. When large perturbations were made to the target limb in hindlimb/hindlimb wipes these resulted in terminated wiping movements rather than adjusted trajectories.

These results suggest spinal frogs use a discrete number of kinematic strategies to achieve successful wiping throughout the workspace. These strategies are performed with high endpoint accuracy relative to the requirements of the task. It seems that the spinal frog chains together a set of movements selected from a finite repertoire.

244.18 **THE INTERACTION BETWEEN SARCOMERE LENGTH CHANGE AND KNEE JOINT KINEMATICS DURING ISOMETRIC TORQUE PRODUCTION IN THE FROG.** R.L. Lieber and J.L. Boakes*. Division of Orthopaedics and Rehabilitation, University of California and Veterans Administration Medical Centers, San Diego, CA 92161.

INTRODUCTION: The purpose of this study was to measure sarcomere length, joint torque, and joint kinematics directly in order to determine the nature of the interaction between muscle properties and joint kinematics during isometric torque production.

METHODS: The dorsal head of the semitendinosis muscle from the grassfrog (Rana pipiens) was chosen for this study due to its well-established sarcomere length-tension relationship (Gordon et al. 1966). The muscle-bone complex, consisting of the pelvis, femur, tibia, and semitendinosis muscle, was placed into a chamber containing chilled frog Ringer's solution (14°C). In 10 specimens, the hip was immobilized at 90° of flexion and the knee manipulated through its range of motion from 0-160° of flexion at 10° intervals while measuring sarcomere length using laser light diffraction (Lieber et al. 1984).

Knee joint torque was determined at 10° intervals by, first, directly stimulating the semitendinosis muscle using bipolar electrodes placed along the muscle length and then calculating knee joint center of rotation at 10° intervals using methods similar to those described by Panjabi (1979).

RESULTS: A linear relationship was observed between sarcomere length and knee joint angle with sarcomere length ranging from 3.5 um at full knee extension to 2.5 um at 160° of knee flexion The regression equation fit to the data indicated that for each 10° increase in joint angle, sarcomere length decreased by about 70 nm.

Semitendinosis lever arm remained relatively constant (about 3 mm) throughout the range 0-160° with two small peaks at about 35° and 105° of flexion. Knee joint torque (calculated as the vector product of lever arm and measured contractile force) increased from 30% maximum at full knee extension, peaked at 140° of flexion, and then decreased to 75% of maximum at 160°.

DISCUSSION: The main result of this study was that maximum joint torque occurred at an angle (140°) which was neither the angle at which muscle force was maximum (160°) nor the angle at which the effective lever arm was maximum (90°). At the optimal knee joint angle (140°), sarcomere length was only 2.6 um corresponding to a muscle force of only 70% maximum. Optimal joint angle thus results from the interaction between muscle properties and joint kinematics and not either property alone.

244.19 **Role of Digastric in Jaw Opening While Chewing Gum of Different Size and Hardness at Various Frequencies.** B. Bishop, O. Plesh* and W. McCall. Depts. of Physiol. and Oral Medicine, State Univ. of New York at Buffalo, Buffalo, NY, 14214

Only fragmentary information exists concerning mechanisms controlling the initiation, extent and termination of jaw opening (JO) and the timing and level of activity in the digastric muscle during chewing. Thus, JO and digastric activity were assessed when pieces of gum of different hardness and size were chewed at different frequencies to obtain new information about control of JO and digastric activity by sensory feedback. Jaw movements in 3 planes were recorded with a Kinesiograph; digastric and medial pterygoid EMGs were detected from implanted wires; and anterior temporalis and masseter surface EMGs were recorded from the right side while adults with normal dentition chewed in time with a metronome set randomly at 46, 66, 100 and 160 BPM. Gums of two hardnesses (soft or hard), and sizes (10 x 18 mm and 0.7 gm, or 20 x 36 mm and 1.4 gm) were chewed on the right in random sequence at each frequency.

Onset of digastric activity never started before cessation of closer activity. When chewing at high frequencies (100 or 160 BPM), JO followed onset of digastric activity but at low frequencies (46 or 66 BPM), JO preceded digastric activity. During the delay the closer muscles were silent showing that the delayed opening was not due to residual closer activity. During slow chewing digastric activity ceased prior to or at peak opening but at high frequencies it ceased after peak opening. Burst duration of digastric activity, although surprisingly stable (238+59 ms) over all experimental conditions, was longer on soft gum than on the hard gum, regardless of gum size. In contrast, peak amplitude of digastric activity was greater on the large gum than on the small gum regardless of gum hardness. Gape was independent of chewing frequency, burst duration, and gum hardness. However, like the peak amplitude of digastric activity, gape was greater when chewing the large gum.

In summary, the onset of digastric activity with respect to opening depends on chewing frequency, whereas digastric burst duration remains relatively stable regardless of chewing frequency, gum size or gum hardness. Both peak amplitude of digastric activity and gape are larger when chewing the larger size gum. We conclude that even though the digastric muscle is a major jaw opening muscle, its activity does not correlate closely with initiation, extent or termination of mandibular opening. Concurrent behavior of all masticatory muscles determines timing and path of jaw movements. Supported by NIDR 5R01DE0671703.

244.20 LARYNGEAL MUSCLE ACTIVATION AND TIMING DURING RESPIRATION, VOCALIZATION, SPEECH AND SWALLOW. C. L. Ludlow, S. Sedory*, M. Fujita* and G. Schulz*. Human Motor Control Section, NINCDS, Bldg.10/5N226, Bethesda, MD 20892.

Activation and timing patterns of two intrinsic laryngeal muscles on each side were contrasted during speech and vocalization with activation patterns during respiration and swallow. Six normal adults, three female, consented to intrinsic laryngeal electromyography. Percutaneous concentric needles were employed to record from the thyroarytenoid (TA) and cricothyroid (CT) muscles on the left and right sides with simultaneous recording of respiratory and laryngeal movements and voice. The experimental conditions included quiet respiration, swallow, vocalization (extended vowel production) and speech (sentence repetition). The percent activation relative to the maximum peak activation during inspiration was computed for vocalization, speech and swallow. Similarly, the percent activation relative to the maximum peak during swallow was computed for respiration, vocalization and speech. Activation onset and offset times for each of the muscles during swallow, vocalization and speech were identified (when the level became > than 150% of the inspiration maximum for onset and < 150% above the minimum inspiration level for offset). The speed of activation was the peak of the first derivative of the rectified signal after averaging with a sliding window of 40 ms.

Mean activations were greater for the TA and CT muscles during inspiration. The peak activation times for the CT and TAs did not differ during either respiratory cycle, suggesting coordinated activation of these two muscles during respiration. The percent activation relative to inspiration was greatest during swallow for the TAs and during speech for the CTs. TA and CT activation onset times were most similar during swallow and phonation when the two muscles tended to act together. The greatest difference in TA and CT onset times occurred during speech when CT activation preceded TA activation. The peak velocity of activation was greatest early during phonation and swallow and later during speech, when associated with syllable stress. The percent increase in activation over inspiration levels were greater for the CTs than the TAs during speech and vocalization. The results demonstrated that laryngeal muscle activation during speech involves separate activation of the CT and TA muscles and a more complex activation pattern. These findings indicated why speech is more likely to be affected by motor control disorders of the laryngeal musculature, than phonation or swallow.

245.1 ANTIBODIES TO DYNORPHIN A (1-13) BUT NOT β-ENDORPHIN INHIBIT ELECTRICALLY-ELICITED FEEDING IN THE RAT. K.D. Carr, T.H. Bak*, T.L. Gioannini* and E.J. Simon. Department of Psychiatry, New York University Medical Center, New York, NY 10016.

The anorectic action of opioid antagonists has been confirmed in numerous animal models including the feeding elicited by lateral hypothalamic electrical stimulation in the rat (Carr & Simon, 1983, 1984; Jenck, Gratton & Wise, 1986). In the present study, highly specific antibodies to dynorphin A (1-13) and β-endorphin were administered ICV to determine the effect of selective peptide inactivation on electrically-elicited feeding. Over an 18 day period, each of seven rats was tested six times; twice under control conditions and twice following administration of each of the antisera. In each test session, stimulation intensity was fixed at 100 μa and four estimates of frequency threshold were obtained in serial order. Mean brain stimulation frequency threshold for eliciting feeding following vehicle infusions was 18.9 ±0.9 pulses per second (pps). Antibodies to dynorphin A (1-13) produced a significant increase in threshold to 28.4 ±2.7 pps ($p<.01$, $t=4.98$, matched pair, two-tailed test). Mean threshold following administration of β-endorphin antibodies was 20.9 ±2.4 pps ($p>.20$, $t=1.17$). Within test sessions serial estimates of feeding threshold increased progressively after administration of dynorphin antibodies (linear trend: $p<.01$, $F(1,18)=12.76$). This pattern is similar to that observed following systemic administration of naloxone (linear trend: $p<.01$, $F(1,27)=21.6$). Central dynorphin A, or one of the other opioid peptides derived from prodynorphin, recognized by the antiserum used, may be involved in the control of ingestive behavior. The anorectic action of naloxone may result from antagonism of dynorphinergic transmission, although a role for other opioid peptides cannot be ruled out.

245.2 SACCHARIN AVAILABILITY NOT PREFERENCE PROMOTES CROSS-TOLERANCE TO MORPHINE IN RANDOMLY BRED RATS. A. Acevedo-Cruz*, R. Knurowski*, and D. Novin (SPON: D.A. VanderWeele). Dept. of Psychology and Brain Research Institute, Univ. of California, Los Angeles, CA 90024.

The observation that ingestion of a palatable glucose-saccharin solution decreases the sensitivity of the analgesic effects of morphine in the rat has led to the suggestion that highly preferred sweet solutions elicit the release of endogenous opioids and lead to the development of cross-tolerance to morphine (Bergman et al., Beh. Neural Biol. 44: 347, 1985). Rats bred for high rates of hypothalamic self-stimulation show a marked preference for saccharin and also develop tolerance to morphine after exposure to saccharin solutions. Conversely, randomly bred rats show moderate preference for saccharin and an attenuated cross-tolerance to the opiate. Since albino rats show large individual differences in their preference for saccharin, and since it has been assumed that preference itself is the decisive factor in the development of morphine cross-tolerance, we tested whether rats with very different preferences for saccharin would differ in the development of the cross-tolerance. Rats with high (HI) and low (LO) preference for a 3mM saccharin solution were identified from a larger pool of rats and their sensitivity to the analgesic effects of morphine assessed in a hot plate test (HPL) after 21 days of access to the solution. A group of rats that had access only to water (W) served as control. Rats were housed in group cages of 4 rats each. Mean daily group intakes were: 310.7 (HI), 157.1 (LO), and 168.9 g (W). HPL values were obtained before (baseline), and at 15 and 30 min after the injection of saline or 2.5 mg/kg morphine. Both the HI and the LO groups showed cross-tolerance to the analgesic effects of morphine as compared to the W group. The HI and LO groups did not differ in their response to morphine. These results suggest that it is the ingestion of saccharin, regardless of preference, that leads to the development of cross-tolerance to morphine. Furthermore, an above-normal ingestion of fluid is not necessary to develop the tolerance, since the LO group became tolerant and ingested the same amount of fluid as the W group.

245.3 EFFECTS OF DOPAMINE AND OPIATE RECEPTOR BLOCKADE ON MORPHINE AND AMPHETAMINE INDUCED FEEDING: INTERACTIONS WITH SWEETNESS. K.R.Evans* and F.J.Vaccarino. (SPON: N. Mrosovsky). Dept. of Psychology, Univ. of Toronto, Toronto, Canada, M5S 1A1.

Previous studies have shown that morphine- (MOR) and d-amphetamine- (AMP) induced feeding can be differentiated when the treated animals are given the choice of sugar, sweetened chow (5% sugar) or unsweetened chow; MOR-treated animals increase their intake of all foods while AMP only increases the intake of sugar. The present studies examine possible interactions between the opiate and dopamine (DA) systems with regard to the differential MOR and AMP effects by combining their treatments with the DA antagonist alpha-flupenthixol (FLU) or the opiate antagonist naloxone (NX).

In the first experiment, rats were tested for MOR- (2.0 mg/Kg) and AMP- (0.25 mg/Kg) induced eating following treatment with FLU in doses of 0.0, 0.05, 0.10 or 0.20 mg/Kg. Intake of sugar, 5.0% sugar/chow mixture and chow was recorded for 1.5 h following drug treatment. Both AMP and MOR increased intake of sugar, which was under all conditions preferred to the other tastes, but MOR also produced small increases in intake of sweetened chow. FLU attenuated AMP-induced feeding at all doses, though only the highest dose attenuated MOR-induced feeding. 0.05 mg/Kg FLU increased intake of sweetened chow in MOR-treated animals. None of the doses of FLU had any effect on SAL-treated animals. In the second experiment rats were injected with NX in doses of 0, 0.125, 0.50 and 1.0 mg/Kg immediately prior to MOR- and AMP- treatment. NX attenuated MOR and AMP induced feeding at all doses. NX decreased feeding in SAL-treated animals only at the 1.00 mg/Kg dose.

Results suggest that the MOR-induced feeding is generally excitatory, whereas AMP has a more specific effect, possibly related to stimulus relevancy (ie. specific increases in sugar intake). Both MOR and AMP-induced feeding seem to require the integrity of DAergic and opiate systems, respectively. Further, since neither FLU or NX had any effect on the ability to discriminate between tastes or on their normal preferences, it is unlikely that endogenous DA or opiate mechanisms control these aspects of feeding behaviour.

245.4 MU OPIOID RECEPTORS IN THE AMYGDALA CONTRIBUTE TO THE CONTROL OF FEEDING. B.A. Gosnell. Dept of Physiology, University of Texas Health Science Center, Dallas, Texas, 75235

Opioid peptides stimulate feeding when injected into the lateral cerebral ventricle or directly into certain regions of the brain. In these experiments, highly selective opioid agonists were injected into the amygdala of rats to determine whether opioid peptides and receptors in this structure are involved in the regulation of food intake. The amygdala has been shown to contain moderate to high densities of opioid-containing fibers and cell bodies (Khachaturian et al., Trends Neurosci. 8:111-119, 1985).

Guide cannulas (unilateral) were implanted with the tips directed toward the central nucleus of the amygdala (AMYG) in male Sprague-Dawley rats. Injections (0.5 μl volume) were made via a cannula which extended 0.5 mm beyond the guide cannula. The peptides tested were Tyr-D-Ala-Gly-(Me)Phe-Gly-ol (DAGO), [D-Ser^2,Leu^5]enkephalin-Thr^6 (DSLET) and dynorphin A (DYN). These peptides represent selective agonists of mu, delta and kappa opioid receptors, respectively.

In the first experiment, DAGO, DYN and DSLET were injected at doses from 0.3 to 3 nmol. DAGO (3 nmol) significantly increased 4 hr food intake (2.6±0.8 g vs 0.5±0.4 g for NaCl-treated controls); DYN and DSLET had no effect. In the second experiment, DAGO increased intake at doses of 1 and 3 nmol. In a third experiment, injections of DAGO and DYN into the AMYG were compared to injections into the medial hypothalamus (HYPO). As expected, DYN (2 nmol) increased 2 and 4 hr intake when injected into the HYPO but not when injected into the AMYG. DAGO (2 nmol), however, stimulated intake when injected into either area. In the fourth experiment, bilateral injections of DAGO into the AMYG (3 nmol/side) were found to be no more effective than unilateral injections. Finally, the feeding effects of DAGO (3 nmol) were blocked by naloxone (25 μg, injected into the AMYG 1 hr after DAGO) and by β-chlornaltrexamine (1 μg, injected into the AMYG 4 hrs before DAGO).

Stanley et al. reported that AMYG injections of [D-Ala^2,Met^5]enkephalinamide stimulated food intake (Soc. Neurosci. Abstr. 10:1103, 1984). The present results support this finding and suggest that mu rather than kappa or delta opioid receptors in the AMYG contribute to the control of feeding. Further, the AMYG appears to differ from the HYPO in relation to the receptor types involved.

245.5 THE EFFECT OF THE MU OPIOID LIGAND, [D-Ala^{2}MePhe^4,-Gly-ol^5] ENKEPHALIN (DAGO) ON FOOD INTAKE IN DIABETIC AND NON-DIABETIC RATS. A.S. Levine, M. Grace*, B.A. Gosnell, C.J. Billington*, Neuroendocrine Research Laboratory, VA Medical Center and Department of Food Science and Nutrition, University of Minnesota, Minneapolis/St. Paul, MN, 55417.

Glucose is known to alter the responsiveness of laboratory animals and humans to a number of opioid effects including nociception, smooth muscle contractility, behavioral tolerance and energy intake. Agonists of the mu, delta and kappa opioid receptor have been shown to increase short-term food intake after intraventricular administration. In the present study we evaluated the effect of central administration of the mu opioid ligand, DAGO, on food intake in diabetic and non-diabetic rats. Male rats were injected with streptozotocin to induce diabetes and cannulas were placed in the right lateral ventricle. In the first study, saline, 1 nmol, 3 nmol or 10 nmol DAGO were injected into a group of diabetic and non-diabetic controls. DAGO failed to stimulate feeding in the non-diabetic rats and only slightly stimulated feeding in the diabetic rats following the initial injection (diabetics: saline = 0.6 ± 0.6 ; 1 nmol = 3.1 ± 0.6; 3 nmol = 3.4 ± 0.4; 10 nmol = 4.9 ± 1.6 g/4 hr ($p < 0.05$); non-diabetics: saline = 0.9 ± 0.5; 1 nmol = 1.1 ± 0.6; 3 nmol = 2.5 ± 1.0; 10 nmol = 1.7 ± 0.5 g/4 hr). After repeated administration the diabetic rats appeared to be more sensitive to the administration of DAGO compared with the control rats. To study this phenomenon in greater detail we injected a different group of diabetic and non-diabetic animals with saline or 10 nmol DAGO (n = 11 per group) and injected them with drug or vehicle twice daily at 0900 hr for a period of five days. Food intake was measured on days 1, 2 and 5; four hours after injection of DAGO. On days 3 and 4 animals were injected with drug or vehicle but food intake was not measured. The effect of repeated injections of DAGO on 4 hour food intake was much more pronounced in the diabetic rats compared to their controls (diabetic rats: day 1 = 1.3 ± 0.6; day 2 = 3.7 ± 0.5; day 5 = 6.8 ± 1.0 g/4 hr. non-diabetic rats: day 1 = 2.4 ± 0.5; day 2 = 0.8 ± 0.4; day 5 = 3.3 ± 0.7 g/4 hr). Saline injection did not alter food intake over the 5 day period in either diabetic or non-diabetic animals. The results of these studies indicate that the mu opioid ligand, DAGO, stimulates feeding in a more reliable fashion after repeated injection. In addition, this "sensitization" is more pronounced in diabetic rats compared with non-diabetic controls. These data further support the concept that the effect of opioids on food intake are different in diabetic animals compared to their euglycemic controls. This work was supported by NIDA 1R01-DA03999-01 and the VA.

245.6 NALOXONE IMPAIRS ACQUISITION IN AN ACTIVE AVOIDANCE PARADIGM IN RATS. G.A. Olson, F. Gundy*, A.J. Kastin, M.F. Pignatiello*, and R.D. Olson. Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148 and V.A. Medical Center, New Orleans, LA 70146.

Although most studies have demonstrated the facilitory effect of naloxone on memory, few have used the active avoidance paradigm. Those that have used it produced contradictory evidence, with findings of enhancement, interference, or no effect with naloxone. No clear-cut variables, such as doseage, task, or species accounted for the differences.

In this study 24 Sprague-Dawley-derived albino rats aged 84-106 days and weighing 342-479 g were placed in a traditional escape/avoidance, bar-press paradigm with a 15 sec warning signal (light), a shock intensity calibrated at 0.511 mA and maximum duration of 30 sec, and a mean ITI of 60 sec (ranging 48-72 sec). Rats were administered either naloxone (0.01 mg/kg) or diluent IP. Injections were given immediately before placing the rats in the apparatus for 10 min of habituation, after which conditioning began. Twenty-five trials were administered each day for 3 consecutive days, followed by a day with 5 warm-up trials and then 25 extinction trials. In extinction half of each group received naloxone and half diluent.

Naloxone impaired acquisition, as indicated by significant day by drug interactions in the ANOVAs for measures of number of avoidances and number and latency of bar presses (avoidances and escapes). In general, the naloxone group showed little learning, but the diluent group did learn by the third day. Extinction results were confounded by the lack of learning by the naloxone group and were not affected by the drug given during extinction itself.

To determine if naloxone simply lowered the pain threshold, thus affecting learning indirectly, a tail-flick test was performed after the same dose of naloxone or diluent (n = 20). All rats were given four trials starting 10 min after the injection; the most deviant score was discarded, and the mean of the remaining three was used. There were no significant differences between the two groups, suggesting that there was no alteration of the pain threshold to account for the differential learning.

Thus, a small dose of naloxone given before training interfered with the acquisition of an active avoidance response in rats.

245.7 ENHANCEMENT OF SUCROSE INTAKE BY THE KAPPA OPIOID AGONIST U-50,488H PERSISTS BEYOND THE PERIOD OF DRUG EXPOSURE. W.C. Lynch and G. Burns.* Department of Psychology, Montana State University, Bozeman, MT 59717.

Opioid agonists are known to facilitate food intake motivated by deprivation, taste, and various other treatments (For review see Levine, A.S., et al. Br. Res. Bull., 14: 663-672, 1985). Suggested interpretations include the possibility that opioids directly stimulate hunger, that they enhance food palatability, or that they reinforce taste preference learning. The present experiment examined the acquisition of a preference for sucrose solutions in naive rats. One purpose was to determine whether mu or kappa agonists given in repeated association with sucrose intake might facilitate preference learning. A second purpose was to determine whether or not drug-induced facilitation of intake persists beyond the period of drug exposure. Forty naive male Holtzman albino rats were randomly assigned to 4 groups. Each day for 15 days (5/week), all animals received a 30 min 2-bottle intake test in which they could select either sucrose (20%, w/v) or tap water. Animals were nondeprived and received injections 30 min before each intake test. Group U-50L received a low dose (0.1mg/kg, sc) of the kappa-selective agonist U-50,488H; group U-50H received a high dose (1.0 mg/kg, sc) of the same drug; group MOR received a moderate dose of morphine sulfate (1.0 mg/kg, sc); and group SAL received a 1 ml/kg (sc) injection of normal saline vehicle. After 10 days of testing, all animals were shifted to SAL injections and intake testing continued for 5 more days.

Preliminary analyses indicate that both morphine and the high dose of U-50,488H inhibit sucrose intake, whereas the low dose of U-50,488H consistently facilitates intake. More importantly, following drug withdrawal the 4 groups maintain these acquired preference differences. This suggests that the low dose of U-50,488H facilitates sucrose intake through an effect on learning and that an established preference is maintained in the absence of further drug treatment. Analysis of within session lick patterns on the 10th day of testing showed that U-50L treatment facilitates intake (relative to SAL) only during the 3rd through the 7th min of the session. This confirms previous reports that opioid agonists affect the continuation rather than the initiation of intake, perhaps due to enhanced gustatory feedback. The failure of U-50H to facilitate intake suggests the importance of receptor selectivity. At the higher dose, U-50,488H inhibited intake in a manner similar to that seen with the mu agonist morphine. Perhaps at this higher dose U-50,488H binds sufficiently to mu receptors to produce morphine-like inhibitory effects that counteract its facilitative effect on the development of preference.

This work was supported in part by a grant to WL from the NSF/MONTS EPSCoR Program (ISP 8011449).

245.8 CHANGES IN IN VIVO OPIATE RECEPTOR BINDING WITH FEEDING IN THE RAT. E.A. Stein. Dept. of Biology, Marquette Univ., Milwaukee, WI, 53233.

It has become apparent that one or more endogenous opioid peptides plays an as yet unspecified role in mechanisms related to consummatory behavior. Opioid antagonists have been shown to suppress feeding (and drinking) when administered centrally or peripherally while agonists generally increase feeding. Central drug administration as well as measurements of peptide levels have begun to map those central sites mediating this behavior. To extend this inquiry, we have utilized an in vivo receptor autoradiography procedure to further delineate those areas which show altered opiate receptor binding after this behavior.

Male Holtzman rats are implanted with chronic jugular catheters and then assigned to either an ad lib feeding group or a 23 hr food deprived (water available ad lib) group for 7 to 10 d. On the day of sacrifice, water is removed from all cages and ½ of the ad lib group is given non-caloric, sweetened chow pellets to which they had been previously exposed. Likewise, ½ of the deprived group were given their daily food, while ½ received no food. Thus four groups were defined: ad lib, ad lib plus palatable, 23 hr deprived, and 23 hr deprived plus food. All animals received .002 mg/kg 15,16 ^{3}H Diprenorphine (Dpr) through the chronic connulae, permitted to eat for 15 min, then returned to their home cage for 5 min to complete nonspecific binding work out. Rats were then decapitated, brains rapidly removed, stored at -70°C until sectioned. Sections (20μ) were cut at -15°C, mounted onto glass slides, dried on a slide warmer and exposed to ^{3}H sensitive film (LKB Ultrafilm) for 4-6 weeks in standard x-ray cassettes (Wolf).

Autoradiograms were analyzed by the ROD method of Gallistel et al., using a Spatial Data 850 Image Analyzer. Grouped data were subjected to analyses of variance followed by student Neuman Kuels analysis. Areas analyzed include the cingulate, frontal cortex, nucleus accumbens, caudate, diagonal band, olfactory tubercle and pirform cortex. Data will be discussed with respect to the modulation of feeding and/or reinforcement mechanisms by opioids.

Supported in part by NIDA grant #DA02234 and funds from the Graduate Dean's Office.

245.9 ATYPICAL ENDOGENOUS OPIOID SYSTEMS AND AN AUTO-ADDICTION OPIOID MODEL OF ANOREXIA NERVOSA Mary Ann Marrazzi, Dept. Pharmacology, Wayne State University School of Medicine, Detroit, Michigan 48201

We have proposed that an atypical opioid system in the BALB/C mouse may resemble that in anorexia nervosa patients and may be involved in the etiology of the disorder (Buck & Marrazzi, 1987). Morphine causes sedation and increases food intake and blood glucose in most species including normal human subjects. In contrast, in BALB/C mice morphine decreases food intake and blood glucose and increases motor activity. This combination of hyperactivity and anorexia also characterize anorexia nervosa. These atypical morphine responses are very interesting in light of a critical role of endogenous opioids in the pathophysiology of anorexia nervosa proposed by our auto-addiction opioid model (Marrazzi & Luby, Int. J. Eating Disorders 5:191- 208, 1986). According to this hypothesis, an initial period of dieting induces the release of endogenous opioids, which then induce a positively reinforcing elation and an addiction to dieting. Endogenous opioids may play a dual role in responding to starvation. They increase food intake to correct it, and they adapt for survival until it is corrected. The latter may involve a down-regulation of function to an essential minimum. If these two responses become uncoupled and addiction occurs to only one component, eating disorders could result. Different balances of these responses may result in different responses to morphine in typical and atypical species, reflecting differences in the underlying opioid systems. Some of the atypical opioid systems may result in a biological predispositon to anorexia nervosa. There is also evidence of opioid release with starvation and for a disturbance of endogenous opioids in anorexia nervosa. The clinical picture of anorexia nervosa resembles that observed in addictive disorders. Narcotic antagonists may be therapeutically useful in interrupting the addictive cycle (Luby, Marrazzi & Kinzie, J. Clin. Psychopharmacol. 7:52-53, 1987 and companion abstract).

In this context, the atypical endogenous opioid systems will be further characterized using strain comparisons and the selective kappa subtype of opioid agonist, U50,488. A spectrum of endogenous opioid systems have been previously described in mice with reference to other opiate actions.

245.10 TREATMENT OF EATING DISORDERS WITH NARCOTIC ANTAGONISTS. Elliot D. Luby* and Mary Ann Marrazzi (Spon. Helene C. Rauch), Depts. of Psychiatry and Pharmacology, Wayne State University School of Medicine, and Dept. of Psychiatry, Harper-Grace Hospitals, Detroit, Michigan 48201.

The auto-addiction opioid model of chronic anorexia nervosa that we have proposed (Marrazzi, M.A. and Luby, E.D., Int. J. Eating Disorders 5:191-208, 1986) suggests that narcotic antagonists may be useful to interrupt the addictive cycle in the treatment of eating disorders. Our initial studies look promising and will be presented here. According to the auto-addiction model, endogenous opioids are released during an initial period of dieting which then cause a positively reinforcing elation and a self-perpetuating addiction. The clinical picture in anorexia nervosa resembles that of addictive disorders. Elevated total endogenous opioid activity in the CSF of anorexia nervosa patients has been reported. Evidence also suggests endogenous opioids are released during food restriction. Although the endogenous opioids increase food intake, they may play a dual role in the response to starvation. They also adapt the organism for survival until the starvation is corrected, by down-regulating function to an essential minimum. This is based on a number of parallels of opiate actions and known adaptations to starvation. If these two responses become uncoupled and addiction occurs to only one of them, eating disorders could result. Addiction to the elation and/or down-regulation without the concommitant opioid drive to eat could result in anorexia nervosa. Addiction to the opioid drive to eat could result in bulimia. Thus, opiate blockade may be useful to interrupt the addictive cycle in the treatment of both anorexia and bulimia. Our initial sutdies with long-acting orally active narcotic antagonists in both anorexia nervosa and bulimia will be reported.

245.11 FEEDING BEHAVIOR IN ADULT RATS EXPOSED NEONATALLY TO OPIATE DRUGS. J. A. Stuckey*, T. R. Insel, and D. C. Jimerson. Laboratory of Clinical Science, NIMH, Bethesda, MD 20892.

Previous studies have shown that neonatal treatments of rats with opiates produce changes in opiate receptors that persist into adulthood (Tsang and Ng, 1980; Handelmann and Quiron, 1983). These receptor changes are associated with changes in behaviors which are thought to be mediated in part by endogenous opiates (Zagon and McLaughlin, 1980; Dow-Edwards and Handelman, 1985). Neonatal treatment of rats with morphine has been shown to accelerate the appearance of naloxone induced suppresion of feeding in rat pups (Aroyewun and Barr, 1983). In this study we are investigating the effects of neonatal treatment of rats with a variety of opiate drugs on adult feeding behavior.

On the day of birth, male pups were randomly assigned to litters of 7-8 pups per litter. On days 1-7 pups received subcutaneous injections of morphine, tifluodom, or naltrexone (0.5 mg/kg dissolved in saline) or saline as vehicle control. Treatments were randomized among the litters, with 7-8 pups receiving each treatment. On day 21 the pups were weaned, and on day 42 placed in individual cages. Rats were adapted to an 18 h food deprivation schedule in which they received a test diet of evaporated milk diluted 1:1 with a 10% w/v sucrose solution for one hour, followed by 5h access to solid pellets as maintanance diet. After adaptation to the testing schedule, rats received s.c. injections of saline or naloxone dissolved in saline 30 min prior to access to the test diet.

After saline injection, the thirty minute intakes were not significantly different between the neonatally treated groups, although the animals treated with morphine neonatally ate slightly more than the animals treated neonatally with saline: saline (19.3 +/- 1.1), morphine (22.3 +/- 1.6), naltrexone (20.2 +/- 1.1), tifluodom (20.8 +/- 1.3), (values are ml +/- SEM). There was a significant difference between groups in percent inhibition of 30 minute intakes by naloxone, $F(3,26)=4.82, p<0.01$, and a significant effect of dose of naloxone, $F(1,26)=13.73, p<0.01$. With 0.1 mg/kg naloxone, both the morphine group (37 +/- 5) and the tifluodom group (35 +/- 5) were significantly different from the saline group (22 +/- 7), $p<0.05$, while with 1.0 mg/kg naloxone only the morphine group (54 +/- 8) was significantly different from the saline group (33 +/- 5), $p<0.05$, (values are percent inhibition +/- SEM).

Neonatal pretreatment with morphine and tifluodom appear to have long term effects on naloxone's inhibition of feeding in adults. Further tests of feeding behavior using other paradigms are being conducted with rats treated neonatally with opiate drugs to determine the full extent to which such treatments may effect feeding behavior. At the completion of behavioral testing brain opiate receptors will be assayed to determine if potential alterations in opiate receptors are correlated with changes in feeding behavior.

245.12 COMPARATIVE EFFECTS OF CCK-8 AND ANALOGS ON ANORECTIC ACTIVITY AND IN VITRO GALL BLADDER CONTRACTION. J. Blosser, S. Augello-Vaisey, M. Barantes, J. Comstock, D. Gawlak, M. Towne, R. Simmons, J. Rosamond. Pharmaceutical Division, Pennwalt Corporation, Rochester, NY 14623.

Cholecystokinin octapeptide (CCK-8) is a potent anorectic peptide which exerts a variety of peripheral effects, including contraction of smooth muscle in gall bladder and intestine and secretion of pancreatic enzymes. Although it is known that certain structural features of CCK-8, such as tyrosine-O-sulfate and the C-terminal heptapeptide are required to elicit these varied responses, possible differences in receptor specificity have not been well explored. We have prepared a series of 13 monosubstituted CCK-8 derivatives comprised of sequential D-amino acid substitutions at each position, or other replacements of the methionines and the N-terminal aspartic acid residue. The present study has compared the potency of these analogs to inhibit food intake with their potency to stimulate guinea pig gall bladder contraction in vitro. Anorectic potency was measured in male Sprague-Dawley rats, trained to eat powdered chow on a 21 hour fast, 3 hour feeding schedule. Different doses of each peptide were administered ip and the dose which inhibited food intake by 50% for the first half hour of feeding was calculated with the aid of the ALLFIT multiple curve fitting program. Analogs with D-amino acid substitutions in positions 1 or 2 (counting from the N-terminus) retained good anorectic activity (ED50 = 1-8 nmol/kg). Single D-amino acid substitutions in positions 3 through 8 showed decreased anorectic activity relative to CCK-8 (9-50 fold). Substitution of methionine in position 3 with methionine sulfoxide did not alter anorectic potency. However, a similar substitution of methionine in the 6 position decreased activity 5 fold while an aminohexanoic acid substitution enhanced anorectic activity 8-fold. In general, similar changes were observed in in vitro gall bladder contractile potencies and a positive correlation could be shown between anorectic and in vitro gall bladder contraction activities ($r=0.86$, $p<.05$, $n=14$). A notable exception was an analog with a succinic acid substituted for aspartic acid in the position 1 which was 80 times more potent in inhibiting food intake but only equipotent to CCK-8 in eliciting gall bladder contraction (EC50=3.5 nM). This apparent disparity may be due, in part, to a greater stability of the succinyl derivative, as evidenced by the greater resistance of succinyl derivatives to aminopeptidase activity in vitro. In conclusion, a positive correlation could be demonstrated between the ability to inhibit food intake and to stimulate gall bladder contraction of the series of mono substituted CCK-8 derivatives. It appears that receptors which mediate these diverse effects are highly similar in their structural specificity.

245.13 CHOLECYSTOKININ ADMINISTRATION DOES NOT INFLUENCE TASTE-EVOKED ACTIVITY IN RAT NTS. B. K. Giza*, T. R. Scott and R. F. Antonucci* (SPON:L. C. Skeen). Dept. of Psych. and Inst. for Neurosci., Univ. of Delaware, Newark, DE 19716.

Physiological factors associated with satiety have been shown to influence taste-evoked neural activity at several levels of the nervous system. Gastric distension, hyperglycemia and moderate hyperinsulinemia are all associated with a decrease in responsiveness to sugars and, less reliably, to other taste qualities. Cholecystokinin (CCK) is a gut hormone and putative neurotransmitter that has been found to induce satiety in a variety of species, including the human. While its effects are known to be vagally mediated, the mechanism and site of CCK's action are unknown. There has been speculation that the satiety effect induced by its exogenous administration could be mediated by alterations in taste sensitivity. We monitored multiunit taste-evoked activity in the nucleus tractus solitarius (NTS) of anesthetized rats during intravenous administration of either plasma (controls) or either 2 or 6 ug/kg CCK-8, quantities sufficient to depress feeding significantly in behavior tests. Taste stimuli were 1.0 M glucose, 1.0 M fructose, 0.1 M NaCl, 0.03 M HCl and 0.01 M quinine HCl. We found no significant changes in responsiveness to any stimulus in the 30 min period following CCK administration. Possible interpretations of this result include 1)the dose of CCK may have been inadequate. While behaviorally salient, 2.0 ug/kg is a small experimental dose. At 6.0 ug/kg, however, CCK probably approaches its threshold for induction of malaise, and so higher doses are to be avoided. Gosnell and Hsaio found no effect of CCK on chorda tympani activity even at 5.0 ug/kg, but a modest response facilitation at 10 ug/kg. The broad physiological effects of a dose of this magnitude, however, make conclusions tenuous. 2)There could be an effect on taste responses that is not apparent in NTS. This is improbable in the rat where NTS is an obligatory synapse and also receives centrifugal projections from both thalamo-cortical and ventral forebrain taste areas. 3)CCK may be a satiety factor whose mechanism does not involve the taste system. 4)CCK may not be a true satiety factor. Evidence supporting its candidacy is strong, yet there are studies whose results suggesting that CCK suppresses feeding only as a consequence of the malaise induced by the quantities administered in many experiments.

245.14 INTERACTION OF CCK RECEPTOR AGONISTS AND ANTAGONISTS WITH PERIPHERAL TYPE CCK RECEPTORS IN THE BRAINSTEM AND PYLORIC SPHINCTER: EVIDENCE FOR DISTINCT RECEPTOR SUBPOPULATIONS. T.H. Moran, L. Shnayder*, R.T. Jensen*, T.K. Sawyer* and P.R. McHugh. Department of Psychiatry, Johns Hopkins Univ., Baltimore, MD, 21205, Digestive Diseases Branch, National Institutes of Health, Bethesda, MD, 20892, Biopolymer Chemistry, Upjohn Co., Kalamazoo, MI, 49001.

We have previously demonstrated the differentiation of central and peripheral type CCK receptors. Binding to peripheral (Type A) receptors is sulphate dependent. In the rat, these recpetors are found in the pancreas, pyloric sphincter, vagal trunk and branches and within the brainstem in the nucleus tractus solitarious (NTS), area postrema (AP) complex. In the present study, we have examined the ability of CCK agonists and antagonists to inhibit the binding of 125I CCK-8 to CCK receptors in the forebrain (Type B receptors), in the brainstem NTS and AP (Type A) and in the pyloric sphincter (Type A). The agonists were a series of CCK analogs with substitutions at various points in the peptide chain. While the potencies of the five agonists varied, two distinguished Type A from Type B receptors, but all showed the same affinity for brainstem and pyloric receptors. A different pattern of results was found for the CCK antagonists. Of the four proglumide derivatives, the potencies (IC50's) for inhibiting binding were uniformly higher for the Type A receptor. Furthermore, compounds 1453 and 1398 demonstrated significantly higher affinities for the pyloric receptor than for the brainstem receptor (1453: pylorus 160 nM, NTS-AP 2.8 uM; 1398: pylorus 180nM, NTS-AP 4.2 uM). The IC50's for 1409 demonstrated an 8 fold higher affinity for the pyloric receptor (120 nM vs 960nM), while 1287 showed an equal affinity (10 uM) for the two sites. The benodiazapine derivative, L-364 (Merck) clearly differentiated peripheral from brain CCK receptors and demonstrated a somewhat greater affinity for the pyloric receptor. Together, these results affirm the Type A / Type B receptor distinction and suggest that peripheral (Type A) CCK receptors represent at least two further subtypes differentiated on the bases of affinities for CCK antagonists. This distinction may allow the identification of the site of action for the satiety effect of CCK. (supported by AM-19302)

245.15 POTENCY OF L-364,718 ON THE BEHAVIORAL ACTIONS OF PERIPHERALLY ADMINISTERED CHOLECYSTOKININ. S. Khosla* and J. Crawley, (Spon: J.N. Crawley) Clinical Neuroscience Branch, National Institute of Mental Health, Bethesda, MD 20892

A newly synthesized antagonist of cholecystokinin, 3S(-)-N-(2, 3-dihydro-1-methyl-2-oxo-5-phenyl-1H-1, 4-benzodiazepine-3-yl)-1H-indole-2-carboxamide (L-364,718), was tested for its ability to block the actions of intraperitoneally administered cholecystokinin (CCK) octapeptide sulfate on feeding and exploratory behaviors. CCK (10 µg/kg i.p.) significantly reduced consumption of a palatable cookie mash to 40% of saline vehicle control levels in a 30-minute free-feeding session, and induced pauses of behavioral inactivity averaging 83 seconds/5 minute session, in male, Swiss-Webster mice fasted overnight. L-364,718 significantly blocked the reductions in feeding and exploration induced by CCK, at doses of the antagonist from 500 ng/kg to 10 mg/kg i.p. Time course analysis showed that the antagonism by L-364,718 (10 µg/kg i.p.) of the behavioral actions of CCK (10 µg/kg i.p.) persisted for at least 60 minutes. These data are consistent with the inital reports by Chang et al.[1] and Lotti et al.[2], indicating that L-364,718 is a potent antagonist of CCK at peripheral CCK receptors.

245.16 THE EFFECT OF ALTERATION OF HORMONAL STATUS OF MALE AND FEMALE RATS ON CHOLECYSTOKININ'S SATIETY EFFECT: PITUITARY IMPLANTS AND NEONATAL STEROID HORMONE TREATMENT. S.A. Wager-Srdar*, J.E. Briggs*, and A.S. Levine (SPON: D. Krahn). Neuroendocrine Res Lab, VA Medical Center and Dept of Food Science and Nutrition, University of Minnesota, Minneapolis/St. Paul, MN 55417.

Several gut-brain peptides are putative satiety factors. It has been reported that reproductive state of the rat affects responsiveness to the short term satiety effects of glucagon, bombesin and cholecystokinin. Cholecystokinin (CCK) is the most extensively studied of the gut petides. Studies utilizing cycling and ovariectomized female rats show that the reliability of CCK's satiating effect is modulated by the level of sex hormones present and the sensitivity of the female rats to CCK's satiating effect varies during lactation.

To further examine the influence of sex hormonal status on CCK's satiating effect, levels of prolactin and gonadal hormones of rats were experimentally altered. Pituitaries from littermate donors were implanted under the kidney capsules of male and female rats which moderately elevated prolactin levels in recipient animals (4-6x). Moderately elevated prolactin did not alter the responsiveness of pituitary implanted male and female rats to CCK compared to sex matched sham operated rats. Another group of female littermates were injected with estradiol on neonatal day 3 and 5. Adult female rats had elevated prolactin levels, delayed sexual maturation and prolonged or anestrous cycles. Neonatal administration of steroid hormones may alter the differentiation of sexually dymorphic regions of the brain. Age-matched cycling and neonatal estrogenized rats were sensitive to CCK's satiating effect.

Effect of CCK (10 µg/kg) on Food Intake

Males	↓	($p < 0.05$)
Females (sham-operated, cycling)	-	N.S.
Females (pituitary implants)	-	N.S.
Cycling females	↓↓	($p < 0.05$)
Neonatal estrogenized females	↓↓	($p < 0.05$)

Sham operated cycling female rats were insensitive to CCK's effect and their response was significantly different from other groups studied ($F(5,84) = 4.642$, $p < 0.05$). The findings of these preliminary studies re-confirm that responsiveness to CCK's satiating effect is altered by reproductive status. It does not appear that moderate elevation of prolactin levels effects this response but more extensive studies are required to confirm these findings.

245.17 OXYTOCIN SECRETION AND DECREASED GASTRIC EMPTYING RATES PARALLEL THE INHIBITION OF FEEDING PRODUCED BY LITHIUM (LiCl) AND CHOLECYSTOKININ (CCK). Monica J. McCann*, Joseph G. Verbalis, and Edward M. Stricker. Department of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Many chemical agents produce a decrease in food intake when administered to rats. However, it is not always clear whether the decrease in food intake results from satiety or from visceral illness. Consequently, we have initiated studies to determine whether biological measures, plasma oxytocin (OT) levels and gastric emptying rates, could discriminate between these two states. More specifically, the effect of LiCl and CCK on OT secretion was compared with plasms OT levels observed in association with feeding.

We found that CCK (10 ug/kg) and LiCl (3-6 mEq/kg) led to 5-10-fold elevations in plasma OT levels. These elevations were far greater than those observed after ingestion of a large meal or distention of the stomach with isotonic saline. Two- to three-fold increases in plasma OT levels also were observed after lower doses of these agents. Thus, high levels of plasma OT appear to be associated with conditions presumed to reflect visceral illness, whereas low stimulation of OT release does not discriminate between satiety and gastric illness. Gastric emptying rates were slowed both by LiCl and CCK, as is observed after infusions of calories into the intestines. Thus, it is unlikely that changes in gastric emptying rates discriminate between illness and satiety.

A second series of experiments examined the extent to which these biological measures predicted food intake in rats. A range of inhibition of feeding was produced by varying the administered dose of LiCl or by giving CCK to animals that had been totally or partially vagotomized by surgery. Peak plasma OT levels after injection of LiCl or CCK were related exponentially to the reductions in food intake ($r = 0.78$). CCK was less able to affect food intake, OT secretion, or gastric emptying when an afferent vagotomy was produced by systemic injection of the neurotoxin, capsaicin. However, in all animals, the inhibition of feeding always lasted much longer than the induced elevation in plasma OT whereas the reduced rates of gastric emptying appeared to have the same time course as the inhibition of food intake.

To summarize, OT secretion and gastric emptying each correlate strongly with food intake in rats, and these interrelated biological measures can be used to study the control of food intake. However, peak changes in plasma OT predict the degree of inhibition of food intake, whereas gastric emptying rates predict the duration of inhibition.

245.18 HINDBRAIN SINGLE UNIT RESPONSES TO GASTRIC DISTENSION AND CHOLECYSTOKININ IN NORMAL AND CAPSAICIN TREATED RATS. S Ritter, RC Ritter, WR Ewart*, DL Wingate*. College of Veterinary Medicine, Washington State University, Pullman WA 99164. WOI Regional Program in Veterinary Medicine, University of Idaho, Moscow, ID 83843 and *Gastrointestinal Science Research Unit, London Hospital Medical College, London E1 2AJ, England

Termination of ingestion involves both mechanical and chemical signals from the gastrointestinal tract. Some of these signals are conveyed to the brain by vagal sensory neurons and there is interaction or integration of various sorts of vagal sensory information in the dorsal hindbrain (Ewart and Wingate, 1984). The neurotoxin, capsaicin, destroys small diameter sensory neurons, including a subpopulation of vagal sensory neurons (Dinh and Ritter, 1986). Recently, Ritter and Ladenheim (1985) reported that capsaicin pretreatment attenuates CCK-induced suppression of food intake but fails to attenuate intake suppression by gastric preloads. These findings, along with other data from our laboratories, suggests that capsaicin might reduce sensitivity to some gastrointestinal sensations while not impairing sensation of others. In order to test this hypothesis, we recorded from single neurons in the nucleus of the solitary tract (NTS) and the dorsal motor nucleus of the vagus (DMV) of rats previously treated with capsaicin or its injection vehicle. Recording was begun 2 weeks after capsaicin treatment. We searched for units in an area from obex to 250 um rostral to obex and 200 um lateral to obex on either side. The maximum depth of our search was 1.1 mm down from the surface. We selected spontaneously active single units whose firing rate was increased or decreased by at least 50% during a 2 ml, 30 sec gastric distension. We then tested these units for their response to near gastric arterial infusion of saline (0.2 ml), CCK-8 (8 and/or 80 ng/0.2 ml) and gastrin (G17). We have recorded 16 units from capsaicin treated rats, 27 units from vehicle treated rats and 7 units from rats receiving no pretreatment. In normal and vehicle treated rats, neurons responding to gastric distension were readily identified and nearly all of these units also changed their firing rate in response to CCK-8. In capsaicin treated rats, gastric distension responsive units were also readily identified. However, most of these units did not respond to CCK or exhibited an attenuated response. Thus, it appears that pharmacologically separable populations of gastrointestinal afferents interact postsynaptically in the dorsal hindbrain. These results are consistent with anatomical findings indicating that capsaicin damages a subpopulation of vagal afferent neurons and support previous data indicating that capsaicin attenuates the behavioural response to CCK but not the response to gastric distension. 245.19 EFFECT OF CHOLECYSTOKININ, BOMBESIN, AND GASTRIN ON GASTRIC EMPTYING AND SATIETY IN THE RAT. K.L. Conover*, S.M. Collins* and H.P. Weingarten (SPON: G.K. Smith). Department of Psychology and Intestinal Disease Research Unit, McMaster Univ. Hamilton Ontario Canada L8S 4K1.

The ability of four gut peptides to inhibit gastric emptying and induce satiety was assessed in the rat. Rate of gastric emptying was measured using a double-sampling procedure after an intragastric infusion of 10 mls of 0.9% saline (Conover et al., Physiol Behav 39: 303-308, 1987). Satiety was assessed in normally feeding rats eating a 15% sucrose solution.

Cholecystokinin octapeptide (CCK-8) in a dose range that retarded gastric emptying (1.4 to 5.6 ug/kg) also suppressed eating. This finding supports the suggestion that inhibition of gastric emptying mediates CCK-induced satiety. However, doses of secretin (14.3 and 28.6 ug/kg) which retarded emptying to a greater extent than 1.4 ug/kg CCK-8 were less effective than CCK in inhibiting eating. Thus, decreased emptying by itself cannot account fully for the satiety action of CCK-8. Bombesin (4 ug/kg) suppressed eating but had no effect on emptying suggesting that the satiety action of this peptide is not mediated via gastric emptying mechanisms. Finally, pentagastrin (in doses as high as 100 ug/kg) did not affect either satiety or the rate of gastric emptying.

245.20 EFFECTS OF BOMBESIN ADMINISTRATION ON TASTE-ELICITED BEHAVIORS OF INTACT AND CHRONIC DECEREBRATE RATS. Francis W. Flynn Dept. of Psychology and Neuroscience Program, University of Wyoming, Laramie, WY, 82071

Bombesin (BBS) is a tetradecapeptide which, when administered either systemically or into the cerebral ventricles, has a suppressive effect on food intake. One way by which BBS may inhibit feeding is to reduce the reinforcing oral sensory properties of the food. To evaluate this possibility, the effects of BBS administration on taste reactivity responses and intraoral intake of sucrose and water were measured in intact rats. Method. Intact rats (N=6) were fitted with intraoral cannula and maintained on 4 daily tube-fed 8 ml meals. One hr following the morning meal, the rats were removed from their home cage and injected (ip) with either 10 ug/kg BBS or an equal volume of isotonic saline. The rat's intraoral cannula were then attached to lengths of PE tubing. The rat was then placed into the clear plastic test chamber and allowed to adapt for 15 min. An infusion pump maintained a constant rate of delivery (0.8 ml/min) of either sucrose (0.1 M) or distilled water. During the first minute of the intraoral infusion, taste-elicited oral motor responses were videotaped for subsequent taste reactivity analysis. The intraoral infusion continued until the taste was rejected from the rat's mouth. The amount consumed was then computed by multiplying the rate of infusion x time spent ingesting. Results: Intraoral sucrose intake volume decreased (6.0 ± 0.7 ml) following BBS injection, $p < .05$. BBS injection also significantly suppressed intraoral water intake (3.8 ± 1.8 ml) under these test conditions, $p < .05$. There was no significant effect of BBS injection on the number of ingestive or aversive taste reactivity responses elicited by either 0.1 M sucrose or water. This suggests that BBS suppresses intake without causing an immediate reduction in the oral stimulating properties of the stimulus. In Experiment 2, the effect of ip BBS (10 ug/kg) and saline (0.15 M) injections on intraoral sucrose (0.1 M) intake was measured in tube-fed supracollicular decerebrate rats using the same taste delivery procedure as above. Decerebrate rats (N=4) ingested significantly less 0.1 M sucrose following BBS injection (1.0 ± 0.2 ml) than following saline injection (5.2 ± 2 ml), $p < .05$. These results show that caudal brainstem mechanisms, in isolation of the forebrain, are sufficient to mediate the anorectic effects of BBS.

246.1 SIDE EFFECTS RATINGS IN GERIATRIC DEPRESSION TREATED WITH NORTRIPTYLINE. R.C.Young, G.S. Alexopoulos,* M. O'Boyle,* A. Dhar,* H. Kutt.* The New York Hospital and Cornell University Medical College, White Plains, N.Y. 10605.

The pharmacotherapy of geriatric depression can be accompanied by subjective side effects. This is true even when drugs having a favorable side effect profile, such as nortriptyline (NT), are used. We assessed subjective side effects in geriatric inpatients treated with NT.

Thirty-four patients with major depressive illness were studied. All were aged > 60 years and met DSM III criteria for major depression. They were in stable physical health. During a 5-7 day evaluation period they were treated with benzodiazepines p.r.n. for anxiety and insomnia. Before, and at weekly intervals during treatment, subjective side effects were recorded with the modified Asberg Scale (Asberg et al, 1970; Ziegler et al, 1978). Depressive symptoms were rated using the 21-item Hamilton Scale (Hamilton, 1960). The patients were treated with NT at an average final dose of 1.2 mg/kg $\pm$ 0.3 mg/kg for 6 weeks. Plasma drug concentrations were assessed during treatment by high performance liquid chromatography.

Both total side effects scale scores (TS) and the sum of scores for anticholinergic items (AC) initially increased (weeks 1 and 2) and then decreased during treatment. TS and AC were each positively and significantly correlated with Hamilton scores during treatment (r=.10 to .57, and .22 to .46, respectively). Correlations between both TS and AC and NT dose (mg/kg) and NT plasma concentrations were low and not significant. Significant positive correlations between both TS and AC and plasma 10-hydroxylated NT concentrations were noted at weeks 5 and 6 (r= .38 to .54, and .42 to .56, respectively.

These preliminary findings suggest that both depressive state and drug effects are determinants of subjective side effect in geriatric depressives. Further investigation of depressive state, hydroxylated metabolite concentrations, and subjective and objective measures of toxicity in the elderly is warranted.

246.2 EFFECT OF ACUTE AND CHRONIC ANTIDEPRESSANT TREATMENT ON SUBSTANCE P CONTENT IN RAT BRAIN. H. Mitsushio*, M. Takashima*, N. Mataga*, and M. Toru* (SPON: R. S. Schmidt). Div. of Mental Disorder Research, N.C.N.P. Nat'l Inst. of Neuroscience, Tokyo 187, JAPAN

Several psychotropic drugs affect substance P (SP) content in the striatum and substantia nigra. Treatment with acute apomorphine, acute d-amphetamine, and chronic antipsychotics decreases, while subacute methamphetamine and chronic lithium increases SP contents in the striatum and substantia nigra. We have found that chronic carbamazepine administration also increased SP content in these areas. Since both carbamazepine and lithium can prevent the oscillation of manic-depressive illness, we were interested in the effects of antidepressant drugs themselves on SP contents.

For the acute study, male Wistar rats were injected 10 or 20 mg/kg (i.p.) of imipramine, desipramine, clomipramine, amoxapine or mianserin, and decapitated 1.0 hr later. For the chronic study, rats were fed the food containing three different doses of these antidepressants (0.25, 0.5 and 1.0 g of imipramine, desipramine, or clomipramine in 1.0 kg of food, and 0.2, 0.4, and 0.8 g of amoxapine or mianserin in 1.0 kg of food) for 40 days.

In contrast to lithium and carbamazepine, chronic treatment with all the antidepressants decreased SP content in the striatum and substantia nigra. Acute treatment caused different effects: imipramine and desipramine decreased SP content only in the striatum; clomipramine and amoxapine didn't alter SP content in either area; and mianserin decreased SP content in both areas. Among the five antidepressants tested, clomipramine and amoxapine decreased SP content only after chronic treatment. This effect is similar to that of antipsychotics. Since these two antidepressants are 10-fold more potent in blocking the D_2 receptor than the other three, the mechanism by which chronic but not acute treatment decreases SP content may be due to a D_2 receptor blocking action. This explanation, however, can not be applied to the other three antidepressants, which also decreased SP content after chronic treatment, as they have little D_2 receptor blocking action. Since chronic treatment with antidepressants has been reported to increase the sensitivity of cingulate cortical neurons to iontophoretically applied SP (R.S.G. Jones et al. Neuropharm. 24, 627-633, 1985), the decrease in SP content after chronic treatment with antidepressants may correspond to the reduction in SP release. Therefore, the chronic treatment of antidepressants may attenuate SP synaptic transmission. The present findings suggest the possibility that alterations in SP neurotransmission may play a role in the pathophysiology of manic-depressive illness.

246.3 LEARNED HELPLESSNESS: WHAT CRITERION SHOULD BE USED IN ANIMAL MODELS ? R.E.Musty, M. Jordan*, and R. H. Lenox Dept. of Psychology and Dept.of Psychiatry, University of Vermont, Burlington, VT 05405

Exposure to inescapable shock leads to learned helplessness LH). Some investigators have used total failure to escape as a criterion for LH (e.g., Overmeier & Seligman, J. Comp. Physiol. Psychol., 1967, 63, 23.), others have used elevated escape latencies (e.g., Sherman et al., Biochem. Behav., 1982, 16, 449. Many laboratories have reported difficulty obtaining LH in rodents using the latter approach. Rats were given preshock (2.0 ma, 5 sec., 80 trials) in one half of a shuttle box. Rats were then tested in a the shuttle box with the mid-wall removed [1.3 ma for 20 trials, each was composed of a 5 sec. 70 db 4000 Hz conditioned stimulus (CS) followed by 40 sec. of shock]. A fixed ratio-2 (FR-2) response was required to escape or avoid shock . Control rats were tested without previous preshock.

An escape deficit (ED) criterion was defined as an escape response of greater than 20 sec. latency on greater than or equal to 13/20 trials. Approx. 40 % of the preshocked rats were "helpless" and about 20 % of the control rats were "helpless" (Fishers exact test, df=1, p< .05, one-tailed). These percentages for the ED criterion are similar to those in the published literature. Profiles of escape latencies over all 20 trials for each animal were examined and 3 profiles emerged: 1. rats which escaped in the first 5 trials, but did not escape more than two times thereafter, 2. rats which responded throughout the 20 trials with highly variable escape latencies and 3. rats which performed at consistently short latencies. A second criterion was then developed and examined: 1. continuous (total) failure (CF) was defined as failing to escape within 45 sec trial in the first 5 trials and at least 80% failure to escape in trials 6-20. Using this criterion, 20 % of the preshocked animals were "helpless" and 10 percent of the controls were "helpless" (Fisher's exact test, df=1, p< .12, one tailed). "Helpless" rats, using the ED criterion includes profiles 1 and 2, but the CF criterion includes only profile 1. Thus, CF may be more descriptive of a homogeneous type of "helplessness". We hypothesized that reducing observed random escape responses and raising task difficulty would yield more reliable LH. Thus, a barrier with a 3 x 3 in. open door was placed between the two halves of the shuttle box. When rats were tested in this situation, either in the preshock or control conditions, the percentage of "helplessness" using the ED criterion increased in both groups, but using the CF criterion, the percentage of "helplessness" increased about threefold in the preshocked group only. These data suggest that the criterion for LH as well as the relative task difficulty can significantly effect the frequency of observed LH and the homogenity of the LH population. Supported by PHS-RO1-MH41571.

246.4 REINFORCING PROPERTIES OF MAGNESIUM AS DEMONSTRATED BY CONDITIONED PLACE PREFERENCE IN MICE. S. I. Lawley* and K. M. Kantak. Laboratory of Behavioral Neuroscience, Department of Psychology, Boston University, Boston, MA 02215.

Recent studies from our laboratory indicate that magnesium has stimulant-like behavioral properties. Because magnesium does have stimulant-like qualities, it was hypothesized that it might also have reinforcing properties as other stimulants do. Our previous studies indicate that magnesium will substitute for cocaine in a conditioned place preference (CPP) procedure. Thus we used the conditioned place preference paradigm in mice to investigate the possibility that magnesium may have its own rewarding properties. Wooden boxes with two dissimilar arms and a central, neutral area were used to condition animals. Side preference was determined on the third day of habituation by that arm in which the animal spent more than 50% of the total time spent in either arm. During the 15-minute test period the number of visits the animal made to each arm was recorded. Magnesium chloride ($MgCl_2$) was injected sc and the animals were conditioned to the less preferred side. Saline was paired on alternate days to the more preferred side. After conditioning the side preference of the animals was again determined in the drug free state. The following day ip injections of cocaine (5.0 mg/kg) were administered to determine if substitution for magnesium conditioning would occur. There were three separate doses of $MgCl_2$ used to condition the animals: 15, 30, and 125 mg/kg. We also used two different lengths of conditioning: a) a conditioning period of 8 days with 4 pairings per drug and b) a conditioning period of 16 days with 8 pairings per drug. With the conditioning period of 8 days, 54% of the animals showed evidence of conditioning as seen in their shift in preference. All these animals maintained their conditioned side preference with cocaine administration, indicating substitution. Following 16 days of conditioning only 22% of the animals showed evidence of conditioning to all doses of $MgCl_2$. These animals also maintained conditioned side preference with cocaine administration. Analysis of total time in the two arms indicates there are no general sedative effects of $MgCl_2$ which could obscure reinforcing effects. These data support the idea that magnesium may have some reinforcing properties as seen in its ability to switch side preference in some animals. This is further supported by the number of visits made by the animals to the preferred sides after conditioning. Cocaine will support magnesium conditioning and thus similar mechanism of action is indicated. But because magnesium appears to have a limited ability to support CPP, it may have a lower abuse liability than cocaine.

246.5 ENHANCEMENT OF SEROTONERGIC FUNCTION BY LITHIUM IN AFFECTIVE DISORDER PATIENTS. L.H. Price, D.S. Charney, P. Delgado*, G.R. Heninger, Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Studies in laboratory animals indicate that lithium has significant effects on serotonergic (5HT) function. Although these findings have been invoked to explain lithium's ability to augment the therapeutic actions of tricyclic (TCA) and monoamine oxidase inhibitor (MAOI) antidepressants, few clinical studies have investigated lithium's effects on central 5HT function in patients. It has been shown that the prolactin response to I.V. tryptophan is blunted in depressed patients compared with healthy controls, while treatment with some, but not all, antidepressant drugs enhances the response. One prior study has demonstrated an enhanced response in healthy subjects treated with lithium. The present investigation utilized the prolactin response to tryptophan to determine the nature and time course of lithium's effects on 5HT function in patients. METHODS: Twenty patients with DSM-III affective disorders gave voluntary informed consent to participate. After a minimum 2-week placebo period (at least 3 weeks psychotropic drug-free), patients received tryptophan 7 grams I.V. infused at a constant rate over a 20-minute period. Samples for plasma prolactin were obtained at intervals before and after the tryptophan infusion. Subjective mood and cardiovascular measures were also obtained. The test procedure was repeated in 13 patients after <14 days and in 11 patients after >28 days of active lithium treatment; 4 patients had repeat testing at both time points. Prolactin was measured by radioimmunoassay. RESULTS: As in previous studies, tryptophan caused significant increases in prolactin. The prolactin response was significantly enhanced after short-term lithium treatment, but enhancement after long-term lithium treatment did not reach statistical significance. CONCLUSION: Like long-term treatment with TCAs and MAOIs, short-term lithium treatment increases the prolactin response to tryptophan in affective disorder patients. Long-term lithium treatment has equivocal effects in such patients, whereas a clear enhancement is seen in healthy subjects. These findings are consistent with the hypothesis that lithium augmentation of TCAs involves changes in 5HT neurotransmission, but suggest that homeostatic responses of the 5HT system to long-term lithium treatment may differ in affective disorder patients and healthy subjects.

246.6 INVOLVEMENT OF VARIOUS 5-HT RECEPTOR SUBTYPES IN THE EFFECTS OF SEROTONIN ANTAGONISTS ON PAG STIMULATION-INDUCED AVERSION. F. Jenck, A.L.M. van Delft* and C.L.E. Broekkamp*. CNS Pharmacology Department, ORGANON International, OSS - The Netherlands.

Serotonin has been suggested to act in the brain through activation of different receptor subtypes (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}, 5-HT_{1D}, 5-HT_2, 5-HT_3). In order to get insight in the functional role exerted by these receptor subtypes in the brain, the effects of serotonin antagonists with differential selectivity for the various subclasses of 5-HT receptors have been tested on aversive brain stimulation. Neurostimulation was applied to the dorsal part of the periaqueductal gray matter (PAG), one of the main cerebral structures subserving brain negative reinforcement.

Rats were trained, in a rectangular cage, to stop an aversive PAG stimulation by escaping from one compartment to the opposite compartment. The minimal current necessary to induce such an escape response was determined: stimulation intensity was held constant and the stimulation frequency was varied in order to measure the frequency threshold inducing escape. This frequency threshold was determined before and following intraperitoneal injection of mianserin, Org 3770, metergoline, ketanserine, pirenperone, (-)pindolol and isapirone (TVXQ 7821).

Mianserin (0.032-32 mg/kg), Org 3770 (0.1-32 mg/kg) and metergoline (0.1-10 mg/kg), which block nearly all 5-HT receptor subtypes decreased the threshold for escape. Opposite effects were obtained with the 5-HT_2 selective antagonists ketanserine (0.32-10 mg/kg) and pirenperone (0.032-1.0 mg/kg) which increased the threshold for escape responses. (-)Pindolol (0.32-3.2 mg/kg) and isapirone (1.0-32 mg/kg), which have selectivity, within the serotonin system, for the 5-HT_{1A} and 5-HT_{1B} subtypes of receptors, did not have any effects. Control experiments were performed with the dopamine antagonist haloperidol, the α_1 antagonist prazosin and the α_2 antagonist yohimbine.

Taken together, these data suggest that the various 5-HT receptor subtypes differentially contribute to the control of central aversive systems in rats:

1) blockade of the 5-HT_2 receptor subtype seems to contribute to inhibit the central aversive systems.
2) blockade of 5-HT_{1A} and 5-HT_{1B} receptor subtypes by (-)pindolol and isapirone does not influence central aversion.
3) the facilitatory effects of acute injection of mianserin, Org 3770 and metergoline on the central aversive systems may be mediated via 5-HT_{1C} or 5-HT_3 receptor subtypes in the brain.

246.7 **Behavioral effects of Thyroidectomy and Antidepressant Therapy.** Laurel A. Freed*, Alexandra Fingesten*, Thomas H. Milhorat and Diana L. Dow-Edwards . (Spon:M. E. Friedlander) Lab. of Cerebral Metabolism, Dept. of Neurosurgery, SUNY Health Science Center at Brooklyn, NY, 11203.

We have found that the metabolic response to imipramine can be altered by varying the thyroid status of the animal (Dow-Edwards, et al., in press). In order to determine whether the behavioral responses to imipramine would also be altered by varying the thyroid state, we thyro-parathyroidectomized (TX) or Sham operated (SO) adult male Sprague-Dawley rats and then housed them under standard laboratory conditions for 2 weeks. On day 14, daily ip injections of either imipramine (10 mg/kg, Sigma) or saline were begun and continued for 2 weeks. Four groups of animals were then evaluated: SO-saline; SO-imipramine; TX-saline; and TX-imipramine. On day 28 post-op 42 rats underwent a 2 day period of testing to determine immobility in the Porsolt test (Porsolt et al., Nature, 1977, vol. 266, p.730-732). The opaque container had 18cm of 30°C water. The length of immobility occuring in the second test period (a maximum of 5 minutes) was recorded. Another 18 rats were examined in an open-field apparatus for a period of 15 minutes. The number of grid lines crossed, number of rearings and duration of wall climbing were recorded. The rats were then sacrificed by decapitation for analysis of plasma T_3 and T_4 levels. Other rats were given imipramine acutely and the Porsolt scores determined.

The results show that T_3 ($p = 0.0004$, ANOVA) and T_4 ($p < 0.001$, ANOVA) levels were significantly decreased compared to control values verifying the completeness of the TX. Chronic imipramine therapy had no effect on the immobility score as determined in the Porsolt test, yet it did significantly decrease the number of gridlines crossed in the open field ($p = 0.010$, ANOVA). TX significantly decreased ($p = 0.05$, ANOVA) the length of time of immobility in the Porsolt test much as acute imipramine did. TX also significantly increased ($p = 0.002$, ANOVA) the incidences of free rearing in the open field. Therefore, chronic imipramine and TX appear to have opposing effects upon the behaviorial indexes measured.

246.8 PRODRUGS OF 2-PHENYLETHYLAMINE: COMPARISON OF THEIR EFFECTS ON LOCOMOTOR ACTIVITY AND ON CONCENTRATIONS OF BIOGENIC AMINES IN BRAIN. D.J. Stewart, A.J. Greenshaw*, G.B. Baker and R.T. Coutts*. PMHAC Research Unit and Neurochemical Research Unit, Department of Psychiatry, University of Alberta, Edmonton, Alberta, CANADA T6G 2B7

The trace amine 2-phenylethylamine (PEA) may play an important role in normal central nervous system function and has been implicated in the etiology of affective disorders. By producing specific elevations of this trace amine with prodrugs, it may be possible to assess its mechanisms of action, particularly with reference to neurotransmitter amine systems. The study reported here investigated the behavioural and neurochemical effects of acute administration of two known prodrugs of PEA, N-cyanoethyl-PEA (CEPEA) and N-propargyl-PEA (PGPEA), in rats.

Three doses of each prodrug were used (0.03, 0.10 and 0.30 mmol/kg, i.p.) and behaviour was measured in a computer-controlled infra-red photobeam activity monitor for 60 min post-injection. Following this, the rats were killed by decapitation and the brains were removed and rapidly dissected into the following areas: frontal cortex, hypothalamus, nucleus accumbens, caudate nucleus and hippocampus. The remaining portions of the brain were combined, termed "the remainder", and retained for analysis of the prodrugs and PEA. High pressure liquid chromatography with electrochemical detection was used for analysis of concentrations of catecholamines and serotonin (5-hydroxytryptamine) and their acid metabolites and electron-capture gas chromatography was employed for analysis of the prodrugs and PEA following derivatization with pentafluorobenzoyl chloride or pentafluorobenzenesulfonyl chloride.

PGPEA induced a dose-related increase in motor activity, whereas CEPEA had a sedative effect. PEA and prodrug levels were significantly higher in the remainder sample after PGPEA than after CEPEA. Both drugs induced dose-related decreases in noradrenaline in the hypothalamus, hippocampus and caudate nucleus and in dopamine in the caudate nucleus and nucleus accumbens. At the highest dose of each prodrug, the ratio of the acid metabolite 5-hydroxyindole-3-acetic acid (5HIAA) to serotonin was increased in the caudate nucleus following PGPEA and in all areas except the hypothalamus following CEPEA. The behavioural and neurochemical effects of the acute administration of these two prodrugs are discussed with reference to brain concentrations of prodrug and PEA and effects on monoamine oxidase activity.

246.9 ANTI-DEPRESSANTS IN AN ANIMAL MODEL OF ANXIETY. S.R. Bodnoff, B. Suranyi-Cadotte, D.H. Aitken*, R. Quirion, and M. J. Meaney. Douglas Hospital Research Center, Dept. of Psychiatry, McGill Univ., Montreal, Canada H4H 1R3.

Both clinical and anecdotal evidence suggest that anti-depressants, when administered chronically, but not acutely, possess intrinsic anxiolytic properties. In the present series of experiments, the anxiolytic property of the tricyclic anti-depressants, desipramine (DMI) and amitriptyline (AMI) were compared with two known anxiolytics, diazepam and adinazolam in an animal model of anxiety. Food-deprived animals were placed into a novel environment containing food. Novelty produces fear or anxiety which suppresses consummatory behavior. Drugs that reduce fear of novelty decrease the latency for food-deprived animals to begin eating.

Adult, male Long Evans rats were food-deprived for 48 hours. One hour prior to behavioral testing, rats received a single i.p. injection of diazepam (2 mg/kg), adinazolam (20 mg/kg), DMI (10 mg/kg), AMI (10 mg/kg) or vehicle. The behavioral testing involved placing rats into individual plexiglas cages lined with beta chips and 12 evenly-spaced food pellets and recording the latency for animals to begin eating. The results showed that chronic (21 days), but not acute injections of the anti-depressants significantly reduced the latency for animals to begin eating in the novel environment, although the percentage decrease relative to controls was not as great as found with typical anxiolytics. The development of the anxiolytic property of the anti-depressants was examined in a time course study in which animals were injected for 1,7,14, or 21 days with either diazepam, DMI, or vehicle. Only animals treated for 2 or 3 weeks with DMI showed a significant decrease in latency to begin eating. Finally, the role of the benzodiazepine receptor (BZR) in mediating the anxiolytic property of the anti-depressants was evaluated using the BZR antagonist Ro15-1788 (20 mg/kg). Animals were injected for 3 weeks with diazepam, DMI, or vehicle. Again, the anti-depressants significantly reduced the latency to begin eating in the novel environment. Although the BZR antagonist fully blocked the anxiolytic property of diazepam, it had no effect when given in conjunction with DMI. These data suggest that the BZR is not directly involved in mediating the anxiolytic effect of the anti-depressants.

246.10 BEHAVIORAL AND NEUROENDOCRINE RESPONSES TO THE 5-HT_{1B} AGONIST m-CPP IN RATS. F. Matos*, M. Shlaftein*, P.M. Whitaker-Azmitia and E. Edwards. (SPON. A. Orr) Department of Psychiatry, SUNY at Stony Brook, New York 11794.

m-Chlorophenylpiperazine (m-CPP), a metabolite of the anti-depressant drug trazodone has been recently characterized as a serotonin agonist with specificity for the 5-HT_{1B} receptor subtype in rodents. The present experiments examine the effect of acute treatment of rats with m-CPP on three parameters whose changes are consistent with the stimulatory action of 5-HT receptors: locomotor activity, 5-HT syndrome, increases in plasma corticosterone.

Locomotor activity was measured with a photocell actimeter one hour after the administration of m-CPP (3 mg/kg, i.p.). Activity was measured for 40 minutes. Activity in m-CPP treated rats was significantly reduced (126 $\pm$ 20 saline controls vs 33 $\pm$ 5 m-CPP; values represent the mean number $\pm$ S.D. of light beams crossed during a 40 minute recording session).

m-CPP induced a behavioral response typically observed after treatment with serotonin precursors and other serotonin agonists. Behavioral scores were recorded for headweaving, forepaw treading, hindlimb abduction, and Straub tail in twenty minute sessions. Headweaving was enhanced ($p < .01$) during the period of 4 - 20 minutes. Hindlimb abduction ($p < .05$ at eight minutes), forepaw treading ($p < .01$ during the period of 10 - 15 minutes) and Straub tail ($p < .01$ during the period of 4 - 10 minutes) were all enhanced in a dose dependent fashion with injection dosage ranging from 1.5 - 12 mg/kg body weight.

m-CPP injection caused an increase in the secretion of corticosterone (6 mg/kg injected i.p.). This increase (+75%) was observed in m-CPP treated rats 24 hours after injection.

Data from these experiments provide evidence for m-CPP effects being mediated through an interaction with 5-HT receptors and thus support the use of this compound as a tool in studies aimed at elucidating the functional role of serotonin in the central nervous system.

246.11 SELECTIVE 5-HT_2 ANTAGONISTS RESULT IN ANTIDEPRESSANT-LIKE ACTIVITY ON A BEHAVIORAL SCREEN FOR ANTIDEPRESSANT DRUGS. G.J. Marek, A. LI*, and L.S. Seiden. Dept. of Pharmacol. & Physiol. Sciences, The University of Chicago, Chicago, IL 60637.

Over the last few years, antidepressant drugs have been demonstrated to have a unique and characteristic effect on rats performing under a differential-reinforcement-of-low-rate 72 sec. (DRL 72-s) schedule of reinforcement. Only antidepressant drugs and electroconvulsive shock increase the reinforcement rate, decrease the response rate and enhance temporal discrimination on the DRL 72-s schedule, an operant schedule of reinforcement (McGuire & Seiden, 1980; Seiden & O'Donnell, 1985; Seiden et al., 1985).

Since antagonism of 5-hydroxytryptamine (5-HT) receptors is one of the most potent actions of several atypical antidepressant drugs such as trazodone and mianserin, we have examined a large series of 5-HT antagonists with varying selectivity for the 5-HT_2 vs. the 5-HT_1 receptor: ketanserin, ritanserin, pipamperone, pizotifen, cyproheptadine, trazodone, cianserin, mianserin, LY53857, metergoline and methysergide. Antidepressant-like activity (increased reinforcement rate, decreased response rate and enhanced temporal discrimination) was seen with administration of 5-HT_2 selective antagonists such as ritanserin, ketanserin, and pipamperone. A lack of effect was seen on the DRL 72-s schedule following administration of non-selective 5-HT antagonists such as methysergide and metergoline. A significant correlation was seen between the ability of these drugs to increase the reinforcement rate on the DRL 72-s schedule and their selectivity for the 5-HT_2 vs the 5-HT_1 receptor (r_s=+0.91, binding data from Leysen et al., 1981). Significant correlations were not seen for the alpha-1 adrenoreceptor (r_s=+0.43), alpha-2 adrenoceptor (r_s=-0.33), histamine-1 receptor (r_s=+0.12) or the dopamine-2 receptor (r_s=-0.07). These results support the hypothesis that the antidepressant-like activity of trazodone and mianserin on the DRL 72-s schedule may be related to selective antagonism of 5-HT_2 receptors. This suggests that the therapeutic action of some atypical antidepressants like trazodone and mianserin could be related to selective antagonism of 5-HT_2 receptors. This research is supported by PHS MH-11191; RSA MH-10562 (L. Seiden) and MSTP Grant GM-07281 (Marek).

246.12 DOWN-REGULATION OF 5-HT_2 RECEPTORS ATTENUATES THE EFFECTS OF TRAZODONE ON RATS PERFORMING ON BEHAVIORAL SCREEN FOR ANTI-DEPRESSANTS. A. Li*, G.J. Marek, L.C. Nguyen*, and L.S. Seiden. (SPON: M. Kleven). Dept. of Pharmacol. & Physiol. Sciences, The University of Chicago, Chicago, IL 60637.

The differential-reinforcement-of-low-rate 72-second (DRL 72-s) schedule of water reinforcement is an effective screen for anti-depressants (O'Donnell & Seiden, 1982; Seiden, Dahms & Shaughnessy, 1985). Only antidepressant drugs and electroconvulsive shock increase reinforcement rates, decrease response rates, and enhance temporal discrimination of rats performing on this schedule. 5-HT antagonists with 100-1000 fold greater affinity for the 5-HT_2 over the 5-HT_1 receptor such as ketanserin, ritanserin, pipamperone, mianserin, and trazodone are similar to anti-depressant drugs in their effects on DRL-scheduled behavior (Marek, Li, Seiden, 1987). Administration of methysergide or metergoline which antagonizes both 5-HT_1 and 5-HT_2 receptors does not affect performance on the DRL 72-s schedule (Marek, Li, Seiden, 1987). Mianserin and trazodone have already been shown to be clinically effective in the treatment of affective disorders. Recently, there have been encouraging results indicating that ritanserin may also be an effective antidepressant. Thus, selective antagonism of the 5-HT_2 over the 5-HT_1 receptor may result in a clinically effective treatment of depression. The effect of trazodone on DRL-scheduled behavior was measured before and during repeated administration of trazodone (10 mg/kg, daily for 14 days). Repeated administration of trazodone down-regulates 5-HT_2 receptors (Riblet and Taylor, 1981). The reinforcement rate increasing effect of trazodone was decreased from day 5 to day 14 of the repeated administration of trazodone. In another experiment, the effects of trazodone were measured before and during a regimen of methysergide injections (10 mg/kg daily for 40 days) that is known to specifically down-regulate 5-HT_2 receptors without affecting 5-HT_1 or B-receptors (Blackshear et al., 1983; Peroutka and Snyder, 1980). Trazodone (5 mg/kg) was tested on days 1, 7, 14, 27, and 38 of the regimen of methysergide injections. Trazodone significantly increased the reinforcement rate on day 1 but not on days 7, 14, 27, or 38. This suggests that the regimen of repeated administration of methysergide attenuated the reinforcement rate increasing effects of trazodone. The results from both of these experiments provide additional evidence that the 5-HT_2 receptor site plays a role in the effects of trazodone on rats performing on the DRL 72-s schedule. This research is supported by PHS MH-11191; RSA MH-10562 (L. Seiden), and MSTP Grant GM-07281 (G. Marek).

246.13 AN ELECTROPHYSIOLOGICAL COMPARISON OF DESIPRAMINE AND THE POTENTIAL ANTIDEPRESSANT, MDL 19,660. S.M. Sorensen, J.M. Zwolshen*, M.W. Dudley, J.M. Kane*, and F.P. Miller. Merrell Dow Research Institute, Cincinnati, OH

MDL19,660(5-(4-chlorophenyl)-2,4-dihydro-2,4-dimethyl-3H-1,2,4-triazole-3-thione) shows potent antidepressant-like activity in behavioral tests but does not inhibit amine uptake or monoamine oxidase activity and is devoid of receptor antagonist activity. In this study, we compared the effects of desipramine (DMI) and MDL 19,660 on the sensitivity of rat cerebellar Purkinje (P) neurons to iontophoretically applied norepinephrine (NE). The sensitivity of these neurons to NE is diminished following chronic administration of DMI and this is thought to be due to the desensitization of beta receptors which is seen following chronic administration with many antidepressant agents (Yeh and Woodward, JPET, 226:126-134, 1983). These experiments were undertaken to determine whether MDL 19,660 also caused a decrease in the sensitivity of P neurons to NE.

Neither compound, administered acutely at doses up to 10 mg/kg i.p., altered the spontaneous firing rate of P neurons or the depression in rate caused by NE. MDL 19,660 did, however, significantly reduce the NE enhancement of GABA responses after acute administration, whereas DMI did not. MDL 19,660 also produced a slight decrease in the response of the P neuron to iontophoresced GABA itself.

When administered chronically (10 mg/kg/day i.p. x 21 days), neither compound altered spontaneous or NE-evoked slowing of P neurons. Both compounds did, however, produce a significant decrease in NE enhancement of GABA inhibition following chronic administration. This subsensitivity to NE was more pronounced in animals chronically treated with MDL 19,660 than for DMI.

The results indicate that MDL 19,660 has a profile which is similar to that of DMI in this experimental system with some important differences. First, MDL 19,660 produced a more marked desensitization to NE enhancement of GABA inhibition than DMI following chronic administration. Second, MDL 19,660 caused a significant decrease in this NE sensitivity after even a single administration, whereas DMI was effective only after chronic administration. The data are consistent with the hypothesis that MDL 19,660 has potential as an antidepressant and further suggest that the compound may have a faster onset of therapeutic activity than DMI.

AMYGDALA AND LIMBIC CORTEX

247.1 THE ORGANIZATION OF THE CANINE CENTRAL NUCLEUS OF THE AMYGDALA. M.L. Estes and C.H. Block, Departments of Pathology and Brain and Vascular Research, The Research Institute of The Cleveland Clinic Foundation, Cleveland, OH 44106.

The central nucleus of the amygdala (CNA) is a limbic structure that is involved in the integration of autonomic function and emotional behavior. A variety of peptides and neurotransmitters have been identified within this nucleus in the rat (Wray and Hoffman, 1983) and rabbit (Block, et al. 1984). Since neuroactive substances are part of both the intrinsic and extrinsic circuitry of the amygdaloid complex, the following studies were conducted to examine the organization of these substances in the canine brain.

Serial frozen sections were cut at 30 μm in the coronal plane and were processed for immunocytochemical localization of vasoactive intestinal polyeptide (VIP), neurotensin (NT), methionine enkephalin (ENK), cholecystokinin octapeptide (CCK), and substance P (SP).

The CNA in the dog lies in the dorsal aspect of the temporal lobe and is bordered by the anterior, lateral, basolateral, and medial amygdaloid nuclei. It is comprised of two major cell groups, the medial (mCNA) and lateral (lCNA). The mCNA is larger in area than the lCNA, occupying the region caudal to the anterior amygdaloid area and extending to the amygdalohippocampal area. Cells of the mCNA can be further divided into three zones. The dorsal and ventral zones are outlined by the fibers of the longitudinal association bundle and stria terminalis and form a capsule around a cell-sparse internal zone. The cells of the dorsal mCNA are round in shape, moderately dark-staining, and have a centrally-located nuclei. They are approximately 20 μm in diameter. The neurons of the ventral mCNA are pale-staining and approximately 14 μm in diameter. The few cells within the internal zone are a mixture of both cell types of the dorsal and ventral group. The lCNA lies lateral and dorsal to the mCNA and appears to be continuous with the putamen, although it does not contain any of the large cells of that complex. The cells of the lCNA are small (approximately 8 μm in diameter), oval, and pale-staining. Fibers containing VIP and NT were primarily localized to the ventral mCNA, whereas ENK-containing fibers surrounded the ventral zone. SP and CCK fibers outlined the ventral aspect of mCNA. Caudally, VIP and SP appeared to be contained within the fibers of the stria terminalis. In addition, ENK - and NT - containing cells were found in the mCNA. CCK - , ENK - ,and SP - containing fibers outlined the lCNA and infiltrated the putamen.

The presence and the anatomical organization of the canine CNA suggest that the neuropeptides may be part of the systems involved in autonomic integration, as demonstrated in other species.

(Supported by NIH grants HL-1454 and HL-37927).

247.2 THE EFFECTS OF EXTREMELY LOW-LEVEL KINDLING STIMULATION UPON THE SOCIAL BEHAVIOR AND AMYGDALOID SLOW-WAVE ACTIVITY IN A SQUIRREL MONKEY (S. SCIUREUS) AND THE INFLUENCE OF DOPAMINERGIC AGENTS UPON THESE EFFECTS. R. L. Lloyd, A. S. Kling, K. E. Tachiki, M. Ghazizadeh,* O. Ricci,* B. Wexler,* and S. Ruane.* Psychiatry Service, VA Medical Center, Sepulveda/UCLA Department of Psychiatry, CA 91343.

Daily low-level electrical stimulation (150 uA @ 60 Hz for 1 sec) was delivered to the amygdala of a squirrel monkey at an intensity which was below threshold, not only for motor convulsions, but also for electrographic seizures and/or synchrony. By the thirteenth stimulation primary after discharge activity was recorded in the amygdala, and by the 68th stimulation, evidence of somatic convulsions appeared, which were primarily autonomic, but which eventually developed into full partial complex seizures. Changes in the social behavior of the stimulated animal occurred prior to the development of overt convulsions. The effects included a fall in social rank, hyper- and inappropriate aggression, paresthesia, and what appeared to be visual hallucinations. In addition, the duration of primary and secondary after-discharge activity appears to be influenced by whether the animal is in isolation or in the presence of conspecifics. These data speak to the issue of whether abnormal electrical activity within the amygdala can produce abnormal social behavior, in the absence of overt signs of seizure activity. In addition, these data argue against the position that the behavioral pathologies observed in temporal lobe epilepsy are due to underlying neuropathies, and that the presence of the electrical sequelae is merely coincidental.

Finally, abnormal behaviors are enhanced by apomorphine, while a biphasic effect upon both the animal's abnormal behaviors and spontaneous electrical discharge activity is produced by the neuroleptic Tiaspirone. The main effect of Tiaspirone is to reduce both the abnormal electrical and behavioral effects of this novel form of kindling.

247.3 **CARDIAC AND RESPIRATORY RELATIONSHIPS WITH UNIT DISCHARGE IN THE HUMAN AMYGDALA AND HIPPOCAMPUS.** R.C. Frysinger, R.M. Harper, and C.L. Wilson. Depts. of Anatomy and Neurology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763.

The amygdala and hippocampus are mesial temporal lobe structures with a close anatomical relationship with autonomic and respiratory control systems. Stimulation and recording studies have implicated the amygdala in control of blood pressure (Frysinger et al., *Exp. Neurol.* **83**:604, 1984) and respiration (Zhang et al., *Exp. Neurol.* **91**:193, 1986). In the cat, amygdala neurons discharge phasically with the cardiac and respiratory cycles in a state-dependent fashion, and tonic discharge rates correlate with spontaneous changes in blood pressure and respiratory rate (Frysinger et al., in preparation, 1987). The hippocampus may play a role in cardiovascular regulation (Versteeg et al., *Brain Res.* **292**:317, 1984), and hippocampal neurons discharge in phase with the respiratory cycle (Radna and MacLean, *Brain Res.* **213**:45, 1981). The extent and nature of such correlations in the human have not yet been explored. We therefore examined cardiac and respiratory relationships with neuronal discharge in the amygdala and hippocampus of humans.

We recorded respiratory air flow and ECG simultaneously with neuronal discharge from the amygdala and pes hippocampi of epileptic patients undergoing chronic depth electrode monitoring during assessment for resective surgery. Cross-correlation histograms were used to test for neuronal discharge timing relationships with onset of inspiration or the QRS complex of the ECG. Inspiratory area, respiratory period and heart rate were calculated on a breath-by-breath basis off-line, and linear regression was used to test for tonic rate correlations with unit discharge rates normalized over the breath.

Amygdala neurons showed both tonic rate correlations with respiratory period and inspiratory area (3/6 each) and discharge timing relationships with the cardiac and respiratory cycle (2/6 each). Hippocampal neurons commonly showed discharge timing relationships with the cardiac cycle (5/11) and tonic rate correlations with heart rate (2/11), but respiratory relationships were rare. It was unusual for a neuron in either area to show both a tonic rate correlation and a discharge timing relationship (2/17).

These results suggest that activity in the hippocampus is closely coupled to cardiac control systems, while the amygdala has links to both cardiac and respiratory systems. The finding in this and previous studies that discharge timing relationships and tonic rate correlations tend to be independent of each other suggests the existence of distinct functional subpopulations of neurons subserving the phasic and tonic aspects of forebrain influences on the cardiovascular and respiratory systems.

247.4 AMYGDALOID PROJECTIONS TO THE PREFRONTAL CORTEX AND ASSOCIATED ROSTRAL STRIATUM: A FLUORESCENCE RETROGRADE TRANSPORT STUDY IN THE RAT. A.J. McDonald. Dept. of Anatomy, Univ. of South Car. Sch. of Med., Columbia, SC 29208.

Studies have shown that the striatal projections of the rat prelimbic and dorsal agranular insular cortex (medial and lateral prefrontal cortex [PFC], respectively) terminate mainly in ventral and dorsomedial portions of the rostral striatum. The amygdala projects to both the PFC and its associated striatal regions. The present study examined the relationship of amygdaloid neurons projecting to these interconnected cortical and striatal fields using the fluorescent retrograde tracers true blue and diamidino yellow. Different tracers were injected into the medial or lateral PFC and their associated rostral striatal regions (nucleus accumbens [NA], dorsomedial caudatoputamen [DMCP], or ventrolateral caudatoputamen [VLCP]. In all NA animals and several DMCP and VLCP animals, knife cuts (1.5-2.0 mm wide) were made just rostral to the striatal injection to ensure that cortically-projecting amygdaloid neurons with axons passing through the striatum would not be artifactually double-labeled by the striatal injections. The pattern of retrograde labeling in the DMCP and VLCP rats with knife cuts appeared to be identical to that seen in the animals that did not receive knife cuts. Medial PFC injections were paired with injections into the NA (n=10) or DMCP (n=14). In the NA group, the topography of amygdaloid neurons labeled by the NA injections (NA cells) was very similar to that of amygdaloid neurons labeled by the medial PFC injections (MPFC cells). MPFC cells and NA cells were found mainly in the medial two-thirds of the basolateral amygdala and the lateral half of the amygdalohippocampal area. Numerous double-labeled neurons were also seen in these regions. Labeling in the DMCP group was similar to that observed in the NA group except that few DMCP cells or double-labeled cells were seen in the lateral nucleus and caudal half of the amygdala. Lateral PFC injections were paired with VLCP injections in twelve rats. Cells in the basolateral amygdala labeled by the lateral PFC injections (LPFC cells) tended to be more laterally situated than those labeled by medial PFC injections. The topography of VLCP cells and double-labeled cells was similar to that of LPFC cells except that very few VLPC or double-labeled cells were seen in the caudal half of the amygdala. The results of this study indicate that amygdaloid neurons projecting to PFC areas and their associated rostral striatal fields have similar topographies. In addition, many amydaloid neurons send axonal branches to both cortex and striatum. These neurons would appear to be able to simultaneously send identical information to the first two links in the prefrontocortical-limbostriatal-ventropallidal pathway. (Supported by NIH grant NS 19733).

247.5 A GOLGI, HISTOCHEMICAL AND IMMUNOHISTOCHEMICAL STUDY OF THE LATERAL ENTORHINAL CORTICAL NEURONS OF THE RHESUS MONKEY. A.A. Carboni(1), P.B. Cipolloni(2), C.L. Barnes(2) and W.G. Lavelle(1). (1) Dept. of Surgery, Div. of Otolaryngology/Head and Neck Surgery, UMass. Med. Center, Worcester, MA 01655. (2) Depts. of Anatomy and Neurology,, BU Sch. of Med. Boston, MA. 02118 and ENR VA Hosp., Bedford, MA 01730.

The neuronal types of the entorhinal cortex of the human and lower species have been described with the Golgi method (Cajal, S., Studies on the Cerebral Cortex: Limbic Structures, trans. L.M. Kraft, Chicago: Year Book Publishers, 1955; Lorente de No', R., J. Psychol. Neurol., 45, 381-438, 1933). We have expanded on these Golgi studies and have further characterized some of the neuronal subpopulations by histochemical and immunohistochemical labeling.

In a series of monkeys, the neurons of the lateral entorhinal cortex (LEC) were impregnated by the rapid-Golgi method (Valverde,F., Contemporary Methods in Neuroanatomy, W.J.H. Nauta and S.O.E. Ebbesson (Eds.), New York: Springer-Verlag, 1970) or the Braitenberg method (Braitenberg, et al., Stain Tech. 42: 277-282, 1967). They were also stained for NADPH-diaphorase enzyme, somatostatin, neuropeptide-Y, cholecystokinin, and substance P. Intervening sections were Nissl stained for cytoarchitectonic localization. The characterization of the neuronal types was based upon the number of spines, dendritic array, axonal arbors and chemical staining.

In general, the neurons found in the monkey LEC exhibit more varied forms than do those of the neocortex but, as in the neocortex, can be segregated into spinous and sparsely spinous types (Cipolloni, et al., Neurosci. Absts. 9: 953, 1983). The predominant type of spinous neuron is the typical pyramidal neuron found in all cortical layers except I and IV (lamina dessicans). A subset of the pyramidal type is the biapical pyramidal neuron and is found in layers II and III. Spinous multipolar neurons with radially arrayed dendrites are frequently found in layers II, III and VI. A cell type in the LEC not routinely found in the neocortex is the spinous tripolar of layer VI.

The sparsely spinous types include multipolar cells of varying sizes and complexity, bitufted and bipolar cells oriented either vertically or horizontally, and the neurogliaform neuron. In layer II, another cell type not seen in the neocotex is a sparsely spinous multipolar neuron which has two predominant dendrites coursing obliquely toward the pia and a horizontal axon that appears locally ramified as do the axons of all the sparsely spinous neurons. Certain of these sparsely spinous neurons can be found in all the cortical layers of the LEC and are the only type found in layers I and IV.

247.6 THE SUBCORTICAL PROJECTIONS OF THE ENTORHINAL CORTEX IN THE RHESUS MONKEY. D.L. Rosene and R.C. Saunders (SPON D. Doudet) Dept. of Anatomy, Boston University School of Medicine, Boston, MA, 02118, and Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

The entorhinal cortex, area 28 on the medial surface of the temporal lobe, has become recognized as a relay from the sensory association areas of the neocortex to the hippocampus. More recently, however, it has been demonstrated that the entorhinal cortex can sustain memory processes after removal of the hippocampal formation (H) and amygdala (A). Connections of area 28 with areas other than the neocortex and the H have, however, been largely ignored. Thus, as part of a larger investigation of the nonhippocampal projections of the entorhinal cortex in the rhesus monkey, we sought to determine, using complementary anterograde and retrograde anatomical tracers, its subcortical projections.

In the thalamus anterograde label was found over the magnocellular part of the medial dorsal nucleus (MDmc), the anterior thalamic nuclei (AntN), the lateral dorsal nucleus and the nucleus centralis latocellularis. Injections of retrograde tracers into the AntN and the MDmc resulted in labeled cells primarily in layer 6 in the sulcal part of area 28 (28S). In addition, there were a few labeled cells in layer 3 of 28S and 28M after the MDmc injection. In the hypothalamus, anterograde label was found over the medial nucleus of the mamillary body (MB) and the lateral hypothalamic area. Retrogradely labeled cells were found primarily in layer 3 of 28S, and to a lesser extent in the medial and caudal part of the entorhinal cortex (28M). All five subdivisions of the entorhinal cortex project to the bed nucleus of the stria terminalis (BNST) and to the intermediate nucleus of the septum. Like the projection to the MB, those to the BNST originate primarily in layer 3. In comparison, the projections to the intermediate septum originate more from layer 5. The entorhinal cortex also projects to the striatum, head of the caudate, and the putamen. These projections appear to arise from layer 5 cells in all subareas of the entorhinal cortex. Furthermore, it is cells in layer 5 which also project to the nucleus basalis of Meynert. In the amygdala, terminal label was found over the lateral basal nucleus, the central nucleus, the cortical nuclei and the cortical transition area. Like the entorhinal projection to the striatum this projection arises from layer 5 cells in all parts of the entorhinal cortex and from layer 3 cells in the prorhinal l cortical area.

The subcortical projections of the entorhinal cortex appear to parallel those from both the A and the H. These projections as well as cortical projections provide a means by which the entorhinal cortex may contribute to memory function independent of the neighboring hippocampus and amygdala.

247.7 A CYTOARCHITECTONIC ANALYSIS OF THE HUMAN ENTORHINAL CORTEX. R. Insausti[1], T. Tuñón[*2], T. Urrutia[*1], L.M. Gonzalo[*1] and J.M.M. Peñuela[*2]. 1. Dept. Anatomy, Univ. Navarra. 2. Dept. Pathology, Hosp. Navarra, Pamplona, SPAIN.

The entorhinal cortex is a component of the hippocampal formation, present in all mammals, but that reaches maximal development in primates, especially in man. The entorhinal cortex is a very important link between the neocortex and the hippocampus; when this pathway is disrupted (i.e. Alzheimer's disease) there are important functional consequences as memory impairment (Hyman et al., Ann. Neurol. 20:472-481, 1986). Recently, it has been defined several cytoarchitectonic fields in the entorhinal cortex of the macaque monkey (Amaral et al. J. Comp. Neurol. in press, 1987). By using these criteria as a guide, we attempted to find out the homologous fields in the human entorhinal cortex.

Brains from autopsies (age range 22-70 years) were obtained shortly after death and fixed with 10% formalin (three cases); four additional cases were perfused through the carotids or carotid and basilar arteries with 4% paraformaldehyde in phosphate buffer. After a postfixation period of 48 hr. the brains were equilibrated with 20% glycerol in phosphate buffer. The brains were blocked perpendicular to the anterior-posterior commissure line and they were cut transversely in a freezing microtome at 50 µm. A one-in-five series was mounted and stained with thionin. Fiber series were similarly prepared; in addition, acetylcholinesterase, neurofilament and somatostatin series were available in one case. Three additional hemispheres were cut horizontally (n=2) or parasagittally (n=1) at the same thickness. Drawings were made with a camera lucida attached to a stereomicroscope at a magnification of 15 times, on which the different cytoarchitectonic features as presence of the lamina dissecans, islands of cells in layer II, etc. were plotted. Additional two-and-three dimensional reconstructions were obtained for the different cases.

The human entorhinal cortex lies at the ventromedial aspect of the temporal lobe. The rhinal surcus makes the lateral border of the rostral entorhinal cortex, being replaced by the colateral surcus at more caudal levels. The human entorhinal cortex has a less distinct lamination than in the monkey, except for a small medial field. We have been able to distinguish homologous divisions as in the monkey. There are no sharp borders between adjacent fields, but rather gradients that run rostrocaudally: the caudal and lateral fields resemble more closely the neocortical fields. There is no a single cytoarchitectonic feature that defines the whole entorhinal cortex; neither the dense clumps in layer II nor the presence of a lamina dissecans are present all over the entorhinal surface. It is rather the multiplicity of techniques that give a better distinction of the different fields.

247.8 RELATIONS BETWEEN CINGULATE CORTICAL CELL DISCHARGE PATTERNS AND HIPPOCAMPAL FORMATION SLOW WAVE THETA ACTIVITY. L.V. Colom* and B.H. Bland*. SPON: (S.H. Roth) Dept. of Psychology, University of Calgary, Calgary, Alberta, Canada, T2N 1N4

The cingulate cortex, along with the hippocampal formation, receives projections from the medial septal and diagonal band nuclei. The cingulate cortex in turn projects to the hippocampal formation via the subicular and entorhinal cortices. Although the majority of research on slow wave rhythms and cell discharge patterns has been carried out on the septohippocampal system, recent research has indicated that there are theta generators and rhythmic cells in the cingulate and entorhinal cortices as well. In the present study we recorded cells in the cingulate cortex of rats anesthetized with urethane, during the spontaneous occurrence of slow wave theta and large amplitude irregular activity (LIA). Electrode tip locations were marked by iontophoretically ejecting Pontamine Sky Blue. The responses of eight of the total of 16 cells recorded were tested during the systemic administration of eserine and 5 cells during the administration of nicotine. In the urethane condition, all 16 cells showed a clear activation during theta compared to LIA (range 2-100 times greater firing). In 13 of the cells, the increase in firing during theta was nonrhythmic with simple spike firing. Two cells were weakly rhythmic, again with simple spike firing and 1 cell showed a high degree of rhythmicity, firing in simple spike rhythmic bursts. All 8 cells tested with eserine were activated in a similar manner as during spontaneous theta and in contrast to hippocampal theta-on cells, nicotine also activated all 5 cells tested. We conclude that the cingulate cortex contains a population of cells whose discharge patterns are clearly related to the hippocampal formation EEG patterns of slow wave theta and LIA. The majority of the cells in the present study were similar to tonic theta-on cells in the hippocampal formation, although one rhythmic neuron was recorded. Furthermore, the cingulate cortex cells were activated by both eserine and nicotine, in contrast to our previous work on hippocampal formation theta-on cells. The latter cells were activated by muscarinic agonists and depressed by nicotine. The site of action of muscarinic and nicotinic activation of cingulate cortex cells requires further study. (Supported by AHFMR and NSERC)

247.9 QUANTITATIVE ASPECTS OF THE HUMAN CINGULATE CORTEX USING A COMPUTER CONTROLLED IMAGE ANALYZER. G. Schlaug, E. Armstrong, A. Schleicher*, K. Zilles, Department of Anatomy, University of Cologne, D-5000 Cologne 41, FRG and Department of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

Cytoarchitectonic studies are based on structural inhomogeneities, which are due to differences in cell densities, size, shape and columnar organization. In this study the varying cytoarchitectural complexities within the cingulate cortex have been quantitatively analyzed using a computer controlled image analyzer (Microvideomat 2, C. Zeiss, FRG). A grey level index (GLI) has been measured, which is defined as the ratio of the area covered by cell bodies to the entire area of the measuring field. The transition zone from allo- to isocortex is characterized by shifts in laminar proportions and cellular densities. The isocortex has lower cell densities in the outer main lamina, but higher cell densities in the inner main lamina than the allocortex. Since the GLI values are also a measure of neuropil proportions, these results are discussed as structural correlates of a relative increase in the receptive and processing capacities of the isocortex over the adjacent allocortex.

In contrast to the posterior cingulate cortex, the anterior part lacks an inner granular layer and shows a lower cell density. This has been substantiated by columnar cell counts showing areal specific differences. In order to investigate the causes for these different cell densities, the dendritic arborization of layer V pyramidal neurons were analyzed in a Golgi-study. These cells have a significant increase in primary basilar dendrites in the anterior cingulate cortex, which leads to an increase in neuropil volume and partially explains the lower cell densities.

The isocortical areas of the posterior cingulate cortex (23 and 31) and the adjacent parietal (7) and visual (19) cortices can be differentiated by quantitative criteria. Besides differing GLI-values and laminar proportions, areas 7 and 19 have a higher degree of columnar organization than areas 23 and 31. A method developed to measure radially oriented and periodical cell columns, shows no significant differences in the width and periodicity of the columns, but their delineability from the surrounding neuropil differs among these areas. The columns may present a basic uniform cortical structure, and their differences in delineability may depend on afferent fiber bundles.

247.10 BEHAVIORAL AND ELECTROPHYSIOLOGICAL EFFECTS OF LESIONS OF THE INSULAR CORTEX IN THE SQUIRREL MONKEY (S. SCIUREUS). A. S. Kling, R. Lloyd, O. Ricci*, M. Ghazizadeh*, B. Wexler* and S. Ruane*. Psychiatry Service, VA Medical Center, Sepulveda/UCLA Department of Psychiatry, CA 91343.

This study is the first report to our knowledge of the effects of bilateral lesions of the insular cortex in primates. Clinical observations and anatomical evidence have suggested that the insula subserves both general and special visceral sensory sensibility. Autonic and somatomotor effects have been observed with electrical stimulation, and deficits in language are seen following stroke in man. Anatomically, the insula receives projections from a variety of limbic structures and projects to both medial and lateral amygdala as well as other structures.

Because of its amygdala projections, we hypothesized that bilateral ablation in a primate species would affect both social/affective behavior and amygdaloid electrical activity. For this study, 3 adult (1 ♂ 2 ♀) S. sciureus were studied for 6 months to 1 year. 1 ♂ and 1 ♀ had a pair of chronic electrodes implanted in the medial and lateral amygdala prior to the insular ablations. Electrical recordings via radiotelemetry were made during presentation of visual, auditory, taste and small stimuli while restrained, and auditory stimuli, food, and a live snake in a social setting. After bilateral ablation of the insular cortex, all 3 subjects exhibited 7-14 days of anorexia and lethargy, followed by (1) omini and hyperphagia, (2) tameness toward handling, (3) excessive genital rubbing by the females, (4) absence of genital display in male, (5) a fall in social rank, (6) decreased social interaction, (7) approach to a live python without fleeing when bitten. Changes in amygdaloid electrical activity include a 25-50% reduction in total power from medial subnuclei to all stimuli. Greater reductions were observed in social versus restrained conditions. In general there was a shift in the distribution of total power from the higher bands to delta and theta. Responses to taste and smell followed the same pattern as auditory and visual stimuli. For the lateral placements, small increases in total power were observed, especially under restrained conditions, to auditory and visual stimuli. The behavioral changes after bilateral insular lesions are strikingly similar to amygdalectomy. Reductions in total power and a shift in frequency distribution recorded from amygdala after the insular cortex lesions are consistent with the predominant role of the medial amygdala in regulation of social/affective behavior and suggests participation of the insular cortex, along with the temporal pole and orbital cortex, in the maintenance of social bonding in primates.

247.11 TOPOGRAPHIC AND LAMINAR ORGANIZATION OF THE CONNECTIONS BETWEEN THE AMIGDALA AND THE ORBITO-INSULO-TEMPORAL CORTEX IN THE CAT. A. Llamas*, F. Clascá* and F. Reinoso-Suárez. Dpt. Morfología, Fac. Medicina, Univ. Autónoma. 28029 Madrid.Spain.

The orbito-insulo-temporal cortex of the cat covers the convexity of the orbital gyrus (GO), and the ventral portions of the anterior and posterior (GSP) sylvian gyri, as well as the lips and bottom of the anterior rhinal, sylvian, and rostral half of the posterior rhinal sulci. This region, which includes the taste area, the granular and agranular insular cortices, the rostral half of areas 35 and 36, and the ventral part of the temporal area (Krettek,J.E. and J.L.Price,J. Comp. Neurol.,172:687,1977) , is heavily interconnected with the amygdala (A). In order to elucidate the detailed topography of these connections, fifty-seven cats received small injections of HRP or HRP-WGA in different portions of OIT or A.

Our rersult indicate that the lateral (AL) and basal (AB) nuclei are the almost exclusive source of amygdaloid projections to OIT. The neurons from which these projections arise are mainly located within the rostral half of these nuclei. AL projects heavily to the caudal two-thirds of OIT. There is a remarkable topographic segregation within AL between neurons projecting to periallocortical or to isocortical areas. AB projects over the whole extension of OIT with a less clear topographical arrangement. The laminar distribution of the axons of AL and AB neurons is different for some OIT regions.

The various OIT sectors show clear differences in their cortico-amygdaloid projections. AB receives projections mainly from the agranular insula and area 35. The central nucleus receives projections from the rostral half of GO, although this nucleus does not project to OIT. The rostral third of OIT sends only very scarce projections to AL. The insular cortex projects heavily to AL, and the distribution of these connections reciprocates the topography of the amygdalo-cortical projections from AL. AL also receives a strong input from areas 35 and 36, but these projections show less topographic segregation. A band of cortex located in the ventrolateral aspect of the GSP strongly projects to AL, while adjacent sectors of this gyrus have nearly no connexions with A. The laminar distribution of the neurons which give rise to the cortico-amigdaloid projections is different for AL and BL, and from one cortical region to another.

The present results confirm and extend previous findings (Llamas,A. et al., Science ,95: 794, 1977; Llamas,A. et al., Neuroscience, 15: 561, 1985) and show that OIT is the most prominent gateway for direct neocortical inputs to A, as well as one of the main targets of amygdalo-cortical connections. The topographic organization of these interconnections may represent an anatomical basis for segregated channels conveying information between the different OIT areas and A. In addition, the connectional heterogeneity shown in this study add support for further parcellation of some nuclei of the cat's amygdaloid complex.

CELL LINEAGE AND DIFFERENTIATION III

248.1 CONDITIONED MEDIUM RESTORES A NORMAL PHENOTYPE TO JIMPY OLIGODENDROCYTES GROWN IN VITRO. P.E. Knapp, W.P. Bartlett[1] and R.P. Skoff. Dept. Anat. and [1]Cell Biol., Wayne State Univ. Sch. of Med., Detroit, MI 48201 and [1]Dept. Anat., The Milton S. Hershey Medical Center, Hershey, PA 17033.

Using immunocytochemical techniques we have shown that oligodendrocytes (OLs) from normal mouse cerebra express galactocerebroside (GC) and 2',3'-cyclic nucleotide 3'-phosphohydrolase (CNP) in cell bodies, processes and large membrane sheets by 7 days in vitro (DIV) (Knapp et al, Dev. Biol., 120:356, 1987). In our system, relatively small numbers of OLs from jimpy (jp) brains are GC+ or CNP+, and jp OLs do not produce the large (>100 um diameter) immunostained membrane sheets which are characteristic of normal cultures. Thus, development and differentiation of OLs is compromised in vitro as well as in vivo. In order to study the interactions of developing jp glia, we grew mixed cerebral cultures from jp brains in normal control medium and in control medium which had been conditioned for 1-2d by cultures consisting primarily of normal astrocytes (CM). CM was either centrifuged (2,000 rpm for 12 min) or passed through a 0.22 um sterile filter before application to jp cultures. After only 7d in CM (8 DIV) jp OLs show marked improvement relative to those grown in control medium. The numbers of both GC+ and CNP+ cells were increased, usually several hundredfold. Growth in the presence of CM had a likewise remarkable effect on the production of immunostained membrane sheets by jp OLs. In these cultures OLs were able to produce and maintain membranes which contained both GC and CNP and which were virtually indistinguishable from those in normal cultures. Our normal OLs produce immunodetectable amounts of myelin proteolipid protein (PLP) after 8-9 DIV, but we do not see PLP incorporation into the membrane sheets even after 4 weeks in vitro. Jp cultures can rarely be immunostained for PLP. When jp OLs are grown in CM as described, PLP immunostaining is observed in cell bodies and processes in a normal pattern. These results show that under the right conditions jp OLs will exhibit normal phenotypic characteristics. Jp OLs, therefore, have the genetic capacity to produce myelin constituents even though this capacity is not normally expressed. CM from jp cultures did not interfere with normal OL development, suggesting that jp cells do not produce "oligodendrotoxic" factors which interfere with OL development. Our results suggest that normal brain cells provide a soluble factor, necessary for normal oligodendrocyte development, which is missing in jp cultures. Astrocytes are the most likely source of this factor since they constitute the vast majority of cells in conditioning cultures. This hypothesis is especially interesting in view of recent studies showing that astrocytes and/or factors produced by astrocytes are important in the expansion and differentiation of OL populations (eg. Noble and Murray, EMBO J., 3:2243, 1984; Bhat and Pfeiffer, J. Neurosci. Res., 15:19, 1986). Supported by NS 15338.

248.2 FURTHER OBSERVATIONS ON THE GLIAL CELL POPULATION OF THE OPTIC NERVE OF THE MYELIN DEFICIENT RAT. K.F. Jackson*, J.P. Hammang*, I.D. Duncan. (Spon: R.L. Sufit). Dept. of Medical Sciences, School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI 53706.

The myelin deficient (md) rat shows a failure of normal CNS myelination, caused by an x-linked recessive lethal gene. This study, the preliminary results of which have already been reported in part (Soc. Neurosci. Abstr. [1986] 427.10), was undertaken to investigate the kinetics of the glial cell population in the optic nerve of this mutant at a wide range of ages, and to determine the cell types involved in division, their morphology, and their ultimate fate. 4 md and 4 normal male littermate rats at 3,6,8,10,12,14,16,18,21,25 and 30 days of age were perfused with Karnovsky's aldehyde fixatives after pulse-labeling with tritiated thymidine. Both optic nerves were removed from each animal, the intracranial segments processed into epon blocks and ultrathin sections taken for EM, with adjacent 1µ sections taken for LM autoradiography. Labeling indices were determined as previously described, and it was found that at 14,16,18,21 and 25 days there were significantly more dividing cells ($p<0.05$) in the md rat optic nerves. At the other ages there was no significant difference between md and control rats. It was also observed that at 18 days there was a significantly higher total glial cell count in the md optic nerve, but this was reversed at 30 days. Counts of pyknotic cells in normal and md optic nerves revealed significantly more cell death ($p<0.025$) at 14 through 30 days in the md rat. EM examination of these cells suggested that many of them were oligodendroglial origin, their cytoplasm containing distended cisterns of RER as described in a previous study (Dentinger et al, 1985. Brain Res. 344:255-266). By comparing the LM autoradiographs with adjacent ultrathin sections examined by EM, dividing cells in the md and control rats at 14 through 25 days were classified according to morphological criteria. The majority of the dividing cell population in the md rat was found to consist of oligodendroglial cells, immature in appearance, and undifferentiated cells, the percentage of which apparently increased with age. At 14 days, 10% of dividing cells in the md rat were astrocytic in type, but this percentage declined to zero in the older mutants. There were more labeled microglial cells in the md rat than in the controls at all the ages studied, many with cytoplasm filled with phagocytosed material. In all the normal animals, the majority of labeled cells were oligodendroglia, with many undifferentiated cell types also taking up thymidine. There were very few labeled astrocytic or microglial cells in these animals. Thus it would appear that in the md rat there may be a defect in the oligodendroglial population, resulting in a protracted division of precursor and immature cell types, the production of morphologically abnormal oligodendrocytes and ultimately a high percentage of dying cells, with a concomitant microglial response and failure of normal myelin production.

(Supported by NIH grant NS23126-02 and NMSS grant 1791-A-1)

248.3 SOLUBLE FACTOR(S) REGULATE THE TIMING OF TYPE-2 ASTROCYTE DIFFERENTIATION IN VITRO. L.E. Lillien and M.C. Raff*. MRC Developmental Neurobiology Programme, Zoology Dept., University College London, London WC1E 6BT, UK.

Previous work on glial cell lineages in the rat optic nerve (O.N.) has demonstrated that oligodendrocytes and type-2 astrocytes develop from a common (O-2A) progenitor: while differentiation in vitro into oligodendrocytes appears to be constitutive, differentiation into type-2 astrocytes requires an inducing agent such as fetal calf serum.

In contrast to cultures of O.N., in cultures of embryonic rat brain we have found that type-2 astrocytes develop in the absence of exogenous inducing agents. In cultures prepared from 15 day embryonic rats (grown in 10% horse serum, selected for its lack of type-2-inducing activity), oligodendrocytes (identified by staining with anti-galactocerebroside [GC] antibody) first appeared after approximately 1 week in vitro, while type-2 astrocytes (defined by staining with A2B5 and GFAP antibodies) were first detected after 16-18 days in vitro (d.i.v.), a time equivalent to post-natal (PN) days 9-11, when type-2 astrocytes are first detectable in vivo. Supernatants were collected from these cultures at 3 day intervals and assayed for their ability to induce O-2A progenitor cells ($A2B5^+$, GC^-, $GFAP^-$ process-bearing cells) to express GFAP. Soluble inducing activity did not appear in the cultures until 16-18 d.i.v., at which time the supernatants induced 20-40% of O-2A progenitor cells from newborn brain or optic nerve to express GFAP.

The timing of the appearance of this activity does not simply reflect a threshold density of cells as the activity appears at the same relative time (equivalent to PN 9-11) over a range of initial plating densities and in cultures prepared from newborn rather than embryonic brain.

Studies of cultures of optic nerve, purified type-1 astrocytes, retina and co-cultures of these tissues suggest that the production of soluble GFAP-inducing activity depends on an interaction between O-2A lineage cells and type-1 astrocytes and does not require neurons.

248.4 CYCLIC AMP INDUCES EXPRESSION OF OLIGODENDROCYTE MARKERS DURING A CRITICAL PERIOD IN CULTURE. David W. Raible and F. Arthur McMorris. The Wistar Institute, Philadelphia, PA 19104.

We have previously shown that the oligodendrocyte enzyme 2',3'-cyclic 3'-phosphohydrolase (CNP) is induced by cyclic AMP analogs in primary cell cultures from 1 day old rat brain. Treatment of 1- to 2-week-old cultures with cyclic AMP analogs increased the amount of CNP protein per oligodendrocyte, not the number of oligodendrocytes per culture. We have now examined the effects of cyclic AMP analogs during the first week of culture, at which time there are few oligodendrocytes present. Cultures were grown on microscope slides, treated with 1 mM dibutyryl cyclic AMP (dbcAMP) or 8-bromo-cyclic AMP at various times, and fixed for immunocytochemistry. When cells were cultured with dbcAMP for three days, the percentage of CNP positive oligodendrocytes increased 3-4 fold. If treatment with dbcAMP was not started until day 7 of culture, no induction in oligodendrocyte number was seen. Similar results were obtained when cultures were stained for the oligodendrocyte markers myelin basic protein (MBP) and galactocerebroside (GC). Induction of oligodendrocyte number was similar in the presence or absence of serum, indicating that serum factors were not necessary for induction. When cultures treated with dbcAMP were grown in the presence of tritiated thymidine, no difference in DNA synthesis was seen in CNP positive cells as compared with control, indicating that dbcAMP does not induce proliferation of young oligodendrocytes. These observations are consistent with the hypothesis that cyclic AMP induces oligodendrocyte differentiation. Supported by NSF BNS 85-18023, NMSS RG1767-A-1 and NIH CA 09171 and NS 11036.

248.5 CONTROL OF SCHWANN CELL MYELIN FORMATION BY BASAL LAMINA. C.F. Eldridge*, R.P. Bunge and M.B. Bunge. Dept. Anatomy & Neurobiology, Washington University Sch. Med., St. Louis, MO 63110.

Observations on tissue culture preparations containing DRG neurons and Schwann cells (SCs), but no fibroblasts, have established that SCs interacting with axons are able to produce basal lamina and fibrous collagen components of endoneurial extracellular matrix and to myelinate axons. SCs grown with neurons in a serum-free defined medium do not assemble basal laminae or form myelin. Ascorbic acid stimulates both SC basal lamina assembly and myelin formation with similar dose-response relationships. This stimulation of SC differentiation by ascorbic acid, however, requires the presence of a non-dialyzable serum component(s); the serum component alone has essentially no detectable effects on SC differentiation. We have hypothesized that ascorbic acid has no direct effects on SC myelin formation, but that instead ascorbic acid acts directly to enable the SC to assemble a basal lamina, which is required for differentiation into a myelin-forming cell. This hypothesis is supported by the following evidence: (1) Oligodendrocytes, instead of SCs, can be grown with DRG neurons in this culture system; these central nervous system myelin-forming cells, which do not produce basal lamina, show no requirement for ascorbic acid (or serum) to form myelin in culture. This result indicates that ascorbic acid is not directly required for myelin biosynthesis or assembly. (2) Although there are few quantitative or qualitative differences in overall protein secretion between SCs cultured with neurons in defined medium or in the presence of ascorbic acid and serum, the formation of triple-helical (pepsin-resistant) type IV collagen is not detectable in the absence of ascorbic acid. The effect of ascorbic acid on SC basal lamina assembly may thus be mediated via effects on the biosynthesis of type IV collagen. (3) Exogenous basal lamina is able to completely substitute for ascorbic acid-stimulated endogenous SC basal lamina production. Thus, a gel-forming extract of EHS sarcoma basal lamina matrix (Matrigel) allows SCs to undertake myelination in the absence of ascorbic acid and serum; type I collagen gels have no similar effect. Surprisingly, purified laminin, but not type IV collagen or basal lamina heparan sulfate proteoglycan, can substitute for ascorbic acid; in the presence of serum, 50 ug/ml (50 nM) laminin promoted the formation of 261 myelin segments/mm^2 (SD=26, three experiments), whereas 50 ug/ml (280 uM) ascorbic acid promoted 293 myelin segments/mm^2 (SD=24). Laminin induces the formation of basal lamina-like structures on abaxonal SC surfaces; these structures contain not only laminin but also heparan sulfate proteoglycan and type IV collagen as assessed by immunofluorescence. The basal lamina may act to promote SC differentiation by influencing the organization of the cell's plasma membrane and cytoskeleton. (Supported by NIH grants NS09923 and NS07071.)

248.6 SCHWANN CELL DIFFERENTIAL EXPRESSION OF P_0 IN THE ABSENCE OF AXONAL INFLUENCE DURING POSTNATAL DEVELOPMENT. Kurt R. Brunden*, Anthony J. Windebank, Joseph F. Poduslo Departments of Neurology and Biochemistry, Mayo Clinic and Mayo Foundation, Rochester, MN 55905

Previous work from this laboratory (Poduslo, J.F. and Windebank, A.J., Proc. Natl. Acad. Sci., 82, 5987-5991, 1985) has revealed that Schwann cell (SC) cultures from permanently transected adult rat sciatic nerves are capable of continued expression of the major myelin glycoprotein, P_0, in the absence of both axons and myelin assembly. In contrast, SCs derived from actively myelinating, 4-day-old neonatal rat sciatic nerves lose the capacity to synthesize P_0 after culture, suggesting that the SCs are capable of reverting to a progenitor state. We now show that the ability of cultured SCs to suppress the expression of P_0 occurs over a short and finite time-span during development. If sciatic nerves of 12-day-old rats are explanted in culture for 5 days followed by [^{3}H]mannose precursor incorporation, active P_0 biosynthesis can be demonstrated. Pulse-chase analysis reveals that newly synthesized P_0 is degraded shortly after its formation. This post-translational catabolism has recently been documented in the permanently transected adult sciatic nerve and has been shown to be due to lysosomal targeting of the glycoprotein from a site at or after the medial Golgi (Brunden, K.R. and Poduslo, J.F., J. Cell Biol., 104, 661-669, 1987). Like P_0 of the transected nerve, the catabolism of the glycoprotein synthesized in the explant cultures from 12-day-old animals can be inhibited by the addition of the Golgi mannosidase II inhibitor, swainsonine (SW). This inhibition is presumably caused by the formation of an oligosaccharide structure that results in the inefficient recognition of P_0 by an undefined lysosomal transport system. P_0 synthesized in the SW-treated cultures is readily labeled with [^{3}H]fucose, indicating that the glycoprotein is routed for degradation sometime after reaching the medial Golgi. These data suggest that the neonatal SCs that are incapable of expressing P_0 after culture are only able to revert to a progenitor state for a finite period, after which they behave much like the permanently transected sciatic nerve. The post-translational degradation of P_0, and perhaps other myelin proteins, appears to be a common mechanism employed by SCs that are deprived of axonal influence. (Supported by NINCDS Grant NS-20551 and by the Borchard Fund).

248.7 DEVELOPMENT OF THE OLFACTORY NERVE FIBER LAYER IN THE OLFACTORY BULB OF MOUSE EMBRYOS. R. Doucette. Department of Anatomy, Univ. of Sask., Saskatoon, Saskatchewan S7N 0W0 Canada.

The olfactory epithelium is an interesting anomaly to the generally accepted pattern of mammalian neurogenesis in that its neurons continue to be produced throughout the entire life of the animal. To reach their target cells in the central nervous system (CNS) the axons of these newly formed neurons must grow through the olfactory nerve fiber layer (ONL), which is comprised of two morphologically distinct types of glial cell. One of these cell types is most definitely an astrocyte, but the other cell type, which is solely responsible for ensheathment of olfactory axons, is more difficult to classify. Doucette (Anat. Rec 210: 385, 1985), who referred to this latter cell type as an ensheathing cell, has hypothesized that it is a morphological variant of the typical astrocyte; this hypothesis implies that during development a common progenitor cell gives rise to both cell types. The aim of the present study was to examine the early development of the ONL. Pregnant Swiss mice were killed by cervical dislocation on days 10 to 16 of pregnancy; the day of the vaginal plug was designated embryonic day 1 (E1). The uterine horns were removed by cesarean section and the embryos were dissected free of the uterus. Following decapitation each head (E10-14) or dissected brain piece (E15-16) was fixed by immersion and embedded in Epon. The first olfactory axons penetrated the rostral wall of the cerebral vesicle (E13-14) prior to its evagination to form an olfactory bulb. From the earliest stage of vesicle evagination the olfactory axons and the cells that accompanied them (see below) formed quite a distinct ONL; even in E16 embryos the ONL was distinctly separate from the rest of the developing bulb, although small fascicles of axons did leave the layer to enter the deeper neuropil. The cells of the ONL were part of a morphologically homogeneous population, and were presumably glial precursor cells (not neurons) because they ensheathed the olfactory axons. Morphologically identical cells were found within the PNS portion of the olfactory nerve fascicles but not in the deeper neuropil of the developing bulb, suggesting that the glial precursor cells of the ONL were of peripheral origin. It was the cytoplasmic processes of these latter cells that gave the ONL such a distinct appearance by clearly separating it from the deeper layers of the bulb. In conclusion, the whole ONL of the E13-16 mouse olfactory bulb is of peripheral origin. If this interpretation proves to be correct, then the implication is that the two glial cell types in the ONL of adult mammals have separate developmental origins; the ensheathing cells arising from the PNS and the astrocytes from the CNS.

248.8 DIFFERENTIATION OF TE671 HUMAN MEDULLOBLASTOMA CELLS: EFFECTS OF RETINOIC ACID, PHORBOL MYRYSTATE ACETATE AND HEXAMETHYLENE BIS-ACETAMIDE ON NEURONAL CHARACTER AND MORPHOLOGY.
Hal N. Siegel, Ph.D. and Ronald J. Lukas, Ph.D., Laboratories of Neurochemistry and Cell Culture, Barrow Neurological Institute, 350 West Thomas Road, Phoenix, Arizona 85013.

The TE671 human medulloblastoma cell line derives from a tumor of presumed neuroectodermal origin. Studies have since demonstrated that these cells possess particular characteristics of mature neurons, including neuron-specific intracellular enzymes and membrane-bound high affinity binding sites for certain neurotransmitters. Immunocytochemical staining demonstrated the expression of the neuron specific cell surface determinant neuron-specific enolase (NSE). In contrast, immunocytochemical analysis shows markers for other neuron-specific antigens, such as synaptophysin and neurofilament proteins, are not normally expressed. The absence of similarly localized glial-specific intermediate filament proteins (glial fibrillary acidic protein, GFAP), suggests this cell line is constituitively, nominally neuronal.

Treatment of low density, dividing cells with media supplemented with various differentiating agents demonstrates that the TE671 cells are capable of multiple differentiated states, initially defined by visually assessed morphology. Culture in micromolar phorbol myrystate acetate (PMA) induces a distinctively different morphology than does addition of millimolar concentrations of hexamethylene bis-acetamide (HMBA) or retinoic acid. Evidence from immunocytochemical determination of NSE, GFAP, synaptophysin, and the 68, 160 and 200 kilodalton neurofilament peptides demonstrates that the neuronal nature of the TE671 cell is magnified by these differentiating protocols, while no similar increase in glial quality occurs.

Thus, the TE671 cell undergoes only neuronal differentiation under the influence of these agents, which in other tissues demonstrate no such uniformity of action. Implications for the continued use of normal/differentiated TE671 cells as a model of central nervous system neurons will be discussed.

248.9 NEUROGENESIS IN MAMMALIAN CENTRAL NERVOUS SYSTEM: AN IN VITRO MODEL FOR OLFACTORY NEURON DIFFERENTIATION.
Brian L. Largent, Ronald G. Sosnowski*, Ernest Barbosa*, and Randall R. Reed*, Department of Molecular Biology and Genetics, Howard Hughes Medical Institute, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The vertebrate olfactory neuronal system is unique among central neuronal systems in that it retains into adulthood the capacity to sustain a population of primary sensory neurons by steady state replacement of mature neurons. This process is accomplished by stem cells which differentiate and mature into primary olfactory neurons - replenishing neuronal cells that have degenerated. Indeed, this process mimics in microcosm many aspects of the developmental process of the nervous system itself - i.e., the maturation and commitment of neuroblasts to specific neuronal phenotypes as well as the death of neurons during the modeling of neuronal and synaptic organization.

We have taken a novel approach to the generation of clonal cell lines possessing the unique properties of primary olfactory neurons. To this end, we are immortalizing primary olfactory neurons by germline transformation of mice with a recombinant oncogene. Specifically, we have constructed a hybrid gene consisting of the early region of simian virus 40 (SV40) - encoding the oncogene product, large T-antigen - flanked 5' by the cell-specific regulatory elements (enhancers and promoters) of the rat gene for olfactory marker protein (OMP), a protein abundantly and uniquely expressed within primary olfactory neurons. Expression of SV40 large T-antigen (T-ag) within cells induces immortalization and/or transformation of those cells. The regulatory elements of the OMP gene should target expression of T-ag to primary olfactory neurons, thereby affecting those cells in a selective fashion within the transgenic mouse. The feasibility of such an approach in transforming and immortalizing specific cell types has been demonstrated in several paradigms (Hanahan, D. (1985) Nature 315:115-122O; Mahon et. al., (1987) Science 235:1622-1628).

Several interesting modifications of this approach utilize hybrid genes encoding various mutants of T-ag. One such variation of this paradigm, replacing wild type T-ag with a temperature-sensitive mutant, allows the regulation of oncogenic potential in cell culture by switching between permissive and non-permissive temperatures, thus, exerting some control over the effects of T-ag on the differentiation state of these cells. In obtaining immortalized neuronal cell lines with minimal transformed properties, two mutants of T-ag which immortalize but do not transform cells may prove to be optimal alternatives to wild type T-ag. We are currently generating transgenic mouse lines for each of these recombinant oncogene constructions. Olfactory neuroepithelium from these transgenic animals should be a source of primary olfactory neurons that will propagate indefinitely in culture. Such cell lines will facilitate a variety of molecular studies ascertaining the specific molecules which give primary olfactory neurons their unique attributes. This scheme for generating immortalized cell lines of defined origin and clonality is generally applicable for other neuronal phenotypes as well - given specific gene regulatory elements can be found to selectively drive expression of the trans-oncogene within a particular set of neurons.

248.10 BROMODEOXYURIDINE IMMUNOCYTOCHEMISTRY TO EXAMINE THE PROLIFERATION AND MIGRATION OF RODENT CORTICAL NEURONS. S.J. Muller, M.W. Miller, and R.S. Nowakowski (SPON: M.M. LaVail). Dept. of Anatomy, Sch. Osteopathic Med. and R.W. Johnson Med. Sch., UMDNJ, Piscataway, NJ 08854.

During development, cortical neuroblasts proliferate in one of two germinal zones, the ventricular or subventricular zone, from which they migrate to the cortical plate. [^{3}H]thymidine autoradiography has been used extensively to trace this early development. Recently, tumor biologists have developed an alternative method for studying cellular proliferation using the immunocytochemical localization of another thymidine analogue, 5-bromo-2'-deoxyuridine (BrdU). We are applying this new methodology to examine the development of the cerebral cortex. Pregnant rats or mice were injected simultaneously with 50 or 100 µg/g of BrdU and with 5.0 or 10.0 µCi/g of [^{3}H]thymidine. Animals were perfused with 70% ethanol 1 hr, 3 days, or 60 days after the injection. Brains were embedded in paraffin and cut at 3-6 µm. Tissue was reacted with a primary antibody against BrdU (Becton-Dickenson) using an avidin-biotin complex procedure (Vector). Immunostained tissue was then processed by standard autoradiographic techniques. In all experimental situations, the distribution of BrdU immunoreactive cells was identical to that of autoradiographically labeled cells. All autoradiographically labeled neurons were BrdU positive. Moreover, there was a high correlation in the intensity of label, i.e., densely-stained BrdU-immunoreactive neurons and heavily-labeled autoradiographically labeled cells were densely BrdU-immunostained. In animals that survived 1 hr after the injection, BrdU-positive neurons were distributed in the ventricular and the subventricular zones and the density of labeling of all cells was comparable. In tissue processed 3 days post-injection, the most densely stained BrdU-positive cells were distributed at the superficial edge of the cortical plate, and less densely stained cells were scattered through the deeper cortical plate, intermediate zone, subventricular zone, and ventricular zone. Following an injection of a rat on gestational day 17 densely-stained immunoreactive neurons were distributed in layers IV and V of the mature cortex, whereas less densely-stained immunoreactive cells were in the supragranular laminae. Thus, BrdU immunocytochemistry is suitable for developmental studies of the nervous system and provides an alternative to [^{3}H]thymidine autoradiography. In one important way, the immunocytochemical technique is superior to the autoradiography in that BrdU-positive cells are distributed throughout the depth of the tissue. Funded by AA 06916, DE 07734, a grant from the UMDNJ Foundation (M.W.M.), and by NS 23647 and a grant from the G.R.S. program of R.W. Johnson Med. Sch. (R.S.N.).

248.11 CELL LINEAGES AND MOVEMENTS IN THE FORMATION OF THE ZEBRAFISH EMBRYONIC AXIS. C. B. Kimmel and R. M. Warga*. Inst. of Neuroscience, Univ. of Oregon., Eugene, OR 97403

Cell lineage analyses during zebrafish development have revealed that clones developing from single gastrula cells are confined to single tissues. Moreover, cells in clones that populate the CNS are often distributed very regularly in the tissue (bilaterally, and periodically along the neuraxis). These restrictions may indicate that either the fates of the progenitor gastrula cells are already specified, or alternatively that the movements of uncommitted gastrula cells are developmentally programmed.

We have monitored the cell divisions, positions, movements, and eventual fates of gastrula cells in live developing embryos. Except for cells whose daughters remain confined to an outer enveloping epithelium, we found no evidence for programming of the plane or pattern of cell divisions. On the other hand, regular patterns of morphogenesis lead predictably to the formation of particular axial structures by cells originating at stereotyped positions in the early gastrula. Cell movements vary according to the germ layer of origin (ectoderm or mesoderm) of the structure that is formed, and these movements appear to more accurately predict cell fate than does cell lineage. The regular arrangements of clonally related neural cells arise as their progenitors successively intercalate with other cells in a manner that appears to be independent of cell lineage, and which may function to elongate the developing embryonic axis. We observed variability in neuron type and position within small clones that seems to argue against a strict role of cell lineage in determining cell fate. We suggest, alternatively, that observed clonal distributions are generated by developmental processes that are driven by morphogenesis - the formation of properly arranged and shaped systems of organs - in which cell lineage is unimportant. Thus it may be that decisions about cell fate are made only during or after the cell migrations that accompany gastrulation. (Supported by the NSF.)

248.12 REGULATION OF PRIMARY MOTONEURON AND ROHON-BEARD NEURON LINEAGES IN FROG EMBRYOS. S.A. Moody. Department of Anatomy and Cell Biology, University of Virginia School of Medicine, Charlottesville, VA 22908.

Fate maps of the number of primary motoneurons (PMN) and primary sensory neurons, the Rohon-Beard cells (RB), derived from each of the blastomeres of the 16-, 32-, and 64-cell stage of the South African clawed frog (Xenopus laevis) have been constructed. As cleavage proceeds, only certain daughter cells remain in the neuronal lineages, seeming as if parcelling of the mother cell cytoplasm also parcels neuronal fate. For example, when blastomere V2.2 divides, its anterior daughter cell (V2.2.2) produces 89% of the mother cell's RB progeny, and its posterior daughter cell (V2.2.1) produces only 11% of them. When blastomere V2.2.2 divides, both daughter cells produce approximately 50% of the mother cell's RB progeny. However, when blastomere V2.2.1 divides, only its anterior daughter cell (V2.2.1.2) continues to be a progenitor of RB neurons. In order to determine whether these lineages are specified at early cleavage stages or are capable of regulation, we have performed experiments in which single 32-cell stage blastomeres were removed microsurgically, and adjacent blastomeres were marked by the intracellular injection of a lineage tracer. The numbers of PMN and RBN produced by each lineage were counted and compared to those produced in an intact embryo.

Several different region-specific responses were observed. Blastomeres that lie on the boundaries of "neurogenic" regions no longer contributed to nervous system when a nervous-system producing neighbor blastomeres was ablated. Some blastomeres in equatorial regions overproduced PMN and others underproduced PMN and RB after neighbor cell ablation. Animal pole blastomeres made the normal numbers of both PMN and RB in ablated embryos. These results suggest that the potential to produce nervous system need not be intrinsically determined at early cleavage stages. Furthermore, certain regions of the blastula show regulative responses and other regions appear to require cell-cell interactions in order to fully express their normal neural lineages. Finally, non-neural branches of the lineages remained qualitatively similar to those in intact embryos except when blastomeres appeared to regulate. In cases in which there was an overproduction of PMN or RB, labeled cells were missing from organs that normally were populated by the labeled blastomere's lineage.

248.13 **MULTIPOTENTIAL PRECURSOR CELLS IN XENOPUS OPTIC VESICLE: A CELL LINEAGE ANALYSIS.** **Richard Wetts and Scott E. Fraser. Dept of Physiol & Biophysics and the Developmental Biology Center, Univ Calif, Irvine, 92717.**

Cell lineage analysis is an important step in understanding when and how different cell types are specified during development. Intracellular injection of cell autonomous lineage tracers offer a means to approach this question at the single cell level. Here, we apply this technique to the study of the terminal lineages in the Xenopus neural retina. To perform a prospective lineage analysis, lysinated rhodamine dextran (LRD) was iontophoretically injected into a dividing cell in the optic vesicle (St. 22-24). After LRD injection, the animals were raised to free-swimming larvae (St. 40-49), fixed in 4% paraformaldehyde in phosphate buffer, embedded in methacrylate, and sectioned at 20-30 microns. Sections were examined with a 100x objective on an epifluorescence microscope equiped with a light-intensifying camera and an image processing system.

The vertebrate retina has 6 major types of glia and neurons located in 3 layers. In order to determine the potential of the injected cell, the goal is to identify the different types of cells which are labeled; identification of the layer is a first step towards this goal. Five of the 35 clones were located in only 1 layer, (mean size: 2.6 cells), 15 clones were distributed over 2 layers (mean: 11.9 cells), and 15 clones were distributed over all 3 layers (mean: 21.9 cells). Because many of the clones included cells of 3 different layers, there must be a precursor cell (in the optic vesicle) for at least 3 different types of cells in the retina. It is possible that this multipotential precursor can give rise to all types of retinal cells. Rods, cones, horizontal, bipolar, amacrine, and ganglion cells have all been identified within clones containing other cell types. Since the optic vesicle cells are often multipotent, developmental restrictions of cell phenotype must occur relatively late in the development of the frog neural retina.

While there is no data yet indicating this, it remains possible that there are restricted precursors (committed to producing only one cell type) as well as the multipotent cells in the optic vesicle. In fact, even those small clones located in 1 or 2 layers did not appear to consist of only one cell type. Furthermore, the same cell types were also seen in the larger clones. Thus, the labeled progenitor may have had the potential of forming many cell types, but actually produced only a limited subset due to the small clone size. This situation cannot be distinguished from a committed precursor: when a progenitor produces only a few cell types (regardless of clone size), the lineage must be challenged by experimental manipulations to determine if the progenitor was committed or not. Thus, the evidence to date supports the existence of multipotential precursor cells in the frog optic vesicle.

248.14 COMMITTED NEURONAL AND GLIAL CELL PRECURSORS IDENTIFIED IN MOUSE NEUROEPITHELIUM. P.F. Bartlett*, K. Wycherley* and K.A. Bailey* (Spon: I. Darian-Smith). The Walter & Eliza Hall Institute of Medical Research, Melbourne 3050, Australia.

The neuronal and glial cells of the central nervous system are derived from a dividing population of neuroepithelial cells that form the neural tube. In order to study the early developmental pathways and the hierarchical arrangement of precursor populations in the CNS, the identification and subsequent isolation of pure populations of cells at various stages of differentiation are required. Furthermore, in vitro systems that support the subsequent differentiation of precursor cells are required to ascertain the full differentiation repertoire of each precursor population. In this report we have used a series of immunological markers combined with cell sorting procedures and in vitro assays to unequivocally identify neuroepithelial cells committed to either the neuronal or glial cell lineages. Our results indicate that as early as E10 progenitor cells in the neuroepithelium can be identified and purified by their surface phenotype and assigned to a specific cell lineage.

The neuronal progenitor cells are identified by their inability to express class I histocompatibility antigens ($H\text{-}2I^-$) in response to interferon-γ (IFN-γ), and they also express the surface ganglioside recognised by the A2B5 monoclonal antibody (Eisenbath et al., Proc.Nat.Acad.Sci, USA 76:4913, 1979). Type 1 astroglia progenitors are $H\text{-}2I^+$ and $A2B5^-$ and also express a surface marker recognised by the WEHY-NEP-6 monoclonal antibody. The NEP-6 marker is exclusively expressed on type 1 astroglial progenitors but is lost prior to glial maturation and the expression of GFAP. These two classes of progenitors have been isolated by flow cytometry, and with the use of high efficiency cell culture, which employs irradiated astroglia as an underlayer, have been shown to differentiate exclusively into cells belonging to either the neuronal or glial lineage. Thus, the neuroepithelium can be divided into distinct subpopulations based on surface phenotype and differentiation potential. This information has been used to construct a flow diagram of the differentiation pathways involved in early neural development. The fact that the vast majority of E9 neuroepithelial cells have a homogeneous surface phenotype ($H\text{-}2I^+$, $A2B5^-$, WEHY-NEP-6^-, $Keratin^+$) suggests that commitment to a particular cell lineage may be occurring during the E9-10 period.

248.15 IMMUNOCYTOCHEMICAL DEMONSTRATION OF THE ADRENERGIC NEUROTRANSMITTER PHENOTYPE IN THE HUMAN NEUROBLASTOMA CELL LINE LA-N-1 FOLLOWING DIFFERENTIATION. S. Sullivan and M.F.D. Notter. Dept. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

The human neuroblastoma cell line LA-N-1 was investigated for expression of adrenergic enzymes before and after differentiation to define the neuronal phenotype. Retinoic acid, a vitamin A analog, has previously been shown to induce morphologic differentiation in this cell line and therefore was employed in this study.

Cells were maintained in F12:MEM (1:1) medium supplimented with 15% heat inactivated fetal calf serum, and grown in a humidified incubator at 37°C with 5% CO_2: 95% air atmosphere. Two days after plating cells the culture medium was replaced with medium containing 10^{-5}M retinoic acid (RA) with subsequent refeeding with RA over the course of a week.

After four days, RA induced LA-N-1 cells to produce long neurites and to change from rounded to spindle shaped cells. After seven days in culture the cells were stained by immunocytochemistry using the PAP method for a number of adrenergic markers and specific neural proteins. Both the differentiated and undifferentiated cells stained positively for neurotransmitter enzymes tyrosine hydroxylase (TH), dopamine beta hydroxylase (DBH) and phenylethanolamine methyl-N-transferase (PMNT). After differentiation the level of staining for TH and DBH was significantly increased. There was no apparent difference in the staining of PMNT after differentiation.

A minority of the cells in these cultures were phenotypically different from the major cell population. They appeared as large flat cells that occasionally extended short processes. This sub-population did not stain for any of the adrenergic enzymes; nor did they stain with the astrocyte specific antibodies to glial fibrillary acidic protein or S100. However, these cells appeared to stain very faintly with neuron specific enolase. Therefore, the two different morphologies appear to be of the neuronal cell type.

Although the LA-N-1 cells stained for the adrenergic neurotransmitter enzymes they were not positive for catecholamine histofluorescence as determined by reaction with glyoxylic acid. Therefore, product may not be stored in these cells and a reuptake system for catecholamines is being examined.

The LA-N-1 cell line has been demonstrated to contain TH, DBH and PMNT suggesting that these cells have the capability of synthesizing catecholamines. If this is so LA-N-1 may provide a human derived supply of adrenergic cells for transplantation studies.

248.16 SECRETION OF TISSUE TYPE PLASMINOGEN ACTIVATOR DURING NEURONAL DIFFERENTIATION OF AN EMBRYONAL CARCINOMA CELL LINE, T. Whitford* and J.M. Levine, Program in Cellular and Developmental Biology and Dept.of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794

Developing neurons secrete plasminogen activators, enzymes which specifically cleave plasminogen to generate plasmin, a highly active, broad range protease. The ability of neurons to regulate the local level of extracellular proteolysis may be important in developmental processes such as cell division, cell migration, process outgrowth and neuron-glial interactions. To understand the role of the plasminogen activator (PA)/plasminogen (PMG) system in neuronal differentiation, we examined the secretion of PAs by an embryonal carcinoma cell line, P19S1801A1, which develops into neuron-like cells after aggregation with retinoic acid and growth as monolayers in a chemically defined, serum free medium.

The appearance of PAs in tissue culture supernatants was assayed in 3 ways: first, with a chromogenic assay in which PA activates PMG to cleave a synthetic substrate (H-D-Valyl-L-leucyl-L-lysine-P-nitroanilide dihydrochloride) generating a product detectable by its absorbance at 405 nm; second, with a PMG-casein-agar overlay of living cells and third, with a PMG containing SDS gel lytic assay described by Pittman (Dev. Biol. 110: 91-110, 1985). All 3 assays demonstrated that the neurally differentiated O1A1 cells secrete PAs. Secretion was maintained for up to 8 days in monolayer culture, at which time greater than 85% of the cells had developed neuritic processes and neurofilament-like immunoreactivity (J. Neurosci., 6:3374-3384, 1986). The appearance of PA activity correlated with the development of neuronal properties: neither undifferentiated O1A1 cells nor cells which were treated with DMSO and grown in serum-containing medium to induce mesodermal differentiation secreted PAs into the culture medium.

The PA secreted by neurally differentiated O1A1 cells was shown to be tissue-type PA (tPA) by 2 criteria. First, on PMG containing SDS gels, the PA activity electrophoresed as a single band of apparent MW of 65kd and it comigrated with authentic tPA. Second, antibodies against tPA but not those directed against urokinase inhibited the activation of PMG in the chromogenic assay.

These results demonstrate that the neuronal differentiation of O1A1 cells is accompanied by the secretion of tPA. Plasminogen activators provide a means by which cells interact with or modify the extracellular environment. Thus tPA may play a role in neurite outgrowth in this model system.

248.17 INDUCTION OF NEURONAL DIFFERENTIATION OF EMBRYONAL CARCINOMA CELLS BY DIFFERENT GROWTH MODULATORS. S.A.D. Sharma*, J.T. Hansen and M.F.D. Notter (SPON: L.G. Abood). Dept. of Neurobiol. and Anat., Univ. of Rochester, Rochester, NY 14642.

Embryonal carcinoma (EC) cells can be induced to differentiate into a number of different cell types, including neurons, depending on their treatment. We have previously reported that a population of neurons induced by retinoic acid (RA)-treatment of P19S18O1A1 (O1A1) mouse EC cells was adrenergic. Here we further characterize the RA-induced neurons and report on the ability of dibutyryl cyclic AMP (db cAMP) and nerve growth factor (NGF) to induce neuronal differentiation.

O1A1 cells were differentiated by growing for 2 days as monolayers followed by 3 days as aggregates in the presence of growth modulator(s): RA (500 nM); db cAMP (500 ug/ml); NGF (375 ng/ml) and db cAMP (500 ug/ml). The dissociated aggregates were then plated onto coverslips and maintained for an additional 6 days in the presence or absence of growth modulator(s). Cultures were therefore 11 days old when examined.

Scanning EM of RA-treated O1A1 cultures showed neurons growing on a background of glia and fibroblast-like cells. Many of the neurons appeared to be multipolar with long processes. The presence of bipolar as well as multipolar neurons was also seen at the light microscopic level. Transmission EM of RA-induced neurons showed neurotubules and neurofilaments typical of normal neurons. The neurons also had a high concentration of normal mitochondria, suggesting that they were metabolically very active. A small number of secretory granules could be seen. We have reported that the RA-induced adrenergic neurons can take up exogenous norepinephrine, and this would be expected to enhance the level of secretory granules. Electrophysiological recordings suggested that the neurons were electrically active. Therefore EM and electrophysiological data from these RA-induced neurons suggest that they have features similar to neurons in normal non-tumorous tissue.

In addition we have found that treatment of O1A1 cells with NGF and db cAMP together, or with db cAMP alone induced neuronal differentiation. Both treatments induced the development of cells with neuronal morphology. Positive immunocytochemical staining for neurofilament protein and neuron-specific enolase were obtained in db cAMP or NGF/db cAMP-treated cultures. The neuronal phenotype was expressed if these cultures were treated continually with db cAMP or NGF/db cAMP for 11 days, or if they were treated for 5 days with these modulators followed by 6 days without stimuli. Therefore the neuronal differentiation appeared to be irreversible. Preliminary observations suggest that NGF/db cAMP is more potent at inducing neuronal differentiation than db cAMP alone. However, further experiments are needed to determine the individual effects of NGF and db cAMP. Comparison of the neuronal properties induced by NGF, db cAMP and RA may provide insights into neuronal induction and development of different neuronal phenotypes in vivo.

248.18 MONOCLONAL ANTIBODIES AGAINST DEVELOPMENTALLY REGULATED MEMBRANE ANTIGENS SELECTIVELY EXPRESSED BY ALL MATURE SLOW FIBRES IN CHICKEN SKELETAL MUSCLE. S. Shahin*, P.F. Bartlett* and J.A.P. Rostas. The Neuroscience Group, Faculty of Medicine, University of Newcastle, New South Wales, 2308, Australia and The Walter and Eliza Hall Institute of Medical Research, Royal Melbourne Hospital, Victoria, 3050, Australia.

Using purified sarcolemma from adult chicken anterior latissimus dorsi (ALD) and posterior latissimus dorsi (PLD) as immunogen, two monoclonal antibodies have been prepared which have a selective reactivity with chicken skeletal muscle. The fibre specificity of the antibodies was determined on frozen sections of ALD, PLD, sartorius, and interior and exterior adductor muscles, by comparing the immunofluorescence staining with the myosin ATPase staining of adjacent sections. In mature muscle, both antibodies recognised slow twitch (type I) and slow tonic (type III) fibres but not fast twitch (type II) fibres. In early embryonic muscle all fibres appeared to express both antigens. Presumptive fast twitch (type II) fibres gradually lost their immunoreactivity during development until, by embryonic day 18, the selective adult staining pattern was established. The antigens recognised by both antibodies appear to be present in, but not confined to, membranes of the tubular system and sarcolemma. Between two weeks and adult the intensity of fluorescence observed on ALD with AA21 decreased with no apparent difference in distribution whereas the intensity of fluorescence with PA20 increased with the intracellular staining becoming more prominent. AA21 showed strong reactivity with heart, brain, pancreas, gizzard, small intestine and blood vessels but no reactivity with kidney, liver or sciatic nerve. By contrast the only other tissue with which PA20 shows strong reactivity was heart. As determined by western blotting of ALD sarcolemma, the major antigens recognised by AA21 and PA20 were proteins with apparent molecular weights of 95-100KDa and 125-140 KDa, respectively. Both antibodies, at high concentrations, detected minor antigens of different molecular weights. With both antibodies the antigens recognised in tissue homogenates were the same as those in ALD sarcolemma as determined by western blots.

248.19 POSITIONAL INFORMATION INFLUENCES EMBRYONIC MUSCLE FIBER-TYPE EXPRESSION. J. Butler* and E. Cosmos. Dept. Neurosci., McMaster Univ. H.S.C., Hamilton, Ontario, Canada, L8N 3Z5.

Recently, using as a marker the impaired wing motility characteristic of dystrophic chick embryos, we verified that thoracic somitic mesoderm transplanted heterotopically to replace brachial somites at 48-52 h in ovo is viable and capable of forming a functional wing musculature (Cauwenbergs et al., Neurosci. Letters 68: 149, 1986). Thus, during early embryogenesis premyogenic cells demonstrate a high degree of plasticity since their ultimate ability to form specific individual muscles is determined by positional signals. To determine whether or not such influences extend to the formation of distinct muscle fiber-types is the objective of the present study. This is an important issue in view of previous in vivo (Butler et al., J. Exp. Zool. 224:65, 1982) and in vitro (Miller and Stockdale, J. Cell Biol. 103:2197, 1986) studies which demonstrate the existence of fiber-type diversification among primary generation myogenic cells of the early chick embryo, a diversity which occurs independent of neural influences. If myogenic cells are endogenously programmed from the somite stage onward to express specific classes of myogenic cells, then brachial muscles derived from thoracic somitic mesoderm should form muscles whose fiber-type profiles reflect the heterogeneity characteristic of muscles formed from in situ thoracic somites (Butler et al., JEEM 95:147, 1986). If, instead, positional information influences fiber-type expression, then the experimental muscles should exhibit profiles characteristic of unoperated brachial muscles.

A total of 177 embryos were subjected to the unilateral replacement of brachial somites by thoracic somitic mesoderm and, to date, 14 surviving intraspecific chick/chick chimaeras between St 35 (8-9 d in ovo) to St 45 (19-20 d in ovo) have been analyzed. Results demonstrate that (1) transplanted thoracic somitic mesoderm forms, on schedule, a complete brachial musculature; (2) the fiber-type composition (myosin ATPase profile) of individual experimental muscles is equivalent to that expressed by either individual contralateral brachial muscles or brachial muscles formed from brachial somites transplanted to donor embryos. Thus, we conclude that positional information influences embryonic fiber-type expression. Furthermore, such an influence is operative during a temporally limited period since limb bud transplants (Laing and Lamb, JEEM 78:67, 1983) performed approximately 20 h later than the present experiments demonstrate that the fiber-type composition of wing muscles transplanted to the leg region is determined by the site of origin, not by the site of transplantation.

ADRENERGIC RECEPTORS

249.1 **PHARMACOLOGY AND BIOLOGICAL ACTIVITY OF BIOTIN-LABELED ALPHA$_1$-ADRENERGIC RECEPTOR LIGANDS.** D. Lorton, C.L. Hix, M. Caron*, and J.N. Davis. V.A. Medical Center and Depts. of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC 27705.

Biotin-labeled alpha$_1$-adrenergic receptor ligands were synthesized and their pharmacology and biological activity characterized. A55453 is an analogue of prazosin and shares its high selectivity and affinity for alpha$_1$-adrenergic receptors. A55453 was modified by biotinylation via amino group substitution using either a short hydrocarbon chain (N-hydroxy succinimidyl biotin, A55453-SC-B) or a long hydrocarbon chain (sulfo succinimidyl 6-(biotin amido) hexanoate, A55453-LC-B) biotin derivative under conditions which produced a 90 - 95% yield.

Biotinylated A55453 derivatives were compared with A55453 for their abilities to compete with [^{3}H]-prazosin for binding to alpha$_1$-adrenergic receptors in rat cortical membranes. The ability of A55453-SC-B and A55453-LC-B to displace [^{3}H]-prazosin from alpha$_1$-adrenergic receptors was similar to A55453 (K_d's, 8×10^{-10}, 1.5×10^{-8}, 1.8×10^{-9} M, respectively). A55453-SC-B was almost as effective as prazosin in inhibiting epinephrine-stimulated K^+ release from dispersed parotid acinar cells, demonstrating the biological activity of A55453-SC-B.

The biotin components of both derivatives retained their ability to bind to avidin following conjugation to the ligand. Conjugation of avidin to A55453-SC-B reduced the affinity of the ligand for the alpha$_1$-adrenergic receptor by 1000 fold. By contrast, conjugation of avidin to A55453-LC-B reduced the affinity of this ligand by only 4 fold. Avidin-conjugated A55453-SC-B did not compete as well for receptor binding as the avidin-conjugated A55453-LC-B, perhaps because of steric hinderance.

Although in vitro receptor autoradiography has allowed localization of many brain neurotransmitter receptors at the light microscopic level, the relationship of receptors to pre- and post-synaptic elements can only be studied with electron microscopy. The data presented here suggests that biotinylated receptor ligand derivatives may provide powerful tools for the localization of membrane bound receptors at the light and electron microscopic levels.

249.2 **QUANTITATIVE AUTORADIOGRAPHY OF [125I]BE 2254 BINDING IN THE RAT BRAIN: LABELLING OF SITES IN ADDITION TO α_1-ADRENERGIC RECEPTORS IN STRIATUM.** D.M. BURNETT* and N.R. Zahniser (SPON: R.S. Lasher) Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

BE 2254 is a potent and selective α_1-adrenergic receptor (α_1-AR) antagonist. In the iodinated form, [125I]-BE 2254 (IBE) has been shown by several investigators to be a very useful radioligand for labelling both peripheral and central α_1-AR's (Kd value = 50pM). We have used IBE along with quantitative autoradiography (QAR) to localize and study α_1-AR's in the rat brain. Image analysis of saturation binding of IBE revealed a distinctly large component of nonspecific binding within the striatum. At a Kd concentration of the radioligand, competition experiments with prazosin (an α_1-AR antagonist with unusually high selectivity) showed that only 35% of the total binding was associated with α_1-AR's within the striatum. In contrast to this and in good agreement with other reports, prazosin displaced IBE binding by 80-90% in other areas of the brain such as thalamus and cerebral cortex. We have attempted to identify this nonspecific binding site(s) in the striatum which is labelled by IBE.

Competition curves against a Kd concentration of IBE were constructed in striatal homogenates for several pharmacologically selective receptor antagonists. In some experiments a saturating concentration of prazosin (1μM) was included to prevent radioligand binding to the α_1-AR's. Compounds examined included: mazindol for competition at the dopamine uptake site, SCH-23390 for the D_1 dopamine receptor, (S)-sulpiride for the D_2 dopamine receptor, pyrilamine and cimetidine for the H_1 and H_2 histamine receptors, respectively, and ketanserin and pirenperone for competition at the $5HT_2$ receptor. Of the compounds tested, only the $5HT_2$ receptor antagonists had activity against IBE binding in the striatum. In the absence of prazosin, both ketanserin and pirenperone displaced IBE with IC_{50} values of 20nM, which correspond to Ki values of 10nM for the α_1-AR. These data agree well with previous reports that ketanserin and pirenperone inhibit, with high affinity, the binding of α_1-AR ligands. When binding to α_1-AR's was prevented by the presence of 1μM prazosin, ketanserin displaced IBE binding further by 40% with an IC_{50} value of 10nM. Pirenperone likewise displaced IBE binding beyond that defined with 1μM prazosin, but its activity was much less potent (IC_{50} value = 0.4μM). These data suggest that IBE may label $5HT_2$ receptors in the striatum. However, additional experiments will be performed to verify this finding. In addition, the use of prazosin to define the nonspecific binding of IBE in the rat brain provides an accurate measurement of specific binding to α_1-AR's for conventional filtration assays as well as for assays using QAR.

249.3 CHARACTERIZATION OF ALPHA-2 ADRENERGIC RECEPTORS IN CHICKEN PINEAL GLAND USING [^{3}H]RAUWOLSCINE. D.B. Bylund, L.J. Petterborg*, C. Ray-Prenger* and P.K. Rudeen. Departments of Pharmacology and Anatomy, University of Missouri Medical School, Columbia, MO 65212.

The avian pineal gland has an endogenous circadian rhythm of melatonin production which can be entrained by either neural or photic inputs. Pharmacologic studies in the intact chicken indicate that norepinephrine may decrease pineal melatonin by the stimulation of alpha-2 adrenergic receptors. Using the antagonist radioligand [^{3}H]rauwolscine, we have identified alpha-2 adrenergic receptor binding sites in membrane preparations of chicken pineal glands. The binding was rapid, reversible, saturable, of high affinity and had the pharmacologic characteristics of other alpha-2 adrenergic receptors systems. Preliminary experiments indicate no marked differences in binding between male and female birds or between glands taken just before lights off and those just after lights on. However, there was an increase in receptor density (B_{max}) with age, but no change in affinity (K_D).

Age	B_{max}, fmol/mg protein	K_D, nM
3 week	150	0.31
4 week	250	0.39
5 week	300	0.36
adult	600	0.49

These results confirm the presence of alpha-2 adrenergic receptors in the chicken pineal gland. The chicken pineal gland should be useful both in understanding pineal function and as a model system for studying alpha-2 adrenergic receptors. Supported by NIH Grant 32931.

249.4 CHARACTERIZATION OF α_2-ADRENOCEPTORS WITH THE AGONIST ^{3}H-UK 14304 IN POSTMORTEM HUMAN BRAIN. J.A. García-Sevilla*, J.J. Meana* and F. Barturen* (SPON: M. Lafarga). Dept. of Pharmacology, Medical School, Univ. of the Basque Country, 48940 Leioa, Bizkaia, Spain.

The full agonist ^{3}H-UK 14304 (5-bromo-6[2-imidazolin 2-ylamino]-quinoxaline) has been used to characterize α_2-adrenoceptors in postmortem human brain following the method described for the rat brain (Loftus et al., Life Sci., 35: 61, 1984) with minor modifications. In cortical membranes the binding at 25°C was rapid (t1/2 of association: 4.6 min) and reversible (t1/2 of dissociation: 14.1 min) and the equilibrium dissociation constant (K_D) determined from these kinetic studies was 0.48 nM. The binding sites for ^{3}H-UK 14304 showed the specificity required for an α_2-adrenoceptor. The rank order of potency of inhibitors of ^{3}H-UK 14304 binding was (-)epinephrine ≈ UK 14304 > clonidine > oxymetazoline > idazoxan > yohimbine >> phenylephrine >>> prazosin > (-) propranolol. Competition curves for most adrenergic drugs were shallow (n_H<1) indicating heterogenous inter actions with ^{3}H-UK 14304 binding sites. The nucleotide GTP also inhibited (K_i=5x10^{-6}M) the specific binding of ^{3}H-UK 14304, suggesting that the radioligand preferentially labelled the high affinity state of the α_2-adrenoceptor. The inhibition constants (K_i) of adrenergic drugs in competing with ^{3}H-UK 14304 were correlated with the K_i of these drugs in competing with ^{3}H-clonidine (r=0.96; P<0.001) which suggested that both radioligands labelled the same α_2-adrenoceptor in postmortem human brain. In the frontal cortex, linear (Scatchard) and non-linear analyses of ^{3}H-UK 14304 binding (10^{-11} - $4x10^{-9}$M) indicated the existence of a single population of non-interacting sites (K_D= 0.23± 0.01 nM; Bmax= 80±12 fmol/mg protein; n= 7). In other brain regions (hypothalamus, hippocampus, amygdala, brainstem, caudate nucleus and cerebellum) the density of α_2-adrenoceptors (Bmax) ranged from 68±10 to 25±6 fmol/mg protein. In these brain regions K_D values for ^{3}H-UK 14304 ranged from 0.32±0.03 to 0.56±0.09 nM. The binding of the full agonist ^{3}H-UK 14304 to post-mortem human brain membranes might be a useful tool for the study of dysfunctions related to the high affinity state of the α_2-adrenoceptor (e.g. endogenous depression) Supported by CAICYT Grant 1244/84 and by a grant from the Departamento de Educación, Universidades e Investigación (Gobierno Vasco).

249.5 COMPARISON OF HIGH AFFINITY BINDING FOR TWO ALPHA$_2$-RECEPTOR AGONISTS, GUANABENZ AND CLONIDINE, IN SHEEP AND RAT CEREBRAL CORTEX. R.K. Zoltoski* and C.E. Dunlap III (SPON: D.J. Goode). Bowman Gray Sch. of Med. of Wake Forest University, Winston-Salem, NC 27103.

Previous studies have demonstrated (^{3}H)clonidine binding with K_d and B_{max} values of 5 nM and 14 pmol/g tissue in rat brain (U'Prichard et al., Mol Pharmacol, 13:454-473, 1977) and 2.37 nM and 5.39 pmol/g tissue in rat cerebral cortex (Fluck et al., Drug Dev Res, 3:91-99, 1983), respectively. The latter investigators also reported guanabenz to inhibit (^{3}H)clonidine binding with a K_i of 0.96 nM, in agreement with the value of 0.9 nM reported by Jarrott et al. (Biochem Pharmacol, 27:141-144, 1979).

We have undertaken a series of experiments employing tritiated guanabenz in our laboratory, which have included radioligand binding studies of (^{3}H)guanabenz in fetal and maternal sheep and rat cerebral cortex homogenates. (^{3}H)GBZ binding in maternal ovine cortex was first-order, of high affinity, and saturable, with a K_d of 6.45 ± 0.95 nM and B_{max} of 415 ± 111 fmol/mg protein. Binding in cortex from fetal sheep (124 - 129 days gestation) displayed a K_d of 5.68 ± 0.97 nM and B_{max} of 195 ± 44 fmol/mg protein. While there appeared a trend toward fewer binding sites in fetal compared to maternal cortex, the values were not statistically different for the sample sizes used.

Interestingly, competition curves for clonidine vs. (^{3}H)GBZ binding produced a K_i value of 400.8 ± 95.0 nM, suggesting different binding sites for (^{3}H)GBZ and (^{3}H)clonidine. To test this observation further, parallel binding studies with both radioligands were conducted in rat cerebral cortex homogenate preparations. (^{3}H)Clonidine binding in rat cortex had K_d and B_{max} values of 1.27 nM and 86.4 fmol/mg protein (6.1 pmol/g tissue) respectively, in good agreement with values obtained by Fluck et al. Competition curves for clonidine displacement of (^{3}H)GBZ binding yielded a K_i value of 313 nM, while guanabenz displacement of (^{3}H)clonidine binding had a K_i value of 1.95 nM, providing further evidence for separate high affinity binding sites for the two drugs.

This research was supported by NIH grant HL34460 and by a research grant from Wyeth Laboratories.

249.6 **AUTORADIOGRAPHIC EVIDENCE FOR ASSOCIATION OF α_2-ADRENERGIC RECEPTORS WITH CENTRAL EPINEPHRINE PATHWAYS USING TWO INBRED RAT STRAINS.** J.R. Unnerstall, M.J. Connors*, J.M. Stolk and D.C. U'Prichard. Dept. Neurology and The Alzheimer Center, Case Western Reserve Univ. Sch/Med, Cleveland, OH 44106; Dept. Psychiatry, Univ. Maryland Sch/Med, Baltimore, MD 21228; and, Stuart Pharmaceuticals, Wilmington, DE 19897.

Two inbred rat strains, Fischer 344 (F344) and Buffalo (Buf), which differ markedly in peripheral and central levels of PNMT activity and brain epinephrine (EPI) content, have been shown to differ phenotypically with respect to a major structural gene locus coding for PNMT. Buf rats exhibit 3-10 fold less PNMT activity than F344 rats in adrenals, brain and other tissues, and also exhibit 3-10 fold lower EPI levels in hypothalamus and brain stem. Homogenate binding experiments have shown a selective increase in a-adrenergic binding sites in the medulla and brainstem of Buf rats as compared to F344 rats. In this report, we have used high-resolution quantitative receptor autoradiographic techniques (QAR) to demonstrate the selective increase of α_2-adrenergic binding sites in Buf rats in brain regions innervated by EPI-utilizing brainstem neurons.

Four Buf and four F344 rats (approximately 6 weeks old) which were bred and raised at the Maryland Psychiatric Research Center (JMS) were utilized in these experiments. The animals were sacrificed by perfusion with 5% sucrose in phosphate-buffered saline and the brains were rapidly removed and frozen over dry ice. Serial cryostat sections (10 μm) were incubated with 1.0 nM [^{3}H]para-aminoclonidine ([^{3}H]PAC) or 2.0 nM [^{3}H]rauwolscine ([^{3}H]RW) in 170 mM Tris-HCL (pH7.4) in the absence or presence of 10 μM phentolamine to define non-specific binding. Under these conditions [^{3}H]PAC or [^{3}H]RW labels approximately 50% of their respective high-affinity binding sites with minimal occupancy at their low-affinity site.

Selective large increases (>100%) in α_2 binding were seen in several forebrain and brainstem regions in the Buf rats that normally are innervated by medullary EPI-utilizing neurons. These include the bed nucleus of the stria terminalis, central and medial nuclei of the amygdala, paraventricular nucleus of the hypothalamus, dorsal medial thalamus, nucleus of the solitary tract, dorsal motor nucleus of the vagus and ventral lateral medulla. Smaller (>50%) but still significant increases were seen in other areas such as the lateral septum, medial preoptic area, anterior hypothalamus, nucleus reuniens of the thalamus, dorsal raphe, dorsal parabrachial nucleus, locus coeruleus and hypoglossal nucleus. Small insignificant changes were observed in areas such as the cortex and hippocampus.

These data confirm and extend the homogenate binding studies and more selectively emphasize the presence of an inverse correlation between regional EPI utilization and α_2 receptor density.

Supported by Nova Pharmaceutical Corp., Baltimore, MD.

249.7 BRIGHT ARTIFICIAL LIGHT SUBSENSITIZES THE PRESYNAPTIC α_2-ADRENOCEPTOR. S.C. Dilsaver* and M.J. Majchrzak (SPON: N.E. Alessi). Dept. of Psychiatry, Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

Supersensitivity of presynaptic α_2-autoreceptors could be involved in the biology of depression. The authors used a thermoregulation paradigm to test the hypothesis that chronic treatment with bright artificial light (at an intensity of 11,500 lux) produces subsensitivity to the hypothermic effects of an α_2 agonist, clonidine. Core temperature was measured using a telemetric thermosensor, the Model VM Mini-Mitter (Mini-Mitter Corp., Sunriver, OR). Full spectrum bright artificial light was emitted from a bank of eight 122 cm long Vita Light tubes suspended 50 cm above the animals. This light unit (Duro Test Corp., Bergen, NJ, Model 5599) is used to treat patients with seasonal affective disorder (SAD). Mini-Mitters were implanted into the peritoneal cavities of 10 adult, male rats. Experiment I involved measurement of hypothermic response to clonidine, 0.1 mg/kg ip, prior to exposure to light, following a week of constant light exposure and one week after light was withdrawn. Core temperature was measured prior to the injection of clonidine and every 10 minutes thereafter for 120 minutes. A second study involved measurement of the thermic response to clonidine, 0.4 mg/kg ip, at baseline and after one and two weeks of treatment in 7 animals. The objective was to demonstrate that multiple injections of clonidine do not alter thermic responsiveness to itself. Nine of 10 animals exhibited blunting of the hypothermic response to clonidine at $\alpha < 0.04$. The mean thermic response of this sample, was -1.22 ± 0.15 (X ± SEM) prior to light treatment and -0.03 ± 0.1°C after chronic treatment ($p < 0.00009$, t=6.74, df=9). A week after the discontinuation of light the mean thermic response of the sample was -1.16 ± 0.14°C. This differed from the response during treatment ($p < 0.0003$, t=5.8 df=9) but did not differ from the baseline response ($p > 0.8$, t=0.2, df=9). Multiple injections of clonidine did not alter thermic responsiveness to itself. Conclusion: Chronic treatment with bright artifical light subsensitizes the α_2-autoreceptor. This is consistent with the reports that other forms of antidepressant treatment, tricyclic antidepressants, and monoamine oxidase inhibitors, ECT and lithium carbonate have the same effect.

249.8 ALPHA-2 ADRENERGIC RECEPTOR INHIBITION OF MELATONIN SYNTHESIS IN CHICK PINEAL CELLS: BLOCKADE BY PERTUSSIS TOXIN AND ACTIVATORS OF THE CYCLIC AMP PATHWAY. B.L. Pratt and J.S. Takahashi. Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201.

Postjunctional alpha-2 adrenergic receptors mediate the regulation of melatonin release by norepinephrine in chick pineal cells (Pratt and Takahashi, J. Neurosci., in press). We have begun to test whether an inhibition of cAMP, caused by norepinephrine-induced alpha-2 receptor activation, is involved in the regulation of melatonin release in avian pineal cell cultures.

The experimental protocol utilized was the same as that described previously to identify the adrenergic receptor subtype pharmacologically (Pratt and Takahashi, Soc. Neurosci. Abst. 12, 384, 1986). We have found that increasing cAMP levels by introducing cAMP analogues, activating adenylate cyclase with forskolin or inhibiting phosphodiesterase with IBMX, all block alpha-2 receptor-mediated inhibition of melatonin release in a dose dependent manner. In all cases, 9 doses of each drug were used to antagonize the inhibition of melatonin release caused by 1 X 10^{-7}M norepinephrine. The relative potencies of cyclic nucleotide analogues were as follows (EC_{50}, mM): 8-bromo-cAMP (0.125), monobutyryl-cAMP (1.0) and 8-bromo-cGMP (>2.0). Cyclic AMP, 8-bromo-5'AMP and 8-bromo-5'ATP were without effect at doses up to 2.0mM. The EC_{50} values for forskolin and IBMX were 0.3uM and 125uM, respectively.

In most systems, alpha-2 adrenergic receptor activation appears to act through an inhibition of adenylate cyclase. This inhibition is mediated by a guanine nucleotide regulatory protein known as Gi or Ni. The function of Gi can be inactivated by pertussis toxin. If norepinephrine decreases cAMP by inhibiting adenylate cyclase, then toxin pretreatment should block the inhibition of melatonin release caused by norepinephrine in chick pineal cells. Pertussis toxin treatment blocked the effect of norepinephrine on melatonin release in a noncompetitive manner. Pertussis toxin-induced blockade was partial at 1 and 10 ng/ml doses and was complete at a 100 ng/ml dose. Although pertussis toxin is known to inactivate several G proteins, the data cited above, showing that activators of the cAMP pathway antagonize the effect of norepinephrine, suggest that pertussis toxin may be blocking the inhibition of melatonin release by inactivating Gi. Further data, measuring the effects of norepinephrine on cAMP levels and identifying the presence of pertussis toxin-sensitive G proteins in avian pineal cell cultures should aid in further understanding of the events initiated by alpha-2 adrenergic receptor activation.

(Supported by NIMH grant MH39592, Searle Scholars Award 85-H-107 and NSF PYI award DCB-8451642 to J.S.T. and NIMH award F32 MH09466 to B.L.P.)

249.9 ALPHA$_2$- ADRENERGIC RECEPTOR-MEDIATED REGULATION OF PHOSPHATIDYL INOSITOL METABOLISM IN HUMAN PLATELETS. H. Mori*, M. Mikuni, T. Koyama* and I. Yamashita*. Dept. of Psychiatry, Hokkaido Univ. Schl. of Med., Sapporo, Hokkaido 060 Japan and Division of Mental Disorders Research, National Institute of Neuroscience, National Center for Neurology and Psychiatry, Kodaira, Tokyo, 187 Japan.

The Metabolism of inositol phospholipids in response to epinephrine was investigated in human platelets using sensitive radioisotopic method of Berridge(1983). In platelets prelabelled with [^{3}H]-myo-inositol, in Ca^{++} free HEPES buffer containing 10mM LiCl which blocks the enzyme inositol-1-phospatase, epinephrine caused a dose-dependent accumulation of inositol-1-phosphate (IP_1) over a concentration range of 1-100uM during the 15 min incubation. The EC_{50} value of epinephrine was 5 uM.

Yohimbine, a selective alpha$_2$-adrenergic receptor antagonist, inhibited ephinephrine-stimulated IP_1 accumulation with a Ki value of 42 nM. Mianserin(1uM), a potent blocker of alpha$_2$ adrenergic receptors, also inhibited 70% of the epinephrine(10uM) response. Prazosin(1uM), a selective alpha$_1$-adrenergic receptor antagonist, failed to inhibit the epinephrine(10uM) response. Ketanserin(1uM), a selective 5HT$_2$ receptor antagonist, failed to inhibit the epinephrine(10uM) response. (-)Sulpiride(1uM), a selective D_2 receptor antagonist, also failed to the epinephrine(10uM) response. Mezerein, a potent protein kinase C activator, inhibited 70% of the epinephrine(10uM) response at a concentration of 100 uM.

The only direct biochemical consequence of alpha$_2$-adrenergic receptor activation thus far identified in the platelet is inhibition of adenylate cyclase. However, our results indicate that epinephrine also stimulates phosphatidylinositol turnover by activating receptors of the alpha$_2$ type in human platelets.

249.10 Electrophysiological Effects of Locally-Applied Adrenergic Agonists at Cerebellar Purkinje Neurons: Receptor Specificity. K.D. PARFITT*, R. FREEDMAN, and P.C. BICKFORD-WIMER. Depts. of Pharmacology and Psychiatry, UCHSC, Denver, CO 80262.

Older literature indicates that when norepinephrine (NE) is applied locally by microiontophoresis to cerebellar Purkinje cells a beta receptor-mediated inhibition of cell firing rate occurs in situ. Using perfusion of NE on an in vitro cerebellar slice or on an in oculo cerebellar transplant, an alpha receptor-mediated inhibition of spontaneous activity was demonstrated. Because of this discrepancy, we investigated the receptor subtype mediating the inhibition of cerebellar spontaneous firing rate using local application of adrenergic agonists and antagonists, in situ, via pressure micro-ejection. Extracellular action potentials of cerebellar Purkinje neurons were recorded from anesthetized Fischer 344 rats. Timolol, a beta receptor antagonist, did not affect NE-induced inhibition in 9 of 12 cells studied. Phentolamine, an alpha receptor antagonist, blocked the effect of NE in 8 of 11 cells. To determine the subtype of alpha receptor involved, the effects of the alpha$_1$ antagonist prazosin and alpha$_2$ antagonists idazoxan and yohimbine were examined. While prazosin had no effect on NE-mediated inhibition, both idazoxan and yohimbine blocked NE-mediated inhibition.

The inhibitory action of NE upon Purkinje cell firing rate was mimicked by the selective alpha$_2$ agonist clonidine; this inhibitory action of clonidine was blocked by idazoxan but not by timolol or prazosin. In addition, the alpha$_1$ adrenergic agonist phenylephrine and the beta adrenergic agonist isoproterenol inhibited Purkinje cell firing rate. Inhibition by phenylephrine was blocked by prazosin but not by timolol or idazoxan. Isoproterenol-induced inhibition was blocked by timolol but not phentolamine. These studies with adrenergic agonists and antagonists indicate that both alpha and beta receptors alter Purkinje cell firing rate; the inhibitory action of locally-applied NE, however, seems to be mediated predominantly via an alpha$_2$ adrenergic receptor. This work was supported by the VAMC and USPHS grant AG04418.

249.11 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF ADRENOCEPTORS MEDIATING THE EFFECT ON ENDOGENOUS NOREPINEPHRINE ON RAT HIPPOCAMPAL PYRAMIDAL NEURONS IN VIVO. O. Curet* and C. de Montigny (spon: L. Vachon). Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Canada H3C 3J7.

The suppression of firing activity of rat hippocampal pyramidal neurons by microiontophoretic application of norepinephrine (NE) is mediated by an α_2 type of adrenoceptor (Curet, O. and de Montigny, C., Neurosci. Abstr., 12: 349.9, 1986). The present study was undertaken to characterize the nature of the adrenoceptor mediating the effect of endogenous NE, released by the electrical stimulation of the locus coeruleus (LC), on dorsal hippocampus pyramidal neurons and to evaluate the modulatory role of terminal α_2 adrenergic autoreceptors on NE neurotransmission.

Male Sprague-Dawley rats (260-300 g) were anesthetized with chloral hydrate (400 mg/kg, i.p.). CA_3 hippocampal pyramidal neurons were recorded extracellularly with five-barrelled micropipettes. The central barrel was filled with 2M NaCl saturated with Fast Green and side barrels with NE (0.1M in 0.2M NaCl; pH 4), acetylcholine (ACh) (0.02M in 0.2M NaCl; pH4) and 2M NaCl for automatic current balancing. ACh was used to activate pyramidal neurons to a physiological range (10-14 Hz). A bipolar concentric electrode (NE 100, DKI) was positioned in the LC. 150 square pulses of 0.5 ms were delivered at 1 Hz with an intensity of 800 µA. The degree of suppression of hippocampal pyramidal neuron firing activity produced by the LC stimulation was quantified from computer-generated peristimulus time histograms.

Prazosin (150 µg/kg, i.v.) reduced the effect of LC stimulation by 86% without altering the response of these same neurons to the microiontophoretic application of NE. The subsequent i.v. injection of idazoxan restored the effectiveness of the stimulation and decreased the effect of microiontophoretic application of NE by 50%.

Increasing the frequency of the stimulation from 1 to 5 Hz reduced its effectiveness by 80%. This reduction of the efficacy of the stimulation by increasing the frequency was abolished by the α_2-adrenoceptor antagonist idazoxan (500 µg/kg, i.v.). Furthermore, clonidine (10 µg/kg, i.v.), an α_2-adrenoceptor agonist, and desipramine (500 µg/kg, i.v.), a selective NE reuptake blocker, reduced the efficacy of LC stimulation by 83% and 84%, respectively. These effects were also reversed by the subsequent i.v. injection of idazoxan.

In conclusion, these data demonstrate that the effect of endogenously released NE on dorsal hippocampus pyramidal neurons is mediated by α_1 adrenoceptors. Since the effect of microiontophoretically-applied NE on the same neurons is mediated by α_2 adrenoceptors, these data provide evidence that, in the CNS, as appears to be the case in the periphery, postsynaptic α_2 adrenoceptors are extrasynaptic, whereas α_1 adrenoceptors are intrasynaptic. Furthermore the present results provide evidence for the potent regulatory role of terminal NE autoreceptors in controlling the release of NE into the synaptic cleft.

249.12 EFFECTS OF CHRONIC COCAINE TREATMENT ON SPONTANEOUSLY FIRING NORADRENERGIC LOCUS COERULEUS NEURONS IN THE RAT. D. K. Pitts and J. Marwah. Dept of Path., Univ. of Med. & Dent. of New Jersey - S.O.M., Camden, NJ 08103.

Previous acute studies using standard extracellular electrophysiological techniques have established that intravenous (iv) cocaine (coc) invariably and reversibly inhibits single identified spontaneously discharging locus coeruleus (LC) neurons in urethane anesthetized rats (Pitts, D.K. & Marwah, J., Life Sci. 38:1229, 1986). The inhibition of LC neurons by iv coc appears to be mediated at least in part by an augmented action of endogenous catecholamines on alpha-2 adrenergic autoreceptors. The following evidence has been previously reported (Pitts, D.K. & Marwah, J., JPET 240:345, 1987) in support of this hypothesis: selective alpha-2-adrenoceptor antagonists (piperoxane & yohimbine) can reverse, or with pretreatment, significantly attenuate the inhibitory effects of coc on LC; reserpine pretreatment significantly reduces inhibition of LC neurons by coc; and finally the local anesthetics procaine and mepivacaine do not significantly affect LC neuron firing rate or action potential waveform in doses greater than those which elicit LC inhibition by coc. Recent studies also suggest that the inhibition of LC neuron activity by iv coc cannot be attributed to cardiovascular effects or anesthetic condition. Pretreatment with the polar alpha-adrenoceptor antagonist, phentolamine (3 mg/kg i.v.), blocks the increase in mean arterial pressure from iv coc administration (1 mg/Kg), but not central LC neuron inhibition. The inhibition of LC neurons by cocaine was also still observed in gallamine paralyzed and artificially ventillated conscious rats. In chronic studies, cocaine (10 mg/Kg i.p.) or vehicle (saline) was administered to rats daily over a three week period. This i.p. dose elicited a pronounced inhibition of LC neurons acutely in urethane anesthetized rats. On testing days one coc and one saline treated rat were surgically prepared for LC recording in the morning and afternoon in an alternating fashion. Once a stable LC neuron was located with the micropipette a challenge dose of cocaine (1 mg/Kg i.v.) was administered. After a minimum of one hour had elapsed, a second LC neuron was located in the same animal and challenged with clonidine (clon, 10 µg/Kg i.v.). The results are summarized below:

Chronic Treatment (n):	SALINE (15)		COCAINE (17)	
Drug Challenge:	COC	CLON	COC	CLON
Baseline Firing Rate:	2.7 ±0.4Hz	2.4 ±0.3	3.4 ±0.4	3.3 ±0.2
Percent Inhibition:	72.9 ±5.3	76.4 ±5.5	57.6 ±6.5	49.6 ±7.8*

*P<0.02 relative to Saline Treated/Clon Challenge (2-tail t-test).

These results suggest that chronic cocaine administration may down regulate alpha-2-adrenoceptors on LC neurons. Further studies employing different dosage regimens are currently being conducted to confirm these preliminary findings. Supported: NIDA DA-04158.

249.13 PHARMACOLOGIC EVALUATION OF CENTRAL ADRENERGIC INVOLVEMENT IN CHLORDECONE-INDUCED HYPOTHERMIA. L.L. Cook,* F.W. Edens* and H.A. Tilson. (SPON: R.D. Myers). Neurotoxicology Div., EPA and Laboratory of Behavioral and Neurological Toxicology, NIEHS, Research Triangle Park, N.C. 27711, and Toxicology Program and Poultry Science Dept., NC State University, Raleigh, NC. 27695.

Chlordecone(CLD) is a neurotoxic chlorinated hydrocarbon insecticide which produces thermoregulatory alterations in addition to tremor and hyperexcitability in rodents following acute, systemic administration. Previous work in our laboratory has shown that CLD-induced hypothermia may be the result of cutaneous vasodilation and that adrenergic receptors, possibly located in the vasomotor control center within the medulla, may be involved (Cook et al., Toxicol. Appl. Pharm., In Press; Cook et al., The Toxicologist, 7:48, 1986). The receptor population within the region of the medulla comprising the vasomotor control center has been shown to be primarily of the α-adrenergic type (Unnerstall et al., Brain Res. Rev. 7:69-101, 1984).

Adrenergic involvement in CLD-induced hypothermia was evaluated in the rat using central pretreatment with 6-hydroxydopamine (6-OHDA) and the α-adrenergic receptor antagonists, phenoxybenzamine and phentolamine, prior to systemic CLD exposure. The effect of IP 75 mg/kg CLD administration on colonic temperature (T-col) in male Fischer-344 rats was measured 7 days after 6-OHDA and 30 min following pretreatment with antagonists by intracisternal (IC) injection. Prior depletion of brain catecholamines with IC 250 µg 6-OHDA administration attenuated CLD-induced hypothermia without affecting basal T-col. Phenoxybenzamine (10 or 20 µg) and phentolamine (5 or 10 µg) also reduced the hypothermic response to CLD. The β-adrenergic receptor antagonists propranolol (50 or 100 µg) and atenolol (10 or 20 µg) did not attenuate CLD-induced hypothermia. These data suggest that CLD-induced hypothermia is a result of alterations involving central α-adrenergic mechanisms in the sympathetic control of vasomotor tone.

249.14 OXYMETAZOLINE INHIBITS THE ADENYLATE CYCLASE OF OK CELLS THROUGH A RECEPTOR DISTINCT FROM THE ALPHA-2 ADRENERGIC RECEPTOR. T.J. Murphy* and D.B. Bylund (SPON: J. Lewis). Dept. of Pharmacology, Univ. of Missouri Medical School, Columbia, MO 65212.

We have recently reported the characterization of alpha-2 adrenergic receptors (A2AR) in the opossum kidney (OK) renal epithelial cell line (Fed. Proc. 46:1445). UK-14,304 (UK), epinephrine (EPI), norepinephrine (NE) and oxymetazoline (OXY) each inhibited parathyroid hormone (PTH) stimulated cAMP production in a dose-dependent manner. Although the effect of UK, EPI and NE could be blocked by A2AR antagonists, the attenuation of cAMP production elicited by OXY was not. In radioligand binding studies using [^{3}H]yohimbine, inhibition binding curves for UK, EPI and NE were shallow and best fit a two-site binding model whereas the curve for OXY was steeper and was consistently better fit by a one-site model. The effect of GTP in these studies was to induce a rightward shift in the UK, EPI and NE inhibition curves whereas GTP was without significant effect on the OXY curve. Thus, OXY behaved as an A2AR antagonist in the binding studies, yet the K_i for binding was quite similar to its EC_{50} value for the inhibition of cAMP production. We have explored the hypothesis that OXY is an agonist at a receptor negatively coupled to adenylate cyclase distinct from the A2AR. We have discounted several alternative explanations for the effect of OXY on cAMP production in OK cells. 1) OXY does not activate a phosphodiesterase (PDE) since its inhibitory effect can be elicited in the presence of PDE inhibitors. 2) OXY is not a PTH antagonist since OXY attenuates forskolin-stimulated cAMP production in the OK cell with a potency similar to its effect on PTH. 3) OXY does not bind irreversibly to A2AR since pretreatment of OK cell monolayers with A2AR antagonists is without effect on the OXY responsiveness and since [^{3}H]rauwolscine saturation binding curves in the presence of increasing OXY concentrations result in a decreased affinity of the A2AR for the radioligand with no change in the B_{max}. The effect of OXY does appear to be mediated through a guanine nucleotide inhibitory protein (G_i) since pretreatment of OK cells with pertussis toxin prevents attenuation of PTH-stimulated cAMP production by both A2AR agonists and OXY. Finally, we have been able to desensitize the A2AR-mediated attenuation of cAMP production by prior treatment of OK cells with EPI. This desensitization appears to be homologous for the A2AR since OXY, but not A2AR agonists, can attenuate cAMP production following EPI pretreatment. We conclude that the effects of OXY are mediated by an inhibitory receptor which is not an A2AR. Supported by NIH Grant 32931.

249.15 SPECIFIC, REVERSIBLE AND STEREOSELECTIVE BINDING OF ^{3}H-L-TYROSINE TO RAT FOREBRAIN (P_2) MEMBRANES. S.P. Arnerić, P. Ernsberger, A.M. May*, P-Y. Cheng* and D.J. Reis. Dept. Pharmacology, Southern IL Univ. Sch. of Medicine, Springfield, IL 62708 and Lab of Neurobiology, Cornell Univ. Medical College, New York, NY 10021

Activation of various peptide receptors present in rat brain slice and synaptosomal-P_2 preparations increase release of endogenous tyrosine (Tyr) through a Ca^{2+}-dependent, regionally selective mechanism (Arnerić et al., J. Neurochem. 48:1581, 1987). This study sought to determine whether Tyr, like classical transmitters, has specific binding sites on neuronal membranes. Membrane fractions (P_2) were prepared from rat forebrain and binding experiments were performed using modified procedures of Sharif and Roberts (J. Neurochem. 34:779, 1980). Microscopic examination of the pellets indicated classical synaptosomal elements with no microvascular contaminants. Membrane fractions were resuspended in 50 mM Tris-HCl buffer (pH=7.2); disrupted with a polytron; then sequentially centrifuged and washed (20 vol. buffer, 3x). Membranes were resuspended in 50 mM Tris-HCl buffer at concentrations ranging from 0.1-0.5 mg protein/tube. Binding was performed in polypropylene microcentrifuge tubes (1.5 ml capacity; 1 ml final vol.) using 100 nM ^{3}H-L-Tyr as ligand and 1 mM L-Tyr to define nonspecific binding. Tubes were centrifuged (16,000 x g; 10 min) to separate bound and free ligand. The supernatants were aspirated; then pellets were rapidly washed and solubilized with protosol for quantification of radioactivity. The specific binding of ^{3}H-L-Tyr was saturable and Scatchard analysis (LIGAND) of the data indicated two populations of binding sites with dissociation constants of high (K_{DH}=3.2±1.4 μM) and low (K_{DL}=252±150 μM) affinities; and density of binding sites B_{Hmax}=598±390 pmol/mg tissue and B_{Lmax}=15,861±12,157 pmol/mg tissue, respectively (N=4). Equilibrium binding of ^{3}H-L-Tyr at 4°C was rapid (maximum: 60-90 min); dissociation following addition of 1 mM L-Tyr was rapid, and complete within 10 min. Heat denaturation (100°C for 5 min) abolished specific binding. Specific binding represented 40-60% of the total binding and was highly dependent on pH (optimum: 7.2-7.5), as well as total protein concentration. Importantly, specific binding of ^{3}H-L-Tyr was stereoselective, since D-Tyr was without effect using concentrations up to 1 mM (122% of control; $p > 0.05$, N=5). Catecholamine and amino acid neurotransmitters such as dopamine, norepinephrine, glycine and GABA did not significantly affect specific ^{3}H-L-Tyr binding (up to 10^{-4}M; $p > 0.05$, N=4-5). A specific inhibitor of Tyr hydroxylase, alpha-methyl-p-tyrosine, was also without effect ($p > 0.05$, N=3). CONCLUSION: These data suggest that specific, low affinity, high capacity, saturable, reversible, stereoselective binding sites for L-Tyr exist on brain (P_2) membranes which are not associated with Tyr hydroxylase. 249.16 BINDING OF [^{3}H]DIHYDROALPRENOLOL TO BETA-ADRENERGIC RECEPTORS IN BRAIN: DIFFERENCES IN BINDING ACCORDING TO CHOICE OF LIGAND FOR MEASUREMENT OF NONSPECIFIC BINDING. S. Dhawan and K.J. Kellar, Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Binding to beta adrenergic receptors in brain have been measured using several different radioactive ligands. One of the most frequently used ligands is [^{3}H]dihydroalprenolol ([^{3}H]DHA). Typically, specific binding of [^{3}H]DHA to beta receptors is defined as the difference between binding in the absence and presence of a high concentration (1-20 uM) of the beta adrenergic receptor antagonist propranolol. This definition of specific binding relies heavily on the presumed selectivity of [^{3}H]DHA and propranolol for beta-adrenergic receptors; however, in fact, the selectivity of these and other beta antagonists has been questioned (Middlemiss et al., Nature 267:289, 1977; Pazos et al., Brain Res. 343:403, 1985; Hoyer et al., Eur. J. Pharmacol. 118:1, 1985). We have compared the binding of [^{3}H]DHA in membranes from rat cerebral cortex and hippocampus using either 1 uM d,l-propranolol, or 40-200 uM l-isoproterenol to define nonspecific binding. In addition, we measured binding of [^{3}H]DHA in the presence or absence of 1 uM serotonin (5-HT).

When propranolol was used to define specific binding, saturation isotherms of [^{3}H]DHA binding were consistent with a 2-site model in both brain areas. The high affinity component had a K_d of 1-3 nM in both areas and represented 50-70% of the sites in the cortex and 30-50% of the sites in the hippocampus. The low affinity component had a K_d of approximately 10-20 nM in both areas. In contrast, when isoproterenol was used to define specific binding of [^{3}H]DHA to beta receptors the data were consistent with a 1-site model with a K_d of 1-2 nM in the cortex and 2-4 nM in the hippocampus. When 1 uM 5-HT was included in the assay, specific binding of [^{3}H]DHA appeared to fit a 1-site even when propranolol was used to define nonspecific binding.

These results indicate that when propranolol is used in the definition of specific binding of [^{3}H]DHA to beta-adrenergic receptors in some brain tissues, a second component of apparent specific binding exists, part of which appears to consist of a serotonin receptor. And further, isoproterenol (40-200 uM) appears to provide a safer measurement of nonspecific binding than does binding in the presence of propanolol.

249.17 EVIDENCE THAT THE REGULATION OF PLASMA TYROSINE AND BRAIN TRYPTOPHAN CONCENTRATIONS BY ANTIDEPRESSANTS IS MEDIATED BY β-ADRENOCEPTORS. D.J. Edwards and D.A. Sorisio*. Dept. of Pharmacology-Physiology, Univ. of Pittsburgh Sch. of Dent. Med., Pittsburgh, PA 15261.

Previous studies have indicated that the antidepressant drug desipramine lowers brain and plasma levels of tyrosine (Tagliamonte et al., J.P.E.T. 177, 475 (1971)). Since agonists and antagonists of peripheral adrenoceptors are known to influence plasma tyrosine and tryptophan levels (Eriksson and Carlsson, Life Sci. 30, 1465 (1982)), we undertook studies to inquire whether effects of antidepressants on these aromatic amino acids also are mediated by α- or β-adrenergic receptors. In the first experiment, we found that 1.25 mg/kg i.p. of norepinephrine (NE) caused a 72% rise in plasma tyrosine after 40 min. This effect was totally prevented by an injection 50 min before NE of the α-blocker phenoxybenzamine (10 mg/kg) but not by imipramine (IMI; 20 mg/kg). Brain tyrosine concentrations were unaffected by both phenoxybenzamine and NE administration, although the latter blocked the ability of IMI to lower brain tyrosine. These data argue against IMI's α-blocking property as being responsible for alterations in brain and plasma tyrosine levels. A second experiment was conducted to test the possibility that IMI's effects on tyrosine or tryptophan are due to stimulation of β-adrenoceptors. Rats were injected with either saline, the β-blocker propranolol (15 mg/kg) or phenoxybenzamine. Twenty min later and 90 min before sacrifice, the rats received an injection of either IMI or saline. Whereas IMI alone reduced plasma tyrosine to 75% of control, this effect was prevented by propranolol but not by phenoxybenzamine pretreatement. On the other hand, both phenoxybenzamine and propranolol failed to block the decrease in plasma tryptophan induced by IMI. In contrast, IMI caused an elevation in brain tryptophan that was completely abolished by pretreatment with propranolol but not with phenoxybenzamine. In another experiment, we injected rats with salbutamol (10 mg/kg), a β_2 agonist that can enter the brain. This drug decreased plasma tyrosine and raised brain tryptophan concentrations. In conclusion, our results suggest that the ability of IMI to lower plasma tyrosine and raise brain tryptophan is mediated by the stimulation of β-adrenoceptors. Supported by NIMH grant #MH 28340.

249PO ROLE OF CORTICOSTERONE IN STRESS-INDUCED DESENSITIZATION OF CORTICAL ALPHA-1 RECEPTORS. E.A. Stone, B.M. McEwen and A.S. Herrera*, Dept. Psychiatry, New York Univ. Sch. Med., New York, NY 10016 and Lab. Neuroendocrinology, The Rockefeller Univ., New York, NY 10021.

Repeated stress is known to reduce the cAMP response to catecholamines in rat brain slices. This effect has been shown to be due to a desensitization of alpha-1 receptors that modulate the cAMP response to beta adrenergic and other receptor stimulation. The physiological factor that mediates this desensitization is not presently established. There is evidence however that corticosterone may be involved since the latter hormone is secreted during stress and has been shown to produce a similar alpha-1 receptor desensitization when administered exogenously. In the present study therefore we have tested the role of corticosterone by examining the effect of adrenalectomy (ADX) on the ability of stress to desensitize these receptors. We have also investigated the actions of acute administration of exogenous corticosterone to determine if the hormone produces an acute sensitization effect on these receptors.

Rats were subjected to bilateral ADX or sham operation. The ADX rats were maintained on a mixture of 0.9% saline and a low dose of corticosterone (10 μg/ml) in their drinking water. Plasma levels of corticosterone in tail vein blood were assayed by RIA. Repeated stress was administered by restraining the rats for 2 h/d for 7-9 days. The ADX rats were found to tolerate the stress well with no fatalities or apparent ill-effects on their general condition. Corticosterone was administered subcutaneously in sesame oil at 50 mg/kg. The cAMP response to beta and alpha adrenergic receptor stimulation was assayed in cerebral cortical slices by previously published methods using norepinephrine in combination with timolol or phentolamine to activate the beta and alpha responses.

Preliminary results indicate that chronic stress reduces the functional response to alpha stimulation (potentiation of the beta cAMP response) in the sham operated but not ADX animals. These findings therefore support a role of corticosterone in the stress-induced desensitization of central alpha receptors. Preliminary results also indicate that acute administration of corticosterone increases the magnitude of the alpha response suggesting that the desensitization to chronic hormone treatment may be linked to an initial sensitization. (Supported in part by grant MH22768).

249PO FUNCTIONAL EVIDENCE FOR DISTINCT ALPHA-2 ADRENERGIC RECEPTOR SUBTYPES IN THE NON-HUMAN PRIMATE A.F.T. Arnsten, J.X.Cai and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Medical School, 333 Cedar St., New Haven, Ct 06510.

The present study defines more precisely the alpha-2 receptor mechanisms underlying clonidine's ability to improve memory in aged monkeys (Science 230: 1273, 1985). We wished to determine whether clonidine's beneficial mnemonic effects might result from stimulation of one or both of two newly proposed alpha-2 receptor subtypes (Boyajian et al. Soc. Neuro. Abstracts, 1043, 1985), one labeled by the alpha-2 antagonist, idazoxan (IDA), and the other by both rauwolscine (RAU) and IDA. This was accomplished by assessing the hypotensive, sedative and memory-enhancing properties of alpha-2 agonists with widely varying affinities for the proposed receptor subtypes.

Drug responsivity was tested in 10 aged monkeys that had previously been shown to exhibit improved memory after the administration of the alpha-2 agonist, clonidine (Science 230:1273,1985). Memory was measured using the delayed response task as previously described (ibid); sedation was scored by a 5 point rating scale. A subgroup of aged monkeys was adapted to chair restraint for blood pressure monitoring.

Two agonists with opposing affinities for the proposed receptor subtypes were examined: BHT-920, which resembles clonidine in having a higher affinity for the RAU-labeled site, and guanfacine, which has more than 14 times higher affinity for the IDA-labeled site (Boyajian et al., 1985). The BHT-920 response profile was similar to that described for clonidine. Low doses substantially decreased systolic blood pressure while higher doses produced marked improvements in memory; at the highest doses tested sedative effects interfered with performance. A completely opposite profile was seen with guanfacine: memory was improved by the lowest doses tested, while blood pressure was lowered in the higher dose range. Little sedation was seen in this dose range. The finding that the behaviorial and cardiovascular effects of alpha-2 agonists can be dissociated according to their affinity for the proposed subtypes supports the the existance of two distinct types of alpha-2 receptors: an IDA-labeled receptor subserving memory enhancement, and a RAU-labeled site involved with blood pressure regulation. The ability of guanfacine to improve memory at doses that have little hypotensive or sedative effects recommends the agonist as a superior candidate for treating age-related memory disorders.

249PO STUDY OF ONTOGENY OF RECEPTORS FOR CATECHOLAMINES AND OTHER NEUROTRANSMITTERS IN CHICK EMBRYO. Stephen Zamenhof. Dept. of Microbiology & Immunology, and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The present work is concerned with a method for the study in vivo of the time of appearance of receptors (or receptors-effectors) for catecholamines and other neurotransmitters, in chick embryo. The substances studied were norepinephrine, dopamine, epinephrine and its antagonist propranolol, carbachol and GABA. They were singly introduced into eggs (albumen) in doses 0.1 to 0.5 μM per egg. Serving as solvent (and as control) was 0.05 ml of Ringer solution for chicks. Solvent alone and GABA introduced at any time (before 13 days of incubation [E13]) did not produce any mortality, suggesting that the procedures used were in themselves non-lethal. In contrast, norepinephrine, dopamine, epinephrine, propranolol and carbachol did not produce any mortality only if introduced before day 8 (E8), but produced sharply increased mortality (60-100%) when introduced on days E8 to E13, with maxima on days E9 to E11, depending on substance used. At the same concentration, dopamine was less effective than norepinephrine. These results are interpreted as indicating the appearance of receptors (or receptors-effectors) for these substances around day E8-E9. In general, these ages agree with single data reported in the literature and obtained by much more laborious in vitro studies. The above natural substances (except propranolol) became lethal to the embryo because they are in excess of the amounts produced and needed at that time by the embryo for optimal development. The receptors themselves may be produced in excess of those needed for reacting with natural amounts of ligands at that time; thus, receptors can accomodate this extraneous excess of neurotransmitters, with lethal effect. Extraneous propranolol gives here the same result as extraneous epinephrine because it lethally blocks the receptors for epinephrine naturally produced by the embryo (same receptors and same time of their appearance). The organ(s) affected which ultimately resulted in lethality is unknown. For those embryos which survived, the weights of embryos, cerebral hemispheres, optic lobes and cerebella did not differ significantly from the controls.

CYCLIC NUCLEOTIDES I

250.1 DIFFERENTIAL EFFECTS OF BENZYL ALCOHOL ON ADENYLATE CYCLASE ACTIVITY IN RAT STRIATAL AND CEREBELLAR MEMBRANES. A. Malnoë (SPON: K. Ornstein). Nestle Research Centre, Nestec Ltd., Vers-chez-les-Blanc; CH 1000 Lausanne 26 (Switzerland).

The lipid fluidizing agent benzyl alcohol (BA) was used to probe the effect of membrane fluidity on adenylate cyclase (AC) activity in synaptosomal membranes from rat striatum and cerebellum. AC activities in these two regions differ in their sensitivity to forskolin (FOR) (40-fold activation in the striatum vs 8-fold in the cerebellum) as well as to Ca^{2+}.calmodulin (2-fold activation in striatum vs 4-fold in cerebellum). Moreover, 5'-guanylyl imidodiphosphate (Gpp(NH)p) is stimulatory in the striatum whereas it has a biphasic effect in the cerebellum.

BA (up to 50 mM) increased basal AC activity in both regions followed by inhibition at 70 mM. Stimulation of AC activity by Gpp(NH)p (10 μM) was strongly enhanced in a dose-dependent fashion by BA in the striatum but not in the cerebellum. In addition, BA increased the stimulatory response to dopamine in the striatum but had no effect on the response to isoproterenol in the cerebellum. The stimulatory effect of BA on the Gpp(NH)p-dependent AC activity was lost upon solubilization of the striatal enzyme in Lubrol PX suggesting that this effect is linked to membrane fluidity. The Ca^{2+}.calmodulin-dependent activation of AC was inhibited at high concentrations of BA (70 mM) in both striatum and cerebellum.

BA was a potent inhibitor of AC activation by FOR in both regions. 50 mM BA decreased the FOR response in the striatum and cerebellum by 50% and 70%, respectively. BA decreased the Vmax with no apparent effect on the affinity of FOR for AC in the cerebellum. The inhibitory effect was also present with the Lubrol-solubilized enzyme indicating that BA is not acting solely through changes in membrane fluidity but that it may also act directly on the enzyme possibly by competing for sites previously occupied by lipids or detergent.

The results demonstrate that striatal and cerebellar AC activities are modulated differently by the lipid fluidizing agent BA suggesting there are differences in the structural organization and/or lipid environment of the enzyme in these two regions. The data further suggest that protein/lipid interactions are involved in the mode of activation of AC by FOR.

250.2 EFFECTS OF DIMETHYLSULPHOXIDE ON CYCLIC AMP PRODUCTION AND INOSITOL PHOSPHOLIPID BREAKDOWN IN GUINEA PIG BRAIN SLICES. D.A. Kendall* and S.J. Hill* (SPON: European Neuroscience Association). Dept. of Physiol. & Pharmacol., Univ of Nottm. Med. Sch., Nottingham NG7 2UH, U.K.

Dimethyl sulphoxide (DMSO) is widely used in biomedical research as a relatively inert vehicle for water insoluble compounds. We have recently used DMSO as a solvent for a number of adenosine receptor antagonists in studies of the effects of adenosine on cyclic AMP (cAMP) production and inositol phospholipid hydrolysis in brain slices. We now report some complex effects of DMSO on second messenger formation which might influence its selection as a suitable solvent for neurochemical procedures.

Inositol phospholipid hydrolysis was monitored by meaurement of total ^{3}H-inositol phosphates (^{3}H-IP) accumulation in the presence of LiCl in brain slices prelabelled with ^{3}H-inositol (Brown et al, J.Neurochem. 42:1379, 1984). ^{3}H-cAMP formation was measured using the ^{3}H-adenine prelabelling method of Shimizu et al (J.Neurochem. 16:1609, 1969).

In guinea-pig cerebral cortical slices adenosine, despite having no effect alone, selectively enhanced the accumulation of ^{3}H-IP due to histamine. DMSO had no effect on the response to histamine alone but it antagonized the potentiation due to adenosine analogues in a concentration dependent manner. The dose response curve to 2-chloroadenosine (2-CA) was shifted 5-fold to the right in the presence of 1.5% DMSO and the potentiation was abolished by 6%. DMSO caused a small increase in ^{3}H-cAMP formation which was possibly due to adenosine release since it was abolished after incubation of slices with adenosine deaminase. The cAMP dose response curve for 2-CA was shifted 3-fold to the right in the presence of 6% DMSO. In contrast cAMP formation due to histamine was enhanced 2.5-fold by 6% DMSO. This effect was on the maximum response to histamine with no change in the EC_{50} value. The effect of DMSO was apparently on the histamine H_2 receptor since the reduced response to histamine seen in the presence of the H_1 receptor antagonist mepyramine was still enhanced by DMSO. These effects on cAMP formation were not specific for histamine or adenosine responses since 6% DMSO enhanced the effect of a depolarizing concentration of KCl (31 mM) by 5.9-fold and reduced that of forskolin (100 μM) by 76%.

Although the mechanism of action of DMSO is, as yet, unclear these data suggest caution in using this agent as an 'inert' vehicle.

Supported by a grant from the Wellcome Trust.

250.3 CALMODULIN ACTIVATION OF ANTERIOR PITUITARY ADENYLATE CYCLASE. S. Okada* and D.V. Greenlee. Dept. of Zoological and Biomedical Sciences and the College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

Rat anterior pituitary membranes were depleted of endogenous calmodulin (crude membranes = 1.22 ug CaM/mg protein; washed membranes = 0.33 ug CaM/mg protein) by washing with EGTA-containing buffers in order to observe calmodulin activation of pituitary adenylate cyclase. Calmodulin (CaM) was assayed using the soluble adenylate cyclase from Bordetella pertussis. The distribution of CaM in the extract was 80% cytosolic/ 20% particulate, which differed from the equal distribution previously reported for CaM in GH_3 pituitary tumor cell membranes. Activation of pituitary adenylate cyclase by CaM in the presence of 200 uM EGTA was Ca^{2+} dependent and occurred in a biphasic manner, with activation at lower and inhibition at higher Ca^{2+} concentrations. Although some activation was observed at 0.5-5 uM calculated free Ca^{2+}, maximal activation by 7 uM CaM occurred at 225 uM added $CaCl_2$, suggesting that maximal activation by micromolar CaM levels requires a high concentration of free Ca^{2+}. In the presence of CaM, Mn^{2+} activated adenylate cyclase at lower concentrations than required in the absence of CaM, indicating that Mn^{2+} could substitute for Ca^{2+} in elliciting CaM activation of adenylate cyclase. In the presence of 200 uM EGTA and 225 uM $CaCl_2$, calmodulin activated adenylate cyclase in a dose-dependent manner up to 25 uM, with "apparent" inhibition occurring at higher CaM concentrations. In contrast to brain adenylate cyclase, micromolar levels of CaM were required to activate pituitary adenylate cyclase, while minimal stimulation occurred at 100 nM calmodulin. The apparent inhibition by higher CaM levels was due to insufficient Ca^{2+}, since addition of optimal Ca^{2+} resulted in further stimulation of the enzyme. Using 2 uM CaM, calmidazolium inhibited CaM stimulation of adenylate cyclase with an $IC_{50}^{!}$ = 4 uM. Higher calmidazolium concentrations were required to inhibit stimulation by 5 uM and 10 uM CaM. These data indicate that (1) anterior pituitary adenylate cyclase is at least 50 fold less sensitive to CaM than is brain adenylate cyclase, (2) anterior pituitary membranes appear to have a lower affinity for calmodulin than GH_3 cell membranes, and (3) CaM can activate pituitary adenylate cyclase in a specific manner, although high Ca^{2+} concentrations are required for maximal activation.

250.4 PHOSPHOLIPASE A2 INHIBITORS ATTENUATE THE MUSCARINIC INHIBITION OF CYCLIC AMP ACCUMULATION IN N18TG2 NEUROBLASTOMA CELLS. K.A. O'Donnell* and A.C. Howlett. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Muscarinic agonists such as carbachol decreased secretin-stimulated cyclic AMP accumulation in intact N18TG2 neuroblastoma cells by 70% to 90%. However, adenylate cyclase in plasma membranes derived from these cells was inhibited only 20% to 30% by muscarinic agonists. This observation led to speculation that multiple effector mechanisms may operate in intact cells to decrease cyclic AMP accumulation in response to muscarinic receptor stimulation. This study tested the hypothesis that arachidonic acid release via phospholipase A2 may be involved in muscarinic regulation of cyclic AMP accumulation in neuroblastoma cells.

Bromophenacylbromide (BPB) and quinacrine were used as two chemically unrelated phospholipase A2 inhibitors. Both BPB and quinacrine attenuated the inhibition of cyclic AMP production by the muscarinic agonist carbachol. Neither compound had any effect on the basal cell content of cyclic AMP or on the stimulation of cyclic AMP production by secretin. The effects of both phospholipase A2 inhibitors were dose-dependent over a range of 1 µM to 100 µM. It was necessary that the phospholipase A2 inhibitor be present during the incubation in order to attenuate the muscarinic inhibition of cyclic AMP production. Preincubation of the cells with either BPB or quinacrine followed by washing the cells and testing for muscarinic inhibition of cyclic AMP accumulation yielded results that were not different from controls. The diglyceride lipase inhibitor, RHC-80267, which does not alter phospholipase A2 or C activities, had no effect on muscarinic inhibition of cyclic AMP accumulation. In order to see if protein kinase C could modify the response, cells were incubated with an active phorbol ester, phorbol 12-myristate 13-acetate (PMA) for 20 min prior to determination of cyclic AMP accumulation. PMA had no effect on basal, secretin-stimulation or muscarinic-inhibited cyclic AMP accumulation. Furthermore, PMA did not alter the ability of quinacrine to diminish the muscarinic inhibition of cyclic AMP accumulation. In summary, the activity of phospholipase A2 may be intrinsic to the muscarinic response in neuroblastoma cells.

250.5 SYNAPTIC MEMBRANE TUBULIN MAY INHIBIT ADENYLATE CYCLASE VIA THE EXCHANGE OF GUANOSINE TRIPHOSPHATE ANALOGS AMONG GTP BINDING PROTEINS. M.M. Rasenick, C.A. Moore* and N. Wang*. Department of Physiology and Biophysics and the Committee on Neuroscience, University of Illinois College of Medicine. Chicago, IL 60680.

GTP-binding proteins which mediate neuronal signal transduction have considerable structural and functional homology. In addition to the binding and hydrolysis of GTP, these proteins interact with cell surface receptor molecules and/or enzymes which generate cellular second messengers. This laboratory has demonstrated, recently (Proc. Nat. Acad. Sci., USA 83: 5439-5443, 1986), that the GTP binding proteins (GN) which inhibit (GNi) or stimulate (GNs) rat cerebral cortex adenylate cyclase, appear to interact directly in the exchange of nucleotide. Such observations raise the possibility that GN proteins couple not only with receptor and effector proteins, but with other GN proteins as well. Microtubules have also been implicated as modulators of the adenylate cyclase system and tubulin, the primary constituent of microtubules, is a GTP-binding protein with structural similarities to other GN proteins. Tubulin binds two moles of GTP/mol dimer and one of the GTP binding sites is exchangeable. Certain hydrolysis-resistant GTP analogs support the polymerization of tubulin, and in doing so, occupy the exchangeable GTP-binding site. Incubation of rat cerebral cortex synaptic membranes with tubulin dimers which have GppNHp bound (tubulin-GppNHp) followed by washing of those membranes results in a stable inhibition of adenylate cyclase. Under identical conditions, incubation of membranes with a GTP binding protein from the rod outer segment (transducin), with GppNHp bound, did not cause inhibition of adenylate cyclase. Tubulin (regardless of the nucleotide bound to it) did not alter the activity of the adenylate cyclase catalytic unit directly. When tubulin was polymerized with the hydrolysis-resistant photoaffinity GTP analog, (^{32}P) AAGTP, AAGTP-tubulin, added to synaptic membranes under conditions which resulted in persistent inhibition of adenylate cyclase, appeared capable of transferring nucleotide to the inhibitory GTP-binding protein, GNi. Transfer of AAGTP from tubulin to GNi, was blocked by prior incubation of the membranes with GppNHp or U.V. irradiation of tubulin-AAGTP (inducing covalent binding of AAGTP to tubulin) prior to exposure of tubulin-AAGTP to membranes. Incubation of membranes with GppNHp subsequent to incubation with AAGTP-tubulin results in a decrease in AAGTP bound to GNi and a compensatory increase in AAGTP bound to the stimulatory GTP-binding protein, GNs. This parallels the reversal of persistent inhibition of adenylate cyclase by addition of GppNHp to the assay. Whereas, GppNHp promotes persistent inhibition of synaptic membrane adenylate cyclase after incubation on ice, tubulin (with AAGTP or GppNHp bound) requires 30 seconds incubation at 23°C to effect adenylate cyclase inhibition. Photoaffinity experiments yield parallel results. These data are consistent with synaptic membrane tubulin regulating neuronal adenylate cyclase by transferring nucleotide directly to GNi and, subsequently, to GNs.

250.6 GDPβS PARTIALLY ACTIVATES ADENYLATE CYCLASE IN NEURAL CELLS. N. Wang*, J.M. Hughes* and M.M. Rasenick (spon. C.L. Melchior). Department of Physiology and Biophysics and the Committee on Neuroscience. University of Illinois College of Medicine, Chicago, IL 60680.

The stable GDP analog, Guanosine 5'O-(2 thiodiphosphate) [GDPβS] has been used for some time as an inhibitor of GTP-dependent processes. GDPβS has been thought to inactivate the GTP-binding proteins [GN], which stimulate [GNs] or inhibit [GNi] adenylate cyclase [AC] and mediate other cellular processes such as ion channels [GNi, GNo, GNk] and phospholipid metabolism [GN?]. Pressure injection or iontophoresis of GDPβS has been utilized by several investigators, often with the assumption that GDPβS interfered with the AC system by preventing AC activation through GNs. Whereas GDPβS is capable of blocking hormone or neurotransmitter-induced AC stimulation (or inhibition); hormone independent effects of this compound have not been studied in neural tissue. We find that GDPβS, when incubated with rat cerebral cortex synaptic membranes, activates adenylate cyclase with an apparent EC50 of 2.4×10^{-7}M (compared to 1.9×10^{-8}M for GTPγS or 3.6×10^{-7}M for GppNHp) but with a Vmax only 50% of the latter compounds. GDPβS displays "partial agonist" kinetics in the activation of adenylate cyclase but is ineffective in the GTP-dependent inhibition of that enzyme, and is capable of mitiating that process by 25-30%.

Whereas, hydrolysis-resistant GTP analogs reverse a persistent AC inhibition (induced by the GTP a photoaffinity analog, azidoanilido GTP [AAGTP]), GDPβS is ineffective in this process or the concomitant nucleotide exchange (Proc. Nat. Acad. Sci. USA 83:5439, 1986) reaction. Thin layer chromatography reveals a minor amount of GTPβS (<5%) contamination, however, this compound is not likely to account for these results as GTP neither activates nor inhibits AC in this preparation.

Permeabilized C6 glioma cells provide a paradigm for GDPβS pressure injection studies in that they provide a method for measuring AC in cells which are largely intact (FEBS Lett. 207: 296, 1986). Unlike the cerebral cortex synaptic membrane preparation, permeabilized C6 cells display AC which is dependent upon β adrenergic agonists for AC activation. GDPβS blocks isoproterenol (IPR) induced AC stimulation, whereas GppNHp or GTPγS promote and accentuate that process. In the absence of IPR, GDPβS elevates permeabilized C6 AC by about 50% at 10^{-4}M. Similar results are obtained in pertussis-toxin treated cells, indicating that GDPβS effects may be independent of GNi, despite the ability of both GN and GNs to bind that nucleotide (see abstract by J.S. Gordon et.al.). We conclude that high doses of GDPβS result in a receptor-independent activation of GNs and that GDPβS may be partial agonist for the GNs protein in certain neural cells and tissues.

250.7 SODIUM FLUORIDE INDUCES CYCLIC GMP FORMATION IN MOUSE NEUROBLASTOMA N1E-115 CELLS. W.S. Lai and E.E. El-Fakahany. Department of Pharmacology and Toxicology, Univ. of Maryland School of Pharmacy, Baltimore, MD 21201.

Sodium fluoride (NaF) has been shown to induce phosphoinositide hydrolysis in a variety of cells (Blackmore et al., J. Biol. Chem. 260: 14477, 1985; Taylor et al., Biochem. Biophys. Res. Commun. 136: 362, 1986; Guillon et al., FEBS Lett. 204: 183, 1986; Paris and Pouyssegur, J. Biol. Chem. 262: 1970, 1987) probably by activating phospholipase C. When mouse neuroblastoma cells (clone N1E-115) were incubated with 20 mM NaF for 5 or 10 min at 37°C in the presence of 10 mM LiCl, there was a significant increase in the accumulation of inositol phosphates. This response was significantly higher than that induced by the muscarinic receptor agonist carbamylcholine (1 mM for 30 min). Many of the calcium-mobilizing receptors that induce increases in phosphoinositide hydrolysis in a variety of tissues elevate the cellular level of cyclic GMP as well. This has also been demonstrated in mouse neuroblastoma N1E-115 cells (Kanba and Richelson, Biochem. Pharmacol. 36: 869, 1987). Therefore, the hydrolysis of phosphoinositides and the formation of cyclic GMP may be interrelated (Berridge, Biochem. J. 220: 345, 1984). Thus, it was interesting to test the effects of NaF on cyclic GMP formation in N1E-115 cells. NaF (5-20 mM) induced cyclic GMP formation in intact N1E-115 cells in both a time- and a concentration-dependent manner. The time-to-peak response was inversely proportional to the concentration of NaF. Again, this cyclic GMP response to 20 mM NaF was much more pronounced than the response elicited by 1 mM carbamylcholine. Such increases in NaF-induced cyclic GMP production were not significantly blocked by the muscarinic receptor antagonist atropine or the histamine H_1 receptor blocker pyrilamine at concentrations that totally inhibited carbamylcholine-and histamine-induced cyclic GMP synthesis in these cells, suggesting that the effect of NaF on cyclic GMP formation was not due to the activation of muscarinic receptors or histamine receptors. Although NaF induced cyclic GMP accumulation in intact N1E-115 cells, it inhibited guanylate cyclase activity in cell homogenates. Phorbol 12-myristate 13-acetate (PMA) has been shown to inhibit carbamylcholine- and histamine-mediated cyclic GMP formation in these cells. However, preincubation of cells with 100 nM PMA for 60 min at 37°C did not inhibit NaF-mediated cyclic GMP synthesis. Thus, our present data demonstrate a novel effect of NaF in inducing cyclic GMP synthesis in neuronal tissue.

250.8 INCREASES IN PHOSPHOINOSITIDE HYDROLYSIS, INTRACELLULAR CALCIUM AND CYCLIC GMP FORMATION BY PHOSPHOLIPASE C. W. Surichamorn, L. Noronha-Blob* and E.E. El-Fakahany. Dept. of Pharmacology and Toxicology, Univ. of Maryland School of Pharmacy, Baltimore, MD 21201 and NOVA Pharmaceutical Corp., Baltimore, MD. 21224.

Activation of some neurotransmitter receptors in mouse neuroblastoma cells (clone N1E-115) results in an increase in phosphoinositide (PI) hydrolysis and a transient elevation in cyclic GMP (cGMP) formation (Kanba and Richelson, Biochem. Pharmacol. 36, 869, 1987). Since the breakdown of PI in several tissues has been demonstrated to be through a specific PI phosphodiesterase (Phospholipase C; PLC) and thereby causes the release of diacylglycerol (DAG) and inositol trisphosphate which act as intracellular second messengers, we decided to investigate the effects of exogenous PLC in mouse neuroblastoma N1E-115 cells. These cells were treated with PLC from B. Cereus and [^{3}H]cGMP and [^{3}H]inositol phosphates ([^{3}H]IP) were determined. PLC increased the accumulation of the total [^{3}H]IP, determined in the presence of 10 mM LiCl, in a time- and a concentration-dependent manner. PLC (5 U/ml) caused a linear increase in the accumulation of [^{3}H]IP up to 15 min . At 10 min, PLC in concentrations of 5, 10, 20, and 30 U/ml stimulated the release of [^{3}H]IP by 5, 7, 9, and 12 fold compared to basal, respectively. This response was completely blocked by neomycin (10 mM). PLC also increased cGMP levels in these cells. The stimulation of [^{3}H]cGMP formation by PLC (5 U/ml) showed a peak effect at 1-3 min which was maintained up to 10 min, then declined gradually. At 5 min, PLC stimulated the [^{3}H]cGMP synthesis with an EC_{50} of 5 U/ml and a maximum effect at 20 U/ml. Also, neomycin (10 mM) completely inhibited this response. At 5, 10 and 20 U/ml, PLC did not directly stimulate guanylate cyclase. It has been suggested that arachidonic acid release might be linked to cGMP formation (Snider et al., Proc. Natl. Acad. Sci. USA. 81, 3905, 1984). The cGMP response to 5 U/ml PLC was inhibited by 45% by the phospholipase A_2 inhibitor quinacrine (300 μM). The lipoxygenase inhibitors eicosatetrayonic acid (50 μM) and nordihydroguaiaretic acid (50 μM) also attenuated the response by 40% and 14%, respectively, whereas the DAG lipase inhibitor monooleoyl glycerol (200 μM) antagonized the response only slightly. In addition, we studied the effects of PLC on Ca^{2+} mobilization using quin-2 fluorescence. PLC (0.01-1.0 U/ml) caused a rapid increase in intracellular Ca^{2+}, while higher concentrations (1.0-20 U/ml) induced a more marked increase. In summary, our findings indicate that exogenous PLC increases PI hydrolysis, intracellular Ca^{2+} and cGMP formation in mouse neuroblastoma cells. Although the latter response is not mediated by a direct activation of guanylate cyclase, it might involve, only in part, the release of arachidonic acid.

250.9 REGULATION BY cAMP AND VASOACTIVE INTESTINAL PEPTIDE OF THE PHOSPHORYLATION OF THREE LOW MOLECULAR WEIGHT PROTEINS IN STRIATAL CELLS IN CULTURE I.Shalaby, J.-A.Girault*, N.Rosen and P.Greengard, The Rockefeller University New York, NY 10021

Three proteins that are substrates for cAMP-dependent protein kinase have recently been purified from bovine striatum. These proteins have Mr values of 16 kDa, 19 kDa (accompanying abstract by Horiuchi et al.) and 21 kDa (Hemmings et al., Soc. for Neurosci. Abst. 12, 281.10). The 16 kDa and 21 kDa proteins are particularly enriched in the striatum whereas the 19 kDa protein is present in all brain regions as well as in certain peripheral organs. These three proteins have been referred to as ARRP-16, ARPP-19 and ARPP-21 for cAMP regulated phosphoproteins with Mr values of 16, 19 and 21 kDa respectively (accompanying abstract by Girault et al.). We have now investigated the effects of cAMP and of agents known to raise intracellular cAMP concentration, on the state of phosphorylation of these 3 proteins in cultured cells from mouse striatum. Reaggregate cultures were prepared from striata of fetal mice at embryonic day 14. Pharmacological studies were performed after 3 weeks of culture. The agents tested were added to the incubation medium for 10 min. The proteins were extracted and phosphorylated with ^{32}P-ATP in the presence of cAMP-dependent protein kinase catalytic subunit. The 3 proteins studied were immunoprecipitated with specific antibodies, separated by SDS-PAGE and the radioactivity incorporated in each protein was counted. Under these conditions of "back-phosphorylation" an increase in the level of phosphorylation in vivo is detected as a decrease in the incorporation of radioactive phosphate into the protein in vitro.

Addition of 8 bromo-cAMP (4mM) increased the phosphorylation of the 3 proteins (decrease in the dephosphorylated form : 64±4% for ARPP-21, 40±6% for ARPP-19, 26±6% for ARPP-16). Forskolin, a potent activator of adenylate cyclase, induced a dose-dependent increase in the phosphorylation of the 3 proteins (maximal decrease in the dephosphorylated form 70% with an apparent EC50 of 0.5-1 micromolar). Vasoactive intestinal peptide (VIP), which is reported to stimulate adenylate cyclase in striatal cells in culture, increased the phosphorylation of the 3 proteins (maximal decrease in the dephosphorylated forms of 40% for ARPP-19 and ARPP-21). Effects of VIP on ARPP-19 and ARPP-21 were observed at concentrations as low as 10-100 pM. In conclusion we have observed that the phosphorylation state of ARPP-16, ARPP-19 and ARPP-21 is regulated by cAMP in cultured striatal cells. In addition, VIP stimulates the phosphorylation of these 3 proteins suggesting that they may play a role in the physiological actions of this neuropeptide in the striatum.

250.10 BASAL GANGLIA-ENRICHED LOW MOLECULAR WEIGHT PHOSPHOPROTEINS : REGULATION BY cAMP AND REGIONAL DISTRIBUTION IN THE RAT BRAIN J.-A.Girault*, A.Horiuchi*, H.C.Hemmings Jr., A.C.Nairn, and P.Greengard, Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021

Three protein substrates for cAMP-dependent protein kinase, with Mr values of 16kDa, 19kDa and 21kDa respectively, have recently been purified from bovine striatum and antibodies have been prepared against them. The 16 kDa and 19 kDa proteins show a high degree of immunological cross-reactivity suggesting a high degree of structural homology (see accompanying abstract by Horiuchi et al.). In the present study we have investigated the in vivo regulation of the phosphorylation of these proteins by cAMP in striatal slices and their distribution in the rat brain.

Slices from rat striatum were preincubated for 120 min. and the compounds studied were added to the incubation medium for 10 min. The proteins were then extracted, phosphorylated with ^{32}P-ATP in the presence of cAMP-dependent protein kinase catalytic subunit, immunoprecipitated with the specific antibodies, separated by SDS-PAGE and the radioactivity incorporated in each protein of interest was counted. 8 bromo-cAMP (4mM) stimulated the phosphorylation of all 3 proteins (the decrease in the dephosphorylated form was : 50±5 % for the 21 kDa protein, 48±5 % for the 19 kDa and 29±6 % for the 16 kDa). Forskolin, a compound that activates adenylate cyclase, induced, in the presence of 0.1mM IBMX, a dose-dependent stimulation of the phosphorylation of all 3 proteins with an apparent EC 50 around 1 micromolar.

The amount of the proteins of interest in each region was determined by phosphorylation/immunoprecipitation as described above and by immunoblot. Both methods gave similar results. The highest concentrations of 21 kDa and 16 kDa proteins were found in the striatum. These proteins were also enriched, but to different extents in the substantia nigra, the globus pallidus, the olfactory tubercle, the amygdala and the cerebral cortex. In contrast the 19 kDa protein was present at similar levels in all brain regions studied including the white matter. This latter protein was also detected in several peripheral organs (e.g. pituitary gland, thymus, pancreas).

In conclusion, in striatal slices the phosphorylation of all 3 proteins is regulated by cAMP. Therefore, these proteins can be referred to as ARPP-16, ARPP-19 and ARPP-21 (for cAMP regulated phosphoproteins of Mr values of 16, 19 and 21 kDa respectively). ARPP-16 and ARPP-21 appear to be enriched in certain types of neurons from the basal ganglia and the cerebral cortex, whereas ARPP-19 is present in all brain regions, possibly both in neurons and in glial cells.

250.11 PURIFICATION AND BIOCHEMICAL STUDIES OF A 90 kDa BASAL GANGLIA-ENRICHED PHOSPHOPROTEIN. Steven Cala* and Paul Greengard (SPON: S. Halpain) Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021

A set of phosphoproteins which are substrates for cyclic AMP-dependent protein kinase (cAMP-PK) have previously been shown to be enriched in the rat basal ganglia (Walaas et al., J. Neuroscience, 3, 291-311, 1983) Like DARRP-32, these substrates are believed to be involved in signal transduction within the basal ganglia. One of these phosphoproteins appears on sodium dodecyl sulphate (SDS)-polyacrylamide gels as a protein doublet with an apparent molecular weight of approximately 90 kDa. The 90 kDa phosphoprotein has been purified from the supernatant of bovine caudate nucleus using chromatography on DEAE-Sephacel, heparin-agarose, and Mono Q (FPLC), ammonium sulphate precipitation, and preparative SDS-polyacrylamide gel electrophoresis.

Gel filtration on Superose 12 (FPLC) revealed two peaks of the 90 kDa doublet with Stokes radii of 38 and 62 A. These values correspond to globular proteins of molecular weights approximately 85 and 240 kDa. These data indicate that the 90 kDa protein exists in its native form as both a single polypeptide and a higher molecular-weight complex.

Analysis of the two 90 kDa proteins using the two-dimensional (2D) gel system of O'Farrell demonstrated that the two forms have slightly different isoelectric points. The 240 kDa form is rapidly phosphorylated upon addition of the catalytic subunit of cAMP-PK and 5uM [^{32}P]-ATP. In contrast, upon incubation with the catalytic subunit of cAMP-PK and 1mM ATP for much longer times, both forms of the 90 kDa are phosphorylated and their patterns on 2D gels become superimposable.

In summary, the 90 kDa basal ganglia-enriched phosphoprotein can be isolated as both a single polypeptide and a more complex form. These two forms appear to differ in their isoelectric point, and this difference is eliminated by phosphorylation.

250.12 PURIFICATION, CHARACTERIZATION AND IMMUNOHISTOCHEMICAL LOCALIZATION OF ARPP-16, A SUBSTRATE FOR cAMP-DEPENDENT PROTEIN KINASE, ENRICHED IN THE BASAL GANGLIA. A. Horiuchi *, E. Gustafson, A.C. Nairn and P.Greengard, Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021

A phosphoprotein substrate for cAMP-dependent protein kinase, which has an apparent molecular weight of 16,000 measured by SDS-polyacrylamide gel electrophoresis, has been found to be enriched in the basal ganglia. The protein, termed ARPP-16, was purified to homogeneity from the supernatant of bovine caudate nucleus following ammonium sulphate precipitation, and chromatography on CM-cellulose, Mono S (FPLC) and C_{18} reverse phase (HPLC). Two-dimensional non-equilibrium pH gradient electrophoresis indicated that the protein is basic with a pI of ~10.6; amino acid analysis indicated the protein contains high levels of lysine. The protein was phosphorylated, in the presence of the catalytic subunit of cAMP-dependent protein kinase and ^{32}P-ATP with a stoichiometry of 1 mol/mol. Two-dimensional tryptic mapping revealed one major phosphopeptide.

Rabbit serum antibodies were prepared against purified ARPP-16. An additional substrate for cAMP-dependent protein kinase, with an apparent molecular weight of 19,000, as measured by SDS-polyacrylamide gel electrophoresis, was found to cross-react with the antibodies prepared against ARPP-16. The protein, termed ARPP-19, was purified to homogeneity by the same techniques used for purification of ARPP-16. ARPP-19 had a two-dimensional tryptic map similar to that of ARPP-16 and had a more neutral pI (8-8.5). Phosphorylation/immunoprecipitation and immunoblot indicated that ARPP-16 was enriched in the basal ganglia. In contrast, these two techniques indicated that ARPP-19 was present in similar levels in all brain regions studied and was also present in non-neuronal tissues (see abstract by Girault et al.)

Immunohistochemical localization of ARPP-16 was studied using the avidin-biotin complex procedure. Under the antibody dilution conditions used, strong immunoreactivity appeared to reflect the levels of ARPP-16. Neurons strongly immunostained for ARPP-16 were concentrated in the caudate-putamen, presumably in medium spiny neurons, and in the olfactory tubercule, claustrum, and layers II, III, and VI of neocortex. The substantia nigra pars compacta contained a plexus of ARPP-16 immunoreactive fibers which appeared to be organized in patches throughout the nigra. Weakly immunoreactive neurons were found in nucleus accumbens and a few immunoreactive axons were found in the globus pallidus.

Supported by USPHS Grant MH-40899.

250.13 ADENYLATE CYCLASE AND G-PROTEINS IN DISCRETE BRAIN NUCLEI: CHARACTERIZATION AND REGIONAL VARIATIONS. R.S. Duman, J. Erdos*, R. Terwilliger*, E. Nestler and J.F. Tallman. Dept. of Psychiatry, Yale University School of Medicine, Abraham Ribicoff Research Facilities and Connecticut Mental Health Center, 34 Park Street, New Haven, CT 06508.

Recent studies have indicated regional variations in G-proteins and the catalytic component of adenylate cyclase in brain (Worley et al., PNAS 83: 4561, 1986). However, these studies were qualitative and did not demonstrate the functional significance of the regional differences observed. In this study discrete brain nuclei were isolated for analysis of adenylate cyclase and G-proteins. Male Sprague-Dawley rats (150g) were sacrificed, the brains rapidly removed, and gross dissection of frontal cortex (FC), hippocampus (Hp) and cerebellum (Cb) performed on ice. Brain nuclei, including the locus coeruleus (LC), dorsal raphe (DR), ventral tegmentum (VT) substantia nigra (SN) and neostriatum caudate putamen (NS), were isolated by taking 15 gauge punches from 0.5-1.0mm coronal cross sections of brain. Adenylate cyclase assays and ADP-ribosylation and immunoblotting of G-proteins were performed using standard procedures.

GTP-stimulated adenylate cyclase activity was highest in the LC, DR and VT (400% basal), intermediate in SN, FC and Hp (150-200% basal) and lowest in the NS and Cb (150% basal). GTP-dose response curves were monophasic in all regions except NS, where inhibition of adenylate cyclase was observed at higher GTP concentrations. GTPγS- (a nonhydrolyzable analogue of GTP)-stimulated adenylate cyclase activity was highest in LC, DR, VT, FC (700% basal), intermediate in SN and Hp (500%), and lowest in NS and Cb (250 and 150% basal). Presumably, adenylate cyclase activity reflects the sum of the influence of Gs and Gi on the enzyme. Therefore, it is possible that the regional differences observed in GTP-regulation of adenylate cyclase activity reflect regional variations in the levels of these G-proteins. This interpretation is supported by the finding that Gi/Go, determined by immunoblotting and pertussis toxin-mediated ADP-ribosylation, is highest in NS and SN. Finally, forskolin (5μm) activation of adenylate cyclase was greatest in NS and SN (1200-1500% basal) intermediate in LC, DR, VT, FC, Hp (700-900% basal), and lowest in Cb (500% basal), suggesting possible regional differences in the amount of adenylate cyclase catalytic subunits as well.

The results demonstrate that analysis of adenylate cyclase and G-proteins can be performed in discrete brain nuclei, and that the brain shows striking regional differences in levels and functional activities of these proteins. In related studies (Erdos et al., Nestler et al., this volume) we have also found regional differences in the regulation of adenylate cyclase and G-proteins by chronic morphine.

250.14 DETECTION OF PHOSPHORYLATING PROTEINS IN THE COCHLEAR NUCLEUS: EFFECTS OF 8-BROMO CYCLIC AMP AND CALCIUM/CALMODULIN. L. Winsky, J.A. Harvey and D.M. Jacobowitz, Dept. of Psychology and Pharmacology, Univ. Iowa, Iowa City, IA 52240 and Lab. of Clinical Science, NIMH, Bethesda, MD 20892.

There has been considerable interest and progress aimed at determining the importance of intracellular second messengers such as cAMP and calcium in the regulation of neuronal function via the phosphorylation of proteins. However, relatively little is known regarding the effects of these molecular signals within sensory nuclei. In this study, we employed two-dimensional gel electrophoresis and computerized optical densitometry to examine the phosphorylation of proteins in the cochlear nucleus, the first order sensory nucleus of the auditory system. Samples of dorsal and ventral cochlear nuclei of rabbits, obtained by micropunch and containing approximately 40 μg protein, were sonicated in Tris buffer containing EGTA and PMSF. Equal aliquots were added to tubes containing Tris and $MgCl_2$ (basal condition) in addition to 8-bromo cyclic AMP or $CaCl_2$ and calmodulin for examining cAMP and calcium/calmodulin stimulated phosphorylation, respectively. Samples were then incubated for 60 sec with 2.5 μCi of ^{32}P-ATP followed by the addition of sample detergent to stop the reaction. Proteins were separated by two-dimensional gel electrophoresis and silver stained. Gels were then dried and placed on autoradiographic film. Inspection of these autoradiograms indicated a number of proteins which were phosphorylated under the basal condition. The addition of calcium and calmodulin to the incubation medium resulted in an increase in the phosphorylation of several acidic proteins (pI < 6) and at least one basic protein (pI > 7.0). In contrast, the addition of 8-bromo cAMP did not produce any apparent increases in phosphorylation but instead resulted in a decrease in the phosphorylation (from basal) of three proteins. Similar patterns of protein phosphorylation and effects of 8-bromo cAMP and calcium/calmodulin were seen in both the dorsal and ventral divisions of the cochlear nucleus. Inspection of silver stained gels revealed one protein (30 kDa, pI 5.2) previously not observed in several other brain areas examined which may be specifically concentrated in the cochlear nucleus or more generally in first order sensory nuclei. In conclusion, these results demonstrate that the cochlear nucleus is an active site of protein phosphorylation. [Supported by USPHS Grant MH16841].

250.15 SPATIAL AND TEMPORAL EXPRESSION OF mRNA ENCODING THE α SUBUNIT OF G_s: MAPPING IN RAT BRAIN BY IN SITU HYBRIDIZATION. R.R. Reed*, B.L. Largent, D.T. Jones*, C. Pearson*, P.F. Worley, and S.H. Snyder. (SPON: K. Braas) Dept. of Molecular Biology and Genetics, Howard Hughes Medical Institute, and Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The G-proteins represent a family of proteins that bind guanine nucleotides and actively participate in many signal transduction processes. Members of this G-protein family are highly conserved at the protein and nucleotide level. To distinguish in our studies among various members of this family, we generated specific oligonucleotide probes to unique 3' untranslated regions of each G-protein cDNA. These probes were used to detect mRNA abundance and distribution in rat brain. The oligonucleotide probes were labeled using a novel technique involving the synthesis of a 58mer oligonucleotide containing 46 nucleotides of target-specific sequence followed by an additional 12 nucleotides (CAR-common annealing region). A second oligonucleotide (22mer), consisting of T_{10} followed by the sequence complementary to the CAR region, was annealed to the 58mer oligo and extended with α-^{35}S-dATP and DNA polymerase. These probes of defined specific activity and uniform length were then used for in situ hybridization studies.

G_s, the stimulatory G-protein, is associated with the receptor-mediated activation of adenylyl cyclase, an enzyme abundant in neural tissues and essential for many types of neurotransmission. Mapping of mRNA encoding the α subunit of G_s reveals abundant hybridization and heterogenous distribution throughout the brain. Control studies confirm the hybridization specificity. G_s mRNA is prevalent throughout the brain, being particularly evident in large neurons such as pyramidal cells of the piriform cortex and hippocampus, and neurons of motor nuclei and reticular formation. Interestingly, the general pattern of hybridization is quite similar to the immunocytochemical distribution of adenosine (K. Braas, et al, J. Neurosci., 6:1952-1961, 1986). Localization of G_s message does not parallel [^{3}H]forskolin binding (a marker for G_s-coupled adenylyl cyclase) in a fashion that might be expected. Notably, cells of the caudate nucleus, whose neurons contain the highest levels of adenylyl cyclase in the brain, demonstrate the lowest abundance of G_s mRNA. This mismatch may suggest that adenylyl cyclase does not exclusively couple through G_s. Alternatively, G_s in other areas of the brain may effect transduction through other second messenger enzymes. Presently, we are examining the modulation of G_s message levels after intracranial injection of the bacterial toxins cholera and pertussis, known to covalently modify Gα subunits. Additionally, the ontogeny of G_s mRNA in embryonic and neonatal brain is being assessed.

250.16 BINDING OF GUANINE NUCLEOTIDE ANALOGUES TO ADENYLATE CYCLASE REGULATORY PROTEINS IN NEURAL CELL MEMBRANES. J.H. Gordon, M.M. Marcus* and M.M. Rasenick. The Chicago Med Schl, N. Chicago, IL 60064 and Dept Physiol and Biophys, U. of Illinois College of Med, Chicago, IL 60680.

Neural cell membranes, when exposed to hydrolysis-resistant analogues of GTP, show a dose-dependent stimulation or inhibition (depending upon assay conditions) of adenylate cyclase (AC). The activation or inhibition of AC persist subsequent to washing of membranes and is independent of neurotransmitter(s). Although the binding of GTP analogues to detergent-solubilized and purified guanine nucleotide binding regulatory proteins (GN) has been studied, the kinetics of guanine nucleotide binding to individual GN in membranes has not been characterized.

Rat cerebral cortex membranes were incubated with either varying concentrations of the hydrolysis-resistant, photoaffinity GTP analog, azidoanilido GTP (^{32}P-AAGTP) or with a constant amount of ^{32}P-AAGTP and varying concentrations of cold GTP analogues. Membranes were incubated for 3 min at 23°C, centrifuged, resuspended in fresh buffer and exposed to UV irradiation for 5 min. Following irradiation the suspension was centrifuged. The resulting pellet was dissolved in sample buffer, subjected to SDS-PAGE and radioautography. Radioactive bands corresponding to AC stimulatory GN (52 and 42 KDa bands; GN_{SH} and GN_S), inhibitory GN (40 KDa doublet composed of GN_i and GN_O) and a novel neural GN (32 KDa band; GN_{32}) were excised from the dried gels and the amount of radioactivity quantitated.

Isotherm analysis revealed that the $GN_{i/O}$ band had the highest affinity for ^{32}P-AAGTP, K_D= 2.12±0.50 μM (mean ± SE), followed by GN_{32} (3.59±0.59), GN_S (4.87±0.64) and GN_{SH} (5.70±1.25). Separation of the $GN_{i/O}$ doublet into its components (i.e. GN_i and GN_O) indicated that these two GN were not significantly different in their binding affinity for nucleotide. Analysis of competition assays indicated that all of the guanine nucleotides studied were similar to AAGTP as they all displayed the highest affinity for the $GN_{i/O}$ band and the lowest affinity for the GN_{SH}. Of the GTP analogues studied GPPNHP displayed the highest affinity for all GN followed by GDPβS>GTPγS>AAGTP>GTP. GppNHp and AAGTP displayed a significantly higher affinity for $GN_{i/O}$ than GN_S; whereas GTPγS GDPβS and GTP (which is rapidly hydrolyzed to GDP) displayed nearly equal affinity for both proteins. Whether these observations are a result of assay conditions or innate affinities is not known at this time. These data indicate that components of synaptic membranes may alter apparent affinity of GN for nucleotide and that the activation/inhibition of AC is a dynamic process with multiple sites of regulation.

250.17 ISOLATION AND CHARACTERIZATION OF THE INOSITOL 1,4,5 TRISPHOSPHATE (IP_3) BINDING SITE. S. Supattapone, P. Worley, J. Baraban and S.H. Snyder. Department of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205

IP_3 appears to be the second messenger responsible for mobilizing calcium from internal stores (Berridge, M.J., and Irvine, R.F. Nature, 312:315, 1984). Therefore, it would be of interest to characterize the binding site for IP_3 in the cell. Previous reports (Worley, P.L., et al., Nature, 325:159, 1987) have demonstrated that the rat cerebellum is a very abundant source of a high affinity IP_3 binding site.

In this study, we have solublized and purified the IP_3 binding site to apparent homogeneity from rat cereblum. The purified receptor is globular and has a Stokes' radius of 10 nm. Therefore, its molecular weight is on the order of one million daltons. While IP_3 binding is reversibly inhibited by 300 nM calcium in crude homogenates and solubilized membranes, the purified binding site is not inhibited by calcium concentrations up to 1.5 mM. Inhibition by calcium could be reconstituted by addition of crude solubilized cerebellar membranes, but not by the cytosolic fraction of cerebellum.

250.18 IDENTIFICATION AND PURIFICATION OF BRAIN TYPE II PHOSPHODIESTERASE: A DISTINCT cGMP RECEPTOR PROTEIN IN MAMMALIAN BRAIN MEMBRANES. M.E. Whalin*, W.J. Thompson*, and S.J. Strada (SPON:H.E.Longenecker). University of South Alabama, Dept. of Pharmacology, College of Medicine, Mobile, AL 36688.

Type II (cGMP stimulated) cyclic nucleotide phosphodiesterase(PDE) as purified from heart, liver, and adrenal tissues shows a preference for cGMP as substrate and displays enhanced cAMP hydrolysis by low, physiological concentrations of cGMP. Our studies of brain Type II PDE indicate it to be the majority of the hydrolytic activity found in membrane fractions. It is not released by either hypotonic or high ionic strength buffers. Detergent solubilization of the Type II PDE does not preserve its regulation by cGMP. However, if released by limited proteolysis using TPCK-trypsin, full cGMP regulation is retained. The solubilized enzyme was purified to apparent homogeneity, utilizing DEAE-cellulose anion exchange, cGMP epoxy-sepharose 6B, and hydroxylapatite chromatography. A 3000 fold increase in specific activity was observed. Its Mr is 240 kD by gel filtration. The subunit Mr of the enzyme determined by SDS-PAGE analysis (7.5%) shows a major protein band at 103-105 kD. Maximum velocities are 157 U/mg and 159 U/mg for cAMP and cGMP respectively. S 0.5 are 28 uM for cAMP and 16 uM for cGMP. The Kact for cGMP stimulation of cAMP hydrolysis at 5 uM substrate is 0.33 uM and maximum stimulation (5 fold) is acheived at 2 uM cGMP. The purified enzyme is phosphorylated by the catalytic subunit of cAMP dependent protein kinase and retains the same subunit Mr. Phosphorylation does not appear to affect cAMP hydrolysis at 5 uM substrate in the absence or presence of 2 uM cGMP, but does reduce cGMP hydrolysis measured at 40 uM substrate by 30%. Monoclonal antibodies produced against purified Type II PDE immunoprecipitate enzyme activity (>90%) with the immunoprecipitate retaining full regulation by cGMP. Immunocytochemical studies are being pursued to define the regional distribution and localization of the Type II PDE observed by activity analysis in related studies (Garrett et al., this volume). This enzyme may constitute a major cGMP receptor and may serve an important regulatory role in controlling the level of cyclic nucleotides during neuronal function.

250.19 **EFFECTS OF SELECTED PHOSPHODIESTERASE (PDE) INHIBITORS ON CALCIUM-INDEPENDENT PDE ACTIVITY AND ROLIPRAM BINDING SITES OF CEREBRAL CORTEX.** L. L. Russo*, L. A. Lebel* and B. K. Koe. Central Research Division, Pfizer Inc., Groton, CT 06340.

Rolipram, Ro 20-1724 and ICI 63197 are selective PDE inhibitors that are markedly more active on the calcium-independent (cyclic AMP) enzyme (IPDE) than on the calcium-dependent (cyclic GMP) enzyme (DPDE). Recently, membranes, as well as soluble extracts, of various rat brain regions have been reported to contain stereospecific, high affinity binding sites for [3H]rolipram. These binding sites display a linear Scatchard plot and apparently consist of several types characterized by very rapid, moderately fast or very slow dissociation of the radioligand (Schneider *et al., Eur. J. Pharmacol.* 127: 105, 1986). In the present study, we confirmed the presence of high affinity binding sites for [3H]rolipram in mouse and rat brain preparations and detected these binding sites in several regions of marmoset brain. In addition, we found that the IPDE of rat cerebral cortex (Craig, *Biochim. Biophys. Acta* 797: 354, 1984) contains high affinity binding sites for [3H]rolipram. Another selective IPDE inhibitor, nitraquazone (TVX 2706; Glaser and Traber, *Agents Action* 15: 341, 1984), was found also to inhibit [3H]rolipram binding. High affinity binding to similar mouse brain preparations and IPDE was found for [3H]nitraquazone, which appears to label the same binding sites as [3H]rolipram. A 2-min association of mouse cortical membranes with either radioligand resulted in binding that was only slowly dissociated by 10 μM rolipram (22 hr).

Since rolipram is a potent inhibitor of IPDE, it was of interest to ascertain if inhibition of IPDE activity correlated with inhibition of binding to rolipram binding sites. For this purpose, we compared the effects of selected PDE inhibitors on hydrolysis of cyclic AMP by rat cortical IPDE and [3H]rolipram (and [3H]nitraquazone) binding to membranes of mouse cerebral cortex. The rank order of inhibitory potency (IC_{50} in nM) on [3H]rolipram or [3H]nitraquazone binding did not parallel the rank order of inhibitory potency on IPDE (IC_{50} in μM) (Table). These results suggest that inhibition of IPDE may be independent of binding to rolipram binding sites.

Compound	IPDE IC_{50} μM	[3H]Rolipram IC_{50} nM	[3H]Nitraquazone IC_{50} nM
Rolipram	0.49	2.6	4.5
(-)Rolipram	0.59	1.6	2.6
GYKI 13380	0.87	15	36
Nitraquazone	1.9	15	18
(+)Rolipram	2.2	5.0	15
Papaverine	4.3	>10000(42%)	>10000(25%)
Proquazone	4.4	7200	10000
Ro 20-1724	6.0	23	50
ICI 63197	6.8	69	160
IBMX	27	780	1500

250.20 **REGIONAL VARIATION OF CYCLIC NUCLEOTIDE PHOSPHODIESTERASE ISOENZYMES IN DISCRETE BRAIN NUCLEI.** R. L. Garrett, Jr*, W. J. Thompson* and S. J. Strada, University of South Alabama, Department of Pharmacology, College of Medicine, Mobile, AL 36688, and R. S. Duman, E. J. Nestler, and J. F. Tallman, Yale University, Department of Psychiatry, New Haven, CT 06508.

Previous studies have shown considerable variations in cyclic AMP and cyclic GMP phosphodiesterase (PDE) hydrolytic activities among different brain regions (Soc. Neurosci. 4: 386, 1974). To further extend these observations, we analyzed the activities of three distinct types of (PDE) isoenzymes in homogenates of eight brain regions, including five distinct nuclei. These areas included cerebellum (CB), dorsal raphé (DR), hippocampus (HC), locus coeruleus (LC), neocortex (NC), neostriatum (NS), substantia nigra (SN), and ventral tegmentum (VT). Discrete nuclei were excised as 1mm punches from coronal brain sections prepared from 150 g, male, Sprague-Dawley rats. Samples were homogenized with buffer conditions designed to minimize proteolysis (Adv. Cyclic Nucleotide Res. 10: 69-92, 1979).

SN showed the highest Type I cGMP hydrolytic activity (specific activity; 82 nmol/min/mg), measured at 25μM cGMP, and Type IV (high affinity) cAMP PDE activity (8.5 nmol/min/mg), assayed at 0.25μM substrate. These activities were 10-20 fold higher in SN than those measured in either DR or LC. The ratio of cGMP to cAMP hydrolytic activity (G/A ratio) was highest in HP and NC and lowest in SN and NS. Type II (cGMP stimulated) PDE activity, assayed at 5μM cAMP in the absence and presence of 2μM cGMP, showed the greatest cGMP stimulation of cAMP hydrolysis in VT and HP (3.3-3.6 fold), and the least in SN and CB (1.4 fold). Consistent with earlier results, the CB contained the lowest specific activities for each form of PDE. The variations in PDE isoenzyme profiles may have important implications with respect to functional differences in cyclic nucleotide mechanisms among discrete brain nuclei. These studies were supported by a grant from the USPHS (GM 33538) and a contract from the United States Air Force (49620-85-K-0014).

BIOGENIC AMINES: TOXINS

251.1 HISTOCHEMICAL LOCALIZATION OF MPTP OXIDATION BY MAO-B IN SEROTONIN AND HISTAMINE NEURONS IN THE MOUSE BRAIN. S.R. Vincent, Division of Neurological Sciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

Conversion of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to 1-methyl-4-phenylpyridinium (MPP+) appears to be a necessary step for the neurotoxic actions of this drug on the nigrostriatal dopamine system. This conversion is mediated by monoamine oxidase (MAO) of the B type. In the present study, MPTP has been used as a substrate for the histochemical localization of MAO activity in the brain of C57 black mice. The localization of MPTP oxidation by MAO in the brain was compared with the distribution of various monoaminergic neurons determined using immunohistochemistry.

Adult male C57 black mice were anesthetized and perfused with buffered aldehyde fixative. MAO activity was demonstrated on 50 μm thick vibratome sections by incubating the sections in 50 mM Tris-Cl buffer (pH 8.5) containing 0.9% MPTP hydrochloride, 0.1% horseradish peroxidase, 0.005% diaminobenzidine, 0.6% nickel ammonium sulfate and 0.9% sodium azide. Sections incubated without MPTP showed no positive reaction. For the immunohistochemical localization of catecholamine neurons sections were incubated with antisera against tyrosine hydroxylase, dopamine-B-hydroxylase and phenylethanolamine-N-methyltransferase. Serotonin and histamine neurons were localized with antibodies to serotonin and histidine decarboxylase.

The distributions of monoamine cell groups observed in the mouse brain were similar to those found in the rat. Tyrosine hydroxylase immunohistochemistry demonstrated that the major dopaminergic cell group in the mouse was in the substantia nigra pars compacta and adjacent ventral tegmental area. These dopamine neurons did not display MAO activity when MPTP was employed as a substrate. Instead, MAO activity capable of oxidizing MPTP was found in other discrete groups of neurons. These included the serotonin and noradrenaline neurons of the brainstem, and the histamine neurons of the caudal hypothalamus. Preincubation of sections with the MAO-A inhibitor clorgyline blocked the MAO staining in noradrenergic neurons, but not in the serotonin or histamine neurons. The activity in these cell groups was inhibitied by the MAO-B inhibitor deprenyl.

These results indicate that MPTP can be converted to the Parkinsonism-inducing toxin MPP+ by MAO-B in serotonin and histamine neurons which innervate the striatum and substantia nigra.

Supported by the British Columbia Health Care Research Foundation.

251.2 **MPTP EFFECTS ARE REGIONALLY SPECIFIC IN MICE - A NEUROCHEMICAL STUDY.** M. Gupta, S.Y. Felten, and D.L. Felten, Department of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

MPTP causes degeneration of the nigrostriatal dopamine system in humans, non-human primates, and rodents. Although degeneration of the nigrostriatal dopaminergic neurons is the most prominent abnormality in human Parkinsonism, additional monoamine cell groups also are known to be affected by this disease. We previously have shown that MPTP treatment in young adult mice also leads to decreased dopamine levels in the nucleus accumbens and olfactory tubercle(dopamine terminal projection sites from neurons of the ventral tegmental area) in a dose-dependent manner, in addition to decreased dopamine levels in the caudate-putamen (Gupta et.al., in: MPTP-A neurotoxin producing a Parkinsonian syndrome, eds. Markey et.al., 1985). In the present study, we investigated whether MPTP treatment in mice produces changes in other monoamines in addition to its already established changes in dopamine levels. Young adult male Swiss-Webster mice were injected intraperitoneally with 3, 30, or 60mg MPTP/kg body weight. Control animals received vehicle injections. Treated and control animals were sacrificed by decapitation 21 days following the last injection. Brains were removed quickly and samples from various regions of the brain, both nuclei and terminal sites, were microdissected, placed in 100mM perchloric acid, frozen and stored in liquid nitrogen. Levels of monoamines were determined using high performance liquid chromatography with electrochemical detection. MPTP treatment increases norepinephrine (NE) levels in the ventral tegmental area and decreases NE levels in substantia nigra, whereas no changes were seen in locus coeruleus, mediobasal hypothalamus, dorsal raphe, medullary raphe, and nucleus tractus solitarius. Furthermore, serotonin levels appeared to be decreased in substantia nigra in a dose-dependent manner, but remained unaltered in dorsal raphe, medullary raphe, mediobasal hypothalamus, and nucleus tractus solitarius. We conclude that MPTP affects only specific monoaminergic regions of the brain while leaving other regions unaltered.

Supported by USPHS grants RO1 AG06060, RO3 MH41435, and R23 NS24291.

251.3 GABA-TRANSAMINASE INHIBITOR PROTECTS AGAINST METHYLENEDIOXY-METHAMPHETAMINE (MDMA)-INDUCED NEUROTOXICITY. D.M. Stone*, G.R. Hanson and J.W. Gibb (SPON: W. Stevens). Dept. of Pharmacol. and Toxicol., University of Utah, Salt Lake City, UT 84112.

The ring-substituted amphetamine analog, 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy"), has been previously implicated as a selective serotonergic neurotoxin in rats, due to its ability to induce immediate (1 h) and prolonged (2 weeks after a single 10 mg/kg dose, unpublished observations) decreases in both the central concentrations of 5-hydroxytryptamine (5HT) and 5-hydroxyindoleacetic acid (5HIAA), and the central activity of the serotonin biosynthetic enzyme, tryptophan hydroxylase (TPH). While the mechanism(s) underlying these toxic changes has not been determined, prolonged effects have been assumed to result from drug-induced damage to serotonergic axon terminals. We have previously attempted to characterize the neurochemical mechanisms of MDMA toxicity by examining the effects on MDMA-induced serotonergic changes of a variety of centrally-acting agents which preferentially influence specific neurotransmitter systems. Because inhibitors of GABA-transaminase, the major enzyme catalyzing GABA degradation, prevent the toxic effects of multiple doses of methamphetamine (Hotchkiss and Gibb, *J. Pharmacol. Exp. Ther.* 214: 257, 1980), the ability of such an agent to prevent the toxic effects of MDMA was examined. In male Sprague-Dawley rats, a single injection of amino-oxyacetic acid (AOAA; 30 mg/kg, i.p.), a GABA-transaminase inhibitor which causes a marked elevation of brain GABA concentrations (Walters et al., *J. Neurochem.* 30: 759, 1978), 30 min prior to MDMA (15 mg/kg, s.c.) significantly attenuated the immediate decrease in neostriatal and hippocampal TPH activity which normally occurs 1 h after MDMA administration (neostriatal TPH was decreased to only 77% of control vs. 63% of control after MDMA alone; $p < 0.005$). Similarly, at the time when maximal serotonergic effects of acute MDMA are normally observed (6 h post-injection), neostriatal TPH activity, while significantly reduced from control, was decreased to only 69% of control, vs. 32% of control after MDMA alone ($p < 0.02$). Finally, the prolonged "toxic" effects of acute MDMA were completely prevented by prior AOAA administration: 1 week after MDMA no residual serotonergic effects remained in AOAA pretreated animals, whereas those rats treated with MDMA alone exhibited significant decreases in both TPH activity and 5-hydroxyindole concentrations. Administration of AOAA (30 mg/kg; 3 doses, 1 every 6 h) beginning 2 h after MDMA did not prevent the toxic MDMA-induced serotonergic changes (those effects persisting 1 week after treatment). These results suggest that increased levels of GABA in the brain may protect central serotonin axons from MDMA-induced damage. While the mechanism of this protective effect remains unknown, the ability of both methamphetamine and MDMA to cause central dopamine release, and the possible involvement of dopamine in the neurotoxic effects of these compounds (Schmidt et al., *J. Pharmacol. Exp. Ther.* 233: 539, 1985; Stone et al., *Neurosci. Abstracts* 12: 608, 1986) suggest a role for central dopamine-GABA interactions in the serotonergic effects of MDMA. (Supported by USPHS grants DA 00869 and DA 04222).

251.4 MECHANISTIC STUDIES ON THE ACUTE DEPLETION OF RAT BRAIN SEROTONIN BY 3,4-METHYLENEDIOXYMETHAMPHETAMINE. C.J. Schmidt* and V.L. Taylor* (SPON: F.P. MILLER). Merrell Dow Research Institute, Cincinnati, OH 45215.

A single injection of the psychedelic amphetamine analogue, methylenedioxymethamphetamine (MDMA), produced a rapid decline in both striatal and cortical concentrations of 5-HT and in the activity of the rate-limiting enzyme for 5-HT synthesis, tryptophan hydroxylase (TPH). In the cortex, 5-hydroxyindoleacetic acid (5-HIAA) concentrations first increased 30 min following MDMA treatment and then declined in parallel with 5-HT. In the same experiment the fall in 5-HT concentrations and TPH activity first reached statistical significance at 60 min indicating transmitter release preceded the loss of enzyme activity and transmitter depletion. Both stereoisomers of MDMA were found to produce a similar loss of TPH activity at 3 hr indicating no stereochemical requirement for this effect of the drug. Blocking N-demethylation of MDMA to methylenedioxyamphetamine by coadministration of piperonyl butoxide had no effect on the loss of TPH activity. Kinetic analysis 3 hr after drug-treatment revealed that MDMA administration caused a 50 percent reduction in the V_{max} of cortical TPH with no significant change in the enzyme's K_m for either tryptophan or the semisynthetic cofactor, $6MPH_4$. Incubation of cortical P2 synaptosomes for 2 hr with 100 µM MDMA had no consistent effect on TPH activity, although synaptosomal levels of both 5-HT and 5-HIAA declined. Similarly, TPH activity was not altered in striatal slices superfused with concentrations of MDMA up to 250 µM for 2 hr. Intracerebroventricular MDMA (400 µg) failed to alter either cortical or hippocampal TPH activity at 3 hr nor were striatal monoamine concentrations affected. Direct stereotactic injections of 300 µg of MDMA into the dorsal raphe area or substantia nigra of metophane anesthetized rats failed to alter cortical or striatal 5-HT concentrations, although striatal concentration of dopamine and its metabolites were elevated after intranigral MDMA. The results suggest that the acute effects of MDMA on serotonergic neurons are the consequence of a relatively complex mechanism possibly requiring MDMA metabolism in vivo.

251.5 ACUTE ADMINISTRATION OF MDMA (ECSTASY): NEUROCHEMICAL CHANGES PERSIST UP TO 120 DAYS IN RAT BRAIN. S.F. ALI, A.C. SCALLET, R.R. HOLSON, G.D. NEWPORT AND W. SLIKKER, JR. Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, Arkansas 72079.

MDMA (methylenedioxymethamphetamine) is a hallucinogenic stimulant and has been used by some health professionals in the field of psychotherapy and by the general public as a recreational drug. Several investigators have reported that acute sc administration of MDMA reduced serotonin (5-HT) and 5-hydroxyindole acetic acid (5-HIAA) content for up to 7 days. Recently we have also shown that in male rats, orally administered MDMA (40 and 80 mg/kg) reduced 5-HT and 5-HIAA concentration in different regions of the brain for up to 4 weeks. The present study was designed to determine if MDMA produced the same kind of effects in the female and the duration of effect. Adult female Sprague Dawley rats were dosed by gavage with either 40 mg/kg of MDMA or saline vehicle once every 12 hr for 4 days. These animals were sacrificed 120 days after the last dose of MDMA. Brains were dissected into different regions including the caudate nucleus, frontal cortex, hippocampus, hypothalamus, amygdala nucleus, cerebellum and brain stem and frozen on dry ice. An HPLC/electrochemical system was used to determine tissue concentration of dopamine (DA), dihydroxyphenyl acetic acid (DOPAC), 5-HT and 5-HIAA. During the dosing and up to 2 weeks after the last dose, we noted fighting behavior in MDMA treated rats. In the frontal cortex, we found a significant ($p < 0.05$) reduction of 5-HT and 5-HIAA. In the hippocampus, significant reductions were observed in 5-HT concentration and 5-HIAA showed the same trend. Other regions did not show any significant changes, although the 5-HT and 5-HIAA reduction pattern was observed. DA and DOPAC did not show any significant changes in any brain region studies. These data suggest that multiple oral doses of MDMA produced significant changes in serotonin metabolism in several regions of the brain for up to 4 weeks (Slikker et al., 1986) and that these changes persist in frontal cortex and hippocampus for up to 120 days.

251.6 NEUROHISTOLOGICAL EFFECTS 120 DAYS AFTER ORAL ECSTASY (MDMA): MULTIPLE ANTIGEN IMMUNOHISTOCHEMISTRY AND SILVER DEGENERATION STAINING. A.C. Scallet, S.F. Ali, R.R. Holson, G.W. Lipe, and W. Slikker, Jr. Division of Reproductive and Developmental Toxicology, NCTR, Jefferson, AR 72079.

MDMA (methylenedioxymethamphetamine) is a hallucinogenic stimulant that has been used by the general public as a recreational drug and by some health professionals as an adjunct to psychotherapy. Several laboratories have described the same pattern of acute MDMA neurochemical effects in rats: rapid and large reductions in serotonin content of terminal regions with smaller decreases in the cell-body-rich brainstem. It is important to determine if these effects are irreversible and whether they are accompanied by neurohistological alterations. Ali et al., (this meeting) reports that serotonin content remains lowered 120 days after 8 doses of 40 mg/kg MDMA over 4 days, primarily in hippocampus. Nerve terminal damage to the caudate nucleus has been shown by silver-degeneration (Fink-Heimer) procedures for the related stimulant MDA (methylenedioxyamphetamine, Ricaurte et al., Science 229:986, 1985). We have applied these procedures together with immunohistochemical labeling of serotonin (5-HT), tyrosine hydroxylase (TH), and dopamine B-hydroxylase (DBH) to determine if similar neuropathology can be identified in MDMA-treated rats and if alterations are detectable long after dosing. Acute treatment with single doses of either 40 or 80 mg/kg doubled the density of silver-impregnated (degenerating) terminals in the caudate nucleus compared to vehicle controls when rats were sacrificed 17 hours after treatment. Eight repeated doses of 80 mg/kg produced a smaller (67%) increase in caudate silver-impregnated terminals when rats were sacrificed 14 days after the initial dose, perhaps because of removal of some of the damaged terminals by repair processes during this time. Additional rats sacrificed 120 days after an 8-dose regimen of 40 mg/kg were pre-treated with tryptophan to enhance serotonin immunohistochemical staining. Despite a normal-appearing population of 5-HT labelled dorsal raphe cell bodies and no change in their numerical density compared to controls, these rats demonstrated a 43% reduction in the density of 5-HT fibers in the stratum lacunosum region of the hippocampus. Lesser changes were evident in other regions or with staining for TH or DBH. These results suggest that some aspects of MDMA neurotoxicity are irreversible at least up to 120 days post-treatment and that there may be regional differences in recovery with the major residual effect on serotonin terminals of the hippocampus.

251.7 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) SUPPRESSES SEROTONERGIC DORSAL RAPHE NEURONAL ACTIVITY IN FREELY MOVING CATS AND IN MIDBRAIN SLICES IN VITRO. T.J. Trulson and M.E. Trulson. Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX 77843.

The synthetic amphetamine analog, 3,4-methylene-dioxymethamphetamine (MDMA) has attracted a great deal of attention recently due to its widespread abuse. This substituted phenylethylamine is structurally related to a large variety of other synthetic and naturally occurring compounds including amphetamine, mescaline, and DOM. Although a close structural analog of certain hallucinogenic drugs, MDMA is neither a true hallucinogen nor a potent stimulant. Rather, MDMA produces a unique state of enhanced emotional and sensory awareness. Since previous studies have shown that certain substituted phenylethylamines have potent actions on serotonin (5HT)-containing neurons, we investigated the effects of MDMA on the activity of 5HT-containing dorsal raphe (RD) neurons in freely moving cats and in midbrain slices in vitro. Cats were implanted for macro- and micro-electrodes as previously described (Brain Res. 163, 1979, 135). After recovery from surgery the cats were placed in recording chambers and allowed to adapt to the novel setting. They then received i.p. doses of dl-MDMA (0.25 - 5.0 mg/kg) and unit activity which was monitored for several hours. MDMA produced a dose-dependent decrease in RD unit activity from approximately 10% at the lowest dose tested to a nearly total inhibition of unit activity at the highest dose ($P<0.01$, ANOVA). An additional group of cats was pretreated with P-chlorolphenylalanine (PCPA), 150 mg/kg/day for 3 consecutive days) and then administered a high dose of MDMA (5 mg/kg). Pretreatment with PCPA greatly attenuated the suppressant action of MDMA on RD neurons. In order to ascertain whether the effects of MDMA on RD neurons are mediated by a local effect on RD cells or due to an indirect action, we examined the effects of MDMA on the activity of 5HT-containing RD neurons recorded from mouse brain slices in vitro. Brain slices were prepared using a standard procedure as previously described (Brain Res. Bull., 18, 1987, 179). MDMA was administered to the incubation bath using a nonpulsating exchange pump. MDMA produced a dose-dependent decrease in the activity of 5HT-containing RD neurons recorded in vitro. An additional group of mice was pretreated with PCPA (400 mg/kg/day for 3 consecutive days) prior to recording. The suppressant effects of the MDMA on RD unit activity was greatly attenuated by prior depletion of 5HT with PCPA. The effects of MDMA on RD neurons appear to be due to the release of 5HT onto autoreceptors since the suppression of unit activity is blocked by depletion of 5HT with PCPA. Thus, the effects of MDMA on the central 5HT system seem to be very similar to those of P-chloroamphetamine.

251.8 (±)METHYLENEDIOXYMETHAMPHETAMINE (MDMA) EXERTS TOXIC EFFECTS ON CENTRAL SEROTONERGIC NEURONS IN PRIMATES. G.A. Ricaurte*, L.S. Forno, M.A. Wilson*, L.E. DeLanney, I. Irwin, M.E. Molliver and J.W. Langston (SPON: J. Hotson) Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305; Dept. of Pathology, Veterans Adm. Med. Ctr., Palo Alto, CA 94304; Depts. of Neuroscience and Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; Inst. for Med. Res., San Jose, CA 95128.

MDMA is a popular recreational drug that has been proposed as a useful adjunct to psychotherapy. Recent reports indicate that MDMA is toxic to central serotonergic nerve terminals in rats. Since studies in rodents do not necessarily predict the toxicity of a drug in primates, this study was undertaken to evaluate the toxic potential of MDMA on serotonergic neurons in the brain of non-human primates.

Eleven squirrel monkeys (Saimiri sciureus) and six cynomolgus monkeys (Macaca fascicularis) were used. MDMA was administered subcutaneously twice daily at approximately 0800 and 1700 hours for 4 days. The following doses were tested: 2.5, 3.75 and 5 mg/kg. Two weeks later, monkeys were killed under deep ether anesthesia and the brain was removed for combined chemical and anatomical analysis.

MDMA produced a selective, long-lasting, dose-related depletion of serotonin and 5-hydroxyindoleacetic acid (5HIAA) in all of the brain regions analyzed (cerebral cortex, caudate nucleus, hippocampus and hypothalamus). The most severely affected area was the cerebral cortex where serotonin was reduced by 90%. Since long-term depletions of serotonin and 5HIAA appear to be reliable predictors of serotonergic nerve fiber degeneration, these results suggest that MDMA damages serotonergic fibers in the primate brain. This was confirmed morphologically by means of immunohistochemical studies which showed that MDMA produced a marked reduction in the number and density of serotonin-immunoreactive axons throughout the cerebral cortex.

The effect of MDMA on serotonergic cell bodies was also examined. MDMA produced no obvious cell loss in either the dorsal or median raphe nuclei. However, in the dorsal raphe nucleus striking cytological changes were found. Numerous shrunken nerve cells were observed which contained brownish-red spherical cytoplasmic inclusions. These inclusions often displaced the nucleus to the periphery of the cell. Whether these changes reflect direct damage to cell bodies or reaction to extensive axonal injury remains to be determined. The eventual fate of these cell bodies needs to be ascertained.

The present results indicate that central serotonergic neurons in non-human primates are very sensitive to the toxic effect of MDMA. Given the increasingly widespread use of MDMA, these findings may have important public health implications.

251.9 A COMPARISON OF THE EFFECTS OF REPEATED DOSES OF MDMA ("ESCTACY") ON BIOGENIC AMINE LEVELS IN ADULT AND NEONATE RATS. D. J. Mokler, S.E. Robinson and J.A. Rosecrans Dept. of Pharmacol. and Toxicol., Va. Commonwealth Univ., Richmond, VA 23298

(±)MDMA was administered to adult rats as a single 40 mg/kg injection or 40 mg/kg (s.c.) every other day for 4 injections. Sixteen days after the last injection rats were killed rapidly and brain area biogenic amine and metabolite levels determined using HPLC techniques. MDMA produced significant depletions of 5-HT and its metabolite, 5-HIAA, in the hippocampus (Hp) and frontal cortex (FC). 5-HT was depleted to 30% of control values in the Hp following single doses. 5-HT levels were unaffected by MDMA in the hypothalamous suggesting a differential effect on 5-HT containing neurons. DA levels were significantly increased in the hypothalamous while frontal cortex NE levels were decreased to 73% of control values following 4 doses of MDMA. These data suggest that MDMA is neurotoxic to 5-HT neurons in the rat.

In a separate study neonate rats were administered MDMA in doses 10,20 and 40 mg/kg (s.c.) on days 4,6,8 and 10. An analysis of biogenic amine turnover (metabolite/-amine ratios) indicated that DA turnover was significantly increased 18 days after the last 4 doses of either 10 or 20 mg/ks (+18-27%), while 40 mg/kg of MDMA, induced a decrease in turnover. A similar increase in 5-HT turnover was observed at lower doses (10 and 20 mg/kg); 5-HT levels were also reduced by at least 25% in all MDMA treated rats. In addition there appeared to a dose-dependent decline in 5-HIAA levels suggestive of an MDMA-neurotoxic effect similar to that observed in the adult.

EFFECTS OF MDMA ON DOPAC AND 5-HIAA LEVELS

DOSE	DOPAC (ng/g)	5-HIAA (ng/g)
0	70.6	499
10	85.6 (+21%)	399 (-21%)
20	85.5 (+21%)	361 (-28%)
40	58.9 (-17%)	324 (-36%)

(D.M.J. was supported a NRSA Fellowship; 1F32DA 05260-01A1)

251.10 THE EFFECT OF MDA AND MDMA ("ECSTACY") ISOMERS IN COMBINATION WITH PIRENPERONE ON OPERANT RESPONDING IN MICE J. A. Rosecrans and R.A. Glennon*, Depts. of Pharmacol. and Toxicol. and Med. Chem., Va. Commonwealth Univ., Richmond, VA 23298.

The optical isomers of MDA and MDMA were evaluated as to their ability to disrupt operant behavior (FR-20) in the mouse. All agonists were administered (i.p.) 15 min prior to behavioral testing; animals received daily injections of saline except on test days which were conducted every 3rd day. Results were expressed as % of vehicle rates of operant responding; vehicle response rates from the day prior to the test session served as control. These compounds as well as S(+)-amphetamine (AMPH) and DOM disrupted behavior in a dose-related manner. ED-50 values indicated the order of potency amongst isomers to be as follows: S(+)-MDA >R(-)MDA>S-(+)MDMA>R(-)MDMA. AMPH was several times more potent than these isomers and disrupted behavior at <1 mg/kg. The preadministration (PRE) of the 5-HT-2 receptor antagonist, pirenperone (PIR), significantly antagonized DOM responding (0.1 mg/kg, s.c. 60 min. prior to 3 mg/kg DOM) supporting previous data obtained in rat drug discrimination studies. In the present studies, pirenperone was observed to antagonize only R(-)-MDA in the mouse operant. The results of this study are in accord with other research conducted in these laboratories. That is, the 5-HT-2 antagonist, PIR, is able to antagonize the effects of R(-)-MDA at a dose comparable to that which blocks the disruptive effects of DOM. On the other hand, this dose of PIR was unable to antagonize the effects of S(+)-MDA or of either optical isomer of MDMA. Apparently, the disruption of behavior produced by the isomers of MDA is via a different mechanism. In addition, the disruptive effects produced by the R(-)-isomer of MDMA appear to be via a mechanism that differs from that implicated for R(-)-MDA (i.e., a 5-HT-2 mechanism).

% DISRUPTION OF OPERANT BEHAVIOR IN PRESENCE OF PIR

APPROX. ED-50 DOSE	(MG/KG)	SALINE PRE	PIR PRE
DOM	3.0	38.6	90.8*
(+)MDA	2.5	53.2	58.2
(-)MDA	3.0	53.0	82.1*
(+)MDMA	3.1	57.9	57.8
(-)MDMA	11.2	48.0	49.5

251.11 NEUROTOXICITY OF METABOLITES OF MDA AND MDMA (ECSTASY) IN THE RAT. S. Y. Yeh* and Fu-Lian Hsu* (SPON: N. Khazan). Neuropharm. Lab., Addiction Res. Ctr., NIDA, Baltimore, MD 21224 and Chem. Res. Devel. & Eng. Ctr., U. S. Army, Aberdeen Proving Ground, MD 21010-5423.

3,4-Methylenedioxyamphetamine (MDA) and 3,4-methylenedioxymethamphetamine (MDMA) destroyed 5-HT axon terminals, and decreased 5-HT and 5-HIAA content in the frontal cortex, hippocampus and hypothamus when administered s.c. to rats (O'Hearn, E. et al.; Yeh, S.Y. et al., Soc. Neurosci. Abstr., 12:1233, 1234). In another study, MDA and MDMA, however, did not destroy 5-HT axon terminals when administered intracerebrally (Molliver, M.E. et al., Soc. Neurosci. Abstr., 12:1234). It was postulated that the neurotoxicity of MDA and MDMA may be due to their metabolites. Alpha-methyldopamine and 4-hydroxy-3-methoxyamphetamine have been identified as metabolites of MDA in the urine of dogs and monkeys. MDA has been found in the urine of human subjects who received MDMA. We postulated that, through beta-hydroxylation of alpha-methyldopamine, alpha-methylnorepinephrine and alpha-methylepinephrine may be metabolites of MDA and MDMA, respectively. Our studies were designed to compare the effects of MDA, MDMA and their metabolites on the motor activity and regional concentration of various brain monoamines and their metabolites.

We either synthesized metabolites of MDA and MDMA or obtained them from Sterling-Winthrop and Merck Sharp & Dohme. Male Sprague-Dawley rats were injected s.c. with either saline (2 ml/kg), or MDA, 4-hydroxy-3-methoxy-amphetamine, alpha-dopamine, alpha-methylnorepinephrine, MDMA, and alpha-methylepinephrine (10 mg/kg) twice daily for five consecutive doses. Motor activity was measured after the first dose. The rats were killed 24 hr following the last injection. Brain concentrations of monoamines and their metabolites were measured using HPLC-EC.

MDA and MDMA dramatically decreased the 5-HT and 5-HIAA levels in the frontal cortex, while the metabolites of MDA and MDMA showed only mild effects. MDA, MDMA, 4-hydroxy-3-methoxy-amphetamine, alpha-methyldopamine and alpha-methylepinephrine decreased 5-HT (85%, 57%, 35%, 16% and 0% of control, respectively) and 5-HIAA contents (78%, 55%, 5%, 7%, and 0%), and generally increased NE levels (48%, -49%, 42% 76% and 7%), respectively. Total horizontal activity induced by MDA, MDMA, 4-hydroxy-3-methoxy-amphetamine, alpha-methyldopamine, alpha-methylnorepinephrine, alpha-methylepinephrine and saline were 16823, 26614, 2335, 2520, 3042 and 1217 counts, respectively. After 3 and 4 doses of alpha-methylnorepinephrine, 3 and 4 out of five rats died, respectively. It was concluded that the neurotoxicity of the metabolites of MDA and MDMA administered s.c. was less than that of the parent compound.

251.12 **PSYCHOTROPIC AMPHETAMINES HAVE DIFFERENT SITES OF ACTION AT SEROTONERGIC (5-HT) SYNAPSES: A COMPARISON OF p-CHLOROAMPHETAMINE (PCA) AND 3,4-METHYLENEDIOXYAMPHETAMINE (MDA) WITH 2,5-DIMETHOXY-4-METHYLAMPHETAMINE (DOM).** U. Berger*, G. Hung*, M.E. Molliver and R. Grzanna. Dept. of Neuroscience, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

Several of the psychotropic amphetamines that are widely used drugs of abuse have been shown to act at central 5-HT synapses and to cause degeneration of 5-HT axons. In an attempt to characterize the relationship between drug action and neurotoxicity, we studied the acute effects of the amphetamine derivatives PCA, MDA and DOM on central 5-HT axon terminals using immunocytochemistry (ICC) and neurochemical assays.

Rats (12/group) received a single i.p. injection of PCA (10mg/kg), MDA (20 mg/kg), fluoxetine (9 mg/kg), MDA (20mg/kg) plus fluoxetine (9mg/kg), DOM (2 mg/kg or 23.5 mg/kg), or saline (controls). Animals were sacrificed 4 hours later. For morphologic analysis, rats were perfused and brain sections processed for 5-HT ICC. For assays of 5-HT and 5-hydroxyindoleacetic acid (5-HIAA), tissue blocks from frontal and parietal cortex, hippocampus and striatum were assayed by HPLC with electrochemical detection. ICC revealed a dramatic reduction in the number of 5-HT-containing axons in cortex, hippocampus and striatum 4 hours after administration of PCA and MDA. Assays of transmitter levels confirmed the marked depletion (>70%) of 5-HT and 5-HIAA in each of these brain regions. The 5-HT uptake inhibitor fluoxetine has no effect on 5-HT staining or concentration when given alone; depletion of 5-HT is prevented when fluoxetine is administered along with PCA and MDA. In rats treated with DOM, there is no reduction in staining of 5-HT axons and no effect on 5-HT and 5-HIAA levels in frontal cortex and hippocampus; DOM produced only a slight decrease of 5-HT markers in parietal cortex and striatum. No degeneration is seen after DOM at long survivals.

The drug induced decrease in transmitter levels and in staining of axons reflects profound depletion of 5-HT in axon terminals. The rapidity and magnitude of this depletion indicate that PCA (as previously shown) and MDA cause marked release of 5-HT from forebrain axon terminals. Those drugs which cause release also produce degeneration of axons. We suggest that psychotropic amphetamines may be divided into two classes with different sites of action: one type (DOM) acts postsynaptically at 5-HT_2 receptors (Glennon & Titeler, Life Sci. '84), while the other (PCA & MDA) acts presynaptically to release 5-HT from axon terminals. Since PCA and MDA but not DOM produce degeneration of 5-HT axons in long-term experiments, the ability of psychotropic amphetamines to cause massive release of 5-HT appears to be related to the potential neurotoxicity of these compounds. [Support: USPHS #MH41977 and NS15199]

251.13 **ADMINISTRATION OF p-CHLOROAMPHETAMINE (PCA) IN NEWBORN RAT: SELECTIVE ABLATION OF FINE SEROTONERGIC AXONS IN NEOCORTEX.** M.E. Blue and M.E. Molliver. Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

Recent studies in adult rats have shown that the substituted amphetamines, MDA, MDMA and PCA are neurotoxic to serotonergic (5-HT) axons in forebrain. Fine fibers with small, pleomorphic varicosities are selectively vulnerable to the effects of these neurotoxins, whereas coarse, beaded fibers are resistant. Previous studies report that, unlike the effects observed in the adult, PCA does not reduce brain levels of serotonin when administered to neonates. The aim of the present study was to characterize the neurotoxic effects upon 5-HT axons after administration of PCA to newborn rats.

Neonatal rats were given two injections of PCA (10 mg/kg) or saline at postnatal days 3-4 and sacrificed at either one week or one month after treatment. Forebrain sections were processed for serotonin immunocytochemistry. One week after neonatal PCA treatment, the density of 5-HT axons in dorsal neocortex is markedly reduced, with partial recovery seen at one month. Within neocortex, fine 5-HT axons are selectively diminished by the neurotoxic effects of PCA, whereas the density and the distribution of coarse, beaded fibers does not differ from controls. While neocortex is severely denervated, the density of 5-HT axons remains essentially unchanged in striatum and hippocampus, where both fiber types are spared.

The present results demonstrate that PCA is highly neurotoxic to one class of cortical 5-HT axon terminals when administered to neonates. Fine 5-HT axons are selectively ablated by PCA treatment, as reported in adult rats; beaded axons are spared at all ages. While there is evidence for partial reinnervation of neocortex at one month, the initial loss of fine fibers does not induce compensatory sprouting of coarse axons. There are striking regional differences in neurotoxicity after neonatal administration of PCA, which differ from those seen after adult PCA treatment. The effect of PCA on fine 5-HT axons is restricted to neocortex in the newborn. Fine 5-HT axons in striatum and hippocampus survive neonatal administration of PCA, in contrast to the adult rat where PCA denervates these regions of fine axons. These results suggest that the neurotoxicity of PCA is more regionally selective in the neonate. The observed regional differences in neurotoxicity may explain why earlier studies did not detect reduced brain levels of serotonin after neonatal PCA treatment. The sparing of fine 5-HT axons in hippocampus and striatum following neonatal PCA administration indicates that there are age-related differences in the vulnerability of 5-HT axons to PCA. The mechanisms for these age-dependent changes in neurotoxicity are not known. [Support: USPHS grant HD-19920].

251.14 **THE PSYCHOTROPIC DRUG 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) DESTROYS SEROTONERGIC AXONS IN PRIMATE FOREBRAIN: REGIONAL AND LAMINAR DIFFERENCES IN VULNERABILITY.** M.A. Wilson, G.A. Ricaurte, and M.E. Molliver. Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205, and Dept. of Neurology, Stanford Univ. School of Medicine, Stanford, CA 94305.

MDMA is a psychotropic drug that is widely used for recreational purposes by humans. Biochemical and anatomic evidence indicates that MDMA selectively ablates serotonergic (5HT) terminals in the rat brain. The present study was undertaken to characterize the neurotoxicity of MDMA in the primate. Adult macaque monkeys received MDMA (5 mg/kg, s.c.) every 12 hrs. for 4 days. Two weeks after completion of drug treatment, treated monkeys or untreated controls were sacrificed, and the morphology and distribution of 5HT fibers were examined, utilizing 5HT immunocytochemistry.

MDMA produces a striking loss of 5HT terminals throughout the cerebral cortex of monkeys. The degree of denervation is greater than that observed in rats, although the dose of MDMA utilized in this study is lower than that used in rats. Characteristic regional differences are found in the magnitude of denervation produced by MDMA. With some exceptions, the distribution of spared 5HT axons in the primate is similar to that in the rat. Relatively few 5HT fibers survive in frontal and parietal cortex, whereas there is consistent sparing of some of the fibers in other regions, such as striate cortex, the hippocampus, dentate gyrus and amygdala. There are also differences in the laminar distribution of spared fibers among different areas of neocortex. In most neocortical areas, spared fibers are found predominantly in layer I and outer layer II, with scattered fibers in deeper layers. A different pattern is found in striate cortex, where spared fibers are found predominantly in layers IVC alpha and VA; very few fibers are spared in layers I and II. Although the morphology of 5HT terminals in the primate is somewhat more heterogeneous than in the rat, MDMA appears to ablate preferentially the fine 5HT fibers in the monkey, as in the rat (O'Hearn et al., NS Abs 12:1233). In all areas examined, there was sparing of fibers having large spherical varicosities, and loss of fibers having small pleomorphic varicosities. The distribution of spared fibers observed in MDMA-treated animals corresponds to the distribution of fibers having large round varicosities in control animals. These results lead us to propose that in the primate, as in the rat, there are two separate, functionally distinct 5-HT projections which differ in regional distribution, axon morphology, and vulnerability to psychotropic drugs. Moreover, the results indicate the need for caution in the use of MDMA in humans. [Support: USPHS grant #NS-21011 and the Markey Fund]

251.15 **DUAL SEROTONERGIC PROJECTIONS TO FOREBRAIN IN THE RAT: TWO CLASSES OF AXON TERMINALS EXHIBIT DIFFERENTIAL VULNERABILITY TO THE PSYCHOTROPIC DRUGS p-CHLOROAMPHETAMINE (PCA) AND 3,4-METHYLENEDIOXYAMPHETAMINE (MDA).** C. Mullen*, L.A. Mamounas, E. O'Hearn and M.E. Molliver. Department of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Serotonergic (5-HT) neurons in the midbrain raphe nuclei form heterogeneous axon terminals that arborize throughout the forebrain. Two distinct types of 5-HT axons are found in cerebral cortex: (i) **fine axons** with small, pleomorphic varicosities and (ii) **beaded fibers** with large, spherical varicosities. The psychotropic amphetamine derivatives MDA and MDMA have been shown to cause degeneration of 5-HT axons in cerebral cortex and appear to ablate preferentially the fine 5-HT fibers (O'Hearn et al., NS Abs 12:1233,'86). Since PCA is also reported to damage 5-HT axons, the goal of the present study was to compare the neurotoxicity of PCA and MDA and to establish whether these drugs selectively ablate particular types of 5-HT axons. Adult rats were given multiple injections of PCA (10 mg/kg), MDA (20 mg/kg), or saline, sacrificed 1-14 days later and brain sections prepared for serotonin immunocytochemistry. Both drugs produce a marked reduction in the density of 5-HT axon terminals in forebrain, most severe in cerebral cortex, striatum and thalamus. At all survival times, fine 5-HT terminals are almost completely ablated; nearly all spared 5-HT terminals are of the beaded type with large spherical varicosities. These spared, varicose axons are concentrated in restricted forebrain locations: in the subhilar region of the dentate gyrus, the molecular layer of CA1, olfactory glomeruli, lateral entorhinal area (layer III), posterior cingulate (layer II), parietal and occipital cortex (layers I-III) and the ventricular plexus. The beaded 5-HT axons have the same regional distribution and density in control animals as in animals treated with MDA or PCA. Since both drugs cause the same neurotoxic effects, they are likely to have a common mechanism and site of action. In conclusion, this study distinguishes two classes of 5-HT axons in the rat forebrain based on selective vulnerability to neurotoxic drugs; fine axons are highly sensitive to PCA and MDA while beaded axons are resistant to these drugs. Since other studies show that the neurotoxicity of PCA and MDA depends on binding to the 5-HT uptake carrier, we suggest that there may be different subtypes of 5-HT uptake receptors that are associated with the two axon types. The results lead us to propose that there are two separate, functionally different 5-HT projections which differ in axon morphology, regional distribution, and response to psychotropic drugs. Moreover, we report elsewhere in this volume that the two 5-HT projections arise from different sets of cells located in separate raphe nuclei. [Support: USPHS grants #NS-15199, NS-21011 and MH-09538.]

251.16 **DUAL SEROTONERGIC PROJECTIONS TO FOREBRAIN HAVE SEPARATE ORIGINS IN THE DORSAL AND MEDIAN RAPHE NUCLEI: RETROGRADE TRANSPORT AFTER SELECTIVE AXONAL ABLATION BY p-CHLOROAMPHETAMINE (PCA).** L.A. Mamounas and M.E. Molliver. Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

The serotonergic (5-HT) innervation of cortex arises primarily from the dorsal (DR) and median raphe (MR) nuclei of the midbrain. A recent anterograde transport study suggests that axons arising from the DR are structurally different from MR axons: DR axons are fine with small, fusiform varicosities (fine fibers); MR axons are coarse with large, spherical varicosities (beaded fibers). In addition, the substituted amphetamines MDA, MDMA and PCA have been shown to cause selective degeneration of fine 5-HT axon terminals in cortex, while sparing beaded fibers. The goal of the present study was to determine whether or not the drug-resistant (i.e., beaded) fibers in cortex have a different origin in the raphe from the drug-sensitive (i.e., fine) fibers. Assuming that only intact axons are capable of taking up and transporting an injected label, we employed retrograde axonal transport to compare the distributions of cortically-projecting raphe neurons in PCA-treated vs. control animals.

The following experimental paradigm was used: 1) adult rats were administered two i.p. injections (24 hr. apart) of either PCA (6 mg/kg; n=4) or saline (n=4); 2) after one week, the fluorescent dye Fluoro-gold (FG; 2% in 200 nL NS) was microinjected into parietal cortex; 3) one week later, the rats were sacrificed. In midbrain sections, the locations of retrogradely labeled raphe neurons were quantitatively mapped; ablation of cortical 5-HT axons was verified by immunocytochemistry.

In parietal cortex of PCA-treated rats, there was a marked loss of fine 5-HT axons with complete sparing of beaded axons, when compared to controls. FG injection sites were confined to the parietal cortex in all cases. In control animals, both DR and MR nuclei contain numerous retrogradely labeled neurons (cell ratio DR:MR, 1.2:1). After PCA treatment, the number of retrogradely labeled neurons in the DR nuclei was markedly reduced (80% decrease), when compared to controls. However, there was no decrease in the number of labeled neurons in the MR nuclei (PCA-treated rats; DR:MR, 0.26:1).

These results demonstrate that the DR projection to cortex is selectively vulnerable to the neurotoxic effects of PCA, whereas the MR projection is resistant. Also, fine and beaded 5-HT axon terminals in cortex arise from different sets of cells located in separate raphe nuclei (DR and MR, respectively). Therefore, we propose that there are two anatomically and functionally separate 5-HT projections to cortex having different 1) nuclei of origin, 2) axon morphology, 3) regional distributions and 4) pharmacological properties. [Support: USPHS #NS-15199, MH-09538]

251.17 **SEROTONERGIC (5-HT) PROJECTIONS FROM DORSAL RAPHE, RAPHE OBSCURUS, AND RAPHE PALLIDUS TO THE MOTOR NUCLEUS OF THE TRIGEMINAL NERVE: DIFFERENTIAL VULNERABILITY OF THEIR AXON TERMINALS TO p-CHLOROAMPHETAMINE (PCA).** J.-M. Fritschy*, W.E. Lyons*, M.E. Molliver and R. Grzanna (SPON: B.E. Kosofsky). Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

We have demonstrated a dual innervation of the forebrain by two classes of 5-HT axons which differ in their vulnerability to neurotoxic amphetamines (O'Hearn et al., NS Abs. 12:1233) and have separate origins in the dorsal and median raphe nuclei (cf. Mamounas and Molliver, this volume). The present study was conducted to determine whether two classes of 5-HT axons in the brainstem can be differentiated by their vulnerability to PCA. The motor nucleus of the trigeminal nerve (MoV) was chosen for this analysis since it receives a dense 5-HT input. This input is of functional significance since 5-HT release induced by PCA has been shown to have a powerful influence on the excitability of motoneurons.

Retrograde transport of rhodamine (Rh) labeled latex beads was combined with 5-HT immunohistochemistry to identify 5-HT neurons that project to MoV. Control rats were compared to rats which received two i.p. injections of 10 mg/kg of PCA 24 hours apart two weeks prior to microinjections of the fluorescent tracer. After 7 days, brainstem sections were processed for 5-HT immunohistochemistry and analyzed in a fluorescence microscope. Rh labeled 5-HT cells were observed bilaterally in three raphe nuclei. In control rats, approximately 100 Rh labeled 5-HT cells were found in the dorsal raphe nucleus (DR); 400 Rh labeled 5-HT neurons were observed in the nucleus raphe obscurus and raphe pallidus. Following treatment with PCA, there was an 80% decrease in the number of 5-HT cells in the DR that were retrogradely labeled from MoV. In contrast, the number of labeled 5-HT cells in the raphe obscurus and raphe pallidus was not different from that determined in control rats.

This study demonstrates that three separate raphe nuclei give rise to the 5-HT innervation of MoV. Our study provides evidence for two pharmacologically distinct classes of 5-HT axons in brainstem as has been shown in the forebrain. Axons originating from the DR but not those originating from cells of the raphe obscurus and raphe pallidus are vulnerable to the neurotoxic action of PCA. In a separate study (cf. Berger et al., this volume) we show that the neurotoxicity of PCA is closely linked to release of serotonin from 5-HT axon terminals. The present data may explain clinical reports that, in humans, jaw clenching consistently follows ingestion of psychotropic amphetamines (e.g., MDMA). This behavioral symptom may result from massive release of 5-HT from DR axon terminals leading to enhanced excitability of motoneurons in MoV. [Support: USPHS grants NS-15199 and MH 41977].

252.1 DIFFERENTIAL EFFECTS OF N-n-PROPYLNORAPOMORPHINE (NPA) ISOMERS ON NIGRAL AND VENTRAL TEGMENTAL DOPAMINE NEURONS. R.F. Cox*, J.L. Neumeyer and B.L. Waszczak. Northeastern Univ., Boston, MA 02115

R-(-)-NPA is a potent agonist on substantia nigra (SN) and ventral tegmental area (VTA) dopamine (DA) neurons. Recent reports suggest that the S-(+)-isomer exhibits limbic-selective antagonist actions in behavioral studies (Psychopharmacol. 88: 158, 1986) and agonist activity at DA receptors in vitro (Mol. Pharmacol. 25: 18, 1984). Since the electrophysiological effects of S-(+)-NPA have not been studied, extracellular single unit recording studies were carried out to determine if NPA isomers display regional selectivity in altering firing rates of SN and VTA DA neurons.

R-(-)-apomorphine (APO), R-(-)-NPA, and S-(+)-NPA, all from single synthetic lots, were administered intravenously in logarithmically increasing doses at 1 min intervals to chloral hydrate anesthetized male Sprague-Dawley rats. Mean doses (in ug/kg) to inhibit firing rates by 50% (ID50) were:

	SN			VTA*	
	APO	R(-)NPA	S(+)NPA	R(-)NPA	S(+)NPA
ID_{50}	5.3 ±1.3	0.53 ±0.07 ^{a}	514.4 ±106.6 ^{a,b}	0.50 ±0.08 ^{a}	149.6 ±30.2 ^{a,b,c}
n	10	10	9	11	8
potency ratio	1	10	0.01	10.6	0.04

a =p<.01 vs. APO; *b*=p<.01 vs. R(-)NPA; *c*=p<.01 vs. S(+)NPA in SN

* 1 cell insensitive to R-(-)-NPA and 3 cells insensitive to S-(+)-NPA not included.

Haloperidol (HAL; 0.2 mg/kg) readily reversed inhibitions due to APO and R-(-)-NPA in both cell groups. However, HAL (0.2-0.8 mg/kg) fully reversed S-(+)-NPA-induced inhibitions for only 2 of 6 VTA cells tested; for the other 4 cells, only partial reversals were attained with doses up to 1.6 mg/kg HAL. Tests for a possible antagonist action of S-(+)-NPA revealed that doses to 0.9 mg/kg failed to reverse inhibitions due to R-(-)-NPA, although subsequent i.v. HAL fully reversed these inhibitions. A prior 40 ug/kg dose of S-(+)-NPA may, however, shift to the right the dose-response curve for R-(-)-NPA in the VTA (ID50=1.06 ug/kg ± 0.47, n=3, 0.05<p<0.1), or render more cells insensitive to R-(-)-NPA (n=3).

These results confirm that R-(-)-NPA is a potent agonist, whereas S-(+)-NPA is a weak agonist, with some antagonist potential, on midbrain DA cells. Further, S-(+)-NPA shows regional selectivity in that VTA DA cells are inhibited by lower doses than SN DA cells. While a reported 0.1% enantiomeric impurity with R-(-)-NPA would account for the inhibition of DA neurons with S-(+)-NPA, it would not explain its selective effects on VTA cells, the impaired ability of HAL to reverse these effects, nor its possible antagonist actions. Supported by NIH NS 23451.

252.2 DIFFERENTIAL EFFECTS OF DOPAMINE AGONISTS AND ANTAGONISTS ON THE SPONTANEOUS ELECTRICAL ACTIVITY OF A9 AND A10 DOPAMINE NEURONS. A.M. Kabzinski*, M.R. Szewczak*, M.L. Cornfeldt* and S. Fielding (SPON: F. Huger). Dept. of Biological Research, Hoechst-Roussel Pharmaceuticals, Inc., Somerville, NJ 08876.

Dopamine (DA) receptors have been subdivided into D-1 and D-2 on the basis of biochemical and pharmacological studies (Kebabian and Calne, 1979). D-1 receptors are associated with the adenylate cyclase enzyme and can be labeled with (3H)-thioxanthene ligands. D-2 receptors, not linked to a cyclic AMP system, bind (3H)-butyrophenones with high affinity, whereas D-1 receptors do not. Single cell sampling techniques were used to examine the in vivo effects of DA D-1 and D-2 receptor agonists and antagonists on the activity of rat A9 (substantia nigra, zona compacta, SNC) and A10 (ventral tegmental area, VTA) spontaneously firing DA neurons.

Both D-2 antagonists, haloperidol and sulpiride, acutely increased the number of spontaneously active DA neurons in both the A9 and A10 regions as compared to controls. Chronic administration of haloperidol and sulpiride markedly reduced the number of firing DA cells below control levels in both areas. In contrast, acute treatment with the D-2 agonists, LY-171555, RU-24213 and pergolide, decreased the number of DA neurons below control levels in the SNC and VTA while repeated administration increased the number of DA neurons above controls in both areas. The DA D-1 antagonist, SCH-23390, as well as the DA D-1 agonist, SKF-38393, appeared to have no effect, after both acute and chronic administration, on the number of spontaneously firing DA neurons in the SNC and VTA. These results provide evidence that D-2 receptors, but not D-1 receptors, are involved in the control of neuronal activity of DA cells in the A9 and A10 areas.

252.3 **DEPRESSION OF DOPAMINE NEURON FIRING RATES BY THE SELECTIVE DOPAMINE AUTORECEPTOR AGONISTS, (-)3-PPP and (-)HW-165.** W.E.Hoffmann* and M.F.Piercey (G.Vogelsang, Spon.), CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Two hydroxyphenyl-piperidines, (-)3-PPP ((-)-3-(3-hydroxyphenyl)-N-n-propylpiperidine HCL, Hjorth et al., Psychopharmacology 81:89, 1983) and (-)HW-165 (trans-(4aS,-10bS)-(-)-7-hydroxy-1,2,3,4,4a5,6,10b-octahydrobenzo(f)quinoline HBr, Hjorth et al., Arch. Pharm. 333:205, 1986), each thought to be selective agonists at the dopamine (DA) autoreceptor, were electrophysiologically evaluated for their effects on firing rates of DA neurons. Male Sprague-Dawley rats were anesthetized with chloral hydrate (400 mg/kg i.p.). Extracellular glass microelectrodes were used to record from single DA neurons which were identified by their characteristic long duration (>2.5 msec.), positive-negative or positive-negative-positive action potentials, and slow firing rates (Bunney et al., JPET 185:560, 1973). Final identification required histological verification that the electrodes were located in the areas of DA cell bodies in the substantia nigra pars compacta (SNPC) or ventral tegmental area (VTA). Consistent with their proposed autoreceptor agonist roles, both agents inhibited DA neurons by a haloperidol-sensitive mechanism. However, both agents behaved as partial rather than full DA agonists. In the SNPC, both (-)HW-165 and (-)3-PPP had similar potencies (ED50's were 86 ug/kg for (-)3-PPP vs 180 ug/kg for (-)HW-165) and depressed DA neurons by similar amounts (approximately 70% for (-)3-PPP vs approximately 80 % for (-)HW-165). Although in unanesthetised animals (-)HW-165 is known to inhibit DA synthesis most effectively in mesolimbic/mesocortical regions, we found that, in our anesthetized animals, (-)HW-165 depressed firing rates of mesolimbic/mesocortical DA cells in the VTA no more effectively than it depressed basal ganglia DA cells in the SNPC. It is concluded that the selectivity of these agents for DA autoreceptors as compared to DA postsynaptic receptors is accounted for by a combination of their partial dopaminergic agonist activities and the more sensitive state of DA autoreceptors.

252.4 ELECTROPHYSIOLOGICAL ACTIONS OF CHOLECYSTOKININ AND CR 1409 ON IDENTIFIED RAT DOPAMINERGIC NEURONS. A.S. Freeman and L.A. Chiodo. Laboratory of Neurophysiology, Center for Cell Biology, Sinai Research Institute, Detroit, MI 48235.

The localization of cholecystokinin octapeptide (CCK-8) in midbrain dopaminergic (DA) neuronal cell bodies is extensive in medial A9 and in A10, sites of origin of the mesolimbic DA projection. DA cells in these areas are excited by microiontophoretically applied sulfated CCK-7 and CCK-8. These findings, combined with other data showing pronounced CCK-8 effects in the nucleus accumbens pointed to a selective action of CCK-8 on mesolimbic DA systems. On the other hand, we previously found that i.v. CCK-8 has the ability to excite as well as to modulate the apomorphine (APO) sensitivity of nigrostriatal DA cells identified with the antidromic activation mapping technique. The present study includes an examination of the effects of microiontophoretically applied CCK-8 on identified nigrostriatal DA neurons.

Microiontophoretic electrodes were guided into the lateral two-thirds of A9; the recording sites were marked and histologically identified in order to confirm electrode placements. Application of CCK-8 (9 uM, pH 8.0; 10-50 nA; 1-2 min ejection periods) produced increases of 10-50% in the firing rates of 6/12 nigrostriatal DA cells antidromically activated from the head of the caudate nucleus (8.0+0.5 msec latency; stimulation currents of 0.5-2.5 mA). These results strongly suggest that CCK-8 can directly excite a subpopulation of nigrostriatal DA neurons. Whether or not this sensitive group of DA cells also contains CCK-8 remains to be determined.

CR 1409 (lorglumide, Rotta Res. Lab.) is a potent peripheral CCK receptor antagonist. We have begun to assess the effects of CR 1409 on identified DA neurons. CR 1409 was injected in i.v. doses of 0.005-10 mg/kg while recordings were obtained from nigrostriatal or mesoaccumbens DA cells. Cumulative injections produced no marked changes in firing rate although transient decreases or increases in firing rate were occasionally observed, especially with high bolus doses. In some cases, CR 1409 pretreatment diminished the potency and efficacy of APO to inhibit nigrostriatal DA cell firing rate. Experiments are in progress to assess the ability of CR 1409 to block CCK-induced excitations. (Supported by MH-41557.)

252.5 ALPHA-2 RECEPTOR ANTAGONISTS, BUT NOT GABA, 5-HT, OR OPIATE ANTAGONISTS, AUGMENT RESPONSIVENESS OF LOCUS COERULEUS NEURONS TO STIMULATION. P. E. Simson and J. M. Weiss. Dept. of Psychiatry, Duke University Medical Center, Durham, NC 27710.

Spontaneous activity of locus coeruleus (LC) neurons is inhibited by stimulation of a variety of receptor types. Stimulation of alpha-2 adrenergic receptors (Svensson, T. H., Bunney, B. S. and Aghajanian, G. K., Brain Research, 92:291-306, 1975) and opiate receptors (Korf, J., Bunney, B. S. and Aghajanian, G. K., Eur. J. Pharmacol., 25:165-169, 1974) potently depress the spontaneous activity of LC neurons; additionally, stimulation of GABA (Cedarbaum, J. M. and Aghajanian, G. K., Brain Research, 112:413-419, 1976) and 5-HT receptors (Segal, M., J. Physiolol (London), 286:401-415, 1979) reduce LC firing rates.

The influence of alpha-2 receptors has been the most extensively studied of the inhibitory receptors. Aghajanian initially proposed that alpha-2 receptors produce the period of quiescence (PSI) that follows a burst of firing (Aghajanian, G. K., Cedarbaum, J. M. and Wang, R. Y., Brain Research, 136:570-577, 1977), although more recently Andrade and Aghajanian (J. Neurosci., 4:161-170, 1984) presented evidence that PSI is produced independently of alpha-2 receptors. Recently, we demonstrated that, in addition to whatever role these receptors play in PSI, alpha-2 receptors modulate the responsiveness of LC neurons to stimulation (Simson, P. E. and Weiss, J. M., J. Neurosci, in press). Whether or not this ability to regulate LC responsiveness is unique to alpha-2 receptors, however, has yet to be determined. The studies reported here examined whether blockade of other inhibitory receptors would produce similar alterations in the responsiveness of LC neurons as was produced by alpha-2 blockade.

In contrast with the markedly augmented responsiveness of LC neurons to stimulation following alpha-2 blockade, administration of pharmacological agents to block other receptors that inhibit LC activity did not increase responsiveness of the LC. Responsiveness of LC neurons did not change following administration of the GABA antagonists bicuculline and picrotoxin. Similarly, the 5-HT antagonists cyproheptadine and methysergide failed to augment responsiveness of LC neurons.

The opiate receptor antagonist naloxone also produced no change in responsiveness of LC neurons. In the case of opioid receptors, it could be argued that blockade of these receptors (by naloxone) would not be expected to increase responsiveness unless high levels of agonist were present. To test this, animals were implanted with pumps that released morphine continuously for over one week. Seven days after implantation of the pump, opiate receptor blockade by naloxone markedly increased spontaneous activity of LC neurons but failed to alter LC responsiveness.

These results extend our previous findings that alpha-2 receptors play a major role in regulating the responsiveness of LC neurons to excitational influences, and point to the possibility that alpha-2 receptors are unique in this regard.

252.6 ELECTRICALLY-EVOKED RELEASE OF NOREPINEPHRINE IN THE RAT CEREBELLUM: AN IN VIVO ELECTROCHEMICAL STUDY. K. Pang, P. Bickford-Wimer, G.M. Rose and G.A. Gerhardt, Depts. of Psychiatry and Pharmacology, UCHSC, Denver, CO, 80262 and Medical Research Service, VAMC, Denver, CO 80220.

The noradrenergic projection to the cerebellum originates from the pontine nucleus locus coeruleus (LC), and terminates primarily in the inner portion of the molecular layer and in the granule/Purkinje cell layers. Although this pathway has been well studied anatomically and physiologically, the release of norepinephrine following electrical stimulation of the LC has yet to be demonstrated in vivo. In the present study, we used in vivo electrochemical techniques to measure norepinephrine release following electrical stimulation of the LC.

Male Sprague-Dawley rats were anesthetized with urethane and electrochemical signals were recorded from the cerebellum using Nafion-coated graphite epoxy electrodes. The location of the LC was determined by lowering an electrode in the appropriate region and verifying that recorded neurons had broad action potentials and responded to noxious stimuli (e.g. tail pinch). Once neurons with these characteristics were found, the recording electrode was removed and replaced with a stimulator. Electrochemical electrodes were placed in the cerebellar vermis, ipsilateral to the LC stimulator. The placement of recording and stimulation electrodes was verified post-mortem. Electrochemical measurements were performed using chronoamperometric recording techniques (-0.20 to 0.45 volt pulses) with sampling rates ranging from 0.30-10.0 Hz.

Electrochemical signals from locus coeruleus stimulation (10 Hz, 10 sec, 10-30 volts) were typically less than 300 nanomolar in magnitude and lasted for 20-40 seconds following cessation of the stimulation. Signals were voltage dependent, reproducible after a five minute delay, and observed predominantly in the granule/Purkinje cell layer. Stimulation-evoked signals were not observed in the cerebellar white matter. The temporal characteristics of these signals are in excellent agreement with the electrophysiological effects of locus coeruleus stimulation.

In conclusion, these studies provide evidence for the release of norepinephrine in the cerebellum following electrical stimulation of the locus coeruleus. In addition, the data support the conclusion that in vivo electrochemical methods manifest sufficient sensitivity and temporal capabilities to measure the low levels of norepinephrine released by electrical stimulation.

252.7 **IN OCULO HIPPOCAMPUS/LOCUS COERULEUS CO-TRANSPLANTS: ELECTROPHYSIOLOGICAL EVIDENCE FOR FUNCTIONAL CONNECTIVITY IN VITRO** M. Mynlieff and T.V. Dunwiddie. Dept. Pharmacology, Univ. of Colo. Hlth. Sci. Ctr., Denver, CO 80262 and Denver Vet. Ad. Med. Res. Serv., Denver, CO 80222.

Previous studies have shown the feasibility of co-grafting fetal locus coeruleus (LC) and hippocampal tissue into the anterior eye chamber of adult rats, and recording extracellular activity in oculo (Taylor, et al., Exp. Br. Res., 39: 289, 1980). In the present study, we have investigated such co-transplants and single hippocampal transplants after removal from the eye chamber, and utilized both extracellular and intracellular electrophysiological analyses to assess the connections between the co-transplants.

To prepare co-transplants embryonic LC tissue from Sprague-Dawley rats was transplanted to the anterior eye chamber of sympathetically denervated 6-8 week old rats, followed four weeks later by co-transplantation of fetal hippocampal tissue. After 12-15 months in oculo the co-transplants were dissected from the eye and placed in a standard in vitro recording chamber.

Single hippocampal grafts responded in a characteristic manner to perfusion with medium containing 8.25 mM potassium and 3.3 mM penicillin; repetitive interictal spikes were observed with an average frequency of 0.54 Hz +/- 0.20 (n=5). The frequency of the interictal spikes could be modulated by noradrenergic agonists. In 5 out of 6 transplants tested, isoproterenol (1-10 uM) increased the rate, while in 3 out of 3 transplants norepinephrine (10-40 uM) in the presence of timolol (1 uM) decreased the spiking rate. Thus as we have previously shown in the hippocampal slice preparation, beta-adrenergic receptors increase spiking and alpha-adrenergic receptors reduce such activity. However, in the double transplants, interictal spikes in response to K^+/penicillin perfusion were either completely absent or occurred with a very low frequency (average = 0.08 Hz +/- 0.03, n=6), suggesting that the LC has an inhibitory influence on the hippocampal graft. Furthermore, we have been able to demonstrate that in some of the grafts, local application of GABA via micropressure ejection to LC neurons inhibited the firing of the LC neurons, but caused an increase in the activity of the hippocampus co-graft. In combination with the studies in the single hippocampal transplants, we hypothesize that the LC tonically inhibits the hippocampal co-graft via effects on alpha-adrenergic receptors. In summary, the initial electrophysiological analysis of the co- transplants in vitro indicate that there is a functional connection between the hippocampus and LC in oculo and that the integrity of this connection can be maintained in vitro.

Grant Support: USPHS DA 02702 and VA Medical Research Service.

252.8 FUNCTIONAL COMPARISON OF THE INTRACELLULAR AND EXTRACELLULAR ELECTROPHYSIOLOGICAL CHARACTERISTICS OF DOPAMINE-CONTAINING NEURONS IN VITRO. P.D. Shepard and B.S. Bunney, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Electrophysiological studies utilizing intracellular recording techniques have provided important insights into the neurophysiological characteristics of dopamine (DA) neurons in vivo (c.f. Grace and Bunney, In: Neurotransmitters in the Vertebrate Nervous System, 1986). Although recent work has demonstrated the feasibility of conducting similar studies in vitro, as yet there are no adequate criteria which permit definitive identification of midbrain neurons as dopaminergic. In the present experiments, we have extended our earlier studies on the electrophysiological and pharmacological characteristics of presumed DA-containing neurons (Silva and Bunney, Soc. Neurosci. 12:411.16) to include a comparison of intra- and extracellular recordings from substantia nigra (SN) brain slices. Coronal slices (400 uM) were prepared from a block of tissue containing the SN. Slices were transferred to an air-interface perfusion chamber and continuously superfused (2 ml/min) with oxygenated artificial CSF. Conventional extra- and intracellular recording techniques were employed (Grace and Bunney, Neurosci.10:301, 1983). DA-containing neurons in the SN were tentatively identified by their extracellular electrophysiological and pharmacological characteristics. In agreement with previous in vitro studies (Silva and Bunney, Soc. Neurosci. 11:311.12), SN neurons which were inhibited by DA (10 uM) exhibited long duration (2.7-3.5 ms) action potentials with little variation in interspike interval. Basal firing rates of these putative DA neurons, recorded in slices maintained at 36°C, ranged from 2 to 8 impulses/s. These cells were found to be extremely sensitive to fluctuations in ambient temperature, averaging a change in rate of 1 impulse/sec/degree. In some experiments, it was possible to obtain intracellular and extracellular recordings from a single SN neuron. In agreement with similar studies conducted in vivo, (Grace and Bunney, Neurosci. 10:317, 1983), differentiation of intracellularly recorded action potentials gave rise to a waveform nearly identical to that obtained extracellularly. Spontaneously occurring intracellular action potentials (45-60 mV) were observed to arise from slow 'ramp-shaped' depolarizations and were followed by a prominent after-hyperpolarization (AHP). Brief application of hyperpolarizing current pulses (0.1-0.9 nA; 250 ms duration) resulted in electrotonic potentials characterized by a time-dependent reduction in amplitude, indicative of a slowly-developing inward (anomalous) rectification. Addition of tetraethylammonium to the bathing media significantly attenuated both the AHP and inward rectification. Supported by USPHS grants MH28849, MH25642, MH14276 and the State of CT.

252.9 DETERMINATION OF THE RECEPTOR SUBTYPE MEDIATING DOPAMINE-INDUCED ELECTROPHYSIOLOGICAL RESPONSES IN THE RAT MEDIAL PREFRONTAL CORTEX
S. R. Sesack and B. S. Bunney, Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT

The mesoprefrontal dopamine (DA) system originates within the ventral tegmental area (VTA) and terminates in the deep layers of the medial prefrontal cortex (PFC). Electrophysiological studies have shown that cells within the PFC are inhibited by iontophoretic DA and by stimulation of DA cells in the VTA. Which subtype of DA receptor (D1 or D2) mediates these inhibitory responses? Simultaneous activation of D1 and D2 receptors has been reported to underly DA's effects in some postsynaptic areas (Carlson et al., Br. Res. 400:205, 1987). The purpose of this investigation was, therefore, to examine the responses of PFC neurons to selective D1 or D2 agonists and antagonists in order to determine whether the actions of DA in the PFC are mediated by one or both receptor types. Rats were prepared for extracellular recording by a low cerveau isole transection under temporary halothane anesthesia. Standard microiontophoretic techniques and intravenous administration were used to compare local and systemic drug effects.

Microiontophoretic experiments showed that the D2 selective antagonist, sulpiride, blocked DA-induced inhibition on 83% of cells tested (N=30), whereas the D1 selective blocker, SCH23390, antagonized DA on only 25% of cells (N=12). The results of agonist studies were surprising in that 87% of DA-sensitive neurons were not inhibited by the D2 selective agonist, LY171555 (N=62); 85% did not respond to the D1 selective agonist, SKF38393 (N=46); and co-iontophoresis of LY and SKF did not inhibit any of the cells tested (N=17). The non-selective agonist, pergolide, however, did induce an inhibitory response in 64% of the DA-sensitive neurons tested (N=28). In contrast, preliminary experiments using intravenous drug administration showed that LY171555, in doses as low as 5 ug/kg, produced a profound inhibitory effect on DA-sensitive PFC cells. SKF38393, in doses up to 20 mg/kg, induced only a slight decrease in the activity of DA-sensitive neurons. Furthermore, this dose of SKF did not potentiate the response of PFC cells to subthreshold doses of LY171555.

Contrary to studies in non-cortical postsynaptic areas, experiments in the PFC, involving co-administration of selective agonists, failed to provide evidence for a potentiating interaction between D1 and D2 receptors. Our studies with iontophoretic antagonists and systemic agonists suggest that in the PFC, DA is acting through a receptor with D2 characteristics. However, the predominant lack of response of DA-sensitive neurons to locally applied selective agonists suggests that DA in the PFC may be acting through a receptor which does not conform to the classical definition of either D1 or D2 subtypes.

252.10 **STIMULATION OF THE TEGMENTAL DOPAMINE REGION MODULATES SENSORY RESPONSES OF SINGLE UNITS IN NUCLEUS ACCUMBENS AND STRIATUM.**
Charles H.K. West and Richard P. Michael. Department of Psychiatry, Emory University School of Medicine, and Georgia Mental Health Institute, 1256 Briarcliff Road, Atlanta, GA 30306.

Dopamine in the mesolimbic and nigrostriatal systems is thought to act as a modulator of input to neurons in dopaminergic terminal regions. Behavioral experiments have shown that alterating dopaminergic function can produce changes in sensorimotor integration. Sensory input to the striatum has been shown electrophysiologically, and we recently demonstrated that sensory stimuli evoked responses in neurons in the nucleus accumbens-olfactory tubercle region, a major terminal area of the mesolimbic dopamine system (West, C.H.K. and Michael, R.P., Soc. Neurosci. Abstr., 11: 207, 1985).

In this experiment, we tested if these sensory responses could be altered by electrical stimulation of the ventral tegmentum, within the origin of the mesolimbic and nigrostriatal dopamine systems. Single units (N = 65) were recorded in adult male rats (N = 14), anesthetized with chloral hydrate (400 mg/kg, ip) , during the application of sensory (olfactory and somatosensory) and electrical stimuli. The olfactory stimuli were ammonia, cedar oil, ethanol, acrylic solvent and rat urine, applied by cotton swab placed near the rat's nostrils. The somatosensory stimuli were light touch, tail pressure and foot pinch, tested both ipsilaterally and contralaterally to the side of recording. Electrical stimuli were applied via bipolar electrodes in the ventral tegmentum and consisted of one sec trains of square wave pulses at 100 Hz, 0.2 msec in duration at an intensity of 400-500 μA. Increases or decreases in spontaneous firing rates in response to sensory stimuli were recorded in nucleus accumbens, olfactory tubercle, striatum, preoptic area and diagonal band of Broca. More than half of all units studied were responsive to one or more types of sensory input, with 30% of units responsive to olfactory stimuli and 64% responsive to somatosensory stimuli. Responsive units that remained stable were subsequently tested with electrical stimuli, and many of these units showed a change in sensory responsiveness for a period of 1-5 min after application of a single electrical stimulus train. These changes consisted of enhancement or reduction of a sensory response and were observed in units primarily located in nucleus accumbens and striatum. Both excitatory and inhibitory sensory responses were affected by electrical stimulation, and the direction of the sensory response did not influence the type of modulatory effect obtained. The effect was most frequently observed on responses to somatosensory stimuli, especially when the response was greater on one side than on the other. Usually the response to contralateral rather than ipsilateral stimuli was altered by tegmental stimulation. Preliminary tests indicate that haloperidol (0.3 mg/kg, ip) can block the effect of electrical stimulation. Results suggested that dopamine may modulate neuronal reponses to certain sensory stimuli, which may represent a neurophysiological substrate for controling behavioral reactions directed toward sensory inputs.

252.11 A DOPAMINE MEDIATED IPSP DUE TO AN INCREASE IN POTASSIUM CONDUCTANCE.
P.J. Williams , Q.J.Pittman and B.A. MacVicar. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

Secretion of hormones from the melanotroph of the pituitary pars intermedia (PI) is under direct neural control. An inhibitory dopamine (DA) pathway from the hypothalamus has been suggested and a recent report identified an IPSP in melanotrophs possibly mediated by DA. We are now able to confirm that a hyperpolarization of the melanotroph following stalk stimulation is mediated by a DA-activated K^+ conductance. In the presence of bicuculline (100 μM), to block GABA-ergic IPSPs, stalk stimulation produced a 5-25 mV IPSP with a duration of up to 60 seconds accompanied by a decrease in cell input resistance. These effects of stalk stimulation could be mimicked by pressure-pulse application of DA (1 mM, 25-500 msec pulses, 5-15 psi) from a micropipette adjacent to the recording site. Application of GABA (in the presence of bicuculline) or saline had no effect. Both the DA and stalk stimulation induced IPSPs were abolished by dopamine D-2 antagonists (sulpiride 50 μM, domperidone 2.5 μM). When IPSPs to both stalk stimulation and DA application were obtained in the same cell, the reversal potentials for both responses were identical. We conclude that the stalk stimulation induced IPSP is mediated by DA acting at a D-2 receptor.

The IPSP reversal potential varied with $[K^+]$ from -76 ± 10 mV at 15 mM K^+ to -136 ± 10 mV in 2 mM K^+. A semi-log plot of reversal potential against $[K^+]$ was linear and showed that the reversal potential shifted by 65 mV for a 10 fold change in $[K^+]$. This is very close to the value of 62 mV predicted by the Nernst equation at the temperature of these experiments (35°C). This suggests that the conductance increase during stalk stimulation is due to increased potassium conductance.

Since DA effects on hormone release from PI are mediated by a G-protein induced inhibition of adenylate cyclase we determined the effects of pertussis toxin, a G_i inactivator, on the stalk-stimulation-induced IPSP. Rats were injected with 10 μg of toxin in 15 μL saline into a lateral ventricle. On the 3rd postoperative day recordings were made from the PI as before. In 14 cells from 5 animals GABA mediated responses were obtained to stalk stimulation, while DA mediated IPSPs were absent. Exogenous DA was also without effect. We conclude that stalk stimulation causes a DA mediated IPSP in the melanotroph due to an increase in K^+ conductance. A G-protein is integral to this effect. The melanotroph is a promising system for the investigation of dopaminergic transmission.

252.12 D-1 DOPAMINE RECEPTOR STIMULATION ENABLES FUNCTIONAL RESPONSES TO D-2 DOPAMINE RECEPTOR AGONISTS.
S.R. Wachtel, L.M. Bednarz*, R.J. Brooderson*, S. Hjorth§, and F.J. White, Neuropsychopharmcol. Lab., Univ. of Illinois, Champaign, IL 61820; and §Dept. of Pharmacol., Univ. of Göteborg, S-400 33 Göteborg, Sweden.

Although D-1 and D-2 dopamine (DA) receptors exert opposing effects on many biochemical indices of neuronal function, recent electrophysiological and behavioral evidence indicates that these receptors also exert parallel and synergistic effects. White (EJP, 135, 1987) reported that iontophoretic (IONTO) application of the D-1 agonist SKF 38393 (SKF) enhanced the inhibition of rat nucleus accumbens (NAc) neurons produced by the D-2 agonist quinpirole (QUIN). Furthermore, pretreatment with the tyrosine hydroxylase inhibitor α-methyl-p-tyrosine (AMPT), which produced 85% depletion of DA in the NAc (removing tonic D-1 stimulation by DA), significantly attenuated the inhibition produced by IONTO QUIN. This attenuation was reversed by IONTO SKF, suggesting that D-1 receptor stimulation enabled the response to QUIN.

In support of electrophysiological studies, D-1 receptor activation also enabled stereotyped behavioral responses to D-2 agonists in rats. The s.c. administration of SKF (4-16 mg/kg) enhanced the stereotyped behavior induced by QUIN (0.25-2 mg/kg) to the same level produced by the nonselective D-1/D-2 agonist, apomorphine (0.25-2 mg/kg). In addition, SKF restored sterotyped responses to QUIN which had been abolished by AMPT pretreatment.

In contrast to the ability of DA depletion to attenuate the inhibitory effects of QUIN on NAc neurons, AMPT failed to alter the inhibitory response of IONTO SKF on NAc cells. In addition, D-1 behavioral responses did not require D-2 stimulation since SKF-induced grooming was not abolished by either AMPT or by combined pretreatment with AMPT and reserpine (>95% depletion). In fact, SKF reinstated normal levels of grooming which were eliminated by DA depletion. Thus, it appears that D-1 receptor function is less dependent on activation of D-2 receptors.

Finally, we studied the D-2 somatodendritic impulse-regulating autoreceptor on DA neurons in the ventral tegmental area (VTA) to determine if it might also be "enabled" by D-1 receptor stimulation. In contrast to D-2 receptors in the NAc, the VTA autoreceptor did not require stimulation of D-1 receptors to express its effects. The ability of QUIN to inhibit A10 DA cells was not altered by i.v. or IONTO administration of either SKF or the D-1 antagonist SCH 23390 (i.v.), or by pretreatment with AMPT.

In conclusion, whereas D-1 receptor-mediated responses did not appear to require simultaneous stimulation of D-2 receptors, both electrophysiological and behavioral experiments indicate that functional responses of the postsynaptic D-2 receptor, but not the D-2 DA autoreceptor, require concurrent activation of D-1 receptors. (Supported by USPHS grants DA-04093 and MH-40832)

252.13 CHARACTERIZATION OF THE EFFECTS OF PUTATIVE AUTORECEPTOR-SELECTIVE DOPAMINE AGONISTS IN THE MESOACCUMBENS DOPAMINE SYSTEM. P.A. Johansen and F.J. White. Neuropsychopharmacol. Lab., Univ. of Illinois, Champaign, IL 61820.

Previous studies have shown that dopamine (DA) autoreceptors are of the D-2 subtype and are 3-10 times more responsive to DA agonists than postsynaptic D-2 receptors. Moreover, several compounds which appear to be autoreceptor-selective DA agonists (ASDAs) have been identified. Unlike classical DA agonists, ASDAs decrease locomotion in normal rats. Electrophysiological studies in the nigrostriatal DA system support an autoreceptor selective profile for several putative ASDAs. Because hyperactivity of the mesoaccumbens DA system may be involved in schizophrenia, ASDAs might have therapeutic value. Therefore, the present study determined the effects of several putative ASDAs in the mesoaccumbens DA system using extracellular single-unit recording.

The putative ASDAs (-)3-PPP, BHT 920, and (-)HW 165, and the classical DA agonist (+)3-PPP, were studied on mesoaccumbens (A10) DA neurons and their target cells within the nucleus accumbens (NAc) of chloral hydrate anesthetized rats. These drugs inhibited the firing of A10 DA cells with ID50 values of 3, 144, 640, and 790 µg/kg for BHT 920, (+)3-PPP, (-)HW 165 and (-)3-PPP, respectively. (-)HW 165 and (-)3-PPP were partial agonists since the highest dose (2.56 mg/kg) caused only partial inhibition (≈ 60%).

BHT 920 and (-)3-PPP increased NAc cell firing after i.v. injection presumably due to disinhibition resulting from autoreceptor stimulation. However, when administered by iontophoresis (IONTO), BHT 920 and (-)3-PPP caused current-dependent inhibition of NAc cells, suggesting an agonist action at postsynaptic D-2 receptors and questioning the notion of autoreceptor selectivity. Since D-1 stimulation enables postsynaptic D-2 effects in the NAc, it is possible that the lack of postsynaptic D-2 behavioral and electrophysiological effects following i.v. administration of (-)3-PPP and BHT 920 is due to the fact that ASDAs require D-1 receptor enabling to elicit postsynaptic effects. Presumably such enabling would be lost because stimulation of the more sensitive D-2 autoreceptors decreases impulse-dependent release of DA which would normally provide the necessary D-1 receptor "tone".

Preliminary IONTO and behavioral experiments appear to support this idea. Concurrent IONTO of the D-1 agonist SKF 38393 with BHT 920 or (-)3-PPP onto NAc neurons potentiated their inhibitory effects. Following i.v. BHT 920, IONTO BHT 920-induced inhibition was attenuated, but was reinstated by SKF 38393; the latter effect was reversed by the D-1 antagonist SCH 23390. Behaviorally, s.c. administration of SKF 38393 (4 mg/kg) with either (-)3-PPP (4 mg/kg) or BHT 920 (0.1 mg/kg) reversed the typical sedative response to these ASDAs, resulting in enhanced locomotion. (Supported by USPHS Research Grants MH-40832 and DA-04093)

252.14 REPEATED ADMINISTRATION OF APOMORPHINE AT LOW DOSES: EFFECTS ON THE SENSITIVITY OF SOMATODENDRITIC AUTORECEPTORS ON A10 DOPAMINE NEURONS. M.C. Jeziorski and F.J. White. Neuropsychopharmacol. Lab., Univ. Illinois, Champaign, IL 61820.

Despite clinical trials testing the ability of low doses of dopamine (DA) agonists to reverse symptoms of schizophrenia, the physiological effects of repeated administration of "autoreceptor-selective" doses are not well understood. Rebec and Lee (Brain Res., 250:188, 1982) reported that nigral (A9) DA cells in rats treated with 50 µg/kg s.c. apomorphine (APO) twice daily for 5 days exhibited excitatory or decreased inhibitory responses when challenged with i.v. APO. Because the mesoaccumbens DA system is thought to be involved in the pathophysiology of schizophrenia, the present experiments investigated the effects of repeated treatment with low doses of APO on the sensitivity of impulse-regulating somatodendritic autoreceptors on A10 DA cells in the ventral tegmental area (VTA) of chloral-hydrate anesthetized rats.

Extracellular single-unit recording techniques revealed that pretreatment with twice daily s.c. injections of 50 µg/kg APO for 7 days failed to alter the sensitivity of A10 neurons to i.v. injections of the D-2 DA agonist quinpirole (QUIN) (ID_{50} = 11.2 µg/kg) relative to control (ID_{50} = 9.8 µg/kg). However, A10 DA cells in identically treated rats exhibited reduced inhibitory responses to iontophoretically applied DA. These apparently conflicting effects could be the result of compensatory super-sensitivity of postsynaptic receptors on nucleus accumbens (NAc) neurons in response to the decrease in synaptic DA produced by repeated autoreceptor stimulation. Hypothetically, supersensitive NAc cells projecting back to GABAergic VTA interneurons would be inhibited by agonists at i.v. doses of QUIN that are normally considered autoreceptor-selective. The consequent release of inhibition of VTA interneurons would enable these cells to decrease A10 cell firing and compensate for alterations in autoreceptor sensitivity. According to this model, repeated treatment with higher doses of APO would stimulate both DA autoreceptors and postsynaptic receptors and prevent supersensitivity in feedback cells, thus isolating the subsensitive response of A10 cells to systemic administration of agonists. In fact, QUIN challenge in rats pretreated with 250 µg/kg APO on an identical 7 day schedule significantly ($p < 0.05$) decreased sensitivity in A10 cells (ED_{50} = 17.7). Additional experiments are presently ongoing to determine: 1) if ibotenic acid lesions of the NAc followed by 7 day pretreatment with the low dose APO regimen will result in subsensitivity of DA autoreceptors in response to i.v. QUIN; 2) the effects of repeated doses of other D-2 selective and non-selective DA agonists, including longer acting compounds; and 3) the comparative effects of repeated autoreceptor stimulation on A9 and A10 cells. (Supported by USPHS Grants MH-40832 and DA-04093)

252.15 ELECTROPHYSIOLOGICAL EFFECTS OF REPEATED COCAINE ADMINISTRATION ON THE MESOACCUMBENS DOPAMINE SYSTEM. D.J. Henry, M.A. Greene*, S-Y. Chen* and F.J. White. Univ. of Illinois, Champaign, IL 61820.

Behavioral evidence has demonstrated that the potent rewarding effects of cocaine are mediated, in part, by the mesoaccumbens dopamine (DA) system projecting from A10 DA cells within the ventral tegmental area (VTA) to the nucleus accumbens (NAc). Yet, little is known regarding the physiological alterations occurring within this system following repeated cocaine administration. Previous studies in our laboratory have demonstrated that cocaine exerts inhibitory effects on the activity of mesoaccumbens DA neurons. This effect appears to be due to both DA autoreceptor stimulation and to activation of NAc-VTA feedback pathways which may be engaged because of the preferential inhibition of NAc neurons (Einhorn et al., J. Neurosci, in press). The present experiments were designed to assess possible alterations of these effects following repeated cocaine administration.

Extracellular single-unit recording techniques were used to determine whether repeated cocaine administration might reduce the sensitivity of impulse-regulating A10 DA autoreceptors in chloral hydrate anesthetized rats. Following 14 days of repeated cocaine injections (10 mg/kg either 1 or 2 x/day, i.p.), the inhibitory effects of low i.v. doses of the DA agonist apomorphine (APO) were significantly reduced as compared to control rats. Thus, the ID50 values for APO were 11.05 ± 2.0 µg/kg in the control rats, 17.2 ± 4.53 µg/kg in the 1 x 10 mg/kg/day rats and > 50 µg/kg in the 2 x 10 mg/kg/day rats. Iontophoretic application of DA to A10 DA neurons in rats treated with 2 x 10 mg/kg/day also resulted in significantly less inhibition than that observed in control rats although the degree of subsensitivity was less than that observed with i.v. APO. These results indicate that A10 somatodendritic autoreceptors become subsensitive following repeated cocaine administration but also suggest that other mechanims such as feedback pathway activation may also be reduced in these rats.

Preliminary studies on NAc neurons suggest that the responsiveness of these cells to iontophoretic DA is significantly increased in rats that had received 2 x 10 mg/kg/day of cocaine. Such supersensitivity of postsynaptic DA receptors could be due to reduced occupancy of these receptors during repeated cocaine administration, perhaps as a result of diminished DA levels. However, HPLC-EC analysis revealed normal levels of DA in the NAc of rats that received cocaine at up to 2 x 30 mg/kg/day for 14 days. Therefore, it seems likely that other mechanisms are responsible for the apparent increase in the sensitivity of NAc cells to DA. Whatever the mechanism, the increased sensitivity of NAc DA receptors combined with A10 autoreceptor subsensitivity may help to explain cocaine-induced behavioral sensitization. (Supported by USPHS Research Grants MH-40832 and DA-04093)

252.16 THE EFFECT OF METHYLPHENIDATE ON THE COERULEO-CORTICAL NORADRENERGIC SYSTEM OF THE RAT: AN ELECTROPHYSIOLOGICAL STUDY. D. Lacroix and A. Ferron. Centre de recherche en sciences neurologiques (Dép. de physiologie), Université de Montréal and Dép. de psychiatrie, Hôpital Ste-Justine, Montréal, Canada, H3C 3J7.

Methylphenidate (MPH) is the drug of choice in the treatment of attention deficit disorder with hyperactivity in children. Biochemical studies indicate that MPH promotes the release and blocks the reuptake of noradrenaline (NA). Our previous studies have demonstrated that methylphenidate reduced the spontaneous firing rate of locus coeruleus (LC) neurons and decreased the number of spontaneously firing cortical units inhibited by electrical stimulation of the LC (Lacroix and Ferron, Soc. Neurosci. Abstr. 12: 479, 1986). The present study was undertaken to examine the effects of therapeutic doses of MPH on the responsiveness of cortical neurons to microiontophoretically applied NA and on sensitivity of NA autoreceptors in LC. Three groups of rats were compared: 1) controls; 2) naive rats given a single i.v. dose of MPH (650 µg/kg); 3) rats treated with MPH for 7 days (2 mg/kg, i.p., bid). In group 3, the recordings were made 18 h after the last i.p. injection of MPH. The responsiveness to NA was assessed in the sensori-motor cortex of urethane anaesthetized rats with the IT_{50} method, i.e. by measurement of the current (in nA) X time (in sec) required to obtain a 50% depression of firing rate. The sensitivity of NA autoreceptors in LC was measured by determining the effects of a single dose of i.v. clonidine (4-12 µg/kg) on spontaneous neuronal activity. After a single i.v. dose of MPH in naive rats, there was a reduction in the responsiveness of cortical neurons to NA. In rats treated with MPH for 7 days, responsiveness to NA was nearly twice lower (1286 vs 791) and the effect of i.v. clonidine on LC neuron firing was weaker than in the controls (2-fold decrease). In such MPH-treated animals, the same acute dose of MPH (650 µg/kg), who induced a 50% reduction in the spontaneous firing rate of LC neurons in controls, failed to decrease the activity of LC. These findings suggest that, following MPH treatment, cortical NA neurotransmission is markedly reduced in its efficacy. Such data indicates that the noradrenergic system may have a role in the mode of action of MPH and could explain the therapeutic effects of MPH.

252.17 **NOREPINEPHRINE ALTERS THE PASSIVE MEMBRANE PROPERTIES AND SYNAPTIC RESPONSES OF RAT DORSOLATERAL SEPTAL NEURONS *IN VITRO*.** K. D. Phelan, H. Hasuo*, M. J. Twery, and J. P. Gallagher. Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550

The dorsolateral septum (DLS) receives projections from brainstem noradrenergic neurons and displays a high density of adrenergic binding sites. In the present study, we investigated the effects of norepinephrine (NE) on the passive membrane properties of rat DLS neurons in a submerged *in vitro* slice preparation using intracellular recording techniques. In addition, we examined the effects of NE on synaptic potentials evoked by local stimulation in DLS and in the diagonal band nucleus (DBN).

Application of NE (0.1-10 *u*M) produced concentration dependent membrane hyperpolarizations and decreased input resistance (33 of 38 cells). Superfusion of NE at the highest concentration tested resulted in membrane potential hyperpolarizations of 2-14 mV and input resistance decreases of 15-45% (n=21). The NE induced membrane hyperpolarization reversed around -90 mV indicating an increase in K conductance. No desensitization of these NE effects were observed. Tetrodotoxin had no effect on NE induced hyperpolarizations (n=4). Pretreatment with phentolamine suppressed or completely blocked the effects of NE on the passive membrane properties of these neurons (n=3). The population of NE responsive cells included DLS projection neurons identified by their antidromic activation following DBN stimulation (15 of 20 tested).

Superfusion of NE also altered the synaptic responses of DLS neurons. The late hyperpolarizing potential (LHP) evoked by local DLS (n=33) or DBN (n=2) stimulation was suppressed or completely blocked by NE. This effect was dependent on the concentration and duration of treatment. In addition, NE suppressed or completely blocked the $GABA_A$ mediated fast inhibitory postsynaptic potential (f-IPSP) arising from local stimulation of DLS (n=33) or DBN (n=14). The recovery of the f-IPSP usually occurred along with that of membrane potential and input resistance, whereas the LHP suppression could persist up to 40 minutes. Superfusion of NE also reduced the hyperpolarizing effect of baclofen.

These results demonstrate that NE alters the passive membrane properties of DLS projection neurons at a postsynaptic alpha adrenergic receptor and also depresses inhibitory synaptic potentials. The NE induced depression of the baclofen response suggests that NE is affecting the LHP (which is believed to arise from activation of a bicuculline-resistant, baclofen-sensitive $GABA_B$ receptor) through a postsynaptic site. The present evidence also indicates that NE affects the LHP and f-IPSP through separate membrane processes. These findings support the idea that noradrenergic inputs to DLS modulate intrinsic information transfer in rat septum. (Supported by MH-39163 to JPG).

252.18 **EFFECTS OF PREFRONTAL CORTEX STIMULATION ON LOCUS COERULEUS DISCHARGE.** C. Chiang, M. Ennis, V.A. Pieribone and G. Aston-Jones (SPON: R. Bartus), Dept. Biol., New York University, NY, 10003.

Previous studies report innervation of the locus coeruleus (LC) region from prefrontal cortex (FCx). Recent tracing studies in our laboratory revealed FCx innervation of central gray but no direct input to LC. However, FCx may significantly influence LC discharge through less direct pathways, providing a link between neo and paleo brain substrates of cognitive processes. Here, we assess the influence of FCx activation on LC. Bipolar electrical stimulation of medial FCx in anesthetized rats was presented through 250-um wires, and extracellular recordings were obtained from individual LC neurons with glass micropipettes.

FCx stimulation (1.0 mA, 0.5 Hz) yielded the following: Of 27 LC cells, 10 (37%) exhibited inhibition only, 9 (33.3%) were antidromically activated, and 1 was synaptically activated. Inhibition from FCx stimulation may reflect effects of collaterals from antidromically driven LC cells. To test this hypothesis, similar experiments were performed in rats 7-10 d after 6-hydroxydopamine (6-OHDA) injections to destroy LC forebrain projections. In these 3 rats, 0/16 LC cells were antidromically activated from FCx, and only 2/16 cells (11%) were even weakly inhibited (84 ms mean duration compared to 206 ms in controls). Thus, most if not all the observed inhibition from FCx in intact animals may have resulted from intracoerulear collateral interactions.

Surprisingly, a greater number of LC cells (8/16) were synaptically activated in the 6-OHDA lesioned subjects, with a mean onset of 42 ms and mean duration of 34 ms. It seems possible that the emergence of excited cells in the lesioned rats resulted from removal of antidromically-induced collateral inhibition. This possibility is supported by the finding that the onset latencies for excitation in lesioned animals was very similar to that for inhibition in intact subjects (45 ms).

While it is conceivable that such low-security activation could result from FCx inputs to distal LC dendrites outside LC proper, our results may be more consistent with a polysynaptic pathway: The excitatory responses were relatively long in latency (42 ms) and weak (<32% of the amplitude of LC responses to footpad stimulation). In contrast, FCx stimulation evoked a short latency (5 ms) and large amplitude response (more than twice that seen in LC) in the adjacent lateral dorsal tegmental nucleus. Interestingly, train stimulation of FCx (20Hz for 0.5 s) yielded more potent LC responses (3X those of single pulse tests) in 12/16 cells (mean onset = 128 ms). Additional studies are in progress to better specify the circuit mediating FCx's influence on LC.

252.19 SPIKE FIRING OF SINGLE LOCUS COERULEUS NEURONS DURING EXPERIMENTAL EPILEPTIC SEIZURES IN THE RAT. S. Yamaguchi and M.A. Rogawski, Neuronal Excitability Section, Medical Neurology Branch, NINCDS, NIH, Bethesda, MD 20892.

A wide variety of evidence has implicated central noradrenergic systems in regulating the generation and spread of the epileptic discharge in various animal seizure models. Treatments which deplete brain norepinephrine (NE) decrease the seizure threshold and enhance the intensity and duration of seizures. Conversely, drugs that increase brain NE levels have a protective effect on seizures. Lesion studies have indicated that forebrain NE projections from the locus coeruleus (LC) may be of critical importance in this regard and, in fact, electrical stimulation of the LC in man has been demonstrated to have an antiepileptic effect. Recent biochemical studies have indicated that the activity of tyrosine hydroxylase (TOH), the rate limiting enzyme in NE biosynthesis, is increased in actively spiking areas of human epileptic neocortex [Sherwin et al., *Neurology* 34:927-933, 1984; Nadi et al., *Neurology* 37 (Suppl. 1):106, 1987]. In the present study, we sought to directly determine the firing of LC neurons during seizures. Rats were lightly anesthetized with chloral hydrate, artificially ventilated and paralyzed with gallamine. (Animals were prepared in strict accordance with *NIH Guide for the Care and Use of Laboratory Animals.*) The EEG was continuously monitored with cortical screw electrodes. Viability of the preparation was assessed with EKG and arterial blood gas measurements from a femoral catheter. Glass micropipettes filled with NaCl-pontamine sky blue solution were driven into the LC Single LC units were identified by their slow, regular firing pattern and characteristic response to noxious stimulation consisting of a brief burst of spikes followed by a prolonged pause. Recording sites were verified by postmortem histological examination. Seizures were induced by i.v. administration of pentylenetetrazol (100 mg/kg; PTZ). The firing frequency of LC neurons increased markedly during the period immediately prior to the intense electrographic seizure induced by PTZ. During the seizure, most units were quiescent. After the frank electrographic seizure, intermittent cortical spiking occurred for ~30 min. During this period, some LC neurons demonstrated bursting that coincided temporally with cortical spiking, whereas other neurons remained silent. We speculate that activation of LC neurons prior to the seizure discharge and during the afterdischarge may represent an autoregulatory mechanism, which when removed promotes epileptic activity. Since TOH is induced with increased LC activity, LC bursting as occurred during the afterdischarge may account for the enhanced enzyme activity observed in experimental seizure models and in epileptic human brain. These results are consistent with the concept that LC neurons participate in an intrinsic CNS system that dampens seizure activity.

252.20 RESPONSES OF NEURONS IN THE AVIAN LATERAL GENICULATE TO NOREPINEPHRINE. K.S. ELMSLIE* AND D. H. COHEN. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794 and Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201.

Visually conditioned heart rate change in the pigeon has been developed as a model system for cellular studies of associative learning. In this system the avian equivalent of the dorsal lateral geniculate nucleus (LGNe) transmits effective conditioned stimulus (CS) information, and a class of LGNe neurons shows enhancement of light(CS)-evoked discharge over associative training (J. Neurosci., 6:627). This class consists of cells with increased discharge to the CS and decreased discharge to the unconditioned stimulus (US), foot-shock. The response of these neurons to the US requires an input from locus coeruleus (LC) (Neurosci. Abstr., 8:666) which must be intact for associative modification of the LGNe neurons (Neurosci. Abstr., 11:1109). Since electrical stimulation of LC can substitute for foot-shock as an effective US (Neurosci. Abstr., 9:641), the input from LC is both necessary and sufficient for transmitting US information to LGNe.

In this study neurotransmitter(s) that might mediate the responses of these LGNe neurons to the US were investigated. Norepinephrine (NE) was chosen for initial study, since it is synthesized by LC neurons and NE-containing fibers are found in LGNe. Five-barrel microelectrodes were used to record activity of single cells and to assess their responses to iontophoretic application of various agonists and antagonists.

Responses to NE of 52 LGNe neurons were characterized. Maintained activity was decreased by NE in 29 cells and increased in 11. Two responded sinusoidally, and 10 were unresponsive. Cells whose activity was decreased by NE tend to be situated posteromedially in LGNe, while those excited by NE tend to be located anterolaterally; unresponsive cells were not preferentially distributed. The alpha-agonist phenylephrine was less effective than NE in modifying maintained activity. The beta-agonist isoproterenol was relatively ineffective, and the beta-antagonist sotalol did not block the NE-induced decrease in maintained activity.

These preliminary data suggest that the decreased activity of LGNe neurons in response to application of NE is mediated by an alpha-receptor.

253.1 BEHAVIORAL AND BIOCHEMICAL EFFECTS OF THE BETA ADRENERGIC AGONIST SOM-1122. James M. O'Donnell. Los Alamos National Laboratory, Los Alamos, NM 87545

Experiments were carried out to assess the behavioral and biochemical effects of SOM-1122. SOM-1122 inhibited the binding of ^{125}I-iodopindolol (IPIN) in vivo in cerebral cortex and cerebellum in a dose-dependent manner, indicating that the drug was centrally active following peripheral administration. This made it of interest to study its ability to bind to and activate beta adrenergic receptors in rat brain, since it has been suggested that centrally acting beta adrenergic receptor agonists might represent a new class of antidepressant drugs. SOM-1122 inhibited the binding of IPIN to membranes prepared from rat cerebral cortex (primarily beta$_1$ subtype) and cerebellum (primarily beta$_2$) in vitro in a concentration-dependent manner. As observed with other beta adrenergic agonists, guanosine triphosphate (GTP) regulated the binding of SOM-1122. This effect of GTP was greater in the cerebellum, suggesting that, like the beta agonist clenbuterol, SOM-1122 exerts somewhat greater agonistic activity at the beta$_2$ subtype of the receptor. SOM-1122 increased the level of cyclic AMP in slices of rat cerebral cortex in a concentration-dependent manner; the EC_{50} was 2.2 μM and the maximal stimulation was to 190% of control levels. Propranolol antagonized the ability of 10^{-3} M SOM-1122 to increase the levels of cyclic AMP in slices of rat cerebral cortex in a concentration-dependent manner (apparent K_I = 58 nM), indicating that the ability of SOM-1122 to increase levels of cyclic AMP was due to an interaction of the agonist with beta adrenergic receptors.

Previous work in our lab has shown that other centrally acting beta adrenergic agonists (e.g., clenbuterol and prenalterol) are behaviorally active. Furthermore, the behavioral effects of these compounds resemble those reported for established antidepressant drugs. SOM-1122 reduced the response rate and increased the reinforcement rate of rats responding under a differential-reinforcement-of-low-rate 72-sec (DRL 72-sec) in a dose-dependent manner (ED_{50} = 0.05 mg/kg). SOM-1122 also reduced response rate under both components of a multiple fixed-interval 5-min, fixed-ratio 30-response schedule (ED_{50} = 0.02 mg/kg). Pretreatment with a dose of 1.0 mg/kg propranolol antagonized the effects of 0.1 mg/kg SOM-1122 on behavior maintained under both the DRL and multiple fixed-interval, fixed-ratio schedules.

The results of the present experiments indicate that SOM-1122 is a high-affinity, partial agonist at beta adrenergic receptors. It is centrally active and appears to be somewhat beta$_2$ selective. SOM-1122 is behaviorally active and its effects on behavior are generally similar to those reported previously for other centrally acting beta adrenergic agonists as well as for proven antidepressant drugs. The behavioral effects of SOM-1122 appear to be mediated by beta adrenergic receptors since they are antagonized by propranolol.

253.2 SELECTIVE ALTERATION OF THE BEHAVIORAL EFFECTS OF THE D-1 AGONIST SKF 38393 FOLLOWING THE DESTRUCTION OF 5-HYDROXYTRYPTAMINE NEURONS. R.F. Kucharik* , P.M. McGonigle, M.S. Kreider, I. Lucki (SPON: D.J. Brunswick). Departments of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

In order to characterize the influence of 5-hydroxytryptamine (5-HT) neurons on behaviors caused by the activation of D-1 receptors, grooming behavior and oral dyskinesias induced by the selective D-1 agonist SKF 38393 were studied in rats following the destruction of 5-HT neurons by the neurotoxin 5,7-dihydroxytryptamine (5,7-DHT, 200 ug ICV) . In control rats, SKF 38393 caused a dose-dependent increase in bouts of grooming behavior (ED50=2.8 mg/kg, IP), with a mean peak response of 20.4 ($\pm$ 2.2, 1 SEM) grooming bouts measured 10-60 min. after injection at 10mg/kg. Rats administered 0.9% NaCl showed 4.8 $\pm$ 1.4 grooming bouts during the same period. 5,7-DHT treatment enhanced the increase of grooming behavior by SKF 38393, causing a 60% increase in the peak effect at 10 mg/kg (32.0 $\pm$ 4.9) whereas the ED50 for SKF 38393 was unchanged. Although grooming bouts caused by the D-1 agonist were more frequent in the 5-HT-depleted rats, their average duration was significantly shorter. SKF 38393 also increased oral dyskinesia episodes in control rats, with a peak effect of 17.5 $\pm$ 1.3 at 10 mg/kg. In contrast to grooming behavior, however, the frequency of oral dyskinesias caused by SKF 38393 was unaltered by 5,7-DHT treatment, (peak effect = 18.0 $\pm$ 2.6). Thus, depletion of brain 5-HT content caused a selective enhancement of grooming behavior by the D-1 agonist SKF 38393.

Measurement of telencephalic monoamine content from control and lesioned rats confirmed that 5,7-DHT treatment produced an 87% reduction of 5-HT content without significant change in either norepinephrine or dopamine. The effect of 5,7-DHT treatment was also studied on the density of D-1 and D-2 receptors in various brain regions using quantitative autoradiography. D-1 receptors were measured using the specific binding of the selective D-1 antagonist (3H)-SCH 23390. D-2 receptors were meausured by the specific binding of the selective D-2 antagonist (3H)-spiperone. Dopamine receptors were studied in: 1) the ventral caudate nucleus; 2) dorsal caudate nucleus; 3) nucleus accumbens; 4) olfactory tubercle; and 5) substantia nigra. No significant change in dopamine receptors were measured in any brain region studied. The changes in behavioral effects of the D-1 agonist SKF 38393 caused by the destruction of 5-HT neurons are probably not due simply to an alteration in the number of dopamine receptors.

253.3 YOHIMBINE ACCELERATES RECOVERY AND CLONIDINE AND PRAZOSIN REINSTATE DEFICITS AFTER RECOVERY IN RATS WITH SENSORIMOTOR CORTEX ABLATION. Richard L. Sutton and Dennis M. Feeney. University of New Mexico, Departments of Psychology and Physiology, Albuquerque, NM 87131

D-amphetamine (D-AMPH) accelerates recovery of locomotor (beam-walking) ability after unilateral sensorimotor cortex ablation (Science, 1982, 217: 855-857) and this effect is apparently mediated by norepinephrine (NE; Neurosci. Abst., 1984, 10:68). In the present pharmacological study we investigated the effects of various alpha-NE agonists and antagonists (single i.p. injections) on recovery of beam-walking in this model of rodent hemiplegia.

We first tested for effects of drug administration early (24 h) after injury. Beam-walk tests were conducted at 0.5, 1, 3, 6 and 24 h postdrug and then every other day for 15 days. Although yohimbine (YOH) at doses of 0.5 or 5 mg/kg did not significantly alter recovery, a dose of 10 mg/kg of YOH did significantly accelerate recovery of beam-walking ability as compared to saline controls. This accelerated rate of recovery was indistinquishable from that produced by D-AMPH (2 mg/kg). A common mechanism of these drugs is the release of NE and the results strengthen our hypothesis that increased NE early after injury is beneficial for recovery from motor cortex injury. No significant effects on recovery early after injury occurred after injection of clonidine (CLON; 0.1 or 0.4 mg/kg), phenylephrine (2, 4 or 8 mg/kg), or prazosin (PRAZ; 2 or 4 mg/kg). These findings suggest that studies of beta-NE agonists and antagonists might be of benefit for elucidating the mechanism of NE-mediated recovery.

To investigate the importance of NE in maintaining recovery, brain-injured and sham operated rats were administered CLON (0.1 or 0.4 mg/kg), PRAZ (2 or 4 mg/kg), or YOH (0.5, 5 or 10 mg/kg) after they recovered on the beam-walking task (day 17 after surgery). Tests on the beam were conducted at 0.5, 1, 3, 6, 24 and 48 h after drug treatment. While YOH did not affect locomotor performance, injured but recovered rats given PRAZ or CLON showed a significant, and dose-dependent, worsening of beam-walking ability relative to the effects of these drugs in sham operates. These results suggest that the integrity and functional capacities of the alpha-NE receptors are crucially involved in maintaining recovery in this model of brain injury.

253.4 NITROUS OXIDE ACTIVATES NIGRAL NEURONS IN THE RAT N.Passino 1,V.A.Peduto 3,G.P.Carcangiu 1, V.Boi 1 and G.P.Mereu 2. Depts. of Neurosciences 1 and of Exp. Biology 2.Inst.of Anesthesiology 3, Univ.of Cagliari, Italy.

N_2O is known to produce euphoria and analgesia at low (10-30%) and anesthetic effect at high concentration (50-75%). N_2O is also illegally used for its euphoriant properties.Electrophysiological and biochemical evidences suggest that different drugs of abuse,morphine and ethanol (ETH) among others, activate dopamine (DA) transmission.On the other hand ETH, barbiturates, benzodiazepines and general anesthetics (GAs) have a marked depressant action on the activity of those Pars Reticulata (PR), putative GABAergic, cells wich in turn exert a tonic inhibitory control on DA neurons of the Pars Compacta (A9). To further investigate on this issue we have studied the effect of N_2O in comparison with halothane (HLT) on the spontaneous firing of nigral PR and A9 cells.

Rats were prepared for recording as paralyzed and locally anesthetized subjects. N_2O or HLT (mixed to oxygen) were delivered in the trachea via the respiration pump. In 10 out 12 PR cells tested N_2O (25 to 75%) produced a concentration-related activation of their firing rate up to 100% above baseline.Two cells were inhibited.On the contrary HLT (0.5-3%) inhibited all PR cells tested (N=12) up to 2% of baseline. On A9 neurons (N=14) N_2O produced a stimulation proportional to the gas concentrations,up to 60% of baseline,which was completely eliminated by apomorphine (25 ug/Kg). HLT (0.5-1%) induced a temporary stimulation while higher concentrations (1.5-3%) inhibited A9 cells (N=9).In all experiments the cell activity returned to basal value by removing the gas administration.

The results suggest that the euphoriant effect of N_2O might involve DA activation but not DA receptors blockade. They also indicate that GAs differ in their electrophysiological effect in the CNS. It has been theorized that GAs and ETH fluidize the cellular membranes thereby facilitating the Cl channel opening. In this way the unspecific action of GAs may be transduced in a specific GABA-mimetic effect. Therefore it is likely that the HLT-induced activation of A9 neurons might be secondary to the inhibition of PR cells while the elucidation of the mechanism by which N_2O stimulates both A9 and PR neurons will require further investigations.Supported by Italian MPI grant.

253.5 BRAINSTEM AND HYPOTHALAMIC NOREPINEPHRINE LEVELS FOLLOWING ACUTE AND CHRONIC STRESS IN THE BORDERLINE HYPERTENSIVE RAT (BHR). V.P. Mitchell* and J.E. Lawler. Physiology Program and Department of Psychology, University of Tennessee, Knoxville, TN 37996.

The borderline hypertensive rat (BHR), the F1 cross between SHR and WKY, develops permanent blood pressure increases when exposed chronically to tail-shock stress. The current study sought to determine whether acute or chronic exposure to such stress results in changes in brain norepinephrine (NE) levels. Forty-four male BHR were divided randomly into four experimental (E) groups, and were sacrificed following either 3 days, or 4, 10 or 16 weeks of shock exposure. An additional 44 male BHR served as age-matched controls (C). Following decapitation, brains were sliced (300 um) and sections were identified for bilateral punches of the following nuclei: A1, A2 and locus coeruleus (LC) in the brainstem, and posterior (PH), dorsomedial (DMH), ventromedial (VMH), paraventricular (PVH), anterior (AH) and supraoptic (SO) in the hypothalamus. All samples were assayed for NE using HPLC-EC. Significant ($p < 0.05$) differences between E and C groups are depicted below (Mean±SEM).

NE (pg/ug protein)

Time	Nucleus	BHR (C)	BHR (E)
3 days	A2	20.1±4.6	39.8±2.3
	PH	32.0±5.4	12.5±1.5
	LH	27.3±4.9	15.1±2.1
	SO	23.9±2.2	15.4±1.6
10 weeks	A2	34.5±6.2	63.8±7.4
	A1	10.8±1.1	17.4±2.5
	LC	23.4±5.5	56.0±8.9
16 weeks	VMH	33.0±4.8	50.8±5.3
	PVH	47.0±5.6	77.8±8.8

These data indicate that BHR respond to an acute shock stress with a decrease in hypothalamic and an increase in brainstem NE. Chronic exposure induces a temporary increase in brainstem NE and, ultimately, increases NE in the VMH and PVH, two nuclei thought to be involved in sympathetic outflow. Thus, central catecholaminergic pathways appear to be involved in the chronic response of the BHR to tail-shock stress. (Supported by HL19680 & HL01395)

253.6 LOW DOSE CAFFEINE MODULATION OF CAUDATE DOPAMINE RELEASE AS MEASURED BY IN VIVO ELECTROCHEMISTRY IN THE FREELY MOVING RAT. M.E. Morgan, D. Dunn* and R.E. Vestal*. Clin. Pharmacol. and Gerontology Res. Unit, V.A. Medical Center, Boise, ID 83702, and Dept. Med. Univ. of Washington, School Medicine, Seattle, WA

Caffeine (C) is found in numerous over-the-counter medications and foods. Theophylline (T) is used in the treatment of asthma and chronic obstructive pulmonary disease. Both of these methylxanthines (MX) are central nervous system (CNS) stimulants. Although the MX are antagonists of the action of adenosine in the brain, the precise mechanisms of CNS stimulation are unknown. Adenosine has been shown to inhibit CNS neurotransmitter release. It is not clear, however, if the consequence of adenosine antagonism by the MX is always an increase in neurotransmitter release. We have previously shown that MX-induced caudate dopamine (DA) release is dose dependent. C, 250 and 500 µmole/kg, decreased caudate DA release by 30 and 68%, respectively. In contrast, T, 250 µmole/kg, increased and 500 µmole/kg decreased caudate DA release by 25 and 50%. Since C is more lipid soluble than T, these effects may be due to differences in MX caudate concentrations. Therefore, we examined the effects of a low dose of C on caudate DA release using in vivo electrochemistry in freely moving rats. Male Sprague-Dawley rats (250-350 gm) were anthestized with choral hydrate (150 mg/kg, i.p.) and ketamine (50 mg/kg, i.p.). Stearic acid carbon paste electrodes (250 µ) were implanted into the left caudate. Ag/AgCl reference and auxiliary electrodes were implanted through separate bur holes. The entire apparatus was fixed in place with cranioplastic cement. The animals were allowed a 24 hr recovery period. Electrochemical oxidations were made with a BAS DCV-5 voltammeter with the current output processed by semidifferentiation. After achieving a steady baseline release, animals were injected with C, 75 µmole/kg, i.p. Caudate DA release was monitored for 150 min.

Per Cent Control of Mean (± SEM) Baseline Peak Heights

Time (min)	0	20	40	60	100	150
Dose (µmole/kg)						
75	99±2	123±7*	133±8*	139±11*	116±5	107±5

n= 5 experiments; * $p < 0.05$ vs 0 min

C significantly increased DA release over a 60 min period with a gradual return to baseline by 150 min. These data taken together with our previous findings indicate that there is a concentration dependent threshold effect of C on caudate DA release. Such that low doses increase and high doses decrease caudate DA release.

253.7 EEG SYNCHRONIZATION AND SEDATION INDUCED BY SIMULTANEOUS BLOCKADE OF D-1 AND D-2 RECEPTORS INSTEAD OF SELECTIVE BLOCKADE OF EACH RECEPTOR SUBTYPE. P. Bo*, E. Ongini, G. Azan* and F. Savoldi*. Inst. of Neurology C. Mondino, Univ. Pavia, School of Med., I-27100 PAVIA, Italy

Blockade of dopamine (DA) receptors by neuroleptics tends to produce sedation as shown by increased sleep time, reduction of arousing response to sensory stimuli and slowing of brain electrical (EEG) activity. We evaluated the EEG and behavioral effects of the selective compounds SCH 23390 and raclopride which block either D-1 or D-2 receptor subtype, respectively. Groups of rabbits were prepared for the measurement of EEG activity (neocortex and hippocampus). EEG was analyzed visually and by spectral power analysis. Gross behavior was also observed. The unselective neuroleptic haloperidol (0.3 mg/kg iv) induced EEG synchronization (increased slow waves and spindle activity) associated with sedation. Power density spectrum in the range of 0.1 - 20 Hz markedly increased after treatment. The D-1 antagonist SCH 23390 by itself (0.03 - 0.3 mg/kg iv) produced little or no EEG change and no evidence of sedation. Periods of slow waves occurred sporadically. Computerized EEG analysis showed moderate increases of total power density. The D-2 receptor blocker raclopride alone (1 - 3 mg/kg iv) produced weak changes of the EEG activity, mostly short periods of slow waves, and slight increases of total power. No sedation was noted. Although both selective antagonists were studied at doses above those minimally effective, they produced slight EEG and behavioral changes which were not comparable with the marked actions produced by haloperidol. Interestingly, when raclopride (1 mg/kg) was given after treatment with SCH 23390 (0.03 mg/kg) there was a marked synchronized EEG activity associated with a state of sedation and diminished responsiveness to sensory stimuli.
The data indicate that EEG synchronization and sedation, classically associated with neuroleptic treatment, do not depend upon the selective blockade of either D-1 or D-2 receptors, but, instead, require concurrent blockade of both receptor subtypes.

253.8 ONE WEEK HIGH DOSES OF HALOPERIDOL REDUCES MARKEDLY THE NUMBER OF SPONTANEOUSLY ACTIVE MIDBRAIN DOPAMINE NEURONS. Rex Y. Wang and Melissa Tsai*, Depts. of Psychiatry and Behavioral Science and Pharmacology, SUNY at Stony Brook, Stony Brook, NY 11794.

Chronic haloperidol treatment (CHAL; 0.5 mg/kg/day s.c.) has been shown toproduce a time-dependent reduction in the number of spontaneously active dopamine (DA) neurons in both the substantia nigra pars compacta (A9) and ventral tegmental area (A10). However, the reduction in the number of active DA cells/track occurred much earlier in A10; after one week, the number of active A10 DA cells/track was already significantly below control, whereas the number of active A9 DA cells/track remain unchanged until after three weeks (White and Wang, Life Sci., 32:983-993, 1983). The CHAL-induced effect was reversed by the DA agonist apomorphine (APO), suggesting that the effect was due to depolarization inactivation (DI). Acute HAL produced a rate elevation and, at higher doses, also caused DI in a subpopulation of DA cells, indicating that HAL-induced DI is dose-dependent (Hand et al., Brain Res., in press). The aim of the present study was to decide whether treatment of rats with high doses of HAL shortens the time needed for the development of DI for both A9 and A10 DA cells.

Male Sprague-Dawley rats were treated with HAL (5 mg/kg/day s.c.) for 3 or 7 days. Standard extracellular single unit recording techniques were used to monitor the DA neuronal activity and to count the number of spontaneously active DA cells per track as previously described.

Our preliminary results show that rats treated with HAL for one week resulted in an almost total absence of spontaneously active DA cells in both A9 and A10 regions. The effect produced by one week 5 mg/kg/day of HAL treatment is significantly greater than that produced by 6 to 8 weeks continuous treatment with 0.5 mg/kg/day of HAL. Even with 3 days treatment, HAL induced a marked reduction in the number of spontaneously active DA neurons; the effect was greater in A10 than in A9. The reduction of spontaneously active DA neurons caused by HAL was reversed by acute APO (100 µg/kg iv), suggesting that the HAL-induced effect was due to the process of DI. In short, high doses of HAL caused an earlier onset of DI for both A9 and A10 DA cells.

Combined, the results from the present and previous studies indicate that HAL-induced DI is not only time-dependent but also dose-dependent. If antipsychotic drug (APD)-induced DI of A10 DA cells is associated with the alleviation of schizophrenic symptoms as inferred from previous studies, our results may form the basis for further studies on "rapid neuroleptization." Attention should be paid particularly to those atypical APDs which may have lower potential for causing neurological side effects. (Supported by USPHS Grants MH-41440, 41696 and 00378 awarded to R.Y.W.).

253.9 ANTIDROMIC ACTIVATION OF MESO-ACCUMBENS DOPAMINE NEURONS FOLLOWING CHRONIC HALOPERIDOL TREATMENT. J.A. HARPER AND REX Y. WANG, Dept. of Psychology, SUNY at Old Westbury, Old Westbury, NY 11568 and Dept. Psychiatry and Behavioral Science, SUNY at Stony Brook, Stony Brook, NY 11794.

Chronic haloperidol treatment (CHAL) has been shown to cause a time-dependent reduction in the number of spontaneously active A9 and A10 dopamine (DA) neurons, and to induce an irregular firing pattern in many of the cells that remain active (White and Wang, 1983a). Both of these effects occur earlier and to a greater extent in A10 cells than in A9 cells. Since the time course for the reduction of A10 DA activity corresponds to the time course of decreased plasma HVA levels of schizophrenics and clinical improvement of schizophrenic symptoms, it was proposed that the inactivation of A10 and A9 DA neurons produced by CHAL may be related to the delayed onset of pharmacotherapy and extrapyramidal side effects (EPS), respectively. Subsequent studies employing typical and atypical antipsychotic drugs (APDs) supported this hypothesis (Chiodo and Bunney, 1983; White and Wang, 1983b). Chiodo and Bunney (1983) presented some evidence suggesting that the remaining active A10 DA cells following chronic APDs treatment are primarily, if not exclusively, mesocortical neurons. They suggest that the prefrontal mesocortical DA system may not be involved in some form of psychosis. However, this conclusion is premature because whether mesolimbic DA cells remain spontaneously active has never been systematically tested. The present study was designed to determine whether some of these remaining active DA cells following CHAL are meso-accumbens projecting cells.

Male Sprague-Dawley rats (350-450g), maintained on haloperidol (1.5 mg/kg/day) dissolved in drinking water were used. Spontaneously active A10 DA cells were identified using standard electrophysiological criteria (e.g. bi- or triphasic waveforms with a width of >2.5 ms and an inflection in the initial positive component, firing rate of 1-10 Hz etc.); these cells were then antidromically activated from the nucleus accumbens (NAc).

Many spontaneously active DA cells following CHAL can be antidromically activated from the NAc. To ensure that the results were not due to stimulating mesocortical DA fibers of passage, the experiments were repeated in CHAL rats whose prefrontal and cingulate cortices had been lesioned 1 week earlier. The cortical lesions presumably caused retrograde degeneration of mesocortical DA fiber projections because few of them have axon-collaterals. Half of spontaneously active DA neurons could still be activated antidromically. These results support the contention that a small portion of both meso-limbic and meso-cortical DA cells remain active following CHAL. (Supported by USPHS Grants MH-41440, 41696, 00378 to RYW. and RR-08180 to JAH).

253.10 SUPERSENSITIVITY TO DOPAMINE AND CHOLECYSTOKININ OF NUCLEUS ACCUMBENS CELLS FOLLOWING CHRONIC TREATMENT WITH HALOPERIDOL OR CLOZAPINE. Xiu-Ti Hu and Rex Y. Wang, Dept. of Psychiatry and Behavioral Science, SUNY at Stony Brook, Stony Brook, NY 11794.

A subpopulation of dopamine (DA) neurons in the ventral tegmental area (VTA or A10) also contain cholecystokinin (CCK); DA/CCK projections terminate primarily in the medial part of the nucleus accumbens (NAc). Lesions of ascending DA fibers in the medial forebrain bundle by 6-hydroxydopamine resulted in the development of denervation supersensitivity of NAc cells to both DA and CCK (Hu and Wang, Neurosci. Abstr. 11:743, 1985). Chronic HAL treatment (CHAL) induced an increase of binding sites for both DA and CCK. Curiously, a recent abstract by Debonnel and de Montigny (Neurosci. Abstr. 12:1319, 1986) reported that CHAL caused a supersensitivity of NAc cells to CCK but not to DA; they suggested the effect produced by DA in the NAc was mediated by an adrenoceptor other than D1 or D2 DA receptor subtypes. This view is not supported by our finding that the inhibition produced by iontophoresis of DA (ionto-DA) can be blocked by either the typical antipsychotic drug (APD) HAL or atypical APD clozapine (CLOZ). In the present study, we decided to clarify further the effects produced by chronic treatment with APDs on NAc cells.

Male Sprague-Dawley rats were treated with either HAL (0.5 mg/kg/day s.c.) or CLOZ (20 mg/kg/day, s.c.) for 4 weeks. A seven-day withdrawal period was allowed before the experiments began. Both spontaneously active cells and glutamate (GLUT)-evoked activity were studied by using the technique of extracellular recording and microiontophoresis. ID50s for DA and ED80s for CCK on NAc neurons recorded from both APD treated and control groups were systematically compared.

Our results confirm the finding that the sensitivity of NAc cells (n=18) to ionto-CCK was markedly enhanced in CHAL rats. However, unlike the report of Debonnel and de Montigny (1986), we observed that CHAL also enhanced the inhibitory responses of NAc cells (n=10) to ionto-DA. When compared to those of controls the dose-response curves for both CCK and DA shifted to the left in CHAL rats. Moreover, the responses of NAc cells to both D1 agonist SKF-38393A (n=16) and D2 agonist LY-171555 (n=13) were enhanced, suggesting that CHAL-induced DA supersensitivity may be mediated via both D1 and D2 DA receptor subtypes. Similarly, the sensitivity of NAc cells to ionto-DA (n=8) and CCK (n=14) was also strikingly increased in the CLOZ rats.

In conclusion, our results suggest that chronic treatment with APDs is effective in inducing the development of supersensitivity of NAc cells to both DA and CCK. They support the view that CCK might have an important role in mediating the therapeutic actions of APDs. (Supported by USPHS Grants MH-41440, 41696 and 00378 to RYW).

OPIATES, ENDORPHINS AND ENKEPHALINS: PHYSIOLOGICAL EFFECTS III

254.1 DYNORPHIN A SELECTIVELY INHIBITS THE RELEASE OF OXYTOCIN FROM ELECTRICALLY STIMULATED ISOLATED RAT NEUROHYPOPHYSES. C.A. Bondy*, H. Gainer, J.T. Russell*, LNN, NICHD and LNC, NINCDS, NIH, Bethesda, MD 20892.

For some time it has been known that physiologically stimulated oxytocin (OT) release *in vivo* is under endogenous opioid inhibition and that this effect appears to occur at the level of the axon terminals of the neural lobe. Studies of the effects of various opiates on hormone secretion from isolated neural lobes *in vitro* , however, have produced confusing results, probably due to the use of non-specific opiate agonists and diverse stimulus protocols. Since it has recently been established that substantial amounts of dynorphin A are co-localized with vasopressin (VP) in the magnocellular terminals of the neural lobe and that the opiate receptors of the neural lobe are restricted to the κ subtype, we hypothesized that the dynorphin A (DYN A) co-packaged and therefore co-released with VP inhibits release from neighboring OT terminals. In order to test this hypothesis we made use of the previously defined frequency dependent pattern of VP and OT secretion in our system. Using isolated rat neurointermediate lobes(NILs) incubated *in vitro* we have shown that a constant 600 pulse stimulus delivered at a frequency of 4 Hz results in evoked release of both VP and OT that is significantly above baseline, but only ≈20% of maximal, and that secretion is further facilitated by increasing the frequency of the 600 pulses up to a maximum level of release at 12 Hz for VP and 20 Hz for OT. If the relevant opioid inhibitor is being released from VP terminals, we expected that the effect of exogenous DYN A might be evident at a submaximal release frequency (4 Hz) while obscured by high levels of endogenous DYN A release at 12 Hz. Conversely, we predicted that naloxone would have little effect at 4 Hz and maximal effect at 12 Hz where VP (and therefore DYN A) secretion is maximal. The stimulus protocol consisted of 600 pulses of 3V, 0.5ms delivered via a platinum electrode impaling the NIL. Each NIL received two periods of electrical stimulation at the same frequency (S1 and S2), with or without drugs during S2. We tested the effects of DYN A 1-8 and 1-17 and naloxone at stimulus frequencies from 4 to 30 Hz with 6-10 individual NIL's for each experiment.

Both dynorphin 1-8 and 1-17 (2μM) produced a significant reduction in OT release during the 4 Hz stimulus (<50% of control) and this effect was abolished by naloxone (10 μM). Neither form of DYN A, however, had any effect at stimulus frequencies of 12 or 30 Hz at concentrations up to 10μM. Naloxone (10μM) did not affect OT release during the 4 Hz stimulus, however it produced a highly significant amplification of OT release at a stimulus frequency of 12 Hz (≈280%). None of these agents had a significant effect on VP release at any frequency tested. A frequency dependent secretion curve (4, 8, 12, 20 &30 Hz) was established for OT and VP release in the presence of naloxone, and it was found that both hormones now attained maximal release at 12 Hz. These data support the hypothesis that DYN A released in parallel with VP during in vitro stimulations of the rat NIL inhibits simultaneously stimulated OT release. While these findings highlight the complex interactions that may occur even in relatively simple systems, their physiologic relevance remains to be explored.

254.2 OPIATE TOLERANCE ALTERS NEUROTRANSMITTER REGULATION OF THE HYPOTHALAMO-PITUITARY-ADRENAL AXIS. D.M. Ignar and C.M. Kuhn. Duke Univ. Med. Ctr., Durham, NC 27710.

The hypothalamo-pituitary-adrenal axis of the rat is stimulated by administration of mu and kappa opioid receptor agonists. Tolerance develops to this effect following chronic administration of these agents. In order to determine the interactions of opioid neurons with other neural mediators of CRF release, a model of opiate tolerance in rats was employed.

Adult male Sprague-Dawley rats were injected with increasing doses of morphine (20 mg/kg to 40 mg/kg), the kappa agonist U50,488 (1 mg/kg to 5 mg/kg), or saline twice daily for 5 days. Challenge doses were given subcutaneously 36 hours after the end of chronic treatment. Rats were decapitated 1 hour after drug administration and blood was collected for measurement of serum corticosterone by radioimmunoassay.

Complete tolerance to morphine (10 mg/kg) or U50,488 (1 mg/kg) occurred after chronic morphine or U50,488 treatment, respectively. No cross-tolerance of morphine tolerant rats to U50,488 or U50,488-treated rats to morphine was observed.

Administration of drugs which stimulate HPA axis secretion to morphine or U50,488 tolerant rats yielded the following results: 1) The stimulatory effect of physostigmine (0.1 mg/kg) was twice the control level in morphine-treated rats while its effect was almost negligible in U50,488 tolerant rats. 2) The quipazine response of morphine tolerant rats was reduced to 50% of the control response while chronic U50,488 had no effect. 3) The effect of clonidine (0.025 mg/kg) was significantly attenuated in both morphine and U50,488 treated rats.

These results suggest that both mu and kappa receptors modulate the noradrenergic neurons involved in CRF release, whereas mu receptors may specifically regulate serotonergic neurons and kappa receptors modulate cholinergic neurons. The absence of cross-tolerance may be explained by opioid subtype specific neural adaptations which occur after chronic opiate administration.

254.3 TIME COURSE OF RETURN OF MORPHINE STIMULATION OF PROLACTIN RELEASE IN THE LACTATING FEMALE MODEL. P. Callahan, J. Janik and J. Rabii. Department of Biological Sciences, Rutgers Univ., Piscataway, NJ 08855.

We have previously reported that the lactating female model is insensitive to morphine stimulation of prolactin release. This insensitivity appears to be due to the physiological state of suckling. Post-partum females in which suckling was terminated for 4 days showed a significant morphine induced prolactin increase in 50% of the animals tested. The purpose of these studies was to further investigate the time course of this insensitivity to morphine stimulation of prolactin release. In addition, the effect of morphine administration on the activity of the TIDA neurons was determined by measuring DOPA accumulation in the median eminence of the lactating female.

Lactating females between days 4-10 post-partum were used in all studies. These dams were separated into three groups. In all groups, animals received an injection of morphine sulfate (5 mg/kg, iv) on day 4 post-partum, 2 hours after pups were removed. The pups were sacrificed and the dams were housed individually until they were again injected with morphine on day 8 (group 1), day 10 (group 2) or day 12 (group 3). Blood samples were withdrawn through previously implanted jugular cannulae, immediately prior to and 15, 30 and 45 minutes after injection. Only 50% of the dams in group 1 showed a significant morphine induced prolactin increase. 75% of the dams in group 2 and 100% of the dams in group 3 showed a significant prolactin secretory response to morphine administration. These results suggest that there is a recovery period following the lactation state which is responsible for the return of the pre-lactation sensitivity of prolactin to morphine stimulation. Additionally, it is interesting to note that DOPA accumulation in the median eminence was not altered by morphine administration in the lactating model. These results suggest that the insensitivity to morphine stimulation of prolactin release may be mediated, at least in part, by an insensitivity of the TIDA neurons to inhibition by morphine administration. (Supported by the Busch Memorial Fund.)

254.4 **CHANGING ROLE OF NE IN EOP INHIBITION OF LH SECRETION IN NEONATAL FEMALE RATS.** **E. Field, G. Kuhn and M. Doron*. Dept. of Pharmacology, Duke University Medical Center, Durham, NC 27710.**

Luteinizing hormone (LH) inhibition by CNS endogenous opioid peptides (EOP) requires functional noradrenergic (NE) neurons in prepubertal and adult female rats. Inhibitory EOP tone is particularly pronounced in neonatal females, as evidenced by the marked LH rise after naloxone (NAL). However, adrenergic stimulation does not elicit similar LH responses in female neonates, suggesting that EOP modulation of LH secretion at that age may involve neuronal pathways other than or in addition to NE. To test this hypothesis, we pretreated adult, 25 and 5 d.o. rats with NE antagonists and synthesis inhibitors before challenge with NAL and measured subsequent LH responses.

NAL (0.1 - 2.0 mg/kg sc) or saline was administered 20 min prior to decapitation in 5 d.o. and 25 d.o. females to generate a dose response curve, and a supra-maximal concentration of 2 mg/kg NAL was chosen for later experiments. In 5 d.o., 25 d.o. and adult diestrous rats, NAL induced a 12-, 4- and 2-fold rise in LH, respectively, within 20 min ($p < 0.05$), suggesting a functional but declining EOP inhibition of LH. In 25 d.o., the α-adrenergic antagonist, phentolamine (10 mg/kg ip) completely blocked the NAL-induced LH rise ($p < 0.05$). Diethyldithiocarbamate (DDC, 400 mg/kg ip), a NE synthesis inhibitor, or reserpine (0.5 mg/kg ip) also prevented the NAL-induced LH rise at this age ($p < 0.05$). DDC also blocked the post-NAL rise in LH in intact adult rats ($p < 0.05$). In 5 d.o. females, on the other hand, phentolamine, reserpine or DDC only slightly attenuated the LH rise following NAL ($p < 0.05$). However, NAL still elevated serum LH 7-9 fold after these drug treatments ($p < 0.05$). Interestingly, DDC itself induced a rise in LH in 5 d.o., but not 25 d.o. or adult, female rats ($p < 0.05$). Clonidine (CLON, 0.1 mg/kg sc), an α-adrenergic agonist, had no effect on serum LH levels in 10 d.o. female rats. In contrast, NE inhibition markedly raised serum corticosterone (CS) levels in neonatal and older rats.

These results support our hypothesis that stimulation of NE secretion mediates the rise in LH following opiate blockade in prepubertal and adult female rats, but plays at most a minor role in neonates. Furthermore, the LH rise following DDC treatment of neonatal, but not older, rats and the lack of LH response to CLON in neonates suggests that the post-synaptic α-adrenergic receptor modulating LH secretion in adults, unlike CS, is not functional in neonates. Alternatively, the balance of pre- and post-synaptic effects of NE agents on LH might change during ontogeny. In female neonates, EOP neurons may inhibit LH secretion by directly inhibiting LHRH neurons or through other pathways, e.g. serotonergic or dopaminergic, in addition to NE. **(Supported by NIDA grant #DA-02739.)**

254.5 THE MU-1 ANTAGONIST NALOXONAZINE DOES NOT BLOCK THE BETA-ENDORPHIN OR DADLE INDUCED PROLACTIN INCREASE DURING LACTATION. J. Janik, M. Baumann*, P. Callahan and J. Rabii. Department of Biological Sciences, Rutgers Univ., Piscataway, NJ 08855.

We have previously reported that lactating females are not sensitive to morphine stimulation of prolactin release. However, this model does show a prolactin secretory response to both beta-endorphin and d-ala-d-leu-enkephalin (DADLE) administration which is not reversed by naloxone. It has been reported that naloxonazine (NAZ) is a specific antagonist of the mu-1 site and blocks the morphine induced prolactin increase in male rats (Spiegel et al., Sci. 217:745, 1982). The purpose of this study was to examine the effects of this antagonist on the beta-endorphin and DADLE induced prolactin increase in the lactating female model.

Lactating females between days 6 and 10 post-partum were used in all studies. Animals received intraventricular implants on day 2 post-partum and were allowed to recover for at least 6 days following this surgery. They were implanted with jugular cannulae 24 hours prior to their use in an experiment. NAZ (20 mg/kg, iv) or saline was administered at the time of jugular cannulation. On the day of the experiment, animals were separated from their pups 2 hours prior to the administration of the opiate peptides. Blood samples were withdrawn immediately prior to and 15, 30 and 45 minutes after beta-endorphin (0.5, 2.5, 5 or 10 µg, ivt) or 5, 15 and 30 minutes after DADLE (2.5, 5 or 10 µg, ivt) administration.

All doses of beta-endorphin and DADLE produced a significant increase in circulating levels of prolactin. There was no difference between the saline and NAZ pretreated groups and NAZ alone had no effect on basal levels of prolactin. It appears that these peptides do not produce an increase in prolactin via a mu-1 opiate receptor subtype. These results confirm our previous findings that this model is insensitive to the mu agonist morphine with respect to stimulation of prolactin release. It appears likely that this particular receptor subtype does not play a physiologically significant role in the regulation of prolactin release during lactation. (Supported by the Busch Memorial Fund and the Anne B. and James H. Leathem Scholarship Fund.)

254.6 **ESTRADIOL/PROGESTERONE REGULATION OF HYPOTHALAMIC NEUROPEPTIDE mRNA LEVELS.** P. Camp and J.D. White. Dept. Medicine, Div. Endo., SUNY, Stony Brook, NY 11794.

Depending on the treatment duration, estradiol (E_2) and progesterone (P_4) can induce or block LH and prolactin (PRL) surges independently in ovariectomized (OVX) rats by acting within the hypothalamus. The goals of these studies are to determine: 1) the E_2/P_4 effect on several hypothalamic neuropeptide mRNA levels and 2) whether the mRNA levels can be correlated with E_2/P_4 effects on LH or PRL levels. One week after OVX (day 0), E_2 Silastic capsules were placed sc at 0900. Some rats also received P_4 capsules sc at 0900 on either day 0, 2 or 4. In this paradigm, serum steroid levels were within the physiological range. Rats were sacrificed at 1500 on day 0, 1, 2, 3 and 5. Control (OVX) animals were sacrificed on day 0 and day 5. Blood was collected for RIA of LH and PRL levels. Hypothalami were dissected and rapidly frozen on dry ice for mRNA determination. Total RNA was isolated using an SDS/urea extraction, repeated phenol/chloroform extraction and ethanol precipitation. RNA was separated using formaldehyde denaturing agarose gel electrophoresis and a MOPS buffer system. The RNA was transferred to nylon membrane by electrotransfer,then was covalently cross-linked to the membrane with uv light and used for northern analysis.

In the intial analysis the mRNAs coding for preproenkephalin A and for preprovasoactive intestinal peptide (VIP) were quantitated. The preliminary results suggest that estradiol initially decreases then increases preproenkephalin mRNA relative to the levels measured in OVX animals. Progesterone treatment further increases preproenkephalin mRNA levels. These steroids appear to have a similar effect on preproVIP mRNA. The effects of E_2/P_4 on tyrosine hydroxylase mRNA and preproopiomelanocortin mRNA content in the hypothalamus will also be assessed. (Supported by NIH MH-42074)

254.7 PRESENCE OF β-CASOMORPHIN IMMUNOREACTIVE MATERIAL IN PLASMA OF BEAGLE NEONATES AFTER MILK INTAKE.
M. Singh*, C.L. Rosen*, K.J. Chang, and G.G. Haddad (SPON: A. Karlin). Department of Pediatrics, Columbia University, New York, NY 10032, and Wellcome Research Labs., Research Triangle Park, NC 27709.

β-casomorphin-7 (BCM), a potent μ-opioid agonist, is a fragment of bovine β-casein (C). Administration of BCM elicits analgesia, enhances release of insulin and somatostatin, and induces hypoventilation. If BCM exists in plasma, it may elicit opioid activity in neonates since their blood brain barrier is not well developed. We are reporting BCM immunoreactive material (BCMIR) in the plasma of 2- and 4-wk old beagle puppies after feeding C using a sensitive, efficient new procedure for extraction of BCM. Blood (2.5 ml) was drawn at 0, 2, 4, and 6 hr after feeding 25 to 35 ml of either C or a soy protein (non-casein) based formula to puppies after a 3-hr fast. BCMIR was extracted from plasma and assayed by RIA with I^{125}-BCM and anti-bovine BCM. The extraction procedure yielded recoveries of 78±3 (mean±SD, n=12) in samples up to 0.05 p-moles per ml plasma and 90.5±2.5 with 0.5 p-moles per ml plasma. Feeding of C resulted in significant elevation of BCMIR in both age groups. In contrast, no change was noted after intake of soy protein. Baseline BCMIR was detected in all puppies. Older puppies reached peak values at 2 hr while younger puppies peaked at 4 hr and remained high at 6 hr as can be seen from table below.

HR AFTER FEED	0	2	4	6#
C (N=8) 2 WK	0.13±.01	0.14±.01	0.26±.05*	0.24±.02*
C (N=4) 4 WK	0.08±.01	0.14±.01*	0.14±.01*	-
SOY(N=5) 2 WK	0.20±.03	0.22±.01	0.23±.02	-

mean ± SD of p-moles/ml plasma, * p< .01, # n=3

The BCMIR was resistant to proteolysis though BCM added to the same plasma was rapidly degraded. Due to the negligible cross-reactivity of BCM antibody to BCM-4, 5, and 6, BCMIR is not likely to be smaller than BCM. We conclude that an increase in BCMIR was detectable in plasma of beagle neonates after C feeding, but not soy feeding; the metabolism of BCMIR appeared age dependent. We speculate that the observed levels of BCMIR may have physiological significance since BCM infusion of similar magnitude has been shown to alter pancreatic endocrine function.

254.8 OPIATE BLOCKADE IN TREATING BULIMIA - A COMPARISON OF LOW-DOSE VS HIGH-DOSE NALTREXONE.
M.S. Gold, J.M. Jonas*, A.L.C. Pottash. Research Facilities and Eating Disorders Program, Fair Oaks Hospital, Summit, NJ 07901.

Bulimia, the syndrome of binge-eating and purging, is a disorder of unknown etiology. Endogenous opiates, which are known to modulate ingestive behavior in mammals, may play a role in the genesis of this disorder, and appear elevated in bulimic individuals (Fullerton DT, et al. Psychol Medicine, 16:59, 1986). Two open-studies of naltrexone, a long-acting, orally administered opiate blocker, have suggested that this medication may be of use in treating bulimia (Jonas JM, Gold MS, Lancet, i:807, 1986; Jonas JM, Gold MS, Int J Psych Med, 16(4):305-309, 1986-87), while a blind study using naloxone suggested that this short-acting opiate blocker also attenuated binging (Mitchell JE, et al., Biol Psychiatry, 21:1399, 1986). One important question which has not been answered is whether dosages of naltrexone (50-100 mg per day) which block the effects of exogenous opiates and which might therefore act at the mu receptor are effective in decreasing binging behaviors in humans. The answer to this might reveal clues as to the mechanism of action of naltrexone in bulimia, and would aid in the clinical use of this medication. We compared two dosage schedules of naltrexone in a group of 10 bulimic individuals. All patients met DSM-III criteria for bulimia, and all were binging and purging on a daily basis. Five subjects received 50-100 mg of naltrexone (low-dose) daily for 4-6 weeks, and 5 subjects received naltrexone in doses of 200-300 mg daily (high-dose) for 4-6 weeks. In the high-dose group, there were significant reductions in binging ($p < .01$), and purging ($p < .01$) at the end of the study. In contrast, there was no significant effect on binging or purging in the low-dose group with 3 subjects experiencing no change in symptoms while 2 subjects had a decrease of less than 50%. Three subjects in the low-dose group then received high-dose naltrexone. Two of the 3 experienced complete resolution of symptoms, and 1 subject reported a 75% reduction in binging and purging. It appears from these open-study design, preliminary data that dosages of naltrexone which adequately block exogenous opiates have no effect on binge-eating. One explanation of this phenomena may be that different opiate receptors are responsible for dependency and addiction (possibly mu) while other receptors underlie modulation of feeding behavior (possibly kappa). If naltrexone is to be used in treating bulimia, higher doses may be needed. Opiate blockers with greater affinity for the kappa receptor may prove superior in the treatment of eating disorders.

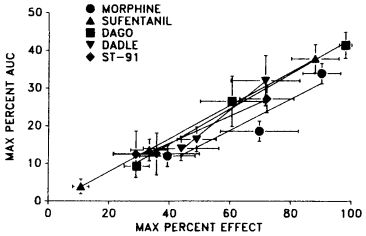
254.9 **COMPARISONS OF FEEDING ELICITED BY MORPHINE AND DYNORPHIN(1-13) MICROINJECTIONS INTO SELECTED BRAIN SITES.**
Margaret E. Hamilton[1] and Michael A. Bozarth[2] [1]Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec, Canada H3G 1M8. [2]Department of Psychology, State University of New York at Buffalo, Buffalo, NY 14260.

Microinjections of both morphine and dynorphin(1-13) (DYN) into the ventral tegmental area (VTA) have been shown to elicit dose-dependent feeding in satiated animals (Hamilton & Bozarth, Soc. Neurosci. Abstr. 12:412, 1986). In addition, animals will lever-press to self-inject morphine into the VTA, indicating that opioids in this region are rewarding. It was of interest to examine the effects of these two compounds in a number of other brain regions where opioids have been associated with either feeding or reward. Male, Long-Evans rats were permanently implanted with stainless steel guide cannulae aimed at the VTA, the nucleus accumbens (NAS), the paraventricular nucleus of the hypothalamus (PVN), the periaqueductal gray area (PAG) immediately dorsal to the VTA, or the substantia nigra--pars reticulata (SNR) which receives dense dynorphin innervation. Either morphine (0, 1, 3, or 10 nmoles) or DYN (0, 0.003, 0.03, 0.1, 0.3, or 3 pmoles) in a fluid volume of 0.5 μl was delivered in random dose order. Behavior was observed and recorded for 15 minutes following drug administration. Animals received all doses of both drugs; morphine and DYN administration was counterbalanced within groups.

Consistent with our earlier data, DYN in the VTA was 50,000 times more potent than morphine in eliciting feeding. Eating elicited by morphine injected into the NAS was lower than but not significantly different from VTA morphine. DYN in the NAS produced feeding duration scores similar to those for the VTA at doses up to 0.1 pmoles; however, at the two higher doses VTA DYN produced significantly more feeding than NAS injections. Morphine in the PVN failed to produce feeding; in fact, at the higher doses behavior became erratic and disorganized, and animals frequently appeared stuporous. DYN in the PVN, however, elicited a weak dose-related feeding response. Preliminary data suggest that neither drug in the PAG is effective in eliciting feeding. Morphine in the SNR did not produce feeding, and DYN in the SNR failed to elicit a robust feeding response even at 100 times higher doses than those effective in the VTA. SNR DYN injections appeared to increase grooming behavior. Drinking was not increased significantly by either compound in any of the brain regions examined.

254.10 TIME COURSE OF TOLERANCE DEVELOPMENT TO ANTINOCICEPTIVE AGENTS IN RAT SPINAL CORD.
Craig W. Stevens and Tony L. Yaksh*, Dept. of Pharmacology, Mayo Graduate School of Medicine, Rochester, MN 55905

The time course of tolerance to chronically infused antinociceptive agents in spinally catheterized rats was examined by daily hot plate testing to determine whether agents acting at the same and/or different sets of receptors display distinguishable rates of tolerance development. Male Sprague-Dawley rats (250-300 g) were tested on a 52.5°C hot plate on the morning of day 0, implanted with a lumbar intrathecal catheter connected to a continuous-delivery osmotic minipump (Alza Corp. Model 2001, 1μl/h) and tested daily thereafter at 10:00 a.m. for one week. Separate groups of rats (N = 6-8 per dose) received saline or 1 of 3 half-log spaced concentrations of μ opioid receptor agonists; morphine (2, 6 or 20 nmol/h), sufentanil (0.06, 0.2 or 0.6 nmol/h), D-ala^2,N-methyl-phe^4,gly^5-ol-enkephalin (DAGO; 0.1, 0.3 or 1 nmol/h); a δ opioid agonist, D-ala^2-D-leu^5-enkephalin (DADLE; 2, 6 or 20 nmol/h); or an α_2-adrenergic agonist, the polar analog of clonidine, ST-91 (3, 10 or 30 nmol/h). All treatment groups displayed a dose-dependent increase in hot plate latency which were maximum on day 1 and returned to saline-infused control levels by 3 to 5 days. The raw latency (in secs) was converted to maximum percent effect (MPE) by the formula: MPE = (post-pre)/(60-pre)*100. The area under the time-course curve (AUC) was calculated from these MPE-values using a trapezoidal approximation and expressed as a percent of maximum possible area under the time-course curve (max percent AUC). Thus if an infusion dose of an agent produced maximum peak response (MPE = 100%) for each day after pump implant, then the max percent AUC (integral of the time-course curve) would also equal 100%. The ratio of the peak response (max percent effect) to the integral of the time-effect curve (max percent AUC, an index of the rate constant for the development of tolerance) was independent of dose and similar for all drugs (see Fig.). This similarity of rate constants suggests the involvement of common mechanisms in the development of tolerance to these several drugs. Given the absence of a symmetrical cross tolerance between μ, δ and α_2-preferring drugs (Soc. Neurosci. Abst. 12:618, 1986) the tolerance mechanisms, though common may be independent. (NIH grant DA-02110 and Mayo Fdn.)



254.11 I.P. INJECTION OF CSF FROM OPIATE-ABSTINENT RATS PRECIPITATES ABSTINENCE SYNDROME IN OPIATE-DEPENDENT MICE. D.H. Malin, D.S. Marullo*, J.R. Lake*, V. Balasubramanyam*, J.B. Murray*, and P.A. Farley*. (SPON: S.R. Burzynski) Univ. of Houston-Clear Lake, Houston, Texas 77058.

In previous studies from this laboratory, CSF from opiate abstinent rats precipitated opiate abstinence signs when infused into the third ventricle of opiate-dependent rats. To aid the characterization of the active CSF factor, a more convenient non-stereotaxic assay procedure was desirable. We not report that i.p. injection into morphine-pelleted mice can serve as such a procedure.

Subjects were 12 30-35g male ICR mice and 24 300g Sprague-Dawley rats. Sixteen donor rats were rendered dependent by one week of subcutaneous morphine infusion (1.8 mg/kg/hr) via Alzet 2ML1 osmotic minipump. Eight donor rats were infused by the same procedure with saline alone. Under ether anesthesia, 75 µl CSF was withdrawn from the cisterna magna of each rat six hours after removal of the minipump (allowing for clearance of morphine).

Eight mice were rendered dependent by s.c. implantation with pellets containing 75 mg morphine base. Four mice served as "sham" implanted" controls. Three days after implantation, each mouse was injected i.p. with 150 µl of CSF. Four mice (Group A) received a morphine pellet followed by CSF from morphine dependent and abstinent rats. Four mice (Group B) received a morphine pellet followed by CSF from saline-infused rats. Four mice (Group C) were sham implanted followed by CSF from morphine-infused rats.

Each mouse was placed on an elevated platform and observed for abstinence signs under "blind" conditions for 45 minutes. The predominent sign observed in the first 10 minutes after injection was abdominal writhing. Shakes, tremors, seizures, ataxia and jumping from the platform were observed after 20 mins. Overall signs across all categories are presented below.

Table 1. Overall Abstinence Signs (mean + SEM)

A. Morphine Treated Donor/Morphine Treated Recipient	25.3 ± 8.1
B. Saline Treated Donor/Sham Treated Recipient	0.5 ± 0.3
C. Morphine Treated Donor/Saline Treated Recipient	1.5 ± 0.3

ANOVA revealed a significant treatment effect, $F(2,9)=9.0$, $p < .01$. Dunnett's multiple comparison procedure indicated that Group A showed significantly more signs than either of the other groups, $p < .01$. These results are consistent with the hypothesis that chronic opiate treatment induces the occurrence of an abstinence-precipitating substance with opiate-antagonist properties. (Supported by NIDA Grant R03 DA03966 and UH-CL Organized Research and Alumni Assn. Grants.)

254.12 A ROLE FOR THE NUCLEUS ACCUMBENS IN OPIATE DEPENDENCE. G.F. Koob, T.L. Wall, and F.E. Bloom, Division of Preclinical Neuroscience and Endocrinology, Scripps Clinic and Research Foundation, 10666 N. Torrey Pines Rd., BCR 1, La Jolla, CA 92037

Previous work in our laboratory has established that the region of the nucleus accumbens is an important substrate for the acute reinforcing effects of heroin in non-dependent rats with limited access to the drug. (Vaccarino, Bloom and Koob, 86:37-42, 1985). Injections of the hydrophilic opiate antagonist methylnaloxonium into the nucleus accumbens were effective in increasing heroin self-administration at significantly lower doses than those observed after injections of methylnaloxonium into the lateral ventricle or the ventral tegmental area. However, previous studies of the neural substrates of physical dependence to opiates have revealed multiple sites of action including the periacqueductal grey and the dorsal thalamus. In studies on opiate physical dependence, rats were trained on a fixed ratio-15 schedule of responding for food (45 mg Noyes pellets) and were implanted with chronic indwelling intraventricular or intracerebral cannulas aimed at the periaqueductal grey, dorsal thalamus or nucleus accumbens. The animals were made physically dependent on opiates by subcutaneous implantation of three 75 mg morphine pellets over 6 days. Very low doses of subcutaneously injected naloxone (50 µg/kg) produced a dramatic suppression of operant responding. Similar effects were observed with intracerebroventricular (ICV) administration of methylnaloxonium in doses of 60 to 250 µg. Local injections of methylnaloxonium into the periacqueductal grey or dorsal thalamus produced dose effect functions similar to that following ICV injection. Injections of methylnaloxonium into the nucleus accumbens produced a suppression of responding at significantly lower doses of methylnaloxonium (4-16 nanograms). These results suggest that the opiate receptors in the region of the nucleus accumbens responsible for the reinforcing properties of opiates may also be responsible for compensatory changes associated with opiate withdrawal such as "dysphoria". Results suggest that neuronal elements in the region of the nucleus accumbens may play an important role in the neurobiology of opiate reinforcement and dependence. (Supported by NIDA grant DA-04043 and NIAAA grant 06420).

254.13 NEURO-IMMUNOMODULATION, CENTRAL OPIOIDS AND THE IMMUNE RESPONSE TO BACTERIAL ENDOTOXIN. Q. Collard*, P.M. Dougherty*, K.J. Krajewski* and N. Dafny (SPON: J. Willmore). Dept. of Neurobiology and Anatomy, Dept. of Psychiatry and Behavioral Sciences, The Univ. of Texas Med. Sch. at Houston, P. O. Box 20708, Houston, TX 77225.

Muramyl Dipeptide (MDP), which is the smallest biologically active subunit of the lipopolysaccharide moiety of gram negative bacterial cell walls, has a variety of immunologic and neuropharmacologic activities. For example, 200.0 ug/kg MDP or its 6-O-stearoyl derivative injected systemically (i.p.) two hours before administration of 1.0 mg/kg naloxone to morphine dependent rats results in profound attenuation of the severity of the precipitated withdrawal syndrome. In addition, it has been shown that this same dosage of MDP reduces morphine-induced anti-nociception, while not affecting the development of tolerance to morphine. The goal of the present investigation is to establish that these effects of MDP are due to direct alterations of opioid activities in the CNS. To this end, we undertook an investigation of the dose-response characteristics of varying dosages of MDP upon the severity of eight signs of naloxone (1.0 mg/kg) precipitated withdrawal when injected directly into the brain via a previously implanted intracerebroventricular (i.c.v.) guide canula in 180-200 g male Sprague-Dawley rats (N = 32) made physically dependent upon morphine by subcutaneous morphine pellet (75 mg) implantation. The results of this study are compared with the effect of systemically injected MDP upon withdrawal severity. The results of these two studies indicate the following:

1) MDP attenuates the eight signs of naloxone precipitated withdrawal severity in a linear dose-related manner upon direct injection into the brain.
2) Moreover, intracranial and systemic administration of MDP result in similar effects upon opiate withdrawal severity.

These results indicate that MDP can indeed act directly upon the brain to alter CNS opioid activities. In addition, the present observation suggests that products of the immune response to bacterial infection can alter brain activity and thus provide a sensory immunologic information channel to the CNS.

254.14 IMMUNE SUPPRESSION AND CENTRAL OPIOID ACTIVITY. K. Henderson*, P.M. Dougherty*, K.J. Krajewski* and N. Dafny (SPON: R. Wiggins). Dept. of Neurobiology and Anatomy, and Dept. of Psychiatry and Behavioral Sciences, The Univ. of Texas Med. Sch. at Houston, P. O. Box 20708, Houston, TX 77225.

Cyclosporin A (CsA) is a novel undecapeptide of fungal origin with profound immunosuppressive activity. However, neuromodulatory activity for this peptide has also been suggested by the demonstration of a reduction in the severity of opiate withdrawal induced by 1.0 mg/kg naloxone following systemic (i.p.) injection of 15 mg/kg CsA. This same dosage of CsA also modifies the acute anti-nociceptive activity of morphine while not affecting the development of tolerance to morphine. These actions have been suggested to be due to actions of CsA within both the CNS and the immune system. To better define the actions of this agent upon these opioid phenomena, two studies were undertaken. First, we undertook an investigation into the dose-response characteristics of varying dosages of CsA upon eight signs of naloxone-precipitated opiate-withdrawal behavior following direct administration of the compound into the brain via a previously implanted intracerebroventricular (i.c.v.) guide canula placed within the lateral brain ventricle in 180-200 g male Sprague-Dawley rats previously made physically dependent upon morphine by subcutaneous drug pellet (75 mg) implantation. These results are compared and contrasted with those obtained for the effects of 15.0 mg/kg CsA administered systemically upon the same eight signs of withdrawal. In the second study, the interaction of CsA with morphine and naloxone upon the electrophysiologicic activity of four discrete brain areas essential for various opioid behaviors is assessed in 180-200 g male Sprague-Dawley rats previously implanted with permanent semi-microelectrodes. The results indicate the following:

1) CsA reduces opiate withdrawal severity in a "U"-shaped, dose-related manner following direct administration into the brain.
2) However, systemic administration of CsA yields a better reduction in any sign of withdrawal measured.
3) CsA alters the expected effects of morphine and naloxone upon the sensory-evoked responses recorded from the superior colliculis and the medial basal hypothalamus.

These results indicate that CsA has direct actions on the brain, in addition to its well known immune-modulatory effects. In addition, these results suggest that the effects of CsA upon withdrawal behavior may be related to an alteration of opioid activities in hypothalamic and other subcortical structures.

254.15 NEURO-IMMUNOMODULATION, CENTRAL OPIOIDS AND THE IMMUNE RESPONSE TO VIRUS. J.R. Lee*, P.M. Dougherty*, K.J. Krajewski* and N. Dafny. Dept. of Neurobiology and Anatomy, and Dept. of Psychiatry and Behavioral Sciences, The Univ. of Texas Med. Sch. at Houston, P. O. Box 20708, Houston, TX 77225.

It was reported that Interferon-alpha (IFN), a family of glycoproteins associated with the immune response to viral infection, can alter CNS activity and thus may provide a means for the immune system to transmit information into the brain. For example, 150.0 IU IFN/g.b.w. injected systemically (i.p.) two hours prior to administration of 1.0 mg/kg naloxone in morphine-dependent rats results in a dramatic attenuation in the severity of the signs of opiate withdrawal. This same dosage of IFN (injected i.p.) alters the development of tolerance to morphine while not affecting its acute pharmacologic properties of anti-nociception, catalepsy and catatonia. The goal of the present report is to establish that these effects of IFN are due to direct alterations of opioid activities in the CNS. To this end, we undertook an investigation of the dose-response characteristics of varying dosages of IFN upon the severity of eight signs of naloxone-precipitated withdrawal, when injected directly into the brain via a previously implanted guide canula within the left lateral ventricle (i.c.v.), in 180-200 g male Sprague-Dawley rats made physically dependent upon narcotics by subcutaneous implantation of a 75 mg morphine base drug pellet. Since these methods are identical to our previous studies with systemically injected IFN, except for route of peptide administration, a comparison of the effect of i.p. versus i.c.v. IFN upon withdrawal severity precipitation by naloxone is also presented. The results of these two studies indicate the following:

1) IFN reduces opiate withdrawal severity in a "U"-shaped, dose-related manner upon direct administration into the brain.
2) Systemic administration of IFN is more efficacious than intracranial administration of the agent in reducing the severity of all eight signs measured.

These results indicate that IFN can indeed act directly upon the brain to alter CNS opioid activities. However, IFN has peripheral sites of action in addition to the brain which yield an enhanced alteration of opioid phenomena. This suggests that products of the immune response to viral infection can alter brain activity by both direct and indirect means and thus provide sensory immunologic information to the CNS.

254.16 **EFFECT OF PRENATAL ETHANOL ON ADULT OPIOID MEDIATED ANALGESIA.** **R.A. Baker, and W.J. Shoemaker. Neuroscience Program, Univ. of Connecticut Health Center, Farmington, CT 06032.**

Prenatal ethanol exposure produces a variety of behavioral, neuroanatomical and gross morphological changes. One such change is significantly higher levels of β endorphin in mid and hind brain regions of newborn rats (Shoemaker et al., 1983, Monogr. Neural Sci. 9:130). Previous studies using a tail-flick test have reported enhanced analgesia after foot-shock stress in rats prenatally exposed to alcohol (Nelson et al., 1985). In the present study two different forms of stress-induced analgesia (SIA) were employed: 24 hr. food deprivation and 5 minute room temperature swim (RTS). Analgesia was measured as latency to lick the hind paw on a hot plate at 55± .5°C measured with a hand-held stop watch. Pregnant rats were fed one of four diets from day 7 of gestation until delivery. One group (BSP) was pair fed the same liquid diet with a second (BSA) group whose diet was 5% ethanol. The other two controls received a more nutritious liquid diet and standard laboratory rat chow. All offspring were fostered to control mothers at birth and weaned at 28 days of age. Testing was performed at 3 to 4 months of age on a 17 by 19 cm hot plate in a 34 cm high clear plexiglass chamber at 55°C. No animal was tested more than once per day at any test condition. In all test situations, BSA male offspring showed the highest level of analgesia. That is, at baseline conditions, after 24 hour food deprivation stress and after a 5 minute forced swim in 21°C water, male animals prenatally exposed to ethanol had the longest latencies compared to pair-fed controls or to other well nourished control groups. Although females demonstrated similar baseline levels of analgesia and also similar quantitative responses to stress as the males, there were no differences among pre-natal ethanol exposed and several control groups in response latencies to any of the conditions in females. The 24 hour food deprivation stress, believed to generate an opioid mediated analgesic response (McGiven, et al., 1979), produced only a small increment in analgesic latency above baseline. Five minute forced swim at 21°C, another opioid mediated analgesic stress, produced more robust increases in paw lick latency (nearly double in most groups; more than double in BSA males). We found the latencies after RTS to be highest immediately following the swim (within 2 minutes) compared to assessments made at 15 minutes post stress. One interesting observation regards the sex differences seen in these antinociception tests. Similar to what we and others have observed in a variety of behaviors, the male-female differences between the prenatal alcohol offspring is much attenuated compared to controls

254.17 PERINATAL EXPOSURE TO MORPHINE INDUCES HYPERINNERVATION BY MET-ENKEPHALIN AND SUBSTANCE P NEURONS IN THE CNS. A.M. Di Giulio, B. Tenconi*, A. Mannavola*, P. Mantegazza*, °P. Restani*, °C.L. Galli* and °A. Gorio. Dept. of Medical Pharmacology and °Inst. of Pharmacological Sciences, Univ. of Milano, 20129 Milano, Italy.

The endogenous opioid systems seem to be implicated in the natural trophic regulation of the growth and development of the CNS. Evidence in support of this hypothesis has been gathered by in vivo and in vitro studies. The perinatal exposure to morphine or to its congeners causes a retardation in somatic and neurobiological development in human infants and in laboratory animals. In addition, cultured cells treated with narcotics or with opioid peptides show a clear reduction in growth rate. This effect is stereospecific and it is blocked by coadministration of narcotic antagonists. Recent data have shown an increase in brain size and an enhancement of proliferation of both neurons and neuroglia following the administration of naltrexone to newborn rats. All these data indicate that opiate receptors mediate a trophic response, an effect observed both in neurons and glia.

In order to gain more informations on the physiological role of the endogenous opiate system in the control of bra on, and in the attempt to understand the mechanism by which narcotics impair cell function and growth in the developing neural system, we have followed the development of enkephalin containing neurons in various brain areas of rats exposed to morphine during the fetal life and lactation. In the same experimental conditions, we have also monitored the development of substance P containing neurons. The results obtained indicate that the perinatal exposure to morphine markedly influences the rate of CNS development by causing a significant hyperinnervation by both met-enkephalin and substance P neurons, an effect particularly evident in the nucleus caudatus, cortex and pons-medulla oblongata. At birth the levels of both peptides are higher than normal in morphine-treated animals, and such a difference is magnified with growth.

254.18 ACUTE HYPOTENSIVE, BRADYCARDIC EFFECTS BUT CHRONIC PRESSOR ACTIONS AFTER INTRAVENOUS INFUSION(S) OF MORPHINE TO CONSCIOUS, UNRESTRAINED RATS. J.A. Thornhill, C. Townsend & L. Gregor. Dept. of Physiology, Univ. of Saskatchewan, Saskatoon, Sask. Canada, S7N 0W0.

Experiments were designed to (1) investigate and compare the hemodynamic (blood pressure, BP and heart rate, HR) changes in conscious unrestrained, male Sprague-Dawley rats following acute versus repeated intravenous (iv) infusion of morphine sulphate (MS) and (2) the possible receptor mechanisms mediating those acute and chronic responses. Conscious rats (~300 g) received an acute infusion (136 ul/min), via the femoral vein catheter (surgery done 48 hr prior under sodium pentobarbital anesthesia) of the following drugs: (A) sterile physiological saline for 15 min, followed by (B) morphine sulphate, BDH (1.47 mg/ml) for 15 min totalling 7.5 mg/kg then (C) naloxone HCl, DuPont Chemicals (0.735 mg/ml) for 10 min totalling 2.5 mg/kg. BP was monitored via femoral arterial catheter (into abdominal aorta) in conjunction with PD23ID BP transducer and Grass 7B polygraph. Chronic morphine responses were measured after the same iv infusion doses of morphine in rats previously given twice daily subcutaneous injections of MS (5 mg/kg) for 3 or 6 days before retesting. Other pretreatment studies were done whereby equimolar doses (0.35 umoles) of atropine, free base or phentolamine HCl were given iv 5 min before an acute or repeated infusion of MS. Acute MS infusion caused a transient but profound hypotension related to marked decrease in HR. After 1.0 min of MS infusion the bradycardia and hypotension lessened. Subsequent naloxone infusion caused an initial increase in MHR and mean arterial pressure (MAP) but after 5 min, BP and HR returned to control levels. Pretreatment with atropine blocked the acute bradycardic and hypotensive effects of MS. Infusion with the same dose of MS in the 3 day, chronically-treated MS group caused MAP to transiently increase over the first few minutes. Subsequent naloxone infusion 10 min later caused both MHR and MAP to rise again in this group. Animals previously injected for 6 days with MS showed a greater initial pressor response to the 7.5 mg/kg infusion dose of MS with MHR increasing during the latter stages of the 15 min period. Interestingly, chronic MS animals pretreated with phentolamine before iv infusion of MS had the subsequent pressor effects of MS blocked. These results suggest that the hemodynamic responses of conscious rats following acute versus repeated iv infusion of MS are different. The acute, classical bradycardic and hypotensive effects of MS are antagonized by muscarinic receptor blockers while the pressor actions of repeated MS infusion are antagonized by α receptor antagonists like phentolamine suggesting a possible vasoconstrictor action.

254.19 LOCOMOTOR ACTIVITY SHOWS PROGRESSIVE INCREASES FOLLOWING REPEATED EXPOSURE TO A STRESSOR SIMILAR TO THOSE OBSERVED FOLLOWING REPEATED EXPOSURE TO MORPHINE. M. Leyton* and J. Stewart (SPON: N. White). Center for Studies in Behavioral Neurobiology, Psych. Dept., Concordia Univ., Montreal, Quebec, Canada, H3G 1M8.

The present experiments were done to determine whether a parallel could be found between the progressive increases in locomotor activity observed following repeated exposure to morphine and the possible effects of repeated exposure to a stressor, and whether previous repeated exposure to a stressor would alter the locomotor responses to morphine.

Rats were exposed to 20-min. sessions of mild, inescapable foot-shock and were observed in this environment for a further 60 min. Immediately after shock animals displayed a freezing response (5 min.) followed by increasing activity that in the later part of the session exceeded that of a no-shock control group. Over five such sessions the initial freezing remained, but the period of hyperactivity progressively lengthened in duration.

Two weeks following this stress regimen these animals were tested in the absence of shock. At this time, previously shocked animals again displayed a freezing response that was followed by 20 min. of increased activity relative to the no-shock group. On subsequent tests animals were administered either 0.5 or 5.0 mg/kg i.p. of morphine sulphate and monitored for activity. Under the lower dose of morphine the difference between the previously shocked animals and the no-shock group was similar to that seen under saline. With the higher morphine dose, however, previously stressed rats were more active than the no-shock group throughout the entire period of observation.

To determine whether the changes in responsiveness to morphine might be observed in animals tested in an environment other than that in which they were shocked, other animals were exposed to 30 min. sessions of shock on consecutive days and monitored in a different environment 20 h. later. Shocked animals were found to be more active in the neutral environment than were animals in a no-shock group throughout the four post-shock test days. In subsequent tests given under saline and after repeated morphine injections this difference between groups was maintained. Thus, the stress-induced changes in locomotor activity were relatively permanent and not dependent on explicit re-exposure to the shock environment. In a final test given under saline, the non-shocked animals were found to display an activity profile strikingly similar to that which had been displayed by the previously shocked animals prior to their exposure to morphine. This comparison suggests that repeated exposure to either shock or morphine has similar effects on locomotor activity.

254.20 MORPHINE SELF-ADMINISTRATION, EEG AND BEHAVIOR IN MORPHINE POST-ADDICT RATS CHRONICALLY TREATED WITH METHADONE OR PENTAZOCINE. Gerald A. Young, Avraham Naharin* and Naim Khazan. Dept. of Pharmcol. and Toxicol., Univ. of Maryland Sch. of Pharm., Baltimore, MD 21201.

Previously, we found that morphine and methadone post-addict rats exhibited severe immediate abstinence, and a long-lived protracted abstinence reflected by abnormal EEG and behavioral arousal, rather than EEG slow-wave bursts and stuporous behavior, in response to morphine challenges (Psychopharmacologia 29: 271-276, 1973). Protracted abstinence has been ascribed as a major factor in relapse to opioid abuse. We also found that, in contrast to methadone substitution, ethylketocyclazocine (EKC) substitution for morphine in self-administering rats resulted in miminal signs of abstinence upon EKC withdrawal (Pharmacol. Biochem. Behav. 19: 711-713, 1983). Furthermore, EKC challenges in EKC post-tolerant rats demonstrated a lack of protracted abstinence (Eur. J. Pharmacol. 125: 265-271, 1986). Therefore, we hypothesized that kappa opioid maintenance in morphine post-tolerant rats, in contrast to methadone (mu) maintenance, might lead to a protracted abstinence syndrome of lower severity and to a lower tendency for morphine self-administration. Adult female Sprague-Dawley rats were made tolerant to and physically dependent on morphine by a series of automatic i.v. injections of increasing doses over seven days. After two weeks of morphine withdrawal, rats were given either a series of automatic i.v. methadone injections or automatic i.v. pentazocine (kappa) injections. Two weeks after withdrawal, all rats were returned to their experimental cages and given the opportunity to lever press for 10 mg/kg injections of i.v. morphine on an FR-1 schedule of reinforcement. Morphine self-injections in methadone post-tolerant rats produced primarially EEG and behavioral arousal. In contrast, morphine self-injections in pentazocine post-tolerant rats produced EEG slow-wave bursts and behavioral stupor. Thus, differences in protracted abstinence were found, while establishment of morphine self-administration was similar in the two groups. It is suggested that the use of a more complex schedule of reinforcement may reveal differences in morphine self-administration in the methadone vs. pentazocine post-tolerant rats. NEURONAL DEATH II

255.1 PRELABELED RED NUCLEUS AND SENSORY-MOTOR CORTEX NEURONS 10 WEEKS AFTER SPINAL CORD TRANSECTION. R.L. McBride, E.R. Feringa and J.N. Pruitt, II.* Veterans Administration Medical Center and Medical College of Georgia, Augusta, GA 30910.

Strategies to induce axonal regeneration of axotomized CNS neurons in adults must consider the time course of changes in those neurons. While our previous studies supported the hypothesis that red nucleus and sensory-motor cortex neurons die after spinal cord transection, the possibility remains that they survive in an inactive, atrophic state. A major problem in these studies is the positive identification of axotomized neurons mixed in larger neuron pools.

In this study we have prelabeled sensory-motor cortex and red nucleus neurons projecting to the lumbar enlargement with the retrogradely-transported fluorescent dye Fluoro-Gold (Fluorochrome, Inc.) prior to spinal cord transection. Ten 7 week-old female rats were anesthetized with ketamine and xylazine. Five ul of Fluoro-Gold was injected into the L-5 cord segment of each rat. Four days later, five of the rats were reanesthetized and the spinal cord completely transected at T-9. Ten weeks after transection all rats were anesthetized and perfused with saline followed by 10% formalin. Labeled neurons were counted on 30 um frozen sections using a fluorescence microscope. In the cortex, every fifteenth section was counted (7 sections per rat) and in red nucleus every other section was counted (22 sections per rat). In cortex, 1250.5±105.1 (mean ±SEM) neurons were counted in control rats and 1681.5±164.4 in transected rats. In red nucleus, 1631.2±147.6 labeled neurons were counted in control rats and 1401.8±118.6 in transected rats. Differences between control and transected rats are not statistically significant.

Three weeks after a T-9 spinal cord transection, we found no difference from controls in the number of sensory-motor cortex or red nucleus neurons prelabeled by an L-5 injection of Fluoro-Gold. Previous studies interpreted as showing cell death were based on greatly reduced anterograde (tritiated proline) transport, counts of cells labeled by retrograde HRP transport in areas containing axotomized neurons, and total neuron counts on H&E stained sections. The disparities in results of this experiment and previous studies could be due to an altered physiological state of the neurons. However, we are also investigating the possibilities that: (1) there are qualitative and/or quantitative differences in labeling by HRP and Fluoro-Gold at different spinal cord levels, or that (2) the injection of L-5 with Fluoro-Gold results in death of some neurons.

255.2 VENTRAL HORN MOTOR NEURONS 10 WEEKS AFTER SPINAL CORD TRANSECTION. E.R. Feringa, R.L. McBride, and J.N. Pruitt, II.* Veterans Administration Medical Center and Medical College of Georgia, Augusta, GA 30910.

In preliminary studies, based on counts of neurons on H&E stained sections, we reported loss of smaller ventral horn neurons of L-5 following a T-9 spinal cord transection in adult rats (J Neuropath Exptl Neurol 44:355, 1985). Subsequently, Eidelberg (Soc Neurosci Abst 12:1422, 1986) reported loss of large ventral horn neurons of L-5 after cord transection. This cell loss suggested that some neurons, deprived of descending input, died. This could be of clinical significance in amyotrophic lateral sclerosis and in efforts to provide functional recovery after spinal cord injury. Because we have been unable to confirm our earlier results, we again studied the fate of ventral horn neurons, this time labeling the motor neurons supplying the sciatic nerve prior to sacrifice.

We transected the spinal cord at T-9 in six seven-week old female rats anesthetized with ketamine and xylazine. Ten weeks later, under anesthesia, the right sciatic nerve of these rats and five age and sex matched isogeneic controls was severed above the popliteal fossa and the proximal cut end soaked for one hour in a 1% aqueous solution of the retrogradely transported fluorescent dye true blue (Sigma). Four days later the rats were deeply anesthetized and perfused with saline followed by 10% formalin.

Frozen sections, 30 um thick, of the L-5 cord segment were cut, mounted on slides and studied under a fluorescence microscope. Labeled neurons were counted on every fifth section (36 sections per rat). The mean number of labeled ventral horn neurons in control rats was 393.0±76.0 and in transected rats was 436.5±41.9. These studies fail to demonstrate a loss of ventral horn neurons supplying the sciatic nerve 10 weeks after spinal cord transection. Marked shrinkage of neurons could have resulted in miscounting of neurons in the earlier studies. We are currently using morphometric analysis of the labeled neurons to assess this possibility.

255.3 FATE OF MOTONEURONS AFTER LIMB AMPUTATION IN POSTNATAL MICE. L. Lee Crews* and Donald J. Wigston (SPON: J. Manning). Department of Physiology, Emory Univ. School of Medicine, Atlanta, GA 30322.

The response of motoneurons to injury is variable. Whether they degenerate or recover to restore function depends on the extent of the injury, the species of the animal, and its age. We have characterized the response of motoneurons to limb amputation in mice between postnatal day 14 (P-14) and adulthood because we are interested in the possibility that neurons continue to depend on peripheral targets for survival during postnatal development. Our protocol entailed labeling the motoneurons that project to the biceps brachii muscles in both forelimbs with a long-lasting marker, followed by unilateral amputation at the midhumeral level and subsequent examination of the labeled motoneurons.

Motoneuronal cell bodies were labeled by pressure-injecting the fluorescent retrograde tracer Fluoro-Gold (1 µL; 2%) into the biceps muscles of anesthetized mice at P-12, P-19, and in adulthood. Two days later, animals were reanesthetized and one forelimb was amputated. One to six weeks post-amputation, the animals were killed by intracardial perfusion of fixative. The spinal cord (segments C1-T3) was immediately dissected, sectioned frozen, and viewed with epi-illumination (Leitz A cube). Fluoro-Gold-labeled motoneurons on the amputated side were then compared with those on the uninjured side.

The result of this comparison, for all ages studied, was that the fluorescent motoneurons on the amputated side were both fewer in number and smaller than those on the unamputated side. In general, the younger the animal at the time of the injury, and the longer the post-amputational survival time, the greater the extent of motoneuronal atrophy and death. We believe the consistent response to injury of motoneurons within each age group will allow us to use this system as an in vivo assay for testing potential sources of growth factors that might affect motoneuron survival.

255.4 DO CORTICOSPINAL PROJECTION NEURONS DIE AFTER SPINAL TRANSECTION IN THE NEONATAL RAT? C.A. Bates and D.J. Stelzner. Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, NY 13210.

It has been demonstrated that axonal lesion in the immature animal can lead to extensive retrograde degeneration and cell death. A previous study analyzing cortical neuronal density suggests that the corticospinal projection system does not respond to axonal lesion in the immature animal with the loss of corticospinal projection neurons (Ramirez & Kalil, JCN:1985). We have looked more directly at the corticospinal projection neurons after axotomy.

0.5ul of Fluorogold (2%) or Fast Blue (2%) were injected bilaterally into the upper thoracic spinal cord of rats on postnatal day (PND) 3 or 4. On PND 6, the spinal cord was transected above the injection site between C4 and C6 and the animals were allowed to survive until the weanling stage. Control animals were sacrificed on PND 6/7 or allowed to reach weanling stage without transection. The animals were sacrificed by transcardiac perfusion with 10% formalin under ether anesthesia. The brain and spinal cord were sectioned at 30um and the sections viewed with epifluorescent light microscopy using UV light.

In all cases, there was extensive fluorescent labeling of cells in the parietal cortex of the rat. In animals sacrificed as weanlings, the cells are located in layer Vb and their areal distribution is similar to the normal distribution of corticospinal projection neurons in weanling controls. In animals sacrificed on PND 6/7, the areal distribution appears to extend more laterally than in either the normal or transected animals. These cells may be "destined" to die as suggested by Humphrey et al (Neurosci Abs:1986) or they may die as a result of damage to their axons incurred during the injection. Nonetheless, the "normal" areal distribution of corticospinal projection neurons in parietal cortex is unaffected by spinal transection. Although all corticospinal axons projecting to the injection site are severed, a large proportion of the neurons certainly survive. This differs from the rubrospinal system in which spinal hemisection in the neonate leads to a massive loss of cells in the red nucleus (Prendergast & Stelzner, JCN:1976). The survival of corticospinal neurons may be related to their ability to send collaterals to multiple targets during development. Alternatively, their axons may remain above the lesion site forming aberrant connections. Supported by NS079740 (CAB) and NS14096 (DJS).

255.5 A TEST OF THE COMPETITION HYPOTHESIS. EFFECTS OF SUPERIOR CERVICAL GANGLION LESIONS ON POSTNATAL TRIGEMINAL CELL DEATH. Tim O'Connor and Derek van der Kooy, Neurobiology Research Group, Dept. of Anatomy, University of Toronto, Toronto, Ontario, Canada. M5S 1A8.

The trigeminal ganglion provides the major sensory innervation for the cerebral vasculature and the superior cervical ganglion (SCG) provides the major sympathetic innervation of the same target. In the adult it has been suggested that transmitter levels in these two projections may be modulated by the competition for available nerve growth factor at the cerebral vessels. Many more trigeminal ganglion cells have axons projecting to the cerebral vasculature in neonatal rats than adults. Approximately 50% of the cells with neonatal prjoections die between posntatal day (PND) 5 and PND 90. We asked whether SCG lesions at birth could decrease postnatal trigeminal cell death as would be predicted by the competition theory. At the day of birth (PND 0) rats had their left SCG removed. At PND 3 True Blue (a fluorescent tracer that remains in labeled cell bodies for months without significant loss) was applied to the left middle cerebral artery (MCA). Rats were sacrificed at 5, 25, 55 and 90 days of age. Non-lesioned controls received the same PND 3 True Blue applications and the same survival times. A second group of SCG lesioned animals did not have True Blue applied to their left MCA until 2 to 4 days prior to sacrifice. This allowed determination of the number of trigeminal cells that had maintained axons innervating the MCA at the various times of sacrifice. A second group of non-lesioned siblings received the same True Blue applications 2-4 days prior to sacrifice.

Preliminary results suggest that SCG lesions do not prevent cell death, but instead may promote it. That is, more of the trigeminal cells that project to the MCA at PND 5 have died by PND 90 in the SCG lesioned animals compared to their non-lesioned sibling controls. However, more of the cells that survive in the SCG lesioned group maintain their axon projection to the vasculature compared to the non-lesioned group. In the non-lesioned group, fewer trigeminal cells die, but more of those that survive eventually retract their axons from the vasculature. Thus, a loss of the competition from the SCG does not prevent trigeminal cell loss, but prevents axon retraction from a population of surviving trigeminal cells that normally retract their axons. Thus, the loss of a competitive influence postnatally can result in two seemingly opposite effects. The loss of competition augments the amount of neuronal cell death and yet also permits maintenance of axons that the surviving perikarya normally retract. The augmentation of cell death contradicts the competition hypothesis, although the decrease in axon retraction supports its intent.

255.6 EARLY LOSS OF UBIQUITIN-PROTEIN CONJUGATE IMMUNOREACTIVITY PRECEDS DELAYED NEURONAL DEATH IN THE RAT HIPPOCAMPUS FOLLOWING TRANSIENT CEREBRAL ISCHEMIA. K.G. Magnusson and T.W. Wieloch, (SPON: S.R. Whittemore) Lab. for Exp. Brain Research, Lund Hospital, University of Lund, S-221 85 Lund, Sweden.

Ubiquitin is a small protein widely distributed in all eucaryotic cells, which has been demonstrated to participate in the ATP-dependent breakdown of proteins, and implicated as a factor in DNA transcription, thus playing a key role in cell survival.

Transient cerebral ischemia causes selective neuronal damage in certain areas of the brain, while other areas are resistant to the insult. In some areas such as the CA1 region of the hippocampus neuronal necrosis is not observed until several days postischemia. Although transmitter mediated processes have been shown to influence the developement of ischemic neuronal damage, the intracellular processes underlying these events are unknown.

We have studied the changes in ubiquitin-protein conjugate immunoreactivity (UIR) in rat brains subjected to reversible cerebral ischemia. Ischemia of a duration of 15 minutes was induced in male Wistar rats under isoflurane/nitrous oxide anesthesia, using the bilateral common cartotid occlusion model combined with hypotension. Following 0, 30 min, 2h, 6h, 24h, 48h, and 72h of recovery, the animals were perfusion fixed and sectioned on a vibratome. The sections were processed for immunochemsitry using a polyclonal antibody directed against ubiquitin-protein conjugates (gift from Dr A. Haas, University of Wisconsin, Milwaukee) and stained using the avidin-biotin-peroxidase method.

In normal control brains UIR was found in all neurons of the hippocampus. Cell body structures as well as dendrites were stained. During ischemia no marked changes were observed. Thirty min-2h following recirculation UIR was lost in the dendrites of the pyramidal and granule cells in the hippocampus. By 6h postischemia UIR in the cell soma vanished. In the dendrites of the dentate gyrus (DG) UIR recovered in the outer two thirds but was absent in the inner third of the molecular layer. Over the period of 1-3 days UIR recovered, first in the DG, then in the CA3 pyramidal neurons, and finally in CA2. CA1 neurons never recovered UIR at any time postischemia. In the early recovery phase the interneurons showed extensive UIR which persisted up to two days postischemia. Our data demonstrate:

1. A rapid loss of UIR postischemia in all hippocampal pyramidal and granule cells, while interneurons show a relative increase in UIR.
2. UIR recovers postischemia (DG>CA3>CA1) and is inversely related to the susceptibility of the neurons to ischemic damage (CA1>CA3>DG). The recovery within the dendritic field is laminated and correlated with the distribution of NMDA and adenosine A1 receptors.
3. UIR never recovers in irreversibly damaged neurons, and thus precedes delayed neuronal death.

We propose that the loss of UIR postischemia reflect a loss of ubiquitination of proteins. The postischemic loss of ubiquitination seems not to be due to lack of ATP but rather to a receptor mediated phenomenon. An irreversible loss of ubiquitination in the CA1 region could lead to an excessive accumulation of proteins (heat shock proteins, regulatory proteins), receptor dysfunction, and disturbances in DNA transcription leading to cell death.

255.7 DELAYED INTRAVENTRICULAR NGF INFUSION REVERSES AXOTOMY-INDUCED LOSS OF MEDIAL SEPTUM CHAT-POSITIVE NEURONS. T. Hagg*, H.L. Vahlsing*, M. Manthorpe, and S. Varon. Dept. of Biology, Univ. California San Diego, La Jolla, CA 92093.

Unilateral aspirative fimbria-fornix transection in the adult rat brain causes large reductions in the number of recognizable ipsilateral medial septum cholinergic neurons, i.e. neurons stainable for choline acetyltransferase (ChAT) or acetylcholinesterase (AChE). The cholinergic cell loss is accompanied by a substantial reduction in the number of cresyl violet stainable neurons. Several investigators have recently reported that Nerve Growth Factor (NGF) prevents most of the cholinergic cell number reduction and also some of the cresyl violet cell loss. The question addressed in this study was whether the disappearance of ChAT-positive neurons represents i) the actual death of the axotomized cholinergic neurons, which NGF infusion is able to prevent, or ii) a reduction in their ChAT (or AChE) content, which NGF might not only prevent but possibly also reverse. NGF or vehicle was continuously infused into the ipsilateral ventricle for 14 days beginning immediately, 7 or 14 days after fimbria-fornix transection. The rats were then examined at 7, 14, 21 and 28 days post-lesion for ChAT-positive medial septum neurons. In the absence of NGF treatment, the number of ChAT-positive neurons dropped to about 35% of contralateral, unlesioned numbers after 7 days and then to a baseline of about 15% after 14 days or longer. When NGF treatment was started immediately after fimbria-fornix transection, 75% of the ChAT-positive neurons survived. When treatment was begun on day 7 or 14, between 50% and 70% survived. Thus delayed administration of NGF causes an increase in the number of ChAT-positive neurons, indicating a reappearance of these neurons. These data suggest that the apparent loss of cholinergic neurons induced by the fimbria-fornix transection may be largely a loss of ChAT-stainability rather than actual neuronal cell death, at least within the time frames examined.

255.8 INHIBITORS OF PROTEIN SYNTHESIS AND RNA SYNTHESIS PREVENT NEURONAL DEATH CAUSED BY NERVE GROWTH FACTOR DEPRIVATION.

D.P. Martin, R.E. Schmidt, P.S. DiStefano, O.H. Lowry*, and E.M. Johnson, Jr. Dept. of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

A paradigm was developed to study the mechanism by which nerve growth factor (NGF) permits the survival of dependent neurons. Dissociated sympathetic neurons from E21 rats were grown in vitro for 7 days in the presence of 50 ng/ml 2.5S NGF. Cultures were then deprived of NGF by adding 1% polyclonal antiserum against NGF. The first changes appeared 18-24 hours after deprivation when the neurites became thin and discontinuous. By 30-36 hours about half the neuronal population had died and those that remained had small cell bodies which appeared dark under phase contrast microscopy. By 48 hours the culture dish was covered with degenerated neuronal debris and very few intact neurons. Replacement of the NGF at this point had no ameliorative effect and the debris gradually lifted off the dish over the next several days.

The earliest observable ultrastructural change was disruption of the neurites 12-18 hours after deprivation. The ultrastructure of the dying cell body was characterized by an accumulation of "lipid droplets", changes in the nuclear membrane, and dilation of the rough endoplasmic reticulum. Mitochondrial and lysosomal alterations did not appear to be critical factors.

The death of NGF-deprived neurons was characterized biochemically by assessing [^{35}S]methionine incorporation into TCA precipitable counts and by measuring the release of the cytosolic enzyme adenylate kinase into the culture media. Methionine incorporation began to decrease about 12 hours post-deprivation and was maximally depressed by 36 hours. Adenylate kinase began to appear in the culture media about 30 hours after deprivation, reaching a maximum by 54 hours.

Neuronal death caused by NGF deprivation was entirely prevented by inhibiting protein or RNA synthesis. Cycloheximide, puromycin, actinomycin-D, and ultraviolet irradiation all prevented neuronal death subsequent to NGF deprivation as assessed morphologically with phase contrast microscopy and biochemically by assessing methionine incorporation and adenylate kinase release into the media. Inhibitors of lysosomal function (leupeptin and chloroquine) did not prevent death. Protein or RNA synthesis must be inhibited within 12-15 hours of NGF deprivation to prevent cell death. Since at this time no morphological changes were observed, these results suggest that cells are "committed" to die prior to significant morphological change. We propose that NGF, and presumably other neurotrophic factors, maintain neuronal survival by suppressing an endogenous, active "death program".

255.9 ROLE OF CATALASE IN PROTECTION BY NERVE GROWTH FACTOR FROM HYDROGEN PEROXIDE. K. Werrbach-Perez*, L. Apffel*, G. Jackson* and J.R. Perez-Polo. Dept. of Human Biological Chemistry and Genetics, Univ. of Texas Medical Br., Galveston, Texas 77550

The nerve growth factor protein, NGF, has been shown to play a central role in the regulation of cell death phenomena for some neurons of the peripheral nervous system and lesioned neurons of the basal forebrain. NGF may also function in an immunoregulatory capacity and has been shown to act as a neurite promoting and tropic factor for some peripheral neurons.

It has been suggested that under in vitro conditions CNS neurons behave as if in a lesion induced state in terms of trophic dependence on the free radical scavenging enzyme catalase and also that there is a shift in energy metabolism for these cells resulting in a further dependence on catalase. Here we report that NGF protects the rat pheochromocytoma cell line PC12 and the human neuroblastoma cell line SK-N-SH-SY5Y from free radical induced death using 6-hydroxydopamine as a generator of quinones and hydrogen peroxide, a hydroxyl generator as well as hydrogen peroxide directly applied to the cells. Catalase mimics this effect in a specific fashion whereas superoxide dismutase has no effect and DMSO confers some partial protection. After screening several cell lines only those lines with neuronal properties were found to have relatively low levels of endogenous catalase and glutathione transferase activity. It was thus of interest to find that NGF specifically induces catalase and glutathione transferase activity but has no effect on superoxide dismutase levels in these cells and that this NGF protection is abolished by a small molecular weight inhibitor of the catalase enzyme. These results are in agreement with the hypothesis that under the metabolic conditions of tissue culture, NGF protects from peroxidative damage and subsequent cell death by inducing catalase. Whether similar events take place during early neuronal development and provide a mechanism for the regulation of neuronal cell death is not known but we would maintain that such a hypothesis is in agreement with our in vitro data.

255.10 NATURALLY OCCURRING SOMATIC MOTONEURON DEATH IN THE SPINAL CORD OF THE TURTLE EMBRYO (Chelydra serpentina). S. E. McKay*[1], R. R. Provine[2], and R. W. Oppenheim[1] (SPON: B. T. Troost). Dept. Anatomy, Wake Forrest Univ. Sch. of Med., Winston-Salem, NC 27103[1], and Dept. of Psychol., Univ. Maryland Baltimore County, Catonsville, MD 21228.[2]

The death of motoneurons in the spinal cord of the snapping turtle was described to learn more about neurogenesis in this rarely studied organism and to evaluate the generality of findings about motoneuron death from the widely studied chick embryo. Eggs were collected from clutches laid in the laboratory by eight wild caught females, and incubated at 30° C. Two to four embryos per age were sampled at 8-, 10-, 12-, 14-, 15-, 18-, 20-, 24-, and 60-days of embryonic age. (Hatching occurs at 60 to 70 days at 30° C.) Spinal cords were fixed in Carnoy's solution, sectioned at 8-12 µm and stained with thionine. Pycnotic (dying) cells in the ventral horn region were counted in every tenth section.

Pycnotic motoneurons were rare in pre-motile 8- and 10-day embryos. Pycnotic neurons were more numerous by 12 days, the age of onset of the first axial body movements, after which their numbers increased gradually until 15 days, the age of onset of limb movement. The number of dying motoneurons increased sharply between 15 and 18 days. After reaching a peak at 18 days, the number of pycnotic neurons declined gradually until 24 days. Pycnotic neurons were rare at 60 days, a few days before hatching. The above developmental trends in pycnotic motoneuron numbers were characteristic of brachial, thoracic, and lumbar cord regions.

It is significant that both the turtle and chick embryos experience substantial motoneuron death during the first half of incubation and that the peak rate of neuronal death coincides with the onset of limb movement. (For chick data, see Hamburger, V., and Oppenheim, R. W., Neurosci. Commentaries, 1 (1982) 39-55.) This concurrence of events in two organisms that differ so greatly in evolutionary history, morphology, physiology, locomotion, and length of incubation, suggests that the correlation between the onset of neuromuscular function, especially limb movement, and motoneuron death may be a general feature of vertebrate spinal cord development.

255.11 THE PREVENTION OF NATURAL MOTONEURON CELL DEATH BY SOMATOSTATIN. C.L. Weill. Depts. of Neurology and Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

Somatostatin (SRIF) appears in the spinal cord before the onset of synaptic transmission, and about 24 hr after the peak of natural motoneuron cell death. Thus, could SRIF regulate the extent of motoneuron cell death?

Chick embryos (Harco X Partmer red) were treated with SRIF on embryonic days 5 through 9 by daily injections onto the egg shell membrane, sacrificed on day 10, their body weight and embryonic stage determined, the lumbar spinal cord dissected, fixed in Carnoy's, stained en bloc, embedded in paraffin, and serially sectioned transversely at 10 um. All dark staining cells associated with the lateral motor column (LMC) containing at least one nucleolous were counted at 400 x. Uncorrected data are presented as the mean +/- SEM with n noted. Significance was assessed using the Mann-Whitney U-test and correlations assessed by evaluating Spearman's Rho.

The number of available motoneurons per LMC on embryonic day 6 is 22,838 +/- 731 (n=6). This number declines by 35% to 14,815 +/- 472 (n=16) by day 10. Treatment with 0.5 nmole of SRIF increased survival by 13.2% relative to control to 16,767 +/- 367 (n=9), while 2.5 nmole increased survival by 22.3% to 18,113 +/- 367 (n=7). Thus, SRIF prevents the death of 24.3% and 41.1% respectively, of those cells that would normally die by day 10. The increase in survival is statistically significant at the 95% confidence level; P=0.012 at 0.5 nmole and P=0.001 at 2.5 nmole. Body weight for controls was 2.417 +/- 0.039 gm (n=45) and for 0.5 nmole SRIF 2.717 +/- 0.064 gm (n=9, P=0.004) and 2.5 nmole, 2.580 +/- 0.034 gm (n=9, P=0.059). Toe length for controls was 5.13 +/- 0.03 mm (n=30) and for 0.5 nmole SRIF 5.22 +/- 0.05 mm (n=9, P=0.092) and for 2.5 nmole SRIF 5.24 +/- 0.05 mm (n=9, P=0.031). Thus, a significant increase in body weight was observed at 0.5 nmole of SRIF, while a significant increase in toe length was observed at 2.5 nmole of SRIF. The number of surviving motoneurons did not correlate with either body weight or toe length in controls, however body weight did correlate with toe length (rho = 0.6795, n=12, P=0.015). Cell number also did not correlate with either body weight or toe length with SRIF treatment, but body weight did correlate with toe length; 0.5 nmole SRIF, rho = 0.8809, n=9, P=0.002 and 2.5 nmole, rho = 0.9357, n=9, P<0.001.

These data demonstrate that SRIF at doses in the nanomolar range effect a statistically significant increase in the number of motoneurons that survive natural motoneuron cell death, thus suggesting a possible role for SRIF in motoneuron development. Supported by NIH grant NS18642.

255.12 REDUCTION OF NATURALLY OCCURRING MOTONEURON DEATH BY SERA FROM PATIENTS WITH DENERVATING DISEASE. L.J. Haverkamp, R.W. Oppenheim, S.H. Appel, D. Prevette, and J.L. McManaman. Dept. of Neurology, Baylor College of Med., Houston, TX 77030 and Dept. of Anatomy, Wake Forest Univ. School of Med., Winston-Salem, NC 27103.

Immune factors have been implicated in the pathogenesis of ALS, with the occasional reports of detrimental effects of ALS sera on cultured neurons supporting such an involvement. We have applied an in vivo system - naturally occurring cell death of motoneurons (MN) in the developing chick embryo - to the hypothesis of blood-borne factors acting upon motoneurons in ALS.

Sera from ALS and control patients, heat-inactivated and extensively dialyzed, were applied daily to the chorio-allantoic membrane from E6 through E9. On E10, the embryos' spinal cords were processed for histology and cell counts performed. Contrary to prediction, 5 of 11 ALS sera resulted in a significant rescue of motoneurons in the lumbar lateral motor column (LMC) during the cell death period. The active sera resulted in a range of 1500-4500 more motoneurons (N=4-5, $p<.05$ for each serum) compared to saline controls (MN number = $12\text{-}13 \times 10^3$). Counts of neurons in the DRG and symapthetic ganglia, and measurements of motoneuron nuclear diameters reveled no effect of active ALS sera on these parameters, while numbers of thoracic motoneurons were significantly increased and numbers of pyknotic neurons in the LMC significantly decreased.

This rescuing effect is not confined to ALS, however, but was also produced by 3 of 10 control sera so far tested. The active sera were obtained from patients with potentially denervating disorders, namely denervating polyneuropathy, and Guillain-Barre' and post-polio syndromes.

These results indicate that sera from a sizable proportion of patients with ALS and other denervating diseases may induce an alteration of normal motoneuron-target communication, possibly through effects on the levels of target-derived neurotrophic factors. In support of this possibility, we have also been able to ameliorate motoneuron death by applications of extracts of E9 chick embryo muscle.

255.13 **CELL DEATH IN THE DEVELOPING MOUSE CEREBELLUM: FURTHER STUDIES OF NUMERICAL MATCHING BETWEEN PURKINJE AND GRANULE CELLS IN +/LC CHIMERAS.** M.W. Vogel, K.Sunter*, and K. Herrup. Dept. of Human Genetics. Yale Med. School. New Haven, CT 06510.

Recent studies of neuron-target populations have emphasized the importance of quantitative matching as a rationale for naturally occurring cell death. Herrup and Sunter (J.Neurosci. ,7:829, 1987) found that the relationships between granule and Purkinje cells in sg/sg chimeras and inbred mice are colinear. In +/Lc chimeras, however, Wetts and Herrup (Dev. Brain Res., 10:41,1983) found up to a four-fold increase in the ratio of surviving granule to Purkinje cells over wild type values and proposed a curvilinear function relating granule to Purkinje cell numbers. Purkinje cells are a primary site of gene action in both mutants; however, while sg/sg Purkinje cells fail to develop granule cell synapses, +/Lc Purkinje cells degenerate beginning in the first postnatal week of development after synaptogenesis has begun. To clarify the role of these transient Purkinje:granule cell relationships, we have counted both cell types in sagittal sections of 14 additional half-cerebella of +/Lc chimeras and +/+ and +/sg control chimeras.

The granule to Purkinje cell relationships in inbred mice and in sg/sg and control chimeras were found to be colinear. Linear regression of the combined control and sg/sg chimera data shows that the y-intercept is not significantly different from zero ($P>0.05$). The analysis of additional +/Lc chimeras, however, revealed that the relationship between Purkinje and granule cells in the +/Lc chimeras is also best described as linear ($R^2=0.94$). The slopes for the regression equations of +/Lc chimeras and the sg/sg chimeras are not significantly different ($P>0.05$). This result suggests that the numerical matching between granule and Purkinje cells follows the same function in both experimental situations. However, the Y-intercept of the +/Lc chimera line falls at 7.2 million granule cells. The implication of this is that this number of granule cells are present in every +/Lc chimera in addition to those present due to numerical matching. These data are consistent with two hypotheses. First, the increased survival of granule cells may reflect a pleiotropic effect of +/Lc gene action that allows increased granule cell survival. Second, Caddy *et al* (Neurosci. Abst. 12:1583, 1986) have shown that the dendrites of wild type Purkinje cells in +/Lc chimeras appear de-afferented. The increased granule cell survival may reflect a Purkinje cell deafferentation response that allows increased granule cell survival.

255.14 EVIDENCE OF WEAVER GENE ACTION IN THE PREMIGRATORY GRANULE CELL. R. Smeyne and D. Goldowitz. Dept. of Anatomy, Thomas Jefferson University, Philadelphia, PA 19107

Neurological mutants provide a useful tool to study development. By analyzing abnormal phenotypic expression of mutant genes, one can dissect out important developmental events. One such mutant is the homozygous weaver mouse (wv/wv) which is characterized by a loss of granule cells. The granule cell loss is attenuated in the heterozygous weaver mouse (wv/+). It has previously been shown that the granule cell is a primary site of gene action. The cause of the weaver granule cell death is unknown, although it has been speculated that the granule cell death is due to the cells' inability to migrate from the proliferative external granule layer (EGL) to the internal granule layer. The purpose of this study is to isolate a time-point when the weaver granule cell phenotype is first expressed, thereby suggesting the mechanism by which granule cells die.

From the day of birth (PO) through post-natal day 8 (P8), wv/wv, wv/+, and +/+ mice were deeply anesthesized and perfused with modified Bouin's solution. Brains were removed, dehydrated, blocked in the midsagittal plane and embedded in paraffin. Serial sections were cut at 6 u and every 20th section was mounted and stained. The sections were analyzed for total cerebellar area, total area of the EGL, total number of cells in the EGL, number of mitotic figures in the EGL, and number of dead/dying cells in the EGL.

Examination of the sections revealed that as early as P4, significant differences were found between the three genotypes in all parameters studied except for the number of mitotic figures. At P2, the only significant difference found between genotypes was the number of dead/dying cells found in the EGL. This difference was also seen at PO.

The defect seen in the weaver mutant mouse has been described as a migration defect. In this study, the three different genotypes (wv/wv, wv/+, and +/+) can be differentiated as early as PO based upon the percentage of dead/dying cells present in the EGL. Since granule cell migration begins around P4, the ability to delineate differences between the 3 genotypes prior to the start of granule cell migration suggests that the impaired granule cell migration is not the first step which is affected by the weaver gene. Prior to migration, the granule cell must undergo its terminal differentiation, which includes exit from the cell cycle as well as process extension. This study suggests that the weaver gene may cause one of these earlier developmental processes to go awry.

256.1 DEVELOPMENTAL EXPRESSION OF CHOLINE ACETYLTRANSFERASE IN DROSOPHILA. L.A. Carbini*, V.J. Maines* and P.M. Salvaterra. Division of Neurosciences, Beckman Research Institute/City of Hope, Duarte, CA 91010.

Genes and the action of their products can potentially be regulated at a number of different control points. In this study we have measured the steady state levels of choline acetyltransferase (ChAT) mRNA throughout the developmental stages of Drosophila. We have also determined the levels of ChAT protein by Western blots and the amount of enzyme activity at the same developmental stages and compared these parameters with the mRNA levels.

Total RNA samples were used for Northern or dot blot analysis and probed with a ChAT specific cRNA. ChAT mRNA could be detected approximately 6-7 h after oviposition and the maximum amount of ChAT mRNA was found in 24-25 h old organisms. ChAT mRNA decreased by the 3rd larval instar, increased during late pupation and decreased again in adult flies. The relative proportions of ChAT mRNA in 1st larval instar, 3rd instar, pupae, and adult were 1: 0.6: 0.9: 0.3 when expressed per organism. Northern analysis showed a single major RNA band with a Mr of approximately 5.0 Kbase pairs and two minor bands of 9.0 Kb and 11.0 Kb (probably pre-spliced mRNA) in all developmental stages.

A pattern of increasing activity was observed throughout development. A sharp increase was seen from the 1st larval instar up to the 3rd larval instar with a less marked increase in the pupal and adult stages. In contrast to ChAT mRNA levels, no decrease was observed for ChAT activity during pupation. This may reflect the relative turnover rates of mRNA and protein. Western analysis of ChAT polypeptides showed a single major protein band with a Mr of 75 Kdaltons throughout development.

The single size observed for ChAT mRNA and protein throughout development make it unlikely that regulation occurs by splicing or postranslational modifications. If ChAT protein turnover is slower than mRNA turnover, the enzyme activity levels seem to reflect the availability of mRNA which may indicate that the major control point for active ChAT expression is at the level of transcription. Supported by NIH-NINCDS.

256.2 **REGULATION OF CHOLINE ACETYLTRANSFERASE ACTIVITY IN CULTURED EMBRYONIC RAT SPINAL CORD.** D. Lombard-Golly*, A. Chalazonitis and J.A. Kessler. Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neuronal development and neurotransmitter expression are influenced by the environment of the neuron. The present study was undertaken to define factors regulating development of cholinergic spinal cord neurons, and to determine whether the two principal populations of cholinergic spinal cord neurons, motor neurons and intermediolateral autonomic neurons, are regulated by the same factors. Levels of the biosynthetic enzyme, choline acetyltransferase (CAT), were examined in dissociated cell cultures of embryonic rat spinal cord to define cholinergic development. Initial experiments determined that optimal neuronal survival was achieved using embryos at day 14.5 of gestation, and all subsequent studies used spinal cords at this stage. During the first week of culture, CAT activity was strikingly dependent upon cell density. Cultures established with $0.75x10^6$ cells per 35 mm dish contained no detectable CAT activity after 7 days in culture, whereas cultures established using 10^6 cells contained 1.14 nmol product per mg protein per hr (nmol/mg/hr), and cultures using $1.5x10^6$ cells contained 2.09 nmol/mg/hr. However, by 14 days CAT activity was almost identical (2 nmol/mg/hr), at all three densities. Thus the differences in CAT activity in younger cultures apparently reflected density dependent differences in regulation of CAT rather than differences in cholinergic neuron survival. Development of CAT activity was examined in cultures of ventral (motor neuron enriched) and mediodorsal (intermediolateral neuron enriched) spinal cord. Levels of CAT were high in ventral cord cultures (3.3 nmol/mg/hr after 14 days in culture) compared to whole cord cultures, whereas levels of CAT in mediodorsal cultures were extremely low (0.47 nmol/mg/hr). Current studies are directed towards defining differences in regulation of CAT activity and cholinergic neuron survival in cultures of ventral versus mediodorsal spinal cord.

256.3 **CHARACTERIZATION OF A MEMBRANE ASSOCIATED MOLECULE WHICH STIMULATES CHOLINERGIC AND PEPTIDERGIC TRANSMITTER EXPRESSION IN SYMPATHETIC NEURONS.** V. Wong and J.A. Kessler. Depts. Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neuronal contact with other cell membranes and with extracellular matrix (ECM) plays an important role in regulating neuronal growth and development. The present study was undertaken to characterize cell surface molecules that influence cholinergic and peptidergic transmitter expression. Treatment of cultured sympathetic neurons with membranes prepared from adult rat spinal cord stimulated levels of choline acetyltransferase (CAT) activity and induced substance P (SP). The active molecule was extracted from spinal cord membranes by 4M NaCl, suggesting that it is a membrane associated molecule. Treatment of sympathetic neurons with the 4M NaCl extract of this membrane-associated neurotransmitter stimulating molecule (MANS) for 1 week increased CAT activity 5-fold and induced SP to a level of 23 fg/neuron. Moreover, simultaneous treatment with nonneuronal cell-derived soluble factors strikingly facilitated the effects of MANS on both CAT activity and SP expression (see Kremer, Wong, and Kessler, this volume). Tyrosine hydroxylase (TH) activity in the same cultures was not affected. MANS increased CAT activity in a dose dependent manner, effective at a dose as low as 800ng/ml and achieving saturation at 3.25ug/ml. MANS was also solublized from spinal cord membranes by 100mM octylglucoside (OG), but not by 50mM OG or 0.1% Triton. CAT-SP-stimulating property of MANS was destroyed by treatment with trypsin or heat-inactivation, but was stable at 37 C. Testicular hyaluronidase, a glycosidic enzyme, also destroyed MANS activity. Our observations suggest that MANS is a membrane associated molecule with an active site that appears to include 2 domains: (1) a protein which is sensitive to trypsin, and (2) a glycosaminoglycan (GAG) which is sensitive to hyaluronidase.

256.4 **FACILITATORY INTERACTIONS BETWEEN SOLUBLE AND MEMBRANE-ASSOCIATED TRANSMITTER STIMULATING FACTORS OCCUR AT THE mRNA LEVEL.** N.E. Kremer, V. Wong, J.A. Kessler. Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neurotransmitter phenotypic expression is influenced by the environment of the neuron. The present study examines facilitatory interactions between soluble and membrane-associated factors in the regulation of sympathetic neuron transmitter expression. Previous studies have shown that coculture of sympathetic neurons of the rat superior cervical ganglion (SCG) with ganglion non-neuronal cells induces expression of substance P (SP, Kessler, 1984) and elevates choline acetylytransferase (CAT) activity (Patterson and Chun, 1974). Treatment of cultured sympathetic neurons with plasma membranes derived either from ganglion non-neuronal cells or from spinal cord also induced SP expression and elevated CAT activity, indicating that neuronal contact with other membranes regulated transmitter expression. Treatment of sympathetic neurons with medium conditioned by ganglion non-neuronal cells or with rat fibroblast conditioned medium (RFCM) increased CAT activity but failed to induce expression of SP. Simultaneous treatment with membranes and RFCM resulted in a striking facilitatory increase in both SP and CAT.

A membrane-associated neurotransmitter stimulating molecule (MANS) which mimics the presence of non-neuronal cells (cf Wong and Kessler, this volume) has been solubilized from rat spinal cord membranes. Treatment of sympathetic neurons with MANS induced SP expression and elevated CAT activity. Treatment with both MANS and RFCM synergistically elevated levels of both SP and CAT. This facilitatory interaction was clearly seen at the mRNA level. Preprotachykinin (PPTI, encoding substance P) mRNA was measured using Northern blot analyses. Pure neuronal cultures contained no detectable PPTI mRNA, whereas neurons cocultured with non-neuronal cells had high levels of the mRNA. Pure neuronal cultures treated with RFCM also did not contain PPTI mRNA, but RFCM potently increased mRNA levels in neurons cocultured with non-neuronal cells. Treatment of pure neuronal cultures with MANS induced PPTI mRNA reproducing the effects of non-neuronal cells, and simultaneous treatment with RFCM and MANS resulted in further increases in mRNA levels.

Thus neuronal contact with other membranes or with MANS induced expression of SP and elevated CAT activity. Soluble factors in RFCM also increased CAT activity but did not induce SP expression. However, RFCM strikingly facilitated the effects of membrane contact or MANS treatment on both SP expression and CAT activity. These observations indicate that the effects of soluble factors and cell-cell contact interact in determining neurotransmitter expression.

256.5 LOSS OF THE CAPACITY OF INTRINSIC ENTERIC NEURAL PRECURSORS TO EXPRESS A CATECHOLAMINERGIC PHENOTYPE IS CORRELATED WITH INVASION OF THE DEVELOPING CHICK GUT BY SYMPATHETIC NERVES T. P Rothman, H. M. Mackey*, and M. D. Gershon. Department of Anatomy and Cell Biology, Columbia Univ., Coll. of P & S, New York, NY 10032.

The adult enteric nervous system (ENS) contains noradrenergic sympathetic axons derived from neurons located outside the bowel; however, there are no intrinsic catecholaminergic neurons. On the other hand, transient catecholaminergic (TC) cells can be found in the enteric mesenchyme during development of the mammalian, but not the avian gut. These TC cells disappear from the mammalian bowel on the day the sympathetic innervation reaches the developing bowel. The current experiments were done to assess the catecholaminergic potential of avian enteric neural precursors and to determine whether this capacity is lost coincidentally with the arrival of the sympathetic nerves in the gut. We tested the hypothesis that crest cells that colonize the avian bowel are able to express a catecholaminergic phenotype, but fail to do so when they develop within the enteric mesenchyme. Accordingly, the chick small intestine (days E7-E9) was dissociated with trypsin (0.25%) in Ca^{2+}/Mg^{2+}-free solution and the separated cells were plated on collagen and grown *in vitro*. Cultures were grown in an enriched medium containing chick embryo extract (10%) and horse serum (20%). As noted previously (Mackey et al., 1986), many cells from day E7 bowel expressed tyrosine hydroxylase immunoreactivity (TH-IR). TH-IR was not expressed by cells in similar cultures from gut dissociated at days E8 or E9. The timing of the arrival of the sympathetic nerves in the bowel *in situ* was studied radioautographically, following incubation of tissues with ^{3}H-norepinephrine (^{3}H-NE; 0.02-0.2 μM) in the presence of the MAO inhibitor, pargyline (0.1 mM). At day E 7 no nerves were labeled in the foregut or in its surrounding connective tissue. At day E8, ^{3}H-NE labeled nerves in the connective tissue dorsal to the esophagus, gizzard, small, and large intestines. Moreover, labeled nerves were also found within the dorsal mesenchyme of the developing gizzard, intestines, and pancreas. Labeling did not extend fully around the circumference of the gut at any level. Neural uptake of ^{3}H-NE was antagonized by desmethylimipramine (1-100 μM). Intensity of neural labeling was concentration-dependent, but extraneuronal labeling was seen in tissues incubated at the higher concentration of ^{3}H-NE (0.2 μM). Extraneuronal, but not neuronal, labeling was inhibited by normetanephrine (10 μM). By day E9, ^{3}H-NE-labeled nerves were found in both myenteric and submucosal plexuses around the entire circumference of the bowel, although labeling was much more intense in the caudal than proximal intestine. It is concluded that crest cells that migrate to the avian gut are capable of expressing a catecholaminergic phenotype, although they do not do so *in vivo*. This capacity can be revealed by dissociating the bowel and growing the enteric neural precursors out of the enteric microenvironment, *in vitro*. As in mammals, the ability of avian crest cells to express a catecholaminergic phenotype is lost coincidentally with the arrival of sympathetic nerves in the gut. These observations are consistent with the idea that sympathetic nerves influence phenotypic expression by enteric neural precursors. Supported by NIH grants, HD 21032, HD 20470, NS 15547, and by the MOD (1-747) and the Robert Wood Johnson Fdn.

256.6 IN SITU HYBRIDIZATION OF mRNA FOR PREPROTACHYKININ (PPT) AND SOMATOSTATIN (SOM) IN ADULT RAT DORSAL ROOT GANGLIA (DRG). Deborah B. Henken[1], Alan Tessler[1,2], Marie-Francoise Chesselet[1], Alan Hudson[2], Frank Baldino, Jr.[3], and Marion Murray[1]. [1]The Medical College of Pennsylvania, Philadelphia, PA, [2]Philadelphia VA Hospital, Philadelphia, PA, and [3]E.I. Dupont Co., Wilmington, Delaware.

Peptide synthesis is regulated by transcriptional and translational mechanisms. As a first step in distinguishing these mechanisms we have compared the distribution of mRNA's for specific peptides with the existing immunocytochemical evidence. Immunocytochemical techniques permit the localization of peptides within discrete populations of DRG neurons and have served as useful methods for examining the regulation of neuronal metabolism during regeneration. DRG neurons are commonly subdivided into small and large; peptidergic neurons are among the small neurons. We have used hybridization probes to identify the neurons which contain mRNA for the precursors of the tachykinins substance P and substance K (preprotachykinins, PPT) and for somatostatin (SOM). For PPT, antisense (test) and sense (control) RNA probes were labelled with ^{35}S-UTP during transcription from cDNA's cloned from a human brain library in an SP6-containing vector (Affolter et al., 1986). The cDNA fragment was a 345 base region containing exons 2 through 6 of the PPT gene. For SOM, a 39-base synthetic oligonucleotide probe complementary to the 3' coding region of SOM_{28} mRNA, was 3'-end labelled with a-^{35}S dATP and terminal transferase. Following in situ hybridization, specific mRNA-containing neurons in lower lumber DRG of young adult Sprague-Dawley rats (200-250 gm) were visualized with light microscopic autoradiography. Neurons which contained the mRNAs in each DRG were mapped and the areas of both labelled and unlabelled neurons were measured. The antisense probe for PPT mRNA labelled an average of 17% of the total cell population. No somata were labelled with the sense probe. The average cell area for the labelled population was 420 um^2. The synthetic oligonucleotide for SOM mRNA labelled 10% of the total cell population with an average cell size of 560 um^2. Both these populations are in the size range of small DRG neurons. However, cells that contain PPT mRNA are significantly smaller then those that contain SOM mRNA (Student's T-test; $p<.05$), in agreement with previous studies using immunocytochemistry (Price, 1985). These results suggest that immunocytochemical methods for localizing PPT and SOM can be correlated with in situ hybridization for localizing PPT and SOM mRNA's and that these techniques can be used to study the mechanisms that regulate metabolic changes.

256.7 THE DEVELOPMENT OF AXONS CONTAINING TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN THE SPINAL CORD OF THE NORTH AMERICAN OPOSSUM, DIDELPHIS VIRGINIANA. R.R. Pindzola, R.H. Ho, and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210.

We have previously used the peroxidase antiperoxidase technique (PAP) to study the distribution of tyrosine hydroxylase immunoreactive axons (presumably catecholaminergic) in the spinal cord of the adult opossum (Pindzola et al., Neurosci. Abstr., 12: 1547, 1986). In addition, we have combined retrograde labelling methods with immunohistochemistry to determine the origin of these axons. The results of those studies have been used as endpoints for developmental analysis.

Opossums are born 12 days after conception, in a very immature state. At birth, axons showing tyrosine hydroxylase immunoreactivity (TH), using the PAP method, are present in the spinal cord where they are limited primarily to the marginal zone. Such axons appear most numerous in the dorsolateral marginal zone, the region containing most of them in the adult animal. By postnatal day (PND) 6 (24 mm snout-rump length, SRL), TH axons are obvious in the intermediate zone and some are found within the presumptive intermediolateral cell column. A few TH axons are found in the developing dorsal and ventral horns by estimated PND 15 (35mm SRL). By estimated PND 44 (76 mm SRL), the pattern of TH innervation in the spinal cord resembles that in the adult. The density of TH axons at some stages of development appears greater than in the adult.

At birth TH cell bodies are present in most, if not all, of the brainstem areas providing TH projections to the spinal cord in the adult animal (Pindzola et al., Neurosci. Abstr., 12: 1547, 1986). Since there are few TH perikarya in the spinal cord at birth, we assume that most of the TH axons in the spinal cord originate within the brainstem. TH perikarya are found more frequently in the spinal cord at estimated PND 10 (28 mm SRL) and they become even more numerous and widespread at later ages before diminishing to adult levels.

In summary, our results suggest that: 1) TH axons of brainstem origin are present in the spinal cord of the newborn opossum, and 2) TH axons innervate the developing grey matter over an extended period of time. These data, considered in light of those published previously on the development of serotoninergic projections to the spinal cord (DiTirro et al., J. Comp. Neurol., 213: 241-261, 1983), indicate that monoaminergic axons are among the first from the brainstem to reach spinal levels. Even so, anatomical evidence for direct control over postsynaptic targets occurs considerably later. (Supported by NS-10165)

256.8 MOLECULAR SPECIES OF SOMATOSTATIN IN DEVELOPING RAT RETINA. D.M. Ferriero and S.M. Sagar. Neurology Service, V. A. Medical Center and Department of Neurology, University of California, San Francisco, CA 94143.

Somatostatin (SLI) has been found by radioimmunoassay (RIA) and immunocytochemistry (ICC) in the retina of many vertebrate species. In the rat and rabbit the major species of SLI present is somatostatin-14 (SS-14). In the guinea pig and cow, the major species is somatostatin-28 (SS-28) and in the fish and chick, there are equal amounts of both forms. The functional implication of the species differences in chromatographic patterns is unknown; in particular, it is unknown whether the SS-28 species or any other fragment of the prosomatostatin molecule has a function different than that of SS-14. In the guinea pig SS-28 is the only species present from embryonic through adult life. In the chick the molecular forms differ in the embryo from the adult. It is unknown currently which species predominates in the fetal rat retina, or whether the species changes as development proceeds.

We have previously shown that SLI appears as early as E16 in high quantities (4.5 ng/mg protein) and decreases to barely detectable levels at an early postnatal age (P4 = 0.09 ng/mg protein); gradually returning to adult levels (0.46 ng/mg protein) after eye opening. Gel permeation chromatography was performed on retinal extracts corresponding to the above developmental times to address the issues of molecular species preservation through ontogeny. We have found that there are three forms present at E16: a large MW species, SS-28 and SS-14. This is true at E19 as well, but at P4, the SS-14 disappears completely. In the adult retina, there is a large MW species present, with SS-14, but no SS-28, as previously reported.

Therefore, there is a switch during retinal development from SS-28 and SS-14 to SS-14 only in adult retina, with a transient phase of SS-28 expression only at a time when SLI is barely detectable by ICC and RIA. Possibly, differential gene processing or other posttranslational events generate different products during development to cue the developing retina. The relationship of the switch (SS-28 → SS-14) and the decline of SLI prior to synaptogenesis is intriguing and may illustrate a developmental role for SLI.

256.9 CHANGES IN THE IMMUNOSTAINING PATTERN OF CHICK SPINAL CORD 5-HT NEURONS GROWN IN CULTURE OVER DIFFERENT LENGTHS OF TIME. R.R. Maez*, P.C. Allgood* and J.A. Wallace (SPON: G. Wild). Dept. of Anatomy, University of New Mexico School of Medicine, Albuquerque, NM 87131.

Serotonergic (5-HT) neurons are found in the spinal cord of chick embryos from 7 days of incubation (E7) through hatching (E21). In a detailed study of the number of 5-HT neurons in the chick spinal cord at different embryonic ages, we have reported changes in the number of anti-5-HT immunostained cells during embryogenesis (Brain Res. Bull. 17:297, 1986). Changes in 5-HT cell numbers include a drop of over 40% of total cord 5-HT cell counts determined at E17 from the plateau of approximately 3,500 5-HT neurons that were estimated to occur from E9 to E12. Subsequent to E17, 5-HT cell counts increased at the time of hatching back to the values obtained for the earlier ages, suggesting that the reduced number of spinal cord 5-HT cells detected at E17 was not due to cell death. Here we report initial qualitative observations on changes in the immunostaining patterns of spinal cord 5-HT neurons grown in vitro over two time periods that would approximate the in ovo ages where the 5-HT cell counts in the chick spinal cord would be at their early plateau or at their later reduced levels. For comparison with other central 5-HT neurons, cultures of chick embryonic brainstems were grown for similar time periods under identical culture conditions. Spinal cords from embryos at E8, or brainstems from animals at E6, were removed and dissociated with trypsin. Cells were plated onto four-chambered Lab-Tek Tissue Culture glass slides coated with collagen, at a density of 5 x 10^5 cells per chamber. The slides were incubated with 5% CO_2 and air at 37°C, and cultured for either 5 or 10 days. The cultures were then fixed and stained by anti-5-HT immunocytochemistry using the ABC peroxidase technique. Spinal cord and brainstem cultures incubated for 5 days demonstrated deeply-stained 5-HT neurons of various morphologies. In contrast, spinal cord cultures incubated for 10 days possessed numerous examples of dark, immunostained axonal endings that were connected either to unstained or to only very lightly-stained cell bodies. This specific anti-5-HT staining pattern was rarely encountered within spinal cord cultures incubated 5 days or within brainstem cultures incubated for 10-12 days. The frequent occurrence of cultured spinal cord cells which do not fully express the 5-HT phenotype in their perikarya, yet have 5-HT immunostaining in their axonal processes, may mimic the in ovo situation at E17, wherein fewer spinal cord 5-HT cell bodies could be detected immunocytochemically. These findings may provide an in vitro model to study factors regulating neurotransmitter phenotype expression in neurons of the CNS. Supported by NSF grant BNS-8511079 and NIH grant RR-08139.

256.10 CHARACTERIZATION OF A NEURECTODERMAL SEROTONINERGIC CELL LINE. H. Tamir, M. D. Gershon, S. H. Hsiung, and K. P. Liu. NYS Psychiat ric Inst. and Dep'ts. of Psychiatry and Anatomy and Cell Biology, Columbia University, P&S, New York, NY 10032

The parafollicular (PF) cell of the thyroid gland is embryologically derived from the neural crest. In adults, PF cells contain calcitonin and also, in some species, serotonin (5-HT), calcitonin gene related peptide (CGRP), and somatostatin. PF cells have been isolated from sheep thyroid. The secretory vesicles of these cells co-store calcitonin and 5-HT and contain, in addition, a 45 kDa protein that specifically binds 5-HT (SBP). The same protein is found in serotoninergic neurons in the brain and in the gut. Since enteric serotoninergic neurons and thyroid PF cells are derived from the same region of the neural crest (vagal), it is possible that the two types of cell arise from a common precursor that expresses an endocrine phenotype when it develops in the thyroid and a neural phenotype when it develops in the bowel. The recent observations that PF cells are induced to extend neurites and to exress CGRP in preference to calcitonin when treated with nerve growth factor (NGF) supports this hypothesis. Moreover, following treatment with NGF, PF cells do not survive unless grown on enteric smooth muscle. Since further analysis of the plasticity and serotoninergic neural potential of PF cells would be greatly facilitated if experiments could be done on an appropriate cell line, we characterized the neural and serotoninergic properties of human medullary (PF-derived) thyroid carcinoma cells (TT cells, first isolated by Leong et al.). TT cells were grown on plastic in an enriched medium containing 10 % fetal bovine serum. The cells were found to display calcitonin, CGRP, somatostatin, and 5-HT immunoreactivities, but they did not contain substance P. The cellular concentration of 5-HT was measured in washed cells by high pressure liquid chromatography and was found to be 1-5 fg/cell. When incubated with ^{3}H-5-HT (1.0 μM), TT cells concentrated the amine (~5- to 25-fold). This uptake was inhibited by fluoxetine and zimelidine (1.0 μM), specific inhibitors of the neuronal uptake of 5-HT. When incubated with ^{3}H-L-tryptophan (50 μM), TT cells produced ^{3}H-5-HT and ^{3}H-5-hydroxyindoleacetic acid; therefore, TT cells must contain both tryptophan hydroxylase and monoamine oxidase. TT cells also were found to contain a ~45 kDa SBP (binds ^{3}H-5-HT; K_{D1} = 8 nM; K_{D2} = 23 nM). ^{3}H-5-HT binding to TT cell SBP was inhibited by 1.0 μM reserpine, 140 mM Na^+, 1.0 mM Ca^{2+}, and 1.0 μM thiol reagents. These properties are similar to those of neural SBP. The SBP of TT cells also cross-reacted with antisera generated against 45 kDa SBP purified from rat brain and could be shown in TT cells by immunocytochemistry. It is concluded that cultured TT cells express serotoninergic neural properties, not all of which (uptake of ^{3}H-5-HT) are expressed by PF cells *in situ*. Supported in part by grants NIMH 37575; NS12969.

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT I

257.1 VITAMIN A-INDUCED SUPPRESSION/ENHANCEMENT OF PROTEIN GLYCOSYLATION AND NEURULATION. Y. Ersahin*, L.I. Nelson*, R.G. Higbee, D.G. McLone, and P.A. Knepper. Division of Neurosurgery, Children's Memorial Hospital and Northwestern University Medical School, Chicago, IL 60614.

Glycoconjugates play major roles in critical cellular functions, e.g., cell migration and cell-to-cell adherence, which are involved in neural tube closure. Previous studies from our laboratory reported biochemical methods for isolating neuroepithelium before, during, and after completion of neurulation (Johnson et al., Neuroscience Abstr., 12:1360, 1986). In this study, the effects of maternal administration of Vitamin A on protein glycosylation were correlated to the process of normal and abnormal neurulation. Pregnant mice were given IP injections of 1,000 or 5,000 IU of Vitamin A (Aquasol parenteral; USV Pharmaceutical Corp.) diluted with deionized water on the evening of day 8 (day 8.5; at the time of initial closure of the neural tube) and on the morning of day 9. Control mice received IP injections of deionized water. On day 12, the embryos were photographed with dark-field illumination, and placed in 100% ethanol for 24 hours at 4°C to stabilize the tissues for microdissection of the neuroepithelium. The lower IU dose of Vitamin A resulted in a low incidence of neurulation defects and the higher IU dose resulted in defects of all live embryos.

The neuroepithelium was solubilized in lysis buffer for one- and two-dimensional polyacrylamide gel electrophoresis, and Western blots using peroxidase-coupled lectins. Proteins were detected by silver staining. Two-dimensional maps of Vitamin A-treated neuroepithelium indicated that 15 spots (approximately 13% of observed proteins) varied, i.e., appeared, disappeared, or changed in their coordinates from the control catalog. In Vitamin A-treated defective embryos with cranial cysts, a marked suppression in glycosylation was observed in two Con A-binding proteins, 20 and 30 Kd, whereas in Vitamin A-treated normal embryos, a marked enhancement of the glycosylation was present in these proteins. Similarly, in Vitamin A-induced caudal neural tube defects occurring with dysgenesis of the caudal cell mass, a reduction of the glycosylation was also observed in the 20- and 30-Kd proteins. Additional studies are in progress to further characterize the glycosylation patterns by additional peroxidase-coupled lectins.

These results indicate that (1) changes in protein glycosylation parallel the events of neural tube closure; and (2) abnormal neuroregulation in the Vitamin A-induced defects may involve abnormalities in the glycosylation of certain proteins in the neuroepithelium.

257.2 COMPARISON OF c-SRC EXPRESSION AND HYPERTHYROIDISM IN CEREBELLAR MUTANTS. A. Messer, J.S. Brugge*, B. Eisenberg*, A. Lustig*, P. Maskin* and D.I. Martin. Wadsworth Ctr. for Laboratories and Research, NYS Dept. of Health, Albany, NY, 12201; School of Public Health Sciences, SUNY, Albany, NY; Dept. of Microbiology, SUNY, Stony Brook, NY.

In order to understand the mechanisms involved in cerebellar development, a knowledge of the hierarchy of commands used to create the mature cerebellum would be useful. The present studies examine three different aspects of cerebellar development, combining mutants which specifically and reproducibly perturb the normal sequence with thyroid hormone (T4) and/or the proto-oncogene c-src. Mutants were staggerer (sg/sg), missing or abnormal Purkinje cells from birth, granule cells degenerate shortly after migration; Lurcher (Lc/+), degeneration of all Purkinje cells during weeks 2-5, subsequent loss of most granule cells; weaver (wv/wv), degeneration of granule cells due to intrinsic failure to migrate.

A neuron-specific form of pp60c-src has been reported (Brugge et al, Nature 316, 524). The loss of this altered form (designated pp60c-src(+) due to its slightly larger size) generally correlated with the loss of granule cells and Purkinje cells from the cerebella of mice carrying the sg and Lc mutations, with the most pronounced changes observed in cerebella from the more severely affected sg mice. The expression of c-src(+) in wv mice is qualitatively and quantitatively quite different. From the earliest time points, there was a significant reduction in the levels of c-src(+), with no further loss of this form during the period of maximal neuronal differentiation. This suggests an early, predegenerative absence of c-src in wv, which is defective in granule cell migration.

Hyperthyroidism is known to cause premature proliferation and differentiation in the cerebellum. However, T4 does not seem to accelerate the peak of thymidine kinase activity in sg mice, consistent with the hypothesis that intact Purkinje cells mediate this process. In Lc mice, on the other hand, a very mild degree of induced hyperthyroidism leads to significant changes in levels of the amino acids taurine, glutamate, aspartate and GABA at P14, as well as changes in the developmental patterns of these amino acids from P14 to P28. These results suggest that in Lc cerebellum, T4 actually accelerates the program of Purkinje cell degeneration.

Thus, a mutation intrinsic to granule cells affects neuronal c-src presymptomatically, while two mutations intrinsic to Purkinje cells show c-src levels which apparently reflect total neuronal degeneration, yet show differential responses to hyperthyroidism.

257.3 TWO FORMS OF $pp60^{src}$ ARE DIFFERENTIALLY EXPRESSED IN DEVELOPING CNS. Otmar D. Wiestler* and Gernot Walter*. (SPON: A.E. Traynor). Department of Pathology, University of California, San Diego, La Jolla, CA 92093.

$pp60^{c\text{-}src}$, the protein-tyrosine kinase encoded by the proto-oncogene c-src, is highly active in the brain. It was shown recently that two forms of src protein, detectable in CNS tissue, are generated by differential splicing of c-src mRNA. These two proteins, designated pp60+ and pp60 were studied during CNS development. We found differential regulation of pp60+ and pp60 in distinct areas of the developing mouse brain and at different stages of neurogenesis. One form, pp60, was seen at a low level at embryonic day E9. Its activity increased 50-fold in forebrain and midbrain reaching a plateau in the perinatal period. A trace amount of the other form, pp60+ was first detected in E10 embryonic brains. Between E10 and E18, this protein increased approximately 200-fold in forebrain and midbrain. In the cerebellum, the time course and the level of expression of pp60+ and pp60 were markedly different with constant amounts of both proteins throughout development. These regional and temporal differences in pp60+ and pp60 protein-tyrosine kinase activity corresponded to similar changes in the amounts of pp60+ and pp60 protein. Therefore, c-src appears to be regulated at the level of protein synthesis rather than by changes in its specific kinase activity. We also assayed the c-src kinase in two mutant mouse strains, staggerer and weaver, with postnatal degeneration of cerebellar granule cells. The results indicate that granular neurons provide the main source of pp60+ in the cerebellum. In situ hybridization and immunocytochemical studies are in progress to determine the cellular and subcellular localization of the two proteins in the developing and mature CNS.

257.4 TIME OF APPEARANCE OF mRNA FOR GLUTAMIC ACID DECARBOXYLASE (GAD) DURING RAT BRAIN DEVELOPMENT. R.W. Bond* and D.I. Gottlieb (SPON: G. Cole). Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Glutamic acid decarboxylase (GAD) catalyzes the formation of GABA and is localized primarily in neurons utilizing GABA as a transmitter. It is thus a good marker for studying how neurons become different from one another. Recently, a cDNA which encodes feline GAD has been obtained by A. Tobin's laboratory (Kaufman et al., Science 232: 1138, 1986); this cDNA has been generously given to us. We have used this as a probe to study the appearance of GAD mRNA in the developing rat brain.

The feline GAD cDNA was subcloned as a 2.1 kb EcoR I-Hind III fragment into the Bluescribe plasmid (pBS-Stratagene, Inc.). ^{32}P-labeled antisense RNA was transcribed using T3 RNA polymerase. mRNA was prepared from rat brains by standard methods using guanidine hydrochloride extraction followed by isolation of $PolyA^+$ RNA. The $PolyA^+$ RNA was run on formaldehyde agarose gels and transferred to nitrocellulose (Northern blot). As reported by Tobin's lab (Soc. Neurosci. Abstr. 12: 1458) the cDNA hybridizes to a 3.7 kb mRNA from brain. There is no hybridization to rat muscle or liver RNA.

To study the expression of the GAD gene during development we prepared $PolyA^+$ RNA from whole brains of rats of the following ages: embryonic day 15 (E15), E18, postnatal day 1 (d1), d6, d20, and d60. Northern blots of these preparations showed that a substantial level of mRNA for GAD was present by E15. Two major features of the developmental pattern of GAD mRNA were noted. First, in the adult brain the only detectable band was at 3.7 kb, while at E15 an additional band of higher molecular weight was present at a level of about 30% of the main band. The relative amount of this additional band decreased steadily with age. Second, the amount of GAD mRNA increased markedly between E15 and d1. In the d1 brain, the amount per total $PolyA^+$ RNA was similar to the adult. This is in marked contrast to the levels of GAD enzyme activity in whole brain. At birth the specific activity of the enzyme is about 15% that of the adult. Adult levels are reached about three weeks after birth. The regulatory mechanisms which account for this disparity are not known.

The feline GAD clone has been used to isolate a cDNA from a rat brain λGT-11 library. The clone contains a 2.1 kb insert. Hind III cuts this into a 1.3 and a 0.8 kb piece. The 0.8 kb piece is from the 3' end of the cDNA and does not hybridize with the feline clone. This is consistent with the presence of a 3' untranslated portion of the GAD mRNA (A. Tobin, personal communication; Kobayashi et al., J. Neurosci., in press). The 5' 1.3 kb piece recognizes the same rat mRNA as the feline clone does. (Supported by NIH grant NS12867.)

257.5 **DEVELOPMENT OF SUBSTANCE P mRNA IN SEROTONERGIC CELLS OF THE MEDULLARY RAPHE** Bruce Daugherty*, Ronald P. Hart, and G. Miller Jonakait, Dept. Biological Sciences, Rutgers University, Newark, N.J. 07102

Substance P (SP) is co-localized with serotonin (5-HT) in cells of the medullary raphe nuclei. Few studies have addressed the issue of coordinate regulation of these co-localized neurotransmitters during development. In order to begin to examine the factors that affect the development of multiple neurotransmitters within individual brain nuclei, we have undertaken a study to document the initial expression and subsequent development of SP in the raphe. Since the earliest event in gene expression is transcription, we have measured mRNA specific for the SP preprohormone at different times during development.

A discrete midline segment of the medulla was dissected from rats of gestational days 14 (E14) through adulthood. Total RNA was isolated and subjected to Northern blot analysis using a radioactive cDNA probe for rat preprotachykinin (pGem 2-31-1, kindly provided by J. Krause, Washington University, St. Louis, MO). Northern blots revealed a single hybridizing band about 1100 base pairs in length. Quantitation of SP RNA was performed by densitometric scanning of the Northern blots.

SP message was barely detected at E14 (0.6 densitometric units [DU] per raphe), the earliest age examined. Maximum levels of SP message were detected at postnatal day 13 (P13; 101 DU per raphe), falling thereafter to adult levels of about 18 DU per raphe. The sharpest increase occurred between E21 and P2.

In order to determine whether SP message measured in postnatal raphe nuclei was co-localized with 5-HT, 3-day-old rat pups were injected intracisternally with saline or with 5,7-dihydroxytryptamine (5,7-DHT; 50 ug) to selectively destroy 5-HT neurons. All pups were pretreated with desipramine (20 mg/kg) to prevent neurotoxic effects to catecholamine neurons. After four weeks, the dorsal raphe was removed and assayed for tryptophan hydroxylase (TPH) to monitor 5-HT neuronal destruction. The medullary raphe was divided at the midline; one half was used for total RNA isolation for Northern analysis, the other half for SP determination by radioimmunoassay. Consistent with the studies of Towle *et al.* (1985), 5,7-DHT injection resulted in a 80-98% reduction in TPH activity with no concomitant change in SP peptide. By contrast, however, SP message declined by about 30%. Reasons for the maintenance of SP message are under investigation. (Supported by NS 23687. GMJ and RPH are Johnson & Johnson Discovery Research Fellows.)

257.6 **SEROTONIN, SUBSTANCE P AND TRH DEVELOPMENT IN ORGANOTYPIC TISSUE CULTURE OF EMBRYONIC MOUSE BRAIN.** G. Miller Jonakait and Sandra Schotland*, Dept. of Biological Sciences, Rutgers University, Newark, N.J. 07102

Substance P (SP) and thyrotropin-releasing hormone (TRH) are co-localized with serotonin (5-HT) in cells of the medullary raphe nuclei (Johansson *et al.* 1981). While several studies have documented the initial appearance and subsequent development of 5-HT, SP and TRH in the central nervous system of mammals, few studies have addressed the issue of coordinate regulation of co-localized neurotransmitter substances during embryonic development. In order to examine the factors that control development of multiple neurotransmitters within individual brain nuclei, we have grown presumptive raphe nuclei in organotypic tissue culture, an environment in which mammalian embryonic brain is easily accessible and manipulable.

Tissue was obtained from E13 mice. A discrete midline segment extending from mesencephalon through rhombencephalon was dissected intact or was separated into "midbrain" (MB) and "medullary" (MO) fragments. Tissue was explanted onto collagen coverslips and grown for up to 2 weeks in Maximow depression chambers. Tryptophan hydroxylase (TPH), the rate-limiting enzyme in 5-HT biosynthesis, was barely detectable at explantation. After one week in culture, however, TPH activity registered 24±2.5 ng 5-hydroxytryptophan formed/hr/culture in the undivided cultures. After 2 weeks, TPH activity had increased almost 2.5-fold above the 1-week level. Immunocytochemical analysis of the cultures confirmed a widespread distribution of 5-HT-positive cells and fibers throughout the explant. Substance P, monitored by radioimmunoassay (Kessler *et al.*, 1981), was detected after two days in culture, and attained a level of 111.7±9.8 pg/culture after two weeks. TRH activity (Manaker *et al.*, 1985) was 56.0±2.2 pg/culture after two weeks *in vitro*. Therefore, developmental increases in TPH, SP, and TRH occur in culture, mimicking the condition *in vivo*. Whether SP and TRH are co-localized with 5-HT in culture awaits immunohistochemical analysis.

In four separate experiments, MB and MO fragments, when grown apart on separate coverslips, developed 1.57-2.26 times the TPH activity that developed in the undivided piece. By contrast, SP activity was additive, the amount of SP present in the undivided piece being equal to the sum of the MB and MO fragments. MB and MO fragments grown in the presence of 1 uM pargyline did not develop increased TPH activity, suggesting that 5-HT itself may be inhibiting TPH development. These data indicate that factors (including, possibly, 5-HT itself) affecting the development of TPH in the cultures are not acting simultaneously to affect SP. (Supported by NS 23687. GMJ is a Johnson & Johnson Discovery Research Fellow.)

257.7 CHEMICAL DIFFERENTIATION OF SOMATOSTATIN NEURONS IN RAT NEOCORTEX: IMMUNOHISTOCHEMISTRY, IN SITU HYBRIDIZATION AND NORTHERN BLOT ANALYSIS. C.C.Naus, F.D.Miller*, J.H.Morrison and F.E.Bloom. Division of Preclinical Neuroscience and Endocrinology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

The chemical differentiation of somatostatin (SS) neurons in rat neocortex was characterized by molecular biochemical and morphological methods. A cDNA specific for pre-prosomatostatin mRNA was used to probe a Northen blot of adult rat brain regional poly(A)+ RNA, and the results agree, in general, with known distribution patterns of SS neurons. Northern blot analysis of whole brain poly(A)+ RNA shows an increase in pre-prosomatostatin mRNA from barely detectable at E14, to unquestionally detectable at E16, peaking at P1, to decline through P23 to the adult level. Similar analysis of poly(A)+ RNA isolated form cerebral cortex at various times postnatally shows an increase between P9 and P15, with a slight decrease in the adult. Immunohistochemical analysis of immunoreactivity to SS14, or its N-terminally extended form, SS28, reveals a significant development of this system by late gestation (E20). At this point SS28(1-12), the predominant SS form detected, is mainly in neurons of the subplate, with less detectable immunoreactivity in the intermediate zone and cortical plate. By P2, neurons in the subplate exhibit detectable SS28 and SS28(1-12). Although cellular immunoreactivity is no longer detectable in the cortical plate or marginal zone at P2, a very dense plexus of SS28(1-12) fibers is seen in the subplate, marginal zone and intermediate zone, with relatively few fibers in the cortical plate. At P8 to P10, the neuronal immunoreactivity remains largely restricted to the subplate, and immunoreactive fibers appear lessened. By P12, a dramatic shift in immunoreactivity occurs with supragranular SS28 neurons now prominent, and SS28(1-12) neurons and fibers greatly diminished. There is a gradual decrease in the number of SS28 neurons from P12 to adult, when these neurons exhibit a bilaminar distribution; neurons containing SS28(1-12) are now sparsely distributed throughout the cortex, while SS28(1-12) fibers densely innervate layer I and V-VI. A similar pattern of development can be seen using in situ hybridization with a probe specific to pre-prosomatostatin mRNA. Furthermore, individual cortical neurons appear to increase their transcription of the SS gene from E20 to P12, as revealed with in situ hybridization. These results demonstrate the dynamic nature of the chemical differentiation of neocortical SS neurons, at the level of gene transcription, mRNA translation and subsequent post-translational modification of these peptides. Supported by MRC and Huntington Society of Canada, NIH grants NS22347, AA06420 and McNeil Laboratories.

257.8 DEVELOPMENT OF PEPTIDERGIC SYSTEMS IN THE SPINAL CORD OF THE BRAZILIAN GRAY SHORT-TAILED OPOSSUM: FUNCTIONAL AND MORPHOLOGICAL STUDIES. C.A. Fox*, C.D. Jacobson and S. Jeftinija. Dept. of Veterinary Anatomy, Iowa State University, Ames, Iowa 50011.

The distribution of neuroactive peptides in the spinal cord as well as their effects on spinal neurons have been studied in adult animals. However, very little is known about the functional and anatomical development of these systems. To study this we have utilized the Brazilian gray short-tailed opossum, Monodelphis domestica, a small, pouchless, marsupial easily bred in the lab. Initial results on methionine-enkephalin (m-ENK) localization in the spinal cord of adult animals indicate that the spinal cord contains a large amount of m-ENK like immunoreactivity. The areas which had the most abundant concentrations of m-ENK were in laminae I, V and X. Also, there are scattered collections of m-ENK like immunoreactivity in the ventrolateral cell groups in the ventral horn. In general, these results are in agreement with those found for the North American opossum (DiTirroet al., JCN 213, 1983). To test the responsiveness of the developing spinal cord neurons to peptides an in vitro spinal cord preparation of 11-13 day old pups was used (day 1=day of finding pups). This period equals that of the perinatal rat. After laminectomy under ether anaesthesia, the lumbosacral segment of the spinal cord was removed. This preparation was pinned in a Sylgard-lined chamber and continuously perfused with 95% O_2/5% CO_2, at 31±1°C. Intracellular recordings of neurons were obtained using glass micropipettes filled with 3M K-acetate (100-120MΩ). The passive and active electrical properties were investigated by injecting depolarizing and hyperpolarizing current pulses. Neuronal input resistance (105-223MΩ) and time constant (5.6-15.7ms), were measured at a resting membrane potential of 55-62mV. The threshold for an action potential produced by depolarizing pulses was between -40 and -50mV. The amplitude of the action potential measured from threshold to peak was 42-55mV; the duration measured at the threshold was 2.3 to 4.8ms. Bath application of substance P ($5x10^{-6}$M) produced a reversible depolarization associated with an increase in synaptic activity. Similarily, an excitatory depolarization was observed in response to vasoactive intestinal polypeptide (10^{-5}M) and thyrotropin releasing hormone (10^{-6}M). In addition, glutamate and N-methyl-D-aspartate had an excitatory action. Acetylcholine, nicotine and muscarine produced a depolarization associated with an increase in synaptic activity. (D-Ala, D-Leu)enkephalinamide (10^{-5}M), however, produced a reversible hyperpolarization of 2-5mV lasting between 4-8 minutes. These results indicate that the Brazilian opossum is a model in which the sensitivity of spinal cord neurons to putative neurotransmitters during development can be studied. Supported by NIH grants HD-16148 and 2S07 RR07034.

257.9 DEVELOPMENTAL EXPRESSION OF DARPP-32 IN MOUSE CORPUS STRIATUM. N.L. Rosen, I. Shalaby, T. Kurihara, M.E. Ehrlich, H.C. Hemmings, Jr. and P. Greengard. The Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, 1230 York Avenue, New York, NY 10021.

DARPP-32 is a neuron-specific phosphoprotein, which is a substrate for cAMP-dependent protein kinase. It is found in dopaminoceptive neurons that possess D_1 receptors, particularly the medium spiny neurons of the basal ganglia. It is hypothesized that DARPP-32 is involved in the processes of neuromodulation that follow D_1 receptor-stimulated generation of cAMP. We have developed a quantitative Western blot assay for DARPP-32 that is linear in the range of 2-100 ng of DARPP-32, as well as a DARPP-32 cDNA clone. With these tools we have looked at the appearance of DARPP-32 and its mRNA in the basal ganglia of embryonic and postnatal mice.

The corpus striatum was dissected from CD-1 mice (Charles River) sacrificed at ages between embryonic day 14 and adult. Pooled samples were sonicated for protein determination in 1% SDS at 70°, followed by heating at 95° for 5 min. Samples of 0.25 mg protein were subjected to SDS-PAGE and proteins blotted onto nitrocellulose paper. The blots were developed by successive incubations with monoclonal antibodies against DARPP-32, rabbit anti-mouse IgG, and I-125 labelled protein A. Radiolabelled bands located by exposure to X-ray film were cut and counted in a γ-counter. Appropriate DARPP-32 standards were included for quantitation. Total cellular RNA was prepared from tissue that had been dissected onto dry ice. Ten microgram RNA samples were separated by electrophoresis on a 1.2% formaldehyde gel, transferred to nitrocellulose and hybridized with an antisense ^{32}P-RNA probe transcribed from a full length DARPP-32 cDNA (T. Kurihara et al., J. Neuroscience, in press). Relative DARPP-32 mRNA levels were determined by densitometry of the autoradiogram.

The amount of DARPP-32 mRNA increased dramatically between birth and the end of the first week of postnatal life, and then more slowly approached adult levels by the end of the third week. The amount of the phosphoprotein itself increased markedly throughout the first three postnatal weeks, reaching near-adult levels by the end of the third week. Thus, the major increase in expression of DARPP-32 occurs after the arrival of dopaminergic input during fetal life and immediately following the cessation of neuron production (R.R. Sturrock, J. Anat. 130:243, 1980). It correlates closely with the appearance of adenylate cyclase activity, and the beginning of formation of dendritic spines. (Supported by USPHS NS 00988 and MH 40899 and by a grant from the American Parkinson Disease Association.)

257.10 DEVELOPMENT OF THE BASAL FOREBRAIN CHOLINERGIC NEUROTRANSMITTER SYSTEM. L.J. Thal, D.M. Armstrong, E. Gilbertson, S.R. Deputy, F.H. Gage. Dept. Neurology, San Diego VA Med. Ctr., Dept. Neurosciences, Univ. of California, San Diego, La Jolla, CA 92093

As a correlative to our anatomical investigations into the development of forebrain cholinergic neurons we employed biochemical methods to assay choline acetyltransferase (ChAT) activity within discrete anatomical loci of the developing forebrain. Fetal tissue was obtained from timed pregnant Sprague-Dawley rats. At least four brains, obtained from one or more litters, were examined from each of the following times: embryonic day 14 (E14), E18, birth, postnatal day 1 (PD1), PD5, PD10, PD16, PD20, PD30, PD60 and PD180. From prenatal brains five anatomical regions were assayed for ChAT: medial septum/diagonal band (MS/DBB); magnocellular preoptic/substantia innominata (MgPO/SI); striatum; anterior cingulate/frontoparietal cortex (ACg/FrPa); and hippocampus. Similarly, seven regions were examined from postnatal brains: MS; DBB; MgPO/SI: medial striatum; lateral striatum; ACg/FrPa; and hippocampus.

ChAT activity was first detected on E18 in the MS/DBB and MgPO/SI (10 nmoles ACh/hr/mg protein) (Cholinergic perikarya were first detected by immunohistochemical methods on E14, four days earlier. In the striatum ChAT levels were barely detectable until after birth, thereafter enzyme activity increased first in lateral then in medial striatum. Following birth and continuing through the first month, all forebrain regions exhibited a dramatic rise in ChAT activity reaching levels beyond that observed in the adult. This rise in enzyme activity correlates with our anatomical observations of intense amounts of peroxidase reaction product during the first three weeks of development. In the hippocampus and neocortex ChAT activity was first detected several days later than in the MS/DBB or MgPO/SI. These target areas, however, also exhibited a dramatic increase in enzyme levels following birth. In summary, our findings support dynamic postnatal changes in ChAT expression.

257.11 IMMUNOCYTOCHEMICAL LOCALIZATION OF TRANSFERRIN AND MALATE DEHYDROGENASE IN THE DEVELOPING RAT NERVOUS SYSTEM. G.J. Markelonis, T.H. Oh, T.L. Dion*, B.S. Bregman and M.A. Pugh*. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, Maryland 21201.

Transferrin accumulates within neurons of the developing nervous system of humans, sheep, pigs and chickens. To assess the relationship of this accumulation with the ontogeny of oxidative metabolism, we studied the immunocytochemical localization of transferrin (Tf) and the mitochondrial form of malate dehydrogenase (mMDH) in developing neural tissues by the peroxidase-antiperoxidase method. Rabbit antirat Tf was obtained commercially and gave a single band of reaction product (MW = 80 kd) on Western blots. Antibodies to porcine heart mMDH were elicited in a rabbit. Western blot analysis showed that this antiporcine mMDH antibody reacted with the mMDH from porcine, rat or avian tissue but not with the cytosolic MDH from several species. Tf was first detected in rat brain neurons at about the 18th embryonic day and reached a peak at about the 6th postnatal day. All neurons were immunoreactive with large neurons throughout the brain showing a strong reaction for Tf. From this time onward, the level in brain neurons gradually decreased until adulthood. However, Tf immunoreactivity still remained strongly evident in capillary endothelial cells. The localization of Tf within rat spinal cord neurons peaked as early as the first postnatal day and remained elevated to the 6th postnatal day. By contrast, reactivity for Tf within dorsal root ganglia (DRG) neurons was intense as early as the 18th embryonic day and diminished only gradually. Mitochondrial MDH, a marker for oxidative metabolism, appeared to reach a peak after the crest of intraneuronal Tf had been observed. For example, brain and spinal cord MDH immunoreactivity increased with intense staining in the cell bodies and fibers of neurons from the 6th to the 13th postnatal day; immunoreactivity gradually diminished into adulthood. The gradient of reactivity was low in some areas of the brain but more intense in areas containing large neuronal cell bodies such as the red nucleus. This occurred after the peak of intraneuronal Tf at day 6 and suggested a precursor-product relationship. By contrast, immunoreactivity for neuron-specific enolase, a glycolytic enzyme, showed a developmental pattern that differed from either Tf or MDH in that reactivity appeared later in development and was less intense. These data suggest that as cerebral metabolic rates begin to increase as early as 5-6 days after birth in the rat, an increase in mMDH occurs coincident with the onset of oxidative metabolism. Furthermore, this rise in intraneuronal mMDH follows the peak of intraneuronal Tf and suggests that Tf supplies the iron required for the synthesis of other mitochondrial ferroproteins. Supported by the NIH (NS 20490-GJM and NS 15013-THO).

257.12 **EFFECTS OF PRENATAL 8-OH-DPAT & TFMPP ADMINISTRATION ON THE DEVELOPMENT OF SEROTONERGIC NEURONS & RECEPTORS** A.Shemer, E.Van Bockstaele, P.M.Whitaker-Azmitia, E.C.Azmitia Dept.of Biology. Washington Square Center for Neural Science, New York University,New York, N.Y.10003. and Dept. of Psychiatry, SUNY at Stony Brook, Stony Brook, N.Y.11793

Serotonin has been shown to have an important role to play in the development of the brain. We have shown previously in an in vivo and in vitro model that the serotonergic agonist 5 Methoxytryptamine (5-MT) has a biphasic effect on the outgrowth of serotonergic neurons. A low dose of 5-MT (0.1 mg/kg) administered to pregnant rats produces an inhibition of neurite outgrowth in neonates while a high dose (3 mg/kg) produces enhanced outgrowth in target areas of serotonergic innervation.This biphasic response may be acting through two different $5HT_1$ receptors : the $5\text{-}HT_{1a}$ has been observed on midbrain raphe cell bodies, a possible autoreceptor; the $5\text{-}HT_{1b}$ has a tenfold lower affinity and appears to be located in target areas.

In order to further establish the role of these two high-affinity receptors during development we decided to investigate the effects of prenatal 8-Hydroxy-2 (DI-n-Propylamino) Tetralin (PAT) a specific $5\text{-}HT_{1a}$ agonist and 1-(3-(trifluoromethyl) phenyl)-piperazine (TFMPP) a specific $5\text{-}HT_{1b}$ agonist. Both drugs were administered daily at 1mg/kg i.p.to pregnant Sprague-Dawley rats from day 12 of gestation to birth. The neonates were killed on day 1 and 15 postnatally. The high affinity uptake of 3H-5HT (50nM) was performed in a synaptosomal preparation . Receptor binding was carried out in a membrane preparation using 3H-5HT (0.5nM - 20.0nM).

TFMPP, working through the $5\text{-}HT_{1b}$ receptor replicated the enhanced outgrowth to target areas observed after a high dose of the agonist 5MT. High affinity uptake into the forebrain was significantly increased on D1 & D15. PAT treated rats showed no significant changes in uptake measures. Receptor binding reflected differential effects of the prenatal PAT and TFMPP administration : the PAT caused reduced binding in the high affinity component of the $5\text{-}HT_{1a}$ receptor, whereas the TFMPP did not produce a similar inhibition.

These results suggest that the $5\text{-}HT_{1a}$ and the $5HT_{1b}$ receptors are functional prenatally in the rat and produce differential effects on the development of serotnergic neurons. Supported by NSF grant 5-259-272.

257.13 DEVELOPMENTAL CHANGES OF NEURAL CELL ADHESION MOLECULE (N-CAM) IN RETINAL AFFERENTS TO OPTIC TECTUM. P. Streit and I. Kulka*, Brain Research Institute, University of Zurich, CH-8029 Zurich, Switzerland

At which stage of ontogeny does the 'adult' (A) form of N-CAM appear in a well defined 'in vivo' system, which allows analysis at the level of a particular neuronal cell type? Is this appearance correlated in time with certain events in the development of the system investigated? Which mechanism brings about the developmentally regulated change from the 'embryonic' (E) to the A form, the so- called 'E to A conversion'? - Intraocular injection of [^{35}S]-methionine in chicken embryos at different stages of development led to biosynthetic labeling of N-CAM which was axonally transported in the retinotectal pathway. After different survival times, N-CAM was immunoprecipitated from detergent extracts of tectal tissue by a monoclonal antibody selected to react with both forms of the molecule. Labeled N-CAM was autoradiographically analysed following SDS-polyacrylamide gel-electrophoresis. - Labeling was found almost exclusively in the tectum contralateral to the injected eye in this mostly crossed projection. Newly synthesized and transported A form of N-CAM could first be observed at incubation day 16, i.e. after the time of synapse formation, after the periods for generation and degeneration of retinal ganglion cells and with the onset of myelination in this pathway. If tracer was injected on day 15, labeled N-CAM was immunoprecipitated in its E form even on day 19. No processing of the E form to the A form of N-CAM seemed to occur following axonal transport and incorporation into the cell surface membrane in this 'in vivo' system. 'E to A conversion', thus, seems to be the result of a change of programs for the neuronal synthetic machinery. If a relatively slow turnover of N-CAM is assumed, the coexistence of E and A forms can be expected at the cellular level for a period of several days and may result in graded adhesion forces. Besides such a modulatory function of the E to A conversion, the newly appearing A form could have an inductive action in the process of myelination, or it could be involved in the stabilization of synapses.

257.14 NEURONAL REGULATION OF MEMBRANE ACETYLCHOLINE (ACh) RECEPTORS AND SODIUM (Na) CHANNELS IN DEVELOPING RAT MUSCLE. L. Bambrick and T. Gordon. SPON: P. Braun), Dept. of Biochemistry, McGill Univ., 3655 Drummond Drive, Montreal, Quebec, H3G 1Y6 and Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alberta, T6G 2H7.

During the development of mammalian skeletal muscle in vivo, the muscle membrane becomes specialized with incorporation of voltage-sensitive Na channels and the restriction of high densities of ACh receptors to the neuromuscular junction. This differentiation is nerve-dependent (Sherman & Catterall, J. Gen. Physiol., 80: 753, 1982). We have studied the effects of denervation and presynaptic blockade of ACh release with botulinum toxin (BoTX) to investigate the mechanism of the neuronal regulation of these membrane proteins.

Triceps surae muscles were denervated by sciatic nerve section or their neuromuscular transmission blocked by subcutaneous injection of BoTX at 1, 7, 14, 21 and 28 days after birth. Three to 7 days later, muscles were homogenized for assay of Na channels and ACh receptors using ^{3}H-saxitoxin (^{3}H-STX) and ^{125}I-alpha-bungarotoxin (^{125}I-BTX) as specific radioligands in equilibrium binding and saturation binding assays, respectively. Both denervation and BoTX-blockade inhibited or reversed the normal developmental increase in Na channel and decrease in extra-junctional ACh receptor numbers measured relative to muscle protein, weight or fiber diameter. The effects of denervation were always greater than those of BoTX-blockade, in contrast to our earlier work with adult rats in which BoTX-blockade was as effective as denervation in altering the numbers of Na and ACh receptors in the muscle membrane (Bambrick & Gordon, J. Physiol., 382: 69, 1987).

Both results are consistent with the idea that neuronal control of Na channels and ACh receptor incorporation into the muscle membrane is mediated via functional neuromuscular transmission. The finding that BoTX-blockade, which is complete for evoked but not for spontaneous ACh release, is less effective in neonatal animals suggests that membrane depolarization may be sufficient to control the incorporation of Na channels and to decrease the incorporation of ACh receptors into the developing membrane. Depolarizations in response to the small, spontaneous release of ACh in BoTX-treated junctions would be insignificant in the adult. However, in the neonatal muscle in which depolarization would be enhanced by high input resistance, longer ACh receptor open times and lower levels of acetylcholinesterase, membrane depolarization may be sufficiently large to exert a significant trophic effect in controlling membrane protein synthesis.

258.1 ELECTROENCEPHALOGRAPHIC NEUROTOXICITY STUDY OF THE FIRE ANT POISON AMDRO. G.M. Strain and M.C. Graham*. Veterinary Physiology, Pharmacology, and Toxicology, Louisiana State University, School of Veterinary Medicine, Baton Rouge, LA 70803.

Amdro (American Cyanamid, AC 217,300) is a novel insecticide of the amidinohydrazone class marketed for treatment of red imported fire ants and roaches. Amdro has low toxicity (male rat oral LD50 = 1131 mg/kg, techical grade) but because the fire ant formulation is in soybean oil on corn meal it is highly attractive to domestic and wild animals. Seizures have been observed in dogs, cats and birds after accidental poisoning, and neurotoxicity has been reported after long-term dosing in calves (Evans et al, Am J Vet Res 45:1023; 1984). No neurotoxic effects were detected with somatosensory, auditory, or visual evoked potentials in F-344 and hooded male rats during 10 days of recording after a single oral dose of Amdro concentrate (Strain and Graham, Soc Neurosci Abstr 12:93; 1986). We now report the effects of Amdro on the electroencephalogram of male F-344 rats. A single dose was used to simulate an actual poisoning, since technical Amdro has a 1 hour half-life in sunlight and repeated exposures are unusual.

Subjects were divided into two treatment groups: vehicle control (oleic acid in soybean oil) and Amdro concentrate in vehicle. The Amdro concentrate dose was equal to 0.75 X LD50 of technical Amdro. EEG were recorded from chronic screw electrodes before dosing, and at hours 1, 4, and 8 and at days 1, 2, 3, 4, and 7 after dosing. Recording span was chosen based on the elimination rate of Amdro in the rat (90% in 9 days). EEG were recorded on FM tape and later analyzed on an Apple-based IQS EEG 4000 spectral analysis system. Six 10-second artifact-free epochs recorded between left and right cortex were averaged for each rat; a grand average was then computed for each treatment group at each measurement time. EEG power was calculated in 1 Hz bands from 0-30 Hz, but most of the power and all of the variation occurred in the 0-10 Hz range.

The EEG power spectrum in control rats showed two peaks, at 4 and 7-8 Hz. Dosing with Amdro produced an increase in power in the low frequencies and an approximately 1 Hz shift to the left of both peaks. The effect was maximum at 24 hours, but did not resolve until day 7. The rats receiving vehicle control displayed similar frequency and power changes, but the change in EEG power was less marked and the frequency shift had resolved by day 2. Thus, both treatments produced sedative effects. Initial effects could be attributed to "postprandial" lethargy, but would not have persisted for subsequent days; circadian activity rhythms should also have affected the pre-dosing and day 7 EEG recordings. Therefore, the results likely reflect a previously unrecognized CNS depressant effect of oleic acid and an additional sedative effect of Amdro.

Supported by LA SVM Grant 610 and American Cyanamid.

258.2 CYTOTOXIC MECHANISM OF *Pyrularia* THIONIN. K.-P. Shaw, F.C. Kauffman, V.P. Vernon*[1], and E.X. Albuquerque. Dept. Pharmacol. & Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201 & [1]Dept. Chem. Microbiol. Brigham Young Univ. Provo, Utah 84602.

Pyrularia thionin (PT) isolated from *Pyrularia pubera* Michx. (Santalaceae) is a 47-amino-acid, basic peptide which has high homology with wheat purothionin and mistletoe viscotoxin. It has been used for many years for the treatment of neoplastic disease and has been suggested as a possible chemotherapeutic agent for cancer patients (Vernon *et al.*, *Arch. Biochem. Biophys.* 238:18, 1985). The purpose of these experiments was to characterize the cytotoxicity of PT on spleen lymphocytes and hepatocytes from rats by a simple dye extraction assay and to study the effect of PT on the electrophysiological properties of frog sartorius muscles. The IC_{50} of PT for cell viability based on dye uptake by isolated hepatocytes and lymphocytes, were 0.15 μM and 40 μM, respectively. PT (0.5 μM) potentiated the contraction of indirect twitch of the sartorius muscle by 20% within the first 5 minutes and caused complete inhibition within 30 minutes. The membrane potential of sartorius muscle was depolarized by 80% with PT 80 nM and by 60% with PT 60 nM. Alteration of membrane potential in the presence of PT was a calcium-dependent phenomenon. Preincubation with verapamil (10 μM), a calcium channel blocker, for one hour and subsequent addition of PT (60 nM) for another hour protected the membrane from depolarization. After washout of verapamil, treatment with PT (60 nM) for one hour depolarized the membrane potential from 95% to 40% of control values. No protection of membrane depolarization occurred in the presence of either indomethacin (100 μM), a cyclo-oxygenase inhibitor, or tetrodotoxin (330 nM), a sodium channel blocker. However, preincubation of sartorius muscles with the phospholipase A_2 inhibitor, dexamethasone (1 to 100 μM for 3 hours), and continuous presence during one more hour exposure to PT (60 nM), preserved the membrane potential at a level of 80 to 90% of control values. A 37% increase in the frequency of miniature endplate potential was recorded during the first 10 minutes of exposure to PT (0.05 μM). In summary, the data suggest that the cytotoxic effect of PT may be directly related to calcium influx due to the activation of phospholipase A_2. Different membrane-phospholipid compositions may underlie different sensitivities to the toxin. (Supported by Directed Research Initiative Funds from the Univ. Maryland and NIDA Grant DA 02804).

258.3 GANGLIOSIDE TREATMENT REDUCES PERIPHERAL NERVE ELECTROPHYSIOLOGIC ALTERATIONS INDUCED BY VINCRISTINE ADMINISTRATION. F. Di Gregorio*, G. Favaro*, C. Panozzo*, A. Schiavinato*, E. Lini* and M.G. Fiori. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy

Vincristine (VCR) is an antiblastic drug used against several types of tumors. Doses and duration of VCR treatment are limited by the drug side effects, which often affect the peripheral nervous system. To study the possibility of peripheral nerve protection against VCR neurotoxicity, the effect of simultaneous treatment with a mixture of bovine brain gangliosides (Cronassial®, Fidia) was tested. The rabbit was chosen as experimental animal since it resulted much more sensitive to VCR than smallest laboratory animals. A first group of rabbits was treated once a week for five consecutive weeks with 0.2 mg/kg VCR (Lilly) i.v. and with either phosphate buffer solution (PBS) or ganglioside mixture dissolved in PBS (50 mg/ml, at daily doses of 1 ml/kg given i.v. six times a week for the entire period of VCR administration). Controls were injected i.v. with PBS. A second group of rabbits was treated according to the same protocol, but the VCR dose was raised to 0.25 mg/kg. At the end of the treatment animals were sacrificed, and sciatic nerve and its branches dissected out. Compound action potential (CAP) amplitude and area, and nerve conduction velocity (NCV) were measured by in vitro standard technics. Other nerve segments were processed for light and electron microscopy. Treatment with 0.2 and 0.25 mg/kg VCR + PBS reduced NCV by 17.6% and 23.7% respectively. Monophasic CAP area and peak amplitude were affected in a dose-dependent manner, decreasing respectively by 22.3% and 34.6%, after 0.2 mg/kg VCR + PBS administration, and by 35.3% and 45.6% after 0.25 mg/kg VCR + PBS. Histologic and ultrastructural observation demonstrated the presence of nerve fiber degeneration which was more frequent at the high VCR dose. Morphometric analysis on sural nerves myelinated axons of control and 0.2 mg/kg VCR-treated rabbits, evidenced the increased frequency of tiny fibers, coupled with decreased frequency of myelinated axons of larger size. This could suggest that axon regeneration and remyelination take place in rabbit VCR neuropathy, as a consequence of degenerative events. Ganglioside treatment was effective in reducing alterations of all the electrophysiologic parameters, in 0.2 mg/kg VCR-treated rabbits, being the NCV reduction limited to 11.8%, CAP area to only 3.9%, and CAP peak amplitude to 18.7%. Ganglioside protective action on CAP area and amplitude was maintained at the high VCR dose as well, the decrease being limited to 21.6% and 25.2%, respectively. These observations suggest that ganglioside treatment could reduce the loss of functional nerve fibers which affects rabbit sciatic nerve after VCR administration.

258.4 CYANIDE-INDUCED NEUROTOXICITY: ATTENUTATION BY CHLORPROMAZINE. E.U. Maduh*, B.K. Ardelt*, J.D. Johnson*, J.L. Borowitz* and G.E.Isom* (SPON: G. Yim). Department of Pharmacology and Toxicology, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

Chlorpromazine (CPZ) has been demonstrated to be an effective cyanide antidote with its greatest efficacy displayed when combined with the classic antidotes, sodium nitrite and sodium thiosulfate (Kong et. al., Toxicol. Appl. Pharmacol. 71: 407 3). Since the presumed site of cyanide lethality is the central nervous system, the objective of the present study was to determine the interaction of chlorpromazine with cyanide in neural systems. Tremors produced by KCN administration to mice are correlated with increases in brain calcium and accompanied by peroxidation of brain lipids. These toxic manifestations are prevented by pretreatment with diltiazem, a calcium channel blocker. This study examines the ability of CPZ to alter the KCN-induced increase in cellular calcium and neuronal lipid peroxidation. KCN (1-10 mM) increased [Ca]i in rat pheochromocytoma (PC-12) cells as indicated by the fluorescent dye quin II. This effect was blocked by diltiazem or CPZ (0.1 mM) added 15 min to the cells prior to addition of KCN. Peroxidation of brain lipids in mice administered KCN 15 mg/kg (sc), as determined by the conjugated diene method, was blocked by pretreatment with CPZ or diltiazem. Furthermore, production of lipid peroxidation in fresh mouse brain slices (0.3mm) induced by 0.1 mM KCN was blocked by 0.1 mM diltiazem or 0.1 mM CPZ. These observations suggested CPZ protects neuronal cells against damage by cyanide by preventing calcium influx into the cells and by decreasing lipid peroxidation of membranes. (Supported in part by PHS grant ES04140).

258.5 EFFECT OF 1,1,2,TRICHLOROETHYLENE ON THE HIPPOCAMPAL FORMATION OF THE DEVELOPING RAT. L.G. Isaacson*, T. Kravetz*, D.H. Taylor*, and R.J. Pfohl*. (SPON: R.G. Sherman). Dept.Zoology, Miami Univ., Oxford, OH 45056.

1,1,2 Trichloroethylene (TCE), an industrial solvent and degreaser, has been detected in the drinking water of several municipalities and poses a potential health hazard to the general population. Previous behavioral and biochemical studies in our laboratory indicate that the hippocampus of the developing rat may be affected by exposure to TCE. The present study utilizes immunocytochemical and histochemical techniques in order to assess damage to the hippocampal formation which might result from exposure to TCE in rat pups while in utero and during lactation.

Dams were given drinking water containing 312 or 625 ppm TCE while pregnant and during lactation. Thus, rat pups were exposed to TCE while in utero and postnatally through dam's milk. At post-natal day 21, they were sacrificed by aortic perfusion. Frozen sections were processed for choline acetyltransferase (ChAT) immunocytochemistry. Alternate sections were stained for the presence of myelin using a modification of the Heidenhain procedure (J. Neurosci. Meth.7:289-294). Also, selected sections were stained for the presence of degenerating axons and terminals using a modification of Fink-Heimer silver degeneration stain.

Examination of sections from TCE treatment groups stained for the presence of myelin revealed a dramatic decrease in staining activity in the stratum lacunosum-moleculare of the dorsal hippocampus, an area which has been shown to receive input from the entorhinal cortex. The axons of the mossy fiber pathway and the fornix appeared unaffected. Following Fink-Heimer staining, degenerating axonal fibers were observed in the stratum lacunosum-moleculare and in the stratum radiatum of treated animals. No difference in ChAT immunoreactivity, either in neuronal or axonal immunolabeling, was ascertained at the light microscopic level.

These results indicate that the area of the developing hippocampal formation which receives input from the entorhinal cortex appears to be affected by exposure to TCE. In contrast, cholinergic input, which originates primarily from the septum, appears to remain intact. Thus, the changes observed in the hippocampus may explain the behavioral dysfunctions observed in rats exposed similarly to TCE.

258.6 INTRACORTICAL AF64A INFUSION IN THE RAT INDUCES AN ATROPHY AND LOSS OF CHOLINERGIC CELL BODIES WITHIN THE NUCLEUS BASALIS MAGNOCELLULARIS (nBM). P.R. MOUTON* and G.W. Arendash (SPON: R. Shannon). Section of Physiology and Development, Department of Biology, University of South Florida, Tampa, Florida 33620.

Ethylcholine mustard aziridinium ion (AF64A), a selective irreversible inhibitor of high-affinity choline uptake located on cholinergic terminals, has been proposed as a useful agent in the development of animal models for the cholinergic hypofunction and memory loss characteristic of senile dementia of the Alzheimer's type (SDAT). Previously we have reported that following low dose intracortical AF64A infusions, specific decreases in cholinergic markers occur within the cerebral cortex through at least 10 weeks post-infusion, resulting in a variety of learning/memory deficits with a similar time course. It is not known, however, whether such treatment is toxic to the cell bodies of cholinergic neurons located in the nBM, which provides the primary cholinergic innervation to the fronto-pairetal (FP) cortex. We report in the present histochemical analysis that a significant atrophy and loss of cholinergic neurons in the nBM occurs by 3 weeks following AF64A infusion into the rat FP cortex.

Adult male Sprague-Dawley rats received two 1.0 ul infusions of AF64A (1 nmole/1 ul) or vehicle into the FP cortex bilaterally. We have previously reported that, at the dose and volume of AF64A used in the present study, only minimal non-specific tissue damage occurs in the neuropil adjacent to infusion sites and no decreases are seen in monoaminergic or peptidergic (somatostatin or neuropeptide Y) markers within the cortex. Three weeks after such AF64A or vehicle infusion, all animals were pre-treated with di-isopropylfluorophosphate (DFP: 2.0 mg/kg, i.m.) and sacrificed five hours later. Following brain perfusion and removal, 30 um serial sections were cut through the level of the nBM utilizing a freezing microtome. Sections were histochemically stained for acetylcholinesterase (AChE) followed by Nissl counter-staining for cell body visualization. Widths and lengths of dark AChE-positive cell bodies within the anterior and middle nBM were made in addition to AChE-positive cell counts in the same nBM regions. A highly significant 37% decrease in the cross-sectional area of nBM cholinergic neurons was observed in AF64A-treated rats compared to vehicle-treated animals (412 ± 23 vs. 649 ± 32 um^2). Moreover, the density of cholinergic neurons within the nBM of AF64A-treated rats was significantly lower (by 35%) compared to that of controls.

These data indicate that AF64A can be a specific cholinotoxin for a sizable number of neurons comprising the nBM-to-cortex cholinergic pathway. Furthermore, those nBM cholinergic neurons that survive cortical AF64A treatment apparently do so in an atrophic state. The data support a use of AF64A in the development of animal models for SDAT based on cholinergic dysfunction.

258.7 THE EFFECTS OF PYRETHROIDS ON PAIRED PULSE INHIBITION IN THE HIPPOCAMPUS OF THE RAT. M.E. Gilbert, C. Mack* and K.M. Crofton*. Northrop Services Inc, RTP, NC 27709 and U.S.EPA, Neurotoxicology Division, RTP, NC 27711.

The pyrethroid insecticides have been divided into two classes on the basis of their biochemical actions and behavioral indices of toxicity. Both types of pyrethroids have effects on Na conductance, and Type II pyrethroids have been reported to have GABA-antagonistic effects through interaction with the picrotoxin binding site. Cismethrin (CSM) and deltamethrin (DLT) are Type I and Type II pyrethroids, respectively. We attempted to demonstrate a dissociation between the pyrethroid types by testing their actions on GABA-mediated inhibition in the perforant path-dentate circuit of the hippocampus in the conscious, unrestrained rat. We anticipated a decrease in GABA-mediated recurrent inhibition with DLT that would be manifested in a larger response to the second pulse of the pair at brief IPIs (20-50ms) following treatment with DLT but not CSM. A bipolar stimulating electrode was placed in perforant path and a recording electrode in the hilus of the dentate gyrus. One week after surgery, animals were delivered pairs of stimulus pulses (biphasic square waves, each 0.1ms in duration, once every 10s) at interpulse intervals (IPI) of 20-1000ms, before and 3-5h after oral administration of 10-15mg/kg of DLT or 20-30mg/kg of CSM in a corn oil vehicle. These dose levels produced strong behavioral reactions typically reported for the pyrethroids (e.g. profuse salivation, tremor, writhing movements). Intensity of the stimulation was initially chosen to produce a response 75% of the maximal population spike (PS). After dosing, the amplitude of the PS was altered, so intensity was adjusted to equate the size of the spike in the pre- and post-dosing tests. The PS evoked by the two pulses was measured and the amplitude of the response to pulse 2 expressed as a percentage of the amplitude of the response to pulse 1. This percentage was then compared between baseline and post-dosing tests. DLT (N=5) actually enhanced paired pulse inhibition up to and including the 500ms IPI, an effect opposite to a picrotoxin-like action. CSM (N=6) had no effect upon paired pulse inhibition. These findings suggest that DLT does not act through a GABA antagonistic mechanism in this system. It is unlikely that DLT is acting as an agonist of GABA-mediated inhibition since all but the longest IPIs were affected. Pyrethroids also act on neuronal membrane ion channels, prolonging Na permeability through formation of a modified open state of the Na channel. Type II pyrethroids produce a depolarizing block of nerve activity which has been attributed to summation of long lasting depolarizing afterpotentials. This action of pyrethroids on Na channel kinetics may account for effects on paired pulse inhibition in the hippocampus.

258.8 THE SUPPRESSIVE EFFECTS OF ANESTHETIC, HALOTHANE, ON REACTIVE SYNAPTOGENESIS IN THE RAT DENTATE GYRUS. E. Uemura, E.D. Levin, R. DeLuna, and R.E. Bowman. Dept. of Veterinary Anatomy, Iowa State Univ. Ames, IA 50011, Dept. of Psychology, UCLA, CA 90024, Dept. of Psychology, Univ. of Wisc. Madison, WI 53715.

Halothane is one of the most widely used inhalation anesthetic agents. It is typically used at 1.5% concentration (15,000 ppm) in conjunction with nitrous oxide. We report that in rat received entorhinal electrolytic lesions, halothane exposure considerably slows down reactive synaptogenesis of the rat dentate gyrus, but also that the initial delay in the reactive synaptogenesis did not result in permanent deficits in synaptic pupulation. Male rats (n=72, 60 days old Sprague-Dawley) were used in the study. Rats were separated into three groups: unlesioned control (n=24), lesioned control (n=24), and experimental (n=24). Starting on the day after unilateral entorhinal lesioning, the experimental group were exposed to 100 ppm halothane (8 hours/day) for 15 days. At days 2, 15, 25, and 30 post-lesion, six rats from each group were killed for electron microscopic quantitation of synapses. Tissue from the outer molecular layer of the dentate gyrus were block-stained with 1% ethanolic phosphotungustic acid, and number of synapses per unit volume of tissue was calculated.

The synaptic density was similar in the unlesioned control ($F=1.795$, $df=3,20$, $P>0.18$). However, in both the lesioned control and experimental groups, a significant loss of synapses was observed in the dentate gyrus ($F=38.0$, $df=6,60$, $P<0.0001$). The maximum loss occured at two days after the entorhinal lesions. Although the synaptic replacement followed with age in these two groups, the replacement was notably faster in the lesioned control. The lesioned control rats recovered about 73% of the lost synapses by day 15 post-lesion. By day 30 post-lesion, synaptic density in those rats reached 88% of the unlesioned control value. The experimental group demonstrated the inhibitory effect of halothane on reactive synaptogenesis in the dentate gyrus ($F=71.64$, $df=3,20$, $p<0.0001$). The rate of synaptic recovery was very low during the time rats were exposed to halothane. Only 17% of the lost synapses were restored by the day 15 post-lesion. However, suppression of reactive synaptogenesis for 15 days did not induce a permanent synaptic deficit. Rapid recovery of the synaptic population followed when halothane exposure was terminated. Thus, by day 30 post-lesion, the synaptic density in halothane-exposed rats attained the lesioned control values ($t=1.6479$ $df=20$, $p>0.12$). This suppressive action of halothane suggests its utility as a research tool for delaying synaptogenesis during selected developmental epochs or recovery from brain lesions, to study the relationship between synaptic and behavioral recovery. Supported by March of Dimes grant 15-56.

258.9 REMAK AND SCHWANN CELL SUSCEPTIBILITY TO LOCAL ANESTHETIC-INDUCED INJURY IN RAT SCIATIC NERVE. M.W. Kalichman, H.C. Powell*, R.R. Myers*. Anesthesia Research, V-151, VA Med Ctr, San Diego, CA 92161.

Local anesthetics can be neurolytic (e.g. Myers et al., Anesthesiology 64: 29, 1986); however, little is known about the etiology or mechanisms of the resulting nerve injury. Using a model developed in this laboratory, numerous studies have been conducted examining the neurotoxicity of a representative group of local anesthetic agents including chloroprocaine, etidocaine, lidocaine, and procaine. Surveys of the tissue exposed to toxic concentrations of these agents suggested the possibility that the severity of Schwann cell injury was dependent on the type of Schwann cell. Two types of Schwann cell are found in peripheral nerve: Remak cells which do not myelinate associated nerve fibers and Schwann cells (SC-M) which myelinate nerve fibers. To test the hypothesis of differential sensitivity to nerve injury, tissue was examined from a study in which 3 concentrations of each of 4 different local anesthetics were tested. Test solutions were injected near the sciatic nerve of female Sprague-Dawley rats. After 48 hours, the nerves were removed and prepared for light and electron microscopy. One-micron-thick sections from a representative block from each nerve were evaluated by light microscopy and ultrathin sections for electron microscopy were cut from blocks that were sufficiently well-fixed. Five of these blocks were randomly selected for this study. Electron microscopy was done on a Zeiss 10 electron microscope at 2000x.

Remak cells, SC-M, and the number of injured cells were counted in each negative representing a 41 X 44 um non-overlapping cross-section of the largest fascicle from the selected nerve block. Cytoplasmic vacuolization (VAC) and the disruption of the basal lamina (BLD) occurred with approximately twice the frequency in Remak cells (58% and 62%) compared to SC-M (22% and 20%). Conversely, lipid droplets were significantly more frequent in SC-M (9% vs. 2%). Chi-squared calculations for comparisons of each of these three pairs of proportions indicated a highly significant difference in susceptibility between SC-M and Remak cells ($P \ll 0.001$).

VAC and BLD are significant pathologic features of Schwann cell necrosis. The relative absence of lipid droplets in the cytoplasm of Remak cells supports the hypothesis that these inclusions are indicative of a protective mechanism in the SC-M. Since other histopathological and functional evidence is consistent with the hypothesis that the relative potencies of local anesthetics as neurolytics and as anesthetics are comparable (Co Tui et al., J Pharmacol Exp Ther 81: 209, 1944), it is worth noting that the present results demonstrate greater injury to those Schwann cells associated with small, pain-carrying fibers -- a mechanism consistent with local anesthesia.

258.10 NEUROTOXICOLOGICAL ASSESSMENT OF 3-ACETYL PYRIDINE IN RATS. V.C. Moser,[1] K.F. Jensen,[2] J.P. O'Callaghan,[2] and R.C. MacPhail.[2] [1]Northrop Services, Inc, RTP, NC 27709 and [2]U.S. EPA, Neurotoxicology Division, RTP, NC 27711.

3-Acetyl pyridine (3AP) produces a characteristic cerebellar ataxia presumably due to the loss of the inferior olivary neurons, the source of cerebellar climbing fibers. In the present experiment we established a profile of the neurobehavioral effects of 3AP using a functional observational battery (FOB). The FOB is a series of observations and measurements that can be rapidly applied to toxicant-treated rats, and includes home-cage and open-field observations, neuromuscular and sensorimotor tests, and physiological measures. Evaluations were made according to U.S. Environmental Protection Agency testing guidelines so as to determine dose-, time-, and sex-related toxicant effects. Long-Evans hooded rats of both sexes (N=10/dose) were dosed i.p. with either saline, 40, 50, or 60 mg/kg 3AP. Testing occurred immediately before dosing and at 4 hr, 1, 4, 10, and 23 days after dosing. Three rats from each dose group were perfused with 4% paraformaldehyde 35 days after dosing. Alternate sections from the region containing the inferior olive were either stained with cresyl violet to estimate cell loss, or prepared for immunohistochemical localization of glial fibrillary acidic protein (GFAP)-like reactivity. In addition, samples of a corresponding region were taken from an additional three rats per dose group and assayed for GFAP by RIA. The effects of 3AP on muscle tone and equilibrium were most outstanding and lasted from 1 day to the last day of testing (23 d). Effects of 3AP included altered gait (ataxia and tip-toe walking), decreased muscle resistance and grip strengths, increased landing foot splay, and catalepsy. Decreased motor activity, general signs of toxicity, and hypothermia were observed only on days 1 and 4 post-dosing. The highest dose was lethal to 2 males and 1 female, between 1 and 7 days after dosing; these rats showed dypsnea, lacrimation, salivation and marked debilitation. Females were much less affected on many of the measures by 3AP than were males. There were fewer neuromuscular effects in females, for example, no changes in grip strengths or landing foot splay were obtained. In addition, a dose of 40 mg/kg was sufficient to produce significant effects on gait in males, but only the highest dose (60 mg/kg) was effective in females. Histological examination revealed a dose-dependent loss of large neurons, and gliosis in the region of the inferior olive of both male and female rats. In summary, 3AP profoundly affected primarily neuromuscular function in rats. In males, but not females, the extent of morphological changes appeared to correspond to the extent of functional deficits.

258.11 POLYCHLORINATED DIBENZOFURANS REDUCE CELLULAR DOPAMINE AND NOREPINEPHRINE CONCENTRATIONS IN PHEOCHROMOCYTOMA (PC-12) CELLS. R.F. Seegal, W. Shain, B. Bush*, P.W. O'Keefe* and K.O. Brosch*. Wadsworth Center, NYS Dept. of Health, Albany, NY 12201.

Polychlorinated biphenyls (PCBs) are ubiquitous environmental contaminants shown to produce neurological dysfunctions in humans and behavioral and neurochemical changes in animals. We have recently demonstrated (NSA, 12, 91, 1986) that PCBs decrease PC-12 cellular concentrations of dopamine (DA) and norepinephrine (NE). However, PCBs are often contaminated during manufacture and use with the more toxic polychlorinated dibenzofurans (PCDFs). In order to determine whether PCDFs are also neurotoxic we studied the effects of PCDFs alone and in combination with PCBs on catecholaminergic function of rat PC-12 cells in culture.

PCDFs were separated from the PCBs (Aroclor 1254) by Florisil column chromatography. Gas chromatography-mass spectrometric analysis showed that the PCB fraction contained PCDFs below the 1 ppb detection limit. The PCDF fraction contained over 95% of the 20 ppm total PCDFs present in the original Aroclor mixture. Nearly confluent cultures of PC-12 cells were exposed to various concentrations of PCDFs, PCBs only, or PCDFs + PCBs (Aroclor 1254) for 24h. These mixtures were dissolved in dimethylsulfoxide (DMSO) and diluted in growth media. The final DMSO concentration was 0.1%. PCB concentrations ranged from 0.1 to 100 ppm. PCDF concentrations were made equivalent to the concentrations in the Aroclor 1254 mixture and ranged from 2 ppt (equivalent to .1 ppm PCB exposure) to 2 ppb (equivalent to 100 ppm PCB exposure). After exposure, cells were washed with HEPES-buffered Hanks and extracted with 0.2N perchloric acid containing 200 mg/l EDTA. Cell supernatants were analyzed by high-performance liquid chromatography with electrochemical detection. Catecholamine content of each well was normalized to protein content by incorporation of radioactive amino acids. Values of amino acid incorporation were converted to mg protein after independently assaying total protein and amino acid incorporation in parallel wells. Changes in catecholamine content are expressed as percent of DMSO-vehicle control values.

Exposure to clean PCBs produced a significant reduction at only the highest exposure level, while exposure to PCBs + PCDFs (the original Aroclor mixture) produced significant reductions of DA and NE concentrations at concentrations ≥ 1 ppm (a 50-65% inhibition at the 100 ppm exposure level). Exposure to PCDFs only at the 200 ppt level (equivalent to 10 ppm of Aroclor 1254) produced a 15-20% reduction in DA and NE concentrations and a 25-35% reduction at the 2 ppb level. These effects on catecholamine function are not due to cell loss since neither PCBs nor PCDFs decreased the protein content of the wells.

These results represent the first experimental evidence that PCDFs are capable of altering catecholaminergic function. The magnitude and direction of change induced by these three mixtures (e.g. PCBs, PCBs + PCDFs, PCDFs) suggests that the effects of PCBs + PCDFs are additive, with PCDFs possessing neurochemical action at concentrations of between 4 and 5 orders of magnitude lower than that shown following exposure to PCBs only.

258.12 Characterization of Specific [^{3}H]PK 11195 Binding Sites in Rainbow Trout Brain Membranes. A.J. Eshleman* and T.F. Murray. Toxicology Program/College of Pharmacy, Oregon State University, Corvallis, Or. 97331

Peripheral benzodiazepine binding sites (PBS) have been labelled in rat brain, kidney and heart using both [^{3}H]RO5-4864 and [^{3}H]PK 11195, a non-benzodiazepine isoquinoline carboxamide derivative. Previous reports have indicated low or undetectable levels of PBS in non-mammalian vertebrates when labelled with [^{3}H]RO5-4864. We now report measurement of a high affinity binding site for [^{3}H]PK 11195 in rainbow trout (Salmo gairdneri) brain, using a modified P_2 fraction. Equilibrium binding of [^{3}H]PK 11195 to brain membranes was determined in hypotonic buffer at 4°C following 100 min. incubation. Specific binding was defined as the difference between binding in the absence and presence of 10μM PK 11195. Equilibrium binding analysis yielded a K_d of 1.6±0.2 nM for PK 11195, as determined both by competition experiments and by non-linear least squares analysis of saturation isotherm data. The maximal binding capacity in whole trout brain was 1.1±0.05 pmol/mg protein. Regional distribution was not uniform and relative densities of sites were spinal cord > rhombencephalon > optic tectum > olfactory bulb > cerebellum > cerebrum. The range of densities in these brain regions was 5 fold.

Competition experiments revealed that the sites labelled by [^{3}H]PK 11195 in trout brain have a unique pharmacological profile compared to those in murine brain. The K_d for PK 11195 in mouse cerebral cortex was 1.8±0.9 nM, similar to the trout. However, RO5-4864, which has high affinity in the mouse (IC_{50}=10.3±8.8 nM) has low affinity in the trout (IC_{50}=106μM). Furthermore, diazepam was 100 fold, and clonazepam 15 fold, less potent at the trout brain sites. In contrast, RO15-1788, a central benzodiazepine receptor (CBR) antagonist, had a low potency (IC_{50}=44μM) in trout with no effect in the mouse. Other compounds which showed efficacy only in the trout include CGS 9896 and CGS 8216, pyrazoloquinolines with agonist and antagonist activity, respectively, at the CBR in rat brain, with IC_{50}'s of 1.1±0.4μM and 2.3±0.4μM for [^{3}H]PK 11195; and diltiazem, a benzothiazepine Ca^{2+} channel antagonist, with low μM affinity. However, two structurally dissimilar Ca^{2+} channel antagonists, verapamil, a phenylalkylamine, and nifedipine, a 1,4-dihydropyridine, had less interaction with this site, giving no effect in either species or high μM displacement in the trout only. The Type I pyrethroid, permethrin, had low μM potency in both species, while deltamethrin, a Type II pyrethroid, had high nM potency in the mouse and no effect in the trout. The physiological significance of this unique binding site in Salmo gairdneri brain membrane remains to be determined. (Supported by NIEHS Center grant ESO3850).

258.13 AMIODARONE-INDUCED LAMELLAR INCLUSION BODIES ARE A MARKER OF DRUG USE RATHER THAN CELL DAMAGE.
A.J. Windebank, C. Schreiber*, and M. Blexrud*(SPON: J. Whisnant). Department of Neurology, Mayo Clinic, Rochester, MN 55905.

Amiodarone is an anti-arrhythmic drug which may produce peripheral neuropathy. Because it intereferes with lipid metabolism, it has been postulated that the drug disrupts myelination. However, clinical and biopsy studies suggest a pathologic process primarily involving the axon. We have directly investigated the effect of amiodarone on dorsal root ganglion (DRG) neurons in vitro. Three aspects of cell function were studied quantitatively; cell survival, neurite extension, and accumulation of cytoplasmic inclusion bodies (IB). All studies were carried out using E15 DRG in medium supplemented with 15% calf serum and 100 ng/ml 7S NGF. Amiodarone was added to media and actual concentration measured by HPLC.

Cell Survival. Dissociated neurons were plated into dishes with a grid pattern etched on the surface. Neurons were counted for 2 days in control medium and then sequentially for 12 days following addition of amiodarone (0-10 µg/ml) containing medium. There was no significant effect of drug on cell survival.

Neurite Extension. DRG explants were placed on a collagen surface. Incubation was carried out in control medium or the same medium with amiodarone (0.3, 2.2, 3.9, 16.7, and 32 µg/ml). Radial neurite outgrowth from individual explants was measured sequentially for 48 hours and then DRG were fixed and embedded for quantitative microscopy. Rate of neurite outgrowth was significantly ($p < .02$) affected at the highest concentration (control: .38 ± .02 mm/day; .39 ± .02 at 0.3 µg/ml; .36 ± .02 at 2.2 µg/ml; .31 ± .01 at 3.9 µg/ml; .33 ± .02 at 16.7 µg/ml; and .29 ± .02 at 32 µg/ml).

Accumulation of IB. Typical lamellar IB were identified by electron microscopy and counted in transverse sections of DRG explants. They were never seen in control neurons but appeared at the lowest concentration of drug used (0.2 µg/ml) within 48 hours. The number of IB increased with increasing drug concentration at low levels and then reached a plateau (IB/cell profile: 0.0 ± 0.1 in controls; 4.0 ± 0.6 at 0.2 µg/ml; 6.7 ± 1.4 at 1.0 µg/ml; 6.9 ± 1.2 at 2.0 µg/ml; 8.6 ± 0.7 at 3.9 µg/ml; 8.8 ± 1.4 at 5.1 µg/ml; 8.6 ± 1.5 at 9.8 µg/ml; 8.8 ± 1.0 at 16.7 µg/ml).

We conclude that the appearance of IB occurs rapidly at concentrations below the lower end of therapeutic levels (1-3 µg/ml in serum). However, cell damage measured by survival or axonal extension is not affected until higher concentrations. This would lead to the hypothesis that lamellar IB seen in tissue are a marker of drug use rather than of drug induced cell damage.

258.14 EFFECT OF GAMMA RADIATION ON AGGRESSIVE BEHAVIOR IN MALE SWISS WEBSTER MICE. D.M. Maier* and M.R. Landauer* (SPON: L. Cockerham). Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

The resident-intruder paradigm was used to assess the effects of gamma radiation on aggressive behavior in male Swiss Webster albino mice. Resident mice (individually housed) were exposed either to 10 Gy (1000 rads) cobalt-60 radiation (N=13) or were sham-irradiated (N=13). A weight-matched isolated male mouse of the same strain was designated as the intruder and was not exposed to radiation. Aggressive behavior was assessed 2 days prior to irradiation and during the first week postirradiation by placing intruders into the resident's home cage for 5 min. Immediately prior to this test, resident mice were given a preference test in which they could investigate a chamber housing their weight-matched intruder or an uninhabited chamber which served as a control for non-social investigation (Landauer, M.R. and Balster, R.L., Psychopharmacology, 78:322, 1982). Locomotor activity, assessed as the number of crossovers between the two stimulus compartments, was concurrently recorded over the 15 min preference test.

Over the course of resident-intruder testing, aggressive behavior was greatest in both groups of mice on the first test session (2 days prior to treatment). By 7 days postirradiation, the number of attacks and total attack time were significantly decreased in the mice exposed to 10 Gy radiation compared to sham-irradiated animals. Irradiated mice also exhibited an increase in the latency to fight on this day. Locomotor activity between the two groups did not differ until day 7 post-irradiation when the irradiated animals showed a significant decrease in the number of crossovers. On all test days, investigation of the conspecific was greater than investigation of an uninhabited compartment for sham-treated mice. However, in the irradiated mice, the preference for the conspecific decreased after irradiation and had completely disappeared by 7 days postirradiation.

The results of this experiment indicate that a dose of 10 Gy gamma radiation did not significantly decrease aggressive behavior, locomotor activity, or social investigation until 7 days postirradiation. All animals exposed to 10 Gy died 8 to 9 days postirradiation. A dose-response study is now in progress to determine the effects of sublethal doses of gamma radiation on social behavior.

258PO PERINATAL UPREGULATION OF BENZODIAZEPINE RECEPTOR ONTOGENY: "FEARLESS" AND MORE EFFICIENT GOAL-DIRECTED BEHAVIOR OF MATURE, FOUR MONTHS OLD RAT PROGENIES. T.J. Marczynski, M.C. Hawkins*, P.G. Swann*, A.F. Krivograd* and M. Dugich*. Department of Pharmacology, University of Illinois College of Med., Chicago, IL 60612.

For 3 weeks, between gestation day 14 and postpartum day 14, pregnant and subsequently lactating rats had ad libitum access to Purina Chow and drinking water. In the 1st group of 10 rats, water contained a benzodiazepine antagonist, RO 15-1788 (17.5 mg dissolved in 3 ml of the vehicle and added to 1 L of tap water); in the 2nd group, water contained diazepam (DZ; 35 mg/L), and in the 3rd group water contained a comparable volume of the vehicle (LaRoche Co.). On the average, the pregnant and subsequently lactating dams consumed 2.9 mg/kg/day of RO 15-1788, or 5.3 mg/kg/day of DZ. On the postpartum day 15, the lactating dams regained access to plain tap water. The litters were reduced to 6-7 pups per dam by removing the females on postnatal day 2.

The gross development of the male offsprings was comparable in all three groups, as judged by their viability, weight gain and motor skills. However, the mature 4 months old offsprings (N=9) that had been perinatally exposed to RO 15-1788 displayed a significantly different behavioral profile than the control (N=9) or the DZ-exposed progenies (N=9): a) During 13 daily trials in the Radial Arm Maze, they readily habituated to novel environment, their exploratory activity was uninhibited by "intimidating" visual and auditory stimuli (a pendulum with a ticking clock that swung 1 ft over the center platform of the radial maze), whereas both the control and the DZ-exposed offsprings tended to "hide" in the least illuminated part of the maze; b) their mean latencies to explore all 8 alleys and to collect all baits were significantly shorter (2.4 min; $p<0.0002$) than for the control group (3.5 min) or the DZ group (5.3 min); c) they made much fewer errors in the maze, as defined by Olton & Samuelson (J. exptl. Psychology, Animal Beh. Processes, 1:97, 1976); their ratio between the sum total of errors and the number of collected baits over thirteen 20 min daily trials equaled 212/936, and was smaller ($p<0.0001$) than the ratios of 305/929 and 322/913 for the control and the DZ-exposed group, respectively; d) they had a much better control over their bowels and urinary bladders than either the control or the DZ-exposed animals, as judged by the urination/defecation scores ($p<0.0003$); and e) at the age of 5 months, they had an approximate 66% increase in the density of benzodiazepine binding sites in the hippocampal formation, as compared to the control or the DZ-exposed offsprings [$p<0.02$; the Peritz' multiple comparison test based on Scatchard analysis of binding assays described by Medina et al. (Europ. J. Pharmacol. 90:125, 1983)].

The results indicate that: 1) perinatal exposure to RO 15-1788 stimulates the ontogeny of benzodiazepine bindings sites in the hippocampus; 2) the increased density of these binding sites is retained in adult animals and confers to them "immunity" to emotional stress normally caused by novel and "threatening" environmental stimuli; and 3) the emotional stability apparently allows the animals to perform more efficiently in the Radial Arm Maze.

258PO FURTHER EVIDENCE THAT 5,6-DIHYDROXYTRYPTAMINE MEDIATES SOME OF THE NEUROTOXIC EFFECTS OF METHYLAMPHETAMINE: 5,6-DHT-INDUCED NEURONAL DEGENERATION IN THE SOMATOSENSORY CORTEX. L.S. Seiden and D. Commins*. Department of Pharmacol. Physiol. Sciences, The University of Chicago, Chicago, IL 60637.

Methylamphetamine (MA) and some related drugs including methylenedioxyamphetamine, methylenedioxymethylamphetamine (MDMA), and parachloramphetamine (PCA) are toxic to serotonergic neurons. Administration of these drugs to rats produces long-term neurochemical deficits indicative of nerve terminal destruction, including depletions of 5-hydroxytryptamine (5-HT) and 5-hydroxyindoleacetic acid, and a reduction in the number of high affinity uptake sites for 5-HT. 5,6-Dihydroxytryptamine (5,6-DHT), a serotonergic neurotoxin, has recently been detected in the rat brain following administration of MA or PCA leading us to speculate that the endogenous formation of 5,6-DHT from 5-HT may mediate the neurotoxic effects of MA and related drugs on the serotonergic system.

In addition to their toxic effects on serotonergic neurons, MA, PCA and MDMA cause degeneration of neurons in a restricted area of laminae III and IV of primary somatosensory cortex. We hypothesize that two factors may account for the selective degeneration of these particular non-serotonergic neurons. First, these neurons may receive a particularly dense serotonergic projection so that the local concentration of 5,6-DHT formed from 5-HT following administration of MA or related drugs is high enough to damage the somatosensory cortical neurons despite the fact that they are not serotonergic. Secondly, these neurons may themselves possess some property that makes them more susceptible than other non-serotonergic neurons to the toxic effects of 5,6-DHT.

In the present experiment we tested the latter hypothesis by infusing 125 µg of 5,6-DHT or vehicle unilaterally into the lateral ventricle of rats. The rats were perfused 1-2 days after surgery with 10% formal saline and their brains were processed according to method I of Fink and Heimer. Preliminary results indicate that the distribution of degenerating neurons in the rat somatosensory cortex following infusion of these high doses of 5,6-DHT is similar to that seen after administration of MA, PCA and MDMA, supporting our hypothesis that: 1) endogenously produced 5,6-DHT mediates the neurotoxic effects of MA and related drugs and 2) neurons in laminae III and IV of the somatosensory cortex are selectively affected by MA and related drugs because they are more sensitive to the toxic effects of 5,6-DHT than other neocortical neurons. This research is supported by NIDA DA-00085; USPHS MH-14274 Training Grant. L. Seiden is the recipient of RSA MH-10562.

259.1 NEUROTENSIN SELECTIVELY ATTENUATE DOPAMINE INHIBITION OF MIDBRAIN DOPAMINERGIC NEURONS. W.-X. Shi* and B.S. Bunney (SPON: S.H. Koslow). Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Many lines of evidence suggest an interaction between neurotensin (NT), a tridecapeptide, and dopamine (DA) in the mammalian central nervous system. A number of reports have indicated that NT has physiological and behavioral effects that resemble those of DA antagonist. These observations have led Nemeroff to postulate that NT could be an endogenous neuroleptic (Nemeroff, C.B., Biol. Psychiatry, 15:283,1980). We report here that NT can selectively attenuate the response of midbrain DA neurons to microiontophoretically applied DA.

Male rats weighing between 280-320 g were used. The animals were anesthetized with chloral hydrate. Extracellular neuronal signals were recorded through the central barrel of a seven-barrel micropipette. One of the outer barrels was filled with 0.5 m NaCl and used for the automatic neutralization of tip current. Others were filled with either NT (0.5 mM in 5 mM NaCl, pH 6.0), DA (0.1 M, pH 4.0), GABA (0.05 M, pH 4.0), glutamate (0.01 M, pH 8.0) or NaCl (5 mM, pH 6.0). DA neurons were identified on the basis of established extracellular electrophysiological criteria (Grace, A.A., and Bunney, B.S., Neurosci., 10:333,1983).

As previously reported for DA neurons in the substantia nigra (SN) (Andrade, R. and Aghajanian, G.K., Soc. Neurosci. Abstr., 7: 573,1981), we found that NT could produce dose-dependent significant increases in the firing rate of DA neurons in both the ventral tegmental area (VTA) and the SN. However, in most cases, NT either had no effect or only produced small to moderate increases in firing rate. On the other hand, NT significantly antagonized the inhibition of SN and VTA DA cells induced by local application of DA. The specificity of this action of NT is suggested by the finding that NT had no measurable effects on either GABA-induced inhibition or glutamate-induced excitation of these same DA neurons. The effect of NT on DA-induced inhibition also was dose-dependent and without a change in baseline activity.

NT-containing neurons and fibers are found in both the VTA and the SN. High densities of NT binding sites are also found in these areas (Lazarus, L.H., et al., Neuropharmacol., 16:625,1977; Young, W.S., III, and Kuhar, M.J., Brain Res., 203:273,1981). The striking depletion of such sites following experimental (6-OHDA) lesion of DA neurons suggests their location is on DA cells (Quirion, R., et al., Brain Res., 327:385,1985, Palacios, J.M. and Kuhar, M.J., Nature, 294:587,1981). These facts support the hypothesis that the observed modulatory effects of NT on DA cell activity may reflect an underlying physiological action of endogenous NT.

259.2 EFFECTS OF CHOLECYSTOKININ AND DOPAMINE ON THE MEMBRANE PROPERTIES OF MESENCEPHALIC DOPAMINE CONTAINING NEURONS STUDIED IN VITRO. M.S. Brodie and A.L. Mueller, Abbott Laboratories, Abbott Park, IL 60064.

Neurons of the substantia nigra (SN) and ventral tegmental area (VTA) which are presumed to contain dopamine have been demonstrated to have unique electrophysiological characteristics in vivo. These include a low firing rate (0.5 to 5 Hz), a broad action potential (2.5 to 5 msec) and an obvious inflection on the rising phase of the extracellularly recorded action potential. These cells are inhibited by local application of dopamine and by the systemic administration of the dopamine agonist apomorphine. We have previously reported that presumed dopamine-containing neurons of the VTA recorded in vitro have characteristics similar to those observed in vivo. In addition, it has been reported that administration of cholecystokinin octapeptide (CCK-8), which is colocalized with dopamine in some neurons of the VTA, potentiates the inhibitory action of dopamine on the firing rate of these cells in vivo. We also observed this action with extracellular recordings of neuronal activity of these cells maintained in vitro. To extend our earlier observations, we have used intracellular recording techniques in attempts to uncover the specific membrane effects of dopamine and CCK-8. Sprague-Dawley rats (100-200 gm) were sacrificed and coronal slices (300 uM) containing the ventral tegmental area and substantia nigra were prepared. A rostral section of the VTA was chosen for study, since a larger percentage of neurons which contain both CCK-8 and dopamine are found there. Intracellular recordings were made using glass microelectrodes containing 2M KCl (40-80 MOhm). Stable recordings were obtained which could be maintained for up to four hours. Dopamine, in concentrations of from 10 to 50 uM, reduced the firing rate of those cells which exhibited spontaneous activity. In agreement with observations reported by others, dopamine decreased the input resistance of cells of the SN and some cells of the VTA. There was, however, a distinct population in which the dopamine-induced reduction in spontaneous activity was accompanied by a resistance increase. Addition of CCK-8 (5-10nM) to the superfusion medium depolarized the cell membrane; this depolarization was not accompanied by an increase in firing rate. Consistent with observations made extracellularly, prior administration of CCK-8 produced a potentiation of the inhibitory effect of dopamine on firing rate, but no clear potentiation of the effect on membrane potential or resistance was seen. While cells of the VTA exhibit a large degree of heterogeneity, those cells in which dopamine inhibition is potentiated by CCK-8 may be a select, more homogeneous population useful for studying the neuromodulatory role of CCK-8 in the central nervous system.

259.3 CHOLECYSTOKININ OCTAPEPTIDE (CCK8) POTENTIATES GABA-INDUCED INHIBITION OF DOPAMINE NEURONS IN THE RAT VENTRAL TEGMENTAL AREA IN VITRO. J.D. Stittsworth, Jr., A.L. Mueller, and M.S. Brodie. Dept. of Neurosci., Abbott Laboratories, Abbott Park, IL 60064.

Previous studies have suggested the presence of a GABA-ergic input to the ventral tegmental area (VTA). It has been proposed that this GABA-ergic input modulates DA function and alterations of this modulation may play a role in the etiology of schizophrenia. In vivo administration of either GABA or baclofen usually inhibits the firing of DA neurons; however, excitation is sometimes seen. We have previously demonstrated that CCK8 applied to DA-containing neurons in the VTA excites these neurons and potentiates the DA-induced inhibition of these neurons. Previous in vivo work suggests CCK8 potentiates GABA effects (Bunney et al., 1975, Neuronal CCK). The purpose of this study was to determine if CCK_8 might also affect GABA-induced actions, and to determine the specificity of these interactions using a VTA brain slice preparation.

Coronal brain slices, containing the VTA and SN, were prepared from male Sprague-Dawley rats (75-150 gm). Extracellular recordings were obtained from DA-containing neurons. Neurons were presumed to be DA-containing based on a spontaneous firing rate of 0.5-4.0 Hz, an action potential duration >2.5 msec, and a characteristic spike waveform. Drugs were added to the recording chamber dropwise in known concentrations and changes in the spontaneous firing rates were measured. GABA (1 uM - 100 uM), bicuculline methiodide (BMI, 10 nM - 10 uM) and baclofen (3 nM - 300 nM) were used for this study. Before a GABA agonist or antagonist was used, the neuron was tested for responsiveness to DA; only neurons responsive to DA were used in this study. Application of GABA to the recording chamber produced a dose-dependent inhibition of neuronal firing. When CCK_8 preceded the GABA-induced inhibition, potentiation of inhibition was observed in 56% of the neurons tested. Application of BMI, a GABA-A receptor antagonist, to the recording chamber resulted in a dose-dependent increase in firing of the DA neuron. BMI blocked the GABA-induced inhibition in 63% of the neurons tested. When it was possible, CCK8/GABA interactions were studied following the application of BMI. It was observed that CCK8 still potentiated GABA-induced inhibition of those neurons not affected by BMI. In another series of experiments, baclofen, a GABA-B agonist, was tested on DA neurons. Baclofen application to the bath resulted in a dose-dependent reduction of DA neuronal firing. This baclofen-induced inhibition of neuronal firing was potentiated following CCK8 application. These data suggest that both GABA-A and GABA-B receptors are present in the VTA, and that inhibition of DA neuronal firing by GABA via a GABA-B type receptor is potentiated by CCK8.

259.4 CHOLECYSTOKININ OCTAPEPTIDE POTENTIATES THE INHIBITORY RESPONSE MEDIATED BY A D-2 DOPAMINE RECEPTOR IN THE RAT VENTRAL TEGMENTAL AREA IN VITRO. A.L. Mueller, J.D. Stittsworth, Jr. and M.S. Brodie. Abbott Laboratories, Abbott Park, IL 60064.

We have reported previously that exogenously applied cholecystokinin octapeptide (CCK8) elicits an excitation of midbrain dopamine (DA)-containing neurons in the rat ventral tegmental area (VTA). In addition, CCK8 potentiates the DA-induced inhibition of these same neurons (Mueller et al., Soc. Nsci. Abst., 1986). Biochemical and pharmacological data suggest the existence of two subtypes of DA receptors, D-1 and D-2, within the CNS (Stoof and Kebabian, Life Sci., 1984). The purpose of the present study was to utilize agonists and antagonists relatively selective for these receptor subtypes (Stoof and Kebabian, 1984) in order to determine whether the DA-induced inhibition of VTA neurons which is potentiated by CCK8 is mediated via an action of DA at a D-1 or D-2 receptor.

Coronal slices of mesencephalon were prepared from male Sprague-Dawley rats (75-150 gm) as described previously (Brodie and Dunwiddie, Soc. Nsci. Abst., 1985). Extracellular recordings were obtained from presumed DA-containing neurons identified on the basis of their spontaneous firing rate (0.5-4.0 Hz), and action potential duration (>2.5 msec) and waveform. Drugs were added directly to the recording chamber in known concentrations, and changes in spontaneous firing rate were measured. All neurons were initially tested for their inhibitory response to exogenously applied DA (3-50 uM). DA-induced inhibition was blocked totally by the D-2 antagonist, 1-sulpiride (1-10 uM). CCK8 administration did not restore a DA-induced inhibition in the presence of 1-sulpiride. The D-2 agonist, LY-171555, produced a dose-dependent inhibition of DA neuronal firing (1-300 nM). In addition, this LY-induced inhibition was potentiated by CCK8 in 7/10 neurons. On the other hand, the D-1 agonist, SKF-38393 (300 nM - 300 uM), elicited no changes in firing rate, either alone or following CCK8 administration. Neither did the D-1 antagonist, SCH-23390 (500 nM - 10 uM), produce any measurable alterations in spontaneous firing rate. Taken together, these findings suggest that CCK8 modulates the inhibitory action of DA at a D-2 receptor subtype on midbrain DA-containing neurons.

259.5 DOPAMINE-GABA INTERACTIONS : EVIDENCE THAT ONLY D2 RECEPTORS CONTROL THE ACTIVITY OF THE GABA SYSTEM. R. Bernasconi*, T. Leonhardt*, D. Aryee*, A. Steulet*, P. Martin* M. Williams and S. Bischoff* (SPON: W. Haefely). Biol. Res. Lab., Pharmaceutical Div., Ciba-Geigy Ltd., CH-4002 Basle, Switzerland.

Anatomical, physiological and pharmacological data indicate the existence of important interactions between the GABA and dopamine (DA) neuronal systems. We have studied the effects of specific D1 and D2 agonists and antagonists on cortical and hippocampal GABA turnover in mice. GABA turnover was estimated by measuring the accumulation of GABA after GABA-T inhibition with gabaculine This GABA accumulation seems to be nerve-impulse dependent, and may reflect GABAergic neuronal activity (Perez de la Mora, M., Fuxe, K., Hoekfelt, T. and Ljungdahl, A. Neurosci. Lett. 5:75, 1977).

Stimulation of DA receptors by apomorphine, a mixed D1/D2 agonist, dose-dependently reduced GABA turnover, the threshold dose being between 0.25 and 0.5 mg/kg s.c. In contrast, the selective D2 antagonist sulpiride (100 mg/kg i.p. or 300 mg/kg p.o.) had no effect on either GABA levels or on GABA turnover. However, sulpiride antagonized the reduction of GABA turnover rate produced by apomorphine. Since apomorphine alone did not modify either GABA levels or GABA-T activity (Perez de la Mora, M., Fuxe, K., Hoekfelt, T. and Ljungdahl, A., Neurosci. Lett. 1:109, 1975) the above results suggest the existence of important GABA-DA interactions within the cortex and the hippocampus. They also indicate that the reduction in GABA turnover induced by apomorphine is dependent only on the occupancy of the D2 receptors. This hypothesis was supported by the fact that SCH 23390, a D1 antagonist, which by itself failed to change the concentration of endogenous GABA and only slightly decreased GABA turnover, did not antagonize the effect of apomorphine. On the contrary, SCH 23390 (0.2, 0.6 and 1.0 mg/kg i.p.) slightly, but significantly enhanced the reduction in the rate of GABA synthesis produced by apomorphine.

Since clinical experiments indicate that there is only a correlation between the clinical antipsychotic doses of various neuroleptics and their potencies at the D2 receptor, these results suggest that GABAergic neurotransmission may be involved in the mechanism of action of neuroleptics.

259.6 STRIATONIGRAL SUBSTANCE P NEURONS RESPOND NONUNIFORMLY TO LOSS OF DOPAMINERGIC INPUT IN STRIATUM. C.J. Cruz* and R.M. Beckstead (SPON: L.D. Middaugh). Department of Neuroscience, University of Virginia, Charlottesville, VA 22908.

Removal of dopaminergic input to the striatum by either pharmacological manipulations (chronic administration of dopamine antagonists) or by a 6-hydroxydopamine (6-OH-DA) lesion of the nigrostriatal dopamine projection has been repeatedly demonstrated to affect peptide neurotransmitter dynamics in striatal neurons. Levels of opioid and tachykinin peptides in terminals of striatal efferent neurons are changed by these treatments, for example, as are the amounts of mRNAs encoding their precursors in the striatum. Following removal of DA input to striatum, depletion of substance P (SP) (a tachykinin peptide synthesized in the striatum and found in high quantities in striatonigral axon terminals) in whole substantia nigra can be detected by microdissection and RIA. We sought to determine whether in fact this loss represents a uniform depletion of SP in all striatonigral neurons or whether there are differences among striatonigral SP neurons in their responsivity to loss of dopamine. We present here evidence obtained by SP radioimmunocytochemistry and quantitative autoradiography for a subpopulation of striatonigral SP neurons which maintain near normal SP levels in their terminals following chronic haloperidol or a unilateral 6-OH-DA lesion despite a loss of total nigral SP.

Adult rats were either subjected to a unilateral nigral 6-OH-DA lesion or begun on a regimen of the dopamine antagonist haloperidol (2 mg/kg s.c. daily). Animals were perfused 3-28 days later with buffered formalin, and the brains were processed for SP radioimmunocytochemistry using [^{3}H]-biotin. The biotin bound to sections using this procedure correlates well ($r > 0.95$) with the amount of radioimmunoassayable SP present. Midbrain images generated by apposition of labeled sections to LKB Ultrofilm were analyzed by quantitative autoradiography and comparisons of the nigral distribution of biotin were made between 1) the lesioned and control sides of 6-OH-DA animals and 2) drug and vehicle rats.

A 20-30% loss ($p < 0.01$) of SP in whole SN was detected after both treatments. Careful examination of the regional distribution of SP in treated animals revealed, however, that the content of SP in afferents impinging on the middle, medial pole of SN is virtually unaffected by a 6-OH-DA lesion and only slightly decreased (12%) by chronic haloperidol. We conclude that 1) there exists a subpopulation of striatal SP neurons projecting to middle, medial SN which are resistant to the SP-depleting effects of striatal DA denervation and 2) when examining brain antigen levels, radioimmunocytochemistry and quantitative autoradiography together allow the determination of small regional differences which would go undetected by conventional microdissection/RIA methodology.

259.7 DOPAMINE RECEPTORS MEDIATE ALTERATIONS IN STRIATO-NIGRAL DYNORPHIN AND SUBSTANCE P PATHWAYS. I. Nylander*, L. Terenius* (SPON: L. A. Bettinger) Department of Pharmacology, Uppsala University, Uppsala, Sweden.

Dynorphin peptides are present in a striato-nigral pathway parallel to the substance P pathway, and evidence for an interaction between nigro-striatal dopamine neurons and peptidergic neurons has been presented (Christensson-Nylander et al. Exp. Brain Res. 64: 169-192, 1986; Herrera-Marschitz et al. Exp. Brain Res. 64: 193-207, 1986). This study investigated the effect of different dopamine receptor acting substances on opioid peptides and substance P.

Substance P and the proposed prodynorphin (proenkephalin B) derived peptides: dynorphin A, dynorphin B, (Leu)enkephalin-Arg^6 and (Leu)enkephalin were measured in substantia nigra, globus pallidus and striatum after a subacute (5 doses every 6h) treatment of rats with a number of dopamine agonists and antagonists. Drugs selective for the dopamine D1 and D2 receptors, respectively, as well as unselective drugs were used. After decapitation and dissection the tissues were extracted with 1 M acetic acid and the extracts were applied to ion exchange columns to separate and purify the peptides. Each peptide was measured using a radioimmunoassay procedure.

In substantia nigra, levels of immunoreactive dynorphin A and dynorphin B were increased after treatment with a D2-antagonist (sulpiride, 100 mg/kg) and a D1-agonist (SKF 38393, 15 mg/kg), while a D1-antagonist (SCH 23390, 0.1 mg/kg) reduced levels. A corresponding increase of nigral (Leu)enkephalin levels were found after sulpiride treatment. In contrast to dynorphin peptides, (Leu)enkephalin-Arg^6 levels were markedly increased after both D1- and D2-(LY 171555, 0.5 mg/kg)-stimulation. Substance P tended to be reduced after D1-stimulation and treatment with all the dopamine antagonists; the reduction was significant with sulpiride and cis-flu-penthixol (0.1 mg/kg).

Peptide levels were also measured in striatum and globus pallidus, and were generally affected as in substantia nigra.

The results in this study present further evidence for different effects of dopamine receptor agents on dynorphin levels compared to substance P. Effects on the proposed prodynorphin derived peptides (Leu)enkephalin and (Leu)enkephalin-Arg^6, only partly paralleled the effects on dynorphin levels, suggesting the D1 and D2 receptors elicit different responses on different products from prodynorphin, that is, differentially affect processing.

259.8 IN VITRO EXPERIMENTS ON INTERACTIONS BETWEEN DOPAMINE AND NEUROTENSIN RECEPTORS IN THE RAT STRIATUM. H. Ishida*, S. Kito and R. Miyoshi (SPON: M.Shimoyama). Third Department of Internal Medicine, Hiroshima University School of Medicine, 1-2-3 Kasumi, Minami-ku, Hiroshima 734, Japan.

Functional relationship between neuropeptides and conventional neurotransmitters is one of the most up-to-date themes in field of neuroscience. In the present study, we investigated effects of neurotensin (NT) on dopamine (DA) receptor binding in relation with DA receptor subtypes from viewpoints of receptor binding and release experiments using brain slices.

Wistar strain male rats weighing 200g were decapitated. After rapid removal of the striatum, P_2 fractions of the tissue were prepared by the method of De Robertis et al. The resulting pellets were resuspended in 50mM Tris/HCl buffer (pH7.4) and used for binding experiments. To examine NT's effect on the striatal DA D1 receptor, either NT or its analog, NT(1-8), was added in the DA/^{3}H-SCH23390 inhibition experimental system. As the results, both NT and NT(1-8) had effects of converting a part of D1 high affinity binding sites to low affinity ones, when analysed by our computer system. Such effects of NT on D1 receptor were equally obtained by adding GTP instead of NT. When both NT and GTP were added in this binding system, the effects were not additive and results were exactly the same to the cases in which either NT or GTP alone was used. NT and its analogs' effects on DA/^{3}H-spiperone inhibition, that is D2 agonist receptor, were also examined and similar effects of NT on D2 agonist binding were confirmed. From a viewpoint of neuropeptide-neurotransmitter interaction, it is of interest to examine DA receptor agonists' effects on ^{3}H-NT binding or NT-induced accumulation of phosphatidylinositol (PI) metabolites. In this study, striatal slices were incubated with ^{3}H-myo-inositol. After washing, they were incubated with NT and/or DA in presence of 10mM LiCl and released PI metabolites were assayed following the Berridge's method. It was confirmed that DA also exerted some effects on the NT-induced PI turnover showing reciprocal relations between NT and DA systems.

259.9 INTERACTIONS BETWEEN DOPAMINE AND ACETYLCHOLINE IN THE OLFACTORY TUBERCLE AND NUCLEUS CAUDATE. H. Suarez-Roca* and L.X. Cubeddu. Div. Clin. Pharmacol., Univ. North Carolina, Chapel Hill, NC 27514.

The olfactory tubercle (OT) is a limbic structure which receives a dense dopaminergic innervation from the ventral tegmental area and also contains the most rostrally located cholinergic cells in the brain. It has been suggested that there is a lack of interaction between the dopamine (DA) and acetylcholine (ACh) neurons in the limbic structures (Consolo et al., 1977; Bluth et al., 1985; Salama et al., 1986). We conducted a comparative study on the electrically-evoked release of DA and ACh from OT and nucleus caudate (NC) and its modulation by DA receptors. Slices were labelled with 3H-DA and 14C-choline and then superfused. Comparable magnitude of DA and ACh release was evoked by electrical stimulation from both regions. Apomorphine (APO), a D1-D2 agonist, and LY-171555 (LY), a D2 agonist, inhibited DA and ACh release from OT and striatum with similar EC50 and Emax. However, the maximal inhibition of ACh release achieved with APO, LY or DA in the OT was only half of that observed in the NC. In both regions, the inhibitory effects of DA agonists on DA and ACh release were markedly reduced when the number of electrical pulses and/or the frequency of stimulation were increased. l-Sulpiride, a DA D2 antagonist, increased the release of DA and ACh from OT in direct relationship with the frequency of stimulation. In the OT increases in synaptic DA achieved by administration of amphetamine or by blockade of the neuronal uptake pump with nomifensine inhibited the release of ACh. Again these drug treatments produced only a 40-50% inhibition of ACh release. SKF 38393, a D1 agonist, had no effect per se on DA or ACh release in OT slices from control or from reserpine-treated animals (2 mg/Kg, s.c. for 3 or 7 days). With exception of one specific dose combination, coadministration of SKF 38393 and LY produced no additive or synergistic effects on DA or ACh release from OT. APO and LY-induced inhibition of DA and ACh were antagonized by l-sulpiride. Although 30 nM SCH 23390 had no effect, a higher concentration (300 nM) of the D1 antagonist, reduced APO-inhibition of DA and ACh release, without affecting the inhibitory action of LY on DA and ACh release. These observations suggest: 1. The efficacy and potency of drugs acting on striatal and limbic DA receptors modulating DA or ACh release is strongly dependent on the basal activity of the neurons. 2. Ventral tegmental and nigro-striatal DA neurons projecting to the OT and striatum, respectively, are under efficient autoreceptor control. The DA autoreceptors are of the D2 subtype. 3. Inhibition of cholinergic function by DA is less efficient in OT than in the striatum. 4. A possible synergistic interaction between DA D2 and D1 receptors on DA and ACh release from OT, cannot be ruled out. (Supported by NIH Grant NS 21645-02)

259.10 EFFECTS OF SELECTIVE D1 AND D2 AGONISTS ON REGIONAL SEROTONIN AND DOPAMINE METABOLISM IN THE RAT. R. Trifunovich* and D. Wirtshafter (Spon: P. Tueting). Dept. Psychology, Univ. Ill. at Chicago, Chicago, Ill., 60680.

Several workers have reported that systemic administration of the mixed D1/D2 agonist apomorphine leads to an increase in serotonin levels in the striatum, suggesting an interaction between central dopamine and serotonin systems. In the current study we attempted to replicate these results and extend them by examining the effects of selective D1 and D2 agonists.

Apomorphine (3 mg/kg) produced a large decrease in the concentrations of DOPAC and HVA in both the striatum and nucleus accumbens consistent with the notion that this drug inhibits the activity of dopaminergic neurons. Apomorphine also produced a 37% increase in serotonin concentration in the striatum, without influencing serotonin levels in the nucleus accumbens. Identical results were observed after combined injections of the D1 agonist SKF-38393 (20 mg/kg/ and the D2 agonist quinpirole (3 mg/kg).

Injections of SKF-38393 (20 mg/kg), a selective D1 agonist, resulted in a small, but significant, decrease in striatal levels of DOPAC and HVA 30, but not 60 min., following injection. These treatments, however, were without any effect on striatal serotonin levels. In contrast, treatment with the selective D2 agonist quinpirole (3 mg/kg) produced a large decrease in the levels of striatal dopamine metabolites and a 33% increase in striatal serotonin levels. The concentration of 5H1AA was, however, unchanged resulting in a significant decrease in the ratio of 5H1AA to serotonin.

The results of these studies suggest that dopamine D2, but not D1, receptors modulate the activity of serotonergic neurons projecting to the striatum. In contrast, the activity of serotonergic cells projecting to the nucleus accumbens does not appear to be modulated by dopamine.

259.11 λ-AMINOBUTYRIC ACID (GABA) TRANSAMINASE INHIBITION: EFFECTS ON STRIATAL DOPAMINE (DA) METABOLISM. C.F. Saller, M.J. Czupryna*, and A.I. Salama. Department of Pharmacology, Stuart Pharmaceuticals, A Division of ICI Americas Inc., Wilmington, DE 19897.

The accumulation of GABA, following the inhibition of GABA transaminase, in striatonigral and substantia nigra (SN) neurons has been used as a measure of GABA turnover. However, in attempting to assess the effects of haloperidol, a DA receptor antagonist, on GABA accumulation in the SN and in the superior colliculus (SC), which receives a GABAergic input from the SN, we found that the inhibition of GABA transaminase appeared to profoundly alter the response to haloperidol.

GABA concentrations in rat SN and SC were measured using a sensitive automated HPLC assay, which permits the quantitation of the dansyl chloride derivatives of GABA and its precursor glutamate (Saller and Salama, in preparation). DA and its two major metabolites, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), were measured using an automated HPLC system with electrochemical detection (Saller and Salama, J. Chromatog. 309:287, 1984). All animals were killed by microwave irradiation, focused on their heads, to avoid postmortem increases in GABA concentrations.

In agreement with Walters et al. (J. Neurochem. 30:759, 1978), the accumulation of GABA was linear as a function of time for at least 75 min in both the SN and SC following the inhibition of GABA transaminase with aminooxyacetic acid (AOAA, 25 mg/kg, i.p.). By itself, AOAA also produced small, but significant, decreases in striatal DOPAC and HVA concentrations. More importantly, when AOAA was given 15 min prior to haloperidol (1 mg/kg, i.p.), the ability of haloperidol to elevate striatal DOPAC and HVA concentrations, at either 30 or 60 min after haloperidol, was greatly reduced. These observations are in accord with the well known inhibitory influence of GABAergic neurons in the SN on nigrostriatal dopaminergic transmission. Thus, the data indicate that the accumulation of GABA following GABA transaminase inhibition is apparently sufficient to dramatically alter dopaminergic transmission, particularly in response to the DA receptor antagonist haloperidol. Moreover, these findings suggest that the elevations in GABA produced by GABA transaminase inhibition, by altering dopaminergic activity, may also alter the activity of GABAergic neurons that are innervated by DA-containing neurons, confounding measurements of GABA turnover.

259.12 **COMPARISON OF CHOLINESTERASE ACTIVITIES AND MUSCARINIC AND DOPAMINERGIC RECEPTORS AMONG THREE DIFFERENT RAT STRAINS: S.D., WKY AND SHR.** D. K. Lim, Y. Ito, A. B. Porter, B. Hoskins, I. K. Ho and R. W. Rockhold. Dept. Pharmacol. and Toxicol., Univ. MS. Med. Ctr., 2500 North State Street, Jackson, MS 39216, USA

The cholinesterase activities in liver, blood and brain and the dopaminergic and muscarinic receptors in specific brain areas from three rat strains were studied.

Male Sprague-Dawley (S.D.), Wistar-Kyoto (WKY) and spontaneously hypertensive (SHR) rats were used at 9 weeks of age.

The blood pressures in S.D., WKY and SHR rats were: 117±4, 120±6 and 169±7 mmHg, respectively, measured by a tail-cuff method.

Serum cholinesterase activity in WKY was significantly lower (50%) than activity in other strains. However, the acetylcholinesterase and butyrylcholinesterase activities in whole blood, liver and brain (striatum) were not significantly different among the three strains.

Studies of dopaminergic receptors revealed that the densities (B_{max}) of both D-1 ([^{3}H]-SCH 23390 binding sites) and D-2 ([^{3}H]-spiperone binding sites) receptors in striatum were significantly higher in SHR rats than in other strains. However, there were no differences in the affinity constant (K_d). Neither B_{max} nor K_d was different between S.D. and WKY. The receptor densities of D-1 and D-2 in striata from SHR rats were 34% and 18% higher than densities in striata from S.D. and WKY; respectively. The receptor density of D-2 in hypothalami from SHR rats was also higher than other strains (32%). Furthermore, the higher density in hypothalami from SHR rats was mainly due to the high population of D-2 receptors in posterior hypothalamus. In the anterior hypothalamus, the D-2 receptor density in SHR rats was slightly lower than that in WKY rats. In substantia nigra, the density of D-1 receptor was highest in SHR rats followed by WKY and S.D. rats.

In studies of muscarinic receptors, the number of [^{3}H]-QNB binding sites in striata from S.D. rats was lower (18%) than those from WKY and SHR rats. However, muscarinic receptor properties (K_d and B_{max}) were the same in hypothalami.

These results suggest that the metabolism of certain substances are different among these strains due to the different enzyme activities. Also, the different activities of dopaminergic and cholinergic neurons among these strains may alter the response to different drugs. Finally, the results also suggest that altered dopaminergic nerve activity plays an important role in the development of hypertension. (Supported by National Institute on Drug Abuse, DAO4264.)

259.13 THE EFFECT OF NICOTINIC STIMULATION ON DOPAMINE RELEASE FROM DISSOCIATED MESENCEPHALIC CELLS IN CULTURE. S. Welner*, H. Mount, P. Boksa, R. Quirion and R. Wise (Spon: J.V. Milligan). Douglas Hospital Research Centre, Verdun, Québec. and Centre for Studies in Behavioral Neurobiology, Concordia University, Montreal, Québec.

Recent behavioral evidence indicates that, in rats, nicotinic stimulation of cells in the ventral tegmental area (VTA) results in an increase in locomotor activity, an effect said to be mediated by the release of dopamine (DA). As well, electrophysiological studies show modulation of firing of VTA-DA neurons by systemic nicotine administration. Whether nicotinic stimulation in this area acts directly on dopamine neurons or whether it acts through another system to disinhibit or modulate the dopaminergic pathway, however, is not known. We investigated this question using a system of dissociated cells where the normal neuronal organization between DA neurons and other neurons which modulate these DA cells is likely disrupted. Therefore, one is able to examine direct effects of agonists on DA cells.

Suspensions of mesencephalic cells obtained from day 15 embryonic rat brain were cultured in a serum-containing medium for 5 to 7 days. Initial studies indicated that the cells are capable of taking up [^{3}H]DA (50 nM) and releasing it in response to high concentrations of K^+ (56 mM). This release is blocked in the presence of an inhibitor of DA uptake into dopaminergic neurons (benztropine, 5 μM) but not by an inhibitor of amine uptake into noradrenergic neurons (desipramine, 5 μM) or into serotonergic neurons (fluoxetine, 1 μM).

We found that cytisine, a potent nicotinic agonist, at nanomolar concentrations, induces the release of labelled DA from these cultures. This effect can be blocked by administration of the nicotinic antagonist mecamylamine (1 μM). Cytisine also induces the uptake of $^{45}Ca^{++}$ into these cultures. We studied the localization of nicotinic receptor sites using a new ligand, [^{3}H] methyl carbachol, which appears to be more selective for high affinity nicotinic sites and found that these sites are present in the VTA. Therefore, the present findings indicate that nicotinic stimulation of DA neurons in the VTA appears to be a direct rather than an indirect effect. Since DA pathways projecting from the VTA have been implicated in other systems of reward, such as that involving the opiates, the present result may also have some importance in understanding the central mechanism by which tobacco smoking produces its rewarding effect. 259.14 GLUTAMATERGIC STIMULATION OF DOPAMINE RELEASE FROM DISSOCIATED MESENCEPHALIC CELLS IN CULTURE. H. Mount, S. Welner*, P. Boksa and R. Quirion. Depts. of Pharmacology and Psychiatry and Douglas Hospital Research Centre, McGill University, Verdun, Qué. H4H 1R3 Canada.

The ventral mesencephalon contains neurons involved in the formation of nigrostriatal, mesolimbic and mesocortical dopaminergic pathways. It is also known to receive excitatory inputs from cortex and striatum. Dissociated primary cell cultures from fetal rat mesencephalon (Welner et al. this meeting) were used to demonstrate and characterize receptor-mediated stimulation of dopamine (DA) release from these neurons by excitatory amino acids.

Embryonic cells were taken at day 14 of gestation, mechanically dissociated and grown in medium containing 10% serum. On the sixth day in culture, cells were loaded with [^{3}H]-DA (50 nM) in the presence of desipramine (0.5 μM). Five min exposure to L-glutamate (GLU) resulted in Ca^{2+}-dependent release of loaded DA. In separate experiments, at 0.1 mM and 1.0 mM, GLU also stimulated uptake of $^{45}Ca^{2+}$ into cells. N-methyl-D-aspartate (NMDA), kainate (KAIN) or quisqualate (QUIS) also produced concentration-dependent release of [^{3}H]-DA. Maximal GLU- and NMDA-stimulated release were observed at 0.1 mM. KAIN was equipotent with GLU at concentrations up to 0.1 mM, but was more than twice as potent at 1.0 mM. The concentration-response curve for QUIS showed lower potency and was biphasic, reaching a maximum at 10 uM. Cis-2,3-piperidine dicarboxylic acid (<5 mM), a glutamate antagonist, produced concentration-dependent inhibition of GLU- and KAIN-stimulated DA release.

Three lines of evidence suggest that GLU-induced acute excitotoxicity cannot account for the release of [^{3}H]-DA. First, normal DA uptake and stimulated release were observed in cells preincubated for 10 min with GLU, NMDA or KAIN (0.1 mM) before loading of [^{3}H]-DA. Second, GLU-stimulated release was not dependent on extracellular Cl^- or Na^+. Third, 30 min exposure to GLU, NMDA, or KAIN (1.0 mM) did not cause a measurable increase in leakage of a cytosolic marker (lactate dehydrogenase) from cells into the medium.

These results suggest that dopaminergic neurons in the mesencephalon are directly stimulated by excitatory amino acids.
