Autoradiographic methods were applied to the characterization of hallucinogen-specific receptors using two $5HT_2$ specific ligands, ^{125}I-LSD, and a new psychotomimetic radioligand, [^{125}I]-4-iodo-2,5-dimethoxyphenylisopropylamine (^{125}I-DOI). The R(-) and S(+) enantiomers of ^{125}I-DOI were synthesized to radiochemical purity at a specific activity of 1700 Ci/mmol and 1200 Ci/mmol, respectively. In rat cortical homogenates R(-)-[^{125}I]-DOI showed saturable, specific binding (Kd: 1.41 nM, Bmax: .112 pmol/mg protein, one site model). Sixteen micron rat forebrain sections incubated in 200 pM concentrations of each enantiomer showed high densities of specific binding in the cortex (layer IV), claustrum, lateral olfactory tracts, nucleus acumbens, and diagonal band. Both enantiomers were completely displaced from all sites by unlabelled DOI and unlabelled LSD (1 uM). Sections incubated with ^{125}I-LSD under identical conditions showed a similar pattern of regional specific binding. ^{125}I-LSD also showed specific binding in the caudate-putamen, while ^{125}I-DOI showed virtually no specific localization in this region. Incubation of 200 pM ^{125}I-LSD or the ^{125}I-DOI enantiomers in the presence of various hallucinogens and hallucinogen analogs (500 nM) showed selective, regional displacement. ^{125}I-LSD was specifically displaced from the claustrum and cortex, but not from the caudate, nucleus acumbens, or olfactory tracts, by both enantiomers of DOI and DOB, but not by the inactive analog alpha-ethyl DOM. The tryptamine hallucinogens DMT and 5-MeO-DMT at 500 nM partially displaced ^{125}I-LSD. ^{125}I-DOI showed a similar displacement pattern in the presence of these unlabelled ligands. The displacement of two psychotomimetic radioligands from binding sites in the claustrum and cortex by members of each structural class of hallucinogens provides evidence that indole, ergoline, and phenylisopropylamine hallucinogens act at common receptors located in these brain regions.

311.15 COLOCALIZATION OF TRANSMITTER BINDING SITES ON THE LEVEL OF HIPPOCAMPAL LAYERS IN THE RAT AND HUMAN BRAIN. K. Zilles*, A.Schleicher, E.Horvath, D.Spencer. Anatomical Institute, University of Köln, 5000 Köln 41 and Troponwerke, 5000 Köln 80, FRG.

Information processing in the hippocampus depends on the action of many different transmitters. As a first step, to analyze possible interactions, the correlation in regional distribution of receptors for the classical transmitters acetylcholine (ACh), glutamate (Glu), GABA and serotonin (5-HT) was studied in all regions and layers of the rat and human hippocampus on frozen sections (20µm) with quantitative receptor autoradiography. The muscarinic ACh receptors were labelled with (3H)N-methyl-scopolamine(0.2nM), the M1 subtype with (3H)pirenzepine (5-10nM), The M2 subtype with (3H)oxotremorine-M, the Glu receptors with (3H)L-glutamate (100nM) both in presence or absence of Ca^{++}/Cl^{-}, the GABA receptors with (3H)muscimol (5-10nM), the 5-HT1 receptors with (3H)5-HT (2.5nM), and the 5-HT1A subtype with (3H)ipsapirone (5nM). Specific binding was measured in presence of the respective unlabelled compounds with an image analyzer (Zilles,K. et al., J.Neurosci.Meth., 18:207,1986).

The comparison of the quantitative distribution pattern of the actual binding sites with the immunohistochemically identified axonal terminals shows a clear mismatch in all cases, which suggests a different regulation of transmitters and their receptors. The comparison between the distribution in rat and man shows a high similarity in the Glu receptors, but no concordance in 5-HT receptors, which indicates caution in generalizing the rat model. The most important result is the colocalization of some, but not all of these receptors on the level of hippocampal layers. High correlations between the distributional pattern of 5-HT1A receptors on one side and M1 or Glu receptors on the other side, as well as between M1 and Glu receptors have been found. This can be an argument for interactions of different receptors in the same layer, which has already been demonstrated for Glu and α_1-adrenoreceptors (Nicoletti,F. et al., Proc. Natl.Acad.Sci.USA, 83:1931,1986).

311.16 NEURONS IN THE ROSTRAL VENTROLATERAL MEDULLA OBLONGATA CONTAIN MULTIPLE MESSENGERS. D.E. Millhorn, T. Hökfelt and K. Seroogy. Dept. of Physiology, University of North Carolina, Chapel Hill, N.C. 27514 and Dept. of Histology, Karolinska Institute, Stockholm, Sweden.

Although it is generally accepted that neuronal networks in the ventrolateral aspect of the medulla oblongata play an essential role in control of the respiratory and cardiovascular systems, relatively little is known about the chemical nature of cells in this region of the brainstem. The present study was devoted to identifying coexistence patterns of neurotransmitters and peptides in a region of the ventrolateral medulla that corresponds anatomically to nucleus paragigantocellularis (PGL).

Adult rats were pretreated with colchicine 24-48 hr prior to transcardial perfusion with a mixture of picric acid and formalin. Sections were cut on a cryostat (14µm) and processed for an indirect immunofluorescence technique that allowed simultaneous identification of multiple chemical messengers in individual cells. In some instances Fluoro-Gold (FG), a retrograde transported dye, was injected into either the nucleus tractus solitarii (NTS) or spinal cord 7 days prior to colchicine pretreatment.

Three types of coexistence (transmitter-transmitter, transmitter-peptide and peptide-peptide) were found. For example, a substantial number of individual cells in PGL stained positive for the classical transmitters serotonin (5-HT) and GABA. Moreover, a number of 5-HT/GABA cells were labelled with FG that had been injected into the thoracic spinal cord. We also found that 5-HT in the region of PGL coexists with several peptides including enkephalin (ENK) and cholecystokinin (CCK). The type of coexistence most often encountered involved the peptides somatostatin (SOM) and ENK. Numerous perikarya that showed positive immunostaining for both SOM and ENK were found at all rostral-caudal levels of PGL. Furthermore, a substantial proportion of the SOM/ENK cells were labelled with FG that had been injected into either NTS or the spinal cord. Finally, we found that essentially all 5-HT somata in PGL and caudal raphe complex as well as the epinephrine-containing cells in the C1 area of the ventrolateral medulla showed positive immunostaining for acetylcholinesterase. (Supported by Swedish MRC grant 04X-2887 and NIH grant HL 33831).

311.17 DISTRIBUTION OF MULTIPLE SECOND-MESSENGER SYSTEMS IN THE TEMPORAL CORTEX AND HIPPOCAMPUS OF THE RHESUS MONKEY. D.L. Price†, M.V. Wagster†, P.F. Worley*§, L.C. Walker† and J.M. Baraban*§. †Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med, Baltimore, MD 21205; §Dept. of Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Some neurotransmitters act through second-messenger systems to modulate synaptic interactions. To help define the role of second-messenger systems in the brain, the distribution of key components of these systems has been mapped in rat brain using in vitro receptor autoradiography [Worley et al., Ann. Neurol. 21:217-229, 1987]; discrete, heterogeneous labeling patterns were demonstrated with [^{3}H] forskolin, [^{3}H] phorbol 12,13-dibutyrate (PDBu), and [^{3}H] inositol 1,4,5-trisphosphate (IP3), which label the Gs-adenylate cyclase complex, protein kinase C, and IP3 receptor binding sites, respectively. Because receptor distributions may vary among species, the present autoradiographic study mapped these receptor sites in the temporal neocortices and hippocampi of two-year old rhesus monkeys (Macaca mulatta) (n = 5). In neocortex, [^{3}H] forskolin autoradiography showed a significant difference (ANOVA, $p < 0.0001$) in binding among six cortical layers, with the highest concentrations occurring in layers II and III and the lowest levels occurring in layer VI. In hippocampus, [^{3}H] forskolin binding was highest in CA4 and the dentate gyrus; the molecular layer showed higher binding than the granule cell layer. In neocortex, [^{3}H] PDBu binding varied significantly (ANOVA, $p < 0.0001$) among the six cortical layers, with the highest binding occurring in layer II and the lowest in layer IV. In hippocampus, [^{3}H] PDBu binding was highest in CA1. In the dentate gyrus, a slightly higher binding concentration was seen in the molecular layer than in the granule cell layer. As in the rat brain, the pattern of [^{3}H] IP3 binding was similar to that observed with [^{3}H] PDBu. In general, binding of the three ligands in temporal cortex exhibited distinct laminar distributions, with binding concentrations higher in the superficial than in deeper neocortical layers. However, in hippocampus the distribution of receptor binding for the adenylate cyclase system was markedly different than that of markers for the phosphatidylinositol system. In areas examined in monkeys, binding patterns of distribution of each of these three ligands were similar to those demonstrated in rat, indicating that the distribution of second-messenger systems may be conserved in mammalian brain.

Tissues were obtained from the Regional Primate Research Center at the University of Washington, supported by NIH grant RR 00166.

MODULATORS II

312.1 INTERACTIONS OF ETHANOL WITH GLUTAMATE AND GABA EVOKED RESPONSES OF CEREBELLAR PURKINJE NEURONS. R.-S. Lee, N. Shimizu, and D.J. Woodward. *Dept. of Cell Biology and Anatomy, The University of Texas Health Science Center at Dallas, TX 75235.*

Acute ethanol intoxication is known to produce substantial impairment of motor function and to result in certain cerebellar symptoms, such as ataxia. Previous studies from this laboratory demonstrated that ethanol may enhance the inhibitory action of GABA on cerebellar Purkinje cell (P-cell) discharge. To further examine the effect, it is of interested to study the action of ethanol on other putative neurotransmitter within cerebellum. The goal of the present study was to determine (1) the effect of acute ethanol intoxication on the response of individual P-cells to glutamate (GLUT), a putative neurotransmitter in cerebellum and (2) whether imidazobenzodiazepine Ro15-4513 (ethyl-8-azido-5,6- dihydro-5-methyl-6-oxo-4H-imidazo [1,5-a] [1,4] benzodiazepine-3-carboxylate), a putative antagonist of ethanol-GABA interaction (P. D. Suzdak et al., Science, 234: 1243-1247, 1986), antagonizes the enhancement of GABA-mediated inhibition by ethanol in P-cells of the cerebellum.

Long-Evans rats were anesthetized with halothane (2.0 % or 0.7 % in oxygen during surgery and electrophysiology, respectively). An intraperitoneal catheter used for administration of ethanol (1.5 to 2.0 gm/kg, 10-15% in saline, w/v) and Ro15-4513 (4-6 mg/kg as a 4% Tween 80 in saline suspension) was implanted before the recording session. Extracellular activity of single cerebellar P-cells was recorded with five-barrel micropipettes. GABA (0.2 M, pH=4.3) and GLUT (monosodium salt, 0.5 M, pH=8.2) were administered by microiontophoretic pulses (10 sec every 40 sec). Spontaneous discharge, and influences to GABA and GLUT responses in P-cells were monitored before and 1 to 1.5 hours after systemic administration of ethanol. A transient inhibition of spontaneous neuronal activity was observed usually within 4-8 minutes of ethanol injection. This effect lasted 2-4 minutes in 5 of the 8 rats tested. After the recovery of spontaneous discharge to control levels, we found: (1) GLUT-mediated excitatory responses were increased (10-35%) (n=5) relative to pre-ethanol values between 15 and 90 minutes post-injection, (2) imidazobenzodiazepine Ro15-4513 (4-6 mg/kg) failed to antagonize the enhancement of GABA-mediated inhibition by ethanol (n=3). These results indicate that ethanol may enhance both the inhibitory action of GABA and the excitatory actions of GLUT on spontaneous discharge of P-cells. The slow onset reaction of P-cell to both GABA and GLUT suggested that a possible indirect metabolic action was elicited by ethanol via systemic administration. Our view is that the modulatory actions of ethanol on synaptic physiology observed in the present study may reflect mechanisms of the CNS effects of acute ethanol intoxication. *Supported by grants AA-3901, DA-02338 to DJW and the Biological Humanics Foundation.*

312.2 PERIPHERAL ADMINISTRATION OF ASCORBATE MODULATES UNIT ACTIVITY IN THE NUCLEUS ACCUMBENS. L.K. White, A. Basse-Tomusk, and G.V. Rebec. Dept. of Psychology, Indiana Univ., Bloomington, IN 47405.

Ascorbate (AA) is present in high concentrations in the mammalian brain, and appears to play a neuromodulatory role in several brain areas. In the neostriatum, AA accelerates the firing rate of neurons when administered intraperitoneally (Ewing et al., Brain Res., 261:101, 1983), or when applied iontophoretically in conjunction with glutamate (Gardiner et al., Brain Res., 344:181, 1985). These results have important behavioral implications because AA appears to modulate certain drug-induced responses that appear to involve neostriatal neurons. AA, for example, potentiates the catalepsy produced by haloperidol and attenuates the behavioral response to amphetamine (Rebec et al., Science, 227:438, 1985). Like the neostriatum, the nucleus accumbens, which also has been implicated in these drug-induced behaviors, contains a high level of extracellular AA. It is conceivable, therefore, that AA modulates neuronal activity in this brain region in much the same way that it does in the neostriatum. As a first step in our investigation of this hypothesis, we monitored the response of nucleus accumbens neurons to systemic injections of AA.

Adult, male rats, anesthetized with urethane, received 500, 1000, or 1500 mg/kg AA via an indwelling intraperitoneal catheter. Single-unit activity in the nucleus accumbens was monitored for at least 1 hour following AA administration. At each dose approximately 80% of all neurons sampled showed a clear change in firing rate that typically began within 15 min. after AA administration and that persisted throughout the recording session. Both excitations and inhibitions were recorded with equal frequency. These results suggest that, as in the neostriatum, AA plays an important neuromodulatory role in the nucleus accumbens.

312.3 **THE MAJOR 27 kDa GAP JUNCTION PROTEIN IS PHOSPHORYLATED BY cAMP DEPENDENT AND Ca^{2+} DEPENDENT PROTEIN KINASES.** J.C. Saez, A.C. Nairn*, D.C. Spray, E.L. Hertzberg+, P. Greengard*, M.V.L. Bennett. Albert Einstein Coll. Med., Bronx, NY *Rockefeller University, New York, +Baylor Coll. Med. Houston, TX.

In a number of cell types intercellular coupling mediated by gap junctions can be modulated by second messengers, for example cAMP and Ca^{2+}, which can have opposite effects. In hepatocytes from rat elevation of intracellular cAMP increases junctional conductance between pairs of cells and stimulates phosphorylation of the major gap junction protein (PNAS 83: 2473, 1986). The present study shows that both Ca^{2+}/calmodulin dependent protein kinase (Ca^{2+}/CaM kinase II) and protein kinase C (both purified from rat brain) phosphorylate the 27 kDa protein in gap junction membranes from either rat or mouse liver. The 21 kDa protein which is particularly abundant in mouse was not phosphorylated by either of these kinases or by cAMP-dPK. The maximal stoichiometry for Ca^{2+}/CaM kinase and for kinase C was 0.3 mol/mol and 0.1 mol/mol respectively. Phosphorylation by kinase C required triton X-100. Moreover, optimal phosphorylation was obtained following addition of phosphotidylserine and diacylglycerol, which presumably at least partially reconstituted the lipid environment for the reaction.

cAMP-dPK, and protein kinase C phosphorylated only serine residues. Ca^{2+}/CaM kinase II phosphorylated mainly serine but also threonine to a minor extent. Two-dimensional tryptic mapping showed that Ca^{2+}/CaM kinase II phosphorylated a different serine from cAMP-dPk. Protein kinase C phosphorylated mainly the site phosphorylated by cAMP-dPK; however additional sites were phosphorylated to a smaller degree. There was no difference between rat and mouse 27 kDa protein in respect to sites and extents of phosphorylation.

A polyclonal antibody that recognizes the 27 kDa protein was used to immunoprecipitate the protein from intact hepatocytes. Cells dissociated into small groups were labeled with ^{32}P (PO_4^{3-}) for 1 hr. Cells were stimulated with forskolin (10 uM), Ca^{2+} ionophore A23187 (40 uM in 1 mM Ca^{2+}) or phorbol ester (PDBu 10-100 nM). Incorporation of ^{32}P into the 27 kDa protein rapidly (5 min) increased during all three treatments. Phosphoamino acid analysis of the immunoprecipitated protein showed only phosphoserine, and tryptic fingerprints were similar to those obtained from the 27 kDa protein phosphorylated in purified gap junctions by either cAMP-dPk or protein kinase C. Although it has been reported that in several cell types phorbol esters cause uncoupling, in this system PDBu or PMA (10-100nM) had no effect on dye transfer (Lucifer Yellow). Measurements of electrical coupling after phorbol ester or A23187 stimulation will help to clarify the role of the different kinases in modulating intercellular communication.

312.4 **HYDROLYSIS OF PI, PIP, AND PIP_2 IN ROD OUTER SEGMENTS OF DARK-ADAPTED BOVINE RETINA IS REGULATED BY DIFFERENT GTP-BINDING PROTEINS.** C.L. Jelsema* and A.D. Ma* (SPON: C.R. Merril). Laboratory of Cell Biology, NIMH, Bethesda, MD 20892.

We have previously demonstrated that light stimulates phospholipase A_2 activity in dark-adapted rod outer segments (DROS) of bovine retina by a transducin-dependent mechanism (Jelsema, JBC,262:163,1987) involving the $\beta\gamma$ subunits of this GTP-binding protein (G protein) (Jelsema and Axelrod, PNAS, in press). We now report that phospholipase C (PLase C) activity in DROS is also stimulated by light and is modulated by pertussis toxin (PT)- and cholera toxin (CT)-sensitive G proteins. PLase C activity of DROS membranes was measured by in vitro assay using either ^3H-inositol-labeled phosphatidylinositol (PI), PI-4-phosphate (PIP), or PI-4,5-bisphosphate (PIP_2) as the phosphoinositide substrate. While PIP was the major PLase C substrate in these membranes, its hydrolysis was unaffected by exposure to light and/or addition of GTPγS. In contrast, hydrolysis of both PI and PIP_2 was increased upon light exposure. While addition of GTPγS had no effect on either PI or PIP_2 hydrolysis in DROS, it markedly enhanced light-induced PIP_2 hydrolysis while inhibiting light-induced PI hydrolysis. This differential sensitivity suggests that the hydrolysis of these phosphoinositides may be regulated by different G proteins. This hypothesis was further supported by the different effects of CT and/or PT pretreatment of DROS on phosphoinositide hydrolysis. PT pretreatment (10 ng/ml) enhanced both basal and light-induced hydrolysis of PI and PIP_2 . In contrast, CT pretreatment (50 ng/ml) had no significant effect on the light-induced hydrolysis of either phosphoinositide, but inhibited basal PI hydrolysis while stimulating basal PIP_2 hydrolysis. The basal and light-induced hydrolysis of both phosphoinositides thus appeared to be regulated by (a) pertussis toxin-sensitive G protein(s), whereas basal hydrolysis was additionally controlled by (a) CT-sensitive G protein(s) able to stimulate PIP_2 hydrolysis and inhibit PI hydrolysis. PIP hydrolysis, which was unaffected by light and/or GTPγS, was inhibited by CT in the presence or absence of light, while PT proved inhibitory only in the absence of light or in the presence of GTPγS. PIP hydrolysis, therefore, also appears to modulated by (a) PT- and CT-senstivite G protein(s), but its regulation is distinct from the regulation of either PI or PIP_2 hydrolysis.

These results demonstrate that multiple G proteins regulate PLase C activity in bovine ROS. More importantly, it appears that hydrolysis of each phosphoinositide is regulated either by different G proteins or by different G protein-dependent mechanisms. A role for transducin in the light-induced hydrolysis of PI and PIP_2 is suggested by the capacity of exogenous transducin to partially restore the light-induced PLase C activity of dark-adapted transducin-poor ROS.

312.5 **PHOSPHORYLATION OF THE α SUBUNITS OF Gi, Go, Gs AND TRANSDUCIN BY cAMP-DEPENDENT PROTEIN KINASE AND THREE ISOZYMES OF PROTEIN KINASE C: SUBSTRATE SPECIFICITIES AND FUNCTIONAL CONSEQUENCES.** A.D. Ma*, S. Jaken*, and C.L. Jelsema* (SPON: B.B. Stanfield). Laboratory of Cell Biology, NIMH, Bethesda MD 20892 and the W. Alton Jones Cell Science Center, Lake Placid NY 12946.

The α but not the $\beta\gamma$ subunits of the GTP-binding proteins (G proteins) Gi, Go, Gs and transducin (T) serve as substrates for protein kinase C and cAMP-dependent protein kinase (A kinase) when assayed in vitro using isolated G protein subunits together with isolated kinases. Three distinct forms of protein kinase C (types 1, 2 and 3) were employed in this study along with the catalytic subunit of protein kinase A. The C kinases, isolated from rabbit brain, have been previously characterized using histone III-S as the substrate (Jaken and Kiley, PNAS, in press). For each of the C kinases, Giα was the preferred G protein substrate. The phosphorylation of Giα observed with C kinase type 2 was 2.5 times that obtained with either C kinase type 1 or 3. In contrast, phosphorylation of Goα was greatest with C kinase type 3, where it approached the level of Giα phosphorylation obtained with this kinase. The phosphorylation of Goα induced by C kinases type 1 and 2 was 30 and 60%, respectively, that obtained with the type 3 C kinase. For both Giα and Goα, the A kinase-induced phosphorylation was less than 5% that observed with the type 3 C kinase. While Giα and Goα were clearly better substrates for the C kinases than for A kinase, the opposite was true for Gsα and Tα. The 52K form of Gsα was phosphorylated equally by kinase A and the C kinases, and its phosphorylation by A kinase was twice that observed with Giα and Goα. The 45K form of Gsα, however, showed a marked preference for the A kinase. The levels of phosphorylation observed with A kinase were at least 4 times that observed with any of the C kinases, and there was again little difference in the phosphorylating capacity of the C kinases. Tα proved to be the least favored substrate for the C kinases, with the type 3 C kinase resulting in phosphorylation levels less than 10% that obtained with Giα or Goα. While the A kinase-induced phosphorylation of Tα was only a third that obtained with the 45K form of Gsα, it was more than double the level of A kinase-induced phosphorylation of Giα and Goα. These results demonstrate that the G protein α subunits are preferentially phosphorylated by different kinases. In addition, the binding of GTP or GDP (or their thiol analogs) as well as the state of association or disassociation of the G proteins (induced either by addition of GTP or GDP or by addition of the $\beta\gamma$ subunits) differentially altered their capacity for phosphorylation by specific kinases. Furthermore, phosphorylation of these α subunits, in addition to previously reported effects on adenylate cyclase activity, was found to alter the role of these G proteins in the modulation of phospholipases A_2 and C. This work was supported by a Howard Hughes Medical Institute Research Scholarship to ADM and a National Research Science Award (1F32MH09423-01) to CLJ.

312.6 GTP-BINDING POLYPEPTIDE PATTERNS OF RAT BRAIN REGIONS AND SUBCELLULAR FRACTIONS. S. P. Mahadik, J. Satav*, and M. J. Modak*. Div. of Neurosci., N. Y. State Psychiatric Institute and Dept. of Biochem. & Molecular Biophys., Coll. of Physicians & Surgeons of Columbia Univ. NY 10032 and Dept. of Biochem. Univ. of UMDNJ, Newark, NJ 07103.

In brain, GTP-binding proteins (G-Ps) are assumed to play functional role in a variety of cellular processes (neurotransmitter and hormonal receptor-mediated signal transduction, ionic homeostasis and protein synthesis). They are considered to exist as a large family of proteins to carry out unique cellular functions. Since each region of the brain consists of several types of neuronal and glial cells it is difficult to identify G-protein associated with a specific cell type or with a specific cellular process. We report the regional and subcellular distribution of G-proteins in adult rat brain. The proteins were labeled by photoaffinity labeling with α-P32-GTP and labeled polypeptides were analysed by SDS-polyacrylamide slab gel electrophoresis followed by autoradiography (Basu & Modak, J. Biol. Chem.262:2369, 1987). The labeling was dependent on the presence of divalent metal ions. Distinct labeling patterns were seen in the presence of Mn, Mg and Ca. In the presence of EDTA three polypeptides (80 kDa, 35 kDa & 24 kDa), which were labeled faintly in presence of Mn, were labeled intensely. Following studies were carried out in the presence of Mn. A total of 18 labeled polypeptides (ranging in molecular wts. 20 to 200 kDa) were identified in cortex, hippocampus, striatum and cerebellum. All but one (73 kDa) polypeptides required UV exposure for stable labeling. The labeling was eliminated by pretreatment with heat or protease or GTP. Labeling was reduced by pretreatment with GDP>ATP and no changes were found after pretreatment with c-GMP and c-AMP. The region-specific differences in the amount of individual G-P were consistently noted. G-Ps of subcellular fractions (nuclei, microsome, mitochondria, myeline and synaptic plasma membranes, SPM) of cerebral cortex were also analysed. Each fraction showed a characteristic pattern. There was an enrichment in a distict set of G-Ps in each fraction. The pre- and postsynaptic neurotransmitter receptor containing SPM fraction showed four major G-Ps (110 kDa, 56 kDa, 48 kDa & 21 kDa) and the concentrations of two of them (56kDa & 21 kDa) were highest compared with other fractions. It is not possible yet to identify these G-Ps with any particular receptor. Observations described here are the first report on the G-binding protein patterns in the various brain regions. These studies should permit determination of the quantitative and qualitative changes in individual GTP-binding proteins as a function of physiological change or as a result of pathological condition.

312.7 IDENTIFICATION, PARTIAL PURIFICATION AND IMMUNOHISTOCHEMICAL LOCALIZATION OF A 94 kD PHOSPHOPROTEIN PRESENT IN ASTROCYTE-LIKE CELLS IN THE BRAIN. A-M. O'Carroll*, J. Patel* and D.M. Jacobowitz, Laboratory of Clinical Science, NIMH, Bethesda, MD 20892.

A cAMP-stimulated phosphoprotein with an apparent molecular weight of 94 kD on SDS-PAGE was identified in the rat neostriatum. Subcellular fractionation of the neostriatum revealed that the 94 kD protein was predominantly localized to the cytosolic fraction. This protein has been partially purified from this source. Purification was monitored by autoradiograpy of ^{32}P-phosphorylated samples separated by SDS-PAGE. The isoelectric point of the phosphorylated protein was revealed to be 4.7 by two-dimensional gel electrophoresis and phosphorylation was found to occur exclusively on serine. A rabbit antibody was prepared to this protein by the injection of the purified protein band cut from a SDS-gel.

Immunohistochemical localization of the 94 kD protein in formalin-fixed vibratome sections revealed astrocyte-like cells with processes in the gray and white matter of the rat and monkey cortex, striatum and cerebellum. Processes were also observed to make connections with blood vessels. In the cerebellum Bergmann fibers were observed in addition to processes which enveloped purkinje cells. In conclusion, preliminary results reveal that we have isolated a 94 kD cytosolic phosphoprotein that appears to be specifically localized to a population of astroglial cells.

312.8 POTENTIATION OF VOLTAGE-ACTIVATED CURRENTS BY SEROTONIN IN XENOPUS OOCYTES INJECTED WITH RAT CAUDATE mRNA. B. Gillo*, S. Sealfon*, T.M. Moriarty*, J.L. Roberts and E.M. Landau. Dept. of Psychiatry and Dept. of Neurobiology, Mt. Sinai School of Medicine and Bronx V.A. Hospital, New York, N.Y.

Oocytes of the African frog Xenopus laevis have the capacity to translate injected foreign messenger RNA (mRNA) and express functional receptors and voltage-activated channels. We used the oocyte electrophysiological preparation to study the interaction of brain serotonin (5-HT) receptors with brain voltage-activated currents.

Total cytosolic RNA was extracted from 15 day old rat caudate nucleus by the urea/lithium chloride method. Total RNA was microinjected into defolliculated Xenopus oocytes (100-450 ng/oocyte). Cells were tested for functional expression of mRNA at least two days after microinjection. Single cells were two-electrode voltage clamped in a standard superfusion apparatus. Voltage step protocols were controlled by micro-computer.

The oocyte was voltage clamped near resting potential. The membrane was hyperpolarized to -100 mV for five seconds followed by a series of depolarizing voltage steps. Voltage jumps from -100 mV to 0 mV evoked two peaks of hyperpolarizing current of 500-3000 nA (T_{out}). Voltage jumps from -100 mV to +40 mV evoked a hyperpolarizing current of 100-1000 nA (H_{out}). H_{out} could be elicited in calcium free medium. These evoked responses were attenuated on repetition of the voltage step protocol.

Bath application of 20 nM 5-HT induced a rapid transient depolarizing current of 500-2000 nA followed by a sustained and slowly decaying 50-200 nA depolarizing current. When the voltage step protocol was run during the sustained phase of the 5-HT response, H_{out} was markedly potentiated (2-5 fold). The second peak of T_{out} was also markedly potentiated. This effect was blocked by 1 uM mianserin.

We show here that the voltage-activated channels expressed in Xenopus oocytes can be modulated by neurotransmitter acting on expressed foreign receptors.

Supported by V.A. Grant 4125-019.

312.9 MODULATION BY SEROTONIN OF A LOCAL INHIBITORY CIRCUIT IN THE HIPPOCAMPAL SLICE. S. A. Springfield. Dept. of Biology, City College of the City University of New York, New York, N.Y. 10031.

Recent evidence from electrophysiological studies has suggested a neuromodulatory role for serotonin (5-HT) in the CNS. I report here a reduction in local inhibition in a hippocampal slice preparation treated with 5-HT.

The experiments were performed on 300-400 um thick transverse slices prepared from rats weighing 150-300 g. The slices were constantly superfused with a bicarbonate-buffered balanced salt solution equilibrated with 95% O_2/5% CO_2 and maintained at 32^{o} C. Evoked population spikes, elicited by electrical stimulation of afferent fibers in the stratum radiatum, were recorded with a single barreled glass microelectrode from the somal layer of CA1 pyramidal neurons. Inhibitory recurrent interneurons were activated by positioning a second stimulating electrode in the alveus of the hippocampus. This placement antidromically activates the axons of CA1 pyramidal cells, the collaterals of which contact the inhibitory interneurons. When the antidromic stimulation followed the afferent stimulation by short intervals (10-150 msec) it produced a reduction in the amplitude of the second spike; whereas longer interstimulus intervals produced facilitation of the second spike. These events have been attributed to the action of GABA-mediated inhibition superimposed upon orthodromic excitation.

Serotonin (10 uM) added to the superfusate elicits a decrease in the amplitude of the population spike evoked from a single stimulus. For paired stimulation, 5-HT administration resulted in an increase in the amplitude of the second spike, evidence of a reduction in local inhibition. This reduction was observed 25-30 min after 5-HT application and persisted for 80 min. Recovery occurred 60 min after 5-HT was eliminated from the superfusate.

These preliminary experiments demonstrate a diminution in the efficacy of GABA-mediated inhibition by serotonin and is consistent with the idea that 5-HT has a modulatory role in the CNS. (Supported by NSF grant BNS 86-06419 and a PSC-CUNY award.)

312.10 ADENOSINE AND (-)-BACLOFEN HAVE A NEUROMODULATORY ROLE IN THE RAT SPINAL DORSAL HORN. I. Kangrga*, M. Randic and S. Jeftinija, (SPON: T. Sowa). Iowa State University, Dept. of Vet. Physiology and Pharmacology and Dept. of Anatomy, Ames, Iowa, 50011, U.S.A.

Adenosine and (-)-baclofen can depress the spontaneous and evoked activity of neurons in the central nervous system, including the spinal dorsal horn. Adenosine deaminase and 5-nucleotidase, the enzymes involved in adenosine metabolism, and a high level of adenosine receptors are present in the spinal dorsal horn. Behavioral studies have also shown that adenosine agonists increase and the antagonists decrease nociceptive thresholds in animals. (-)-Baclofen, a β-chlorophenyl derivative of gamma-aminobutyric acid (GABA), is a selective agonist for $GABA_B$-receptors. To gain more insight into the depressant effects of adenosine and (-)-baclofen, we have investigated the membrane actions of these agents on dorsal horn neurons using the rat spinal cord slice preparation.

Rats 14-26 days old were used. Conventional intracellular recording from dorsal horn neurons using 3M K-acetate-filled microelectrodes was employed. Fast and slow excitatory synaptic potentials were evoked by electrical stimulation of lumbar dorsal roots. All compounds were applied by bath perfusion.

Adenosine (10^{-6} to $5x10^{-5}$M) or 5'(N-ethyl) carboxamide adenosine (NECA, 10^{-6} to 10^{-5}M) or (-)-baclofen (10^{-7} to 10^{-6}M) elicited a dose-dependent hyperpolarization of dorsal horn neurons accompanied by a decrease in membrane input resistance. Spontaneous and evoked fast and slow postsynaptic potentials were inhibited by all three compounds. (-)-Baclofen, in addition, depressed after-hyperpolarization that follows action potential. Concentrations of bicuculline that blocked responses of dorsal horn neurons to GABA had no effect on the depressions of e.p.s.p.s. or the hyperpolarizing effect produced by (-)-baclofen. Spike frequency adaptation is significantly increased following administration of adenosine or (-)-baclofen. In the presence of TTX and TEA, adenosine and (-)-baclofen produced a shortening of duration of the high threshold calcium spike of dorsal horn neurons. Perfusion of slices with caffeine ($5x10^{-6}$ to 10^{-3}M) resulted in a reversible and concentration-dependent antagonism of the adenosine-induced effects on membrane potential and synaptic activities. Caffeine, and theophylline (5×10^{-5} to 10^{-4}M), per se, produced a decrease in resting membrane potential, increased synaptic activity and action potential firing. Caffeine induced also rhythmic oscillations of membrane potential.

It is suggested that adenosine and (-)-baclofen may modulate sensory transmission in the rat dorsal horn neurons through presynaptic sites possibly by decreasing transmitter release and they also may directly regulate the endogenous neuronal excitability through an activation of the postsynaptic recognition sites. Supported by NSF and USDA.

312.11 NEUROTRANSMITTER REGULATION OF LIPID METABOLISM IN CULTURED RAT SENSORY NEURONS, T.M. Perney* and R.J. Miller (SPON: P.J. Kontur). Dept. of Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Recently, several lines of evidence have suggested that the activation of protein kinase C (PKC) is involved in the receptor mediated inhibition of Ca^{+2} currents in sensory neurons. Activation of PKC is often associated with substances that produce their effects by stimulating the breakdown of phosphatidyl inositol-4,5,- bisphosphate (PIP_2). Degradation of PIP_2 catalyzed by the enzyme phospholipase C may then lead to the production of both inositol trsiphosphate (IP_3) and diacylglycerol (DAG). We therefore, examined the ability of norepinephrine (NE) and neuropeptide Y (NPY) to stimulate the hydrolysis of PIP_2 in cultured dorsal root ganglion (DRG) neurons.

We observed that both 1 μM NE and 10 nM NPY stimulated the synthesis of [^{3}H]DAG in DRG neurons prelabeled with [^{3}H]arachidonic acid. In both cases, two peaks of DAG production were observed. The first of these was transient, lasting approximately 30 sec, while the second was more sustained, peaking at 3 min and lasting at least 5 min. Both peaks of NE stimulated DAG formation could be inhibited by 10 μM yohimbine suggesting that this effect was mediated through activation of α_2 receptors. In addition, preliminary studies indicated that synthesis of the first peak of DAG production was blocked by pertussis toxin whereas the second was not.

Interestingly, neither NE or NPY were able to stimulate much release of [^{3}H]IP_3 from [^{3}H] inositol prelabeled DRG neurons. These agents were only able to produce a two fold increase which occured during the first 30 sec of exposure. This result indicates that much of the DAG produced by NE and NPY may not be derived from PIP_2, but possibly from phosphatidylinositol (PI), PI-glycan or even another phospholipid such as phosphatidylcholine. Neither NE or NPY were able to stimulate the release of arachidonic acid (AA) from DRG neurons.

These results for NE and NPY are in contrast to those found for the nonapeptide, bradykinin (BK). BK induced DAG synthesis was similar in magnitude to that produced by NPY and NE. However, IP_3 production was much greater (approx. 10-15 fold stimulation). In addition, BK was a potent stimulator of AA release.

We also examined the ability of NE to produce translocation of PKC in DRG cells. Translocation of PKC from the cytosol to the cell membrane has been related to the activation of the enzyme. We found that 10 μM NE caused a 50% decrease in the amount of PKC in the DRG cytoplasm suggesting movement to another cellular compartment. However, we have not yet been able to demonstrate an increased association of PKC with the cell membrane. This may be due to rapid dissociation of the enzyme during membrane preparation.

These biochemical results are consistent with activation of PKC in DRG neurons by inhibitory neurotransmitters such as NE and NPY, and a role for PKC in the control of DRG Ca^{+2} currents.

312.12 FORSKOLIN AND PHORBOL ESTERS REDUCE THE LARGE TRANSIENT CALCIUM CURRENT IN MOUSE SENSORY NEURONS. R.A.Gross and R.L.Macdonald, Department of Neurology, University of Michigan, Ann Arbor, MI 48104, U.S.A.

Cyclic AMP analogs and forskolin (FOR), an activator of adenylate cyclase, have been used to study the cyclic AMP/A kinase system. These compounds increase or decrease K conductances in various neurons, and enhance Ca conductance in invertebrate neurons and vertebrate cardiac cells. Analogs of diacylglycerol and the phorbol esters activate protein kinase C directly, and have been used to study the phosphatidylinositol-linked second messenger system. These compounds also reduce K conductances but also reduce Ca conductance in vertebrate neurons. We studied the effects of the adenylate cyclase activator FOR and the C kinase activators phorbol 12,13-dibutyrate (PDBu) and oleoylacetylglycerol (OAG) on the three calcium currents in mouse DRG neurons.

Intracellular recordings were obtained with micropipettes filled with 3M CsCl (20-30 MΩ) from mouse DRG neurons in culture. Recording medium (pH=7.3-7.4) suppressed Na and K currents, and contained (in mM): Tris 13.0; choline-Cl 67; KCl 5; TEA 100; $CaCl_2$ 2.0; glucose 5.6; $MgCl_2$ 0.8. A single electrode voltage clamp was used to record calcium currents with a switching frequency of 6-8 kHz and a 70-30 duty cycle. Voltage steps were generated and digitized data stored (2-6 kHz sampling) using a microcomputer. Drugs were applied by pressure and/or diffusion from blunt-tipped (5-20 μM) micropipettes. Three calcium currents were recorded. A small transient current was recorded at -60 to -50 mV when evoked from negative holding potentials (-100 to -90 mV) (T-type). A moderate very slowly-inactivating current was recorded at potentials positive to -20 mV when evoked from holding potentials of -50 to -40 mV (L-type). A large transient current (N-type) was recorded with the L-type current at potentials positive to -40 mV when evoked from holding potentials of -80 mV.

FOR (100 μM) had no effect on the T-type current. Within 2 min of application, FOR reduced the peak current of combined N- and L-type currents without an effect on the late ($\geq$300 msec) current, suggesting a selective effect on the N-type current. Both OAG (50 μM) and PDBu (500 nM) had similar effects, with similar latencies. Effects of all compounds lasted $\geq$ 5 min. The inactive phorbol, 4-α-phorbol, had no effect. The effects of OAG and PDBu were voltage-dependent, being negligible on currents evoked from holding potentials negative to -80 mV, and maximal when evoked from holding potentials of -70 to -50 mV. Although these compounds may have effects other than activation of their respective kinases, these data suggest that activation of A and C kinases may selectively modulate calcium conductances.

Supported by NIH NS01019 to RAG and NIH NS19692 to RLM.

312.13 DEPOLARIZATION OR PHORBOL ESTER TREATMENT STIMULATE EFFLUX OF ARACHIDONIC ACID AND ITS METABOLITES FROM MOLLUSCAN NERVOUS SYSTEM. R.O. Carlson* and I.B. Levitan. (SPON: P. Robinson). Grad. Dept. of Biochemistry, Brandeis University, Waltham, MA 02254

The effects of depolarizing agents and phorbol esters on efflux of eicosanoids (arachidonic acid and its metabolites) were studied with ganglia from the molluscs *Aplysia californica* and *Helix aspersa*. To follow eicosanoid efflux, ganglia were preincubated in appropriate saline supplemented with up to 50 nM [^{3}H]arachidonic acid (specific activity 240 Ci/mmol). [^{3}H]arachidonic acid taken up into the ganglia was found to be stored almost exclusively in neutral lipids and phospholipids. After washing to remove excess [^{3}H]arachidonate not taken up, the efflux of eicosanoids was monitored by measuring accumulation of radioactivity in the medium (containing 5 mg/ml fatty acid free BSA). Exposure of ganglia to elevated KCl or 100 μM veratridine was used to induce depolarization. Eicosanoid efflux increased about 2 fold in response to depolarizing conditions in both *Helix* and *Aplysia*. The phorbol ester 12-O-tetradecanoyl-13-acetate (TPA) also stimulated eicosanoid efflux from both *Helix* and *Aplysia* ganglia, with EC_{50} values of 140 nM and 15 nM respectively. Saturating concentrations of TPA were 500 nM for *Helix* and 200 nM for *Aplysia*, stimulating efflux three times and five times the basal rate, respectively. The inactive phorbol ester, 4-α-phorbol, did not stimulate eicosanoid efflux at a concentration of 1 μM in either molluscan nervous system. Removal of calcium chloride from the bathing medium and addition of 20 mM cobalt chloride completely blocked the effect of depolarizing agents or saturating concentrations of TPA. The effect of varying extracellular $CaCl_2$ concentration was studied more systematically with *Aplysia*. TPA-stimulated eicosanoid release was maximally inhibited when the extracellular $CaCl_2$ concentration was lowered to 100 μM. The results of cobalt substitution and lowering extracellular $CaCl_2$ suggest that the stimulation of eicosanoid release by depolarization or TPA may involve a common mechanism that is dependent on extracellular calcium. Furthermore, the lack of effect of 4-α-phorbol and the TPA dose-response range for *Aplysia* are consistent with a role for C kinase in stimulation of eicosanoid efflux.

312.14 PHORBOL ESTER BINDING SITES IN MAMMALIAN BRAIN. M. Dalpé* and R. Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, Faculty of Medicine, McGill University, 6875 LaSalle Blvd, Verdun, Quebec, Canada H4H 1R3.

It is well known that neurotransmitter receptors are coupled to second messenger systems. Among them, adenylate cyclase and the phosphoinositide (PI) cycle have been extensively studied. Interestingly, products derived from the PI cycle appear to be associated with protein kinase C, a major calcium and phospholipid-stimulated phosphorylating enzyme. Recently, evidences have shown that phorbol esters bind to protein kinase C. Thus, we have used [^{3}H]phorbol 12, 13 dibutyrate ([^{3}H]PDBu) as a way to study the presence and distribution of protein kinase C in mammalian brain. Brains obtained from male Sprague-Dawley rats, male albino guinea pigs and human dying from non-neurological diseases were used in all experiments. Membranes were prepared as follows: Tissues were homogenized in 50 mM Tris.HCl buffer, pH 7.7 at 4°C containing 100 mM NaCl and 1 mM CaCl, and then centrifuged for 15 min at 49,000g. Pellets were resuspended in the same buffer at 25°C. For the assays, 200 μl (1.0-1.5 mg protein) of this preparation was incubated for 45 min in 50 mM Tris.HCl buffer, pH 7.7, containing 100 mM NaCl, 1 mM $CaCl_2$ and various concentrations of [^{3}H]PDBu ranging between 0.1-100 nM (15.8 Ci/mmol; NEN). Incubations were terminated by rapid filtration (3 x 5 ml washes) using a Brandel Cell Harvester. For in vitro receptor autoradiography, brain sections were prepared as described before (Quirion, Eur. J. Pharmacol. 117, 139, 1985) and then incubated with 2.5 nM [^{3}H]PDBu for 60 min as described above. At the end of the incubation, slides were rinsed for 4 min in cold incubation buffer and dipped in distilled water to remove ions. Incubated sections were then apposed to LKB-Ultrofilm for 8-10 weeks. Specific binding was determined as the difference in ligand bound in the presence and absence of 10 μM phorbol 12, 13 - dibutyrate (Sigma). Under these conditions, [^{3}H]PDBu bound with high affinity and specificity (85-90%) to its sites in mammalian brain. Autoradiographic data clearly demonstrated the discrete distribution of [^{3}H]PDBu binding sites in mammalian brain. In rat and guinea pig brain, high densities of sites were especially found in the hippocampal formation, various cortical areas and cerebellum, lower densities of [^{3}H]PDBu binding were present in striatum and hypothalamus. Most brainstem area contained only low densities of sites. In human brain, high densities of [^{3}H]PDBu sites were found in cortical and hippocampal areas. Thus, it appears that the distribution of protein kinase C/[^{3}H]PDBu sites is unique in mammalian brain. We are currently investigating possible alterations in [^{3}H]PDBu/protein kinase C binding characteristics in neurological diseases.

313.1 CLONING OF A NOVEL Mr 60K CALMODULIN-BINDING POLYPEPTIDE WITH PROTEIN KINASE ACTIVITY FROM ADULT RAT BRAIN. C-A Ohmstede*, H. LeVine*, J. Gray*, P.M. Huff*, and N.E. Sahyoun* (Spon: Elizabeth B. Hollingsworth) Department of Molecular Biology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Screening a rat brain cDNA library in lambda gt11 with a monoclonal antibody directed near the calmodulin binding site of the brain-specific Ca^{2+}/calmodulin-dependent protein kinase II(PK-CAMII) produced several clones which also bound labeled calmodulin. Restriction enzyme analysis of one of these clones (C36) demonstrated a 1.2 kb cDNA insert. The recombinant β-galactosidase fusion protein from the C36 lambda lysogen was purified by affinity chromatography on calmodulin Sepharose and was injected into rabbits for the production of antibodies. Western blot analysis of soluble brain extracts demonstrated binding of the C36 antibody to one polypeptide with Mr value of 60K. The antibody, however, did not react with the α or β subunits of PK-CAMII from soluble or post-synaptic density preparations. Moreover, Western blot analysis of fractions from gel filtration columns indicated that the C36 native protein could be resolved from PK-CAMII. Screening many rat tissues by Western blots indicated that the C36 protein was localized to the brain. Developmental analysis indicated that the protein was absent in the newborn rat but was synthesized during the first postnatal week. Immunoprecipitation of rat cytosol with the C36 antibody removed a Ca^{2+}/calmodulin-dependent kinase activity against histones which was not removed with non-immune rabbit serum. The calmodulin-dependent kinase activity was recovered by adsorbing the specific immune complex on Protein A-Sepharose.

The DNA sequence of C36 was determined. The clone contained 1231 bp of sequence including a poly A+ tail. The 5'-end of the clone contained an open reading frame of 480 bp which would code for a peptide of about 18000 molecular weight. Comparison of the sequence with that from a mouse cDNA clone isolated by calmodulin binding demonstrated about 90 % homology in the amino acid coding sequence (Sikela, J.M. and Hahn, W.E., in press). Northern blot analysis with total poly A+ RNA demonstrated hybridization of C36 with 4 RNA species; >9.5 kb, 7.5 kb, 3.3 kb and 2.1 kb.

313.2 CEREBELLAR GRANULAR LAYER. PERSISTENT RETARDED MIGRATION SUBSEQUENT TO DIAZEPAM ADMINISTERED DURING GESTATION IN THE MOUSE. Ma. C. Márquez-Orozco*, A. Márquez-Orozco* and A. Escobar* (SPON: R. Salceda). Embryol. Dept. Sch. of Med., Natl. Univ. of México, P.O.B. 70250, México, D.F., México 04510, Inst. Invest. Biomed., UNAM and National Inst. Neurol. Neurosurg., México 14410.

Diazepam (valium) is a drug amply used as a therapeutic agent during pregnancy and in complications of labor including pre-eclamptic and eclamptic states. The drug is capable of traversing the placental barrier in several animal species including humans. In the fetal nervous tissue it accumulates in most nuclei of the brainstem and in the cerebral and cerebellar cortices. The fetal nervous tissues concentrations of diazepam are eliminated slowly. Previous work has shown retarded neuroblast differentiation in the mesencephalon. The cerebellar cortex is a structure that shows evident immaturity at birth in aetricial animals. Hence, it seemed of interest to study the effect of diazepam upon the maturation process in the cerebellar cortex of the mouse prenatally exposed to diazepam. Diazepam was administered intraperitoneally in a single dose of 2.7 mg/kg b.wt. from the 6th through the 17th day of gestation. Gestation term remained unchanged. The litter were carefully manipulated to help their breathing since all of them showed signs of respiratory insufficiency, hypothermia, and hypotonia. The survivors were mixed with the control litter and transferred to a foster mother for nursing. Feeding was left ad libitum with Purine Chow. After i.p. anesthesia with pentobarbital (35 mg/kg b.wt.) the animals were sacrificed at 120 and 180 days of age by cardiac perfusion with isotonic saline and then with 10% formalin in isotonic solution. The brains were obtained 12 hours later to avoid manipulation artifacts. Fixation by immersion in 10% formalin was continued for a period of 2 weeks. Sagittal sections of each hemisphere were embedded in paraffin, and stained for myelin, nerve cells, and axons identification; a few selected blocks were impregnated with the Golgi technique.

Light microscopy demonstrated in both experimental groups the presence of abundant neuroblasts in the external granular layer, decrease in neuron density of the internal granular layer, paucity of parallel fibers in the molecular layer, as compared with the control group. Quantitative assesment of the neuroblast population in the external granular layer was significant.

Behavioral analysis of the experimental group (swimming, spontaneous motor activity) and some clinical findings correlated well with the histological changes. The results are discussed on the basis of previous experiments involving the mesencephalon and the corpus striatum.

313.3 **Inhibitory Effects of Leu-enkephalin on ^{3}H-5HT Uptake in Dissociated Mesencephalic Raphe Neurons.** **Davila-Garcia M.I., Hou, X.P., Murphy, R. and Azmitia, E.C. New York University. Biology Dept. New York, N.Y. 10003.**

Neuropeptides have previously been demonstrated to have an effect on various neuronal systems during development. We have shown that ACTH peptides are able to stimulate the maturation of serotonergic neurons when these are separated from their target. These trophic influences of neuropeptides are further explored. Our results suggest that Opioid peptides have an inhibitory effect on the maturation of serotonergic neurons grown in culture.

Serotonergic neurons were obtained from slices of mesencephalic raphe of 14 day gestation (DG) rat fetuses. The target cells were obtained from the hippocampus of fetuses 18-19 DG. Neurons were dissociated by gently repipetting with fired polished tips of decreasing diameter. Neurons were plated on poly-L-lysine substrate (15ug/ml) on 96 well culture plates (Limbro). The cells were grown for 2-4 days at 37°C in a CO_2 incubator. The maturation of the serotonergic neurons was assayed by measuring the uptake of ^{3}H-5HT (5×10^{-8}) from the media during a 20 min incubation. Various concentrations of Leu-enkephalin were prepared (1,000-0.01 ng/ml) and administered at the time of plating to cultures of raphe cells alone or to co-cultures with their target tissue. To asses the specificity of leu-enkephalin effects, naloxone (10mM-1000mM) was administered to some of the plates. Morphometric studies of serotonergic cells were done in a bioquant system using a specific 5-HT antibody on 8 well slides (Lab-Tek) prepared in identical manner as the plates and incubated for 24 hrs.

Leu-enkephalin has an inhibitory effect on ^{3}H-5HT uptake by serotonergic cells grown in culture at all concentrations studied and this effect is reversed by naloxone. Neurite cell length is significantly decreased by leu-enkephalin, while cell body area is unaffected. An interesting finding is that naloxone itself significantly stimulates maturation of serotonergic neurons as measured by uptake and it increases cell body area but has no effect on neurite cell length. Parallel studies were performed with CCK-8 and de-sulfated CCK-8 (dsCCK-8). Results showed that de-CCK-8 was equally potent as enkehalin in inhibiting ^{3}H-5HT uptake by cultures of mesencephalic raphe neurons. CCK-8 produced a biphasic response with high concentrations being inhibitory and low concentrations being excitatory. These effects were also shown to be dependent on initial cell densities and reversed by naloxone

313.4 CREATINE KINASE AS A MOLECULAR MARKER IN THE ESTABLISHMENT OF INTERNEURONAL CONNECTIONS IN VITRO. O. Ramírez, V. Alemán, E. Jiménez* and B. Osorio*. Departamentos de Bioquímica and Neurociencias. Centro de Investigación y de Estudios Avanzados del IPN, 07000 México, D.F.

It has been shown that a fast brain neuronal multiplication, from the first to the third day of chick embryo incubation, is accompanied by a 270% increase in the cytosolic creatine kinase (CK) specific activity, in only a 10 hour period at the end of the second day of chick embryo development. Coinciding with the initiation of neuromuscular activity of the chick embryo in vivo, another increase of about 150% brain CK specific activity was observed from the 17th day of incubation until hatching. On the other hand, brain mitochondrial CK activity increased 375% during the same period (J. Neurochem. 28: 411, 1977). In the present work chick brain neurons from stage 30 (day 7) of incubation were cultured on polylysine coated Petri dishes. Cultures were fed on Dulbecco medium during 11 days. At two-day intervals, representative samples were utilized for both phase contrast observation and cytosolic CK assays. It was found that an increase in the number of long axonic and dendritic processes between nerve cell clusters was followed by a 123% increase in cytosolic CK specific activity in only 48 hours from the fifth to the seventh day of culture (Table I). Electrophoretograms of chick embryo brain BB-CK isoenzyme, obtained from in vivo or in vitro neurons, showed an average migration of 3.4 cm as compared to the rat brain BB-CK isoenzyme which migrates 6.5 cm from the origin (Table II).

Table I

Age of neurons in culture (days)	CK specific activity ± SD (n moles/CP/min/mg prot)	No. of bundles between neuronal clusters
1	51 ± 3	Non-observed

313.5 SIMULTANEOUS ANALYSIS OF 5α-REDUCTASE, AROMATASE AND ANDROGEN RECEPTOR LEVELS IN FETAL MONKEY BRAIN. S.A. Sholl and K.L. Kim* (SPON: G. Davis). Wisconsin Regional Primate Research Center, Univ. of Wisconsin, Madison, WI 53715

Although the importance of androgens and estrogens in the development of sexually dimorphic brain activity has been established in rodents, little is known about the prenatal effects of steroids in primates. The availability of tissues has also restricted such efforts. With this in mind, we have begun to investigate steroid enzyme and receptor levels in various regions of the fetal rhesus brain including the medial basal hypothalamus (MBH), amygdala (AMG), corpus callosum (CCAL), cerebellum (CB) and cerebral cortex. To date, 3 fetuses (2 females, 1 male) have been studied at 160 days of gestation and 2 fetuses have been studied at 100 days (1 male, 1 female). Assays were developed to simultaneously assess aromatase, 5α-reductase and cystolic androgen receptor (AR) levels in neural tissue samples from these animals. Tissues were homogenized in a buffer consisting of 10 mM Tris-HCl, 1.5 mM EDTA, 1 mM mercaptoethanol, 25 mM Na_2MO_4 and 10% glycerol. This buffer system was chosen so as to optimize receptor detection as previously reported *(Sholl and Pomerantz. Endocrinol. 117:1625, 1986)*. Enzyme activities were measured in a 50 μl portion of the crude homogenate (~ .1-.6 mg protein) in 2α-^{3}H-testosterone, 1β-^{3}H-testosterone (1.2 μM, T), NADH and NADPH (.4 mM) were added as substrates. ^{14}C-Dihydrotestosterone (DHT) was also included to account for procedural and metabolic loss of the ^{3}H-DHT which resulted from 5α-reductase activity. Aromatase activity was estimated on the basis of ^3H_2O synthesized from 1β-^{3}H-T, while 5α-reductase activity was evaluated from the amount of ^{3}H-DHT formed from 1α,2α- and 1β-^{3}H-T. Samples were incubated for 3 hr, 37°C and the reaction products purified by column and thin layer chromatography. Receptor levels were estimated in 108,000 g tissue supernatants using ^{3}H-DHT (4 nM) as ligand and radioinert DHT (1 μM) as competitor. Free and bound ligand were separated on DEAE-cellulose columns. Both enzymes exhibited linear behavior with time, and the amount of ^3H_2O formed was stochiometrically equivalent to the amount of ^{3}H-estradiol produced. For 5α-reductase activity, K_m = 5.0 μM and V_{max} = 7.9 pmoles/mg protein.hr, while for aromatase activity, K_m = 0.43 μM and V_{max} = 0.83 pmoles/mg protein.hr. Both enzymes were detectable at 100 and 160 days of development. MBH, CB and AMG exhibited the highest levels of reductase activity ($p < 0.001$), while aromatase activity was greatest in MBH, AMG and CCAL ($p < 0.001$). Overall, enzyme rates were higher at the earlier stage of development. AR levels were detectable in all tissues at both stages; however, due to the limited number of samples, results were not statistically significant. These findings indicate that neural tissues, including those from females, have the potential for transforming androgens to products which could have greater or lesser activity. Receptors are also present through which these products could effect a genomic response. This capacity may be important in terms of normal sexual differentiation of neural activities as well as for potential teratogenic changes under abnormal metabolic or physiological conditions. (Supported by NIH grant HD-18865.)

313.6 DISCRIMINATION BETWEEN MU AND DELTA OPIOID RECEPTOR AGONISTS IN CONTROL OF FETAL SHEEP CARDIOVASCULAR FUNCTION. C.E. Dunlap III and R.K. Zoltoski*. Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

Early studies in our laboratory showed the opiate antagonists, naloxone, naltrexone, and levallorphan caused dose-dependent increase in ovine fetal and maternal blood pressure (BP) and heart rate (HR) (Dunlap and Rose, Fed Proc 44:513,1985). Logically, opiate agonists were expected to decrease these cardiovascular responses. However, morphine was found to be pharmacologically inert, producing no effects on either BP or HR when injected intravenously or intraarterially into the fetal sheep ranging from 124 to 135 days gestation (term = 145 days). In some instances the highest doses of morphine used (10 to 20 mg) mimicked the effects seen with opiate antagonists.

When leucine-enkephalin (LEU-ENK) was injected intraarterially over a dose range from 0.2 to 2 mg, a decrease in both BP and HR was consistently observed. The average drop in mean arterial pressure produced by 1 mg of LEU-ENK was -17.11±1.93 mmHg (n=5). Maximal response was extremely rapid, occurring about 22 seconds after the peptide was injected into the tibial artery, and duration of action was short, with mean arterial pressure returning to baseline 2 to 4 minutes after injection. Decreases in BP and HR produced by LEU-ENK were completely blocked by 3 mg of the opiate antagonist, levallorphan, while its pharmacologically inert stereoisomer, dextrallorphan, had no effect on LEU-ENK responses. Levallorphan was found to be 2 to 3 times more potent than naloxone in blocking LEU-ENK effects on fetal BP and HR.

Epinephrine (EPI) (0.04 mg) produced a sustained increase in fetal BP of between 15 and 20 mmHg above baseline (baseline mean arterial pressure = 45 mmHg) and decrease in HR, lasting up to 10 minutes in some experiments. LEU-ENK injected 2 minutes following EPI administration attenuated the EPI increase in BP, primarily through a further reduction in HR. LEU-ENK antagonism of EPI response lasted only 2 or 3 minutes, following which BP again increased in response to the remaining circulating EPI. A less consistent observation was the effect of levallorphan on EPI responses. In several but not all experiments, the area under the response-time curve for a 0.04 mg dose of EPI was significantly increased following levallorphan administration.

These observations lead us to hypothesize that intrinsic regulation of fetal ovine cardiovascular function may in part be mediated by delta, but not mu-type opioid receptors due to the absolute discrimination of these responses for the delta receptor agonist, LEU-ENK, but not the mu receptor agonist, morphine.

313.7 DRUG BINDING SITES IN HUMAN FETAL BRAIN. M. Schlumpf and W. Lichtensteiger. Institute of Pharmacology, University of Zürich, Zürich, Switzerland

Using in vitro autoradiography, drug binding sites are found to be present in human fetal brain towards the end of the first trimester of pregnancy. At this early developmental stage tritiated (N)-methylscopolamine (NMS), flunitrazepam and the benzodiazepine antagonist Ro-15-1788 are labeling regions in lower and upper medulla oblongata rather uniformly. In the course of further development labeling becomes more concentrated in certain nuclear areas. During the first part of the second trimenon, at around the 18th week, muscarinic cholinergic binding sites thus appear in higher amounts in the spinal trigeminal and in the hypoglossal nucleus while benzodiazepine binding sites are seen more heavily concentrated in the area of medial and lateral lemniscus and also in the nucleus of the XII. cranial nerve. The development of a distinctly differentiated pattern might be seen in connection with onset of function. Of especial interest is the coincident labeling by 3H-NMS and 3H-flunitrazepam of the hypoglossal nucleus that is innervating intrinsic and extrinsic musculature of the tongue. Sucking difficulties have been described in infants born to mothers treated with benzodiazepines during pregnancy (Bavoux). In the striatum of 18 to 23 weeks of gestation, muscarinic cholinergic, benzodiazepine and dopamine D2 (sulpiride) sites exhibit an irregular dotted pattern which is similar to the one described for acetylcholinesterase in humen fetal striatum of comparable age (Graybiel). It is expected that in vitro autoradiography will provide information on drug-sensitive periods of defined areas in human fetal brain.

313.8 POSTNATAL EXPRESSION OF ENKEPHALIN AND TACHYKININ GENES IN THE STRIATUM OF THE RAT: MODULATION BY NIGROSTRIATAL DOPAMINE Sivam, S.P., Li, S., Hudson, P., Lee, P., Hong, J-S, and Breese, G.R. Dept. Pharmacol. & Toxicol., Indiana Univ. Sch. Med., Northwest Ctr. Med. Ed., Gary, IN., Lab Behav. Neurol. Toxicol., NIEHS, NIH Research Triangle Park, NC., BSRC, Univ. North Carolina at Chapel Hill, NC.

Previous studies have shown that the nigrostriatal dopaminergic pathway exerts a strong influence to regulate the activity of striatal enkephalinergic and striatonigral tachykiniergic neurons. The purpose of the present study is to elucidate the postnatal development of enkephalin and tachykinin neuropeptide systems of the striatum and their plasticity following neonatal destruction of striatonigral dopaminergic pathway with 6-hydroxydopamine (6-OHDA) in Sprague-Dawley rats. Dopaminergic lesions were made by intracisternal administration of 6-OHDA during an early postnatal period (day 3). The animals were sacrificed at various times (0-35 days) and their striata removed for the biochemical determinations. A combination of methods, namely, radioimmunoassay, molecular hybridization and HPLC were used for the determination of peptides, specific mRNAs coding the precursors and for monoamines and their metabolites, respectively. The rate of postnatal development of proenkephalin-A derived peptide Met -enkephalin (ME) was faster than the development of protachykinin derived peptides substance P (SP) and neurokinin A (NKA). Administration of 6-OHDA during the early postnatal period led to marked depletion of dopamine and its metabolites whereas an increase in 5-hydroxytryptamine and its metabolite was observed. The dopaminergic lesion induced a minor initial decrease followed by a late increase in ME level and a persistent decrease in SP and NKA levels. Preliminary evidence indicates that the development of proenkephalin and protachykinin mRNA closely paralled the development of their respective peptide products. The 6-OHDA lesions did not affect the development of peptides (SP, NKA, ME and cholecystokinin) in the frontal cortex, indicating regional selectivity. These results indicate a differential plasticity of enkephalin and tachykinin systems (that is, an enhanced expression and a retarded expression) as a result of damage to the dopaminergic system. These studies provide evidence for the close interrelationship and interdependence in the striatum between the development of dopamine and neuropeptide systems studied. Further, these studies may be of relevance to the basal ganglia related neurologic and neuropsychiatric diseases in which dopamine may play a role. 313.9 INTERFERON INDUCES DIFFERENTIAL REDISTRIBUTION OF THE 210KDALTON NEUROFILAMENT SUBUNIT IN CULTURED DORSAL ROOT GANGLIA CELL BODIES FROM NORMAL AND TRISOMY 16 MICE. D. MacFabe*, J. Lew*, B. Scott and A. V. Plioplys Surrey Place Centre and Div. of Neurology, Dept. of Pediatrics, Hosp. for Sick Children and Univ. of Toronto; 2 Surrey Place, Toronto, Ont., Can., M5S 2C2

The human 21st chromosome, as the mouse 16th chromosome, codes for the alpha and beta interferon receptors. Cultured fibroblasts from both the human and mouse trisomic conditions have an exaggerated response to exogenously applied interferon. To test whether neurons may display a similar sensitivity to interferon, dorsal root ganglia (DRG) were dissociated and grown in tissue culture. They were taken from gestational age E19 normal and phenotypic trisomy 16 mouse fetuses, and normal 3 month old swiss mice. The cultures were grown on a rat tail collagen matrix in CMRL-1415 medium supplemented with 10% FCS for 42 days prior to interferon treatment. Cultures from each fetus or adult were divided into an untreated group or treated with identical medium with 6700 units of alpha and beta mouse interferon per ml for 48 hours. After fixation with cold methanol and acetone, the cultures were reacted with monoclonal antibody (mab) N210 which recognizes the phosphorylated 210 Kdalton subunit of neurofilaments. The reaction product was revealed using direct PAP techniques with 4-chloro-1-naphthol as colorant. Statistical comparisons were done with the chi-square test.

In normal fetuses and adult mice there was a significant ($p < 0.005$) increase in the percentage of DRG cell bodies stained with mabN210. Trisomic DRG's displayed a similar response to interferon ($p < 0.05$). However, the percentage of staining of untreated trisomic DRG cell bodies was similar to the interferon treated normals.

These results suggest that neurofilament antigen expression may in part be regulated by interferon. Also, trisomic DRG cell bodies express greater mabN210-immunoreactivity than do normals. These findings may be related to the observation of precocious neurofilament antigen expression in Down's syndrome early in life (A. V. Plioplys, J. Neurol. Sci., in print).

MabN210 was kindly provided by Dr. R. B. Hawkes.

313.10 ^{3}H-PCP BINDING AND PCP-INDUCED LOCOMOTOR ACTIVITY AND ATAXIA AFTER PRENATAL EXPOSURE TO PHENCYCLIDINE. T.A. Fico and C. VanderWende. Rutgers University, Dept. Pharm. and Tox., P.O. Box 789, Piscataway, N.J. 08854.

There are very few studies regarding the postnatal consequences of prenatal exposure to phencyclidine (PCP). PCP abuse by pregnant women has been reported, raising questions of safety for the fetus. There are reports of prenatal exposure to methadone enhancing postnatal sensitivity to that drug. Therefore, it was of interest to examine whether prenatal exposure to PCP during different prenatal periods modified postnatal (1) ontogeny of ^{3}H-PCP binding in discrete brain areas and (2) PCP-induced ataxia and locomotor activity.

Pregnant CF-1 dams were injected daily with either PCP (5, 10 or 20 mg/kg) or saline, sc, during mid (E6-15) or late (E12-18) gestation. The litters were culled to 6 males and cross fostered to untreated dams that had delivered within 24 hours. Animals were weaned at postnatal day 21 (P21) and housed in single sex litter groups until P36. On P34-36 four male offspring from each litter were randomly choosen and each received either 0, 2.5, 5.0 or 7.5 mg/kg PCP, sc. Immediately following the injection, the mice were placed on an activity meter and their activity recorded in 6 min. intervals for 1 hr. Ataxia was scored in 15 sec. observation periods at 5 min. intervals for 50 min. using the rating scale of Castellani and Adams (Eur. J. Pharmacol. 73; 143-54, 1981). Another group of animals, prenatally treated as described, and not used in any behavioral test were used in the ^{3}H-PCP binding study. Five - six males of a litter were decapitated on either P21 or P35 and the striatum, hippocampus and cortex were dissected out. Tissue from the members of a litter were pooled. The ^{3}H-PCP binding assay of Zukin et al. (Brain Res. 258; 277-84, 1983) was used.

There was no significant effect of prenatal treatment or period of treatment on total locomotor activity or the temporal pattern of locomotor activity. Male offspring of dams treated in late gestation had greater ataxia scores than did untreated offspring and both had greater scores than did mid gestation offspring. There was a dose-dependent increase in postnatal PCP-induced ataxia with increasing dose of PCP administered prenatally, although this did not reach significance. These results are discussed in respect to the ontogeny of ^{3}H-PCP binding in prenatally treated and untreated offspring.

313.11 ALTERATION OF EFFECTS OF PRENATAL EXPOSURE OF RATS TO MORPHINE OR CLONIDINE BY CROSS-FOSTERING PROCEDURES. E. Lacrosse*, B. Consoliver* and B. Culver Neurosci. Prog., School of Pharm., Univ. Wyoming, Laramie, WY 82071.

The consequences of prenatal drug exposure are likely the result of a complex interaction of indirect drug effects as well as direct pharmacological effects on the developing organism. Perinatal undernutrition, neonatal withdrawal abstinence and alterations in maternal physiology and/or behavior have been suggested to contribute to postnatal effects of in utero exposure of animals to narcotic drugs. We have described a number of parallel effects produced in offspring of rats exposed to either morphine or the α_2-adrenergic agonist clonidine during the last week of pregnancy. However, it is not clear wheather these effects are caused by drug-induced alterations of endogenous opiate and adrenergic systems or by indirect effects. As a first aproach to this problem we report here the results of a study comparing postnatal effects produced by in utero exposure to morphine or clonidine in animals reared by dams that have been administered these drugs or by control dams.

Pregnant rats were assigned to one of 4 treatment groups on gestation day (gd) 14. One group (CL) was implanted with osmotic mini-pumps which infused clonidine at a rate of 2µg/hour; paired controls (CO) were subjected to identical surgical procedures. Rats in the MS group were implanted s.c. with a silastic morphine sulfate (100 mg) pellet on gd 14 and 2 more pellets on gd 17 while paired controls (LA) were implanted with silastic lactose pellets. At parturition entire litters of drug-treated rats were cross-fostered (XF) to paired control dams and vice versa, or were left with their natural dams (ND).

For MS groups, mortality of ND (68%) and XF (62%) was not significantly different. However, the possibility that postnatal rearing factors may affect mortality was suggested by findings of lower mortality in CL pups in the XF (4%) compared to ND (32%) group; by higher mortality of LA pups when reared by MS dams (XF= 14% ND=4%); and by higher mortality of 5-14 day-old CO pups reared by CL dams (XF=5%; ND=2%). Results of tailflick (TF) tests in 2-3 mo. offspring show that postnatal factors are enduring and that effects are seen in adult rats in that drug-treated offspring XF to control dams show attenuated TF latencies while control off spring XF to drug-treated dams show enhanced TF latencies.

These studies indicate the need to examine indirect factors associated with prenatal drug administration. The possibility exists that direct pharmacological effects are not fully operational at early stages of development and thus are less important determinants of the consequences of prenatal drug exposure than are indirect factors.

313.12 MORPHINE ANALGESIA IN NEONATAL RATS AS ASSESSED BY FOREPAW, HINDPAW AND TAIL RETRACTION FROM A THERMAL STIMULUS. M. S. Fanselow[1]*, E. M. Blass[2], and C. P. Cramer[1]. [1]Deparment of Psychology, Dartmouth College, Hanover, NH 03755; [2]Deparment of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

The neonatal period is characterized by dramatic changes in opioid physiology. Less is known about the dynamics of behavioral responsivity to opiates during this period. Therefore, we explored the ontogeny of opiate analgesia in neonatal rats. The analgesic efficacy of morphine sulfate (MOR) was compared on 3 reflexive measures of nociceptive reactivity in rats ranging from 2 to 21 days of age. The response measures were the latency to retract either the front paw, hind paw or tail from a hot-plate. Rats were manually supported by an experimenter (blind to conditions) above the hot-plate and only the tested limb was allowed to contact the heated surface. Even 1-day-old rats were competent to perform these responses, and analgesia was indicated by an elevation in latency. The first experiment tested Long-Evans rats at 2, 7, 14, and 21 days post partum. Five independent groups received 1, 2, or 4 mg/kg MOR or saline (SAL), ip. Latencies were taken for each of the 3 measures (order counterbalanced) for each subject between 20 and 60 min following injection. The hot-plate temperature was 52° C and a 15 s cut off latency was employed. MOR produced a dose dependent analgesia at all ages on all measures. The rats at the 2 intermediate ages were the most responsive. Tail retraction was the least sensitive measure of MOR analgesia at early ages but the most sensitive measure at older ages. The second experiment compared the effects of MOR (.25 mg/kg), naloxone (.25 mg/kg) and SAL on Sprague-Dawley rats at 2, 6, 9 and 21 days of age. A 48°C hot-plate and 25 s cut-off were employed. Response measures were varied in a between groups fashion and drug treatment was counterbalanced across age of testing. MOR produced effects similar to those of the first study. Naloxone treated animals never differed from SAL. The data indicate that neonatal rats have behaviorally functional opiate analgesic systems.

313.13 NIGROSTRIATAL BUNDLE LESIONS IN NEONATES: INCREASED 5-HT BUT DECREASED MODULATION BY 5-HT OF CHOLINERGIC INTERNEURONS
D. Jackson*, J.P. Bruno, M.K. Stachowiak, and M.J. Zigmond. (SPON: R.W. Keller, Jr.) Dept. of Behavioral Neuroscience and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA

6-Hydroxydopamine (6-HDA) destroys dopamine (DA) terminals. However, while adult-lesioned rats show profound neurological deficits, these effects are not observed when lesions are made at 3 days of age. When given to neonates, 6-HDA increases the density of serotonin (5-HT) terminals in striatum. Since DA and 5-HT have several similar effects on striatal function, this additional 5-HT might be responsible for the behavioral sparing. To further explore the role of 5-HT in animals given intraventricular 6-HDA as neonates, we examined striatal acetylcholine (ACh) release, a process that is under the inhibitory control of both DA and 5-HT. Coronal slices (350 uM) of adult striatum were incubated for 20 min at 37°C in Krebs buffer containing tryptophan (5 uM) and either [3H]choline (0.1 uM) or [^{3}H]5-HT (0.1 uM), superfused, and tritium efflux into the superfusion fluid used as a measure of ACh or 5-HT release. Slices were depolarized with bipolar pulses (2 msec, 18 mA, 1 Hz) both 85 min (S_1) and 125 min (S_2) after a 60 min equilibration period. Drugs were introduced 20 min prior to the S_2. Fluoxetine (1 uM), an inhibitor of 5-HT uptake, reduced ACh stimulation-evoked tritium overflow in control slices from caudal striatum by 16% but had no effect on overflow from rostral striatum, a region which contains 62% less 5-HT. This is consistent with an inhibitory influence of endogenous 5-HT on ACh release. However, fluoxetine failed to inhibit ACh overflow from the caudal striatum of lesioned slices, despite an 81% increase in tissue 5-HT content. Moreover, fluoxetine also had no effect on ACh overflow from lesioned slices from rostral striatum, although 6-HDA had increased 5-HT in that region by 337%. Quipazine (1 uM), a direct 5-HT agonist, which inhibited ACh efflux by 20% in both caudal and rostral control slices, had no effect on slices from lesioned animals. Finally, neonatal lesions reduced the stimulation-induced overflow of [^{3}H]5-HT from slices of lesioned striatum by 95%. Taken together these results suggests that while neonatal 6-HDA produces a serotonergic hyperinnervation of striatum, the ability of these 5-HT terminals to release 5-HT is impaired and the sensitivity of cholinergic neurons to 5-HT is markedly reduced. These results may help to explain our recent observation that pharmacological disruption of serotonergic function does not impair behavior in rats given neonatal 6-HDA. (Supported in part by USPHS grant NS19608.)

313.14 METABOLIC MATURATION OF THE BRAIN: A STUDY* OF LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE CAT. H. T. Chugani, D. A. Hovda, M. E. Phelps, and J. R. Villablanca. Depts. of Neurology, Pediatrics, Psychiatry and Anatomy, and Division of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, CA 90024, USA.

We have previously shown, using positron emission tomography, that the anatomical distribution of brain glucose utilization in man undergoes dramatic changes during the first year of life consistent with behavioral, neurophysiological and anatomical changes (Science 231: 840-843, 1986). Furthermore, local cerebral metabolic rates for glucose (LCMRglc) in most regions increase to reach adult rates by 2 years, after which LCMRglc exceeds adult values until adolescence, when LCMRglc gradually declines to approximate adult values again by the end of the second decade (Ann. Neurol., in press). In order to develop an animal model of neurometabolic maturation, we measured LCMRglc of 49 brain regions in 22 kittens during normal postnatal development using [14C]-2-deoxyglucose autoradiography, and compared these rates to those of 5 adult cats. The following developmental time points (in days) were selected: 7 (N=2), 15 (N=3), 30 (N=3), 45 (N=2), 60 (N=3), 90 (N=5), 120 (N=4). LCMRglc at 7 days (range 16-49 umol/min/100g) were generally 50% below adult values, with a lesser distinction among gray matter structures and between gray and white matter than in adults. Although the maturational course varied among regions, LCMRglc in most areas increased from 7 to 45 days to reach adult values and subsequently exceeded adult rates with a peak at 90 days, when LCMRglc in many regions were almost twice adult rates and displayed considerable heterogeneity among structures (range 27-205 umol/min/100g). At 120 days, LCMRglc was generally lower than at 90 days, but still exceeded adult rates. LCMRglc in 9 measured regions (e.g. cerebellum, red nucleus, mammillary nucleus) did not exceed adult rates during development. This developmental profile of LCMRglc is consistent with the neurodevelopmental milestones of the cat in that most neurological functions in the kitten mature during the first three postnatal months (Dev. Psychobiol. 12:101-129, 1979). Furthermore, sensory structures (including visual, auditory and somatosensory regions) show a LCMRglc rise earlier than motor areas (including neocortex, basal ganglia, cerebellum), which also fits well with an earlier development of sensory functions versus fine motor components of locomotion and limb placing reactions. Thus, as in humans, LCMRglc values in the cat are age-specific, at least for most brain regions, and show a period of relative hypermetabolism. These normal maturational metabolic data will serve as baseline values with which to compare neonatal lesion-induced alterations of LCMRglc in assessing functional plasticity in the CNS (USPHS grants HD-05958, 5RO1-MH37916, 2PO1-NS15654; DOE AM03-76-SF00012).

DEVELOPMENT OF INVERTEBRATES II

314.1 LACK OF AN OOCYTE TO NURSE CELL VOLTAGE DIFFERENCE IN DROSOPHILA.
Y.A. Sun and R.J. Wyman
Department of Biology, Yale Univ. New Haven CT 06511

There have been several reports suggesting a voltage difference between the nurse cell and oocyte in insect ovaries (e.g. Nature 286:84, 1980; Devel. Biol. 108:102, 1985). Such a gradient might establish embryonic polarity or be responsible for transport of cytoplasmic materials from nurse cells to oocyte.

Previous studies asserting (J. Cell Biol. 58:172, 1973) or denying (J. Cell. Sci. 81:207, 1986) a voltage difference for these cells also reported low resting potentials of 21mV in Drosophila and 30 to 50 mV for the larger cells of Hyalophora (a moth). These differing results and low potentials suggested that the membrane might have been damaged. We found similarly low resting potentials when the egg chambers were dissected by tungsten needle from the ovary. However, much higher potentials (82 to 92 mV) were obtained when the egg chambers were freed from the ovary with collagenase (1 mg/ml for 5-10 minutes).

An egg chamber consists of an oocyte, 15 nurse cells and an enveloping layer of follicle cells. Measurements were taken with the follicular epithelium intact. When prepared as above the potassium dependence of the membrane potential was log-linear from 2.7 to 100mM with a slope of 52mV for a 10 fold change in $[K]_o$. An extrapolation to zero potential indicates $[K]_i = [K]_o$ at 150mM.

No significant voltage differences were found between oocyte and nurse cell at any time from stage 5 to 10 (stages from King, 1970). Our data do not indicate that a potential difference between oocyte and nurse cell can be developmentally significant at these stages.

Stage	Oocyte mV ±S.D.	Nurse Cell mV ±S.D.	p
5	81.9 ±5.7 (n=7)		
6	90.3 ±5.7 (n=4)	90.3 ±4.5 (n=11)	p>0.5
7	90.0 ±3.3 (n=15)	91.9 ±3.6 (n=41)	p>0.2
8	90.5 ±4.9 (n=19)	91.4 ±3.7 (n=35)	p>0.9
9	90.0 ±4.2 (n=8)	88.1 ±6.2 (n=21)	p>0.5
10	85.2 ±5.0 (n=27)	86.2 ±5.7 (n=58)	p>0.5

At stage 5 the oocyte and nurse cells are not morphologically distinguishable. One value is reported for both. The lower potential at this stage may be due to greater penetration damage related to the small cell size at this stage (10u).
Saline (mM): Na, 50; K, 2.7; Ca, 5; Mg, 17; Cl, 25; glutamate 50; glucose, 10; Hepes, 5; sucrose to adjust osmolarity to 300.

314.2 BETA-GALACTOSIDASE AS A LINEAGE TRACER. R. D. Streck*, S. T. Bissen and D. A. Weisblat (SPON: B. Holton). Dept. of Zoology, University of California, Berkeley, CA 94720.

Knowledge of the lines of descent of the cells that comprise a mature organism is crucial for the understanding of developmental biology and neurobiology. One way to follow cell lineages is to microinject blastomeres with benign, easily detected substances (lineage tracers) that are subsequently inherited by all of the progeny of the injected cell. Horseradish peroxidase (HRP), fluorescent peptides, fluorescent dextrans and biotin-conjugated dextrans have all been used as lineage tracers. Unique properties of various tracers make them advantageous for different lineage tracing applications. We report here that the enzyme beta-galactosidase (β-gal) can also be used as a lineage tracer and that it too has properties that are advantageous for certain experimental applications.

β-gal (10 mg/ml) was pressure injected into identified blastomeres of the embryo of the leech Helobdella triserialis. After development to a later stage, the embryos were fixed and the distribution of β-gal was visualized by staining with "Bluogal" (BRL) for 6-12 hr at 37°C. The dark blue opaque reaction product can be viewed in wholemount or in sections of plastic-embedded specimens. The intensity and distribution of the reaction product is not affected by illumination or during ethanol dehydration and embedding in glycol methacrylate. By comparison with other lineage tracers, we conclude that the β-gal reaction product is confined to known descendants of the injected blastomere and does not perturb normal development; this enables β-gal to be used as a lineage tracer.

In addition, the enzyme or its reaction product is localized primarily in the cell cortex, so that microinjecting a lower concentration (1.0 mg/ml) of β-gal yields embryos in which the interiors of labeled cells are essentially unstained while their borders are clearly delineated by β-gal staining. This makes it relatively easy to discern the shapes of cells, compared to when other tracers are used. Moreover, it facilitates certain types of double label experiments, such as those entailed in studying the cell cycles of identified cells. For this purpose, S phase cells in embryos bearing β-gal-labeled cell lines were pulse-labeled with bromodeoxyuridine (BrdU) and identified by visualization with a peroxidase-antiperoxidase complex, after a biphasic fixation and intervening staining for β-gal (for details, see abstract by Bissen and Weisblat). The identification of S phase cells (brown nuclei) in the line of interest was facilitated because they were outlined by the blue β-gal reaction product.

314.3 CELL CYCLE ANALYSIS IN EARLY LEECH EMBRYO. S.T. Bissen and D.A. Weisblat. Dept. of Zoology, Univ. of Calif., Berkeley, CA 94720.

Segmental tissues of the leech Helobdella triserialis comprise five iterated sets of cells arising from longitudinally arrayed columns or bandlets of mesodermal (m) and ectodermal (n, o, p and q) blast cells. Blast cells are produced by five bilateral pairs of stem cells (M, N, O/P, O/P and Q teloblasts) at the rate of one per hr; older cells lie distal (future rostral) to younger ones in strict accordance with their birth rank. Each m, o and p bandlet contains one class of blast cell, as defined by their definitive fates, whereas there are two alternating classes of blast cells in each n and q bandlet (Weisblat and Shankland, Phil. Trans. R. Soc. B, 312:39-56, 1985). The two alternating classes of blast cells in the n bandlet may differ from the time of their births (Bissen and Weisblat, J. Neurobiol., in press). Moreover, the duration of the first cell cycle and the geometry of the first mitosis differ for each class of blast cell (Zackson, Dev. Biol., 104:143-160, 1984).

To determine what accounts for the variations in cell cycle duration, nuclei of cells in S phase were pulse labeled by incorporation of tritiated thymidine triphosphate (TTP) or bromodeoxyuridine triphosphate (BrdUTP). Embryos containing labeled cells were examined autoradiographically (TTP) or immunohistochemically (BrdUTP) making use of the precise rostrocaudal gradient of development. The cell cycles of the different classes of ectodermal blast cells (21 to 33 hr) differ in the length of their G_2 phases (17 to 29 hr) because they have very short or nonexistent G_1 phases and S phases of approximately equal duration (4 hr). The cell cycles of the mesodermal blast cells also seem to lack G_1 phases and have S and G_2 phases of one and nine hr, respectively.

Cells actively synthesizing RNA were labeled by incorporation of tritiated uridine triphosphate (UTP) and then identified by autoradiography. All seven classes of blast cells commence synthesis of RNA immediately after birth and continue to do so throughout their cell cycle until they enter M phase. The synthesis of RNA in these cells was drastically reduced in embryos treated with a low concentration of α-amanitin (1-2 μM), which suggests that the blast cells are synthesizing some mRNA.

Supported by NIH NRSA HD06692-03 to STB and NSF Grant PCM-8409785 to DAW.

314.4 IDENTIFICATION OF HOMEO BOX GENES IN THE LEECH, HELOBDELLA TRISERIALIS. D.J.Price*, C.J.Wedeen* and D.A.Weisblat. Department of Zoology, University of California Berkeley, California 94720.

Many genes affecting the spatial organization of tissues in the fruitfly, Drosophila melanogaster, contain a homologous nucleotide sequence, called the homeo box, that encodes a putative DNA-binding protein domain of about 60 amino acids. The homeo box seems to have been highly conserved in evolution; genes containing sequences homologous to the homeo box are found in a wide variety of organisms ranging from yeast to humans. As well as being structurally homologous, it is conceivable that homeo box-containing genes from widely separated animal groups have functional homology. Thus, the presence of the homeo box may serve to identify developmentally important genes in organisms other than Drosophila. This would be especially true for organisms that are phylogenetically close to insects, e.g. annelids.

We are interested in the development of the leech Helobdella triserialis. One advantage of studying the leech embryo is that it comprises identifiable and experimentally accessible cells. Therefore it should be possible to examine how genes effect developmental changes at the level of individual cells. We have screened Helobdella for putative homeo box-containing genes by the cross-hybridization of Drosophila homeo-box probes to restriction fragments of Helobdella genomic DNA. Probes were obtained from Drosophila genes with maximally divergent homeo box sequences, including zen, engrailed and Sex combs reduced. Minimal amounts of the unique sequence surrounding the homeo box were included in the fragments used as probes, and we avoided incorporation of repeated sequences other than the homeo box (e.g. the M-repeat, or OPA sequence, a poly-glutamine encoding sequence found in many Drosophila genes).

Results from these experiments demonstrate the presence of six or more genes in Helobdella that cross-hybridize to the homeo box. We are now attempting to clone these genes from a genomic library of Helobdella constructed in the lambda phage vector, EMBL3.

314.5 ACQUISITION OF CENTRAL TARGETS BY OLFACTORY SENSORY NEURONS IN HOMEOTIC ANTENNULES: FUNCTIONAL CONSEQUENCES. DeF. Mellon, H.R. Tuten*, L.M. Hurley*, and M.E. Easley*. Dept. of Biology, University of Virginia, Charlottesville, VA 22901

Biramous homeotic antennules can be generated in the crayfish, Procambarus clarkii, by surgically removing an eye in posthatch juveniles. We have studied the anatomy, central connections, and functional consequences of the olfactory sensory neurons associated with the aesthetasc (chemosensory) hairs on one flagellum of the homeotic antennules. The number of aesthetascs on the homeotic antennules is similar to the normal antennules in all cases examined. Light and electron microscopical studies indicate that aethetascs on the homeotic antennules have a normal compliment of primary sensory neurons. Axons from these neurons terminate within the ipsilateral olfactory centers of the brain, as determined from the uptake and transport of tritiated leucine by olfactory sensory neurons, and the deposition of the radioactive tracer within glomeruli of the olfactory lobe. Crayfish possessing homeotic antennules exhibit a significant lateral bias in olfaction-triggered searching behavior, suggesting that the central connections of supernumerary olfactory sense organs are anatomically and functionally appropriate and are additive to the normal input.

Computer-aided 3-dimensional reconstructions of olfactory lobes from histological sections show that normal growth of the brain is accompanied by increases in the size of existing olfactory glomeruli, by which means normal growth-related additions in the number of primary sensory axon terminations must be accommodated. Our studies show that doubling of the afferent input due to the presence of homeotic antennules results in asymmetric olfactory lobe growth with the side supporting input from the homeotic antennule being up to 25% larger in volume than the contralateral side. The growth can be accounted for by an increase in volume of existing structures, since roughly the same number of glomeruli are found in the olfactory lobes of juvenile and adult crayfishes, and in animals possessing homeotic antennules. Because many crustaceans grow continuously throughout their lifespan, accommodation of additional sensory input from expansion of the peripheral receptive field normally must be an ongoing process. Details of the central reorganization through which this process occurs will be of considerable interest.

314.6 **LEECH GANGLIOGENESIS: IDENTIFIED PERIPHERAL AND SEROTONIN NEURONS ASSUME POSITIONS OF MISSING CONTRALATERAL HOMOLOGUES.**

Duncan K. Stuart, Margaret I. Law, and Steven A. Torrence*
Dept. of Molecular Biology, University of California, Berkeley, CA 94720

How do neurons come to lie in the proper position during development? Prior work has shown that when a major subset of neurons is prevented from forming on one side of the glossophoniid leech nerve cord, their contralateral homologues are distributed over both sides of the nerve cord (Blair 1983, Dev. Biol. 95:65; Stuart et. al. 1987, J. Neurosci. 7:1107). On either side of the embryo a column of cells, the n bandlet, gives rise to these neurons, which can be either labeled or prevented from arising by injecting the bandlet's precursor blastomere with lineage tracer or DNase, respectively. We show that identified neurons that differentiate on the opposite side still occupy normal positions.

In normal embryos of the leech Theromyzon rude none of the neurons derived from a labeled n bandlet crosses the ventral midline, and almost all lie within the chain of segmental ganglia. In each segment three peripheral neurons, nzl-3, are also derived from the n bandlet.

When only one n bandlet was present, the neurons nzl-3 that it produced could be found on either side of the ventral midline and occupied appropriate peripheral positions on either side. In segments where one or more nzl-3 crossed to the opposite side, they were missing on the side of origin.

In embryos with an n bandlet missing, any neuron (or its precursor) derived from the surviving n bandlet was capable of crossing the ventral midline and assuming a position on the contralateral side. The number of neurons found on the opposite side varied among segments, from none to all. Most or all of this crossover occurred early in gangliogenesis. Antibody against 5-HT identified five of these neurons: the anteromedial (am), Retzius (R), ventrolateral (vl), dorsolateral (dl), and posteromedial (pm) 5-HT neurons, which, except for pm, are normally paired in the segmental ganglia. In embryos with an n bandlet missing no more than one of these neurons was produced per segment. The am, R, and pm still occupied relatively normal positions along the ventral midline with axonal projections typical of neurons either on the left or right. In some cases the normally ipsilateral projection of R was bilateral. When one or two lateral 5-HT neurons, vl and dl, crossed over to the other side, they were typically found in the normal positions with the normal projections of their contralateral homologues.

Thus, we find in embryos with a missing ectodermal n bandlet that the remaining n derived neurons differentiate into the expected neurons occupying normal positions on either their normal or the contralateral side. Furthermore, the identity of these neurons is not determined by final position, and neither the commitment to differentiate as a given neuron nor differentiation itself requires a normal spatial arrangement of the clone of cells from which they arise. Since most ganglionic neurons arise from these n bandlets, the mesoderm is an alternative candidate for providing the required spatial information.

314.7 LEECH GANGLIOGENESIS: UNILATERAL MESODERM ABLATION AFFECTS NEURON POSITIONING DIFFERENTLY IN ANTERIOR vs. POSTERIOR SEGMENTS
Margaret I. Law, Steven A. Torrence and Duncan K. Stuart, Dept. of Molecular Biology, University of California, Berkeley, CA 94720.

Unilateral ablation of the mesoderm in leech embryos induces the majority of ganglionic neurons, or their precursors, on the ablated side of the body to cross the ventral midline (Blair,1982, Devel.Biol.89:389-386) This transposition was examined in detail using embryos of the glossiphoniid leech, Theromyzon rude.

Ectodermal and mesodermal tissues on each side of the leech embryo arise from five columns of cells called bandlets. Four of these, n,o,p and q, form ectoderm, with n giving rise to the majority of ganglionic neurons. The remaining m bandlet forms the mesoderm. Unilateral ablation of the mesoderm was accomplished by injecting the m bandlet precursor blastomere with DNAse before gangliogenesis began and before the last mitosis of any neuroblast. To follow the development of the overlying ectoderm, various bandlets were labelled with rhodamine or fluorescein lineage tracers by injecting their parental blastomeres.

Ganglionic neurons or their precursors of the n lineage reliably crossed the ventral midline in embryos with unilateral mesoderm ablations, while ganglionic neurons or their precusors of the o,p and q lineages did not. To examine the distribution of crossed neurons, two lineage tracers were used to differentially label n-derived neurons from the left and right n bandlets. Unilateral ablations were performed after a period of normal development had ensued generating an anterior control region dubbed zone 1. In regions of mesoderm ablation, two patterns of crossover were observed: zones 2 and 3. In the more anterior zone 2 the majority of n-derived ganglionic neurons or their precursors from the ablated side crossed the ventral midline and intermingled with the native n-derived neurons. Three n-derived peripheral neurons (nz1-3) from the ablated side also crossed to the opposite side and found their appropriate peripheral positions. Therefore, crossed n-derived neurons in zone 2 appear to locate their correct, mirror-symmetrical mediolateral position.

In zone 3 the organization of n-derived neurons was disrupted on both sides of the nerve cord and gangliogenesis was abnormal. The zone 2/3 border appeared to be located in the same segmental location regardless of the number of segments of zone 2 anterior to zone 3.

Therefore, mesoderm is necessary for neurons to locate their appropriate positions. Moreover, the mediolateral position of ganglionic neurons appears to be under extrinsic rather than intrinsic control. One possible candidate to provide such positional information is the mesoderm. In addition, the occurrence of zone 3 suggests that the manner in which positional information is either aquired or interpreted in posterior segments of the embryo may be different than in more anterior segments. In normal development such differences could be involved in generating the normal posterior segmental variations.

314.8 LEECH GANGLIOGENESIS: ECTODERM-MESODERM INTERACTIONS IN THE PATTERNING OF IDENTIFIED NEURONS
Steven A. Torrence*, Duncan K. Stuart and Margaret I. Law (SPON: Gunther S. Stent) Dept. of Molecular Biology, University of California, Berkeley, CA. 94720.

Individually identified cells occupy stereotyped positions in the bilaterally symmetrical segmental ganglia of the leech. Previous work has demonstrated that extensive morphogenetic movements, including cell migrations, occur in the normal development of this pattern. Studies reported in companion abstracts suggest that normal position in a ganglion is not required for the differentiation of 5-HT neurons, and that interactions between prospective neural ectodermal cells and the mesoderm are necessary for the genesis of the stereotyped architecture of the leech nerve cord.

To investigate the role of ectoderm-mesoderm interactions in the development of identified neurons, we studied the effects of ablating the mesoderm from the left side of embryos on the 5-HT neurons of the leech Theromyzon rude. Ablations were effected by injection of the lethal enzyme DNase into a precursor blastomere, or by laser irradiation of cells labeled with a photosensitizing lineage tracer dye. The 5-HT neurons were visualized by indirect immunofluorescence. Whether a given neuron originated from the left or right side of the embryo was revealed by differential labeling with fluorescent lineage tracers.

In normal development, all neurons differentiate on their side of origin, and in experimental embryos some 5-HT neurons did differentiate on the mesoderm-deficient left side. However, these cells were not organized in any recognizable spatial pattern.

Many 5-HT neurons (or their precursors) that originated on the left crossed the ventral midline to differentiate on the unablated right side of the embryo. Most dorsolateral and ventrolateral 5-HT cells that crossed occupied positions correct for their new side, and shared these positions with the homologous neurons native to that side. Thus, extra identified neurons from the left were incorporated into the normal organization of the right hemiganglia.

As in normal ganglia, Retzius neurons were found near the ventral midline. Both right and left Retzius neurons were abnormal however, in being found in all possible anteroposterior positions, including the interganglionic connectives. Apparently unilateral mesodermal ablation disrupted control of anteroposterior position for midline cells.

We conclude that the presence of a normal ipsilateral mesoderm is not required either for commitment of the ectodermal precursors of 5-HT neurons to their fates or for their differentiation, but that interactions between ectoderm and mesoderm are required to generate the normal spatial patterning of the neurons. A complete complement of ectoderm was present in these experiments, so interactions among ectodermal cells are not sufficient for such spatial patterning. We propose that during gangliogenesis in the leech, cells that are already committed to specific neural fates use positional cues derived from the mesoderm to find positions appropriate to their fates.

314.9 STEREOTYPED CELL MIGRATION AND THE FORMATION OF THE INSECT ENTERIC NERVOUS SYSTEM IN VIVO AND IN EMBRYO CULTURE.
P.F. Copenhaver and P.H. Taghert. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Stereotyped cell migration is a common feature in the formation of nervous systems in many organisms. It facilitates the local innervation of distal targets and influences the differentiation of the translocated neurons. We have examined the development of the enteric nervous system (ENS) of the moth Manduca sexta and have observed patterns of extensive neuronal migration that are multi-phasic and proceed along stereotyped pathways. We have characterized the sequence of normal neurogenesis and migration that gives rise to the ENS, and we have established a method of culturing these embryos such that both cell lineage analyses and surgical manipulations can be applied.

The ENS of Manduca includes two small anterior ganglia and a diffuse set of neurons that are distributed along the major longitudinal muscle bands of the midgut. At about 35% of embryogenesis, a region of columnar epithelium evaginates from the dorso-posterior margin of the foregut, which then delaminates into a discrete cluster of about 200 presumptive neurons -- the Enteric Crest neurons. Over the next 20% of development, these cells undergo a slow phase of migration, during which the Enteric Crest spreads to encircle the foregut. Dye fills of individual cells revealed relatively simple bipolar morphologies with short processes confined to the Enteric Crest; these processes gradually become longer as circumferential migration progresses. Then between 55-60% the Enteric Crest disperses, as a majority of the cells initiate a rapid longitudinal phase of migration and move in 8 small groups onto the midgut. Some of these neurons subsequently express neuropeptide phenotypes, although the onset of this expression commences only after cell migration is complete and appears to be a function of final soma position along the gut.

The small number of Enteric Crest neurons and the relative simplicity of their cellular environment on the developing gut make this an attractive system in which to analyze neuronal migration and its consequences at the level of individual cells. For these studies we have developed methods that permit extended embryonic development in culture. Under these conditions, embryos dissected out of their egg shells and membranes at 25% of development will undergo complete ENS neurogenesis and cell migration in vitro. Observations both in vivo and in vitro suggest that individual Enteric Crest cells are not pre-specified to follow particular migratory routes and do not appear to be uniquely identifiable. Rather, their final distribution and spacing, and perhaps their phenotypic diversity, may reflect probablistic developmental events. Supported by an NIH Fellowship to P.F.C. (F32NS07957) and NIH grant to P.H.T. (NS21749), a Sloan Fellow.

314.10 ISOLATION OF TISSUE AND STAGE SPECIFIC cDNA CLONES FROM THE NERVOUS SYSTEM OF THE MOTH, MANDUCA SEXTA.
N. Platt*, K.M. Naylor*, P.F. Copenhaver and P.H. Taghert. Dept. Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

We are studying mechanisms of neuronal differentiation in the embryonic nervous system of the moth, Manduca sexta. We have focussed attention on the Frontal Ganglion (FG), an assembly of ~50 neurons that is a part of the enteric nervous system, lies atop the foregut and has many features associated with the larger, more complex segmental ganglia of the CNS. For example, two of the largest neurons (F1 and 2) have stereotyped positions, axon projections and transmitter phenotypes (Copenhaver and Taghert, 1986, Soc. Neurosci. 12, 318). These cells can be visualized by their immunoreactivity with a monoclonal antibody directed against the molluscan neuropeptide SCP_B. By about 40% of embryogenesis, the FG has acquired nearly its full complement of neurons; by 50%, many axons have been extended towards peripheral targets; by 55%, the onset of transmitter expression has begun (as indicated by immunostaining with anti-peptide antibodies). We wished to complement these on-going cellular observations with studies at the molecular level and have adopted a +/- screen in attempting to isolate FG-specific transcripts.

RNA was extracted from the FG (the positive tissue) and abdominal ganglion 1 (the negative tissue: it lacks SCP_B-immunoreactive neurons) from ~3500 Vth instar larvae. Radiolabeled cDNA was used to probe duplicate lifts of a Manduca brain cDNA library that was made in λGt11. After three rounds of purification, we found five individual clones that were moderately to greatly enriched in the FG probe. Cross-hybridization experiments suggest these represent three distinct mRNAs.

In addition to this tissue specificity (i.e., heterogeneous expression within the nervous system), we find evidence of developmental regulation in some of these transcripts. During adult development in Manduca, a general re-organization takes place within the nervous system that includes neurogenesis and programmed cell death. F1 and 2 are no longer SCP_B-immunoreactive by Day 7 of metamorphosis and in fact may have died. We probed the FG-enriched cDNA clones with RNA taken from the Day 7 developing adult FG and found that the relative levels of expression among the clones had changed dramatically. The previously most abundant clone was now barely above background. In addition to sequencing these clones, we are currently performing in situ hybridization to help identify the specific neurons that express the correspondent transcripts.

314.11 EMBRYONIC DEVELOPMENT OF SEROTONIN-LIKE IMMUNOREACTIVITY IN THE CENTRAL NERVOUS SYSTEM OF THE SNAIL LYMNAEA. R. Marois, B.J. Chiasson* and R.P. Croll. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

Although an extensive body of literature exists on early embryogenesis of the pond snail Lymnaea stagnalis and on the organization of the adult nervous system, little is known about embryonic or post-embryonic neural development in this species. In this study immunohistochemical techniques were used to identify a subpopulation of cells expressing serotonin in the central nervous system (CNS) of Lymnaea at hatching and to begin to examine the embryonic origin(s) of these cells.

The fully autonomous hatchling possesses about 250 serotonin-like immunoreactive (SLIR) cell bodies distributed throughout the ganglia of the CNS as either single identifiable cells or as members of identifiable cell clusters. Each cerebral ganglion contains about 20-25 SLIR cell bodies partitioned into five clusters. Within these clusters certain cells can be recognized as identifiable neurons such as the metacerebral giant (MCG) cell. The axonal projection of the MCG can be seen entering the cerebro-buccal connective and eventually the buccal ganglia where it appears to provide the only source of serotonin. At hatching, the pedal ganglia have the highest number of SLIR somata of any of the central ganglia. These cells are largely located within three discrete clusters or within a more diffuse population extending primarily over the anterior and medial surfaces of the ganglia.

Except for the large asymmetric cell (LPeD.1) all identifiable cells and cell clusters of the pedal ganglia form bilaterally symmetric pairs. The pleural ganglia do not contain any SLIR cell bodies although numerous SLIR en passant fibers are detected. The right parietal ganglion contains about 10-14 SLIR cell bodies at hatching whereas the smaller left parietal ganglion exhibits variable labelling of only a few SLIR cells. Within the visceral ganglion 10-20 cells can usually be seen at hatching.

Neural development was also studied and is expressed as a percentage of the total duration of development (about 15 days at 21-23°C). The first detectable expression of SLIR cells at 46-48% of development appears to be delayed by about 7% from the initiation of gangliogenesis. The SLIR somata are initially detected in the cerebral ganglia, then in the pedal ganglia and finally in the remaining suboesophageal ganglia. Shortly after the appearance of SLIR somata, fibres can also be detected within most connectives and commissures. Thus the double ring structure of the adult nervous system is detectable early in development using these techniques.

This work was funded by a grant from NSERC (Canada) to RPC.

314.12 POST-HATCHING DEVELOPMENT OF SEROTONIN-LIKE IMMUNOREACTIVITY IN THE CENTRAL NERVOUS SYSTEM OF THE SNAIL LYMNAEA. B.J. Chiasson* and R.P. Croll (SPON: D. Treit). Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

Post-hatching development of the central nervous system of Lymnaea stagnalis was studied with the aim of bridging the gap in our understanding of the adult central nervous system (CNS) and work in progress on the embryonic CNS. The post-hatching developmental period, which involves about a 20 fold increase in the linear dimensions of ganglia comprising the CNS, was examined using a sub-population of cells exhibiting serotonin-like immunoreactivity (SLIR). All clusters of SLIR cells present in the adult CNS were observed in the hatchling snail, as were all single, identified cells. However, all clusters, with the exception of one in the cerebral ganglion, demonstrated addition of SLIR cells during post-hatching development, although different clusters added cells at different periods. Some clusters only added SLIR cells shortly after hatching, whereas other clusters showed a continual increase in cell number during development. The I clusters of the pedal ganglia underwent another form of SLIR cell addition. Both the left and right I clusters showed gradual increases in cell numbers from hatching (shell length, 1.6mm) until the shell length reached 10-12mm. Cell number within the left I cluster then remained constant at 12-14, whereas the right I cluster increased to about 60 SLIR cells near the commencement of sexual maturity (shell length, 19-23mm). The overall increase in SLIR cell number is from 200-250 in the hatchling to 450-500 in the adult CNS. In addition to increases in cell numbers, post-hatching development in Lymnaea also involves individual cell growth. All cells examined showed continuous growth during post-hatching development. Certain identified cells were observed to have different growth rates. Growth rates of unidentified cells comprising the various clusters were also determined through measurements of both the largest and the smallest cells of each cluster and were found to be less than those of most identified cells.

This study suggests that at least two factors contribute to the large increase in linear dimensions of the ganglia of the CNS. Firstly, SLIR cells approximately double in number from hatchlings to animals approaching sexual maturity. These additions are variable from cluster to cluster. Secondly, individual SLIR cells undergo 3-6 fold increases in some diameters during post-hatching development. It remains to be seen if the expression of neurotransmitter phenotype is a good indicator of cell addition and if these findings can be generalized to neuronal development of the entire CNS.

This work was funded by a grant from NSERC (Canada) to RPC.

314.13 DEVELOPMENT OF THE ASCIDIAN LARVAL NERVOUS SYSTEM: THE SPECIFIC STAINING OF NEURONS. W.-G. Jia and I.A. Meinertzhagen. Dept. of Psychology, Dalhousie University, Halifax, N.S., Canada B3H 4J1.

Despite its chordate affinities, the larva of ascidians (Urochordata: Ascidiacea) has a nervous system which contains relatively few neurons (about 100); these arise from an embryo amply demonstrated to be generally mosaic. They therefore offer the prospect to study the cell-by-cell development of a nervous system which is widely held to be close to the ancestral form of, and thus may provide a model for, that of the vertebrate. In the sea-squirt, Ciona intestinalis, an acetylcholinesterase (AChE) staining technique (Bear, M.F. et al., J. Comp. Neurol., 234:411, 1985) and Met-enkephalin (ME) immunocytochemistry have been utilised to examine the nervous system in the normal larva. Eight to 10 primary sensory cells arranged bilaterally in pairs in the dorsal epidermis and a pair of neurons in the visceral ganglion were found to be AChE-positive, whilst a single caudal neuron in the nerve cord of the tail showed ME-immunoreactivity. This is the first demonstration in the ascidian larva of AChE-positive and ME-immunoreactive neurons and the latter is also the first evidence for neuronal perikarya in the caudal nerve cord, previously thought exclusively ependymal. The evidence reveals the existence of identifiable neurons but not whether the nervous system is entirely determinate. To explore the latter question, experimental embryological studies have been directed towards the CNS.

The mosaic nature of the ascidian embryo has been inferred especially from the results of deletion experiments, which result in the production of partial larvae (Cohen, A. & Berrill, N.J., J. E. Z., 74:91, 1936). Here, "half larvae" have been obtained by ablating the blastomeres of one side of the two- or four-cell stage embryo and the resultant larval CNS cells counted. The number was less in the "half"-larva than half the cells in the intact larva, even though the cell number in other organs was generally exactly half normal. In addition to these numerical findings there exist qualitative departures from mosaicism. The pigment cell from either otolith or ocellus, both of which originate from the right wall of the neural tube in the normal embryo (Willey, A., Q. J. Micr. Sci., 35:295, 1893), was invariably found in the half-larvae, no matter from which embryonic half the latter was derived; more than one larva had both pigment cells. It has been postulated that the development of the ascidian CNS depends upon evocation (Reverberi, G. et al., Acta Embryol. Morph. Exp., 3:296, 1960) from notochordal or entodermal cells. Our results suggest the existence either of some more profound regulative factor affecting CNS differentiation or of some departure in the half larva from the determinate patterns of mitosis (Nicol, D. & Meinertzhagen, I.A., Soc. Neurosci. Abstr. 11:648, 1985) by which the nervous system normally arises.

Supported by NSERC (Canada) grant A0065 (to I.A.M.).

314.14 IMMUNOCYTOCHEMICAL STUDIES OF AN ASCIDIAN LARVAE. C.D. Johnson, R.J. Crowther*, and J.R. Whittaker*
Marine Biological Laboratory, Wood's Hole, MA 02543

The free swimming larvae of ascidians - sea squirts (subphylum Urochordata, class Ascidiacea) are comprised of only a relatively small number of cells (there are probably less than 100 neurons) which are organized in a body plan which shares many features with vertebrates. Studies of larval development, both classical and recent, have focussed on lineage commitment and on the roles of oogenic cytoplasmic determinants in lineage commitment. In modern studies, enzyme histochemical staining and ultrastructural features have been used as markers of differentiation in Ciona intestinalis (review, J.R. Whittaker, Amer. Zool. 27).

We sought to identify additional cell specific probes, particularly those for the larval nervous system, by screening antibodies which bind to putative neurotransmitters, to peptides or to other know proteins. Ciona larvae (18-24) hrs post-fertilization) were labelled in whole mounts; 50-200 animals were used for each different antibody or condition. Animals were fixed either with glutaraldehyde or with formaldehyde and, in some cases were post-fix treated with pronase before exposure to primary antibodies and then to secondary antibodies linked to HRP. Useful reagents identified so far include:

1) Antiserum specific for GABA labels two groups of bilaterally symmetrical neurons in the head, one just posterior to the sensory vesicle, the other in the hind brain region. In addition two neurons in the dorsal nerve of the tail are labelled.

2) Antiserum specific for glutamate labels fiber tracts anterior to the sensory vesicle including cell bodies within the tracts and some cell bodies within the brain.

3) Antiserum to Aplysia small cardioactive peptide B (SCPB) labels granules in mesenchymal cells located in the posterior region of the head.

4) Antiserum to human prolactin labels granules in endodermal cells of the gut.

5) Antiserum to Ciona adult tropomyosin (generated by T.H. Meedel) labels larval muscle fibrils lightly. In late larvae the circular muscle fibrils of the developing adult siphons are intensely labelled.

6) A monoclonal antibody to acetylated α-tubulin labels neural cilia in the sensory vesicle, cilia in dorsal nerve cord and cilia extending from neurons located in the epithelium of the tail.

7) A monoclonal antibody to β-tubulin appears to label all neural fiber tracts.

314.15 REGIONAL DIFFERENCES IN DROSOPHILA WING EPITHELIUM DURING THE TIME OF AXON OUTGROWTH REVEALED BY MONOCLONAL ANTIBODY. M.A. Murray and J. Palka. Department of Zoology, University of Washington, Seattle, WA 98195

Experimental studies (reviewed in J. Palka, 1986, J. Neurobiol., 17:581) show that the axons of sensory neurons in the developing wing of Drosophila behave as if a specific band of epithelial cells, those that will ultimately form the third of the five longitudinal veins, form a preferred growth substrate. We have initiated a search for monoclonal antibodies that might help to reveal a basis for this axon-guiding property of the L3 epithelium and describe here the characteristics of the first antibody recovered, 6G7.

Light microscopic sections of growing wings indicate that 6G7 binds to a component of the epithelial basement membrane. In wild-type animals, staining appears as early as mid-third instar, and is nearly gone by 24 hr after pupariation (AP). From 0 to 6 hr AP the pattern of staining is irregular, occupying about one half the area of the growing wing along its longitudinal axis. By 8 hr AP the pattern is dramatically vein-like, staining longitudinal pre-veins 3,4, and 5, with the strongest staining along L3. Binding persists through the period of wing inflation (12 to 18hr AP) and diminishes considerably by 24 hr AP.

Important events in the transformation of the wing imaginal disc to a mature wing include eversion, elongation, vein formation, sensilla development, axon outgrowth, and cuticle production. From the overall pattern of staining, the 6G7 antigen is a candidate for involvement in elongation and/or vein formation. Initial investigations support this hypothesis. In several mutants in which major segments of the veins of adult wings are missing, we have found a lack of 6G7 binding in the corresponding pre-vein regions of pupal wings.

6G7 staining is strongest along vein L3, the only route taken by axons in the middle of the wing; furthermore, the antigen is present throughout the period of axon outgrowth (0 to 18 hr AP) and is lost thereafter. However, we do not know whether the antigen is related to outgrowth in an instructive way, is simply permissive, or is irrelevant. Culturing wings in the presence of the antibody has no effect on axon outgrowth, but this does not constitute strong evidence since monoclonal antibodies often fail to block the function of their antigens. However, 6G7 does reveal a molecular heterogeneity in the wing which appears to be developmentally regulated, and which may well be involved in one or several important developmental events.

314.16 ANTIGEN 5B12, AN EXTRACELLULAR GLIA-ASSOCIATED PROTEOGLYCAN OF THE ADULT INSECT NERVOUS SYSTEM, IS EXPRESSED UPON EPITHELIAL CELL FILOPODIAL PROCESSES IN EMBRYONIC SENSORY STRUCTURES. M.R. Meyer, P. Brunner*, and J.S. Edwards. Dept. of Zoology, NJ-15, University of Washington, Seattle, WA 98195.

Monoclonal antibody (MAb) 5B12, generated from a glial-enriched crude membrane immunogen, labels a glia-associated antigen located only within the adult nervous system of the cricket Acheta domesticus (Meyer et al., J. Neurosci. 7:512, 1987) and that of other orthopteroid insects. In the adult terminal abdominal ganglion (TG), MAb 5B12 binds to glia of the cortex-neuropile interface and to glia associated with peripheral (e.g. cercal sensory nerves) and central nerve tracts. Immunogold-EM localization techniques demonstrate that the 5B12 antigen has a complex extracellular distribution within the TG; the antigen is abundant in the interface, but is restricted to discrete central neuronal processes within the ganglionic neuropile. These findings suggest that the antigen may be involved in the organization of fiber tracts within the CNS.

The 5B12 antigen is expressed relatively early during embryonic development (ca. 25%), where it is distributed along the luminal surfaces of sensory appendages (cerci, antennae) and limb buds; within the CNS, the antigen is associated with the anterior and posterior commissural tracts, and with regions of germinal neuroepithelium. This distribution pattern persists through mid-development; however, by 95%, reactivity is spread throughout the neuropile and the luminal surfaces no longer bind the antibody. Immuno-EM analysis of the 5B12 distribution in the embryonic cercal appendage demonstrates that the antigen is mainly associated with epithelial cell filopodial processes which are localized at the luminal surface in close apposition with basal lamina and developing nerve fiber tracts.

Western blot analysis of total adult TG proteins characterizes the 5B12 antigen as a M_r 185 kD macromolecule that has the properties of a proteoglycan (e.g. marked sensitivity to hyaluronidase and periodate treatments). Interestingly, although a lower MW component can be resolved in whole embryo immunoblot preparations, the 185 kD band is not readily detectible, suggesting extensive biochemical modification of the antigen with development. Thus, 5B12 antigen expression is developmentally regulated both in terms of its spatial distribution and biochemical nature, and we are currently exploring the possible interrelations between these processes and key events in neural development such as axon outgrowth and guidance. Supported by NIH #NB-07778.

314.17 DEVELOPMENT OF CONTROL OF CILIARY LOCOMOTION IN A GASTROPOD VELIGER. S.A. Arkett* (SPON:R.W. Skelton). Dept. of Biology Univ. of Victoria, Victoria, B.C. V8W 2Y2 CANADA

The ciliated velum of veliger larvae is a temporary structure used for locomotion during the short planktonic stage and discarded upon metamorphosis. The locomotory, pre-oral cilia of competent veligers beat in laeoplectic metachronal waves, but are periodically interrupted by coordinated, velum-wide ciliary arrests. These ciliary arrests have been shown to be caused by a single, regenerative action potential in the electrically-coupled, pre-oral ciliated cells of competent veligers of the gastropod Calliostoma ligatum (Arkett and Mackie 1986). These spikes result from summing EPSPs, which originate from the CNS. Pre-oral ciliated cells arise from prototrochal cells in the trochophore stage and are in turn descendents of the trochoblasts in the gastrula stage. I describe here the development of synaptic activity and action potentials in prototrochal and pre-oral ciliated cells and the rhythmical ciliary arrest behavior of a gastropod veliger, C. ligatum.

Intracellular electrode recordings from ciliated prototrochal cells as early as 45 hours post-fertilization (larvae were raised in the lab at 10-12°C) show a resting potential of -55 to -60mV and small (1-3mV), arhythmic, spontaneous EPSPs. Prototrochal cilia beat asynchronously and show no ciliary arrests. By 50h, arhythmic depolarizations are larger (3-6mV), the characteristic metachronal wave is established, but no spontaneous ciliary arrests are seen. However, injection of a brief pulse of depolarizing current causes a spike and a velum-wide ciliary arrest. This spike and ciliary arrest is identical to those observed in competent veligers. By about 58h, the depolarizations are larger still (12-15mV) and rhythmical, occurring at about 0.5Hz, yet are still subthreshold for ciliary arrest. Spontaneous ciliary arrests are first observed at this stage and these are caused by action potentials that are identical to those recorded from competent veligers. Pre-oral ciliated cells from veligers older than this show rhythmical spiking and ciliary arrests. It appears that prototrochal ciliated cells are capable of spiking very early in development, and that these spikes can cause coordinated, velum-wide ciliary arrests, yet spontaneous arrests are not seen. Neuro-ciliary synapses appear to be established before the velum expands and becomes functional for locomotion, but the 'strength' of these synapses is insufficient to generate suprathreshold EPSPs and no ciliated cell spikes are generated. The development of CNS control of locomotion and the capability of the velum to function as a locomotory organ appear to be closely linked.

314.18 REMODELING OF LEG MOTOR CIRCUITS DURING POSTEMBRYONIC DEVELOPMENT OF THE MOTH MANDUCA SEXTA. K.S. Kent and R.B. Levine, ARL Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

As part of our study of the postembryonic development of leg motor circuits in the moth Manduca sexta, we are continuing to examine the alterations that take place in sensory and motor components as the insect metamorphoses from larva to adult. Previously (Soc.Neurosci.Abs. 12:928), we described sensory and motor neurons of the larval prothoracic leg and reported that larval leg motorneurons (MNs) are retained and are present in the adult. To determine whether these retained larval leg MNs are also adult leg MNs, we are using a persistent, fluorescent tracer (Fluoro-Gold) to label larval MNs and a secondary fluorescent label (Texas Red) for adult MNs. Identified larval leg MNs are retrogradely labeled by injection of Fluoro-Gold into specific larval muscles. After metamorphosis is complete, adult leg MNS are labeled by intracellular injection or by backfilling leg nerves with Texas Red. Double-labeling indicates that certain adult leg MNS are indeed retained larval leg MNs.

To further identify and characterize prothoracic leg MNs in the adult, we have used intracellular recording and dye-injection methods. Like larval leg MNs, adult leg MNs have arborizations in a lateral region of neuropil but have more extensive arborizations than their larval counterparts. Examination of the dendritic arborizations of identified adult leg MNs suggests that certain features are common to particular classes of MNs. For example, flexor MNs innervating muscles controlling distal leg segments (pretarsus, tarsus, tibia) have many, long, sparsely branching processes in the lateral region of neuropil. Extensor MNs and MNs innervating muscles controlling proximal leg segments (femur, trochanter, coxa) have stouter, more densely branching processes in this lateral region and in some cases, extremely dorsal processes that extend to the midline of the ganglion.

We are currently investigating the nature of sensory inputs to these adult leg MNs by recording intracellularly from identified MNs while stimulating mechanosensory and proprioceptive elements of the leg. As in the larva, adult leg MNs are influenced by external mechanoreceptors. Tactile stimulation can elicit coordinated movements of several leg segments. In addition, adult leg MNs are influenced strongly by internal proprioceptors.

Cobalt staining of sensory neurons innervating specific groups of leg sensilla (hairplates, scattered hairs) demonstrates specific patterns of central projections characteristic of the type of sensilla and location on the leg. The apparent overlap at the light-microscope level between the dorsal-most extent of certain sensory processes and the ventral-most extent of MN dendrites suggests the possibility of direct sensory input to certain MNs.

314.19 EFFECT OF AUDITORY DEAFFERENTATION ON THE SYNAPTIC CONNECTIVITY OF IDENTIFIED INTERNEURONS IN ADULT CRICKETS. P.D. Brodfuehrer and R.R. Hoy. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Previous investigations have shown that chronic auditory deprivation of nymphal crickets, T. oceanicus, causes the dendrites of an identified auditory interneuron, Int-1, to sprout and form new functional connections in the contralateral auditory neuropil (Hoy et al., Proc. Nat. Acad. Sci. 82:7772, 1985). This neuropil is normally innervated by Int-1's homolog. In this system there is the potential for competition to occur between Int-1 on the deafferented side and its unaffected homolog on the intact side for synaptic sites in the remaining auditory neuropil. However, nymphal crickets are deaf because their ear appears only after the final molt to adulthood. Thus the neural circuitry of the auditory system may not be completely established when the deafferented Int-1 is forming its new connections. We were interested in determining whether the formation of new connections by the deafferented Int-1 affects the synaptic connections of the intact Int-1 in adult crickets where the auditory circuitry is fully established.

To test this we first demonstrated that auditory deafferentation of adult crickets also causes the medial dendrites of Int-1 to sprout and form new functional connections. These new connections form 4-6 days following deafferentation, and by 28 days following deafferentation these connections have restored most of Int-1's normal physiological responses to auditory stimuli. Secondly, in adult crickets we compared the strength (number of spikes/stimulus) and latency of the response elicited in both Int-1s by 30 kHz sound pulses, and the Int-1 tuning curves as a function of the number of days following deafferentation. If synaptic competition occurs between the Int-1 cell pair, the strength of Int-1's response should systematically decrease with number of days following deafferentation, while the latency and threshold intensities should increase.

In deafferented adult crickets, the strength of the Int-1 response increases with stimulus intensity, while the latency decreases. There was however, no systematic reduction in the strength of the intact Int-1 response to 30 kHz tones or an increase in latency with number of days following deafferentation. Moreover, there was no increase in threshold intensity for the intact Int-1 following deafferentation. Thus our physiological results suggest that competition is not occurring between the Int-1 homologs for synaptic connections in the remaining auditory neuropil.

314.20 HYDROXYUREA-INDUCED EFFECTS PARALLEL RADIATION-INDUCED EFFECTS ON THE DEVELOPING OLFACTORY GLOMERULI IN *MANDUCA SEXTA*. Lynne A. Oland and Leslie P. Tolbert. Dept. of Anatomy & Cell Biology, Georgetown Univ., Washington, DC 20007.

The synaptic neuropils of first-order olfactory centers are organized into discrete glomeruli, thought to have functional roles in the processing of olfactory information. In the antennal lobe of the moth's brain, glomeruli form only in the presence of olfactory afferent axons and are enveloped by glial processes. Our previous studies have suggested that construction of the glomeruli from an early homogeneous neuropil depends upon changes in glial cells and that these changes are induced by the arrival of afferent axons from the antenna. Last year we reported experiments using irradiation to reduce the number of glial cells in the lobe in order to test the hypothesis that glial cells have a necessary role in the formation of glomeruli. We used gamma-irradiation to interfere with glial proliferation at a stage (4/5) when glia are dividing but neurons of the antennal system are all postmitotic and glomeruli have not yet developed. When the number of glial cells was severely reduced, the antennal-lobe neuropil failed to develop glomeruli despite the presence of antennal afferent axons. However, the presence of mild cuticular abnormalities in the treated animals raised the possibility that our findings in the antennal lobe might reflect direct cellular damage rather than the effect of reduction of glial numbers.

In order to circumvent the lack of possible internal controls for irradiation, we have now interfered with glial proliferation using hydroxyurea (HU; 9.5 mg/gm wt.; Truman & Booker, J. Neurobiol. 17:613, 1986) injected through the thoracic cuticle at stage 4/5.

External cuticular features develop in the normal sequence in HU-injected animals, but leg spines and claws are often mildly deformed and the animals' heads, wings, and antennae, though well formed, lack scales. These are the same abnormalities that characterize irradiated animals. Their presence in both experimental groups suggests that they reflect interference with mitotically active epithelial elements and cannot, in the case of irradiated animals, be attributed to radiation damage.

In the antennal lobes, injection of HU results in the desired reduction in number of glial cells. Reduction of the number by more than 2/3 results in a neuropil resembling that of irradiated lobes with an equivalent reduction in glial numbers, i.e. the neuropil lacks normal glomerular organization even though afferent axons are present. The experiments with HU confirm the results obtained with radiation and lead us to conclude that the organization of the antennal-lobe neuropil into glomeruli during development not only depends upon afferent axons, but also requires the presence of adequate numbers of glial cells. Our working hypothesis is that glial cells act as intermediaries in developmental interactions between afferent axons and antennal-lobe neurons. 314PO ORIGIN OF SEGMENTAL DIFFERENCES AND BILATERAL ASYMMETRIES IN THE EMBRYO OF THE LEECH. M. Shankland and M.Q. Martindale*. Dept. of Anatomy & Cellular Biology, Harvard Med. Sch., Boston, MA 02115.

The segmental tissues of the leech arise from a set of 5 bilaterally paired embryonic teloblasts which give rise to stereotyped complements of adult tissue. A given teloblast generates a chain of primary blast cell daughters which represent segmental precursors for its particular cell line. For example, the O teloblast gives rise to a series of o blast cell daughters, each of which contributes a homologous set of descendants to a different body segment. These descendants are restricted to only one side of the midline, and bilaterally homologous structures arise from blast cells generated by the contralateral O teloblast.

Using fluorescent lineage tracers we have examined the origin of segmental differences in embryos of the leech Helobdella triserialis. Segmentally homologous o blast cells give rise to descendant clones of nearly identical cellular composition, with the only known exception being that these blast cells contribute the most distal cell of the nephridial tubule in abdominal segments 2-5 and 8-18, whereas no comparable cell is found in the mature leech in other segments that lack nephridia. By examining early stages of embryogenesis, we found that o blast cells generate a distal tubule cell homologue in every abdominal segment, and that this cell dies prior to terminal differentiation in segments that lack the remaining, mesodermal portion of the nephridium. Using a published method for shifting blast cells along the body axis, we were able to study the development of o blast cells which took part in the formation of ectopic segments, i.e. segments inappropriate for their cell lineage. In such cases the survival or death of the distal tubule cell did not depend upon its normal fate, but rather correlated precisely with the identity of the host segment. Thus, a lineally identified distal tubule cell could either be rescued or murdered by altering the segment into which it was born, and the segmental differences observed in normal embryos seem to derive from a positionally determined pattern of cell death.

There are also segmental differences in the distribution of neurons which stain with a commercial antibody against molluscan small cardioactive peptide B. In H. triserialis, the antibody only stains neurons in the head and abdominal ganglia 1-4. Once the teloblast of origin has been determined, we will ask whether or not the precursor blast cells will generate immunoreactive neurons if shifted to more posterior segments. Among the immunoreactive neurons is an unpaired cell located at the lateral edge of the ganglion. This unpaired cell is found on the right side of ganglia 1 and 3, and on the left side of ganglion 2. Additional experiments should reveal whether this unpaired neuron is the survivor of an initially bilateral cell pair, and to what degree the final pattern of asymmetry is dependent upon cell lineage and cell interaction.

315.1 LIGHT-MICROSCOPIC ANALYSES OF ORGANOTYPIC HIPPOCAMPAL EXPLANTS. J. Fowler, Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Organotypic hippocampal explants have been used as models for studying hyperexcitability (Gahwiler,'83; Fowler et al., '86), innervation by catecholaminergic fibers (Dreyfus et al., '79) & development of granular & granular-like neurons (Zimmer & Gahwiler,'84; Fowler & Crain,'86; Fowler,'86). In the studies reported here, development & maintenance of pyramidal, granular & other neuronal types were assessed with Golgi, HRP & thionin labeling after 1d-8wks in culture. Generally, pyramidal & granular cells were arranged in organotypic arrays approximating field cytoarchitecture in situ & were not displaced or stimulated to migrate (to a significant degree) by dissection trauma, ongoing reorganization, cell death or maturation. When distinctive infra- & supra-pyramidal blades were not evident, the dentate formed a triangular wedge of cells, obscuring the hilar area. Neurons were labeled in all major subfields, including CA1-CA3, subiculum, "molecular layer" & dentate. Pyramidal & granular cells resembled in situ counterparts, with the exception cell bodies (pyramidal) were slightly smaller & dendritic branching not as elaborate as reported for cells (in situ) in juvenile & adult rodents by other authors. Granular & granular-like neurons often had multiple dendrites (2-3; apical, basilar or lateral) that persisted for the duration of the culture period(up to 8 wks). Dendritic spines were evident on pyramidal & granular neurons, although apparent spine density was never as great as reported for juvenile & adult rodents. As in situ, spine shapes were variable & in some cases formed small lumpy enlargements, nodulations or thin needle-like processes (pedunculate). On some neurons, 1 dendrite might have a relative abundance of spines whereas on adjacent branches spines were sparse. While the majority of pyramidal & granular cell bodies resembled similar neurons in situ, a number of features were observed that appeared atypical. A few neurons had large, irregular nodular protrusions, a lumpy, nodular cell body or stubby, foot-like outgrowths. Although most pyramidal-like neurons had apical & basilar dendrites, a few neurons were labeled in which basilar processes were not evident. Whether these unusual features associated with neurons in explant culture are related to immaturity, suboptimal nutrient medium or synaptic reorganization subsequent to denervation & explantation remains to be assessed.

315.2 DEVELOPMENTAL AND GROWTH-ASSOCIATED REGULATION OF THE LIMBIC SYSTEM ASSOCIATED MEMBRANE PROTEIN IN BRAIN EXPLANT CULTURES. F. Keller* and P. Levitt (SPON: M.R. Celio). Inst. of Pharmacology, Univ. of Zurich, CH-8006 Zurich, Switzerland, and Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The limbic system associated membrane protein (LAMP) is a 60 Kd glycoprotein that is expressed early in development in cortical and subcortical limbic regions and associated fiber tracts. In the adult, LAMP remains in the cellular areas on somata and dendrites but is no longer detectable on axons. In the present study, we used the anti-LAMP monoclonal antibody and immunohistochemistry to investigate the distribution and time pattern of development of LAMP in explant cultures. Septal, hippocampal and amygdala cultures, prepared from newborn rats, contained high amounts of the protein. Within the explants, the distribution of LAMP-immunoreactivity was organotypic: e.g. in the amygdala, the staining was restricted to the amygdaloid nuclei, whereas the adjacent pyriform cortex was unstained. In addition, immunoreactivity was distributed on the surface of neurons as well as fibers, similar to that seen during development in situ. Fiber staining was prominent in the outgrowth zones of young cultures and in intraexplant pathways (e.g. between the fascia dentata and the Ammon's horn in hippocampal cultures) as well as in extrinsic pathways (e.g. the commissural fibers in double hippocampal explants). The fiber staining was transient in the explants, comparable to our previous findings in situ. The early neurites growing out from the explants in the first days in culture were strongly immunoreactive, gradually disappearing after the first week in vitro, at a time when fibre maturation proceeded, as shown by acetylcholinesterase histochemistry. An unexpected finding was the decrease in LAMP-immunoreactivity in single explant cultures, beginning at the 2nd of 3rd week in vitro. This phenomenon is not observed in situ, because limbic regions of the adult brain continually express LAMP. The decrease of LAMP in vitro was observed after aldehyde fixation, but not in unfixed or acetone fixed cultures, and seems to reflect antigen modification rather than antigen loss. It was further observed that once LAMP had disappeared from the explants, mechanical tissue damage rapidly induced immunoreactivity in the immediate vicinity of the lesion and on regenerating fibers which grew across the lesion cavity.

These observations suggest that 1) LAMP may be associated with the development of connections in the limbic system, 2) maintenance of LAMP in the mature brain may require intact specific connections between nerve cells, and 3) LAMP may be associated with the repair and reorganization processes that occur after brain injury.

315.3 PROTEIN SYNTHESIS IN GUINEA-PIG HIPPOCAMPAL SLICES: AN AUTORADIOGRAPHIC STUDY USING LIGHT AND ELECTRON MICROSCOPY. P. Lipton & S. Feig*, Depts. of Physiol. and Anat., Univ. of Wisconsin, Madison,WI53706.

The long-term goal of these studies is to examine regulation of protein synthesis in hippocampus by neurotransmitters and by electrical activity. Because of the marked heterogeneity of brain tissue, it is essential to be able to measure synthesis in clearly defined regions. Autoradiography offers the only reasonable way of doing this.

To measure protein synthesis it is essential to remove free radiolabelled precursor (3-H leucine). We have examined the effects of different fixatives on the washout. For electron microscopy it is essential to wash out precursor in warm buffer for 90' prior to fixation. In this case less than 5% of the tissue radioactivity is unincorporated precursor.

Three preincubation techniques have been tried to obtain tissue which synthesizes protein optimally: putting slices immediately into normal buffer with 2.4 mM Ca or 1.2 mM Ca or into OCa/10 mM Mg-containing buffer for 45' prior to switching to 1.2 Ca buffer. Slices from the last method showed distinctly improved morphology and more uniform protein synthesis. This is especially true in the principle cell layers. Interneurons, glia and endothelial cells are well labelled in all three preparations. We are now routinely using this method, after cutting the slices on a vibratome at 450 u. Slices are labelled with 3-H leucine for 90'. Cycloheximide included with the 3-H leucine, reduces observed grain density by at least 90%.

In the optimally prepared slices, observed by L.M., grains are present in all somata, and are also present in neuropil. In the neuropil, observed by E.M., grains are primarily localized in dendritic elements, including spine regions; there may be some localization in pre-synaptic elements. We are examining relative grain densities in different cell types; oligodendroglia are very heavily labelled.

A major aim of the study is to measure synthesis within dendrites. In order to do this dendritic flow must be prevented. The only reliable method here is to sever the dendrites from the somata. We examined the effect of small cuts in the apical region of the CA1 pyramidal cell layer, made immediately after 3-H-incorporation, on the morphology of and grain distribution in the apical dendrites. The surgery caused profound disruption of the dendritic microtubules and some morphological changes. Most importantly, silver grains are present in these dendrites, and are distributed similarly to those in the control dendrites. Thus, it should be possible to study protein synthesis occurring within the dendrites.

315.4 THE TIME OF ORIGIN OF SOMATOSTATIN-IMMUNOREACTIVE NEURONS IN THE HIPPOCAMPAL FORMATION OF THE RAT. P.R. Rapp and D.G. Amaral. Developmental Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037.

Somatostatin-immunoreactive (SSIR) neurons and fibers are present in the hippocampal formation of many vertebrate species including man. While the hippocampus has been widely used as a model for cortical ontogeny, little is known about the development of specific cell types in the hippocampus. It is now possible to determine the time course of neurogenesis of specific neurochemical systems using a combination of immunohistochemistry and [3H]-thymidine autoradiography. Experiments using flattened hippocampal preparations were therefore conducted to determine the time of origin and anatomical distribution of SSIR neurons in the hippocampal formation of the rat.

Timed pregnant Sprague-Dawley rats were given a single I.V. injection of [3H]-thymidine on embryonic day (E) 13, 14, 15, 16, 17, or 18. At approximately 2 months of age the offspring were sacrificed and prepared for immunohistochemistry. Dissected hippocampi were gently flattened and coronal sections (20 µm) were cut on a freezing microtome throughout their rostro-caudal extent. Free floating sections were incubated for 24 hrs. at 4° C in antiserum (SS 309) directed against somatostatin 28. Tissue was then processed according to the avidin-biotin-peroxidase method. Mounted sections were subsequently prepared for autoradiographic visualization of [3H]-thymidine labeled neurons. The distribution of [3H]-thymidine labeled and somatostatin positive (THY-SSIR) cells was plotted using a microscope linked computer digitizing system.

Most hippocampal THY-SSIR cells are generated on E13 and E14. The majority of these cells are generated on E14 and are preferentially added to septal and temporal ends of the hippocampus. Fewer SSIR cells are generated on E15 and only occasional SSIR neurons are born at later embryonic stages. The overall pattern of SSIR neurogenesis also reflects a subiculo-dentate gradient such that SSIR cells generated on E13 are preferentially distributed to the subicular complex, E14 generated cells tend to be positioned throughout the CA1-CA3 fields of the hippocampus, and the majority of cells born on E15 are located in the hilar region of the dentate gyrus. These results, in parallel with previous studies on the neurogenesis of GAD-positive cells, demonstrate that hippocampal SSIR cells are generated during a narrow period between E13-E15. In addition, the present findings demonstrate that computer-assisted quantitative analysis of neurogenesis in the flattened hippocampus can reveal subtle gradients of development which are not apparent in standard preparations.

315.5 BEHAVIORAL MODULATION OF THE INDUCTION OF LONG-TERM SYNAPTIC PLASTICITY IN THE HIPPOCAMPUS. C.R. Bramham* and B. Srebro*. Dept. of Physiol., Univ. of Bergen, N-5000 Bergen, Norway. (SPON:ENA)

The efficacy of neuronal transmission in the major hippocampal pathways changes with the behavioral state of the animal. We investigated the possibility that the ability of neurons to undergo long-term potentiation (LTP) of the perforant path-granule cell system is also modulated by behavioral state.

Fifteen male Sprague-Dawley rats were anesthetized and electrodes cemented in position to allow chronic stimulation of the perforant pathway with recording of evoked potentials and EEG from the dentate hilus. Experiments started at least one week after surgery in environmentally habituated animals and were performed between 8 A.M. and 1 P.M.. Standard field potential measurements were collected in a still-alert state (SAL), slow-wave sleep (SWS), and during rapid eye movement sleep (REM), as defined by behavioral and EEG criteria. On the first 3 days of testing, stimuli were delivered during SAL at regular intervals throughout the experimental period to detect possible fluctuations in the response, and stimulus strength-response curves were collected in SAL and SWS to establish the behavioral modulation pattern of the field potential. On day 4 animals received a high-frequency stimulus train (400 hz, 20 ms, 8 sequences with at least a 10 s rest interval) during either SAL or SWS. A second train was given on the next day (after the response decayed to the baseline level) during the other behavioral state, with the current intensity adjusted to evoke an epsp equivalent to that of the first train. Six of these animals were later tetanized during REM sleep.

The following results were obtained: 1) the pattern of behavioral modulation of field potentials (SAL versus SWS) was as described by others and did not change after tetanization, 2) induction of LTP was more likely to occur during SAL and REM sleep, as compared to SWS, 3) animals which failed to demonstrate LTP in SWS sustained typical LTP when tetanized in SAL, 4) after tetanization in SWS, a long-term depression of the epsp-spike relation occurred as often as LTP, but was not seen in SAL.

The results suggest that the capacity to sustain long-term synaptic plasticity is not a static property of hippocampal neurons but is dynamically modified according to the behavioral state of the animal.

315.6 LONG-TERM POTENTIATION DECREASES DEPENDENCE OF HIPPOCAMPAL DENTATE GRANULE CELL RESPONSE ON THE FREQUENCY OF PERFORANT PATH INPUT. J.R. Balzer*, R.J. Sclabassi and T.W. Berger (SPON: P. Jannetta). Departments of Behavioral Neuroscience and Neurosurgery, Univ. of Pittsburgh, Pittsburgh, PA 15260.

High-frequency stimulation of perforant path (PP) afferents to the hippocampal dentate gyrus (DG) is known to produce long-term potentiation (LTP) of PP-DG synaptic efficacy. We previously have shown that LTP is associated with a decrease in nonlinear properties of the PP-DG projection when those properties are evaluated using the same stimulation intensity pre- and post-LTP (Berger et al., Soc. Neurosci. Abstr., 1984), i.e., when the number of presynaptic elements activated is held constant. To determine whether this represents a saturation phenomenon, we examined nonlinear properties of the PP-DG response using stimulation intensities that equated the number of granule cells activated pre- and post-LTP.

Nonlinear characteristics of the PP-DG projection were determined using systems analytic techniques. For these procedures, a train of 4064 impulses (0.1 ms duration) with randomly varying inter-impulse intervals (Poisson distribution, λ = 500ms) was delivered to the PP of chronically implanted rabbits. Amplitude of the DG population spike was measured in response to each impulse in the train. Stimulation intensity was varied both pre- and post-LTP; one random train was delivered at one intensity each day. Intensities were those producing 5%, 10%, 30%, 50% or 100% of maximum spike amplitude based on I/O curves generated by single impulses delivered at 0.1 Hz.

First order kernels, which reflect the average population spike response to each impulse in the train, were unaltered as a result of LTP. Second order kernels, which reflect the modulatory influence of a previous impulse on the activity evoked by the current stimulus, revealed pronounced decreases in nonlinear characteristics post-LTP. Facilitation, which averages 70-80% pre-LTP when low stimulation intensities (5-10%) are used, is greatly reduced when the number of granule cells activated is equated using low intensities post-LTP. Third order kernels values, which reflect the modulatory influence of the preceding pair of intervals on the activity evoked by the most current stimulus, also were greatly reduced post-LTP. When pre-LTP intensities reached 50% or more, nonlinearities were equivalent to those observed post-LTP, i.e., second and third order kernel values approached zero. These results indicate that LTP is associated with a decrease in the dependence of DG output on the frequency and pattern of PP input, and that post-LTP nonlinear characteristics are independent of the intensity of stimulation. Supported by The Whitaker Foundation and the Office of Naval Research.

315.7 CALCIUM-INDUCED LTP IN THE HIPPOCAMPUS: REGIONAL DIFFERENCES BETWEEN CA1 AND CA3. P.P.H. Leung*, K.G. Baimbridge and J.J. Miller. (SPON.: J.P.J. Pinel) Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada. V6T 1W5

The N-methyl-D-aspartate (NMDA) receptor has been implicated in the induction of long-term potentiation (LTP). It has also been suggested that there is a regional disparity in the distribution of the NMDA receptors within the rat hippocampal formation favoring the regio superior over the regio inferior (Monaghan et al., J. Neurosci., 5:2909, 1985). Furthermore, Harris et al. (in: Excitatory Amino Acid Transmission, 1987) demonstrated that the NMDA antagonist, D-2-amino-5-phosphonovaleric acid (D-APV), blocked the mossy fibre but not the commissural/association activated frequency-induced LTP in guinea pig slices. In view of these differences, we have examined the ability to induce LTP simply by raising extracellular calcium (Ca^{2+}-LTP) (Turner et al., Neuroscience, 7:1411, 1984) in the CA1 and CA3 regions and the effect of D-APV on these responses.

Transverse hippocampal slices prepared from male Wistar rats were allowed to recover in normal artificial cerebro-spinal fluid (CSF) containing 1.5 mM Ca^{2+} and 1.5 mM Mg^{2+}. Stable synaptically activated population spike responses from CA1 (via stratum radiatum) or CA3 (via mossy fibres) were obtained from different slices incubated together in the same chamber to ensure that both were exposed to near identical experimental conditions. We have confirmed our previous report that 5-6 min exposures of artificial CSF containing 4 mM Ca^{2+} and 1 mM Mg^{2+} produced a consistent (200-500%) long lasting potentiation in CA1. However, the same treatment failed to induce a potentiation, and in some cases, actually resulted in a depression of the responses in CA3.

Ten minute pre-treatment by D-APV at 25 uM did not alter the responses in CA3 but exerted a consistent, slight depression (up to 50%) of the control synaptic responses in CA1. This pre-treatment failed to affect the potentiation induced by the high Ca^{2+} media especially over the early potentiation phase (30-45 min post high Ca^{2+}). We did however observe an attenuation of the potentiation response over the extended period which requires further investigation.

These results suggest that the NMDA receptors might partly participate in the normal synaptic responses of the stratum radiatum evoked CA1 responses but not in the mossy fibre evoked CA3 responses in the rat. In view of the failure of D-APV to affect Ca^{2+}-LTP, at least for the early phase, it can be suggested that the induction of LTP involves more than just the NMDA receptor and may be pathway-specific.

315.8 KINDLING ALTERS A CALCIUM DEPENDENT POTASSIUM CONDUCTANCE AND SYNAPTIC TRANSMISSION IN AMYGDALA NEURONS. Po-Wu Gean* and Patricia Shinnick-Gallagher. Department of Pharmacology and Toxicology, The University of Texas Medical Branch, Galveston, TX 77550.

Kindling is the development of seizures following repeated electrical stimulation of certain brain structures. Amygdala kindling is of clinical interest because the behavioral seizures that develop are limbic in nature and related to common forms of human complex partial seizures. The purpose of this research was to analyze normal electrophysiological characteristics of neurons in the basolateral amygdala (BLA) nucleus and to determine the changes that occur in those properties at the membrane level as a result of kindling. Standard electrophysiological recording methods were used in an in vitro rat amygdala slice preparation.

Kindling was produced by daily administration of a subconvulsive stimulus through an electrode implanted in the BLA nucleus. After 11 days, a stage 5 kindled seizure was produced with the same stimulus. A contralateral brain slice was prepared 4-6 weeks after kindling was complete. Data were obtained from 28 control implanted rats and 36 kindled rats.

In the normal and implanted control animals, BLA neurons accommodated in response to injection of a long depolarizing current. An afterhyperpolarization (AHP) due primarily to calcium activated potassium conductances followed the termination of the cathodal current injection. Stimulation of the stria terminalis, an afferent pathway to the BLA, evoked an excitatory postsynaptic potential (EPSP)-inhibitory postsynaptic potential (IPSP) sequence.

Resting membrane potential, input resistance, membrane time constant, and spike amplitude and threshold were not different in control-implanted and in kindled cells. However, in kindled cells, intracellular injection of long depolarizing current pulses elicited action potential firing which did not accommodate. The amplitude of the AHP was unchanged but the 1/2 decay time was significantly shortened in kindled cells (178 $\pm$ 91 ms, n=10) compared to control implanted cells (635 $\pm$ 330 ms, n=6). These data suggest that a Ca-dependent K conductance, an active membrane property, is altered in this chronic model of epilepsy. In addition, stria terminalis stimulation in kindled animals evoked epileptiform discharge in 50% of the neurons and 'extra' synaptic potentials in the remaining neurons. IPSPs were not recorded in kindled cells.

These results suggest that chronic epileptiform activity induced in vivo is maintained in the in vitro amygdala brain slice and that alterations in excitatory transmission and loss of IPSPs as well as a Ca-dependent K conductance contribute to epileptogenesis in the amygdala.

315.9 EFFECTS OF ANOXIA ON SYNAPTIC TRANSMISSION AND CALCIUM CURRENTS IN IMMATURE HIPPOCAMPUS.

K. Krnjević[1], E. Cherubini and Y. Ben-Ari, INSERM U-29, Maternité de Port-Royal, 123 Boulevard de Port-Royal, 75014 PARIS.

In hippocampal slices from adult animals 2-4 min periods of anoxia cause a rapid loss of excitability and synaptic transmission, accompanied by a marked increase in K conductance and some hyperpolarization (Hansen et al. Acta Physiol. Scand., 115, 301, 1982). In addition, voltage clamp studies have revealed a strong but also reversible suppression of Ca current (Krnjević and Leblond, J. Physiol, 1987, in press).

In the present experiments, we have recorded in hippocampal slices from Wistar rats aged 0-15 days (as well as adult rats). The slices were superfused with ACSF at 33-34° gassed with either 95 % O_2 and CO_2 or 95 % N_2 and CO_2. Recording was mainly in CA1 (less often in CA3), spikes and PSPs being evoked by stimulating stratum radiatum.

Anoxia rapidly caused a loss of excitability but synaptic transmission was more resistant in immature than in adult slices and recovery more rapid on reintroducing O_2. In most cases, exposure to N_2 for 2-4 min produced only a partial reduction of EPSPs recorded extra or intracellularly.

In voltage clamp studies, Ca inward currents could be readily demonstrated after treatment with tetrodotoxin. Cs^+ and TEA (in some cases recording electrode contained 2M CsCl instead of the usual 2M KCl). As in mature slices at least two types of Ca current could be distinguished : one transient fast-inactivating, seen exclusively at holding potentials (V_H) of -70 to -90 mV was relative insensitive to Ba^{2+} and Cd^{2+} but blocked by Ni^{2+} (100 uM) : a more sustained current was seen exclusively at holding potentials (V_H) -40 to -50 mV, that was much enhanced by 2 mM Ba^{2+} and blocked by Cd^{2+} (50-200 uM). Both types of Ca current were reversibly depressed by anoxia, but the suppression of the sustained current was much more rapid, being largely complete within 2 min : the transient current disappeared only after 4 or more min.

315.10 EPILEPTOGENIC REGIONS OF HUMAN MESIAL TEMPORAL LOBE SHOW ALTERED CONNECTIVITY AS MEASURED BY STIMULATION-EVOKED FIELD POTENTIALS. C.L. Wilson, M. Isokawa-Akesson, and T.L. Babb Department of Neurology and Brain Research Institute, University of California, Los Angeles, CA 90024.

On the basis of field potentials evoked by electrical stimulation of amygdala and hippocampus, Buser and Bancaud (EEG J., 55:1, 1983) suggested that connections between these mesial temporal lobe structures may undergo modification under the pathological conditions of temporal lobe epilepsy. In the present study, patients were studied during telemetry monitoring of EEG from depth electrodes chronically implanted for recording spontaneous seizure onsets required for the identification of resectable areas of epileptogenesis in medically intractable complex-partial epilepsy patients.

Electrodes stereotactically implanted in amygdala (AM), pes hippocampi (HP), presubiculum and parahippocampal gyrus were were used to deliver biphasic rectangular pulses of 0.1 msec duration at current densities ranging from 5 to 50$\mu C/cm^2$/ph, at a frequency of 0.1 Hz or less. Recordings were made from electrodes in adjacent structures as each site was stimulated with single pulses (imperceptible to patients using the above parameters). Averages based on 3 to 50 stimuli evoked field potentials ranging from 20-50uV at threshold to 0.5-3.0mV. Of the 52 patients tested preoperatively, data from 38 patients who came to surgery as a result of lateralization of an epileptogenic site or region were examined to determine which AM and HP sites evoked field potentials in the adjacent structure.

On the side contralateral to the site of epileptogenesis, AM stimulation evoked clear field potentials in the HP of 15 out of 24 patients (63%), and HP stimulation evoked clear field potentials in the AM of 19 out of 26 patients (73%). AM stimulation ipsilateral to the seizure onset side evoked HP responses in only 5 of 21 patients (24%) and HP stimulation evoked responses in the AM in 9 of 27 (33%) patients. The probability of such a difference in HP response between epileptogenic vs. non-epileptogenic sides during stimulation of AM occurring by chance is $p<.01$ ($\chi^2=6.88$, 2-tail, df=1), and in AM during HP stimulation is $p<.05$ ($\chi^2=5.31$, 2-tail, df=1).

These results agree with the study cited earlier in the significant reduction of amygdala input to a hippocampus associated with epileptogenesis, but differ in the reduction of hippocampal output we found as compared to a facilitation of output which they reported. Our results support a hypothesis of epileptogenic alteration of connections associated with neuronal loss rather than a facilitation of synaptic routes suggested by others, since hippocampal neuronal loss has been documented in this same population of patients on the side of seizure onset (Babb et al., Epilepsia , 25:729, 1984).

315.11 MOCHA: A NEUROLOGICAL MUTANT EXPRESSING PERSISTENT THETA SYNCHRONIZATION OF CORTICAL AND HIPPOCAMPAL NEURONS. J. L. Noebels and R. L. Sidman, Dept. of Neurology, Section of Neurophysiology, Baylor College of Medicine, Houston, TX 77030 and Div. of Neuroscience, Children's Hospital, Boston, MA 02115.

Phenotypic survey of mapped single locus mutations in the mouse reveals the existence of genetic loci which control specific patterns of excitability in central neurons. We find that the coat color mutant mocha (gene symbol mh, Lane and Deol, 1974, chromosome 10, recessive), inherits an enhanced rhythmic pattern of activity normally associated with learning and exploratory behavior. Electrocorticographic (ECoG) recordings from the cerebral cortex and hippocampus in unrestrained mice revealed a persistent and exclusive pattern of high amplitude (>300 μV), 7-7.5 Hz waves (theta rhythm) unresponsive to sensory stimuli. Unlike other inbred mouse strains, the mocha rhythm is not intermixed with fast desynchronized activity. The mutant ECoG phenotype was present bilaterally in 11/14 adult homozygotes. Several mh/mh mice showed the mutant pattern over only a single hemisphere and a high frequency, desynchronized contralateral pattern. In younger mice studied, two showed the trait at 4 weeks postnatal, but one did not display the synchronized rhythm until 6 weeks of age. Heterozygous mh/+ mice (6/6) did not display the persistent theta trait. The littermate control mice, homogygous for the grizzled mutation and wild type at the mocha locus, showed either little theta activity at all (3/6), or steady but low amplitude rhythms. A second neurological deficit of mocha homozygotes (unilateral head tilt due to otolithic degeneration) is also incompletely penetrant, and also exhibits clear axial asymmetry, but is not concordant with the abnormal ECoG trait. Atropine (100 mg/kg) caused a long-lasting disorganization of the mocha ECoG pattern, blocking virtually all theta activity, just as it did in control mice of several strains. A second allele C3H-mh^{2J} can also show a similar background ECoG rhythm.

The mocha mutant thus reveals that the predominance of a specific spectral frequency of brain rhythm can be a heritable trait. Although difficult to breed, mocha offers a singular genetic opportunity to define cellular mechanisms controlling activation of neuronal theta synchrony and to determine the effects of this inherited error of brain signaling patterns on synaptic circuitry underlying learning and memory.

315.12 ALTERED CHOLINERGIC FIBERARCHITECTURE AND SELECTIVE SURVIVAL OF ACHE-POSITIVE HILAR NEURONS WITH HIPPOCAMPAL SCLEROSIS IN HUMAN TEMPORAL LOBE EPILEPSY R.C. Green*, H.W. Blume, S.B. Kupferschmid*, M-M. Mesulam Harvard Medical School, Boston, Massachusetts 02215

Temporal lobe epilepsy (TLE) is a common subtype of human epilepsy which is treated by anterior temporal lobectomy in some medically intractable cases. The pathology of the surgically resected tissue is varied, but the most common finding is hippocampal sclerosis, consisting of neuronal cell loss and gliosis in a characteristic distribution with relative sparing of neurons in the CA2 subregion. We analyzed surgically resected temporal lobe tissue from four patients with TLE who were found to have hippocampal sclerosis on Nissl staining. Adjacent sections were stained for acetylcholinesterase (AChE) with a modification of the Koelle technique. The distribution of AChE fibers in the hippocampi of the patients with TLE was compared to that previously described in the normal human hippocampus (Green et al., Soc. Neurosci. Abst. 12:356, 1986)

In all four cases, the normal distribution of AChE fibers in the hippocampus was disrupted. AChE fibers were lost in a pattern that closely matched neuronal dropout in each case, and fibers were preserved in regions where there was relative sparing of cells. In each case, AChE positive polymorphic neurons within the hilum of the dentate gyrus were relatively spared despite severe loss of the immediately adjacent CA4 pyramidal neurons. In two of the four specimens, the normally heavy juxtagranular staining of AChE along the inner edge of the molecular layer of the dentate gyrus was absent while AChE staining was conspicuous in the outer two-thirds of the molecular layer of the dentate gyrus.

The AChE-rich septo-hippocampal pathway is the major source of cholinergic input into the hippocampus, projecting to neurons in Ammon's horn and to the proximal portion of the dentate granule cell dendritic tree. Loss of the juxtagranular AChE fibers in the molecular layer of the dentate gyrus may reflect a loss of cholinergic input from the septum, suggesting the possibility of septal pathology in some patients with hippocampal sclerosis. The residual AChE fibers in the outer portion of the molecular layer of the dentate gyrus could represent afferents from surviving acetylcholinesterase positive cells within the hilum.

315.13 INTERRELATIONSHIPS BETWEEN HIPPOCAMPAL CA1 AND DENTATE GYRUS: COHERENCE AND PHASE MEASUREMENTS. J.D.Bronzino, M.Grewal*, R.J.Austin-LaFrance* and P.J.Morgane. Dept. of Engineering and Computer Science, Trinity College, Hartford, CT 06106 and The Worcester Foundation for Experimental Biology, Shrewsbury, MA. 01545.

A number of studies have indicated that two regions within the dorsal hippocampal formation, the dentate gyrus and region CA1, are responsible for generation of the 4 -11 Hz rhythmic slow activity (RSA) known as theta rhythm (Bland, B.H. et al., Brain Res., 94:199, 1975; Bland, B.H. and I.Q. Wishaw, Brain Res., 118:259, 1976). In the present study we have utilized power and spectral analysis techniques to quantitatively describe the interrelationships which exist between the electrical activity recorded from these two regions during various vigilance states.

High coherence values (> 0.85) and a consistent phase difference of approximately 170° were found to exist within the theta range of frequencies during REM sleep. Coherence and phase spectrum computed during the vigilance states of slow-wave sleep and quiet waking showed no consistent relationship at any of the frequencies studied. These results agree with previous studies which indicate that whenever theta rhythm is present, the signal obtained from CA1 is consistently 180° out of phase with that obtained from the dentate gyrus (Krug et al., Brain Res. Bull., 6:5, 1981; Leung, W.S., J. Neurophysiol., 52:1051, 1984).

Except for the studies mentioned above, the evidence describing this phase difference has been determined primarily by qualitative observation of the EEG. Our results provide quantitative measures of the degree of interaction of the cellular activity which occurs between CA1 and the dentate gyrus during generation of theta rhythm in the adult rat.

Since the theta rhythm does not appear in the EEG until approximately 8 - 10 days of age, and there is a significant difference in the timing of both the neuro- and synaptogenesis within these hippocampal fields, (i.e., the pyramidal cells of region CA1 are formed entirely during the prenatal period while the granule cells of the dentate gyrus are formed largely postnatally), we intend to follow up these studies in developing rats in an effort to determine whether the measures of coherence and phase spectra are affected by the differential development of these two structures. These measures may then serve as markers of normal EEG development to assess the effects of various brain insults, such as prenatal protein malnutrition, on the development of theta activity within the hippocampal formation.

315.14 PAIRED PULSE INHIBITION IN THE DENTATE GYRUS OF THE POSTNATAL RAT: AN IN VITRO STUDY. A.V.Nowicky, P.G. DiScenna,& T.J. Teyler. Neurobiology Dept., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Extrinsic inhibition of hippocampal pyramidal cells develops late in rat and rabbit CA1, relative to excitatory synaptic events (Mueller et. al., 1984 and Harris & Teyler, 1983). The granule cells (GC) of the dentate gyrus (DG) are generated later than the CA1 pyramids, the majority leaving the mitotic cycle during the week after birth. Therefore we are interested in examining the the expression of extrinsic inhibition in rat pup DG. Orthodromic and antidromic stimulation (OS,AS) of the GCs are used in a paired pulse (PP) paradigm to study this question. Hippocampal slices were obtained from 6-10 day (PN6-PN10) rat pups and maintained under standard conditions. Small concentric bipolar electrode was placed in the developing molecular layer (OS) and in the hilar region (AS). A glass micropipette (2M NaCl, 4-8MOhm) was placed in the GC layer to record extracellular field potentials. The waveforms collected in this manner (OS) commonly had the basic triphasic pattern of the adult DG (P1,N1,P2)., however the potentials were much smaller (<1-2mv.). A stable stimulus at 50-75% max. was used for homosynaptic paired pulse series (.04Hz: 10 to 2000ms ISI). When a good antidromic response was available, a second series was recorded with AS as the conditioning pulse and OS , the test pulse. The results are based on experiments from 33 slices. As expected, the homosynaptic paired pulse series produced a complex pattern. Generally, strong depression of the N1 component was found across 10-40ms ISI (often N1 was completely eliminated). Preliminary analysis of the putative field EPSP slope (P1) also demonstrates a depression of the test pulse, which is similar to that reported for medial perforant path PPs in adults (McNaughton,1980). By PN7, antidromic stimulation inhibits the N1 component of the test pulse, without affecting the EPSP slope. This inhibition is not as strong or as long-lasting as the homosynaptic depression, but still can eliminate the N1 component of the test pulse at >20ms. ISI. This strongly suggests the capacity for feed-back inhibition. At longer ISIs, the antidromic pulse has minimal effects on the test pulse, usually depressing the P2 component. The homosynaptic PP however demonstrates effects on the test pulse out to 2000ms ISI. Bicuculline (1 nl. spritz to cell body) shifted the paired pulse response (short delays) from inhibition to faciliation in a PN9 slice, further supporting the presence of inhibitory circuitry in this relatively young system. Since the CA1 region has a low seizure threshold, the presence of the postnatal dentate inhibitory circuitry may provide protective attenuation of the excitatory input to the trisynaptic circuitry.

315.15 INHIBIITION OF RADIATUM AND ORIENS EVOKED POTENTIALS BY STIMULATION OF THE DISTAL APICAL DENDRITIC FIELD IN RAT AREA CA1. P.G.DiScenna, A.V. Nowicky and T.J.Teyler. Neurobiology Department, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

A few studies have described the inhibition of orthodromically evoked population spikes (area CA1) by a preceeding conditioning stimulus, to neighboring afferents, that is below spike threshold. (Lynch etal,Exp.Neurol.71:527 & others) These findings suggest the operation of feed-forward inhibition (FFI) onto hippocampal pyramidal cells. A number of studies have provided anatomical and physiological evidence for hippocampal FFI (Buzsaki, Prog.Neurobiol.22:131: Somogyi et al,Brain Res.332:143). We report that stimulation in stratum lacunosum-moleculare (LM) can significantly inhibit population spikes evoked by stimulation of stratum radiatum or stratum oriens, in a paired pulse paradigm (area CA1). Our LM stimulation does not produce an observable population spike in CA1, CA3 or the subiculum, but appears at the cell body layer (extracellularly) as a short positivity (variable) followed by a 25-40ms negativity. This response is generally less than 0.5mv amplitude. Stimulation across the hippocampal fissure, in the dentate molecular layer, does not produce this effect. The inhibition can last over 200ms, but is most effective in the range of 10-50ms. where the test pulse spike can be inhibited by 75-100%. By delivering a short burst of LM stimulation (200Hz, 20ms or 40ms) the test pulse inhibition can be extended to beyond 500ms. LM stimulation can also decrease the amplitude of sub-spike threshold test pulses. An initial attempt at observing this phenomenon at the intracellular level was successful. The LM stimulus produces a pure hyperpolarizing event in a pyramidal cell and inhibited the cell's firing to orthdromic stimulation. Presently we are continuing the intracellular investigations, examining in detail the effects on synaptic activity, and computing one-dimensional current source density analysis of the LM stimulation. It is interesting to speculate on the nature and use of this inhibition. The entorhinal cortex (ECx) is a major source of afferents to LM, part of the so-called temporo-ammonic projection. It is not known whether these fibers are collaterals of the entorhinal projection to the dentate gyrus, or whether they arise from a separate neuronal population. Perhaps the ECx plays a dual role in the trisynaptic circuit, shaping output by excitation and inhibition, capable of providing a margin of safety through FFI during periods of intense activity.

315.16 ISOLATION REARING LOWERS DOPAMINE METABOLITES IN RAT MESIAL PREFRONTAL CORTEX AND INCREASES TIMIDITY IN OPEN FIELD. R.R. Holson*, B.J. Gough*, A.C. Scallet and S.F. Ali (SPON: Kang Fan). Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Isolation rearing in rats has been reported to alter forebrain monoamine concentrations and activity in the open field. The precise nature of either effect is as yet uncertain, both as to direction and reproducibility of effects. Two isolation experiments are reported here. In the first, two sets of animals were reared in rigorous isolation (metal hanging cages) or in social housing (3/cage). At 90 days of age, one set of animals was sacrificed. Brains were dissected into five regions: mesial frontal cortex (MFC), hypothalamus, amygdala (Am), entorhinal cortex, and nucleus accumbens, then assayed for serotonin, dopamine and their metabolites by high pressure liquid chromatography with electrochemical detection. At the same age, a second set of animals was exposed for three minutes daily for four consecutive days to the open field. Thereafter, cage conditions were reversed for four months, following which the animals were sacrificed, and MFC and Am were assayed as above. In the second experiment, isolates and socially-reared animals were sub-divided into two groups, one of which received brief handling (5 secs twice a week) after weaning. All subjects were tested as above in the open field. Results were that isolation rearing produced alterations only in MFC, and in this region only the acidic metabolites of dopamine (homovanillic acid and dihydroxyphenylacetic acid) were reduced by 20% in isolates. Four months after reversing housing conditions, the two groups showed identical levels of MFC dopamine metabolites, dopamine, serotonin and its metabolite. Isolates in both experiments displayed strong symptoms of fear in the open field, including heightened defecation and prolonged freezing. Brief handling completely protected against this syndrome. Moreover, the first unhandled socially-reared animal to be taken from the home cage for testing displayed the same fear-like behavior as did isolates, while subsequent animals from the same cage did not. It is concluded that isolation rearing selectively lowers dopamine metabolites in prefrontal cortex. This appears to be a true developmental effect, not simply an acute reflection of differential housing, since four months of reverse housing did not differentially alter MFC dopamine metabolites. Isolation effects on activity are probably due to a lack of social facilitation from odor cues of familiar rats, and hence may be unrelated to isolate MFC dopamine abnormalities.

315.17 MICROCOMPUTER BASED UNIT ACQUISITION AND ANALYSIS SYSTEM. D. ZENDZIAN*, K. AUSTIN*, P.J. MORGANE AND J.D. BRONZINO (SPON C. Siok) TRINITY COLLEGE, HARTFORD CT 06106 AND THE WORCESTER FOUNDATION FOR EXPERIMENTAL BIOLOGY, SHREWSBURY, MA 01545.

Recently there has been considerable interest in determining the cellular events underlying specific types of EEG activity (Busaki, G. et al., Brain Res. Rev., 6:139, 1983). With this in mind, we have developed a microcomputer based unit acquisition and analysis system capable of detecting the occurrence of unit activity based upon a variety of specific waveform criteria (such as spike amplitude, spike width, etc.). This neuronal biosensor provides a specific set of measures including: 1) the time of occurrence at either or both the high and low threshold settings, and 2) the width of the action potential at each threshold, as well as extrapolated to baseline. Unit activity based upon any of these parameters may then be displayed in a variety of histograms which include 1) interspike interval (ISI) histograms, and 2) spike width histograms.

From these histograms the user may then select a particular range of values for one specific criterion (e.g., ISI, spike width), and the system will generate a spike train representing the firing rate of all the units satisfying the selected criterion along with the corresponding EEG. Once the resultant spike train and EEG is obtained, convolution and cross correlation procedures (Leung L.S. and G. Buzsaki, EEG and Clin. Neurophysiol., 56:688, 1983) may be employed to determine the degree of correlation between the cellular events depicted in the spike train and the corresponding EEG activity.

This system, therefore, provides the neuroscientist with a versatile tool to study the interrelationships between specific cellular events and the EEG. Of particular interest is its use in developing a better understanding of the role of neuronal populations in the areas CA1 and dentate gyrus in the generation of the theta rhythm observed in the hippocampal EEG during specific behaviors. This system offers great promise in the classification of different types of cells based upon electrophysiological measures. Efforts along these lines need to be extended to include detection and classification of a wide variety of bioelectric events. Supported by NSF Grant# E41688416708.

AGING AND DEMENTIA: PLAQUES, TANGLES, AMYLOID

316.1 LACTOFERRIN IMMUNOREACTIVITY IN NEURITIC PLAQUES AND NEUROFIBRILLARY TANGLES IN ALZHEIMER'S DISEASE: LOCALIZATION TO THE RHINENCEPHALON AND ADJACENT CORTEX.

A.P. Osmand* and R.C. Switzer (SPON: R.M. Cox). Departments of Medicine, Pathology and Medical Biology, University of Tennessee Medical Center, Knoxville, TN 37920.

Although several major components of the neuritic plaques (NP) and neurofibrillary tangles (NFT) that constitute the pathological lesions of Alzheimer's Disease (AD) have been extensively characterized, the etiology and molecular pathways involved in their initiation and formation are largely unknown. During studies of the distribution of iron and iron binding and iron storage proteins, we have observed the selective presence of lactoferrin (LF) immunoreactivity on both NP and to a lesser extent NFT in AD brain. Using affinity-purified antibody to human LF and avidin-biotin-peroxidase methodology, we have detected LF determinants on NP and NFT in amygdala, hippocampus and entorhinal cortex from 16 of 18 AD cases examined. AD cases included 8 males (age 70-83) and 10 females (age 56-88); LF immunoreactivity was absent from 5 age matched controls without neurological disease (age 61-88) and from 2 AD cases with extensive cortical plaques. Immunochemical specificity was confirmed by antigen inhibition and the use of multiple antisera and affinity-purified antibody at high dilution.

LF immunoreactivity was absent from or considerably reduced in other regions of brain that contained large numbers of NP or NFT as revealed by silver stains, indicating that this protein is not an essential component of these lesions. LF is normally a major protein in seromucous secretions and the granules of polymorphonuclear leukocytes and is a trace constituent of plasma, arising there from leukocyte degranulation. The presence of high levels of lactoferrin in nasal mucous has been described, indicating that the protein may be reaching the brain by anterograde transport along the olfactory tract. Indeed LF immunoreactivity was localized to those regions of brain that receive major input from the olfactory system, most notably in the cortical nucleus of the amygdala and entorhinal cortex. The presence of LF immunoreactivity in both the olfactory bulb and tract was confirmed immunohistochemically.

These observations support the contention that the extensive involvement in AD of those regions of brain that receive primary input from the olfactory system indicates an important role for this pathway in the pathogenesis of AD (Pearson et al. Proc. Nat. Acad. Sci. USA, 1985, 82:4531; Roberts Neurobiol. Aging, 1986,7: 561-567). Furthermore the iron binding sites of LF and reactivity with cellular receptors may involve this protein in the transport of metal ions and metal complexes such as aluminum or aluminosilicates in a majority of cases of AD. (Supported by grants from the NIH [NS23634] and the Robert H. Cole Foundation).

316.2 **LOCALIZATION OF BRAIN SPECTRIN IN ALZHEIMER SENILE PLAQUES.** **L.S. Perlmutter, P. Seubert, H.C. Chui*[1], M. Baudry and G. Lynch. Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717 and University of Southern California[1], Los Angeles, CA 90089-0191.**

Alzheimer disease is apparently a disease of the cytoskeleton. Abnormal accumulations of actin, tubulin, and neurofilament and microtubule-associated proteins have been reported. Abnormalities in brain spectrin, a structural protein which links cytoskeletal elements to the plasma membrane, have yet to be investigated. The present study examines the localization of brain spectrin in relation to thioflavin S-positive amyloid deposits in human brain.

Autopsy samples from Alzheimer diseased (n=4) and, at present, one Parkinsonian patient were immersion fixed in a mixed aldehyde fixative. Regions known to be affected in Alzheimer disease (areas 9, 17, 22, hippocampal formation) were sectioned on a vibratome at 50 *um* thick. Brain spectrin was immunocytochemically localized using a rabbit anti-rat brain spectrin and the biotin-avidin peroxidase technique (Vectastain). Tissue sections were then counterstained with thioflavin S, a fluorescent marker for amyloid proteins. The same tissue section could thus be examined for both brain spectrin-like immunoreactivity (BSLI) and amyloid.

BSLI was seen to line somatic, dendritic and axonal plasma membrane. No BSLI could be identified intracellularly, i.e., in relation to the paired helical filaments. There were, however, extracellular dark circular plexuses of densely immunoreactive processes. These processes formed a fibrous network that was highly distinguishable from the surround. This fine meshwork could be contrasted to the thick knob-like processes seen with an antibody to the microtubule-associated protein, Tau (Wood *et al., PNAS*, 1986, *83*, 4040; personal observations). BSLI plexuses appeared in two forms: (1) immunoreactive processes encircled the amyloid core; (2) immunoreactive processes formed a reticulum over the entire plaque. In these latter cases, the fluorescence was diminished or totally blocked (as determined by comparison with adjacent sections of thioflavin-stained sections from which the primary antibody was omitted). These staining configurations could result from the brain spectrin immunopositive processes forming a sphere around the amyloid core; alternately, they may signify plaques at different stages of development. There were neither BSLI circular plexuses, nor amyloid fluorescence in the Parkinsonian tissue.

These results suggest that brain spectrin is associated with the Alzheimer senile plaque, but not with the neurofibrillary tangle. In light of the recent finding of a protease inhibitor in the plaque (Abraham *et al., J Cell Biochem*, 1987, Suppl. 11D, 193), this staining pattern may reflect a build-up of unproteolized brain spectrin. (Tau antibody was a generous gift from Dr. L.I. Binder. Supported by NIA AG05373 to LSP and AG00538 to GL. This work done in collaboration with the Alzheimer Disease Research Center Consortium.)

316.3 INCREASED DETECTION OF LYSOSOMAL PROTEINASE ANTIGENS ASSOCIATED WITH THE NEUROPATHOLOGY OF ALZHEIMER'S DISEASE. A.M. Cataldo*, R.A. Nixon, C.Y. Thayer*, F.M. Benes and T.R. Wheelock* (SPON: N. Fleming). McLean Hospital, Harvard Medical School, Belmont, MA 02178

Previous studies in non-neural tissue indicate that alterations in the distribution of lysosomal enzymes may play an important role in mediating cell death in response to certain metabolic insults. The proposed mechanism involves the release of latent hydrolytic enzymes, including proteases, into the cytoplasm where certain of these enzymes may act on subcellular structures and lead to irreversible cellular damage. In the nervous system, lysosomes and lysosomal proteinase activities increase during normal aging; however, relatively little is known about lysosomal proteolysis in normal and degenerative states. To investigate the possible involvement of lysosomal proteolysis in neuronal cell death in Alzheimer's disease (AD), we have used specific polyclonal antisera to human brain cathepsin D (CD) and human cathepsin B (CB) to localize these antigens in the prefrontal cortex and hippocampus of postmortem human brain from individuals with AD and age-matched neurologically normal controls. Premortem clinical diagnoses were confirmed neuropathologically. CD and CB immunoreactivity was most abundant within pyramidal cells of neocortical layers III and V and in the large pyramidal cells and dentate neurons of the hippocampus in control and AD brains. At the subcellular level, CB and CD immunoreactivity was localized exclusively to lysosomes that were concentrated in the perikaryon and proximal portions of apical and basal dendrites. In certain neurons from AD brains, immunostaining was especially intense in the lysosomes of basal processes. Unlike neurons, glial cells contained relatively few immunostained lysosomes, and staining in the neuropil was negligible. Qualitative assessment of CB and CD staining suggested an increased immunoreactivity of neurons in AD brains. Preliminary microdensitometric analyses of CD staining in 7 control and 9 AD brains suggested that neurons of all sizes in neocortical layer III of AD brains contained increased immunoreactivity. In addition, senile plaques in AD brains were intensely stained by antisera to both CB and CD. Typically, plaques contained a diffuse ground substance that stained relatively homogeneously and irregular bodies of varying sizes that stained darkly. Some plaques contained one or more neuronal perikarya in various stages of degeneration. In these cells, immunoreactivity was not confined to lysosomes. These results are consistent with the possibility that, in AD, increased expression of lysosomal proteases may be an early response of the neuron to the disease process and that release of cathepsins from lysosomes may mediate aspects of neuronal cell death. Furthermore, lysosomal proteinases appear to increase in one or more cell types during or in response to plaque development and may persist as constituents of the neuritic plaque. 316.4 ALZHEIMER PAIRED HELICAL FILAMENT IMMUNOREACTIVITY IN DOWN SYNDROME BRAIN, L.A. Mattiace[1], D.R. Sparkman*[1], and C.L. White, III[2], Departments of Neurology[1] and Pathology[2], Southwestern Medical School, Dallas, Texas, 75235.

Down syndrome (DS) patients over the age of 40 demonstrate many of the histopathological markers which are associated with Alzheimer disease (AD), including neuritic plaques and neurofibrillary tangles (NFT). Although occurring in both cortical and subcortical structures, the presence of NFT in the cortex appears to correlate clinically with the expression and severity of dementia in both AD and DS (Wisniewski et al., Ann. Neurol., 17:278, 1985).

Ultrastructurally, NFT are comprised of proteinaceous paired helical filaments (PHF), which are morphologically identical in DS and AD (Rubenstein et al., Brain Res., 372:80, 1986). Although previous staining of NFT has been demonstrated by either silver impregnation or thioflavine S or T in both DS and AD tissue, polyclonal antibodies to PHF provide a more specific method for detecting the presence of PHF-containing NFT. Using a monospecific polyclonal antibody to Alzheimer PHF, we studied the immunoreactivity of NFT in a 34 year old DS patient.

PHF protein was isolated at autopsy from the brain of a patient with neuropathologically confirmed AD, and polyclonal antibodies were produced in rabbit. This antiserum has been well characterized in previous studies of AD brain (White et al., J. Neuropathol. Exp. Neurol., 44:368, 1985). Optimal dilution of the antiserum was determined by checkerboard titration.

Brain tissue obtained at autopsy from a patient (age 34M) diagnosed clinically with DS was immersion-fixed in 10% phosphate buffered neutral formalin. Thirty micron floating sections from the temporal neocortex were stained for PHF using a modified peroxidase-antiperoxidase procedure. Negative controls included non-immune serum and antiserum absorbed against both AD and young/normal brain. Adjacent areas were embedded in paraffin and 5 micron sections were stained with hematoxylin and eosin and by the Sevier-Munger silver method for NFT and neuritic plaques.

PHF immunoreactivity was present in tangle-bearing neurons as demonstrated in the silver-stained sections. This study confirms the antigenic similarity between NFT of AD and DS. Immunohistochemical staining using monospecific polyclonal antibodies to PHF provides an additional method for detecting the presence of NFT in DS.

316.5 ALZ-50 APPEARS TO BE ABLE TO DISTINGUISH BETWEEN THE NEURITIC PLAQUES OF ALZHEIMER'S DISEASE AND THOSE OF NORMAL AGING. A. Scicutella*, B.L. Wolozin and P. Davies*. (SPON: C.S. Raine) Depts. of Pathology and Neuro-science, Albert Einstein College of Medicine, Bronx, NY, 10461.

One of the hallmark lesions of Alzheimer's Disease, the neuritic plaque, is also found in relatively small numbers in the brains of normal aged humans and animals (see Selkoe et al, Science, 235,873-876, 1987). One major component of the plaque, the amyloid deposit, appears to be identical in both Alzheimer's Disease and in the normal aged human and animal. These observations have led to the concept that the difference between aging and Alzheimer's Disease is quantitative rather than qualitative. Alz-50 is a monoclonal antibody that reacts with a neuronal antigen present in brains of patients with Alzheimer's Disease but essentially absent from normal brain. In samples of tissue from cases of Alzheimer's Disease, the antibody reacts with both neuronal perikarya and neurites, and is particularly strongly reactive with clusters of neurites surrounding amyloid cores. Staining of neurites in neuritic plaques has been observed in all cases of Alzheimer's Disease examined (more than 50 cases). However, brain tissue from two elderly patients with Parkinson's Disease in which small numbers of plaques were present showed no staining with Alz-50, raising the possibility that plaques produced as a result of normal aging did not contain the Alz-50 antigen.

We have investigated this possibility by examination of brain tissue from patients whose mental status prior to death was well established by neuropsychologic testing. Double staining with Alz-50 and thioflavine S (a very sensitive reagent for the detection of neuritic plaques) was used to determine what percentage of plaques contained the Alz-50 antigen. In 5 cases of Alzheimer's Disease, over 90% of plaques (250 out of 270) detected by thioflavine S were also stained by Alz-50. A number of large clusters of dystrophic neurites stained by Alz-50 but not by thioflavine-S were also apparent in some cases. In tissues from cases with mild memory dysfunction (possible early Alzheimer's Disease), smaller numbers of plaques were found and a variable and lower percentage (25 out of 65) contained Alz-50 reactive neurites. In individuals aged over 80 with normal mental status, plaques were found with no detectable Alz-50 reactivity in cerebral cortex. These results suggest that plaque formation in Alzheimer's Disease proceeds by a process that involves expression of the Alz-50 antigen, while formation as a result of normal aging does not.

Supported by NIH grant MH 38623.

316.6 RE-EXPRESSION OF A DEVELOPMENTALLY REGULATED ANTIGEN IN ALZHEIMER'S DISEASE AND DOWN'S SYNDROME. B.L. Wolozin, A Scicutella*, and P. Davies*. Departments of Pathology and Neuroscience, Albert Einstein College of Medicine, Bronx, New York, 10461.

Alz-50 is a monoclonal antibody prepared by immunization of mice with ventral forebrain tissue from cases of Alzheimer's Disease. By immunocytochemical techniques, abundant neuronal reactivity is present in tissues from patients with this disorder, but little or no staining is found in normal adult tissues. Biochemical studies are consistent with immunocytochemical results, and show that the antibody reacts with a 68,000 dalton protein (A68) in tissue from cases of Alzheimer's Disease. Brain tissues from cases of Down's Syndrome aged over 40 years at death also show abundant staining with Alz 50, and Western blot analysis reveals the antigen to be A68 in these cases.

In attempts to study when Alz-50 reactivity first appears in the brains of cases with Down's Syndrome, we have examined tissue from cases ranging in age from 16 weeks of gestation up to 62 years. Temporal cortex from 5 out of 6 fetal brains (16 to 24 weeks) were entirely negative for Alz-50 reactivity, despite the use of frozen sections and several different fixatives. The 6th cases, a 16 week Down's fetus, did show small numbers of reactive neurons diffusely distributed through cortex. At later developmental stages, all cases examined revealed positive neuronal staining in temporal cortex: stained neurons became obvious at 34 to 36 weeks gestation, and were detected in both Down's and normal brains in the first year of life. Reactive neurons had the appearance of small interneurons, and were located predominantly in layers 5 and 6 of the cortex, as well as in the underlying white matter. Approximately 50 neurons per cm^2 were found, and the number of positive cells did not differ between normal and Down's brain tissue. Both perikarya and neuronal processes were stained, the latter frequently showing a very beaded, varicose appearence. Numbers of stained cells dropped very markedly in tissues from cases aged 2 years or older: less than 1 neuron per cm^2 is found in normal adult brain. Reactive neurons and occasional clusters of reactive neurites reappear in tissue from Down's Syndrome cases aged 20 to 30 years, and in cases of Alzheimer's Disease at more advanced ages. Thus Alz-50 appears to detect a protein with some role in normal brain development, and this protein is re-expressed in both Down's and Alzheimer's Disease.

316.7 IMMUNOHISTOCHEMICAL DEMONSTRATION OF ALZ-50 ANTIGEN AND UBIQUITIN IN PICK BODIES AND NEUROFIBRILLARY TANGLES. S. Love, S. Quijada, T. Saitoh, P. Davies, and R. D. Terry(SPON: R. Katzman). Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093 and Departments of Pathology and Neurosciences, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, NY 10461.

The monoclonal antibody Alz-50 and antibodies to ubiquitin react with neurofibrillary tangles in Alzheimer's disease (Wolozin, B. L., et al Science 232:648, 1986; Mori, H., et al Science 235:1641, 1987). In the present study, these antibodies were used to immunostain sections of brain from cases of Pick's disease, Kuf's disease with neurofibrillary tangles, and from elderly non-demented patients with occasional neuritic plaques and neurofibrillary tangles in the hippocampus. Alz-50 and anti-ubiquitin both immunostained the neurofibrillary tangles and the neuritic components of plaques in the brains from non-demented individuals, the neurofibrillary tangles in Kuf's disease, and Pick bodies. The levels of Alz-50 antigen and ubiquitin were measured by immunoblot analysis of serially diluted brain extracts, obtained within a few hours of death, from 13 cases of Alzheimer's disease, two cases of Pick's disease, and 6 age-matched normal controls. Whereas the amount of Alz-50 antigen in the cytosolic fractions was increased several-fold in Alzheimer's disease and Pick's disease, the level of ubiquitin was similar to that in controls. The concentration of ubiquitin within neurofibrillary tangles and Pick bodies is thought to be due to its conjugation to proteins that are resistant to digestion rather than to increased ubiquitin synthesis.

316.8 DIFFERENTIAL SENSITIVITY OF THE MICROTUBULE-ASSOCIATED PROTEIN, TAU, IN ALZHEIMER'S DISEASE TISSUE TO FORMALIN FIXATION. N.J. Pollock and J.G. Wood* Department of Anatomy and Cell Biology, Emory University School of Medicine, Atlanta, GA 30322.

The microtubule-associated protein, tau, is a family of proteins reported to be normally concentrated in axons. Neuritic plaques (NPs) and neurofibrillary tangles (NFTs) which pathologically characterize Alzheimer's disease (AD) tissue, are located in the neuropil and cell body of affected neurons, respectively. We have previously demonstrated that NFTs and NPs contain a modified form of tau (PNAS, 83:4040-4043, 1986). Immunocytochemistry of formalin-fixed human autopsy AD tissue using two monoclonal antibodies, Tau-1 and Tau-2, shows intense staining of NFTs and NPs while normal axonal staining is less apparent. A biochemical approach was used to assess the effects of formalin on the antigenic sites of tau isolated from human and rat tissue. Highly enriched tau samples isolated from histopathologically confirmed AD tissue were separated by gel electrophoresis and tansferred to nitrocellulose paper. Blots were incubated in 10% neutral-buffered formalin and then processed for Tau-1 immunoreactivity following digestion with alkaline phosphatase. Controls included no formalin fixation of blots and digestion with heat-inactivated alkaline phosphatase.

A progressive decrease in Tau-1 immunoreactivity of the tau bands was observed with increasing times of formalin fixation. Phosphatase digested blots, however, after formalin fixation, demonstrated an increase in Tau-1 immunoreactivity of a subset of bands, as compared to control blots. These results mimic the phosphatase-sensitive Tau-1 immunocytochemical staining of formalin-fixed AD tissue slices. Since the tau isolation proceedure used does not separate normal axonal tau from the pathology-associated modified tau (AD tau), we used rat brain white matter homogenates to test the formalin sensitivity of axonal tau to Tau-1 and Tau-2 staining. Formalin fixation of white matter homogenate blots decreases Tau-1 immunoreactivity of the tau bands. Digestion with alkaline phosphatase after exposure to formalin had no effect. Tau-2, which has a low affinity for rat tau in fixed tissue, does recognize the tau bands on a blot of white matter homogenates. In support of the tissue result, formalin fixation of those blots eliminates Tau-2 immunoreactivity. These results indicate that the lack of good axonal staining with Tau-2 of fixed rat tissue may be due to the formalin sensitivity of axonal tau. These overall results suggest that normal axonal tau has greater sensitivity to formalin than AD tau and support the hypothesis that a modification of AD tau in pathological structures protects it from the effects of formalin with regards to Tau-1 and Tau-2 antigenicity. NS-17731.

316.9 A2B5 ANTIBODY TO A NEURAL SURFACE COMPONENT LOCALIZES TO SITES OF ALZHEIMER DEGENERATION ASSOCIATED WITH BOTH NEUROFIBRILLARY TANGLES AND NEURITIC PLAQUES. C.A. Marotta and R.E. Majocha* (SPON: G. Hauser). Program in Neuroscience and Dept. of Psychiatry, Harvard Med. Sch.; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178; and Massachusetts General Hosp., Boston, MA 02114.

Gangliosides have been implicated in neuronal growth and regeneration under some conditions as well as in reducing neuronal degeneration caused by experimental lesions. Therefore, we have begun to examine the possible role of gangliosides in relation to the degenerative changes that are characteristic of the Alzheimer's disease (AD) brain. Monoclonal antibody A2B5 was originally developed against embryonic retinal cells and was shown to react with a neural surface component present in the ganglioside fraction of brain. Application of the mab to fixed sections of control hippocampus revealed only light background staining that was homogeneous and contained few formed elements. By contrast, similar processing of AD hippocampus revealed intense staining of numerous flame-shaped cells resembling neurons with neurofibrillary tangles (nft). The reaction product partly or completely covered the area circumscribed by the cell boundary. In some cases the antigen was localized in the same cells that were also shown to contain nft as revealed by co-staining with thioflavin S. Examination of adjacent sections stained either with mab A2B5 or with thioflavin S revealed that in a specified area there were 1.5 to 2 times greater numbers of neurofibrillary tangles than sites containing the A2B5 antigen; this suggests that high antigen levels were expressed in a subclass of degenerating neurons. In addition, neuritic processes associated with thioflavin-stained senile plaques also contained the A2B5 component. All immunostaining was eliminated by preincubation of the mab supernatant with a total ganglioside fraction from bovine brain. The role of the A2B5 antigen in neuronal degeneration is unknown and its expression may not be confined to the AD brain. Other neurodegenerative disorders are being examined. Although these early observations raise the possibility that expression of a unique ganglioside may have a protective function in injured or dying neurons, the results do not rule out the prospect that expression of the A2B5 antigen contributes to the degenerative process. Both possibilities are under investigation. Supported by AG02126, AG04522, AG05134, AHAF and McKnight Foundation.

316.10 NEUROFIBRILLARY TANGLES (NFT) OF PROGRESSIVE SUPRANUCLEAR PALSY (PSP) AND ALZHEIMER DISEASE (AD): INFLUENCE OF NEURONAL CELL LOCATION ON ANTIGENIC PROPERTIES. M. Tabaton*, V. Manetto*, L. Autilio-Gambetti, P. Gambetti, V. Fried*, G. Perry. Institute of Pathology, Case Western Reserve University, Cleveland, OH 44106 and St. Jude Children's Research Hospital, Memphis, TN 38101.

This study was undertaken to investigate whether antigenic differences between two types of NFT can be attributed to their different location. Antigenic and solubility properties of subcortical NFT of PSP, which occur subcortically and are made of 15nm straight filaments, were compared to those of subcortical and cortical NFT of AD, composed mostly of paired helical filaments (PHF). Ten cases of PSP and 2 cases of AD were examined. An antiserum to PHF (Ihara et al, Nature 304:727-730, 1983), a monoclonal antibody (Mab) to tau, tau-1 (Binder et al, J Cell Biol 101:1371-1378, 1985), two Mabs to neurofilaments, SMI 34 (Sternberger-Meyer) and 1.1.1 (Autilio-Gambetti et al, Banbury Report 15, 1983) and 4-2D8, a Mab to ubiquitin, all of which stain cortical NFT in AD, were used. Immunostaining was performed on paraffin, vibratome and frozen sections from the pons in PSP cases and from the pons and hippocampus in AD cases. Except for 1.1.1, all antibodies immunoreacted with subcortical NFT in both PSP and AD cases. A quantitative analysis showed a difference in the number of subcortical NFT immunostained by these antibodies. Anti-PHF immunoreacted with 100%, tau-1 with 70%, 42D8 with 50% and SMI 34 only with 10% of the NFT, both in PSP and AD. All antibodies immunostained subcortical NFT after treatment with SDS. Colloidal gold immunoelectromicroscopy of PSP cases demonstrated that the antibodies recognized both the straight filaments and the amorphous material constituents of NFT of PSP. Subcortical NFT of AD were confirmed to consist mostly of PHF (Tabaton et al, Acta Neuropathol 68:218-223, 1985). Our results show that despite their different structure, the 15nm straight filaments of PSP and the PHF of AD, when located in the same brain region, share all their known antigens. They also show that NFT in AD are antigenically different according to their location: pontine NFT lack a neurofilament epitope that is consistently present in cortical NFT. These observations suggest that the antigenic differences between the straight filaments of PSP and PHF of AD are due more to their different location than to their different structure, and that different PHF are expressed by neurons in different locations.

316.11 UBIQUITIN IN ALZHEIMER PAIRED HELICAL FILAMENTS: A STUDY WITH MONOCLONAL ANTIBODIES. G. Perry, P. Mulvihill*, V. Manetto*, V. Fried*, H. Smith*, I. Grundke-Iqbal*, K. Iqbal*, L. Autilio-Gambetti and P. Gambetti. Case Western Reserve Univ., Cleveland, OH 44106; St. Jude Children's Research Hospital, Memphis, TN 38101 and Inst. Basic Research in Developmental Disorders, Staten Island, NY 10314.

Some antibodies raised to paired helical filaments (PHF), the major cellular inclusion of Alzheimer disease, have been found to crossreact with tau or neurofilaments. However, other antibodies to PHF are thought to be directed to determinants unique to PHF, since they have been found not to react with any known protein. Biochemical and immunocytochemical studies have recently demonstrated that ubiquitin (Ub) is a component of PHF (Mori et al Science,235:1641, 1987; Perry et al, PNAS,84:3033, 1987). We have investigated whether antibodies previously thought to recognize unique determinants in PHF react with Ub. We found that 2 of 3 monoclonal antibodies (Mabs) and 1 of 5 antisera raised to PHF are directed to Ub. The Ub epitope recognized by Mab 5-25 resides in a peptide containing amino acid residues 64-76 and that recognized by Mab 3-39 in a Ub peptide containing residues 50-65. Ub epitopes in these regions are not recognized by other available Mabs to Ub. We also tested 8 Mabs to epitopes located between residues 34 and 53 of Ub, but that recognize different conformational determinants of Ub , dependent on the nature of the conjugate. Five of these 8 Mabs react with PHF. These findings indicate a) that Ub is one of the previously unidentified proteins recognized by antibodies raised to PHF, b)that several epitopes along residues 34 to 76 of Ub can be detected in PHF, c) that Ub is conjugated in PHF in various conformations.

Supported by NIH Grants AG00795 and AG05892.

316.12 MODIFICATION OF HUMAN ANTINEUROFILAMENT ANTIBODIES WITH PHTHALOCYANINES. S.E. Kornguth, T. Kalinke* and W. Pietro*. Depts. of Neurology, Physiological Chemistry and Chemistry, University of Wisconsin, Madison, WI 53706.

Human antineurofilament immunoglobulins were attached covalently to cobalt tetracarboxy phthalocyanines (Pc) with retention of immunoreactivity. High titer (>1:1000) antineurofilament antibodies have been observed by us to occur in the sera of patients with visual paraneoplastic syndrome associated with small cell carcinoma of the lung and in patients with diffuse neuropsychiatric lupus erythematosus. The intense blue color of the Pc serves as an excellent marker for histological studies; the metal center of Pc permits applications in magnetic resonance imaging (MRI); the photolytic properties of Pc have applications in chemotherapy. The Pc was activated with a carbodiimide (EDC) and then modified with either diaminoethane (2 DAE:1 Pc) or with polylysine in the solvent dimethylsulfoxide. The diamine and the polylysine provide primary amines which serve as functional groups to crosslink the Pc with dextran or glycoproteins such as immunoglobulins. The amine modified Pc's were then coupled covalently to the periodate oxidized diethylaminoethyl dextran (DEAE dextran) which were then coupled to periodate oxidized immunoglobulins in aqueous systems. Alternatively, the amine modified Pc's were attached directly to the periodate oxidized immunoglobulins. The DEAE dextran maintains the Pc complex in solution in the aqueous solvent. The phthalocyanine-immunoglobulin complexes remain soluble and retain immunoreactivity as demonstrated on western blots. The western blots contained neurofilaments that were resolved on PAGE in SDS. This study now permits the use of phthalocyanines in MRI, photolysis and immunohistochemical procedures.

316.13 ALZ-50 RECOGNIZES AN EARLY NEURONAL ALTERATION IN ALZHEIMER'S DISEASE, INVOLVING NEURONAL PERIKARYA, DENDRITIC TREES, AND TERMINATION ZONES OF SPECIFIC PROJECTION NEURONS. B.T. Hyman, G.W. Van Hoesen, L.J. Kromer, and A.R. Damasio. Depts. of Neurology and Anatomy, University of Iowa College of Medicine, Iowa City, Iowa 52242.

Alz-50 is a monoclonal antibody that recognizes an antigen present in Alzheimer's disease brain but not in the brains of age compatible controls (Wolozin et al., Science 232:648, 1986). This antigen is distinct from the paired helical filament protein of neurofibrillary tangles and from the amyloid protein of neuritic plaques. Immunohistochemical staining with Alz-50 reveals immunoreactivity in Alzheimer brains in neurons that contain neurofibrillary tangles and in some neurons that do not, as well as in the neuritic portion of neuritic plaques and in the neuropil. Both types of neuronal alterations are located selectively in "at risk" lamina and cytoarchitectural fields. Some of the Alz-50 positive, neurofibrillary tangle negative neurons appear to contain immunoreactivity in the neuronal perikarya, throughout the dendritic tree, and in axons. Alz-50 positive neurons that contain neurofibrillary tangles appear to be at various stages of degeneration, and some completely destroyed neurons (tombstone tangles) lack Alz-50 immunoreactivity. These results are consistent with the hypothesis that the Alz-50 antigen precedes and accompanies the deposition of neurofibrillary tangles in neurons, and suggest that Alz-50 recognizes an early neuronal alteration in Alzheimer's disease. The possible localization of Alz-50 immunoreactivity in axons is of particular interest, because in certain areas areas a discrete immunoreactive zone occurs in terminal zones predicted by anatomic tracing studies in the nonhuman primate. For example, the pattern of Alz-50 neuropil immunoreactivity in the molecular layer of the dentate gyrus corresponds exactly to the predicted termination zone of the Alz-50 positive neurons and neurofibrillary tangles in layer II of entorhinal cortex (the perforant pathway). In addition, Alz-50 positive neuritic processes of neuritic plaques are located in this terminal zone. Alz-50 positive terminals corresponding to projections from Alz-50 positive neurons in the subicular cortices to layer IV of entorhinal cortex and to the mammillary bodies are also readily visualized. This staining pattern represents a direct demonstration of involvement of cortical and subcortical projections in Alzheimer's disease. (Supported by NS 14944 and PO NS 19632. We thank P. Davies and B. Wolozin, Albert Einstein College of Medicine, for generously providing Alz-50).

316.14 IMMUNODETECTION OF HUMAN SERUM AMYLOID P-COMPONENT IN ALZHEIMER'S DISEASE. A.B. Scheibel, E. Pommier* and T. Duong. UCLA Departments of Anatomy, Psychiatry and Brain Research Institute, Los Angeles, CA 90024

We are reporting the presence of human serum amyloid P-component in two characteristic hallmarks of Alzheimer's disease. This finding, contrary to results from previous studies, infers a concomitant impairment in the blood-brain barrier.

Human serum amyloid P component (235,000 MW), synthesized only in the liver, is both a normal plasma glycoprotein and a constituent of connective tissues. It has been found in all forms of systemic and localized amyloidosis so far investigated, where it forms a minor but constant constituent (6-14% of mass). In senile dementia of the Alzheimer's type (SDAT), intracerebral amyloidosis occurs in three characteristic microscopic lesions: cerebrovascular amyloid, senile plaques and neurofibrillary tangles. The exact composition of these amyloids is unknown. The presence of human serum amyloid P-component has been demonstrated in cerebrovascular amyloid but not in the senile plaques and tangles in cerebral tissues from patients with SDAT(Westermark et al, 1982; Rowe et al, 1983). Unlike previous researchers, we report here the consistent labelling of senile plaques and tangles, using a polyclonal antibody to human serum amyloid P-component. Our specimens consisted of brains from patients with a verified post-mortem diagnosis of Alzheimer's dementia and control brains from patients with no obvious neurological diseases. Various cortical areas and the hippocampus were dissected from coronal sections of fresh tissue (7-15 hours postmortem) and fixed by immersion. Cut sections were stained using a peroxidase-antiperoxidase method.

In accordance with previous reports, we found serum amyloid P-component positive reaction products in segments of pial arteries, penetrating and intraparenchymal arterioles. The reaction products are unevenly distributed from the tunica media outward and contribute to the lumpy-bumpy appearance of the abluminal portion of the affected vessels. Unlike previous reports, senile plaques in our specimens were also positive to the human serum amyloid P-component antibody. The distribution of reaction products was varied: in some plaques they formed small clumps distributed throughout the fibrillar and nonfibrillar portion. In others, they were mostly observed in the plaque core, which was either stained throughout its extent or only in a surrounding rim. Stained portions of vessels and/or swollen neurites were occasionally observed within the plaques. Unexpectedly, we also obtained antibody positive staining within the neurofibrillary tangles. The pattern of staining followed exclusively the intracytoplasmic distribution of paired helical filaments. The intensity of the antibody staining appeared to correspond to the amount of paired helical filaments within the neurofibrillary tangles. These antibody-positive tangles were also observed within senile plaques.

With a molecular weight of 235,000, serum amyloid P-component would not be expected to penetrate into the brain parenchyma. Our detection of the presence of serum amyloid P-component in brains from patients with SDAT suggests the possibility of an impaired blood-brain barrier. It also points to the universal association of this glycoprotein with all forms of amyloidosis and the possibility that cerebral amyloidosis in SDAT may be partially of extracerebral origin. Supported by the Dorothy Van Ness-Thompson Foundation and the David H. Murdock Foundation for Advanced Brain Studies.

316.15 STRUCTURAL DIVERSITY AND INFRASTRUCTURE OF AMYLOID DEPOSITS IN ALZHEIMER BRAIN. F.M. Benes, J. Reifel*, R. Majocha* and C.A. Marotta. Department of Psychiatry, Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Although the structure of amyloid in Alzheimer's disease (AD) is yielding to analyses carried out at the gene level, little direct information is available with regard to mechanisms related to amyloid accumulation at the cellular and tissue levels. To gain insight into putative regulatory processes, we applied monoclonal antibodies (mabs), directed against a known amyloid protein sequence, to the AD cortex and analyzed the resulting staining pattern of amyloid deposits by means of computer-enhanced imaging procedures. Three mabs were characterized and shown to react with parenchymal and vascular amyloid. The mabs allowed visualization of morphlogically distinct amyloid deposits in the prefrontal cortex that differed with respect to size, qualitative appearance and internal distribution of amyloid epitopes. Previously unappreciated infrastructural details of AD brain amyloid became accessible through computer imaging. All amyloid-stained areas showed gradients of stain density suggesting that either diffusion or coalescence of this protein may be involved in plaque formation. In spite of this characteristic appearance of internal density gradients, at least four structurally discrete morphologic types of amyloid staining were observed: punctate and macular types were most common; more rarely, ring and ring with core configurations were observed. Each type showed a distinct size distribution with punctate being smallest and rings, with or without cores, being largest. Macular amyloid deposits showed a broad distribution of size that overlapped with that of the ring-like deposits. The four groups exhibited further dissimilarity with respect to distribution within the cortical lamellae. Punctate amyloid densities were most numerous and were preferentially localized in layers I and II, while those with a ring-like appearance were least common and primarily found in layers V and VI. Macular amyloid deposits were most commonly found in layer III. Thus, detailed analyses of AD amyloid epitopes has demonstrated non-uniformity with regard to size, morphology and site-specificity. The dissimilarities suggest that the appearance and distribution of amyloid deposits are dependent upon the underlying laminar-specific organization of the cortex. Supported by National Institute on Aging grants #AG02126, AG04522, AG05134; American Health Assistance Foundation and McKnight Foundation awards.

316.16 DISTRIBUTION OF THE ALZHEIMER AMYLOID BETA PROTEIN mRNA IN THE HUMAN AND RAT BRAINS. E.A. Finch,* L.I. Benowitz, S.P. Finklestein, R.E. Tanzi,* E.D. Bird and R.L. Neve. Depts. of Pediatrics, Neurology, Neuropathology, Psychiatry, and Program in Neuroscience,, Harvard Med. Sch.; Dept. of Genetics, Children's Hospital; Neurology Service, Massachusetts General Hosp.; Mailman Res. Ctr., McLean Hosp., Boston and Belmont, MA.

The neuropathology of Alzheimer's disease is marked by deposits of the proteinaceous material amyloid, in the core of extracellular neuritic plaques and the walls of the cerebral microvasculature. Similar amyloid deposits occur in the brains of older Down syndrome patients and, to a much lesser degree, in association with the normal aging process. We have isolated amyloid beta protein cDNAs that were shown to hybridize with messenger RNA that is expressed normally in the brain and other tissues(Tanzi, et al., Science 235, 880, 1987). These findings suggest the possibility that amyloid deposits in Alzheimer's disease may result from either an abnormal expression or post-translational modification of a normal molecular constituent. In order to understand better the normal significance of the amyloid protein gene product, as well as its relevance to the pathophysiology of Alzheimer's disease and Down syndrome, we have used a cDNA to the amyloid beta protein gene (FB68L) to determine the distribution of the amyloid beta protein gene transcript in the mature rat and developing and mature human brains. Northern blot analysis of RNA's from various regions of the adult rat brain showed the 3.7 kb amyloid beta protein RNA to be expressed at highest levels in association (posterolateral) cortex and striatum; modest levels were seen in the midbrain, motor (anterior) cortex, brainstem (medulla), septum, and hippocampus, and very little in the cerebellum.

Strikingly, the amyloid beta protein mRNA is abundantly and homogeneously expressed across human fetal brain subregions. In the adult human brain, however the expression of the amyloid beta protein showed marked regional variation. Levels of mRNA were highest in the frontal pole (A10) and the anterior perisylvian cortex (A44). Moderate hybridization was observed in the posterior perisylvian cortex (A40), the inferior temporal cortex (A20/21), and the cerebellar cortex. Signal was weak in subcortical regions, and in striate, extrastriate, and motor cortices (A17, 18, A4) respectively.

Studies are currently in progress to determine the cellular distribution and relative abundance of the amyloid beta protein mRNA in various human and rat brain regions by in situ hybridization. Preliminary results indicate that it is expressed selectively in layer II of the adult rat and human cortex and in certain cells of the hippocampus. In situ hybridization to primary cell cultures is also being used to gain information about the developmental expression of this gene.

316.17 ANTIBODIES TO THE AMYLOID β-PROTEIN DETECT ~80 kDa BRAIN PROTEIN AT HIGHER LEVELS IN ALZHEIMER THAN NORMAL CORTEX BUT NOT IN CEREBELLUM. D. Selkoe,* A. Saperstein, M. Podlisny and L. Duffy. Center for Neurologic Diseases, Harvard Medical School, Brigham and Women's Hospital, Boston, MA 02115.

The formation of neuritic plaques containing central deposits of extracellular amyloid filaments is a more specific lesion for Alzheimer's disease (AD) than is the neurofibrillary tangle. Neuritic plaques are essentially restricted to 3 conditions: AD, Down's syndrome and normal aging. The hydrophobic 4-5 kDa amyloid protein (β-protein) found in the cores of neuritic plaques is also deposited in some cortical and meningeal microvessels in AD brain. Recent studies show that the β-protein is cleaved from an ~80 kDa precursor encoded by a gene on chromosome 21q near the familial AD gene. Northern analyses reported to date suggest that there are 2 closely spaced mRNAs of ~3.4 and 3.2 kb in human brain and that the message is present in a wide range of non-neural tissues. However, polymers of the cleaved β-protein (i.e., amyloid filaments) accumulate only in the brain, and within brain, only in certain regions. In an attempt to detect any regional differences in distribution or amount of the precursor, we used an antiserum raised to synthetic β-peptide residues 1-28 (not carrier coupled) to examine brain homogenates from 8 pathologically verified AD patients and 3 age-matched controls. On Western blots, the antiserum consistently detected a doublet of ~M_r 80 and 83 kDa in frontal cerebral cortex of all 8 AD patients. Using equal protein loading, this doublet was always present in lower amounts (or not detectable) in frontal cortex from the control patients. Frontal cortex from a case of Down's syndrome also showed the immunoreactive doublet comigrating with that in AD cortex. No immunoreactive bands were detected in cerebellar homogenates from the same AD cases showing the doublet in frontal cortex. Western blots of kidney homogenates from a pathologically-verified AD case and a control also showed no immunoreactive bands. The 80/83 kDa proteins were also detected in higher amounts in AD than control frontal cortex using an antiserum to synthetic β-protein residues 1-45. The immunoreactive proteins were present in the particulate but not the cytosolic fraction of the cortical homogenates. Further studies of their regional and subcellular distribution and attempts to identify the proteins will be presented. The apparent M_r of these proteins and their consistent increase in AD cerebral cortex but not cerebellum suggest that they could represent a cell-specific expression of the β-amyloid precursor protein(s) in brain regions prone to developing amyloid deposits in Alzheimer's disease.

316.18 AMYLOID FIBRILS IN HEREDITARY CEREBRAL HEMORRHAGE WITH AMYLOIDOSIS OF DUTCH ORIGIN SHARE AMINO ACID SEQUENCE WITH ALZHEIMER'S DISEASE β-PROTEIN. E.M. Castaño*, S.G. Van Duinen*, F. Prelli* and B. Frangione* (SPON: E. Simon). Dept. of Pathology, N.Y.U. Med. Ctr., New York, 10016.

Hereditary cerebral hemorrhage with amyloidosis of Dutch origin (HCHWA-D) is an autosomal dominant form of cerebral amyloidosis that has been described in four different families from The Netherlands. The disease is clinically characterized by recurrent strokes starting in the fifth decade of life. The pathological findings include amyloid deposits in the small arteries of the leptomeninges and cerebral cortex and in senile plaque-like structures. These lesions lack the dense amyloid cores and resemble the immature or early plaques described in cases of Alzheimer's Disease and Sporadic Congophilic Angiopathy. No neurofibrillary tangles are present.Immunoperoxidase on brain sections from two cases of HCHWA-D showed that the amyloid deposits were specifically stained by an affinity purified polyclonal rabbit antiserum raised against a synthetic peptide homologous to the 28-residue amino-terminal sequence of Alzheimer's Disease β-protein (anti-SP28). The amyloid fibrils were isolated from the leptomeninges and further characterized by SDS-PAGE, immunoblotting and partial amino acid sequence. The amyloid subunits had a molecular weigth of 4-6 kDa and reacted specifically with anti-SP28. The amino-terminal sequence in both cases revealed homology with Alzheimer's Disease β-protein. However, in contrast to the reported sequence of the vascular β-protein in Alzheimer's Disease, but similar to the β-protein isolated from the senile plaques and neurofibrillary tangles, HCHWA-D vascular amyloid protein had amino-terminal heterogeneity. Recently, it has been reported that neurofibrillary tangles in Guamanian Parkinson-Dementia are composed of an amyloid subunit identical to Alzheimer's Disease β-protein. In this disease, neither senile plaques nor vascular deposits are present.Therefore, β-protein cerebral amyloidosis comprises a spectrum of clinico-pathological entities including vascular types (HCHWA-D, Sporadic Congophilic Angiopathy) and neuronal types (Guamanian Parkinson-Dementia) of amyloid deposition.The full range of lesions is present in most cases of Alzheimer's Disease. Structural variants of β-protein and/or different processing of β-protein precursors synthesized in particular cell types may be responsible for the distinctive patterns of amyloid deposition in this group of degenerative neurological diseases.

316.19 AMYLOID DEPOSITS IN SPORADIC CONGOPHILIC ANGIOPATHY AND HEREDITARY CEREBRAL HEMORRHAGE WITH AMYLOIDOSIS OF DUTCH ORIGIN ARE ANTIGENICALLY RELATED TO ALZHEIMER'S DISEASE β-PROTEIN.

F. Coria*[1], E.M. Castaño*[2], S.G. Van Duinen*[2], M.L. Shelanski[1] and B. Frangione*[2]. Dept of Pharmacology[1] and Dept. of Pathology and Kaplan Cancer Ctr[2]., New York Univ., Sch. Med., New York, N.Y. 10016.

Amyloid deposition is a prominent feature of a number of brain disorders, differing in their neurological manifestations and clinical course, which range from acute vascular syndromes to progressive dementia. The most prevalent among these is Alzheimer's disease (AD) in which the amyloid deposits are mainly composed of a protein of 4kD (β-protein) that forms fibrillar structures within the wall of blood vessels, the neuropil (neuritic plaques) and neurons (neurofibrillary tangles). Because the nature of the amyloid deposits in other types of cerebral amyloidosis is not known, we have conducted immunocytochemical studies on brains from autopsied cases of AD (3 cases), Hereditary Cerebral Hemorrhage with Amyloidosis (HCHWA) of Dutch origin (2 cases), Sporadic Congophilic Angiopathy (1 case). Brains from two patients without neurological involvement were used as controls. Sections from these specimens were incubated with rabbit polyclonal antibodies against: a) a synthetic peptide of 28 residues (anti-sp28), homologous to the NH_2-terminal sequence of the β-protein, b) the main amyloid component of the HCHWA of Icelandic origin, a variant of Cystatin C, an inhibitor of cystein proteinases (Ghiso et al., PNAS, 83:2974, 1986), and c) a purified fraction of paired helical filaments. Bound antibody was revealed with immunoperoxidase. In all of these cases, anti-sp28 antibody stained amyloid deposits around leptomeningeal and cortical vessels and neuritic plaques, but not paired helical filaments. By contrast, anti-paired helical filaments antibodies stained only neurofibrillary tangles, and anti-Cystatin C variant antibody, as well as control preimmune rabbit serum, gave no staining. These findings demonstrate that the amyloid deposits of Sporadic Congophilic Angiopathy, HCHWA of Dutch origin and brain aging are composed of a protein antigenically similar to AD β-protein, and suggests that these three clinically and etiologically different morbid conditions are pathogenetically related. On this basis, they can be tentatively grouped as β-protein diseases.

316.20 POLYPEPTIDE COMPOSITION OF CORPORA AMYLACEA PURIFIED FROM AGED HUMAN BRAIN. D. Gauvreau*, A. Steyaert*, S. Cissé*, M. Blum*+ and G. Lacoste* (SPON: J. Metuzals). INRS-Santé, Pointe-Claire, Canada H9R 1G6, +Dept. Biochemistry, Univ. of Toronto, Canada, M5S 1A2.

Corpora amylacea (CA) accumulation in the CNS is associated with normal ageing. CA are made up of glucose polymers. However, the presence of a small quantity of protein in CA is a consistent finding, although the identity of this protein material is unknown. We developed a method to purify CA from human brain, and we analysed their protein constituents. CA were purified from frozen human brain using sucrose gradient fractionation and density centrifugation on Percoll: CA preparations thus obtained are over 95% pure as judged by visual estimation of PAS-stained material. The protein content of CA was estimated to be 3% of the total CA fraction by weight. SDS-PAGE analysis of CA preparations showed four major polypeptide bands, of molecular weight 100 kd, 94 kd, 40 kd, and 24 kd; these polypeptide species were consistently enriched in all preparations of CA. Amino acid analysis was performed on the 94 kd species, and revealed a high content of glutamic acid, glycine, and aspartic acid.

The presence of the same set of polypeptides in all CA preparations makes it unlikely that proteins are randomly trapped in CA. Rather, it suggests a specific mode of formation for these polyglucosan bodies. Recent reports indicate a significant increase in the number of CA in the hippocampus and frontal cortex of AD patients compared to controls. We are now looking at the protein composition of CA prepared from AD brains. The study of the formation of CA in conditions of degeneration may provide clues to the cellular processes of ageing in the brain.

EPILEPSY: BRAIN SLICES

317.1 POTASSIUM-INDUCED TONIC-CLONIC SEIZURES IN THE MAMMALIAN IN VITRO HIPPOCAMPUS. G. David*, Y. Yaari and M.S. Jensen*. Department of Physiology, Hebrew University School of Medicine, Jerusalem, Israel, and Institute of Physiology, Aarhus University, Aarhus, Denmark.

Mammalian cortical slices have been used extensively for elucidating mechanisms of interictal epileptogenesis. Recently, experimental procedures for inducing ictal (i.e. seizure) patterns of epileptiform discharge in hippocampal slices have been described, allowing in vitro analysis of interictal-ictal transitions and seizure mechanisms.

Perfusing rat hippocampal slices with K^+-enriched (5-8.5 mM instead of normal 3.5 mM K^+) solutions induced interictal bursts in areas CA3 and CA1 of all slices (n = 60) and recurrent ictal episodes in area CA1 in about 50% of the preparations. Seizures were induced only if the divalent ion concentrations were maintained at normal physiological levels (Ca^{++} 1.2, Mg^{++} 1.2 mM), i.e., at approximately half the total divalent ion concentration normally used in slice experiments. Raising $[Ca^{++}]o$ and $[Mg^{++}]o$ to 2 mM suppressed all ictal activity and reduced interictal bursting. Lowering $[K^+]o$ to 3.5 mM abolished all epileptiform activity in CA3 and CA1.

A gradual buildup of $[K^+]o$ (above the already elevated baseline) and interictal afterdischarges precipitated each ictal episode. The seizure itself consisted of a tonic-clonic sequence. During the tonic phase, which lasted several seconds, CA1 pyramidal neurons exhibited sustained depolarizations (ca. 10 mV), marked depression in input resistance, and repetitive discharge coincident with, and apparently triggered by, synchronized population spikes. Concomitantly, the $[K^+]o$ at the stratum pyramidale rose to about 12 mM. Termination of the tonic phase was associated with neuronal spike inactivation and hyperpolarization, from which intermittent bursts gradually emerged, increased in size and duration, and then recurred for many seconds. This clonic phase was ultimately followed by a period of postictal depression, during which interictal bursts and synaptic responses in CA1 were reduced.

Thus, mammalian hippocampal slices rendered epileptic by elevated $[K^+]o$ can produce abnormal discharge patterns (interictal-ictal transitions, tonic-clonic seizures, postictal depression) remarkably similar to those observed in vivo, provided they are not partially anaesthesized by elevated divalent cation concentrations.

317.2 DIFFERENTIAL CHOLINERGIC MODULATION OF INTERICTAL AND ICTAL EPILEPTIFORM ACTIVITY IN THE MAMMALIAN IN VITRO HIPPOCAMPUS. M.S. Jensen* and Y. Yaari. (SPON: S.G. Rayport) Institute of Physiology, Aarhus University, Aarhus, Denmark, and Department of Physiology, Hebrew University School of Medicine, Jerusalem, Israel.

Two patterns of abnormal neuronal discharge are typically manifested by epileptic cortex: (1) the brief, spatially restricted interictal bursts, and (2) the sustained, widely spread, ictal paroxysms (the seizure proper). In some models of experimental focal epilepsy, transitions from interictal "spiking" to maximal seizures are associated with progressive buildup of interictal afterdischarges, suggesting that interictal activity is a progenitor of seizures. We have examined this notion utilizing an in vitro model of hippocampal epilepsy, produced by perfusing rat hippocampal slices with K^+-enriched (5-8.5 mM), otherwise normal, physiological solutions. Slices which become epileptic exhibit interictal "spiking" in areas CA1 and CA3 and recurrent seizures in area CA1.

We found that each interictal-ictal transition in CA1 was associated with a progressive buildup of interictal afterdischarges, commencing several seconds before, and apparently leading to, seizure onset. Addition of neostigmine (1 μM) to the perfusing solution promptly suppressed all interictal bursts (in CA3 and CA1) and afterdischarges (in CA1). This effect was not accompanied by a marked suppression of synaptic responses in CA1. Despite losing their apparent interictal drive, ictal seizures continued to be generated in CA1. Muscarine (1 μM) and carbachol (10 μM) mimicked the effects of neostigmine, while atropine (1 μM) promptly reversed it, leading to the reappearance of interictal discharge in the CA3 and CA1 fields and apparent interictal-ictal transitions in CA1.

We conclude that in the mammalian hippocampus, interictal bursts are sensitive to blockade by activation of muscarinic cholinergic receptors. The finding that muscarinic suppression of interictal bursts does not concomitantly abolish seizures indicates that, at least in the in vitro hippocampus, interictal activity is not a progenitor of seizures.

317.3 NONSYNAPTIC AND SYNAPTIC MECHANISMS GENERATE TONIC-CLONIC SEIZURES IN THE MAMMALIAN IN VITRO HIPPOCAMPUS. Y. Yaari and M.S. Jensen*. (SPON: E. Leike). Dept. of Physiology, Hebrew University School of Medicine, Jerusalem, Israel and Inst. of Physiology, Aarhus University, Aarhus, Denmark.

In clinical and experimental epilepsy, generalized seizures commonly consist of a short tonic phase (sustained mascular spasm) followed by a prolonged clonic phase (repetitive muscular jerks). This tonic-clonic sequence is associated with characteristic cortical electrical activity, indicative of massive neuronal recruitment and synchronization during both phases of the seizure episode. However, the neuronal mechanisms underlying tonic and clonic neuronal discharge are poorly understood.

An in vitro model of tonic-clonic seizures can be produced by perfusing rat hippocampal slices with K^+-enriched (5-8.5 mM), otherwise normal, physiological solutions. This leads to the development of interictal bursts in the CA3 and CA1 fields and to recurrent tonic-clonic seizures in CA1. We have begun to investigate in this model the interrelationships between interictal, tonic and clonic epileptiform activity and report the following: 1) Interictal bursts in CA3 precede by several milliseconds the interictal events, the tonic phase of seizure and each clonic burst in CA1. This may be interpreted as indicating that all epileptiform activity in CA1 is triggered by a "focus" in CA3. 2) However, exposure of epileptic slices to the glutamate antagonist pCB-ρZ (500 μM) or to cadmium (50-200 μM) abolished all interictal activity (in CA1 and CA3) and clonic bursts (in CA1), but did not antagonize the generation of tonic seizures in CA1. Cadmium concentrations of 500 μM, which totally suppressed synaptic responses in CA1, also did not block this form of seizure discharge. 3) Similarly, cutting between CA3 and CA1 in epileptic slices abolished interictal and clonic bursts, but not tonic seizures, in CA1. Repetitive stimulation delivered to the Schaffer collaterals of these isolated CA1 preparations at 0.5-1 Hz produced interictal-like bursts. Following a tonic seizure episode, the same stimuli evoked a series of clonic bursts. 4) Tonic seizures in isolated CA1 preparations were accompanied by a steep transient rise of $[K^+]_o$ to about 12 mM. The $[K^+]_o$ slowly returned to baseline following termination of the seizure episode. Synaptic activation after the tonic phase produced a clonic burst only if $[K^+]_o$ was still markedly elevated.

We conclude that in mammalian hippocampal slices interictal bursts and tonic seizures are produced by disparate mechanisms. As commonly assumed, interictal burst generation depends on synaptic interactions. In contrast, tonic seizures in CA1 are most likely nonsynaptically generated. Their underlying mechanism may be regenerative accumulation of $[K^+]_o$. Synergism between interictal (synaptic) excitation of CA1 and enhanced neuronal synchrony (produced by elevated $[K^+]_o$) may underlie the clonic phase of seizure.

317.4 **NORADRENERGIC INHIBITION OF STIMULUS TRAIN-INDUCED BURSTING (STIB) IN AREA CA3 OF RAT HIPPOCAMPAL SLICES APPEARS TO BE MEDIATED BY ALPHA$_1$ RECEPTORS.** D.M. Taylor, A.C. Bragdon and W.A. Wilson. Depts. of Pharmacology and Medicine (Neurology), Duke University and VA Medical Centers, Durham, NC 27705.

Norepinephrine (NE) influences the development of epilepsy in a variety of experimental models. STIB is an in vitro model of epileptogenesis in which repeated delivery of stimulus trains (STs) leads to the progressive development of spontaneous population bursting in area CA3 of hippocampal slices (Stasheff et al., Brain Res. 344: 296-302, 1985). We previously showed that NE retards epiletogenesis in the STIB model, and presented evidence that this effect is mediated by alpha receptors (Soc. Neurosci. Abstr. 12: 80, 1986). In the presence of 1 uM timolol (TIM) to block beta receptors, 10 uM NE maximally increased the number of STs to spontaneous bursting from a mean of 4.4 to 7.6. This effect was completely blocked by the alpha receptor antagonist phentolamine (100 uM). We now present additional evidence that this anti-epileptogenic effect of NE is alpha-mediated, probably through alpha$_1$ receptors.

Slices prepared from temporal hippocampus were studied in ACSF containing (mM): KCl 3.3, $CaCl_2$ 1.8, $MgSO_4$ 1.2, NaCl 120, $NaHCO_3$ 25, NaH_2PO_4 1.23, and dextrose 10. Slices were stimulated in s. radiatum of CA3a, and extracellular fields were recorded in s. pyramidale of CA3b. Slices producing stable, healthy evoked potentials for at least 15 min were randomly assigned to control or treatment group, after which control or drug-containing ACSF was applied for the remainder of the experiment. After an additional 15 min equilibration period, STs (60 Hz for 2 sec) were applied every 10 min, and the number of stimulus trains needed to elicit spontaneous bursting (#STs to SB) were counted.

As before, NE (10 uM) plus TIM (1 uM) more than doubled the mean #STs to SB from 3.4 to 6.9. This effect was completely blocked by the alpha receptor antagonist phenoxybenzamine (10 uM), and partially blocked by the selective alpha$_1$ antagonist prazosin (1 uM), but was unaffected or even enhanced by the selective alpha$_2$ antagonists idazoxan (10 uM) and yohimbine (1 uM).

These results confirm that NE has antiepileptogenic effects mediated by alpha receptors. Additionally, they show that this effect is not mediated through alpha$_2$ receptors, and suggest it may be mediated through alpha$_1$ receptors.

317.5 INITIATION AND SPREAD OF SYNCHRONIZED NEURONAL ACTIVITY IN NEOCORTEX DURING PARTIAL BLOCKADE OF SYNAPTIC INHIBITION. Y. Chagnac-Amitai* and B.W. Connors. Dept. of Neurology, Stanford Univ. Sch. of Medicine, Stanford, CA 94305.

When synaptic inhibition is strongly suppressed with high doses of the GABA$_A$ receptor antagonist bicuculline methiodide (BMI; $\geq$ 10 μM), slices of neocortex in vitro generate synchronized discharges that resemble the interictal spikes of epilepsy. These discharges have fixed (all-or-none) amplitudes and durations (hundreds of msecs), widely varying latencies to a threshold stimulus, and they spread horizontally without decrement (Connors, Nature, 310:685, 1984). We now report that much lower doses of BMI (i.e. partial suppression of inhibitory synapses) generate very different epileptiform activities.

Coronal slices of rat SI were maintained in vitro, field potentials were recorded simultaneously through 4 separate microelectrodes arrayed horizontally in layer 2/3, monopolar stimuli were delivered to layer 6, and the dose of BMI in the bath was slowly increased from zero to between 0.1 and 1.0 μM.

In control solution, stimuli evoked activity only in a narrow, vertically oriented column above the stimulating electrode. BMI doses between 0.1 and 0.6 μM caused the primary evoked response to spread farther in the horizontal directions, often asymmetrically. The threshold dose for evoked epileptiform activity was in the range of 0.4 to 1.0 μM. Spontaneous field potentials were not observed. These low-dose epileptiform events had clear stimulus thresholds, variable amplitudes, and widely shifting latencies (as long as 500 msec) and durations (10 to hundreds of msecs). Unlike the high-dose BMI state, low-dose epileptiform events were not necessarily initiated within the column above the stimulus, but arose from preferred sites as far as 4 mm away horizontally. These sites were usually within the medial aspect of SI. Horizontal propagation of epileptiform events was slow (about 15-65 mm/sec) and often partial; the distance that events spread could vary from trial-to-trial. Unlike high-dose events, propagating low-dose events were sometimes reflected, e.g. an event propagating from medial-to-lateral would, at a particular point, initiate both retrograde and anterograde events.

Low-dose epileptiform events are distinguished by their preferred sites of initiation, their variable durations and by their partial and reflecting propagation. The former imply spatial non-uniformities of either intrinsic neuronal properties or local circuitry. The data also suggest that the horizontal spread of cortical activity is constrained by GABA$_A$-mediated synaptic inhibition. We hypothesize that horizontally directed inhibitory circuits can strongly modify the movements of epileptiform events.

317.6 STIMULATION-INDUCED STATUS EPILEPTICUS: ROLE OF THE HIPPOCAMPAL MOSSY FIBER PROJECTION. J.P. Vicedomini and J.V. Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Status epilepticus (SE) involves prolonged activation of limbic and related neocortical circuitry and ultimately leads to the degeneration of CNS neurons. We have used two different animal models to study SE: (1) repetitive electrical stimulation of specific hippocampal afferent pathways and (2) intracerebroventricular (i.c.v.) administration of convulsants, such as kainic acid (KA). Previous studies of the KA model suggested that an intact mossy fiber projection is essential for seizure-induced CA3 pyramidal cell death, but not necessarily for the induction of SE. We have now explored this issue further by use of the electrical stimulation model of SE.

Adult male rats were chronically implanted with a recording electrode in the hippocampal CA3 area and a stimulating electrode in the contralateral fimbria. Prior to electrode implantation, either the mossy fiber pathway of the rostral hippocampus was transected or dentate granule cells were destroyed with colchicine on the side of the brain ipsilateral to the recording electrode. After an appropriate postoperative recovery interval, subjects were electrically stimulated according to a protocol which consistently evokes prolonged SE (Vicedomini and Nadler, Exp. Neurol., in press). The electrographic, behavioral and neuropathological consequences of the electrical stimulation were determined.

Fimbrial stimulation eventually elicited at least 1 h of SE in all animals which had been subjected to a mossy fiber transection or in controls which had received no prior lesion. In contrast, none of the colchicine-treated animals developed SE, despite receiving nearly twice the number of stimulus trains delivered to the other subjects and despite having experienced as much as 145 min of afterdischarge. Although the CA3 area and other brain regions suffered extensive neuronal degeneration in subjects with a MF transection and in controls, no such degenerative changes were observed in colchicine-treated subjects. Finally, both MF-transected and colchicine-treated subjects exhibited far fewer and less severe limbic motor seizures than did control rats. These results (1) suggest that at least some mossy fibers must be intact for fimbrial stimulation to evoke SE; (2) support our previous conclusion that afferent pathway stimulation destroys CNS neurons only if it evokes a prolonged period of self-sustained seizure activity and (3) suggest that generalization of the seizure to motor centers requires a substantially intact mossy fiber pathway. The present findings may be reconciled with the somewhat different effects of mossy fiber lesions in the KA model by postulating that a specific interaction between the convulsant and the mossy fiber pathway augments the toxic effect of seizures on CA3 pyramidal cells. (Supported by NIH grant NS 17771.)

317.7 EPILEPTIFORM BURSTING DISPLAYED BY HIPPOCAMPAL NEURONES IN ORGANOTYPIC MONOLAYER CULTURE. C.J.McBain*, P.Boden* and R.G. Hill. Parke-Davis Research Unit, Addenbrookes Hospital Site, Cambridge CB2 2QB, United Kingdom.

The hippocampus in vitro has been shown to be a useful model for the study of epileptiform activity. Many previous investigations have relied however, on pharmacological manipulations to induce epileptiform activity. We show here that explants of neonate hippocampus in long term tissue culture display both spontaneous and evoked seizure-like discharges and paroxysmal depolarising shifts (PDS).

Organotypic monolayer cultures of hippocampal slices from 6-day neonate Wistar rats were prepared and maintained for periods of up to 80 days as described previously (Gahwiler 1981). Conventional intracellular recordings were made from the s. pyramidale of CA1 using K-acetate electrodes (3M, d.c. resistances 80-200MΩ). Cells were considered in two groups, (a) 1-12 days in vitro (DIV) and (b) 12 DIV onwards. Comparable resting membrane potentials were obtained between group (a) and group (b); 60.0±1.4mV (n=10), 61.0±1.4mV (n=11) respectively. The apparent input resistances of cells in group (b), 79±11MΩ (n=11), were twice those observed in group (a), 39±4 MΩ (n=10), which may be indicative of a decrease in membrane conductance. 7 out of 10 cells from group (a) displayed spontaneous and evoked activity comparable to that seen in conventional hippocampal slices prepared from 6 and 21 day old rats. These cells fired action potentials which overshot zero potential followed by either afterhyperpolarisations (AHP) or depolarising after potentials (DAP). Spontaneous and evoked EPSPs and IPSPs could be recorded from these cells. 8 out of 11 cells in group (b) and 3 cells in group (a) however displayed spontaneous or evoked epileptiform discharges. Seizure activity typically commenced with a large paroxysmal depolarising shift (PDS) of 40-50mV resulting in 20-50 action potentials which overshot zero potential. Each PDS had a duration of 1.0-1.5 seconds and occurred at a frequency of 0.08Hz. The PDS activity appeared to be associated with a loss of AHPs and GABA-mediated IPSPs, although cells showed no change in their post-synaptic sensitivity to GABA (100μM). Epileptiform activity was markedly attenuated by the NMDA antagonist D-APV (30μM), Agents which block synaptic transmission (Mg^{2+} (20mM) and tetrodotoxin (1μM)) abolished all epileptiform activity indicating that functional synapses are responsible for these events.

These results suggest that long-term culturing of hippocampal explants may lead to a loss of GABAergic inhibition, allowing the expression of an NMDA receptor mediated depolarisation which may contribute to the generation and maintenance of epileptiform activity. Gahwiler B.H. J.Neuroscience. Methods 4,329-342. (1981)

317.8 **THREE DIMENSIONAL TIME VARYING COMPUTER SIMULATION OF EPILEPTIFORM BURST GENERATION IN THE CA3 HIPPOCAMPAL SUBFIELD.** **E.J. Smith*, D.K. Terry* and J.W. Swann (SPON: R.A. Waniewski). Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, New York 12201**

The epileptiform burst generated in rat hippocampal CA3 region was simulated by a time varying, three dimensional spatial graphics display on a digital computer. The experimental data used to generate the model were obtained from laminar field potentials analysed from rat hippocampal slices exposed to penicillin. The methods used to obtain these data have been reported previously (J. Neurophysiol. 56:1718-1738, 1986). Recordings were made at 25 μm intervals across the CA3 subfield on an imaginary line orthogonal to the pyramidal cell body layer. At each position recordings were obtained from a linear triple microelectrode array. These electrodes were spaced 100 μm apart. The center electrode of the array recorded the field potential while current source density at that location was computed electronically using the recordings from all 3 electrodes. The signals were collected on-line and stored in computer memory. From these data the amplitude of the signals across the CA3 laminae could be obtained for any given point in time. To date we have analysed data collected at 10 msec intervals before, during and after burst generation. Each of these laminar profiles were fit by a seventh order polynominal to yield a smooth function. These functions were plotted in elliptical coordinates which simulated the anatomy of the CA3 subfield. It was assumed that equipotential lines were elliptical in shape with an eccentricity of 0.66. At the present time the animated model consists of twenty sequential frames spaced at 10 millisecond intervals for both potential and CSD. The model provides a clear insight into the spatial distribution of the potential and CSD in the hippocampus and sharply defines the temporal evolution of current sources and sinks during epileptiform burst generation.

(Supported by NIH Grant NS18309 to J.W.S.).

317.9 **LOCALIZED SYNAPTIC INTERACTIONS MEDIATE THE SUSTAINED DEPOLARIZATION OF SEIZURE-LIKE DISCHARGES IN IMMATURE HIPPOCAMPUS.** **J.W. Swann, K.L. Smith* and R.J. Brady. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, New York 12201**

Experiments were performed on isolated segments of the CA3 subfield of 10-15 day old rat hippocampus. Prolonged (5-10 sec) seizure-like discharges were produced by bath application of penicillin. Like in intact slices CA3 pyramidal neurons underwent an intense sustained depolarization during the course of the synchronized afterdischarges. Simultaneously, a slow negative field potential was recorded in the CA3 basilar dendritic layer. We tested the hypothesis that these coincident slow events were produced by local circuit excitatory synapses on pyramidal cell basilar dendrites. To this end we locally applied microdroplets of kynurenic acid (0.5 - 1.0 mM) or MK 801 (50 - 100 μm) to the minislices.

When droplets of either drug were applied to a single site in the basilar dendritic layer of small minislices (500-700 μM along the cell body layer) afterdischarge generation ceased. Most often the PDS was unaltered. Drug application to the apical dendritic layer did not alter the duration of the seizure-like discharges. In larger minislices application of either drug to a single site in the basilar dendritic layer did not block afterdischarges. However, recordings from this site revealed the slow negative field potential to be suppressed and the sustained depolarization to be abolished. Indeed at these sites the synchronized afterdischarges recorded intracellularly now arose either from a resting or hyperpolarized membrane potential. Simultaneous extracellular recordings in the basilar dendritic layer remote from the site of drug application revealed the presence of a large slow negative field potential. We reasoned that at this time the seizure discharges were likely to be generated at such remote sites where excitatory synaptic transmission had been unaltered. In keeping with this scenario, the cells exposed to the drug now had become 'followers' of the distant population, which was being driven to afterdischarge by the tonic depolarization generated in their basilar dendrities. In support of this contention when we applied the drug to the remote site as well, seizure discharges ceased throughout the minislice. These results lead us to suggest: 1) that the sustained depolarization recorded during seizure-like discharges is a separate physiologic process from those of the synchronized discharges, 2) that the depolarization is the product of summated excitatory amino acid mediated synaptic events on basilar dendrites, and 3) that these synaptic potentials play a central role in seizure generation in immature hippocampus.

317.10 EXTRACELLULAR CALCIUM MODULATES THE FREQUENCY OF ICTAL-LIKE DISCHARGES IN PENICILLIN-TREATED IMMATURE HIPPOCAMPAL SLICES. R.J. Brady, K.L. Smith* and J.W. Swann, Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, New York 12201.

Penicillin-treated hippocampal slices taken from immature rats 9-19 days of age exhibit the capacity to produce prolonged ictal-like discharges. Simultaneous extracellular and intracellular recordings in the CA3 region show that these ictal-like events consist of a field epileptiform burst paired with a depolarization shift (DS) followed by a self-sustaining series of afterdischarges. This series can vary from no afterdischarges being present to a prolonged series of up to 30 sec in duration, producing an ictal-like event.

The amount of epileptiform activity in a given penicillin-treated hippocampal slice can be quantified by measuring the percent epileptiform discharge (PED). The amount of time epileptiform activity appears is accumulated and expressed as a percentage of the total collection epoch. In a penicillin treated (1.7 mM) hippocampal slice taken from a twelve day old animal the PED was 5%.

It has been shown that during ictal activity the levels of extracellular calcium decrease. Given the effects on changes in extracellular calcium on cellular excitability and reported effects of divalent cations on excitatory amino acid responses, we tested the effects of changes in extracellular calcium on the pattern of spontaneous afterdischarge generation in penicillin-treated immature hippocampal slices. We have found that decreasing calcium in the bathing media to 1 mM dramatically increased the number of afterdischarges seen during spontaneous epileptiform activity. The PED increased from a control value of 5% to, in 1 mM extracellular calcium, a value of 18.6% Each epileptiform event was an ictal-like discharge with a prolonged series of afterdischarges. Raising the level of calcium in the bathing media to 3.5 mM blocked afterdischarges leaving only the DS and associated field epileptiform burst. The PED decreased to 0.6%.

The mechanisms that underly the effects of a change in extracellular calcium on afterdischarge generation are under investigation. We have not been able to demonstrate a direct effect of calcium changes on CA3 pyramidal cell excitability. Decreasing calcium has been seen to increase the response of CA3 pyramidal cells to iontophoretically applied N-methyl-D-aspartate. However, this effect has not been observed in every cell studied. Increasing calcium has been observed to decrease the N-methyl-D-aspartate response.

317.11 PROLONGED SEIZURE-LIKE DISCHARGES IN IMMATURE HIPPOCAMPAL MINISLICES CAN BE INITIATED BY SINGLE NEURONS. K.L. Smith* and J.W. Swann (SPON: M. Pierson). Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, New York 12201

Miles and Wong (Nature 306:371:1983) have previously demonstrated that interictal epileptiform discharges can be triggered by action potential in single CA3 pyramidal cells in small isolated segments of mature hippocampus. In our laboratory, we have been studying mechanisms underlying penicillin-induced ictal-like discharges in immature hippocampus and wondered whether single CA3 neurons could initiate these prolonged seizure-like events.

Experiments were performed in minislices isolated from the CA3 subfield of 10-15 day old rat hippocampus. In a first series of experiments we attempted to determine the minimal neuronal population size that could support seizure-like discharges. We found that minislices bathed in penicillin and measured 500-700 μm along the pyramidal cell body layer routinely generated ictal-like discharges that were 5-10 sec in duration. These events occurred spontaneously or could be evoked by a single orthodromic stimulus.

Simultaneous intracellular and extracellular recordings from these isolated hippocampal segments showed that the seizure-like discharges were structurally very similar if not identical to those that occur in intact slices. When depolarizing current was applied to single pyramidal cells we found that 58% (22/38) were capable of initiating epileptiform discharges. Following each ictal-like discharge there was a prolonged period of refractoriness during which action potentials in any single pyramidal cells were unable to entrain the population. Suddenly bursts of spikes, which had previously been ineffective, could initiate a synchronous population discharge of up to 10 sec in duration. Interestingly we also found that 40% (4/10) of fast repetitively spiking neurons were also able to initiate the population discharge. We assume these cells are non-pyramidal type neurons.

Paired intracellular recordings (n=10) were made in order to study variations in synaptic interactions between neurons during the cycling in the effectiveness of individual neurons to entrain the neuronal population. Monosynaptic interactions were not observed between pairs of cells. Generally during the period of refractoriness spikes in a presynaptic neurons did not produce an observable response in the other cell of the pair. However, in most pairs a presynaptic train of action potentials resulted repeatedly in a depolarizing potential which immediately preceded depolarization shift generation and the coincident discharge of the population. (Supported by NIH Grant NSI8309.)

317.12 ANTICONVULSANT EFFECTS OF DEXTROMETHORPHAN IN A KINDLING MODEL OF EPILEPSY. H.R. Feeser, J.L. Kadis*, B.Y. Wong*, and D.A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Dextromethorphan (DM), a non-prescription antitussive, has anticonvulsant properties in both in vivo and in vitro seizure models. Work in our lab has demonstrated that both DM and its metabolite dextrorphan (DX) block prolonged ictal afterdischarges and interictal spiking in neocortical slices perfused with low-magnesium artificial cerebrospinal fluid and that the effect of these drugs may be a result of their NMDA-antagonistic properties. DM has also been shown to be effective in blocking maximal electroshock seizures in rats (Tortella and Musacchio, Brain Research 383 (1986) 314-318). We now report the effects of DM on electrical kindling of the amygdala.

Bipolar electrodes were stereotaxically implanted into the left amygdala of male Sprague-Dawley rats. The animals were allowed to recover for one week, then stimulated five times weekly with one-second trains of 60 Hz, 250 μamp square wave pulses. Thirty to forty minutes prior to stimulation, treated animals received i.p. injections of 35 mg/kg DM, while control animals were injected with saline. Length of afterdischarge and seizure intensity following simulation were recorded for all animals. Once fully-kindled, control rats were treated with 35 mg/kg DM prior to stimulation, and the duration and intensity of their seizures following drug treatment were compared to those following saline treatment.

Results to date indicate that DM produces a statistically significant shortening of seizures both in animals treated with DM throughout the course of kindling and in fully-kindled control animals treated acutely with DM. More trials may be required to fully kindle DM-treated rats, but data are not yet sufficient to demonstrate statistical significance. A mild hind-limb ataxia was the only adverse reaction noted in DM-treated animals. These results, combined with the findings that DM and DX antagonize NMDA, suggest that DM may be a clinically useful member of a new class of anticonvulsants.

317.13 EFFECT OF CA AND OTHER ION CHANNEL BLOCKING AGENTS ON THE HIGH AFFINITY BINDING OF DEXTROMETHORPHAN TO GUINEA PIG BRAIN. M. Klein* L.J. Santiago* and J.M. Musacchio. Dept. Pharmacology, N.Y.U. Medical Center, New York, NY 10016.

Dextromethorphan (DM), a dextrorotatory non-narcotic centrally-acting antitussive, binds in the CNS (Craviso and Musacchio, Mol. Pharmacol., 23:629, 1983) to high (Kd 53 nM) and low (Kd 20 μM) affinity sites. The high affinity binding is allosterically modulated by the anticonvulsant phenytoin (PHT). DM, carbetapentane and caramiphen, antitussives which displace [^{3}H]DM with high affinity, protect rats against maximal electroshock seizures (Tortella and Musacchio, Brain Res. 383:629, 1986; Fed. Proc. 46:708, 1987).

To explore the nature of the DM binding sites we tested the effect of several ion channel blockers on the binding of [^{3}H]DM. Prenylamine, cinnarizine and hydroxyzine were very potent competitors with higher affinity for the DM binding sites than [^{3}H]DM itself, with Ki values of 17 nM, 22 nM and 46 nM respectively. Cinnarizine and flunarizine, which have been shown to have anticonvulsant activity, have Ki values of 22 nM and 150 nM respectively. The diphenylalkylamines tested showed a higher affinity for [^{3}H]DM binding sites than for [^{3}H]desmethoxyverapamil sites. By contrast, phenylalkylamines inhibited the binding of [^{3}H]DM in the low micromolar to high nanomolar range. Nifedipine, a dihydropyridine, and diltiazem, a benzothiazepine, were much less potent. These findings suggested that DM sites probably are not related to either dihydropyridine or diltiazem sites.

The Na channel agents tested were very weak competitors for [^{3}H]DM binding sites. Tetrodotoxin showed no effect at concentrations as high as 10 μM. Veratridine and aconitine inhibited slightly at a concentration as high as 300 μM. These results suggest that DM binding sites probably are not associated with Na channels.

Among the K channel blocking agents tested, 4-aminopyridine and tetraethylammonium both inhibited the binding of [^{3}H]DM in their pharmacological range, with Ki values of 0.75 and 1.35 mM respectively. All of the antimalarial K channel blockers tested inhibited [^{3}H]DM binding in the micromolar range. Quinidine was the best competitor for [^{3}H]DM binding sites, with a Ki value of 0.57 μM. The Ki values of other agents were the following (μM): quinine: 9.0; primaquine: 7.3; chloroquine: 1.2; quinacrine: 1.9. Atracurium exhibited a Ki value of 1.9 μM. Pancuronium showed no effect at a concentration as high as 35 μM. These results suggest a possible association of DM binding sites with K channels. Supported in part by the Epilepsy Foundation of America and UPHS grants DA-02013, MH-29591 and MH-17785.

317.14 EFFECT OF ANTICONVULSANT DRUGS AND OTHER AGENTS ON THE HIGH AFFINITY BINDING OF DEXTROMETHORPHAN TO GUINEA PIG BRAIN. L.J. Santiago* M. Klein* and J.M. Musacchio (SPON: R.U. Margolis). Dept. of Pharmacol., N.Y.U. Medical Center, New York, NY 10016.

Dextromethorphan (DM), a dextrorotatory non-narcotic centrally-acting antitussive, binds in the CNS (Craviso and Musacchio, Mol. Pharmacol., 23:629, 1983) to high (Kd 53 nM) and low (Kd 20 μM) affinity sites. The anticonvulsant phenytoin (PHT) is an allosteric enhancer of the binding of [^{3}H]DM. DM, carbetapentane and caramiphen, antitussives which displace [^{3}H]DM with high affinity, also protect rats against maximal electroshock seizures (Tortella and Musacchio, Brain Res. 383:629, 1986; Fed. Proc. 46:708, 1987).

To investigate the interactions between PHT, the DM sites and the anticonvulsant activity of these drugs, we tested the effects of several anticonvulsant drugs on the binding of [^{3}H]DM. SC-13504, an anticonvulsant benzhydryl piperazine, produced a marked increase in the binding of [^{3}H]DM, similar to that previously reported for PHT. SC-13504 produced a 62 and a 200% increase in the binding of [^{3}H]DM at 1 and 10 μM respectively. These effects are due to a two fold increase in affinity without a change in Bmax.

Nafimidone has a Ki of 1 μM, which is compatible with the anticonvulsant ED_{50} in rats (7.2 μmoles/Kg, Walker et al., J. Med. Chem 24:67, 1981). Two other anticonvulsants, hibital and AHR 11748, decreased the binding of [^{3}H]DM 26 % at a concentration of 100 μM. The brain level of AHR 11748 measured at the anticonvulsant ED_{50} is 200 μM in mice, indicating that the anticonvulsant effects of these drugs could be mediated through the DM sites.

Felbamate and zonisamide had no effect at a concentration of 100 μM, and fluzinamide displaced only 10 % of the DM bound at a concentration as high as 1 mM. Ethosuximide, methsuximide, phensuximide and phenacemide had no effect on [^{3}H]DM binding at 100 μM, either. Analogs of PHT, such as mephenytoin, ethotoin and paramethadione were tested up to a concentration of 100 μM, and did not increase the binding of [^{3}H]DM. Competition studies carried out with the inhibitory amino acids GABA and glycine, with taurine, cysteine, aspartate, glutamate as well as kainate, NMDA and 2-amino 5-phosphonovaleric acid showed no effect on [^{3}H]DM binding, indicating that there is no apparent relationship between the site of action of these agents and the DM binding sites.

These findings suggest that the DM binding sites are involved in the mediation of the anticonvulsant activity of several drugs. The study of these sites may help to elucidate the mechanism of action of some anticonvulsant agents, and to discover new ones. Supported in part by the Epilepsy Foundation of America and UPHS grants DA-02013, MH-29591 and MH-17785.

317.15 A NEW ANTICONVULSANT, PR 934-423, ACTIVE AGAINST MAXIMAL ELECTROSHOCK SEIZURES I: MICE STUDIES. G.C. Palmer, R.C. Griffith*, M.J. Ordy, C.W. Becker*, J.M. Frankenheim* and M.L. Stagnitto*. Pharmaceutical Division, Pennwalt Corporation, Rochester, NY 14623

A major problem in treatment of epilepsy is the lack of structurally different, but highly effective anticonvulsants when the primary agent fails because of toxicity or refractoriness to the disease. The present compound (+)-2-amino-N-(1-methyl-1, 2-diphenylethyl) acetamide-HCl or PR 934-423A was developed from computer modeling experiments which demonstrated a potential three dimensional correlation with the pharmacophore pattern of known anticonvulsants. Initial pharmacological screening indicated that PR 934-423A did not produce prominent CNS side effects in mice until large oral doses were administered. PR 934-423A did not possess sedative properties and was found to be orally effective in protecting mice from MES (maximal electroshock seizures). An oral ED50 dose for MES protection was established at 33 mg/kg while an ED50 for neural impairment (failure of mice to climb an inverted screen) was 580 mg/kg. Thus a therapeutic ratio of 17.6 was determined which was less than corresponding ratios for the reference agent phenytoin, but greater than phenobarbital and carbamazepine. Of other compounds synthesized in the chemical series, PR 934-423A possessed a superior efficacy/safety ratio and was thus selected for further pharmacological profiling.

PR 934-423A was essentially ineffective orally against chemically-induced seizures elicited by: pentylenetetrazole (ED50 = 328 mg/kg), picrotoxin (ED50 = 417 mg/kg), bicuculline and strychnine (ED50s > 600 mg/kg).

The margin of safety for orally administered PR 934-423A in mice was 28.1 (lethal dose 50 of 926 mg/kg/ED50 of 33 mg/kg for MES protection). The margin of safety value was less than phenytoin but greater than phenobarbital. The margin of safety after intravenous administration was considerably narrower for PR 934-423A = 3.8 (LD50 of 56 mg/kg/ED50 of 14.7 mg/kg) when compared to phenobarbital.

The duration of action for oral protection of mice against MES was, however, longer than that for carbamazepine, but shorter than phenytoin and phenobarbital. The duration of action for PR 934-423A was, however, lengthened by increasing the dose (≈3 hour at 60 mg/kg and > 6 hour at 120 mg/kg). Both PR 934-423A, as well as the reference compounds had rapid onsets of action (45 minutes or less).

Tolerance to protection of mice against MES did not develop following oral administration for 5 days of either the ED50 or ED99 doses of PR 934-423A, phenytoin and phenobarbital.

Therefore it appears that PR 934-423A is a relatively safe and potent antiseizure drug that might be targeted for clinical effectiveness for treatment of generalized tonic/clonic seizures.

(Appreciation is expressed to R.H. Harvey, M.A. Knowles, L.A. Steiner, S. Phippen for technical assistance).

317.16 A NEW ANTICONVULSANT, PR 934-423, ACTIVE AGAINST MAXIMAL ELECTROSHOCK SEIZURES II: RAT STUDIES. P.M. Colombo*, G.C. Palmer, R.C. Griffith*, G.E. Garske*, C.W. Becker*, M.J. Ordy, J.C. Blosser, M.L. Coan*, and S.A. McCreedy*, (Spon: C.N. Latimer) Pharmaceutical Division, Pennwalt Corporation, Rochester, NY 14623

PR 934-423A or (+)-2-amino-N-(1-methyl-1,2-diphenylethyl) acetamide-HCl was found to be an effective oral anticonvulsant for protection of mice against seizures elicited by maximal electroshock (MES). PR 934-423A was selected for further pharmacological development in the rat. The oral ED50 for protection of male and female rats against MES was 19.8 mg/kg. In neural impairment tests (modified gang plank walking) the oral ED50 was 690 mg/kg. A therapeutic index of 34 was obtained which was superior to the reference agent, phenobarbital. The oral LD50 for PR 934-423A was 940 mg/kg yeilding a margin of safety (LD50/ED50 for MES protection) of 46, a value higher than phenobarbital. However, after iv administration the margin of safety became narrower (7.2) a value less than for phenobarbital.

The duration of action of oral PR 934-423A was determined. At the ED97 dose for MES, the time to peak action was 30 mins and 80% protection was sustained for 6 hrs. Following iv or lower dose oral administration, the plasma half life of PR 934-423A was relatively short (iv 10 mg/kg = t 1/2 of 0.36 hr with a clearance rate of 6.5 l/kg/hr and at total volume of distribution of 2.8 l/kg). At 80 mg/kg (po), drug concentrations in plasma peaked at 30 mins and the t 1/2 was 3.4 hrs. The total amount of drug absorbed was approximately 10%. This rapid metabolism and low rate of absorption most likely accounted for the short duration of action at low doses. When compared to phenytoin, 7 days oral administration of PR 934-423A at the ED97 dose did not shorten hexobarbital-induced sleep time. However, after acute administration PR 934-423A lengthened hexobarbital sleep time, despite its lack of sedative effects when given alone at high doses. The acute response probably represents competition with hexobarbital for metabolic degradation in the liver.

In mechanistic studies, PR 934-423A was evaluated for neurotransmitter receptor affinity in particulate fractions of rat brain. PR 934-423A was ineffective in preventing convulsions elicited by pentylenetetrazol.

Therefore, PR 934-423A appears to be an effective anticonvulsant against seizure spread and would be predicted to be useful in patients with generalized tonic/clonic seizures.

(Appreciation is expressed to L.R. Freedman, M.A. Barrantes, E. F. Cregan, and T.M. Wengenack for technical assistance).

317.17 A NEW ANTICONVULSANT, PR 934-423, ACTIVE AGAINST MAXIMAL ELECTROSHOCK SEIZURES. III: ELECTROPHYSIOLOGICAL STUDIES. L.R. Freedman*, R.C. Griffith and E.W. Harris. Pharmacology Dept., Pharmaceutical Div., Pennwalt Corporation, 755 Jefferson Road., Rochester, NY 14623

There is a great need for anticonvulsants in new structural classes and possessing new mechanisms of action. The compound (+)-2-amino- N-(1-methyl-1,2- diphenylethyl) acetamide. HCl (PR 934-423A) appears to be such a drug. PR 934-423A is effective against MES in mice and rats, with a larger therapeutic index than phenobarbital, carbamazepine or valproate (see Griffith, Palmer, Ordy, Becker and Stagnitto; this session). Computer modelling indicated structural similarities with phenytoin, and like phenytoin it is more effective against MES than chemically-induced seizures. The mechanism of action of PR 934-423A has been investigated using the in vitro hippocampal slice preparation.

Hippocampal slices were prepared from young adult male Sprague-Dawley rats using standard procedures. Slices were submerged in constantly refreshed medium in which compounds were dissolved to yield known final concentrations. Phenytoin (Sodium diphenylhydantoin) was first dissolved in 40% PEG/10% ethanol at 1000 times the desired final concentration. Extracellular synaptic responses were recorded using a 1M NaCl filled glass micropipette placed in CA1. Constant current electrical stimuli were delivered to stratum radiatum near CA2 to activate Schaffer collaterals.

Phenobarbital (up to 300 μM), phenytoin (up to 40 μM) and PR 934-423A (up to 150 μM) were compared in terms of effects on Schaffer evoked population spikes, paired-pulse potentiation of the population spike (25 m sec ISI), and the induction of long term potentiation of the population spike by high frequency stimulation (100 Hz, 100 pulses, 3 times). Recordings were made from stratum radiatum in CA1. Only phenobarbital significantly reduced paired-pulse potentiation and inhibited the induction of long-term potentiation.

In a second series of experiments, spontaneous epileptiform activity was elicited from hippocampal slices using high-potassium/penicillin-G). Phenytoin and phenobarbital both reversibly slowed spontaneous burst firing rate at concentrations at or just above clinically relevant concentrations (10 and 100 μM respectively). In contrast, PR 934-423A up to 100 μM (at least 20 times its estimated effective free levels in plasma) had no apparent effect on spontaneous firing rate.

These data confirm that PR 934-423A acts differently from phenobarbital on CNS tissue, and, insofar as effects in the penicillin-treated slice model reveal, this study also suggests that PR 934-423A acts differently from phenytoin to reduce seizure activity.

317.18 BLOCKADE OF AUDIOGENIC SEIZURES (AGS) IN GENETICALLY EPILEPSY-PRONE RATS (GEPR) BY THE MICROINJECTION INTO INFERIOR COLLICULUS (IC) OF BLOCKERS OF INHIBITORY AND EXCITANT AMINO ACID (EAA) METABOLISM. C.L. Faingold, C.A. Copley*, C.A. Boersma*, So. Illinois Univ. Sch. of Med., Dept. Pharmacology, Springfield, IL 62708

The neural basis for susceptibility of the GEPR to AGS is of considerable interest. The IC has been shown to be the most sensitive of 8 subcortical nuclei tested for induction or blockade of AGS (see Faingold et al., 1987). GABA may mediate sound-induced (binaural) inhibition in the IC. Greater than normal GAD-immunoreactivity is reported in the GEPR IC, and reduced effectiveness of binaural inhibition and of iontophoretically applied GABA is also observed. An EAA may be an excitatory neurotransmitter in IC, and increased release of EAA is also observed in GEPR IC during AGS. Microinjection of an EAA agonist, or a $GABA_A$ antagonist into the IC induces susceptibility to AGS in normal rats (Millan et al., 1986). An EAA receptor antagonist, and GABA agonists are effective anticonvulsants when injected into the IC of the GEPR. However, agents which affect GABA and EAA receptors could exert effects on neurons that are not modulated primarily by these amino acids under normal conditions, as suggested with EAAs in other brain sites.

The present study examined the effects on AGS susceptibility of agents which alter the amino acid metabolism but are not thought to act directly on receptors. GEPRs displaying maximal seizure severity (GEPR-9s) were chronically implanted with guide tubes above IC and tested for AGS sensitivity one week later. Bilateral microinjections (0.5-1.0 μl) of gabaculine (10-100 μg/side) or L-canaline (25-50 μg) were infused into IC. L-Canaline is reported to block the synthesis of EAAs, and gabaculine is reported to block the catabolism of GABA. AGS scores (to a bell at 122 dB SPL) were evaluated according to the scale of Jobe (1981). Seizures were completely blocked (median seizure score = 0) in most animals by 2 hr after gabaculine infusions (N=8, to date), and the animals rarely recovered susceptibility. Ataxia and loss of righting reflex were observed in most animals. Two hours after L-canaline infusions all tonic seizure components were abolished (median score = 2, N=12, to date), and recovery was rarely observed even up to a week later. Thus, inhibition of EAA synthesis by L-canaline produces a sustained block of AGS. This finding along with the previous reports of altered function of EAAs, cited above, strongly support a role for increased EAA action in the IC in initiation of AGS. Inhibition of GABA catabolism by gabaculine irreversibly blocks AGS. This finding along with previous reports on altered GABAergic function, cited above, also strongly support a role of reduced GABAergic function in the IC in initiation of AGS in the GEPR. This apparent imbalance in inhibitory and excitatory influences in the IC may be an important factor in initiation of AGS in the GEPR.

(Supported by NIH NS 21281.)

318.1 STUDIES OF PROPAGATING EPILEPTIC EVENTS IN THE LONGITUDINAL HIPPOCAMPAL SLICE. R.D. Traub, R. Miles and R.K.S. Wong. IBM T.J. Watson Res. Ctr., Yorktown Heights NY 10598 and Dept. of Neurology, Columbia Univ., New York, NY 10032.

Factors which control the spread of epileptic activity are not clear. Do synchronous events propagate at the speed of axonal conduction? If not, what other factors are involved? We examined this question with experimental and simulation techniques.

In experimental studies, longitudinal slices were cut from the CA3 region of guinea pig hippocampus. They were up to 8 mm long, providing good spatial resolution of propagating events. Intra- and extracellular responses to electrical stimulation at one end of these slices did not spread more than 2-3 mm from the stimulus site while synaptic inhibition was functional. Responses propagated at 0.4-0.6 m/s. In contrast, when inhibition was blocked with picrotoxin (PTX), the same stimulus elicited a locally synchronized event which propagated the entire length of the slice. The speed of propagation was 0.1-0.25 m/s.

Thus, propagation of synchronous events does not simply depend on axonal conduction delay in this preparation. Other possible contributing factors include neuronal threshold, the strength of excitatory synapses and their spatial distribution. Effects of varying these parameters were examined using a model constructed with 9000 pyramidal cells (in a 40×225 array, representing a slice 4.5 mm long) and 900 inhibitory cells (450 producing fast, PTX-sensitive inhibition; 450 producing slow, PTX-resistant inhibition). The probability of an excitatory synapse between 2 pyramidal cells was assumed to decay exponentially with intercellular distance (space constant λ_r) and axon conduction delays were included (Traub, Knowles, Miles and Wong, *Neuroscience*, in press). With λ_r = 600 μ, and fast inhibition blocked, stimulation of a cell at one end of the array led to a local synchronized burst which propagated at 0.14 m/s, agreeing with experiment. When λ_r was smaller, propagation was slowed, and as it increased propagation became first faster and then ill-defined, with synchronized activity occurring everywhere at once. In the latter case, a small, spatially diffuse subpopulation was first excited, which in turn stimulated the entire population. Velocity also increased with synaptic strength. Both in simulation and experiment, velocity slowed if small degrees of inhibition were present. When a band of cells was strongly hyperpolarized, propagation was blocked in the hyperpolarized region but reappeared distally after a delay; the duration of the delay increased with the width of the hyperpolarized band. This agrees with experiments where GABA was applied focally to reduce neuronal excitability in a region of the slice. We conclude that the spread of epileptic synchrony depends critically on the spatial distribution and strength of excitatory synapses and neuronal threshold as well as axon conduction. In longitudinal slices, the average projection radius of excitatory connections is significantly less than the extent of the slice.

318.2 ANALYSIS OF FIELD POTENTIALS IN RAT NEOCORTICAL SLICES. A.J. Bean, B.W. Strowbridge* and G.M. Shepherd, Departments of Pharmacology and Neuroscience, Yale University School of Medicine, New Haven, CT 06510.

Extracellular field potentials provide a means for comparing intracellular responses of single neurons to the activity of populations of neurons. As part of a study of the basic circuit organization of cortical regions, we have analysed the field potentials generated in lamina 2 of neocortical slices by electrical stimulation of lamina 6 (cf. Chervin and Conners, Soc. Neurosci. Abst. 12:350, 1986)

Coronal slices of parietal cortex (400 um) were prepared from Sprague Dawley rats (250-350 g.) anesthetized with pentobarbital (50 mg/kg i.p.). Recording (REC) (NaCl or K-Acetate filled glass capillaries) and monopolar stimulating (STIM) electrodes were placed in layers 2 and 6 respectively, under visual guidance.

The response evoked by a weak stimulus when STIM and REC were radially aligned typically consisted of a negative wave with a latency of 4-5 ms. Increasing the stimulus intensity elicted a sharper negativity at a briefer latency, often followed by a positivity. As REC was displaced laterally, similar fields of smaller amplitude were evoked. Intracellular recording revealed an EPSP with a latency which varied with stimulus intensity and was similar to the peak of the negative field response.

The sequence of changes in the field response during the administration of bicuculline (BIC) were examined. Four stages are observed during the application of BIC: 1) the initial negativity increased in amplitude, 2) the positivity increased in amplitude, 3) multiple sharp negative waves were apparent, the positivity was noticably broadened, and a second long duration negativity emerged, 4) the initial negativity was followed by a prominent second negativity with a 700-900 ms duration. Intracellular recordings showed a long duration, large amplitude depolarizing shift with superimposed action potentials that followed the initial negativity of the field response. In the presence of increased Mg^{2+}(4 mM), a low threshold all-or-none large positivity following the initial sharp negativity could be elicited. Increasing the stimulus intensity revealed the higher threshold long duration second negativity.

Our observations are consistent with the initial negativity being associated in part with local synaptic potentials, since its latency resembles that of the EPSP seen in intracellular records, and at low stimulus intensities it is broadened. Thus, the positivity may reflect distant synaptic activity. The enlargement of the positivity during BIC may therefore represent an increased population of cells generating synchronized synaptic potentials. 318.3 DEVELOPMENT OF SYNCHRONIZED BURSTS AND ASSOCIATED NMDA RECEPTORS IN CA2/3 AND CA1 AREAS OF THE RAT HIPPOCAMPUS. S.M. Bawin, B.J. Vasquez, M.D. Mahoney*, C. Lowery* and W.R. Adey. Departments of Neurosurgery, Physiology and Pharmacology, Loma Linda University and VAMC, Loma Linda, CA 92357.

Our laboratory has previously reported that NMDA receptor systems were involved in the generation of delayed synchronized bursts (DSBs) in the CA2/3 region of disinhibited or electrically stimulated adult rat hippocampal slices. DSBs originate in CA2/3 and are synaptically transmitted to CA1 in the adult hippocampus.

We have now studied the development of the generation and propagation of DSBs in hippocampal slices from 6 to 19 days old (d) rats. Concurrent extracellular recordings were obtained in CA1 and CA2/3 (cell layers and dendrites). Test pulses in the Schaffer collaterals induced CA2/3 DSBs in all pup slices following disinhibition of the tissue by bath application of penicillin (1.5 mM). Slices from the younger animals (6-11 d) started to exhibit DSBs after 8-10 min of treatment while slices from the older pups required longer perfusion time (30-60 min). Moreover, spontaneous synchronized bursts (sp. bursts) similar to the evoked DSBs occurred much more frequently in the younger pups. The synaptic transmission to CA1 increased markedly with age. Small DSBs were initially transmitted to CA1 in 6-11 d slices but the responses faded rapidly. By contrast, robust CA1 bursts followed CA2/3 DSBs in slice from older pups. Similar results were obtained in slices perfused in the absence of magnesium, but CA2/3 sp. bursts were much more frequent. Addition of 2-amino-5-phosphonovalerate (APV, 50 uM) to either treatment solution, abolished both sp. bursts and the evoked DSBs.

Iontophoresis of NMDA (20 mM in 20 mM NaCl, -80 nA, 1-30 s) in the CA2/3 apical dendrites triggered the onset of sp. bursts in penicillin-treated slices. This sensitivity decreased with maturation and long lasting (15-30 s) NMDA injections were required in the 14-19 d pup slices. When DSBs were evoked at a rate of 0.2 Hz, NMDA reduced the amplitude of the delayed dendritic EPSP and the bursting stopped for 15-30 s following treatment. Injection of NMDA in the CA1 dendrites induced similar decrease in the transmitted DSBs. In parallel studies, NMDA receptor binding was measured in lysed and detergent treated P2 membrane fractions, using [3H]glutamate (0.1uM) and APV (100 uM). NMDA sensitive binding was reliably detected in both the CA1 and CA2/3 areas of 9, 14 and 19 d pups.

In conclusion, although the NMDA receptor system responsible for synchronized bursting in CA2/3 appears functional in 6-11 d pups, the mechanisms of transmission to CA1 are still poorly developed. Our findings could help explain why focal hippocampal seizures fail to propagate in the immature brain. (Supported by the Veterans Administration and Dept. of Pediatrics, LLU).

318.4 DISINHIBITORY EFFECTS OF A NMDA (N-METHYL-D-ASPARTATE) RECEPTOR ANTAGONIST IN THE HIPPOCAMPAL SLICE PREPARATION. R. Čapek and B. Esplin, Dept. Pharmacology and Therapeutics, McGill University, Montreal, Quebec, H3G 1Y6, Canada.

We have previously reported that phencyclidine reduced inhibition in the hippocampal slice and suggested that this effect may be due to a depression of the inhibitory interneuron with resulting decrease in GABA release (Bourne et al., *Naunyn-Schmiedeberg's Arch. Pharmacol.*, 323:168,1983). One of the actions of phencyclidine is to suppress the NMDA responses in a non-competitive manner (Honey et al., *Neurosci. Lett.*, 61:135,1985). If synaptic activation of the inhibitory interneuron by presumably glutamatergic terminals involves NMDA subtype of the glutamate receptor, then its block could result in disinhibition.

To test this possibility, the effects of a competitive NMDA receptor antagonist, 2-amino-5-phosphonovaleric acid (APV), on inhibition of the CA1 pyramidal cells were investigated using conventional recordings of the field potentials in the superfused hippocampal slice preparation of the rat.

Population spikes in the CA1 pyramidal cell body layer were evoked by orthodromic stimulation of the stratum radiatum. They were inhibited by conditioning stimulation delivered 10, 20, 40, 60 or 80 msec before the orthodromic stimulation either to the alveus (antidromic-orthodromic) or to the stratum radiatum (paired pulse).

APV, dissolved in the superfusion medium in concentrations which did not affect the unconditioned population spike, was perfused for 60 min. In 80 or 100 μM concentration, the drug reduced inhibition at the first three interstimulus intervals in the antidromic-orthodromic test. The effects were qualitatively similar in the paired pulse test. In some experiments, APV attenuated inhibition at the shortest interstimulus interval while producing facilitation at intervals of 20 msec and longer. Lower concentration (40 μM) of APV was without a clear effect. Within 60 min after discontinuation of the drug, the inhibition partly recovered.

These results suggest that NMDA receptors contribute to synaptic activation of the inhibitory interneurons by a single afferent volley, perhaps inducing repetitive firing. In contrast, the discharge of the pyramidal cells evoked by synaptic activation was not affected by a block of NMDA receptors, as repeatedly reported. The functional significance of this difference between the excitatory synapses on the inhibitory interneurons and those on the pyramidal cells remains to be established.

Supported by the MRC of Canada.

318.5 **CHANGES IN SYNAPTIC TRANSMISSION EVOKED IN CA1 SUBFIELD OF THE HIPPOCAMPAL SLICES BY BRIEF APPLICATION OF Mg++-FREE RINGER: A CORRELATE FOR LONG TERM POTENTIATION (LTP)?** C Drapeau*, M Avoli and G Kostopoulos. MNI & Dept of Neurol & Neurosurg McGill Univ.

LTP, a mechanism possibly underlying learning and memory, is a phenomenon in which tetanic stimulation of a set of input fibers potentiates synaptic transmission in that pathway for hours or days. Initiation of LTP in the hippocampus depends upon the activation of N-methyl-D-aspartate (NMDA) receptors, a specific class of receptors for the excitatory amino acid glutamate which become functional only at depolarized membrane potential. This feature is due to a voltage-dependent Mg++ block upon the channels coupled with NMDA receptors. Here we studied in the CA1 subfield of rat hippocampal slices the changes in synaptic transmission which occur when [Mg++]o is brought to near zero. Extracellular field potentials were recorded with 4M NaCl filled micropipettes while stimuli (0.05-0.2Hz) were delivered through an electrode placed in stratum (s.) radiatum to activate the Shaffer collateral, commissural pathway. Perfusion of the slices (n:18) with Mg++-free Ringer for 20-30min evoked a potentiation of the response to s. radiatum stimulation consisting of: (i) an increase in the amplitude and a prolonged decay of the extracellular EPSP recorded in s. radiatum; (ii) an increased amplitude of the population spike recorded at the soma. At moderate intensity of stimulation the amplitude increase of the population spike was 210±18% (mean±SD; $p<0.005$). Furthermore this potentiation was normally observed up to 185min after replacement with control Ringer, the potentiation at 40min being 184±23% ($p<0.005$). In presence of the specific NMDA antagonist APV (50-100µM) the potentiation evoked by Mg++-free Ringer could be observed in only 8 of 13 experiments while no long lasting effects were seen in these experiments following reintroduction of control Ringer. However, once LTP was induced by perfusion with Mg++-free Ringer, APV could no longer affect this potentiation (n:5).

These data show that a brief exposure of the hippocampal slices to Mg++-free Ringer is sufficient to elicit LTP and provide further evidence for a role played by NMDA receptors in the induction of LTP, though not in its maintenance.

318.6 **EPILEPTIFORM DISCHARGES EVOKED BY LOWERING [Mg++]o IN THE HUMAN EPILEPTOGENIC NEOCORTEX MAINTAINED"IN VITRO"** J Louvel*, R Pumain*, M Avoli and A Olivier* (SPON: P Gloor). MNI & Dept of Neurol & Neurosurg McGill Univ, Montréal and INSERM U97, Paris.

Recent experiments have shown that conductances activated by NMDA receptors underlie the bursts of action potentials induced by focal stimuli in human neurons in slices obtained from epileptogenic neocortex (Neurosci Abstr 12:675,1986). NMDA receptors are coupled to a ionophore which is permeable to Ca++, Na+ and K+ and is gated in a voltage-dependent manner by extracellular Mg++. In addition decreasing [Mg++]o in rat hippocampal slices uncovers conductances activated by NMDA receptors and causes epileptiform discharges to appear. Therefore, it appeared of interest to study the effects of perfusing slices of human epileptogenic neocortex with Mg++-free Ringer.

Human slices (1st or 2nd temporal gyrus) were obtained during resection of epileptogenic tissue. Extracellular field potententials and extracellular ionic concentrations (K+ and Ca++) were measured using double-barrelled ion selective microelectrodes. Focal stimulation was delivered through electrodes placed in the white matter or within the cortex. Switching from control to Mg++-free Ringer induced within 50-100min the appearance of spontaneous or stimulus-induced synchronous epileptiform discharges, which could last up to 80s and were characterized by a prolonged negative potential shifts with superimposed fast negative transients. Such discharges were accompanied by increases in [K+]o (maximally 6.2mM from a baseline level of 3.25mM) and decreases in [Ca++]o (maximally 0.23mM from a baseline level of 1.8mM). In any experiments the largest and fastest changes in [Ca++]o and [K+]o occurred at the same sites from which the largest negative field potentials were recorded. Bath application of the selective antagonist of NMDA receptors 2APV suppressed in a reversible manner both spontaneous and stimulus-induced epileptiform discharges. These findings demonstrate that in slices obtained from human epileptogenic neocortex, prolonged epileptiform discharges are generated when [Mg++]o is lowered. Since these discharges were blocked by 2APV, they appear to be related to the activation of NMDA receptors.

Supported by Canadian MRC (MA 8109) & INSERM.

318.7 **EPILEPTIFORM DISCHARGES EVOKED BY LOWERING [Mg++]o: A STUDY OF POST-SYNAPTIC INHIBITORY POTENTIALS IN THE CA1 SUBFIELD OF THE HIPPOCAMPAL SLICE.** V Tancredi & M Avoli. Dept Exp Med, Univ of Tor Vergata, Italy; MNI & Dept of Neurol & Neurosurg McGill Univ.

Synchronous epileptiform discharges can be recorded in hippocampal slices perfused with Mg++-free Ringer. Since this type of discharge is blocked by antagonists of N-methyl-D-aspartate receptors (NMDA), the underlying mechanism appears to be related to the uncovering of NMDA activated conductances. Here we studied in rat hippocampal slices whether inhibitory synaptic mechanisms are preserved in this "in vitro" model of epilepsy. Field potentials were recorded in the CA1 and CA3 subfields with 4M NaCl filled electrodes; CA1 hippocampal pyramidal neurons (HPNs) were impaled with 4M K-acetate filled pipettes. Stimuli were delivered at 0.2-0.02Hz in stratum (s.) radiatum and alveus.

Perfusion with Mg++ - free Ringer induced within 35-40min the appearance of epileptiform bursts (duration: 50-300ms) which occurred at intervals of 1.5-5s and were recorded in both CA1 and CA3 subfield. Disconnection of these two areas abolished spontaneous discharges in CA1 but not in CA3. However, following this procedure, HPNs in CA1 were still capable of generating synchronous discharges of 3-5 population spikes in response to weak stimulation of the s. radiatum. Intracellular recordings demonstrated that these stimulus-induced epileptiform bursts were associated to a prolonged depolarization with multiple discharges of fast action potentials while alvear, antidromic stimuli were capable of inducing a hyperpolarizing, recurrent IPSP. Bath application of the NMDA antagonist aminophosphonovalerate (APV,50µM) reduced the stimulus-induced epileptiform bursts evoked by Mg++-free Ringer in the CA1 subfield. At the same time APV decreased the amplitude and the duration of the recurrent IPSP.

These results show that as in models where GABA antagonists are used to induce epileptiform activity, spontaneous epileptiform discharges evoked by lowering [Mg++]o originate in the CA3 subfield. However, in this type of experimental condition GABAergic potentials are preserved. Furthermore the effects exerted by APV upon the IPSP suggest that NMDA receptors play a role in the recurrent circuit responsible for the somatic hyperpolarizing IPSP generated by CA1 HPNs.

318.8 **EFFECTS OF 4-AMINOPYRIDINE ON CA3 AND DENTATE NEURONS OF RAT HIPPOCAMPAL SLICES.** P Perreault & M Avoli. MNI & Dept of Neurol & Neurosurg McGill Univ.

Previous work has shown that the convulsant 4-aminopyridine (4-AP), a blocker of K+ currents, can potentiate synaptic transmission at both excitatory and inhibitory synapses. Furthermore, in CA1 hippocampal pyramidal cells (HPCs) studied "in vitro", a GABA-mediated long-lasting depolarization (LLD) occurred spontaneously and following orthodromic stimulation in the presence of 4-AP (Brain Res 400: 191-195, 1987). Typical epileptiform events were not observed in CA1 cells. We noted, however, that spontaneous potentials also occurred synchronously in CA3 and dentate areas. This led us to investigate the effects of 4-AP (50µM) on these regions .

Standard rat hippocampal slices were used and cells were impaled with K-Acetate filled microelectrodes using conventional intracellular recording techniques.

As in CA1 HPCs, 4-AP potentiated both the EPSPs and the IPSPs evoked in CA3 neurons by stimulating the mossy fibers. LLD also developed progressively between the early and late IPSPs and partially obscured them. Two to five late spikes (latency varying between 20 and 120ms) of variable amplitude (10-120mV) and usually clustered on the peak of the early IPSP also appeared. Increasing the intensity of the stimulation triggered a burst followed by the LLD and a prolonged hyperpolarization. Bursts sometimes followed by LLD also occurred spontaneously. Focal application of bicuculline (20µM)in the dendritic area could block the LLD but NMDA receptor antagonists (APV and CPP) were without effects on the bursts. In dentate granule cells, GABA mediated LLD also occurred spontaneously and following stimulation of the perforant path. However, bursts were never recorded in this area.

These results suggest that epileptiform bursts can be induced even in the presence of enhanced inhibition. Differences observed among subfields might be related to differences in the intrinsic membrane properties of their cells or in their synaptic circuitry.

318.9 THE 5-HT_{1A} RECEPTOR AGONIST 8-OH DPAT ATTENUATES LOW CALCIUM-INDUCED BURSTING IN THE HIPPOCAMPAL SLICE. A. Obenaus[1], J.M. Klancnik[1,2], J.J. Miller[1]. Dept. of Physiology[1] and Psychology[1,2], Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

Rhythmic synchronous bursting discharges are observed in the CA1 region of hippocampal slices perfused with artificial CSF containing low concentrations of Ca^{2+} (<0.1mM). These bursts are characterized by 2-5 second depolarizing shifts of 4-10 mV in the extracellular DC potential upon which multiple unit activity may be superimposed. This low Ca^{2+} bursting can be followed for 3-6 hours. This phenomenon provides a simple model to study cellular hyperexcitability which occurs in the absence of synaptic transmission. The CA1 region receives significant serotonergic projections from the medial and dorsal raphe nuclei, and is rich in serotonergic binding sites, primarily in the apical dendritic region. Although pharmacological activation of the 5-HT_{1A} receptor subtype appears to decrease neuronal excitability of CA1 pyramidal cells *in vitro* in normal artificial CSF, as measured by evoked population responses, other serotonergic actions in this brain region remain largely unknown. The purpose of the present experiments was to examine the possible modulation of burst discharges in the CA1 region of the hippocampal slice preparation by activation of 5-HT_{1A} receptors. Hippocampal slices (400um thick) were prepared from 200-300 gm male Wistar rats, and maintained in an *in vitro* chamber. After normal responses had been established, the normal artificial CSF was replaced by one low in Ca^{2+}. Burst activity was typically seen after 60-90 minutes after media replacement. A 10 minute perfusion of the selective 5-HT_{1A} receptor agonist, 8-hydroxy-2-(di-*n*-propylamino)-tetralin (8-OH DPAT), resulted in a progressive and dose-dependent (1-30uM) attenuation of burst activity. Both burst amplitude and burst frequency decreased at a dose-dependent rate. The onset of this effect was seen within 10 minutes of perfusion, with the bursts irreversibly decreasing until they disappeared (e.g. at 10uM 8-OH DPAT this occurred within 80-120 min. after perfusion). At lower doses (<10uM.) some slices first exhibited a transient increase in burst rate (but not in amplitude) which was not seen at higher doses. These results indicate a possible role for 5-HT, and particularly the 5-HT_{1A} receptor subtype, in the attenuation of burst activity induced by low Ca^{2+} media. The mechanism underlying this effect remains to be elucidated.(Supported by a Canadian MRC Program Grant to J.J.M.)

318.10 THE EFFECTS OF THE 5-HT_{1A} RECEPTOR AGONIST 8-OH DPAT ON EVOKED RESPONSES IN THE *IN VITRO* HIPPOCAMPUS. J.M. Klancnik[1,2], A. Obenaus[1], J.J. Miller[1]. Depts. of Physiology[1] and Psychology[2], University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

The functional role of serotonin within the hippocampus is largely unknown. Previous studies employing the *in vitro* hippocampal slice preparation have shown that putative 5-HT_{1A} receptor subtype agonists, including the highly selective 5-HT_{1A} ligand, 8-hydroxy-2-[di-*n*-propylamino]-tetralin (8-OH DPAT), decrease population spike amplitude in the CA1 region of the hippocampus. Recent *in vivo* work from our laboratory has found 8-OH DPAT to increase population spike amplitude in the dentate gyrus (DG), a region with greater serotonergic innervation and receptor density than the CA1. The present experiment employed an *in vitro* preparation to investigate the effects of 8-OH DPAT on population responses in the CA1 and the DG.

Hippocampal slices (400 um thick) were prepared from 200-300 gm male Wistar rats and maintained in an *in vitro* chamber perfused with artificial CSF. Population responses evoked by perforant path stimulation were recorded in the DG, and responses evoked by Schaffer collateral stimulation were recorded in the CA1. Stimuli were 0.1 msec. cathodal square wave pulses, at a current which evoked population spikes of approximately one-half maximum amplitude. After collection of baseline data, preparations were perfused for ten minutes with 8-OH DPAT in concentrations from 1.0 to 30.0 uM. Population responses were evoked and recorded at the rate of one per minute over a period of three to five hours.

8-OH DPAT produced a dose-dependent decrease in population spike amplitude in both the CA1 and DG, with a more pronounced effect in the CA1. The drug action exhibited a similar time course in both regions, with a maximum effect occurring at a latency of 10-30 min. after perfusion onset, and a subsequent return to baseline values after one to three hours.

Although these data indicate a similarity of 8-OH DPAT action between CA1 and DG in the hippocampal slice, they show opposite actions between the *in vivo* and *in vitro* preparations. These results suggest that the functional effects in the whole animal may be due to pharmacological action on 5-HT_{1A} receptors at extrahippocampal loci.
(Supported by a Canadian MRC Program Grant to J.J.M.)

318.11 **THE** EFFECT OF LIPID PEROXIDATION ON GABA UPTAKE AND RELEASE IN SYNAPTOSOMES FROM RATS WITH FERROUS-INDUCED SEIZURES. Z.H.Zhang, C.H.Zuo*, X.R.Wu*, Y.Hua* and H.Wang*
Div. of Neurology, Dept. of Pediatrics, First Teaching Hospital of Beijing Medical University, Beijing, People's Republic of China

The deleterious consequences of lipid peroxidation (LP) to membrane function is well established. Both uptake and release of neurotransmitters depend on the intact membrane structure and function. To determine the effect of LP on GABA uptake and release, 10 Wistar rats of 30 days old were devided into 2 groups: C (control, n=5) and F (ferrous-treated, n=5). We observed seizure behavior for 2 hours after intraventricular injection of 10uL of either normal saline (C group) or 300mM $FeSO_4$ in saline (F group). Then, rats were decapitated and synaptosomes were prepared from cortex and hippocampus. The synaptosomes were assayed for LP (thiobarbituric acid test), GABA uptake and release (Ca^{++}-dependent and high K^+-evoked release, Gordon-Weeks PR: Neurosci Letters 1984, 52:205). In F group, LP greatly increased but both uptake and release significantly decreased relative to controls:

	F(n=5)	C(n=5)	F/C
LP (n mole/min/mg protein)	11.10±0.85**	1.26±0.18	881%
GABA uptake (p mole/min/mg protein)	15.82±1.46**	20.87±1.59	76%
GABA release (fractional release rate from 4 to 6 minute after K^+-stimulation, %)	4.92±0.31**	12.31±0.58	40%

(** $p < 0.01$)

Our previous studies showed that intraventricular injection of ferrous caused seizures as well as LP in brain tissue. The present data demonstrated that GABA release was more severely damaged than GABA uptake by LP. This imbalance between release and uptake might reduce the inhibition of GABA, which could contribute to the neurochemical pathogenesis of ferrous-induced seizures.

318.12 INVLOVEMENT OF SUBSTANTIA NIGRA GABA A RECEPTORS IN SEIZURES OF ADULT RATS. E.F. Sperber, D. Zhao* and S.L. Moshé. Albert Einstein College of Medicine, Bronx, NY 10461

Pharmacological activation of the GABA system in the substantai nigra (SN) has been observed to suppress a variety of experimental seizures in adult rats. In order to identify whether the GABA A receptor type is involved in the modification of seizures, we compared the effects of nigral infusions of a GABA agonist, muscimol and a GABA antagonist, bicuculline.

Adult male rats were implanted with bilateral cannulae in the SN reticulata. Following a two day recovery period, rats received one dose of muscimol (12.5-200ng/0.25ul) or bicuculline (25-200ng/0.25ul) at two day intervals. Each drug had its own saline-treated control group. Thirty minutes after the muscimol infusions and 5 minutes after the bicuculline infusions, rats were exposed to flurothyl (FE) convulsions. The latency to the onset of a generalized clonic seizure was considered the seizure threshold.

A series of one-way ANOVAs were used to compare the FE seizure latencies following each drug dose with its respective saline group. Results indicate that rats infused with the higher doses of muscimol, 25, 50, 100 and 200ng/0.25ul had significantly longer seizure latencies than the control rats ($p < .04$). In contrast, rats infused with the higher doses of bicuculline, 100 and 200ng/0.25ul had significantly lower seizure thresolds than the saline-infused rats ($p < .01$). Since both muscimol and bicuculline have a greater affinity for the GABA A receptor, our data suggest that the nigral GABA A receptor is involved in the modulation of seizures in adult rats.

318.13 **BACLOFEN HAS A PRO-EPILEPTIFORM EFFECT IN THE DENTATE GYRUS OF RATS.** D.D. Mott* and A.C. Bragdon. Depts. of Pharmacology and Medicine (Neurology), Duke Univ. and VA Medical Centers, Durham, NC 27710.

Baclofen is a GABA analog with a number of pre- and post-synaptic inhibitory actions on neurons. Baclofen has anticonvulsant activity against some models of epilepsy in vivo and epileptiform activity in vitro. However, baclofen has been shown to be proconvulsive in other models, baclofen has not proven useful against human epilepsy, and baclofen overdose has been reported to cause seizures in nonepileptics. Here we report a proepileptic effect of baclofen in the dentate gyrus alone with evidence for its underlying mechanism.

Hippocampal slices from 100-200 gm male Sprague-Dawley rats were studied in ACSF containing 3.3 mM K^+, 1.8 mM Ca^{++}, and 1.3 mM Mg^{++}. Perforant path (PP) stimulation evoked an EPSP and a population spike (PS) recorded extracellularly in the granule cell layer of the outer blade of the dentate gyrus. For quantitative studies, the PP stimulus intensity was set to produce a PS about 80% of maximal in control ACSF. Recurrent inhibition was induced by antidromic activation of mossy fibers (MF) from CA3c five msec before PP stimulation. Feed-forward inhibition was induced by stimulation of dentate commissural-associational (C-A) fibers in the alveus of CA3 coincident with PP stimulation (Bragdon and Wilson, Soc. Neurosci. Abstr. 10: 549, 1984). For both recurrent and feed-forward inhibition, the degree of inhibition was quantified as the % reduction in the PP-evoked PS. All observations were made first in control ACSF, next after at least 15 min in 10 uM baclofen, and last at least 15 min after washout with control ACSF. All baclofen effects were reversible.

Baclofen reduced the PP-evoked PS mildly, but converted the usual single-PS evoked response to an epileptiform response with two or more population spikes suggesting disinhibition of granule cells. Baclofen reduced recurrent inhibition by about 2/3 -- from 72% to 23% at maximal MF stimulus intensity. Feed-forward inhibition was unaffected by baclofen in 3 of 4 slices, and only mildy reduced (from 60% to 40%) in the fourth slice.

These results show that baclofen has a pro-epileptiform effect on dentate granule cell responses. This appears to result from suppression of recurrent inhibition, rather than from enhanced PP-granule cell excitatory transmission. These results also suggest that baclofen suppresses recurrent inhibition but not C-A feed-forward inhibition. If both forms of inhibition share the same final common pathway of inhibitory interneurons, this raises the possibility that baclofen preferentially suppresses transmitter release from mossy fibers, but not from dentate commissural-associational fibers.

Supported by NIH grant GM 07184 and the Veterans Administration.

318.14 BACLOFEN INDUCES SPONTANEOUS, RHYTHMIC ACTIVITY IN HIPPOCAMPAL SLICE. D. V. Lewis and D. Mott* Depts. of Peds (Neurol.) and Pharmacology, Duke Univ., Durham, NC 27710.

The GABA-b agonist, baclofen, is known to be a powerful antagonist of spontaneous interictal burst activity in the hippocampal slice. However, we have recently observed an unexpected effect of baclofen. At low concentrations, baclofen induces spontaneous, rhythmic, low amplitude sharp waves in the hippocampal slice.

Hippocampal slices (625 uM) were prepared from male Sprague-Dawley rats, 23 to 34 days of age (55 to 130 gms). They were maintained in a submersion chamber with a stimulating electrode in the s. radiatum of the CA2-3 junction and extracellular recording electrodes in the s. radiatum and s. pyramidale of the CA3b region. Artificial cerebrospinal fluid (ACSF) composition was, in mM, NaCl 120, KCl 3.3, CaCl2 1.8, MgSO4 1.2, NaHCO3 25, NaH2PO4 1.23 and dextrose 10 at pH 7.4. Baclofen (+/-) was dissolved in the ACSF in concentrations of 0.1, 0.5, 1.5, 5.0, 20.0 and 100 uM.

At baclofen concentrations of 0.5 and 1.5 uM, rhythmic, spontaneous waves (RSW's) were observed in 8 out of 8 slices, each from a different animal. In several animals, RSW's appeared in 0.1 uM baclofen also, but were difficult to discern from the background noise. The voltage of the RSW's was maximum in the s. radiatum of CA3 and increased with increasing baclofen concentration to reach 0.3 to 0.6 mV in 1.5 uM. In the s. pyramidale, the RSW's were much less obvious and often were lost in the background noise. At 5 uM baclofen and above, the RSW's were suppressed. Washing off the baclofen entirly eliminated the RSW's. Usually, the RSW's were monophasic, negative deflections in s. radiatum from 100 to 200 msec in duration appearing as a sharp wave at slow recording speeds. They recurred rhythmically about every 2 sec in 1.5 uM baclofen, and tended to be more frequent in lower concentrations when they were of lower amplitude. Sampling the extracellular feild in other regions of the slice revealed synchronous RSW's in CA1 and CA2, but not in subiculum, entorhinal cortex or dentate. Preliminary experiments showed that after cutting the Schaffer collaterals in CA2, the RSW's were no longer seen in CA1 but continued in CA3. In one experiment, (-) baclofen was used and also elicited RSW's.

We think these RSW's are analogous to the rhythmic activity reported by Schneiderman (Brain Res.,398:231, 1986) in low levels of penicillin and might relate to a reduction of recurrent inhibition by low levels of baclofen (Ault and Nadler, Br. J. Pharmac.,78:701, 1983). Supported by NINCDS Grant NS22170.

318.15 POTENT CONVULSANT ACTION OF THE ADENOSINE RECEPTOR ANTAGONIST, XANTHINE AMINE CONGENER (XAC). Philip F. Morgan, Jurgen Deckert, Kenneth A. Jacobson*, John W. Daly and Paul J. Marangos, NIH, Bethesda, Maryland 20892, USA

A [^{3}H]Xanthine amine congener of 1,3-dipropyl-8-phenylxanthine ([^{3}H]-XAC) has recently been characterized as a potent adenosine receptor antagonist (Jacobson et al., P.N.A.S. 83:4089-4093, 1986). In the present study, convulsant properties of XAC have been assessed and compared to those of caffeine.

Naive male NIH stock Swiss Albino Mice (25-30g) were infused with convulsants through a lateral tail vein using a 25 gauge butterfly needle fed from a syringe infusion pump as previously described (Morgan and Stone, Br. J. Pharmacol. 77:525-529, 1982). Using this paradigm, convulsion thresholds (i.e. the amount of convulsants required to elicit convulsions) of 39.8+2.0 mg/kg (n=10) and 109.8+2.3 mg/kg (n=10) were calculated for XAC and caffeine respectively. This potent convulsant activity of XAC is to some extent remarkable since a recent study indicates that XAC penetrates poorly into the C.N.S. (Fredholm et al., J. Cardiovasc. Pharmacol. 9:396-400, 1987).

Pretreatment of animals with adenosine receptor agonists (1 mg/kg, i.p., 20 minutes prior to infusion, of either 2-chloroadenosine, cyclohexyladenosine or 5'-N-ethylcarboxamide adenosine) significantly decreased the seizure threshold of both XAC and caffeine (p's < 0.05). Pretreatment of animals with the adenosine uptake blockers, nitrobenzylthioinosine or dipyridamole (0.25 mg/kg, i.p., 20 minutes prior to infusion) did not significantly affect the seizure threshold to either XAC or caffeine. The benzodiazepine agonist diazepam (5 mg/kg, i.p., 20 minutes prior to infusion) significantly increased the seizure threshold to both XAC (p < 0.05) and caffeine (p < 0.01), whereas the benzodiazepine antagonist RO 15-1788 (10 mg/kg, i.p., 20 minutes prior to infusion) significantly increased the seizure threshold to caffeine (p < 0.01), but not XAC (p > 0.05). All vehicles employed were without significant effect on the seizure threshold of either XAC or caffeine (p's > 0.05). The results suggest that actions at benzodiazepine receptors may be a tenable hypothesis to explain the convulsant actions of caffeine, but not those of XAC.

318.16 COMPARISON OF PHYSOSTIGMINE PRETREATMENT, WITH OR WITHOUT ATROPINE SULFATE, AS PRETREATMENT FOR SOMAN-INDUCED SEIZURES IN GUINEA PIGS. N.K. Marshall, D.J. Hinman and J.F. Glenn. Neurotoxicology Branch, U.S. Army Medical Research Institute of Chemical Defense, APG, MD 21010-5425

Pretreatment of animals with physostigmine, a reversible inhibitor of acetylcholinesterase, reduces lethality resulting from exposure to soman (pinacolyl methylphosphonofluoridate, GD), an irreversible cholinesterase inhibitor. While it is important to increase survival following GD exposure, it is also desirable to ameliorate other signs of GD toxicity, e.g., EEG seizures and motor convulsions. In this study we tested the effects of pretreatment with physostigmine and atropine sulfate alone, and combined, in freely-moving guinea pigs.

The EEG was recorded from indwelling cortical electrodes (stainless steel screws). Following a 30 min. baseline recording, the subjects were given one of the following pretreatment(s): (I) saline; (II) saline and physostigmine (0.26 mg/kg); (III) saline and atropine sulfate (4mg/kg); or, (IV) atropine sulfate (4mg/kg) plus physostigmine (0.26 mg/kg). The dose of physostigmine produced 70-80% inhibition of whole blood cholinesterase. The animals were dosed with $2LD_{50}$ GD (56ug/kg, SC) thirty minutes following pretreatment. [Group II also received atropine methylnitrate (4mg/kg, IM) and pralidoxime (2PAM; 25mg/kg, IM) therapy 30 seconds after GD. Atropine methylnitrate was given to block peripheral muscarinic sites and 2PAM to reactivate GD-inhibited AChE peripherally.] The EEG and motor behavior of all animals were monitored for 2 hours following GD administration. In some cases, the animals were re-tested at 24 hours and one week post-GD. The results are summarized in the table below:

Group	(n)	SEIZURE Incidence (%)	SEIZURE $\bar{X}$ Onset (min)	LETHALITY Incidence (%)	LETHALITY $\bar{X}$ Onset (min)	24 Hour Survival (%)
I	(8)	75#	7.0	100	13.5	0
II	(9)	100	5.8	0	-----	N/A
III	(5)	100	8.0	80	25.0	0
IV	(5)	0	----	0	-----	100

Group	(n)	CONVULSIONS Stage 1 (min/%)	Stage 2 (min/%)	Stage 3 (min/%)	MOTOR RECOVERY (min)	(%)
I	(8)	6.4; 100	7.0; 100	8.6; 100	-----	0
II	(9)	3.8; 100	4.5; 100	8.8; 44	N/A*	100
III	(5)	6.8; 100	8.4; 100	11.8; 100	-----	0
IV	(5)	6.2; 100	8.8; 100	----- 0	50.4	100

#2 animals died without seizing; N/A: not available; *observed but not quantified.

The results indicate that pretreatment with physostigmine in conjunction with atropine sulfate was the most effective pretreatment for soman poisoning.

318.17 EFFECTS OF PRENATAL PHENYTOIN AND VALPROIC ACID TREATMENT ON REPRODUCTIVE OUTCOME, DEVELOPMENT AND BEHAVIOR IN RATS. William J. Pizzi and Robert M. Jersey*. Dept. of Psych., Northeastern Illinois University, Chicago, IL 60625.

Recent experimental work in animals has confirmed clinical observations in children of a Fetal Anticonvulsant Therapy Syndrome (FACTS). There are three main symptom clusters associated with FACTS: 1) Congenital Malformations, 2) Growth Retardation, and 3) Behavioral Abnormalities. This report presents the results of two studies examining the toxic effects of two commonly used anticonvulsants, phenytoin (PHT) and valproic acid (VPA).

Pregnant rats were dosed orally from gestational days (GD) 9-18 and allowed to proceed to term. Treatment groups consisted of normal controls (NC), vehicle controls (VC), 100 and 200 mg/kg PHT, 200 and 300 mg/kg VPA, and a VPA group dosed via an ALZET osmotic minipump which delivered approximately 190 mg/kg on GD 9.

Due to space limitations only selected results from Experiments 1 & 2 are presented here. PHT dams showed a significantly reduced weight gain throughout pregnancy with the PHT-200 group actually losing weight over the course of treatment. Both PHT-100 and -200 groups had an increased mortality in offspring followed to PND 30 (41 & 61%, respectively). In light of this high mortality it is important to note that PHT blood levels taken approximately 90 min. after the the last treatment on GD 18 were in the human therapeutic range (11.5 and 26.2mcg/ml, respectively). Birth weights of PHT pups were significantly reduced with a dose-response relationship present. These reduced weights continued to be present at PND 30.

The VPA results are somewhat more complex in that the VPA-pump and VPA-200 groups failed to show differences in birth weights but in several of the PND 30 comparisons they were significantly heavier than controls. The VPA-300 group showed reduced body weights at PND 30.

Convulsive threshold testing failed to show protection from a 50mg/kg pentylenetetrazol challenge dose in any VPA group as recently reported by Sobrian and Nandedkar (1986). The PHT-100 male animals showed an increased duration of maximal seizure activity to the PTZ challenge.

318.18 CNS TRANSPLANTATION IN ANIMAL MODELS OF EPILEPTIFORM ACTIVITY. P.A.Schwartzkroin, O.Lindvall*, P.Brundin* and A.Björklund. Dept. Histology, Lund University, S-22362 Lund, Sweden.

Transplantation of CNS neurons, as an approach to modifying and understanding central nervous system pathologies, has received wide attention. Studies have been carried out with animal models of, for example, Parkinson's, Huntington's and Alzheimer's Diseases -- neuropathologies in which specific cell types or CNS regions are predominantly affected. Relatively little work has been reported in which grafting techniques have been applied to models of epilepsy. This absence perhaps reflects a confusion about which cells are abnormal or lost in epileptic brain, as well as about the multiplicity of factors which can control neural excitability.

We have initiated grafting studies with two models of epileptogenesis: 1) spontaneous interictal spiking produced by intraventricular (icv) injections of kainic acid (KA); and 2) seizure activity produced by kindling. We reasoned that insertion of a population of neuromodulatory neurons might affect the excitability of these systems. Thus, we grafted CNS regions rich in GABAergic and noradrenergic neurons into hippocampus made epileptogenic by KA injections, and into substantia nigra (SN) and amygdala of animals receiving amygdala kindling stimulations. The source of GABA-rich transplants was fetal striatum and ventral mesencephalon (including SN-pars reticulata); NA-rich grafts were derived from fetal locus coeruleus.

Grafting procedures followed the general protocols for cell suspensions. For the KA animals, KA was first injected bilaterally followed at 1 week by cell suspension injections into the CA3 region of dorsal hippocampus and implantation of recording electrodes. Occurrence of interictal spiking was monitored for at least 2 months. The kindling animals receiving amygdala grafts were first transplanted; two to three months later they were implanted with amygdala electrodes and kindling commenced. In these animals, threshold for afterdischarge and time course to stage 5 seizures were assessed. In the kindling group to receive grafts into SN, each rat was first kindled to stage 5 criterion, and cell suspensions were then introduced into nigra through implanted cannulae. Threshold for triggering stage 5 seizures was monitored for two to three months.

Anatomically, we found that grafted neurons introduced into these relatively intact systems survive well. Histofluorescence techniques showed noradrenergic neurons of graft origin in hippocampus of transplanted KA animals; a fiber plexus from these cells was clear in much of dorsal hippocampus. GAD immunocytochemistry demonstrated cells, fibers and terminals of apparent graft origin in both KA-affected hippocampi and in SN of kindled rats. The functional importance of these grafts is not yet clear.

HYPOTHALAMUS

319.1 HYPOTHALAMIC SITES WHERE ELECTRICAL STIMULATION INCREASES METABOLIC RATE IN THE RAT. Peter A. Pawson, E. Preston*, N.Haas* and D.O. Foster*, Division of Biological Sciences, National Research Council Canada, Ottawa, Canada, K1A OR6.

The hypothalamus plays a key role in food intake regulation and thus in the regulation of energy balance. We are interested in the possibility that its role in energy balance also includes modulation of energy expenditure. Male rats (300g) were stereotaxically implanted with monopolar stimulating electrodes. After 1-2 weeks recovery, they were placed in a temperature-controlled chamber (28°C) for measurement of metabolic rate (MR as $\dot{V}O_2$) before and after stimulating various hypothalamic sites for 60 s. Two types of stimulation were used: (a) a set frequency (50 Hz) with current varied stepwise from 100 to 500 microamperes (μA); this method examines the effect of expanding the field of stimulation around the tip of the electrode; (b) a constant current (250 μA) with the frequency of stimulation varied from 10 to 300 Hz to generate a response curve for a focal part of the hypothalamus, providing a finer and more quantitative comparison of different hypothalamic regions. Results from the 2 techniques have, however, yielded similar conclusions. 47 sites have been studied, covering these hypothalamic regions: anterior hypothalamus (AH), paraventricular nucleus (PVN), lateral hypothalamic area (LH), ventral medial hypothalamic nucleus (VMH), dorsomedial hypothalamic nucleus (DM), posterior hypothalamus (PH), and an area between the LH and VMH (mid VMH-LH). The responses in fully conscious rats were as follows: A) 0-40% increases in MR: sites in the PH, LH, PVN and the mid VMH-LH; B) 41-90% increases: DM, the middle and posterior VMH; C) >90% increases: anterior VMH and the AH. In animals that were mildly sedated with Rompun ®, which eliminated any apparent contribution of arousal and body movement to increases in MR, only the stimulation of two contiguous sites, the anterior VMH and the posterior AH, effected appreciable increases in MR (40-60%). These areas thus appear to be the best candidates for further study of hypothalamic regulation of energy expenditure.

319.2 LOCAL ANESTHETICS PROCAINE AND LIDOCAINE STIMULATE CORTICOTROPIN RELEASING HORMONE SECRETION IN VITRO: CLINICAL IMPLICATIONS. A.E. Calogero*, M.A. Kling†, W.T. Gallucci*†, C.Saoutis*, R.Post†, G.P.Chrousos, P.W.Gold*†. DEB, NICHD, NIH and †BPB, NIMH, Bethesda

Local anesthetics like procaine and lidocaine can kindle limbic seizures in animals and produce psychosensory and mood changes, and stimulate the hypothalamic-pituitary-adrenal (HPA) axis in man. Corticotropin releasing hormone (CRH), given i.c.v. to animals, reproduces some of these effects. It causes limbic seizures, behavioral changes characteristic of the stress response, and activation of the HPA axis. CRH hypersecretion and altered limbic responsiveness have been postulated in primary affective disorder. In this regard carbamazepine (CBZ), an anticonvulsant which is particularly effective against limbic seizures, has been employed successfully in the treatment of affective disorders.

To test the hypothesis that CRH participates in some of the central nervous system (CNS) effects of local anesthetics, we examined the ability of procaine and lidocaine to stimulate hypothalamic CRH secretion in vitro and the ability of CBZ to inhibit it.

Single explanted rat hypothalami were incubated in plain medium for 20 min in 3 sequential wells to evaluate basal immunoreactive rat CRH (IR-rCRH) secretion. This was 36±2 pg/well/20 min (n=32). In 2 subsequent 20 min incubation periods, the hypothalami were exposed to graded concentrations of procaine or lidocaine or for comparison to a known CRH secretagogue (serotonin 10^{-9} M). At the end of the experiment each hypothalamus was exposed to 60 mM KCl to test tissue viability. Hypothalami that failed to respond to KCl by a 90% increase of IR-rCRH (5 interassay CV) above baseline were excluded from the analysis. IR-rCRH responses to procaine and lidocaine, expressed as percent IR-rCRH increase above above secretion (after logarithmic transformation) are shown below:

	0	10^{-10} M	10^{-8} M	10^{-6} M	10^{-4} M	Serotonin
Procaine	3.4±1.3 (25)	33±13* (11)	117±31* (7)	168±29* (9)	112±35* (8)	200±52* (17)
Lidocaine	3.4±1.3 (25)	71±14* (7)	95±41* (10)	155±39* (10)	152±31* (10)	200±52* (17)

*p<0.001 ANOVA, followed by Duncan Multiple Range Test

Procaine and lidocaine stimulated IR-rCRH secretion in a concentration-dependent fashion. These responses were inhibited by CBZ (procaine or lidocaine 10^{-6} M alone or with 10^{-6} M CBZ were, respectively, 168±29% vs 38±10%, p<0.001, and 155±39% vs 12±7%, p<0.001).

These findings suggest that CRH may participate in the CNS effects of local anesthetics and that carbamazepine's efficacy in affective illness could be in part related to effects on CRH secretion.

319.3 VASOPRESSIN INNERVATION OF SEXUALLY DIMORPHIC STRUCTURES IN RAT, GERBIL AND HUMAN BRAINS. Geert J. De Vries and Pauline Yahr. Department of Psychobiology, University of California, Irvine CA 92717.

The medial preoptic and anterior hypothalamic areas (MPOA-AH) regulate reproductive functions, such as gonadotropin release and male sexual behavior. Structural sex differences may underlie the sexually dimorphic nature of these functions. Sex differences exist in cellgroup size, synaptic organization, dendritic branching, steroid uptake and neurotransmitter distribution in the MPOA-AH of birds, rodents, carnivores and primates. It is not clear to what extent these sex differences are homologous. One sex difference for which this question may be answered concerns a cellgroup known in gerbils as the sexually dimorphic area pars compacta (SDApc) and in rats as the central part of the medial preoptic nucleus (MPNc). Both lie within larger sexually dimorphic cellgroups, i.e., the SDA and MPN, respectively[1,2], midway between the optic chiasm and the anterior commissure. Both contrast with the surround in that they receive denser inputs from the bed nucleus stria terminalis and lack acetylcholinesterase activity. Moreover, both the SDApc and MPNc are larger in males than in females, although this difference is more extreme in gerbils. The SDApc is often absent in females.

To study whether neurotransmitter input is similar in the SDApc and MPNc, we stained gerbil and rat brains immunocytochemically for vasopressin. We also stained sections of human hypothalamus containing the sexually dimorphic nucleus, which is larger in males than in females[3]. In gerbils, vasopressin fibers densely innervated the medial part of the SDA, but a particularly dense innervation was present in the SDApc. The lateral part of the SDA was lightly innervated by vasopressin fibers. In rats, vasopressin fibers were present throughout the MPN and, as in gerbils, were particularly dense in the MPNc. In the human, vasopressin fibers were more concentrated in the sexually dimorphic nucleus than in its surround. This innervation differed from that seen in the SDApc or MPNc. It was less uniformly distributed over the sexually dimorphic nucleus, and, in some places, was just as dense as in the surround. These data further support a homology between the SDApc and MPNc. They also suggest homology among all three cell groups, the human sexually dimorphic nucleus, the SDApc and the MPNc.

319.4 PROJECTIONS TO THE PROGESTERONE-SENSITIVE SITE OF THE VTA IN HAMSTERS: AN HRP STUDY. C.A. Lisciotto* and J.F. DeBold. Dept. of Psychology, Tufts Univ., Medford, MA 02155.

The ventral tegmental area (VTA), along with the ventromedial nucleus of the hypothalamus (VMH), is an important site for progesterone's effects on sexual receptivity in female hamsters. We have demonstrated with a number of different techniques that both of these brain sites are essential for this response. The critical importance of both the VTA and VMH for receptivity in hamsters is different from the control of this behavior in rats. In rats the VTA seems to be much less important than the VMH for receptivity. Studies on the neural circuitry mediating hormonal effects on receptivity in rats have focused on connections between the VMH and the central gray. The minimal neural circuitry necessary for the induction of receptivity in hamsters has not been worked out but must include the VTA. This study investigates how the progesterone responsive site within the VTA may be connected with other areas of the brain which have already been established as important for sexual receptivity.

HRP (0.02µl, 50% Sigma IV w/v in dH_2O) was stereotaxically injected into the VTA. The stereotaxic coordinates used were the same as those which were effective at inducing receptivity with progesterone implants. Following a 48 hr survival period the hamsters were sacrificed and perfused with paraformaldehyde-glutaraldehyde fixative. Coronal sections of 40 um were cut and processed using tetramethylbenzidine. The number and location of HRP-filled cells, rostral to the injection site were assessed.

Labeled cells were seen in several sites in the diencephalon and mesencephalon. One of the more interesting sites with labelled cells was the ipsilateral VMH indicating that the two critical progesterone sensitive sites in hamsters are directly interconnected. HRP filled cells were also seen in other sites which behavioral studies have implicated in the mediation of receptivity. For example, dense labeling was seen bilaterally in the medial habenula and ipsilateral lateral habenula. Much of the lateral hypothalamus and lateral preoptic area also contained HRP labeled cells. In addition, occasional but consistent labeling was found in the ipsilateral diagonal band, dorsal hypothalamus, zona incerta, peripeduncular nucleus and central gray. Many of the labelled areas have previously been shown to also receive projections from the VMH.

These observations suggest possible routes by which the critical progesterone-sensitive sites for sexual receptivity, the VTA and VMH, may communicate. This is an initial step in establishing the neural circuitry for the hormonal control of receptivity in this species.

319.5 DIFFERENTIAL DISTRIBUTION OF ESTROGEN AND ANDROGEN CONCENTRATING CELLS IN THE RAT MEDIAL PREOPTIC AREA. P.E. Micevych and T.R. Akesson. Dept. of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

The role of the rat medial preoptic area (MPOA) in mediating steroid-sensitive reproductive events is highly sexually differentiated. The exact neural substrates mediating these events have not been elucidated, however the MPOA contains sexually dimorphic structures and the entire region is enriched in steroid concentrating cells. Although testosterone (T) is metabolized to both dihydrotestosterone (DHT) and estradiol (E_2), only androgens masculinize the anatomy of this region during a critical postnatal period. This organizational influence that androgen exerts during development may be reflected in preferential accumulation of androgens in sexually dimorphic regions of the adult. To test this hypothesis, we studied the distribution of T, E_2 and DHT in the preoptic area of male rats. Adult male rats (n = 7) were castrated, two weeks later infused with ^{3}H-T, ^{3}H-E_2 or ^{3}H-DHT and processed for thaw-mount steroid autoradiography. After exposure periods of 4 months (^{3}H-E_2), 14 months (^{3}H-T) and 20 months (^{3}H-DHT), the distribution of steroid concentrating cells was defined as containing 3X the background concentration of reduced silver grains.

At the rostral extent of the MPOA, the anteroventral periventricular nucleus (AVPv) contained approximately four times as many ^{3}H-E_2 as ^{3}H-DHT labeled cells. Similarly, the preoptic periventricular nucleus (PvPO) was observed to be enriched in ^{3}H-E_2 labeled cells with a relative paucity of both ^{3}H-T or ^{3}H-DHT labeled cells. Within the medial preoptic nucleus (MPN) itself, distributions of steroid concentrating cells appeared to correspond to cytoarchitectonic divisions which consist of central (MPNc), anteroventral (MPNav; Bloch and Gorski, Neurosci. Abstr. 13, '87), medial (MPNm) and lateral (MPNl) parts. The vast majority (84%) of cells labeled with ^{3}H-T, ^{3}H-DHT or ^{3}H-E_2 were localized in the MPNm with comparatively few cells present in the MPNl. Within the MPNm, ^{3}H-E_2 labeled cells were uniformly distributed and were not preferentially localized in the MPNc or MPNav in contrast with the distributions of ^{3}H-T and ^{3}H-DHT. Although there were androgen-labeled cells scattered throughout the MPNm, the majority of these cells were localized in the MPNc and MPNav. These two highly sexually dimorphic subnuclei contained approximately 73% of the ^{3}H-T and ^{3}H-DHT labeled cells in the MPN. The present results support the hypothesis that the AVPv and PvPO are preferentially activated by estrogen. Significantly, the MPNc, which is larger in males compared to females, and the MPNav, which is present only in males, appear to be preferential androgen targets. These findings are consistent with the possibility that estrogens and androgens have specific roles in the activation of sexually differentiated processes in the adult male rodent. Supported by NS 21220.

319.6 ESTRADIOL CONCENTRATION BY HYPOTHALAMIC AND LIMBIC NEURONS WHICH PROJECT TO THE MEDIAL PREOPTIC NUCLEUS. T.R. Akesson,[1] R.B. Simerly[2] and P.E. Micevych.[1] [1]Dept. of Anatomy and the Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024 and [2]Howard Hughes Medical Inst. and Salk Inst., La Jolla, CA 92138.

While connectivities of the steroid hormone-accumulating regions of the rat hypothalamus and limbic system have been extensively studied, reports identifying projections of steroid-concentrating cells within these regions are scarce. The medial preoptic nucleus (MPN), itself a major target of gonadal steroids, receives its strongest inputs from other steroid-accumulating regions including the encapsulated (medial) bed nucleus of the stria terminalis (BSTenc), medial nucleus of the amygdala (MeA), ventrolateral part of the hypothalamic ventromedial nucleus (VMHvl), arcuate nucleus (ARC), and amygdalohippocampal zone (AHZ), suggesting pathways which may be involved in the integration of steroid-activated events. In the male hypothalamus, a substantial portion of testosterone is aromatized and subsequently retained as estradiol (E). To determine the distribution and numbers of estrogen-concentrating neurons which are afferent to the MPN, we have combined the techniques of steroid autoradiography and retrograde tract-tracing (see Arnold, Brain Res., 194:210, '80).

Adult male Sprague-Dawley rats received iontophoretic injections of fluorogold (FG) centered in the medial part of the MPN. One week later they were castrated, and one week following castration, 150 µCi hexalabeled estradiol (New England Nuclear)/100 g body weight was infused i.v. over a 50 min. period. Rats were perfused transcardially with 4% paraformaldehyde and brains were processed using standard autoradiographic techniques. Every 4th section capturing the anterior-posterior extent of each nucleus in 3 animals was analyzed by counting all FG, E and double-labeled cells contained in a 220 µm² area/nucleus/section. A 3X background criterion was used to distinguish steroid concentration.

Nucleus	No. of sections	No. of E cells sampled	% labeled by FG ($\bar{X}$ ± SEM)
BSTenc	34	724	31.7 ± 3.7
MeA	46	621	31.6 ± 5.1
VMHvl	30	563	40.9 ± 10.8
ARC	57	722	13.3 ± 1.4
AHZ	30	609	52.8 ± 3.8

Thus, the medial MPN, in addition to having a high capacity to concentrate estrogen, is also a locus of converging projections from estrogen-binding cells distributed in widely divergent regions of the hypothalamus and limbic system. These results provide morphological support for the possibility of multiple sites of estrogenic regulation of a circuitry which mediates autonomic and reproductive functions ascribed to the MPN. (Supported by NS21220 to P.E.M.)

319.7 ESTROGEN/PROGESTERONE TREATMENT IN ADULTHOOD AFFECTS THE SIZE OF MEDIAL PREOPTIC (MPOA) STRUCTURES IN THE MALE RAT. G.J. Bloch* and R.A. Gorski (SPON: B.M. Wenzel). Dept. of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA Sch. of Med. L.A., CA 90024.

The volume of the sexually dimorphic nucleus of the preoptic area (SDN-POA) is greater in male than in female rats. Previous results suggested that males gonadectomized (Gx) for 2 weeks as adults and sacrificed after a single series of estradiol benzoate (EB) and progesterone (P) injections, had reduced SDN-POA volumes compared to those of rats Gx for 4 weeks, but not compared to rats Gx for 2 weeks (Gorski et al., Brain Res., 148, 333, 1978). Because we initially observed a significantly smaller SDN-POA in males Gx as adults, then treated with multiple injections of EB and P to assess lordosis behavior and LH release (positive feedback), we designed a study in which males were given the same regimen of multiple injections. 26 adult male Long-Evans rats were divided into 4 groups: intact,oil (n=6); Gx,oil (7); intact EB+P (6); and Gx,E+P (2 µg/day x 3) +P (500 µg 24 hours later) was started 35 days after Gx and was repeated 10 and 20 days later. After an additional 30 days, EB (30 µg) +P (2mg 73 hours later) was injected, and all animals sacrificed 3.5 to 4.5 hours after P. Gx EB+P males had significantly smaller SDN-POA volumes ($mm^3 x 10^{-3}$) than the other, normal sized groups (16.2±1.5 vs. 23.1±2.4 to 24.7±2.4). In order to characterize further the change in the MPOA, cytoarchitectonic analysis (Simerly et al., J. Comp. Neurol., 225, 151, 1984) was undertaken and revealed that Gx EB+P males had significantly smaller volumes of the medial division of the medial preoptic nucleus (MPNm): 148.7±6.1 vs. 177.8±6.7 to 197.4±6.0; and significantly larger volumes of the anteroventral preoptic nucleus (AVPv): 23.2± 1.8 vs. 16.2±0.7 to 16.6±1.2. The EB+P injections had no effect on the size of the central division of the medial preoptic nucleus (MPNc) or the suprachiasmatic nucleus. In addition, we drew a distinct, cell-dense region within the anteroventral MPNm, just posterior to the AVPv, which we have named the MPNav. This small group of cells was also significantly smaller in the Gx EB+P males (1.7±0.4 vs. 2.7±0.2 to 3.0±0.3) and was found to be virtually absent in females. For comparison, a group of 6 adult, intact Long-Evans females had the following volumes: SDN-POA, 11.3±1.3; MPNm, 90.2±3.5; MPNav, 0.2±0.2; and AVPv, 27.5±2.3. We conclude that treatment of adult Gx male rats with EB+P can cause significant changes in the size of MPOA structures. These changes are all in the female direction: smaller SDN-POA, MPNm and MPNav volumes although not as small as those of females, and a larger AVPv volume which is comparable to that of females. Because intact EB+P males were not different from intact or Gx oil groups, testicular hormones appear to "protect" these structures from the effects of EB+P. (Supported by HD-01182 and HD-7228.)

319.8 DISTRIBUTION OF NEUROPEPTIDES IN THE HYPOTHALAMUS OF GROUND SQUIRRELS. S.Reuss*, J.C. Speh*, E.C. Hurlbut*, R.Y. Moore (Spon: J.D. White). Depts. of Neurology and Neurobiology and Behavior, SUNY, Stony Brook, NY 11794 and Dept. of Biological Sciences, Mesa College, Grand Junction, CO 81501.

We report the immunohistochemical identification of several neuropeptides in the neurosecretory hypothalamic nuclei in the brain of two species of ground squirrels, Spermophilus tridecemlineatus and Sp. richardsonii. Adult animals, originally wild caught, were housed under LD for several months. At time of sacrifice, animals had been in induced hibernation for two months. Thirteen ground squirrels of both sexes (b.wt. 300-500 g) were perfused with periodate-lysine-paraformaldehyde fixative. Brain regions between the optic chiasm and the median eminence were sectioned at 40 um in the coronal plane and either stained with cresyl violet or incubated for immunohistochemical localization of oxytocin (OXY), vasopressin (VP), vasoactive intestinal polypeptide (VIP), corticotropin releasing factor (CRF) or neuropeptide Y (NPY). Immunoreactivity was visualized using the avidin-biotin-peroxidase method.

The light microscopical evaluation revealed no differences in the organization of immunoreactive cells and fibers between the species and, in addition, no sex-specific differences were noted.

The supraoptic nuclei (SON) contain a dense distribution of cells and fibers displaying VP-like immunoreactivity (VP-LI) as well as OXY-LI. In addition, NPY-LI fibers with varicosities and terminals are seen in the SON region. The nucleus supraopticus diffusus, the medially situated continuation of the bilateral SON, exhibit VP-LI and OXY-LI cells and fibers.

The paraventricular nuclei (PVN) exhibit heavily stained cells and fibers displaying VP- and OXY-LI. In addition, weak CRF-LI in cells is observed.

In the suprachiasmatic nuclei (SCN), a few cells (mainly in the ventral third of the nuclei) exhibit VIP-LI. Fibers showing VIP-LI and NPY-LI are found throughout the SCN region, while VP-LI fibers are present mainly in the dorsomedial part, extending caudally into the dorsal projection of the nucleus. VP-LI cells were not detected.

The lateral hypothalamic area (LHA) displays VP-LI and OXY-LI cells as well as fibers reaching the PVN and the SON. NPY-LI cells were seen only in the arcuate nucleus. Furthermore, fibers in the median eminence exhibit strong VP-, CRF- and OXY-LI.

This study was supported by NIH NS16304 to RYM.

319.9 THE DISTRIBUTION PATTERN OF NADPH DIAPHORASE REACTIVE NEURONS IN THE HYPOTHALAMUS: A STUDY IN CATS AND RHESUS MONKEYS. Haitao Hu*, Jayashree K. Rao*, and A. Jayaraman. Depts of Neurology and Pediatrics, Louisiana State University School of Medicine, New Orleans, LA 70112.

The enzyme nicotinamide adenine dinucleotide phosphate diaphorase (NADPH diaphorase) is found in specific subpopulation of cells of the central nervous system. In many areas of the CNS, these neurons also contain neuropeptide Y and somatostatin. Cells with NADPH disphorase are specifically spared in Huntington's disease and are resistant to destruction by several neurotoxins. A study was initiated to map in detail, the pattern of distribution of cells with NADPH diphorase in the CNS of cats and monkeys. This report discusses the distribution pattern of these neurons in the hypothalami of cats and monkeys. Five adult cats and four rhesus monkeys were sacrificed with a solution of 4% paraformaldehyde in phosphate buffer. The brains were cut into 40u thick sections and these sections were processed for NADPH diaphorase histochemistry (Sandell et al., '86). The results show that cells with NADPH diaphorase activity were most prominent in the anterior, middle and caudal levels of the lateral hypothalamus, dorsolateral hypothalamus in an area adjacent to zona incerta, the paraventricular nucleus and in the rostral areas of the anterior hypothalamus. Caudally NADPH diaphorase reactive cells were numerous in the posterior hypothalamus, supramamillary decussation and tuberomamillary nucleus. The dorsomedial and ventromedial nuclei and the anterior supraoptic nucleus also showed moderate number of cells with NADPH diaphorase activity. Only scattered cells with NADPH diaphorase activity were noted in the medial and lateral preoptic region. The infundibular, the suprachiasmatic and the mamillary nuclei were free of NADPH diaphorase reactive neurons. The pattern of distribution of these cells were similar in cats and monkeys. Further details of the colocalization pattern and the mechanisms underlying the survival of cells with NADPH diaphorase activity may contribute to our understanding of the pathogenesis of progressive neurologic deficits and/or the potential contribution to the clinical syndrome by the surviving neurons which contain NADPH diaphorase activity. Supported by the Scottish Rite Schizophrenia Research Program.

319.10 THE MORPHOLOGY OF PARAVENTRICULAR NEURONS CHARACTERIZED BY INTRACELLULAR FILLING OF NEURONS IN FIXED TISSUE SLICES. J.-H. Rho and L.W. Swanson. The Salk Institute, La Jolla, CA 92037.

The paraventricular nucleus of the hypothalamus (PVH) coordinates a wide range of neuroendocrine and autonomic functions. Anatomical studies using immunohistochemical and retrograde axonal transport methods have previously divided this nuclei into several distinct compartments, showing that largely separate populations of neurons project to the median eminence, posterior pituitary, and brainstem/spinal cord. To characterize morphologically different cell types contained within various subdivisions of the PVH, we have utilized a novel intracellular dye-filling method to first retrogradely label distinct subpopulations of neurons and then to iontophoretically inject lucifer yellow (LY) into labeled neurons. Using two different fluorescent tracers, fast blue (FB) injected into the blood, and fluorogold (FG) placed in the spinal cord, neuroendocrine cells, which are localized mostly in the dorsal medial parvocellular (PVHmpd) and magnocellular parts, were distinguished from autonomic neurons, which are localized mostly in the dorsal cap and ventral medial parvocellular parts (PVHmpv). After neurons were injected with LY, their morphological features were drawn with the aid of a computer-based graphics systems.

Neuroendocrine cells, some of which were immunostained with anti-CRF, were usually bipolar with thick proximal dendrites that tapered distally. Dendritic spines were sparse along their dendrites, which usually branched once near the soma and once again near their distal tips. The dendrites of parvocellular neurons in the PVHmpd appeared to be mostly restricted to this part while the dendrites of neuroendocrine neurons in the magnocellular subdivision often extended medially and ventrally beyond its boundaries. Local terminal boutons or short appendages were seen on the axons of neuroendocrine CRF cells in the region just outside the PVH where many GAD-positive neurons are found. In contrast, autonomic neurons were usually multipolar with 3 to 5 dendrites extending from the soma, and were of either the spiny and aspiny type. The spiny cell type was less frequent and several were found in areas ectopic to the dorsal cap and PVHmpv. Many long spines were distributed along the length of its major dendrites, which gradually tapered and extended for 300-400 microns from the cell body. The dendrites of aspiny neurons, on the other hand, were often highly branched, and of uniform thickness; they extended for considerable distances, and in many cases, crossed beyond the boundaries of their cytoarchitectonically-defined cell group. Further mapping of dendritic territories, and a correlation with the localized distribution of the many afferent inputs to the PVH will be necessary to gain an accurate understanding of neuronal information flow through the PVH.

319.11 DISTRIBUTION OF CHOLECYSTOKININ AND METHIONINE-ENKEPHALIN IN THE PREOPTIC AREA AND ANTERIOR HYPOTHALAMUS OF THE BRAZILIAN GRAY SHORT-TAILED OPOSSUM. G.E. Hoffman, C.A. Fox*, T. Larsen*, R.E. Watson, Jr. and C.D. Jacobson. Dept of Neurobiology and Anatomy, Univ. of Rochester School of Medicine, Rochester, N. Y. 14642 and Dept. of Veterinary Anatomy, Iowa State Univ., Ames, Iowa 50011.

The Brazilian gray short-tailed opossum, Monodelphis domestica, is a small, pouchless, marsupial which breeds well under lab conditions. The young are born after a 14 day period of gestation in a sexually undifferentiated immature state and are well suited for developmental studies. Prior to characterizing the developmental patterns associated with the localization of peptide neurotransmitters in the medial preoptic area (MPOA) and anterior hypothalamus (AH), the patterns of the adult animal must be identified. In this study, brains of adult male and female opossums were processed for localization of methionine-enkephalin (m-ENK) and cholecystokinin (CCK) like immunoreactivity. Animals were ether anesthetized and perfused intracardially with saline followed by Zamboni's fixative. Each brain was removed and processed for the immunocytochemical localization of m-ENK and CCK using the avidin-biotin with nickel intensification technique (Watson et al., Peptides 7, 1986; Hancock, M., J. Histochem. Cytochem. 32, 1984). Sections of the MPOA and AH were obtained using a freezing microtome. Antiserum to rabbit CCK and rabbit m-ENK were obtained from Immunonuclear. The results indicate that CCK like immunoreactivity is present in the MPOA and AH. The MPOA contains a light to moderately staining CCK fiber plexus which lies adjacent to the third ventricle. In addition, CCK containing fibers appear to be distributed throughout the paraventricular nucleus (PVN) and the supraoptic nucleus (SON). There is also a dense plexus of CCK positive fibers within the suprachiasmatic nucleus (SCN). M-ENK is distributed throughout the MPOA and AH. In the MPOA there is a wide band of m-ENK positive fibers adjacent to the third ventricle. This dense plexus of fibers follows the boundaries of the MPOA. In the AH m-ENK like immunoreactivity is located adjacent to the third ventricle. There is a dense fiber plexus located within the PVN. However, there is an apparent lack of m-ENK containing fibers within the SON and SCN. These results indicate that the localization patterns of CCK and m-ENK are similar to those observed in the rat and further support the use of this animal in studies investigating development and differentiation of the MPOA and hypothalamus. Supported by NIH grants HD 16148 and 18418 and NS 93625.

319.12 THE ORGANIZATION OF MESENCEPHALIC AND PONTINE AFFERENTS TO THE PARAVENTRICULAR AND SUPRAOPTIC NUCLEI IN THE RAT. M.C. Levin*, E.T. Cunningham, Jr. and P.E. Sawchenko (SPON: S.P. Duckles), The Salk Institute, and Dept. of Neurosci., Univ. Cal. San Diego, La Jolla, CA 92037.

Retrograde and anterograde tracing techniques were used to characterize the distribution and cells of origin of projections from the midbrain and pons to the paraventricular (PVH) and supraoptic (SO) nuclei of the hypothalamus in the rat. After discrete crystalline implants of the retrogradely transported fluorescent dye, True Blue, into the PVH, one group of labeled neurons comprised a continuous thin sheet of cells corresponding to descriptions of a so-called parvocellular part of the subparafascicular nucleus. In addition, labeled neurons were found throughout the longitudinal extent of the central gray, and were especially prominent in its dorsal and ventrolateral aspects. More discrete clusters of retrogradely labeled cells were found in the peripeduncular nucleus, the pedunculopontine nucleus, the lateral dorsal tegmental nucleus, the lateral parabrachial nucleus, the nucleus incertus, the locus coeruleus, the mesencephalic raphe nuclei, and in discrete aspects of the mesencephalic and pontine central tegmental fields. With the exception of the aminergic cell groups, whose projections have been characterized previously, deposits of the anterogradely transported plant lectin, Phaseolus vulgaris-leucoagglutinin (PHA-L), were placed in each of the regions enumerated above. The results confirmed the existence of projections from each region to the PVH, where each of the inputs ramified and gave rise to terminal specializations primarily within the parvocellular division of the nucleus. Only the pedunculopontine and lateral dorsal tegmental nuclei were found to provide projections that ended decisively in the magnocellular division of the PVH and in the SO, though these inputs to the magnocellular neurosecretory system were of only sparse to moderate density. The PHA-L material also revealed a surprising number of pathways interconnecting many of the mesencephalic and pontine cell groups that were found to provide afferent projections to the PVH and SO. The results provide new information concerning potential routes by which visceral sensory information conveyed initially to the nucleus of the solitary tract may reach, and be distributed to, autonomic- and neuroendocrine-related effector neuron populations in the PVH and SO. By contrast, no discrete cell group was identified that might serve as a relay through which somatic sensory information subserving the milk ejection reflex might be conveyed to oxytocin-containing magnocellular neurosecretory neurons.

Supported by NIH Grant HL-35137 and a McKnight Foundation Scholar's award.

319.13 MAMILLARY, SUPRAMAMILLARY AND TUBEROMAMILLARY NUCLEI: CONNECTIONS WITH INFRALIMBIC CORTEX IN RAT. G.V. ALLEN* and D.A. HOPKINS. Dept. of Anatomy, Dalhousie University, Halifax, N.S., Canada, B3H 4H7.

The mamillary, supramamillary and tuberomamillary nuclei form a complex of nuclei in the posterior hypothalamus. Although these nuclei are usually considered to be components of distinct and separate neural systems, there is evidence that they may have some connections in common with the infralimbic cortex and brain stem tegmentum.

In order to investigate further the afferent and efferent connections of these nuclei with the cortex, injections of 0.01-0.02 µL of WGA-HRP were made into the infralimbic cortex and posterior hypothalamus. Following 1-2 day survival periods, the animals were perfused for light and electron microscopy with a buffered aldehyde fixative. For light microscopy, frozen sections were incubated for HRP reaction product with tetramethylbenzidine (TMB). Vibratome sections were incubated in TMB and diaminobenzidine prior to processing for electron microscopy.

At the light microscopic level, infralimbic cortical injections of WGA-HRP produced retrograde and anterograde labeling in the supramamillary and tuberomamillary nuclei, predominantly ipsilaterally. Dense anterograde labeling was also present in the dorsal parts of the medial mamillary nucleus, especially the medially located pars medianus. Following injections of WGA-HRP into the mamillary region, retrograde labeling was seen in the infralimbic cortex. At the electron microscopic level, labeled axon terminals were observed in the mamillary, supramamillary and tuberomamillary nuclei. Labeled terminals contained round synaptic vesicles and formed mainly asymmetric synaptic junctions with dendritic profiles. Labeled terminals were not observed in synaptic contact with neuronal somata. Label was present in somata and dendrites of the tuberomamillary and supramamillary nuclei.

The results demonstrate that the mamillary, supramamillary and tuberomamillary nuclei have complex synaptic relations with the infralimbic cortex. In particular, parts of the medial mamillary nuclei receive selective inputs to certain subdivisions from cortex (infralimbic and subicular) and brain stem tegmentum. In addition, the supramamillary and tuberomamillary nuclei appear to be reciprocally connected with the infralimbic cortex.

Supported by MRC of Canada.

319.14 **MAGNOCELLULAR TUBEROMAMMILLARY (TM) NEURONS PROJECT TO BOTH PARTS OF THE RAT SUPRAOPTIC NUCLEUS.** G.I. Hatton, Q.Z. Yang, and M.L. Weiss. Neuroscience Program, Michigan State Univ., E. Lansing, MI 48824-1117.

Supraoptic (SON) neurons are known to be affected by histamine stimulation, both in vivo (Brain Res. 78:151, '74) and in vitro (Neuroscience 16:307, '85) but the origin of an endogenous histaminergic input is unknown. The TM neurons are one possible source of histaminergic input (Handbook of Chemical Neuroanatomy, vol. 3: 126, '84) and retrograde tracing data suggest that TM may project to SON (Neurosci. 15:135, '85). As part of our studies of SON inputs, we made micropressure injections of fluorescent tracers (Fluoro-gold, 1-2% in distilled water, supplied by L.Schmued; or rhodamine-labeled microspheres, Tracer Technology, Bardonia, NY) into the SON. We noted that injections of tracer into the anterior (SONa) or the tuberal SON (SONt) labeled areas known to project to the SON (JCN 218: 121, '83; Neurosci. 15:135, '85), and resulted in retrogradely labeled cells within TM both ipsilateral and contralateral to injection site. Light fiber labeling was sometimes seen in the supraoptic decussation. Injections into SONt resulted in notably more cells labeling in the contralateral TM than after injections into SONa. Since the SONt contains a higher percentage of vasopressin producing neurons than the anterior portion, this suggests that TM neurons may show specificity. To confirm this projection, we have begun to investigate this pathway electrophysiologically in the in vitro horizontal slice preparation, which contains the TM and both parts of the SON. Intracellular recordings from cells in SONt (n=1) and SONa (n=2) show short latency excitatory responses (2-4 ms for SONa and shorter latency for SONt) to constant current stimulation (bipolar stimulating electrode, evoked by currents as low as 50 nA) of the area containing TM ipsilaterally. These cells were subsequently injected with Lucifer Yellow and will be immunocytochemically identified for peptide content. Further work is needed to confirm the amine content of TM neurons projecting to SON and to examine the contralaterally projecting TM cells. Supported by NIH grant NS 16942 and NS 09140 and NRSA Postdoctoral grant NS 08125 to MLW.

319.15 **FLUORESCENT TRACER INJECTIONS INTO PARAVENTRICULAR (PVN) AND SUPRAOPTIC (SON) NUCLEI DOUBLE LABELS NEURONS WITHIN SUBFORNICAL ORGAN (SFO) OF THE RAT.** M.L. Weiss and G.I. Hatton. Neuroscience Program, Michigan State University, E. Lansing, MI 48824-1117.

We hypothesized that single neurons in the SFO, nucleus medianus (NM) and organum vasculosum lamina terminalis (OVLT) would terminate on both the PVN and SON nuclei via collateral innervation, since these nuclei are midline structures and project to both PVN and SON. Thus, we injected anesthetized rats (Equithesin) with one of the two tracers: Fluoro-gold (1-2% in water; supplied by L. Schmued) or rhodamine-labeled microspheres into the PVN and the other tracer into SON of male rats. These tracers are not taken up by fibers of passage, they resist fading and they do not leach out of retrogradely filled neurons to label surrounding glia. Survival after injection ranged from 3-7 days, at which time animals were anesthetized and perfused with normal saline then 4% neutral buffered paraformaldehyde. Brains were frozen sectioned at 50 um and arranged in three adjacent sets consisting of every third section. One set was counterstained, a second was cleared in xylene and coverslipped for epifluorescent observation, the third set was reserved as backup. To date we have injected 27 rats, 2 animals had injections which were well-confined to the anterior SON but the PVN injections had slightly spread to include the zona incerta and reuniens nucleus of the thalamus. These two cases had retrogradely filled neurons within areas known to project to PVN and SON (JCN 218:121,'83; Brain Res.Bull.14:143,'85). We found many singly labeled cells within SFO, NM and a few within the core of OVLT. Doubly labeled cells (doubles) were found predominantely within the anterior ventral portion of the SFO within cells which were not brightly labeled. Brightly labeled cells tended to contain a single label, but they could be found adjacent to doubles. From the most anterior ventral portion of SFO through its middle (approx. 150 um caudad), the doubles tended to be clustered together along the edges of the nucleus. We plan to further confine our injections and to provide a more complete mapping of the distribution of doubles throughout the brain, especially the caudal brainstem. Supported by NRSA Postdoctoral award NS 08125 to MLW and NIH grant NS 09140.

319.16 MICROINJECTION OF KAINIC ACID INTO THE VENTRAL MEDIAL NUCLEUS OF THE HYPOTHALAMUS PREVENTS MURICIDAL BEHAVIOR IN RATS. D.M. Meenan* and C.F. FERRIS. Department of Physiology, University of Massachusetts Medical Center, Worcester MA. 01655.

It has been shown by numerous investigators that large electrolytic lesions to the posterior hypothalamus can prevent muricidal behavior in rats. The purpose of the present study was to examine mouse killing in rats following placement of discrete lesions in the hypothalamus by the microinjection of small volumes (20 nanoliters) of the neurotoxin kainic acid. Long Evans rats (n=26) were anesthetized with pentobarbital and stereotaxically implanted with 26-gauge guide cannulae aimed at the ventromedial nucleus (VMN) or the paraventricular nucleus (PVN). All rats were individually housed and maintained on a 14:10 L:D cycle for 18 days. Muricidal behavior was tested by placing a 6-8 week old mouse in the home cage of a rat for 60 min. Rats were considered to be spontaneous mouse killers if, over three consecutive days, they killed the mouse within 10 min after being placed in their cage. After the muricidal behavior was determined rats were unilaterally microinjected with 0.1 µg of kainic acid in a volume of 20 nanoliters. Four days later rats were sacrificed, the brains fixed, histologically processed and examined for the location of the lesions using the stereotaxic atlas of Konig and Klippel. Out of the total 26 rats only 5 displayed altered behavior in response to the kainic acid lesions. Four rats were prevented from killing while one rat which had not shown muricidal behavior killed its mouse. The four rats prevented from mouse killing had lesions in the VMN and/or the ventral portion of the the dorsal medial hypothalamus. The one rat that displayed muricidal behavior in repsonse to the microinjection of kainic acid had a lesion that was medial to the DMH and dorsal to the VMH. The remaining 21 rats had lesions in the posterior hypothalamus (n=3), PVN (n=5), fornix (n=3), basal stria terminalis (n=2), nucleus reuniens thalami (n=4), anterior hypothalamus (n=1), and stria terminals (n=2). These data suggest that discrete chemical lesions in the area of the VMH can alter muricidal behavior. (Supported by NIH grant NS-23557)

319.17 Hypothalamic tanycytes and brainstem neurons identified by monoclonal antibody 3D10. S.A. Tobet, D. Blank*, and T.O. Fox, Dept. Biochemistry, E.K. Shriver Center, Waltham, MA 02254 and Prgm. Neuroscience, Harvard Medical School, Boston, MA 02115

To examine the regulation of hypothalamic development, we are using monoclonal antibodies obtained after immunizations with neonatal rat brain. Some of the antibodies obtained recognize particular neural elements that are distributed widely throughout the neuraxis while others are restricted to certain cell groups. One especially selective antibody, 3D10, binds to one cell type in the hypothalamus (HYP) and selected cell groups in the brainstem.

For immunizing BALB/c mice, the HYP and temporal lobe (TL) were removed from neonatal rats (postnatal day 4: P4), homogenized in saline, and injected i.p. Three days after the second immunization spleens were removed and fused with NS-1 myeloma cells. Supernatants from hybridoma cells were screened immunocytochemically on 20 micron sagittal sections from P4 rat brains. Further characterization of 3D10 immunoreactivity was carried out using free-floating 50 micron tissue sections from neonatal rats that were perfused with saline followed by 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.4). Using HRP-conjugated secondary antibodies (anti-IgM), 3D10 antigen(s) were visualized as 3,3'-diaminobenzidine reaction product.

The 3D10 immunoreactivity appeared intracellularly in restricted populations of cells. In the HYP, reaction product was seen in subsets of tanycytes (TYs), with the greatest number around the organum vasculosum of the lamina terminalis (OVLT) and in the region of the median eminence. Immunoreactive product was apparent throughout the entire length of individual TYs. In brainstem intense staining occurred in a subset of locus ceruleus (LC) perikarya and in cells that appear to be part of the A5 noradrenergic cell group. Lower levels of immunuoreactivity were also seen in neurons of the raphe nuclei.

The selectivity of 3D10 for TYs in the third ventricle and for LC raises the possibility that the coincident immunoreactivity in these cells results from transport of molecules secreted into the cerebrospinal fluid (CSF). It has been proposed that tanycytes transport substances from the CSF; in addition, the LC lies directly adjacent to the fourth ventricle, with some processes reaching the ventricular surface. Alternately, these selected cells might synthesize a common epitope. Experiments are underway to characterize the 3D10 antigen(s) biochemically and to test these hypotheses. Supported by NIH Research Grant HD-20327, Training Grant HD-07251, and MR Core Grant HD-04147.

319.18 **INTRACELLULAR RECORDINGS OF THERMOSENSITIVE NEURONS IN RAT HYPOTHALAMIC TISSUE SLICES.** M.C. Curras, S.R. Kelso and J. A. Boulant. Department of Physiology, Ohio State University, Columbus, OH 43210; and Department of Biological Sciences, University of Illinois, Chicago, IL 60680

Rostral hypothalamic neurons are considered important in thermoregulation. About 40% of these neurons are sensitive to hypothalamic temperature, and many of these thermosensitive neurons receive afferent input from peripheral thermoreceptors. To understand the basis of neuronal thermosensitivity, 3 M KCl or K acetate microelectrodes were used to study the effect of temperature on intracellular activity recorded from neurons in frontal tissue slices of the rat hypothalamus. This study only includes neurons showing stable membrane potentials of at least -45 mV and action potentials in response to depolarizing pulses. Determinations were made of the effects of temperature on firing rates, resting membrane potentials, input resistances, and postsynaptic potentials. Most neuronal activity was recorded in the preoptic area and anterior hypothalamus while tissue temperature was changed 3-5°C above or below 37°C. Neurons were classified as warm-sensitive, cold-sensitive or temperature-insensitive based on their firing rate responses to tissue temperature. A subpopulation of the temperature-insensitive neurons included "silent" neurons which produced no spontaneous action potentials, regardless of temperature.

At neutral temperatures (35.8°-37.6°C), hypothalamic neurons had a mean resting membrane potential of -65 mV and a mean input resistance of 167 megohms. Regardless of thermosensitivity, most neurons showed an increase in input resistance during decreases in tissue temperature. Some warm-sensitive and cold-sensitive neurons displayed ramp-like depolarizations preceding action potentials. In both types of thermosensitive neurons, these ramp-like depolarizations and the frequency of action potential generation were greatly affected by inhibitory and excitatory postsynaptic potentials, suggesting that synaptic networks are important determinants of hypothalamic neuronal thermosensitivity.

(Supported by grants from NIH, NSF and AHA.)

319.19 OSMOSENSITIVITY IN BRAIN SLICES: HYPOTHALAMUS AND HIPPOCAMPUS. R.D. Andrew, B.A. Ballyk and M. Fagan. Anatomy Dept., Queen's University, Kingston, Ontario K7L 3N6

In the intact rat, a 5 - 50 milliosmole (mOsm) increase in plasma osmolarity increases the firing rate of magnocellular neuroendocrine cells (MNCs). These cells synthesize oxytocin or vasopressin in the paraventricular nucleus and supraoptic nucleus (SON) of the hypothalamus and release them from axon terminals in the neurohypophysis. Osmosensitivity is apparently retained but reduced in coronal hypothalamic slices. It has been suggested that increased excitatory synaptic traffic plus an intrinsic depolarization of the MNC itself accounts for MNC osmosensitivity (Leng et al., 1985, Vasopressin p. 333).

Our extracellular recordings from SON revealed that 60% of rat MNCs (n=12) and 42% of cat MNCs (n=36) became more excitable during a 65 mOsm increase of the superfusing solution. Paradoxically, 7 of 7 MNCs tested also displayed an increase in the orthodromic spike threshold evoked 0.5 mm dorsal to SON during this large increase in osmolarity. This unexpected reduction in excitability was further examined in the hippocampal slice preparation.

Population potentials recorded in the stratum pyramidale of CA1 were evoked antidromically from alveus or orthodromically from CA3. Over 5 min, a 35 mOsm increase by addition of NaCl reduced the antidromic population spike by 31% and the orthodromic spike amplitude by 29% (n=8). With a 65 mOsm increase, the reduction was 40% and 66%, respectively (n=7). With an intermediate 52 mOsm increase using mannitol, the reduction was 35% and 36%, respectively (n=9). All of these responses were reversible. Intracellular recordings from CA1 neurons revealed that, although the action potential threshold usually did not increase, the amplitude of the compound EPSP (evoked at a level straddling spike threshold) was reduced in 10 of 11 cells. Each of these changes in hippocampus elicited by raising the osmolarity may be explained by an increase in threshold of the conducted action potential along CA1 and CA3 axons. Whether synaptic transmission itself is also affected requires further study.

In conclusion, when the osmolarity of the superfusate increases, there is an apparent increase in the threshold of the conducted action potential as gauged from evoked antidromic and orthodromic field potentials of CA1 cells. In hypothalamic slices, a similar effect on neurons presynaptic to MNCs could explain why evoked orthodromic input to MNCs is reduced as the osmolarity increases.

319.20 ELECTROPHYSIOLOGICAL EXAMINATION OF NEURONS IN THE BED NUCLEUS OF THE STRIA TERMINALIS: CHARACTERISTIC PROPERTIES AND RESPONSES TO AMYGDALOID AND HYPOTHALAMIC STIMULATION. M. Dalsass and A. Siegel. Neurology, VA Medical Center, East Orange, NJ 07019, and Dept. of Neurosciences, New Jersey Medical School, Newark, NJ 07103.

The bed nucleus of the stria terminalis (BNST) can powerfully modulate such emotional forms of behavior as quiet biting attack, affective defense and flight behavior. Several of the possible anatomical pathways associated with these BNST elicited behaviors have been described. The BNST receives major inputs from the amygdala and hypothalamus and in turn, projects its axons, in part, to the hypothalamus, midbrain periaqueductal gray matter and the nucleus of the solitary tract, target structures that play key roles in the regulation of emotional behavior and autonomic nervous system function. Little is presently known about the electrophysiological properties of the BNST or of the possible role it may play as an integrative structure for amygdaloid and hypothalamic inputs.

Rats were anesthetized with chloral hydrate and stimulating electrodes were placed in the medial amygdala, lateral amygdala and hypothalamus. Glass micropipettes (5-40 mohms), filled with 2M K citrate and fast green dye, were used for extracellular recording in the BNST.

BNST neurons typically showed slow (2.8±2.4 HZ; mean ± SEM) spontaneous firing rates and relatively long duration (2.2±0.37 msec; mean ± SEM) action potentials. They could be orthodromically activated from one or more stimulating sites with latencies of 7 to 14 msec. In addition, the BNST appears to be organized so that the amygdaloid and hypothalamic inputs show increasing convergence along its dorsal to ventral extent. Some neurons were also antidromically activated from sites in the hypothalamus and basolateral amygdala with latencies of 4 to 7 msec. Their slow conduction velocity (0.65 m/sec) indicates that these neurons are unmyelinated. The results show that: 1) most BNST neurons have characteristic neuronal features with regard to spontaneous discharge rate and spike duration, 2) BNST neurons can be antidromically activated from sites in the amygdala and hypothalamus, and 3) the majority of BNST neurons respond orthodromically to stimulation from these sites, with the greatest convergence occurring near the ventral border. The results suggest that the ventral aspect of the BNST may play an important role in integrating inputs from the amygdala, hypothalamus and brainstem.

FEEDING AND DRINKING VI

320.1 THE FAILURE OF PERIPHERAL BUT NOT CENTRAL ANGIOTENSIN II RECEPTOR BLOCKADE TO REDUCE SALT APPETITE IN THE RAT. A.N. Epstein, S.Y. Chow*, R.R. Sakai* and D.A. Wilson*. Univ. of Pennsylvania, Dept. of Biology and Psychology, Phila. Pa. 19104 USA

The salt appetite of the sodium deplete rat is completely suppressed by concurrent central blockade of angiotensin II (ANG II) and aldosterone (ALDO) receptors (Sakai et al, AJP 1986). Central blockade of only one of these hormones causes only a partial reduction of the salt appetite, supporting our earlier idea that the hormones of sodium conservation act synergistically to arouse salt appetite in the rat. Here we examine whether ANG II of renal or of central origin is the important synergist.

Rats were fitted with either an intracerebroventricular (ICV) cannula (n=6) or an intravenous (IV) jugular catheter (n=6) and were sodium depleted by combining natriuresis (furosemide, 10 mg/rat, SC) with removal of ambient sodium. At least 18 hours after the beginning of the depletion 3% NaCl was returned for 2 hours and the rats were free to express a salt appetite.

Peripheral ANG II receptors were blocked in sodium depleted rats by continuous IV (cIV) infusion of the ANG II receptor antagonist SARILE (SAR-1, ILE-8 ANG II) at a dose of 10 ug/min beginning two hours before and continuing during the two hour access to 3% NaCl. There was no suppression of 3% NaCl intake by the end of the 2 hour access period (veh infusion 9.6 ± 2.9 ml; SARILE 10 ug/min 9.8 ± 2.6 ml) despite the blockade of peripheral ANG II receptors as shown by the failure of cIV ANG II (64 ng/min for 15 minutes) to evoke water drinking at the end of the appetite test.

In contrast, central blockade of ANG II receptors (continuous ICV SARILE, 25 ug/hr, 2 hrs before and during the 2 hr appetite test) reduced salt appetite (veh vs SARILE; 6.3 ± 0.8 ml vs 4.3 ± 0.7 ml at 30 min; veh vs SARILE; 8.0 ± 0.7 ml vs 6.3 ± 0.5 ml at 120 min), and blocked water drinking to a pulse ICV injection of ANG II (6 ng) at the end of the two hour appetite test.

The failure of peripheral but not central blockade of ANG II receptors to reduce depletion-induced salt appetite suggests 1) the activation of peripheral ANG II receptors is not necessary for the expression of depletion-induced salt appetite whereas activation of central ANG II receptors is important for expression of the behavior, and 2) the role of peripheral ANG II may be to evoke the release of aldosterone which then a) promotes renal sodium conservation and b) participates in the synergy with ANG that leads to arousal of salt appetite.

320.2 **SALT APPETITE AND EXCRETION TO VENTRICULAR ANGIOTENSIN: FOREBRAIN OR HINDBRAIN?** D.A. Fitts and D.B. Masson* (SPON: G. Clark). Univ. of Wash., Seattle, WA, 98195.

Angiotensin II (ANG) infusion into the anterior cerebral ventricles causes drinking of both water and NaCl solutions in rats. The site(s) of action for the effect on water intake is near the anterior ventricles, because large doses of ANG injected into the fourth ventricle (4V) have no effect. However, chronic infusions of ANG into the area postrema (AP) or 4V reportedly increase daily intake of 0.15 M NaCl, suggesting that forebrain infusions of ANG might cause NaCl intake by ANG traveling to the 4V.

The present experiments tested infusions of 0, 10, 100, or 1000 pmol/h ANG in the 4V for 3 h in an effort to stimulate salt drinking. Rats received one 4V infusion at 4.6 µl/h in the presence of both water and 0.3 M NaCl for drinking. Urine was analyzed for Na, K, and osmolality. Other rats with cannulas in the lateral ventricles (LV) received an infusion of 0 or 100 pmol/h ANG at the same volume under the same conditions.

Nine vehicle-infused rats with 4V or LV cannulas drank 0 to 2.5 ml of water or NaCl in 3 h. Nine rats with verified 4V cannulas all drank similar amounts of water and NaCl to these controls regardless of the dose of ANG. By contrast, 5 rats receiving 100 pmol/h ANG in the LV rapidly drank both water and NaCl, averaging 23 ml water and 11 ml NaCl in 3 h. No rat given any dose of ANG into the 4V drank as much water or NaCl as the least rat infused into the LV.

Excretion of Na, K, and total solutes were unaffected by infusions of ANG into the 4V, even at the very large dose of 1000 pmol/h. Infusions of 100 pmol/h ANG into the LV of animals not allowed to drink Na more than doubled Na excretion over 2-4 hr.

Na ingestion and excretion were unaffected by ANG infusions into the 4V, but ANG in the LV dramatically increased both. Thus, these effects of short term ANG infusions into the anterior ventricles are not caused by posterior travel of the infusate. Our results do not necessarily refute findings of increased NaCl drinking by 4V and AP infusions because of large differences in the methodologies of the two studies.

320.3 THE CENTRAL VASOPRESSIN AND/OR OXYTOCIN SYSTEMS MAY BE NEURAL SUBSTRATES FOR THE REGULATION OF SODIUM APPETITE. K.A. Gruber*, S.L. Eskridge*, and M.F. Callahan (SPON. M. Levitt). Wake Forest University Medical Center, Winston-Salem, North Carolina 27103.

Sodium (Na) appetite can be produced by Na depletion (e.g. diuretics), by other treatments which disrupt fluid/electrolyte balance, or by stress. Angiotensin II (A-II) and aldosterone (ALDO), a mineralocorticoid, are two hormones whose circulating levels are increased by Na depletion. Exogenous administration of A-II or ALDO produces Na appetite, and simultaneous administration results in a potentiated effect. Attenuation of diuretic-induced Na appetite can be produced by A-II or mineralocorticoid receptor antagonists. Since intracerebroventricular (ICV) administration of A-II or ALDO receptor antagonists are more effective in attenuating Na appetite than peripheral administration, a central site-of-action is indicated (Sakai et al A.J.P. 251:R762, 1986). Recently, atrial natriuretic peptides (ANP) have also been shown to attenuate Na appetite. Despite the demonstration of numerous substances or states which regulate Na appetite, a common neural substrate(s) responsible for these effects has not been identified.

We have recently shown that activation of the central vasopressin (VP) or oxytocin (OX) systems are common pathways for centrally acting factors to increase sympathetic drive (e.g. Gruber and Eskridge A.J.P. 251:R476, 1986). Activators of VP or OX neurons include A-II, ALDO, hypertonic saline, and stress; while A-II receptor antagonists and ANP are inhibitors. Thus, there appear to be parallels between VP/OX neuron regulation, and regulation of Na appetite. To address the question of the role of the central VP and/or OX sytem in Na appetite, we measured diuretic-induced Na appetite in rats after blockade of CNS V_1 VP/OX receptors.

Rats were given access to water and 3% saline for 48 hours. The saline was removed, each rat given 2 X 15 mg injections of furosemide 3 hours apart, and a low sodium chow was provided. Twenty hours later food and water were removed, and the rats given ICV infusions of Earles balanced salts solution (EBSS) or a V_1/OX receptor antagonist (100 ng/0.5 ul/min for 30 min). No behavioral effects of the antagonist infusion were noted. The infusion was stopped, and solutions of fresh water and 3% saline were again offered. Each rat was appraised of the availability of saline by touching the drinking spout to their lips. Rats infused with EBSS drank 6-12 mls of saline in 2 hours. In contrast, adminisration of a V_1/OX receptor antagonist significantly reduced saline consumption by ~50%.

The results provide prelminary evidence that activation of central VP and/or OX systems may induce Na appetite.

320.4 EFFECTS OF CHORDA TYMPANI NERVE SECTION ON THE IMMEDIATE AND LONG-TERM EXPRESSION OF SODIUM APPETITE IN RATS. G.J. Schwartz*, Monell Chemical Senses Center, & H.J.Grill (SPON: P. Glimcher), Dept. of Psychology, Univ. of PA, Phila., PA 19104.

To determine the contribution of chorda tympani afferent input to the expression of sodium appetite in the rat, rats with bilateral chorda tympani (CT) nerve section received 24-hr. two-bottle preference tests and taste reactivity tests when sodium replete and sodium deplete. In preference tests, sodium deplete CT rats demonstrated a significant increase in the absolute intake of and preference for 0.5 M NaCl, as did sham-denervated controls. In taste reactivity tests, sham-denervated rats shifted their response to 1 min., 1 ml intraoral infusions of 0.5 M NaCl from a pattern of mixed ingestive and aversive responses to a pattern of exclusively ingestive responses when sodium deplete. CT rats, however, failed to show this shift from mixed aversive and ingestive responses to a pattern of solely ingestive responses. In addition, sham-denervated rats showed an increased in the latency to reject a 0.5 M NaCl infusion when sodium deplete, while CT rats failed to show this increase. Neither CT nor sham-denervated rats altered their taste reactivity responses to 1 min., 1 ml intraoral infusions of 0.1 M sucrose or 0.0001 M Quinine hydrochloride as a function of sodium depletion. The results suggest that CT afferent input is necessary for the increase in the ingestive consummatory response to NaCl in sodium deplete rats. In addition, it appears that gustatory input remaining following bilateral CT nerve section is sufficient to mediate an increase in the absolute intake of and preference for NaCl in sodium deplete rats.

320.5 SUBFORNICAL ORGAN (SFO) LESIONS IMPAIR DIURESIS-INDUCED WATER AND SALT INTAKES. R.L. Thunhorst, K.A. Ehrlich* & J.B. Simpson. Dept. of Psychology, Univ. of Washington, Seattle, WA 98193.

The SFO participates in thirst generated by angiotensin II (AII), but involvement of the SFO in salt appetite generated by AII, or other stimuli, has not been demonstrated. In the present experiment, we determined effects of SFO lesions on water and salt intakes in response to furosemide diuresis and low sodium diet, a procedure which elevates plasma AII. Rats on ad libitum water and 0.3 M NaCl received SFO lesions (n=8), control lesions (n=6) or sham surgery (n=7). Testing occurred 8 days after surgery. Prior to testing, food, water and 0.3 M NaCl were removed from the cages and funnels were positioned for urine collection. Fluid intakes from glass burettes were recorded for 2 hr in two separate measurement periods. The first 2-hr measurement period began 1 hr after furosemide diuresis (20 mg/kg i.p.) and included water as the sole drinking fluid. This period was followed by 20 hrs access to low sodium diet and water. The second 2-hr measurement period began with the removal of the low sodium diet and included water and 0.3 M NaCl in choice. This period was followed by 20 hrs access to regular chow, water and 0.3 M NaCl. Initial body weights did not differ between groups. In the first 2-hr period, SFO lesions significantly reduced drinking rate (ml/30 min) and cumulative 2-hr intakes. However, the cumulative 22-hr intakes, UV, water balance, UNaV, and weight loss after diuresis were not different between groups (all F's (2,18) $\leq$1.45). Thus, the groups achieved equivalent hydrational status by 22 hr post-furosemide with low sodium diet. In the second 2-hr period, SFO lesions significantly reduced 2-hr cumulative 0.3 M NaCl intakes, but not rate of intake, compared with the other groups, and significantly reduced water balance compared to sham rats. There were no effects of lesion on 2-hr water intake, UV, UNaV, or Na balance (all F's (2,18)$\leq$3.13). Effects of lesion on cumulative Na balance (24 hr post-furosemide) did not achieve statistical significance. Lesion condition did not affect intakes recorded after the second 2-hr period. We conclude that SFO lesions impair the initial ingestional responses to fluid and electrolyte loss via diuresis and low sodium diet, but these animals show complete compensation for these deficits by 24 hr.

320.6 THE SALT INTAKE OF RAT DAMS INFLUENCES THE SALT INTAKE AND BRAIN ANGIOTENSIN RECEPTORS OF THEIR ADULT OFFSPRING. Karen E. Moe. Dept. of Psychology, Washington State University, Pullman, WA 99164-4830

Sodium-replete rats consume salt. When sodium-depleted, they consume even more. The renin-angiotensin system is an important component of the regulationof this salt appetite. The appetite appears very early in life, but little is known about the contribution of influences during development to its expression in adults. Contreras and his colleagues have shown that manipulation of maternal salt intake can influence the salt intake of weanling-aged rats (Dev. Psychobiol. 20:111, 1987) and the ratio of water-to-salt intake of adult offspring (by affecting water but not salt consumption; J. Nutr. 113:1051, 1983). The work reported here shows that the salt intake of adult offspring is positively related to maternal salt intake. Moreover, changes in maternal salt intake also result in long-term modification of brain angiotensin receptors.

Female Sprague-Dawley rats were given a sodium-deficient food to which NaCl had been added (0.1, 1., 4% by weight). A week later, they were mated. The dams and their litters remained on the diets until postpartum day 25-27, when Purina rat chow replaced them.

At 70 days postpartum, the now-adult offspring were individually housed with ad lib access to Purina chow and distilled water. A few days later, 0.15 M saline was also provided. 24-hr intakes of both water and saline were recorded. There was a positive relationship between the level of maternal sodium intake and the amount of saline consumed during adulthood. Mean 24-hr saline intakes for males: 20 $\pm$ 4, 24 $\pm$ 7, 43 $\pm$ 10 (0.1%, 1%, 4% diet group, respectively). Mean 24-hr saline intake for females: 20 $\pm$ 4, 33 $\pm$ 4, 37 $\pm$ 10 ml (0.1%, 1%, 4% diet group, respectively).

Later, binding to brain angiotensin receptor sites was assessed in the female offspring, using 125-I-angiotensin II (8 concentrations) and a standard tissue homogenate technique. Binding was assessed in two regions important for the regulation of blood pressure and fluid balance: (1) tissue containing the area postrema & nucleus of the solitary tract (AP/NTS); (2) tissue from the anterior dorsal region of the third ventricle, containing the septum, subfornical organ and portions of the median preoptic area (SFO/SEP). Maternal sodium intake was positively related to receptor density in the SFO/SEP but negatively related to receptor density in the AP/NTS. Receptor affinity was negatively related to maternal sodium intake in the SFO/SEP and positively related in the AP/NTS. It is not clear fromthese experiments whether there is a causal relationship between the receptor changes and the saline intake changes. However, regardless of the nature of the relationship, these results suggest that changes in maternal salt intake may have long-term consequences for the regulation of blood pressure and fluid balance (including salt appetite).

320.7 THE ABILITY OF ANGIOTENSIN II VS. ANGIOTENSIN III TO AROUSE A SALT APPETITE IN RATS. Charles R. Bredl and Karen E. Moe. Dept. of Psychology, Washington State University, Pullman, WA 99164-4830.

Angiotensin acts with aldosterone to elicit salt appetite in rats (Fluharty & Epstein, Behav. Neurosci., 97:746, 1983). Angiotensin II (A II) has generally been considered the active ligand for most phenomena regulated by angiotensin, while angiotensin III (A III) is described as a metabolite with weaker activity. However, the electrical properties of A III cause it to "stick" to untreated glassware more than A II does, and the purity of commercially-supplied A II and A III differ. Moreover, metabolism of A III is much quicker than that of A II, both in blood and brain (Harding et al., J. Neurochem., in press). Previous studies comparing the relative efficacy of A II vs. A III at behavioral actions did not control for these factors. When they are taken into account, A III and A II are equipotent at producing pressor and dipsogenic responses (Wright et al., Am. J. Physiol. 249:R514, 1985). In addition, Wright et al's work with the aminopeptidase inhibitors amastatin & bestatin (which block the conversion of A II to A III, and of A III to smaller fragments, respectively) suggests that A III, and not A II, is the centrally active form of angiotensin. With regard to salt appetite Mutter et al (Br. Res., 322:347, 1984) reported that a salt appetite could be elicited in pigs by both A II and A III, but they did not control for the factors described above. The work presented here assessed the relative potency of A II vs. A III at eliciting salt appetite in rats, controlling for those factors

Male Sprague-Dawley rats were given subcutaneous injections of DOCA (synthetic aldosterone precursor; 1 mg/day) or its oil vehicle for 6 days. On days 5 & 6, the rats received intracerebroventricular injections of cerebrospinal fluid (CSF), A II & A III (angiotensin doses: 10, 100 pmoles/2 µl CSF) in counterbalanced order. Water and 0.3 M saline consumption were recorded at 5, 10, 15, 20, 30 & 60 min after ICV injection. As shown in the table below, A III and A II were equipotent at arousing a salt appetite in DOCA-treated rats. These results agree with recent work comparing the ability of the two angioensins to elicit pressor & dipsogenic actions (above).

The effect of pretreatment with aminopeptidase inhibitors (amastatin & bestatin) on A II- and A III-induced salt appetite will also be presented. Together, these results may help define which form of angiotensin is biologically active & the critical mechanisms involved in salt appetite.

Angiotensin II		Angiotensin III	
10 pmoles	100 pmoles	10 pmoles	100 pmoles

320.8 ANGIOTENSIN II MAY MEDIATE A HISTAMINERGIC MECHANISM FOR FOOD-RELATED DRINKING IN THE RAT. F.S. Kraly and R. Corneilson*. Dept. of Psychology, Colgate Univ., Hamilton, NY 13346.

Adult male Sprague-Dawley rats (n=23) were tested for 1 hr for eating and drinking after 24-hr deprivation from food. Tests were begun by offering pelleted chow 10 min after injections of drugs or 0.9% NaCl. Blockade of central and peripheral angiotensin converting enzyme (ACE) activity using 100 mg/kg s.c. Captopril (CA) inhibited water intake by 33% (p(.01) and water to food ratio (W:F) by 36% (p(.01). Whereas i.c.v.t. 25 ug CA failed to affect food-related drinking (p's).10), 25 ug i.c.v.t. CA combined with .5 mg/kg s.c. CA (a dose that blocks only peripheral ACE) inhibited water intake by 31% (p(.01) and W:F by 20%. These results suggest that the renal renin-angiotensin system plays a role in drinking elicited by eating in the rat.

Subsequent work revealed that 100 mg/kg s.c. CA inhibited water intake by 23% (p(.05) in 12 rats in which combined antagonism of H_1 and H_2 receptors for histamine, using i.p. dexbrompheniramine (DXB) and cimetidine (C), inhibited water intake by 22% (p(.01) following 1 mg/kg DXB plus 16 mg/kg C and by 36% (p(.001) following 2 mg/kg DXB plus 32 mg/kg C. When 100 mg/kg s.c. CA was given simultaneously with i.p. DXB and C, the water intake was inhibited by 23% (p(.05) after CA plus 1 mg/kg DXB and 16 mg/kg C and by 38% (p(.001) after CA plus 2 mg/kg DXB and 32 mg/kg C. Thus, the effects of CA and DXB plus C were not additive for inhibition of food-related drinking.

Finally, 100 mg/kg s.c. CA inhibited (p's(.001) drinking elicited by 2.5 or 20 mg/kg s.c. histamine. In contrast, i.p. 1 mg/kg DXB plus 16 mg/kg C (treatment sufficient to abolish drinking elicited by s.c. histamine) failed to inhibit drinking elicited by 0.12 mg/kg s.c. angiotensin II.

In summary, (1) blockade of peripheral and central ACE inhibits food-related drinking and drinking elicited by s.c. histamine, and (2) such blockade of ACE and blockade of H_1 and H_2 histamine receptors are not additive in their effects on inhibition of food-related drinking. These findings together support the hypothesis of renal renin-angiotensin mediation of a histaminergic mechanism for drinking elicited by eating in the rat.

320.9 EFFECTS OF IMMUNONEUTRALIZATION OF BRAIN PEPTIDES ON WATER INTAKE IN THE RAT. C.R. Franci* and S.M. McCann. Department of Physiology, UTHSCD, Dallas, TX 75235.

Water intake elicited by overnight water deprivation was analyzed in different groups of male rats bearing indwelling cannulae in the third cerebral ventricle (3V) following intraventricular (icv) microinjection of 2 µl of normal rabbit serum (NRS), angiotensin II antiserum (AB-AII), atrial natriuretic peptide antiserum (AB-ANP), vasopressin antiserum (AB-VP) or oxytocin antiserum (AB-OT). Animals were used twice with the first injection of normal rabbit serum or the experimental antiserum followed by reversal of the treatment one week later. Water was offered immediately, one or three hours after icv injection. There was no difference in water intake between the control session (NRS) and the experimental session (AB-AII, AB-ANP, AB-VP or AB-OT) when water was offered immediately after icv injection. Water intake was highly significantly reduced at all times measured, (i.e. from 15 minutes to 4 hours) when the water was offered 1 hr after icv injection of AB-AII; however, the other antisera did not significantly impair drinking with this protocol. When water was offered three hours after icv injection, it occurred normally following injection of NRS, was almost completely inhibited by antisera against AII but was also significantly inhibited, although less so, by antisera against ANP, VP and OT. To further examine the specificity of the antisera effects, AII was injected icv in normally hydrated rats and the effect on water intake observed. Three hours after icv injection of NRS and antibodies against ANP, VP or OT there was equivalent water intake induced by AII; however, AB-AII dramatically reduced the dipsogenic effect of AII. In these hydrated rats no animal drank water following icv injection of isotonic sodium chloride, NRS or AB-AII three hours before. Thus 1 hr following injection of antisera, only AB-AII reduced water intake elicited by overnight deprivation, but 3 hours after injection AB-VP and AB-OT and AB-ANP were partially effective. The specificity of the AII antiserum effect was shown by the fact that it was the only antiserum which could alter AII-induced drinking. The results suggest that although AII is primarily responsible for dehydration-induced drinking, the other peptides may play a permissive role, since their antisera were partially effective, at least at fairly long times after antiserum injection, which would allow the diffusion of all antiseras to the effective sites within the hypothalamus.

320.10 THE EFFECTS OF IBOTENATE LESIONS OF THE MEDIAN PREOPTIC NUCLEUS ON DRINKING BEHAVIOR IN THE RAT. J. T. Cunningham*, M. J. Sullivan, G. L. Edwards, R. Farinpour*, and A. K. Johnson. Departments of Psychology and Pharmacology, and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242

Electrolytic lesions of the anteroventral region of the third ventricle produce permanent response deficits to challenges (e.g., Angiotensin II [ANG II]; hypertonic saline [HTS]) that produce drinking responses and vasopressin release in normal animals. More recently, similar response deficits in rats have been demonstrated with electrolytic lesions of the median preoptic nucleus (MnPO) (Mangiapane et al., Neuroendo., 37: 73-77, 1983; Gardner and Stricker, AJP, 248:R224-R230, 1985). In the present study, the excitotoxin, ibotenic acid, was used in an attempt to determine if these drinking response deficits were due to the destruction of either fibers of passage or cells contained in the MnPO.

Adult male rats were injected with either vehicle (1 ul) or ibotenic acid (5 ug/1 ul) in the ventral MnPO. All subjects were then tested for drinking responses to ANG II (1.5 and 3 mg/kg sc) and HTS (3% and 12% 1 ml/100 gm b w). Rats with ibotenic acid injections into the MnPO drank significantly less water to both the 3% and the 12% doses of HTS than did the vehicle-injected controls. However, the ibotenic lesioned rats did not show a drinking response deficit to either dose of ANG II. This differential effect of ibotenic acid on drinking behavior suggests that its effects are not due to mechanical damage or a motor performance deficit but that the drinking response to HTS is mediated by a population of MnPO neurons that are sensitive to the neurotoxic effects of ibotenic acid.

(Supported by NIH Grant HL14388)

320.11 **SUBFORNICAL ORGAN CONNECTIVITY AND DRINKING TO CAPTOPRIL OR CARBACHOL IN RATS.** D.B. Masson* and D.A. Fitts. Univ. of Wash., Seattle, WA. 98195

Transection of the efferent and afferent connections of the subfornical organ (SFO) at its rostral stalk decreases drinking to peripheral angiotensin II (ANG) similar to ablation of the SFO itself. Other drinking responses, such as those to captopril (CAP) or carbachol (CBC), are reduced by SFO lesions. This study investigates whether CAP and CBC might also act through the well established neural connections of the rostral pole of the SFO.

Captopril studies. Lesions were placed with a rotating wire knife through the wall of the third ventricle between the rostral pole of the SFO and the anterior commissure. Control rats had either sham lesions (knife not extended) or histologically identified missed cuts. In acute drinking studies, control rats of both types drank 3.5±2 ml of water in 90 min following ip injection of 4 mg/kg CAP. Rats with complete transections drank significantly less, 1.3±1 ml. Other rats received CAP for 5 days at 0.1 mg/ml in the water with 0.3 M NaCl also available. All groups, regardless of the lesion condition, increased NaCl intake from baseline levels. Both studies affirm the importance of the SFO and its rostral connections in CAP-related water, but not saline, intake.

Carbachol studies. Groups of rats with knife cuts or control lesions received a 4-μl lateral ventricular (ICV) injections of either 1.2 or 4 nmol CBC. All rats drank water rapidly within the first 15 min, and rats at the higher dose continued drinking during the second half of the 30-min test. The lesion made no difference in the response, with data for transected rats falling between sham and missed cut rats at both doses. The transected rats showed deficits in drinking to ip CAP.

Conclusion. Our data support the hypothesis that CAP causes drinking via an angiotensinergic mechanism acting at the SFO, because the rostral connections of the SFO are critical for drinking to occur to both CAP and ANG. However, the data do not support the hypothesis that the SFO is a unique receptor site for ICV carbachol.

320.12 EFFECTIVE THYROXINE ON DIPSOGENIC RESPONSIVENESS TO ISOPROTERENOL IN FOOD-DEPRIVED RATS. Michael J. Katovich, LI-Fen Yeh and Stephen P. Baker (SPON: J. Poulakos), Dept. of Pharmacodynamics College of Pharmacy, University of Florida, Gainesville, FL 32610.

The effect of thyroxine (T4) replacement on the increased beta-adrenergic dipsogenic responsiveness of fasted rats was studied in male Sprague-Dawley rats. Food-deprivation significantly decreased serum thyroxine (T4) and triiodothyronine (T3) levels, increased the dipsogenic response to isoproterenol and elevated renal beta-adrenergic receptor concentration. Daily administration of T4 (40 ug/kg) to food-deprived rats restored serum thyroid levels to normal. Thyroxine replacement also reduced the increased beta-adrenergic dipsogenic responsiveness in the food-deprived rats to control levels. In addition, daily administration of thyroxine reduced the beta-adrenergic receptor concentration in renal cortices to that observed in controls. Thyroid treatment tended to decrease the isoproterenol-induced renin release in food-deprived rats and increase the response in the control rats. These results suggest that the relative hypothyroid state observed in the food-deprived rat may be responsible for the increased concentration of renal beta receptors and the enhanced activation of the renin-angiotensin system resulting in an increased dipsogenic response induced by isoproterenol. Collectively, the data reaffirm the interaction of thyroid hormone and beta-adrenergic responsiveness, although it is of interest that in regards to renal beta-receptors the concentrations are decreased to normal whereas previous studies in hypothyroid rats demonstrate an increase to normal of cardiac beta-receptors. This would suggest thyroid hormone may normalize a response in an opposite direction depending on the direction of the disturbance. (Sponsored by NIH grants HD 18133, HD 19742, HL 32099 and GM 34905).

320.13 AN INCREASE IN MEAN ARTERIAL PRESSURE (MAP) BY IV INFUSION OF PHENYLEPHRINE (PE) INHIBITS THE DRINKING RESPONSE TO SC INJECTIONS OF HYPERTONIC SALINE IN THE RAT. M.M. Robinson. University of Western Ontario, London, Ontario, Canada, N6A 5C1.

It has been previously shown that the pressor response to IV infusion of angiotensin II inhibits the drinking response (Robinson & Evered, 1987). The present study investigated whether an acute rise in MAP is also inhibitory to the drinking response to SC injection of hypertonic saline. Rats (350-450 g) were tested in pairs and were infused IV with either PE (250 ug/ml) or with isotonic saline as control. The rate of infusion was identical in the paired animals and was varied (0.5-1.0 ml/h) to raise and maintain the MAP of the PE treated rat 25-35 mmHg above preinfusion values for the duration of the experiment. Fifteen minutes after the start of the IV infusion, each pair of rats was injected SC with either isotonic saline, 1.5 or 4 M NaCl (0.5 ml/100 g b.w.). The SC injection of hypertonic saline caused a dose dependent increase in the 60 min water intake of control rats and of rats whose MAP was raised with PE. However, the drinking response of the PE treated rats was significantly lower at both doses of hypertonic saline (1.5 M: 3.5 $\pm$ 0.9 vs 5.8 $\pm$ 0.5 ml; 4 M: 6.1 $\pm$ 1.7 vs 11.2 $\pm$ 1.2 ml, $p < .05$). PE had no effect on the drinking response to S.C. isotonic saline (2.1 $\pm$ 0.3 vs 2.4 $\pm$ 0.5 ml). PE increased urine output in rats given either 1.5 M NaCl (13.6 $\pm$ 1.0 vs 7.0 $\pm$ 1.1 ml, $p < .05$), or 4 M NaCl (15.1 $\pm$ 1.4 vs 11.7 $\pm$ 1.3 ml, $p < .05$) Total solute and Na^+ excretion were greater in rats given 4 M NaCl than 1.5 M NaCl (7.7 $\pm$ 0.6 vs 4.5 $\pm$ 0.5 osmols; 2.7 $\pm$ 0.3 vs 1.2 $\pm$ 0.1 equivalents Na^+, $p < .05$). Raising MAP in rats given 1.5 M NaCl also increased solute and Na^+ excretion (6.3 $\pm$ 0.7 vs 1.2 $\pm$ 0.1 osmols; 2.1 $\pm$ 0.1 equivalents Na^+, $p < .05$), but had no further effect on solute or Na^+ excretion in the rats given the higher dose of hypertonic saline. In rats treated similarly, but not allowed to drink, hypertonic saline caused a dose dependent increase in plasma osmolality and Na^+ concentration which was not affected by increasing MAP with IV infusion of PE. In summary, an acute rise in MAP inhibits the drinking response to SC injections of hypertonic saline. Generally, this effect cannot be attributed to a decrease in plasma osmolality or Na^+ concentration, nor to a pressure natriuresis, although with the 1.5 M NaCl dose the latter may have been a contributing factor. (Robinson, M.M. & Evered, M.D. 1987, Am. J. Physiol., 252:R754-R759.)

320.14 NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY WITHIN THE AVIAN BRAIN REVEALS CENTRAL LOCI THAT MAY BE SENSITIVE SITES FOR STIMULATING FEEDING BEHAVIOR. W. J. Kuenzel. Dept. of Poultry Sci., Univ. of Maryland, College Park, MD 20742.

Neuropeptide Y (NPY) has been shown to be a potent stimulator of food intake in mammals following intracerebronventricular (ICV) administration to rats (Levine, A. S. and J. D. Morley. Peptides 5:1025(1984); Clark, J. T. et al. Endocrinology 115:427(1984)) or when directed to the paraventricular nucleus (Stanley, B. G. and S. F. Leibowitz. Life Sci. 35:2635(1984)). The neuropeptide likewise effects feeding in birds. Five µg of NPY administered ICV in chicks consistently produces a doubling of food intake during the first hour compared to saline injected controls. Experiments were conducted to ascertain the distribution of NPY-like immunoreactivity within neuronal cell bodies and fibers throughout the chick brain. Avian pancreatic polypeptide and NPY antisera were used as primary antibodies in two immunocytochemical procedures. The first was an indirect immunofluorescence technique using a secondary antibody conjugated to fluorescein isothiocyanate. The second was the avidinbiotin complex (ABC) method utilizing peroxidase. Chicks were perfused with physiological saline followed by 4% paraformaldehyde.

The most densely stained fibers and terminals with NPY-like immunoreactivity occurred within and about the paraventricular nucleus and the region immediately surrounding the ventral and anterior region of the third ventricle. Structures around the third ventricle that had densely stained fibers included the periventricular hypothalamic nucleus, medial portion of the suprachiasmatic nucleus, paraventricular organ, inferior hypothalamic nucleus, infundibular nucleus and median eminence. The hippocampus had numerous densely stained neuronal cell bodies.

A group of structures showing clear NPY-like immunoreactivity included the lobus parolfactorius, organum vasculosum of the lamina terminalis, bed nucleus of the stria terminalis, a fiber network that extended from the lateral ventricle of the forebrain through the lateral and medial septal nuclei to the third ventricle at the level of the sub-septal organ (sub-fornical organ), the ventromedial hypothalamic nucleus and the nucleus tractus solitarius.

Structures showing some immunoreactivity included portions of the olfactory bulb, hyperstriatum accessorium, subcommissural organ, nucleus of the basal optic root, area ventralis of Tsai, interpeduncular nucleus and stratum griseum et fibrosum superficiale.

In light of the dramatic effect of NPY on food intake in mammals and birds, it would be of value to examine structures showing high NPY-like immunoreactivity to determine their possible role in affecting appetite.

320.15 NEUROPEPTIDE Y (NPY) FACILITATES RECOVERY OF FEEDING FOLLOWING LATERAL HYPOTHALAMIC LESIONS IN RATS. B. Roland, C.V. Grijalva, M.W. Gunion, L. Goehler, and J.E. Morley. Dept. of Psych. and Med., UCLA, Los Angeles, CA 90024; and V.A. Med. Center, Sepulveda, CA 91343.

It has been demonstrated that intracerebroventricular (ICV) and hypothalamic injections of neuropeptide Y (NPY) elicits feeding and drinking behavior in rats (Clark et al, Endocrinology, 115:427, 1984; Gray & Morley, Life Sci, 38:389, 1986; Stanley, Chin & Leibowitz, Br. Res. Bull., 14:521, 1985). To discern whether the lateral hypothalamus (LH) is a predominant site of action of NPY, the LH was lesioned in order to test whether NPY-induced feeding would be abolished. Two groups of albino male rats were matched for body weight, were given anodal electrolytic lesions of the LH (1.2 ma for 10s) and then immediately were implanted with cannulae in the lateral ventricle. All rats were deprived of food overnight and were tested for feeding behavior the next morning. Testing consisted of presenting the rats with chow pellets, chocolate chip cookies or cookie mash (cookie and water slurry) and the acceptance of the various foods was recorded. On Day 1 postoperatively, all rats were injected ICV with 2µl BSA saline. Pre- and post-injection, the rats were tested to see if they demonstrated the typical symptoms of aphagia and adipsia, which are associated with the LH syndrome. On Day 2, one group (SAL, N=6) was injected ICV with 2µl saline and the other group (NPY, N=8) was injected with 10µg/2µl NPY. The 2 groups were tested pre- and post-injection for feeding on the various diets. Injections and testing continued up to Day 7.

The results indicated that NPY significantly facilitated the recovery of feeding behavior. In the postinjection food tests, NPY enhanced feeding behavior (acceptance of the cookie mash or cookies) from Day 2 ($p<0.02$) up until Day 6 ($p<0.02$). The SAL group did not show this effect. Once feeding was promoted by NPY, feeding was sustained independent of NPY. The NPY group significantly increased the preinjection acceptance of food by Day 3 ($p<0.018$). It was not until Day 7 that the SAL group exhibited significant recovery of ingestive behavior. Despite the fact that NPY infusions promoted eating in LH rats, the NPY group continued to lose weight over the first 5 days and were not significantly different from the SAL group until Day 6 ($p<0.05$). By Day 6, the NPY rats were at 81% of their preoperative body weight, while the SAL rats were at 75%. These results indicate that although the LH is involved in ingestive behavior, it may not be the predominant site of action of NPY. NPY may therefore facilitate recovery of function by stimulating areas outside of the LH.

320.16 EFFECTS OF BILATERAL PARTIAL MIDBRAIN TRANSECTIONS ON FEEDING AND DRINKING INDUCED BY NEUROPEPTIDE Y (NPY) IN RATS. JL Steinman, MW Gunion & JE Morley. GRECC, VAMC, Sepulveda, CA 91343.

NPY robustly increases both food and water intake (FI,WI) when infused into the lateral or 3rd ventricle (3V) or directly into hypothalamic regions in rats. In addition to forebrain modulation of FI & WI, we recently found that brainstem (4V) infusion of NPY is equally effective in elevating FI & WI. The present study asked whether rostro-caudal fibers connecting 4V areas to feeding-related forebrain areas mediate the effects of 4V-NPY on FI & WI.

Rats were implanted with 3V or 4V cannulae 7 days after receiving bilateral midbrain knife cuts (KC) or sham treatment. Groups are abbreviated as follows: 3V+KC = 3K; 3V+Sham = 3S; 4V+KC = 4K; 4V+Sham = 4S. One week after cannulation, testing began with 0, 2.5, 5 or 10 ug NPY/3 ul saline-BSA given in a counterbalanced design. FI & WI were measured 1 & 2 hr post infusion. Partial midbrain transections reduced the effect of 4V infusions of NPY on both FI & WI and of 3V infusions of NPY on WI only.

NPY significantly elevated 2-hr cumulative FI in a dose-dependent fashion in all groups of rats. Difference scores (DS) were calculated, subtracting FI after 0 dose infusions from FI after NPY (2.5, 5 or 10 ug doses) infusions. When comparisons were made of the DS, the effect of NPY on FI was reduced significantly in 4K as compared to 4S rats (see below). KC did not alter the increase in FI after 3V infusions of NPY. KCs also affected NPY-induced drinking. While NPY increased WI in both 3S & 4S groups, this increase was attenuated significantly in 3K & 4K groups (see below).

Increased FI after brainstem stimulation by NPY probably requires fiber connections to the forebrain which were severed in this experiment, while forebrain stimulation by NPY does not require these or adjacent fibers. By contrast, the dipsogenic effects of NPY, whether induced at sites near 3V or 4V, appear to depend on fibers traversing through the midbrain.

NPY INCREASES FI & WI ABOVE 0 (CONTROL) LEVELS

	group	DS (2.5 - 0)	DS (5.0 - 0)	DS (10.0 - 0)
FI (g/hr) X ± sem	3S	1.1±.7	2.1±.9	3.7±.7

320.17 EFFECT OF NEUROPEPTIDE Y ON INGESTIVE BEHAVIORS OF RATS FOLLOWING AREA POSTREMA/NUCLEUS TRACTUS SOLITARIUS ABLATION. C. Shawn Kreig*, Jon N. Kott, Nancy J. Kenney and Stephen C. Woods. Dept. Psychology Univ. Washington Seattle, WA 98195.

Following ablation of the area postrema and subjacent caudal-medial aspect of the nucleus tractus solitarius (AP/cmNTS), rats decrease food intake and body weight. Cell bodies of the NTS contain neuropeptide Y (NPY), a brain-gut peptide which acts centrally to increase food and water intake. This study examines the effect of central administration of NPY on food and water intake of AP/cmNTS-lesioned rats.

Seventeen male Long-Evans rats were fitted with lateral ventricle (LV) cannulae under pentobarbital anesthesia. One week later, 8 rats received thermal AP/cmNTS ablations and 9, sham lesions under pentobarbital anesthesia. Rats were maintained on ad lib pelleted chow and water throughout the study Testing began 5 days after the second surgery. On test day 3, each rat received 5 ug NPY in 1 ul isotonic saline. On test days 1, 2 and 4 (control days), each rat received an equivolume injection of isotonic saline. Food and water intake were measured .5, 1, 2, 4 and 24 hr following the LV injections.

Food Intake: During the first 30 min following injection, food intakes of both sham- and AP/cmNTS-lesioned rats were greater on the NPY test day than on control days ($p<.01$ in each case). Four hours after NPY injection, cumulative food intakes of both groups remained elevated ($p<.01$ for each comparison). Total 4-hr intakes of lesioned rats did not differ from those of sham-lesioned animals. Rats in both groups compensated for the initial increase of feeding on the NPY test day by decreasing food intake between 4 and 24 hr after the injection ($p<.01$). Total 24-hr food intake on the NPY test day did not differ from that on control days for either group. AP/cmNTS-lesioned rats did eat less than controls over the entire 24-hr following NPY injection as is typical of the total daily intake of rats during the first 2 weeks following AP/cmNTS ablation ($p<.01$).

Water Intake: NPY treatment resulted in increased water intakes by both lesioned and sham-lesioned rats during the first 4 hr after injection ($p<.05$ for each comparison). Water intake was decreased from 4-24 hr following NPY administration such that total 24-hr water intakes of both lesioned and sham-lesioned rats on the NPY test day did not differ from those on saline control days. Cumulative water intakes of lesioned rats did not differ from those of sham-lesioned rats at either 4 or 24 hr on either the NPY test day or on control days.

These data suggest that AP/cmNTS ablation does not destroy responsiveness to the ingestive effects of LV NPY.

320.18 BRAIN SEROTONIN AND CARBOHYDRATE APPETITE: DOES THIS PHYSIOLOGICAL CORRELATION OCCUR IN INSECTS? R.W. Cohen, S. Friedman and G.P. Waldbauer. Dept. of Entomology, University of Illinois, Urbana, IL 61801.

The neurotransmitter serotonin (5-hydroxytryptamine) has been implicated in the control of carbohydrate appetite in rats and humans. It is well known that insects produce serotonin, and research has shown that serotonin has functions that generally parallel those in mammals. Thus, it may be asked whether serotonin is involved in determining the level of carbohydrate intake by insects.

One possible candidate for the study is the corn earworm, Heliothis zea (Lepidoptera: Noctuidae), a major pest of field crops in the Western Hemisphere. A previous study (Waldbauer et al., Physiol. Zool. 57: 590, 1984) has shown that final instar corn earworm larvae, like laboratory rats, have the ability to self-select a balanced diet from a choice of two diet cubes which are identical except one lacks only protein and the other lacks a digestible carbohydrate. These larvae consume a ratio by weight of about 80% protein and 20% carbohydrate. Direct measurements of brain serotonin, using an HPLC assay, show that an increase in brain serotonin levels is correlated with increased carbohydrate consumption by the caterpillars. Brain serotonin levels are diminished in larvae that fed on protein diets. To assess the impact of brain serotonin levels on actual carbohydrate intake, we performed two pharmacological experiments involving the incorporation of p-chlorophenylalanine (PCPA), a known mammalian inhibitor of serotonin, and tryptophan (serotonin precursor) into diet cubes of self-selecting larvae. Larvae feeding on PCPA-treated diets had reduced brain serotonin levels and increased their carbohydrate consumption, whereas those feeding on tryptophan-treated diets decreased their carbohydrate consumption accompanied by a relatively large increase in brain serotonin levels. The data suggest that this correlation between serotonin and carbohydrate appetite may be prevalent throughout the animal kingdom. The correlation also suggests that nutrient self-selection is mediated by internal feedback involving neurotransmitters which monitors nutrient intake.

320.19 SEROTONIN ANTAGONISTS AND FEEDING. Paul J. Fletcher* (SPON: T. Wishart). Psychiatric Research Div., Saskatchewan Health, CMR Bldg., Univ. of Saskatchewan, Saskatoon, Sask., S7N OWO, Canada.

It has been proposed that 5-HT systems are involved in the control of satiety. However, in contrast to the well-documented anorectic effects of direct and indirect 5-HT agonists only a small number of reports have described increased food intake following treatment with 5-HT antagonists. The present experiments examined the effects of two 5-HT antagonists, methysergide and cyproheptadine, in three different paradigms.

In the first paradigm non-deprived male Sprague-Dawley rats were given daily access to a 35% sucrose solution. Methysergide (1.25, 2.5 and 5 mg/kg) did not alter sucrose intake over the first 1/2 h of testing, but at 1 h and 2 h intake was reduced by 5 mg/kg methysergide. Cyproheptadine (2.5, 5, 10 mg/kg) also failed to alter sucrose intake at 1/2 h but a dose-dependent decrease was observed at 2 h. In a second paradigm rats were given daily access to a sweetened wet mash diet. Methysergide did not alter food intake over the first 1/2 h, but a dose of 5 mg/kg reduced intake at 1 and 2 h. Cyproheptadine induced a dose-dependent decrease in intake at 1/2 h, but this effect was not apparent at 2 h. The failure to observe an increased intake was not due to an insensitivity of the tests employed since chlordiazepoxide (5 and 10 mg/kg) markedly increased the consumption of sucrose and the sweetened mash diet. In a third paradigm methysergide and cyproheptadine were administered after 1/2 h access to a sweetened mash diet, a procedure which induced satiety in vehicle treated animals. Methysergide significantly enhanced subsequent food intake. Cyproheptadine induced a modest increase in food intake in this test. Chlordiazepoxide markedly increased food intake in satiated animals.

These results show that 5-HT antagonists can induce decreases, increases or no change in food intake depending upon the feeding paradigm employed, and the time period examined. This indicates a complex relationship between 5-HT antagonism and feeding. However, since increased food intake following treatment with 5-HT antagonists was observed only in fully satiated animals this may support the hypothesis that 5-HT systems are involved in the process of satiety.

320.20 ZINC DEFICIENCY CONDITIONS TASTE AVERSIONS IN RATS. D. S. Cannon*, L. E. Carrell* and I. L. Crawford. Departments of Psychiatry and Neurology, University of Texas Health Science Center at Dallas and Veterans Administration Medical Center, Dallas, TX 75216.

Decreased food consumption by zinc deficient rats is usually assumed to be the result of an anorexigenic pathophysiological state (e.g., Essatara, M. et al., Physiol. & Behav., 32:475, 1984). The present study investigated the possibility this decreased food intake is due to learned aversion to the deficient diet rather than to anorexia. Similar learned aversions have been demonstrated following other dietary deficiencies (Rozin, P. & Kalat, J.W., Psychol. Rev., 78:459, 1971). Three groups of Sprague-Dawley rats were studied. One group (ZD) was fed ad libitum a biotin-enriched Zn deficient diet containing 20% spray dried egg white and <1 ppm ZN (Wallwork, J.C. & Crawford, I.L., Fed. Proc., 46:885, 1987). Two control groups were fed a similar diet containing 25 ppm Zn. One control group was fed ad libitum (AL) and the second group was pair fed (PF) the mean consumption of ZD rats the previous day. After 3 weeks, an assay of plasma Zn from tail blood documented metal deficiency in Group ZD. The means of Groups ZD, PF, and AL, respectively, were 0.46, 1.14, and 1.18 ug/ml, $F(2,25)=46.2$, $p<.001$ All animals were then offered a zinc-normal lab chow with which they were familiar. The means of Groups ZD, PF and AL, respectively, during the first hour the lab chow was presented were 6.8, 9.2 and 1.8 g, $F(2.27)=46.2$, $p<.001$; and during the first day, 16.8, 26.0, and 21.8 g, $F(2.27)=13.9$, $p<.001$. To control for the effect of group differences in body weight, first day consumption was reanalyzed using analysis of covariance with body weight as the covariate. The residual means for the three groups were 24.1, 28.4 and 12.1g, $F(2.26)=14.9$, $p<.001$. The 1 hour and weight-adjusted 24 hour data suggest there was little general anorexia in Group ZD. After 2 weeks on the zinc-normal diet, plasma Zn in Group ZD had returned to normal levels. All groups then were offered the Zn-deficient diet, and Group ZD consumed significantly less than either of the other groups. Means of Groups ZD, PF and AL, respectively, were 5.3, 19.2, and 20.7 g, $F(2.27)=47.3$, $p<.001$. Even with weight as the covariate, Group ZD consumed significantly less than either other group. These results indicate Zn deficiency conditions aversion to associated foods.

CONTROL OF POSTURE AND MOVEMENT VII

321.1 ON A NEW ANALYTICAL APPROACH TO THE STABILITY AND PROGRESSION OF A BIPED. Y. Hurmuzlu* and G.D. Moskowitz* (SPON: W. Freedman) Drexel University, Department of Mechanical Engineering and Mechanics, Philadelphia, PA 19104.

The missing factor in all previous locomotion studies is a complete understanding of the role of the impact of the limbs with the ground and switching of the body weight from one limb to the other in the overall locomotion picture. In this work a numerical code was developed for modelling the dynamics of a general multibody chain system, which is based on the kinetostatic approach (Vukobratovic, M. and Potkonjak, V., Springer Verlag, 1982). The impact and switching effects were included in the model. The stability of the nonlinear system was studied by utilizing phase plane portraits (i.e. a plot of the joint velocities versus the corresponding joint angles). Impact and switching play the most important role in achieving a stable gait. The dynamics of an inverted pendulum is modified by the occurrence of impact and switching, which results in asymptotically stable limit cycles on the phase plane portrait. The proposed ideas and principles have already been verified for three and four element, three dimensional models. To demonstrate the ideas clearly, without getting lost in the details of a very complicated model, a three element, two dimensional example was used. The system proves to be asymptotically stable for a wide range of perturbations in joint velocities and rotations. The regions of stability and instability are presented on an overall phase plane portrait.

321.2 SCALING CHARACTERISTICS OF MUSCLE ANTAGONISTS IN ACCURATE, STEP ISOMETRIC CONTRACTIONS. D. M. Corcos, G. L. Gottlieb, G. C. Agarwal and B. Flaherty*, Dept. of Physical Education, University of Illinois at Chicago and Depts. of Neurosurgery and Physiology, Rush Medical College, Chicago, IL 60612.

We have previously shown that agonist EMG quantity increases as movement distance and target width increase. This is because greater forces can be generated for longer movements and for movements to larger targets. The findings for antagonist muscles are less clear since larger EMG quantities are not associated with longer movements in all subjects. We have also shown that agonist and antagonist EMG increases as inertial load increases. The increases in muscle activation are related to the increased inertial forces involved in the movement. Since both these paradigms are complicated by the fact that muscle length is changing, we conducted a set of isometric experiments to ascertain the relative scaling of muscle groups when force and force precision are manipulated.

Subjects generated isometric step flexion contractions at 18, 36, 54 and 72% of their maximal voluntary contraction (MVC) at four levels of force precision (3, 6, 9 and 12% of MVC). This paradigm is the isometric equivalent of a Fitts' task in which different distance movements are made to different size targets. Four surface EMGs were recorded from biceps, brachioradialis, lateral head of triceps and long head of triceps. EMG quantity increased in both agonist muscles as force increased. In some subjects, as force increased, both antagonist muscles decreased in quantity. Least antagonist EMG occurred for MVC. In other subjects, agonist and antagonist EMG both increased as greater force was generated with most EMG for MVC. We are currently investigating the extent to which these different "strategies" for antagonist muscle activation are modifiable by changes in how the task is performed.

321.3 HOW DO HUMANS MODULATE THE STRIDELENGTH DURING LOCOMOTION? Aftab F. Patla, J.M. Silviera*, Neural Control Lab, Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

One of the most common adaptation that we have to make during locomotion is the alteration of the stridelength to meet the demands imposed by the terrain. Based on kinematic measures Warren et al. (J. Exp. Psych., 12:259, 1986) proposed that stridelength is controlled by modulating the vertical impulse applied during the stance phase. Power analysis during locomotion (Winter, D., J. Motor Behav., 15:302, 1983) suggests three possible mechanisms for the control of stridelength: 1) "push off" during late stance; 2) "pull off" during early swing; 3) "braking" during late swing. The purpose of this study was to examine the modulation of the muscle activity patterns when subjects are asked to voluntarily lengthen their stridelength.

Subjects (n=6) walked on a treadmill at their normal self paced speed. They were instructed to increase their ipsilateral stridelength and break a photocell switch placed at the end of the treadmill when a buzzer, triggered by the ipsilateral heel switch sounded. The buzzer came on unexpectedly and randomly at heel contact (HC) or toe off (TO). EMG signals from the tibialis anterior (TA), medial gastrocnemius (MG), biceps femoris (BF), vastus lateralis (VL), rectus femoris (RF), along with footswitch signals and the stimulus plus photo cell signal were collected. For each condition (HC & TO) the strides during which the subject altered the stridelength (P) as indicated by the photocell signal, and normal strides (N) were rubberbanded (to 100%) and ensemble averaged. Following this, average EMG (AEMG) values were calculated for the following durations in the stride: 30-50%, 50-70% and 80-100% representing push off, pull off and braking action. Ratios of AEMG in "P" over AEMG in "N" were calculated for each of the three durations and compared to ratios of two separate "N" strides.

The most consistent (at least 4 subjects) changes in the EMG for the HC condition were: 1) increase in the push off action (↑MG, ↑BF, ↑VL - extensor activity at the ankle, knee and hip); 2) increase in the pull off action (↑TA, ↑MG, ↑BF, ↑RF - flexor activity at the ankle, knee and hip), and 3) reduced braking action (↓BF) and increased knee extension (↑VL). These results suggest that we can and do alter more than the vertical impulse to alter stridelength. The interesting aspect of the results in the TO condition was the fact that 4 subjects were unable to change their stridelength in the cycle when the buzzer sounded. These subjects showed minimal changes in the stride when the buzzer sounded. The TO condition presents subjects with only one option to alter their stridelength: reduced braking action. Thus these results suggest that at least two of the three options (↑push off, ↑pull off, ↓braking) are required to lengthen the stridelength.

321.4 AGONIST AND ANTAGONIST ACTIONS DURING THE DYNAMIC PHASE OF HUMAN STEPPING. L. Carrière and A. Beuter. Dept. de Kinanthropologie, Université du Québec à Montréal, Montréal, P.Q., H3C 3P8.

In order to grasp the relationship between electrophysiological (EMG) activation patterns and the corresponding Kinematic properties it is important to take into account the conditions under which muscles act on the bones. The purpose of this study was to examine the relationships between EMG activation patterns and kinematics of the dynamic phase of stepping performed at natural cadence. Kinematics and EMG parameters were analyzed on six subjects stepping over an obstacle of three different heights (25, 50 and 75% of shank length). A videomotion analysis system was used to track the displacement of reflective markers on the lower limb joints. Surface bipolar electrodes were secured on the rectus (RF) biceps (BF) femoris and semitendinosus (ST) muscles. Electrokinematic phase plots generated with EMG and kinematic data revealed a generally consistent pattern across subjects although cocontraction became larger in the landing phase and the diagrams were scaled up as obstacle height increased. The duration of the flexion phase was not affected by obstacle height. The bursts generally appear in the following order: BF-ST (simultaneously), RF during the flexion phase, and RF and BF-ST (simultaneously) in the extension phase. In most subjects there was very little EMG activity during the transition from flexion to extension. While the activation patterns were similar across subjects, the amplitude and duration of the different EMG episodes varied and influenced the shapes of the electrokinematic phase plots. In most subjects, there seemed to be a consistent timing in reaching knee flexion velocity across height conditions but there was a shift toward earlier knee extension velocity. This pattern is reversed in one subject and seems to be due to BF activity after the transition phase. Results indicate that in general during the dynamic phase of stepping the activated biarticular muscle acts as an agonist on the distal joint whereas it acts as an antagonist on the proximal joint, hence the CNS seems to favor the control of the distal joint actions. From the results it appears that the subjects used either a continuous feedback control mode or a more ballistic control mode in which feedback was used mostly in the final phase of motion across all conditions.

321.5 RELATIONSHIP BETWEEN INTERNAL AND EXTERNAL FORCES ACTING ON THE CAT HINDLIMB DURING OVERGROUND LOCOMOTION. E.G. Fowler*, R.J. Gregor, R.R. Roy, J. Hodgson* and J. Broker*. Kinesiology Department and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Three components of the ground reaction force (GRF) have been reported by Manter for a single cat (3.3 kg) during overground locomotion (J. Exp. Biol. 15:522-540, 1938). Recently, several investigators have reported tendon forces from selected hindlimb muscles during treadmill locomotion (J. Neurophysiol. 41:1203-1216, 1978; J. Biomech. 17:685-694, 1984).

The purpose of this investigation was to evaluate hindlimb kinetics by measuring both GRFs and muscle forces during overground locomotion in the cat. The right achilles, left plantaris, and both tibialis anterior tendons of a 4.2 kg cat were implanted with tendon buckle transducers. The achilles tendon was implanted with a modified oval buckle (J. Biomech. 16:691-701, 1983) while all other tendons were implanted with an E shaped buckle (J. Neurophysiol. 41:1203-1216, 1978). The floor of a plexiglass enclosed walkway was instrumented with a specially designed force platform. Two piezoelectric elements (Kistler 9251A) capable of measuring vertical (Fz) and horizontal (Fy) components of the GRF were secured between two metal plates. The force platform was isolated from the surrounding walkway and a piece of wood identical to the floor surface was attached to the top plate for concealment. The cat then stood and walked over the platform while high speed films (100 fps) were taken and synchronized to tendon forces and GRF records. Separate trials were then recorded for right and left hindlimb contact with the force platform during the support phase of slow walking.

Peak Fz during stance was 17.3N for the right and 23.1N for the left hindlimb. Peak achilles tendon force was 20.7N while peak plantaris forces was 13.6N. Peak tibialis anterior forces were 3.9N on the right and 3.6N on the left side.

321.6 STRIDE LENGTH VARIABILITY AND THE AVERAGE VELOCITY OF HUMAN GAIT. N.H.Mayer, M.Ridenour* and L.Kent*. Temple University and Moss Rehabilitation Hospital, Philadelphia, PA 19141

Movement whose endpoint is a target with explicit visual boundaries was described by Fitts as having a loglinear relationship between movement time (MT), movement amplitude (A), and accuracy (W, target width), ($MT=a+b\log_2[2A/W]$). For movements where endpoint targets are not guided by explicit visual boundaries, Schmidt proposes that accuracy is proportional to the average velocity of the subject's movements ($W_e=a+b[A/MT]$), where W_e is the effective target width. This study examines the Schmidt model with respect to a human locomotion paradigm, where visual guidance of endpoint accuracy is usually absent. Using analogous measures of locomotion, we applied Schmidt's model in the following hypothesis: If stride time and stride length are controlled by the experimenter as independent variables but the accuracy of the stride is not visually monitored by the subject, then stride length variability will be proportional to the average gait velocity.

Fifteen healthy adult female subjects participated in this study. Each test consisted of 16 random combinations of stride length and stride time repeated three times, for a total of 48 trials. Stride length ranged from .8 to 1.6m, stride time ranged from 8 to .7s, with a projected velocity ranging from .1 to 2.2m/s. Subjects paced on an electronic walkway by the auditory cue of a metronome, which indicated stride time, and a visual cue (a .125m width floor marker), which indicated stride length. Subjects were instructed to be as accurate as possible to both the marker and the beat.

Both stride time and stride length cues had significant effects on the variability of actual stride length. A linear relationship was observed between stride length variability and the velocity of walking (r=.9), i.e. the ratio of stride length and stride time.

Schmidt's model is supported by the results of this study, namely that stride length variability is proportional to average gait velocity when endpoint accuracy is not guided by explicit visual boundaries. However, compared to the upper limb tasks that led to the development of Fitts' and Schmidt's models, interpretation of endpoint variability may be more complicated in lower limb tasks such as gait.

321.7 SPEED-RELATED CHANGES IN HINDLIMB INTERSEGMENTAL DYNAMICS DURING THE SWING PHASE OF LOCOMOTION. D. Wisleder*, J. L. Smith, and R. F. Zernicke. Laboratory of Neuromotor Control, Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Although motion-dependent feedback from the hindlimb can affect the stereotypic output of lumbosacral central pattern generators during locomotion, basic synergies and many details of the neuromuscular pattern remain after limb deafferentation (*e.g.,* Grillner, S. & Wallen, P., *Ann. Rev. Neurosci.* 8: 233-261, 1985). Nevertheless, some elements of the deafferented pattern show variations that may be related to speed-dependent modulations in hindlimb intersegmental dynamics during the swing phase of locomotion. To examine possible reasons for these variations, rigid-body dynamics can be used to quantify how the trajectories of limb segments can be influenced by muscle contractions, gravitational forces, and interactive forces that are related to angular and linear velocities and accelerations of limb segments (*e.g.,* Smith, J.L. & Zernicke, R.F., *Trends NeuroSci.*, 10: 123-128, 1987). Preliminary data for normal cats suggest that significant interactions occur between motion-dependent torques and muscle torques during the swing phase of locomotion (Hoy, M.G. & Zernicke, R.F., *J. Biomechanics* 18: 49-60, 1985). These initial data, however, were collected for a limited range of speeds, and our present study subtantially extends those initial data by examining the coordination of muscular and interactive hindlimb torques for a wide range of locomotor speeds and gait modes.

Normal adult cats (2.4-3.0 kg) were trained to locomote on a motorized treadmill at speeds (0.4 to 3.0 m s^{-1}) that elicited walking, trotting, and galloping gaits. Hindlimb trajectories were recorded, using high-speed ciné film (100 frames s^{-1}), for at least three different speeds within each of the three gait modes. Joint centers were digitized, and angular and linear kinematic data were smoothed and differentiated (Hatze, H. *J. Biomechanics* 14: 13-18, 1981). A planar, three-segment (thigh, leg, and paw) rigid-body model of the cat hindlimb (Hoy, M.G. & Zernicke, R.F., *J. Biomechanics* 19: 867-877, 1986) was used to examine intersegmental dynamics during the swing phase of locomotion.

With increases in speed of locomotion, the intralimb interactive torques and muscular torques increased significantly. In particular, at the knee joint during the second half of swing when the paw is lowered for contact by ankle extension (E-1 phase), torques arising from leg angular acceleration tended to extend the knee, while a flexor muscle torque at the knee counteracted that tendency. With slow walking, interactive knee joint torques may have been sufficient to decelerate knee extension without requiring contractions of posterior thigh muscles, such as the semitendinosus. At higher speeds of locomotion, however, the knee torques related to leg angular acceleration increased significantly, and substantially elevated knee flexor torques were needed to counteract the tendency of the knee to extend. Supported by NIH grant NS 19864.

321.8 ROLE OF CENTRAL AND PERIPHERAL MECHANISMS IN THE PAW-SHAKE RESPONSE. G.F. Koshland and J.L. Smith. Department of Kinesiology, UCLA, Los Angeles, CA 90024

Our previous work demonstrated that paw-shake responses could be elicited in chronic spinal cats after extensive deafferentation (DEAFF) of the hindlimb (Koshland *et al., Neurosci. Abst.* 1983). In this study, we examined details of the neuromuscular patterns preserved or altered after DEAFF. For the control condition, responses were evaluated in five adult cats recorded three months after spinalization (T-12) and then three to five months after unilateral ganglionectomy (L3-S1) for the experimental condition. Responses were elicited in spinal cats by wrapping tape around the paw, but after DEAFF, the paw was insentient, but noxious stimuli applied to an area of the upper thigh consistent with the S2 receptive field evoked similar multicycle responses.

After DEAFF, responses were difficult to evoke, and data from one cat were excluded because only single-burst reponses were elicited. On average, the number of cycles per response in the DEAFF limb was 5 ±2 cycles, or five cycles less than that during control responses (10 ±2 cycles). Cycle periods, defined as the interval between successive lateral gastrocnemius (LG) onsets, were more variable and longer (DEAFF 125 ±32 ms; control 98 ±15 ms). After DEAFF, cycle periods within a single response remained relatively constant over successive cycles, while under control conditions, the duration of successive cycle periods increased linearly from 68 ms to 112 ms.

With DEAFF, LG burst duration was unchanged as brief bursts of 40 ms occurred during each cycle. In contrast, activity of the tibialis anterior (TA) and vastus lateralis (VL) was altered by DEAFF. With feedback, TA and VL burst durations increased with increasing cycle periods, but after DEAFF, burst durations of both muscles were brief (35-45 ms) and unaffected by cycle period. These results suggest that spinal mechanisms in the DEAFF cat set muscle activation at a minimal duration, but with motion-dependent feedback, TA and VL burst durations are modulated by and related to the limb dynamics as well as the cycle period.

Some aspects of the paw-shake synergy were also altered. In the DEAFF limb, TA onset occurred later in the cycle and preceded the LG burst by 26 ±10 ms, regardless of cycle period. Under control conditions, TA onset occurred earlier in the cycle, and the interval preceding the LG burst was correlated with TA burst duration ($r = 0.63$) and cycle period ($r = 0.81$). Under both conditions, LG onset occurred 15 ms before TA offset, and the resulting cocontraction was an immutable feature of the pattern. In most DEAFF responses, VL and TA were coactive, similar to the mixed synergy described for control conditions (Smith *et al., J. Neurophysiol.* 54: 1271-1281, 1985). In 20% of the responses from three DEAFF cats, however, VL onset was delayed and coincidental with LG bursts, similar to the extensor synergy more typical of walking and scratching in the cat.

The results suggest that spinal networks responsible for the paw-shake response set minimal criteria, while hindlimb afference modifies the temporal structure of successive cycles, burst durations of the TA and VL, and possibly the intralimb synergy. Supported by a NIH grant, NS 19864.

321.9 **RHYTHMIC MODULATION OF CUTANEOUS AFFERENT MEMBRANE POTENTIAL DURING FICTIVE LOCOMOTION IN THE CAT.** J.P. Gossard *, J.-M. Cabelguen *, P.Saltiel * , T. Drew , S. Rossignol , Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Québec, Canada, H3C-3J7.

Our previous studies have shown that there is a rhythmic modulation of dorsal root potentials (DRPs) during fictive locomotion in the cat and that even individual primary afferent fibres may antidromically discharge rhythmically. The aim of the present project was to study the spontaneous and evoked presynaptic events in single, identified, cutaneous primary afferents during fictive locomotion.

Nineteen cats were decorticated under steroid anaesthesia and paralysed. Locomotion-related activity was recorded from selected hindlimb muscle nerves (Sartorius and Vastus Lateralis) as well as from the proximal stump of the cut dorsal root (L6) using Ag/AgCl electrodes. Intracellular DC recordings of primary afferent fibers were made with glass micropipettes filled with potassium citrate. Impaled afferent fibres whose membrane potential was greater than 45 mV were identified by high frequency (>700Hz) stimulation of Peroneal Superficialis and Tibialis Posterior nerves. Primary afferent depolarisation (PAD) was evoked in the identified fibre by stimulation of the other cutaneous nerve (single pulse, 200 μs, 60-150 μA).

Forty percent of the 140 units retained showed clear rhythmic fluctuations of their membrane potential at the periodicity of locomotion. The majority of them were not spontaneously discharging. Typically, there were two peaks of depolarisation per cycle. The first, and usually the largest, occurred near the maximum of flexor activity, the second, near the peak of extensor activity. The relative amplitude of each depolarisation could vary from one afferent to another in the same experiment although the extracellularly recorded DRPs did not change. Each peak of depolarisation was followed by a trough of hyperpolarisation. The first one was synchronous with the flexion-extension transition, the second one, with the extension-flexion transition. Some units showed only the flexion-related depolarisation and the subsequent hyperpolarisation. Furthermore, it was possible to evaluate the changes in the amplitude of evoked PADs throughout the locomotor cycle. PADs were minimal during the flexor activity, increased during the flexion-extension transition and reached their maximum amplitude during the period of extensor activity.

These results thus indicate that central networks responsible for the generation of locomotion cyclically modulate the membrane potential of cutaneous primary afferent fibres as part of the locomotor program. The maximal depolarisation of the cutaneous fibres during the period of flexor activity suggests that the efficacy of transmission in cutaneous pathways would be reduced at the presynaptic level in that phase. This might be reflected in the reduction of PADs evoked between cutaneous fibres in that period. The relative importance of these central mechanisms as well as movement-related mechanisms in the control of cutaneous reflexes during real locomotion is under study. 321.10 INTERLIMB COORDINATION OF REPETETIVE RHTYMIC MOVEMENTS. A.M. Gentile and R.A. States* Teachers College, Columbia University, NY,NY 10027.

Prior research has indicated potency of the walking cycle in determining upper limb movement cycle (Craik, R. et al. in R.M. Herman et al., Neural Control of Locomotion, 1976; Muzzi et al., Human Movement Sciences, 3:337-354, 1984). The present study examined coordinative patterns in a non-locomotor task involving all four limbs to elucidate conditions under which coupling strength varies.

Four variations of a task involving cotemporaneous rhythmic movement of the upper and lower limbs were tested using 22 Ss. Single- or multi-joint claps were combined with alternating single-joint foot taps or multi-joint "step-like" movements. All testing was done with Ss seated at a table. Timing of clapping and tapping movements was measured by recording contact of the Ss' hands with each other and contact of the feet with floor plates. For each S, time of hand contact was plotted against normalized lower limb cycle using foot contact as the central reference point. The standard deviation of that distribution was used as a measure of coordinative linkage.

Results indicated significant differences in coordinative linkage when the upper and lower limbs were engaged in movements of different extents. Large clapping movements combined with small foot taps yielded little linkage between the two cycles, whereas large "step-like" movements appeared to entrain clapping cycles. One explanation for these results is that unlike large arm movements, large multi-joint leg movements activate a locomotor synergy that promotes tightly coupled coordination of all four limbs.

An ancillary finding showed that coordinative linkage was a stable characteristic for individuals. Retesting of the small clapping and tapping task after a two month interval produced high correlations for coordinative linkage (.74), clap and tap periods (.94 & .88), and tap variability (.74).

321.11 **Cutaneous Reflexes Evoked by Mechanical Stimulation During Locomotion in the Same Chronically Implanted Cats Before and After Spinalisation.** M. Bélanger, T. Drew, J. Provencher* and S. Rossignol. Centre de Recherche en Sciences Neurologiques, Dépt de Physiol., Univ. de Montréal, Montréal, Québec, Canada, H3C-3J7.

Previous studies have shown that adult cats can walk with the hindlimbs following spinalisation at T13. To study the adaptability of this spinal locomotion, we examined the responses to mechanical perturbation of the hindlimb during locomotion in the same chronically implanted cats before and after spinalisation.

EMG activity was recorded from flexor and extensor muscles of the hindlimbs while cats walked on a treadmill at speeds of 0.3-0.4 m/s. A digital time code allowed the EMG signals to be synchronized with a simultaneous video recording. Mechanical stimulation to the dorsum of the paw was applied at random during the swing phase of locomotion with a rigid rod to which a microswitch was attached. After a period of 7-9 weeks of control experiments the cats were spinalised at either T10 or T13.

In the pre-spinalised condition, mechanical stimulation evoked an initial locking of the ankle which was followed by pronounced knee flexion. Subsequent flexion of the ankle joint further removed the foot from the stimulation. On the other hand, the hip angular movement was little affected by this stimulation. The EMG responses to mechanical perturbations were relatively similar to those observed in previous studies of intact cat (Wand et al. **Exp. Brain Res.**, 38: 109-114, 1980). Short latency excitatory responses in an ankle flexor (TA) (8 ms) and extensor (GL)(20 ms) muscles acted to stabilize the ankle joint. As importantly, there were also very large short latency excitatory responses in FDL which undoubtedly contribute to the locking of the ankle. The knee flexion is at least partly explained by the very large responses evoked in St (15 ms). Small excitatory responses were also observed in the hip flexor muscles (Srt & Ip) (12 ms). Secondary responses (>50 ms) were seen in several muscles. They were especially marked in the TA, as observed by Wand et al. (1980), and were probably responsible for the subsequent ankle flexion.

Kinematic analysis of the post-spinalised perturbed cycles showed that the joint angular patterns were very similar to those observed before spinalisation. However, the degree of knee flexion observed was much greater so that the ankle joint was raised above the knee joint. Overall the post-spinalised EMG responses were similar to those observed prior to spinalisation. However, secondary responses, especially in TA, were notably decreased.

In summary, the complexity and timing of joint angular movements and EMG responses to mechanical stimulation were preserved after spinalisation. This demonstrates that the spinal cord can not only generate the basic locomotor rhythm but is also capable of integrating the sensory inputs arising from a perturbation to produce a functional and well adapted compensatory response.(Funded by the Canadian MRC, T.D. is Funded by FRSQ and M.B. is supported by NSERC).

321.12 MAPPING BASAL FOREBRAIN SITES AT WHICH ELECTRICAL STIMULATION ELICITS LOCOMOTOR STEPPING IN THE ANESTHETIZED RAT. H.M. Sinnamon. Lab. of Neuropsych., Wesleyan University, Middletown, CT 06457.

The basal forebrain has been implicated in the initiation of locomotion. This study attempts to localize the critical regions by mapping with low current levels. Rats were initially anesthetized with a barbiturate (25 mg/kg) and mounted in a stereotaxic apparatus such that electrically-elicited stepping movements turned a wheel. Maintenance anesthesia was provided by periodic intraperitoneal injections of Nembutal (7 mg/kg) and injections of Xylocaine into the scalp incision. The basal forebrain was stimulated with 50 Hz, 0.5-duration pulses at currents of 25 and 50 uA in trains of 10-sec duration delivered through glass pipettes, 50-70-um tip diameter, filled with either 5M Sodium Acetate or 2M Sodium Chloride. Stimulation was applied at 200 um steps, first with three 10-sec trains of 50 uA and next with three 25 uA trains. If they were negative, the general ability of the rat to locomote was confirmed by stimulating the posterior hypothalamus through a fixed electrode. The pipette was fixed at the deepest point in the last penetration and it was the reference in constructing the map.

The best studied region to date is at the level of the posterior medial preoptic area; it is represented by 195 stimulation sites in 12 electrode penetrations. With 25 uA, locomotion was elicited by stimulation in a confined cluster of sites centered in the lateral hypothalamus. The lateral edge of the cluster merged only as far as the medial aspect of the substantia innominata/ventral pallidum. Increased currents (50 uA) increased the lateral and medial extent of the lateral hypothalamic cluster only slightly but did reveal another cluster around the nucleus reuniens of the anterior thalamus. Poststimulation locomotion was associated with sites in the bed nucleus of the stria terminalis. Bracing responses, characterized by pelvic flexion and forelimb extension was consistently elicited by stimulation of the internal capsule and the ventral pallidum. The general pattern of results is consistent with proposal that activation of axons originating in the lateral preoptic area can produce locomotion in this preparation.

321.13 DEVELOPMENT OF THE PEDUNCULOPONTINE NUCLEUS. II. IN VITRO. R. D. Skinner, D. L. Davies, C. Conrad*, V. Henderson* and E. Garcia-Rill (SPON. J. Johnson), Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Cholinergic neurons in the pedunculopontine nucleus (PPN) (and laterodorsal tegmental nucleus - LDT) are known to be selectively labeled using the NADPH diaphorase histochemical technique (Vincent et al. '83). NADPH diaphorase labeling of PPN and LDT neurons is evident at the time of birth (see accompanying abstract). The present study was undertaken to determine if PPN (and LDT) cells could be cultured and identified in vitro using this histochemical technique. Neuron-enriched cultures were prepared from the dissected midbrain tegmentum of embryonic Sprague-Dawley rats at gestational ages of 16 and 19 days. Cells were dissociated by trypsinization (0.2%) and trituration, seeded onto poly-L-lysine coated glass coverslips and cultivated in Dulbecco's Modified Eagle Medium fortified with fetal bovine serum (10%), penicillin and streptomycin. The nutrient medium was replenished 3 times a week; cultures were incubated at 37°C in a humidified atmosphere of 5% CO_2 and air. Cultures were serially harvested at 5-day intervals for 20 days. They were fixed in 4% paraformaldehyde, incubated (1 mM NADPH, 0.2 mM nitroblue tetrazolium, 5 mM sodium malate) at 37°C for 1-2 hr, rinsed and photographed. Cultures then were processed for neurofilament localization immunocytochemically in order to identify neurons. The antiserum to neurofilament was a gift of Dr. D. Dahl. Both the unlabeled peroxidase-antiperoxidase and indirect immunofluorescent (FITC) techniques were utilized.

The cultures consisted of dispersed neurons and some epithelioid cells presumed to be glia. During the first 5 days in culture the neurons elaborated extensive neuritic arbors and the glia proliferated to form a subconfluent cell carpet. NADPH diaphorase labeling first became evident at 10 days in culture but was maximal at 15 and 20 days. Large numbers of astrocyte-like cells were NADPH diaphorase positive, making it imperative to confirm the presence of neurofilaments in any NADPH diaphorase labeled cells. A small percentage of neurofilament-containing cells also was found to be NADPH diaphorase positive.

These findings suggest that a small population of midbrain tegmentum neurons are present in culture and may represent PPN and LDT neurons (based on NADPH diaphorase labeling). However, it has not been demonstrated that a separate or additional population of neurons from the midbrain tegmentum does not manifest NADPH diaphorase labeling in culture. NADPH diaphorase labeling in the PPN was not observed in intact gestation day 16 and 19 brains (but is evident at birth). Similarly, cultures did not begin to demonstrate NADPH diaphorase labeling until 10 days in culture.

Supported by PHS grants NS21981 (RDS) and AA07145 (DLD).

321.14 DEVELOPMENT OF THE PEDUNCULOPONTINE NUCLEUS. I. IN VIVO. C. Conrad*, V. Henderson*, R. D. Skinner, P. Abraham* and E. Garcia-Rill (SPON. J. Johnson), Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Previous findings from our labs suggest that the pedunculopontine nucleus (PPN) in the rat may be part of the mesencephalic locomotor region, an area known to modulate spinal locomotion oscillators (Skinner et al. '84). Developmentally, there appears to be a transition period in the nature of supraspinal control of locomotion at around two weeks of age. Spontaneous locomotor movements may occur in an adult animal in which the spinal cord was transected before 15 days of age, but transection after that time appears to permanently inhibit the occurrence of such movements. This study is part of a series of experiments tracing the postnatal development of the PPN in the rat brain. One aim is to determine if obvious morphological changes occur in development which may be related to the effects mentioned. Neonatal (0-24 days) rat brains (n=50) were processed using the NADPH diaphorase histochemical technique, which selectively labels PPN (and laterodorsal tegmental - LDT) cholinergic neurons (Vincent et al. '83). After fixation with 1% paraformaldehyde -1.2% glutaraldehyde, 50μ sagittal sections of the brainstem were cut on a vibratome, incubated at 40°C for 15-60 min, mounted, dried and coverslipped. Labeling was evident in the PPN and LDT at all ages studied. PPN cells with an evident nucleus were drawn and measured. The mean cell body area was constant for the first 8 days (0-2, 181±54μ^2; 3-5, 196±17μ^2; 6-8, 175±14μ^2), then increased markedly over the next 9 days (9-11, 284±52μ^2; 12-14, 394±96μ^2; 15-17, 498±58μ^2). At 18-20 days there was a decrease in mean cell area (370±129μ^2), followed by another increase at 21-24 days (440±55μ^2). Labeled adult PPN neurons have a mean area of 316±26μ^2. Distributions of cell body areas revealed that all cells appeared to grow significantly, peaking in size at 15-17 days. A loss of the larger cells appeared to occur at 18-20 days (perhaps accounting for the decrease in mean cell size at that age), while at 21-24 days an increase in the number of small cells suggests that shrinkage of the population at large had occurred. However, even at 21-24 days cell size was larger than in the adult.

These results suggest that a peak in cell size coincides with the 15 day transition period described. Reorganization after that time suggests the occurrence of some large cell loss with overall shrinkage of cell size over the next several days. Due to the variation in level of labeling across animals, exact cell counts were not considered reliable. These changes may reflect highlights in the development of locomotor control.

Supported by PHS grant NS21981.

321.15 RHYTHMIC AND TONIC ACTIVITY OF CELLS IN THE AREA OF THE PEDUNCULOPONTINE NUCLEUS IN RELATION TO FICTIVE LOCOMOTION. E. Garcia-Rill and R. D. Skinner, Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205-7199.

Previous studies have established the presence of low threshold locomotion-inducing stimulation sites in the posterior midbrain, by definition the mesencephalic locomotor region (MLR), in the area of the pedunculopontine nucleus (PPN) as well as in the cuneiform nucleus (CF) (Shik et al. '66, Garcia-Rill et al. '82). The present study was carried out in the fictive spontaneous locomotion preparation in order to determine the presence of rhythmic and/or tonic unit activity in the CF and PPN in relation to alternating or tonic neurographic activity of limb nerves in the absence of peripheral input. In addition, selective histochemical labeling of cholinergic PPN neurons using the NADPH-diaphorase technique (Vincent et al. '83) was carried out in order to localize architectonically those recording sites marked with Fast Green.

Of the 231 neurons studied in the posterior midbrain, 48% were related to fictive spontaneous locomotion. In the area dorsal (CF) to the NADPH-diaphorase positive region, 32% (14/44) of the cells studied showed related activity. Of these, 72% displayed bursting in relation to neurogram "bursts", while 28% fired tonically during ("on"), or stopped firing tonically during ("off") alternation. Within the NADPH-diaphorase positive region (PPN), 49% (71/145) of cells showed related activity, only 23% of these were "bursters" while 77% were "on" or "off" cells. In the area ventral to the NADPH-diaphorase positive area (pontine reticular formation) 69% (27/42) of the cells studied showed related activity, mostly of the "burster" type (70%) compared to the "on/off" type (30%). However, neurons in this area were found to respond to passive movement of the limbs and their activity appeared to reflect ascending spinal input. Cells studied in more dorsal locations (CF and PPN) were not modulated by peripheral input.

These results indicate a segregation of cells related to ongoing rhythmic activity compared to those related to the onset and termination of alternation. In general, the CF appears to be more related to the frequency of rhythmic activity while the PPN appears to be more related to the duration of rhythmic episodes. These findings may be related to the differential neurochemical control of locomotion evident in the MLR, in which injections of GABA antagonists in increasing amounts can induce stepping at higher and higher frequencies (i.e. walk-trot-gallop), whereas injections of Substance P in increasing amounts can induce longer and longer episodes of locomotion (at the same stepping frequency) (Garcia-Rill et al. '86,'87).

321.16 ELECTRICAL ACTIVATION OF RAT LATERAL GASTROCNEMIUS-SOLEUS (LGS) AND TIBIALIS ANTERIOR (TA) MUSCLES BY SIMULATING TEMPORAL PATTERNS OBSERVED DURING TREADMILL LOCOMOTION: DOES CO-CONTRACTION INFLUENCE STEP CYCLE FREQUENCY? R.S. Hutton, R.R. Roy and V.R. Edgerton. Depts. of Psychology and Kinesiology, University of Washington, Seattle, WA 98195, and U.C.L.A., Los Angeles, CA 90024.

The frequency of cyclical limb movements may be limited by mechanical interactions of antagonistic muscles at higher cycle rates (Hutton & Enoka. Exp. Neurol. 93:369, 1986). This problem was investigated by electrically simulating activation patterns and monitoring muscle forces in LGS and TA muscles of 6 Sprague-Dawley rats (350-400 g). Based on EMG data recorded from freely moving rats (Roy, Hutchison & Edgerton, Med. Sci. Sport Ex. 18:S45, 1986), SOL mean cycle (c) durations (time between EMG onset of one cycle to EMG of next cycle), c/s, burst durations (BDs), and TA onset times (OTs) following SOL EMG onset were determined at 3 treadmill speeds (See Table). Muscle force was monitored from the detached tendons or

m/min	n	Cycle Duration (ms)	c/s	BDs (ms): SOL	TA	TA OTs (ms)*
40	7	294	3.4	149	80	140
54	6	246	4.1	106	71	125
67	5	219	4.6	94	66	110

* Taken from step cycles in one animal.

directly at the approximate insertion sites using a Statham transducer. To determine mechanical interactions attributed to the slow-twitch SOL muscle, forces were measured with the LGS intact or after the SOL was denervated.

With tendons detached, TA force temporally overlapped with LGS force over periods ranging between 20-50 ms at 3.4 c/s and 0-50 ms at 4.1 c/s. Overlap in forces at 4.6 c/s ranged between 0-10 ms. LGS force traces were asymmetrical, taking longer to return toward baseline than the time to peak force. Without SOL, force patterns were more symmetrical. In contrast, co-contractions were not observed when LGS contractions followed TA activation. At all cycle frequencies, above baseline residual forces (range: 50-400 g) in LGS were only seen during subsequent TA activations. Without SOL, LG forces approached baseline values (0-250 g). TA forces always reached baseline before LGS or LG activation. With tendons intact, phase relationships in onset forces were markedly improved and no co-contractions were evidenced across cycle velocities. All muscle forces reached baseline before subsequent activation. LGS or LG force patterns now appeared symmetrical. Therefore, co-contraction does not influence faster step cycle frequencies but at lower cycle frequencies may serve to stabilize the foot at toe-off (end of E_3 phase). Factors associated with mechanical coupling of LGS and TA through the foot (e.g., torque, viscoelastic properties) appear to improve phase relationships and force onset-offset symmetry at all cycle frequencies tested.

321.17 CUTANEOUS REFLEX RESPONSES IN CAT POSTERIOR THIGH MUSCLES DURING TREADMILL LOCOMOTION. C.A. Pratt, C.M. Chanaud and G.E. Loeb. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20892

Chronically implanted bipolar "patch" electrodes sutured onto the fascial surfaces of the posterior thigh muscles were used to record the electromyographic (EMG) responses evoked by stimulation of ipsilateral hindlimb cutaneous nerves during treadmill locomotion. Single biphasic pulses were delivered every 1500 ms via chronically implanted nerve cuff electrodes to the saphenous, plantar, superfical peroneal (SP) or sural nerves at stimulus strengths ranging from 1.2xT (times threshold) to 8xT. Thresholds for different afferent populations were determined on the basis of the shape of the evoked volleys recorded in tripolar nerve cuffs placed on either the femoral or sciatic nerves. The following muscles were implanted in various combinations in five cats (a=anterior, p=posterior, m=middle): biceps femoris (BFa,m,p); semitendinosus (ST); gracilis (GRa,m,p); semimembranosus (SMa and SMp); tensor fascia latae (TFLa and TFLp); tenuissimus (TEN); caudofemoralis (CF) and adductor femoris (AF).

Consistent reflex responses were produced at stimulus strengths of 2-4xT which activated fast conducting fibers (50-70 m/s); slower fibers (30-40 m/s) were stimulated at 8xT. The responses included short latency (8-10 ms) excitation, P1 (estimated central delay of 1.7-3.7 ms); a P2 excitation occurring at a latency of 30-34 ms, and inhibition at latencies of 14-16 ms.

All four nerves had similar excitatory effects on the knee flexors BFp, ST and TEN. Typically, low threshold stimulation produced gated P1 responses during the late stance (E3) and flexion (F) phases of the step cycle when these muscles are normally active. At higher stimulus strengths, an ungated P1 response appeared throughout all phases of the step cycle, and, at 8xT, a gated (late E3-F) P2 response was also produced. All nerves had similar inhibitory effects on the hip extensors CF and BFa.

The reflex responses in the remaining muscles were not as stereotyped. Some muscles (SMa, GRm, GRp, TFLa, TFLp, AF) responded differently to different nerves. For instance, SP produced P1 and P2 excitatory responses in GRm while plantar and sural produced inhibition. Interestingly, excitatory responses were evoked by some nerves in the extensors GR, SM and AF during stance (E2-E3). Different responses could also be produced by the same nerve in different regions of a single muscle (BF, see above, and GR; plantar stimulation produced P1 and P2 responses during E2-E3 in GRa, inhibition followed by excitation in GRm and no effect or inhibition in GRp).

The regionalized specificity of cutaneous reflexes in mechanically complex muscles, some of which are differentially activated during locomotion, suggests a high degree of specificity in the premotoneuronal circuitry for different task groups.

321.18 CUTANEOUS REFLEXES IN THE CAT DISTAL HINDLIMB AND THEIR GATING DURING NORMAL TREADMILL WALKING. G.E. Loeb. Lab. of Neural Control, NINCDS, National Institutes of Health, Bethesda, MD 20892

As a probe of functional connectivity in the spinal cord, cutaneous nerve stimuli were delivered via chronically implanted cuff electrodes on the plantar and superficial peroneal nerves. Sciatic nerve volleys were recorded to determine thresholds for various fiber classes and estimated arrival time at the spinal cord. Bipolar, epimysial "patch" electrodes were used to record EMG responses with little or no signs of cross-talk even during large reflexes in adjacent muscles. Three cats were implanted similarly to record from soleus (SOL), medial or lateral gastrocnemius (MG or LG), plantaris (PLA), flexor digitorum brevis (FDB), flexor hallucis longus (FHL), flexor digitorum longus (FDL), peroneus brevis (PB), peroneus tertius (PT), peroneus longus (PL), tibialis anterior (TA), extensor digitorum longus (EDL), and biceps posterior (BP). Central delays given below were calculated (+2 ms) by subtracting estimated sensory and motor transmission times based on distances.

Thresholds for both plantar and peroneal stimulation were 35-50uA (0.1ms) which activated 60 m/s fibers; EMG reflexes were noted but no visible change in gait was seen on videotape. At 2-4xT (times threshold), >20 m/s fibers were activated and swing phase trajectory changes were noted. At 7-10xT, >10 m/s fibers were activated and noticeable yielding during stance phase was noted, but the animals showed no break in stride or apparent discomfort.

Most EMG responses consisted of some combination of short latency excitation or inhibition (P1 or N1, 1-3 ms central delay) and/or long latency excitation (P2, 10-12 ms). Plantar stimulation at 1.2-1.5xT produced P1 responses in EDL, FDB, and PL; P2 responses in FDL and BP; and N1 responses in SOL, MG, PLA, PT, and PB. Peroneal stimulation at 1.2-1.5xT produced P1s in FDL and BP and N1s in SOL, LG, PLA, FHL, PB, and EDL. With increasing intensity (4-8xT), BP, TA, and FDL became dominated by P2 responses. FDL and PL were particularly variable among the three animals; neither was consistently recruited during the slow walking employed.

Some excitatory reflexes were phased completely differently than normal recruitment. The P1 in TA was largest during E2-3 (stance) phase for all plantar stimulation levels. EDL tended to be inhibited during its two bursts of locomotor activity in E1 and E3 phases and had a P1 response during F phase and P1+P2 during E2.

The general impression from examining 36,000 stimulus-response pairings was that there appears to be an extraordinary specificity of spinal connectivity associated with individual muscles, in terms of cutaneous fields, fiber classes, step-cycle phases, central path lengths, and in some cases, strategies specific to individual animals. Taken together with the specifically phased recruitment of each of these distal muscles during the step cycle, it would seem that the central pattern generator has much greater internal complexity than is suggested by most models now being considered.

321.19 COMPARISON OF TREADMILL AND OVERGROUND LOCOMOTION IN THE CAT. J.W. Blaszczyk and G.E. Loeb (SPON: C.J. Heckman). Lab. of Neural Control, NINCDS, National Institutes of Health, Bethesda, MD 20892.

For convenience, locomotion is usually studied on a treadmill instead of overground. Previous reports of differences in interlimb coordination between the two situations (e.g. Wetzel et al.,1975, J.Neurophys. 38: 492-501) have made only vague suggestions regarding psychological effects of the visual environment.

Five cats moved at their preferred gait along either a 1m long treadmill or a 3m long, similarly enclosed, stationary walkway. Limb placement patterns at speeds of 0.5-1.3 m/s were recorded on video (60 fields/s) and analyzed as still fields using a video disk. Duration of the swing and stance phases and horizontal amplitude of the swing phase (stride length) were calculated for all four limbs. The duty factor (DF) was defined as the mean fraction of the step cycle for which a foot was on the ground; because this was found to be the same for all limbs, the means are given below. Phase differences between limbs were defined by the time interval between the onsets of the stance phases divided by cycle duration; differences below are between ipsilateral fore and hind limbs.

Under both conditions, animals tended to walk with either of two stable gaits: walking gaits in which the DF was 0.6-0.75 (i.e. three limbs were on the ground at a time on average), and trotting gaits in which the DF was about 0.5 (i.e. only two limbs were on the ground at the same time). However, for overground locomotion, the animals almost always adopted the conventional diagonal gaits (phase differences of about 0.25 for walk and 0.5 for trot), whereas in the treadmill, the animals often adopted the "pacing" equivalent of both gaits (phase differences of 0.1-0.2 between ipsilateral limbs).

By adopting the pacing variants, the animals were able to maintain the more stable walking DF at higher effective ground speeds because they could use a longer stride length (mean increase of 18%) without having their front and hind feet collide. In fact, animals on the treadmill were often noted to start out with diagonal gaits and make transitions after such collisions, particularly when walking near the front of the belt. The transitions consisted of prolongations of the hindlimb stance phases for 1-2 step cycles until the ipsilateral phase shift approached zero.

On the treadmill, the animal can see that it is walking toward a non-moving barrier directly in front of it. By maintaining the highest possible DF, the animal presumably improves its stability and ability to stop abruptly (e.g. if the belt stops moving). As effective ground speed increases, DF can be maximized either by reducing swing phase duration (apparently inefficient; not seen) or by increasing stance duration, which increases stride length beyond that allowed by the interlimb-girdle spacing. The latter requires either placement of one set of feet lateral to the other (not seen at these speeds but known to occur in some forms of gallop) or the phase-shifted pacing gaits observed in this study.

321.20 AN ELECTROMYOGRAM-TO-FORCE PROCESSOR AND ITS TESTING IN CAT HINDLIMB MUSCLES. J.L.F. Weytjens and G.E. Loeb (SPON: F.J.R. Richmond). Lab. of Neural Control, NINCDS, National Institutes of Health, Bethesda, MD 20892

EMG signals are easily recorded from most muscles during unrestrained behavior, but they provide only limited and often misleading suggestions about the mechanical roles of individual muscles because of the many non-linear, time-varying, and muscle-specific factors involved in actual force production. Therefore, a general purpose electromyogram-to-force (EtoF) processor would be of great value to experimentalists seeking to understand quantitatively the biomechanics of normal behavior and the control problems that must be solved by the central nervous system.

Such an EtoF processor requires an adequate mathematical representation of muscle that is both complex enough to account for the effects of kinematic factors such as muscle length and velocity and general enough to be applicable to muscles of different fiber types and architectures, yet simple enough to be mathematically tractable. For this study we used a unipennate model consisting of a parallel arrangement of a contractile element, a spring and a linear dashpot, in series through an angle of pennation with an elastic tendon. The contractile element was described multiplicatively by a first order linear differential equation for the "active state" which used bin-integrated EMG as input, a Gordon-Huxley-Julian-type active force-length relationship, and a Hill-type force-velocity relationship, augmented to include negative (active lengthening) velocities. Both the parallel elasticity of muscle and the series elasticity of tendon were modeled as nonlinear springs, with exponential force-length relationships below a transition length and linear ones above it. For this model we derived a system of two ordinary differential equations, which used EMG and muscle length (as functions of time) as inputs and produced fiber length, fiber velocity, angle of pennation, and muscle force (as functions of time) as outputs. Using appropriate initial conditions, this system is solvable for both passive and active muscle.

To test the model, one medial gastrocnemius muscle in each of five cats was implanted chronically with EMG electrodes (bipolar, epimysial "patch"), a muscle path-length transducer (saline-filled silicone rubber tubing with electrodes, stretched from origin to insertion), and a tendon-strain transducer (E-shaped clip onto tendon). Following recovery from surgery, the animals were videotaped and the signals from the implanted devices were recorded during natural behaviors, including locomotion at various speeds, jumping, paw-shaking, and scratching. Preliminary results indicate that accurate predictions of the time course of muscle force under naturally occurring dynamic conditions are within the reach of this model.

CATECHOLAMINES: CELL CULTURE

322.1 IDENTIFICATION OF LIVING DOPAMINERGIC NEURONS IN CULTURES OF THE MESENCEPHALON BY UPTAKE OF THE FLUORESCENT SEROTONIN ANALOGUE 5,7 DIHYDROXYTRYPTAMINE A.P. Mariani*, N.L. Silva and J.L. Barker (Spon. R. Nelson) Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892

Recently, Vaney (1986) described the visualization of serotonin-accumulating neurons in the mammalian retina following uptake of the fluorescent serotonin analogue, 5,7 dihydroxytryptamine (5,7 DHT). Similar serotonin analogues have long been known to be accumulated by dopaminergic neurons in the retina and we reasoned that 5,7 DHT might also be used to label and identify living dopaminergic neurons derived from the mesencephalon. Such an approach would allow focused single cell analyses and cell biological studies of identified, living dopaminergic neurons. Without a method to identify the living dopaminergic neurons, these studies would be difficult as dopaminergic neurons constitute one of the rarest transmitter phenotypes in the CNS. The mesencephalons of embryonic day 13 rats were dissected, dissociated and grown in vitro for 3 weeks. The cultures were then incubated with 5,7 DHT ($10\text{-}50 \times 10^{-6}$ M) for up to 1 hr. and examined in a fluorescence microscope with a water immersion objective. A small proportion of the neurons displayed a weak, but well-defined deep blue-violet fluorescence in both their cell bodies and processes. Spectral analysis of the fluorescence revealed that the emission peaked at 420 nm when excited at 365 nm. These "blue cells" were then photographed and their positions marked. Following fixation in aldehydes, the cultures were processed for both aldehyde-induced (Faglu) fluorescence and tyrosine hydroxylase (TH) immunohistochemistry. All of the "blue cells" recovered showed Faglu-induced fluorescence and over 80% were immunoreactive for TH, the rate-limiting enzyme in the catecholamine synthetic pathway. Based on these experiments, we conclude that the uptake of 5,7 DHT can be used to identify living dopaminergic neurons derived from the mesencephalon.

322.2 ELECTROPHYSIOLOGICAL PROPERTIES OF CATECHOLAMINERGIC NEURONS CULTURED FROM THE RAT MESENCEPHALON

N. L. Silva, N.L. Harrison*, A.P. Mariani* and J.L. Barker, Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20892

Catecholaminergic (CA) neurons from the embryonic rat mesencephalon can be maintained in culture and identified by fluorescence microscopy (adjoining poster, Mariani et al.). After 2-4 weeks in culture, recordings were made from both CA and non-CA neurons at room temperature using the whole-cell patch-clamp technique. Patch pipettes were filled with a standard 'intracellular' solution containing K gluconate sometimes supplemented with ATP. The external medium was a HEPES-buffered saline containing 1.5mM Ca and 1mM Mg.

All neurons had resting potentials between -50 and -60mV and many exhibited spontaneous action potentials (APs) and postsynaptic potentials. Depolarizing current injection elicited TTX-sensitive APs. CA neurons (n=20) had a mean input resistance of 420 Mohm; APs had an overshoot of 38mV, threshold of -33mV, and mean duration of 8.8ms (range 4.0-22.0). Non-CA neurons (n=9) had similar input resistance (425 Mohm), AP overshoot (40mV) and threshold (-31mV) but mean duration was 4.9ms (range 3.1-8.5). In some CA neurons, AP repolarization appeared biphasic, exhibiting a characteristic 'shoulder' that was reversibly reduced by the local application of 0.2mM Cd. Application of Cd to nearby non-CA neurons was not observed to shorten AP duration (see figure).

After blockade of APs with TTX, voltage-clamp recordings revealed the existence of three different outward currents in both types of neurons. A transient outward current was activated by steps from -60mV to potentials more positive than -40mV, inactivated at depolarized potentials and deinactivated by hyperpolarization. This current was sensitive to 4-aminopyridine. Two sustained outward currents were observed, one senstive to Cd or Co, the other seen in the absence of internal Ca accumulation and sensitive to TEA. Both CA and non-CA neurons responded to GABA with an increase in conductance and membrane current that reversed in polarity near -65mV.

The above results indicate that CA neurons cultured from the embryonic rat mesencephalon and identified by fluorescence microscopy are electrically and chemically excitable. Further, it appears that some CA neurons can be distinguished electrically on the basis of a broad AP that is reduced in duration by Cd.

322.3 **LIVE ADRENAL CHROMAFFIN CELLS ACCUMULATE THE FLUORESCENT SEROTONIN ANALOGUE 5,7-DIHYDROXYTRYPTAMINE.** R.A. Cruciani*, A.P. Mariani*, U. di Porzio, N.L. Silva and J.L Barker.(SPON: G.D.LANGE). Lab. of Neurophysiol. NINCDS., NIH, Bethesda, MD 20892

It has been shown both in vivo and in vitro that serotonin (5-HT) and 5-hydroxytryptophan (precursor), are substrates of an uptake mechanism in adrenal medullary chromaffin graules of different species. However it is still unclear whether the chromaffin cells themselves synthesize 5-HT. The results of Brownfield et al. support an internal regulating mechanism of 5-HT content, possibly by local synthesis. However Verhofstad and Jonson reported that an inhibitor of tryptophan hydroxylase had no effect on adrenal 5-HT content which suggests that the 5-HT present in chromaffin cells originates externally . Despite this controversy it has been shown in immunohistochemical studies that 5-HT and epinephrine co-exist in chromaffin cells. This methogology requires fixation of the tissue and experiments on living cells have not been performed. 5,7-dihydroxytryptamine (5,7-DHT) is a cytotoxic 5-HT analogue that is accumulated by serotoninergic neurons and fluoresces when excited by UV light allowing the visualization of live indolamine-accumulating neurons as shown in the retina by Vaney. In the present report we show that 5,7-DHT is accumulated by living chromaffin cells both in suspension and in cell culture. Chromaffin cells isolated from the adrenal medulla of 10 day and 6 week old rats were incubated for 1 hr with 2.5 and 25 µM 5,7-DHT and examined in a fluorescence microscope. When excited at 365 nm, the indolamine-accumulating chromaffin cells displayed a well defined "blue" fluorescence. The stained cells were photographed and marked and the cultures fixed in paraformaldehyde. Immunohistochemistry with antisera directed against tyrosine hydroxilase (TH) the rate limiting enzyme for catecholamine synthesis and phenylethanolamine N-methyltransferase (PNMT), demonstrated that all of the cells identified by 5,7-DHT fluoresence contain TH or PNMT. According to Brownfield et al., 75% of the adrenal medullary cells are 5-HT-containing using an antibody to 5-HT and immunohistochemistry. In living cells we have demonstrated that virtually all the medullary TH or PNMT immunoreactive cells can accumulate 5,7-DHT as well. Whether this finding implies that all the chromaffin cells contain 5-HT requires further investigation. Data on the specificity of the uptake mechanism will be also presented.

322.4 MOLECULAR MECHANISMS FOR THE LONG-TERM REGULATION OF TYROSINE HYDROXYLASE (TH) IN CULTURES OF BOVINE ADRENOMEDULLARY CHROMAFFIN (BAM) CELLS.

J.F. Reinhard, Jr., M.K. Stachowiak*, R.J. Slepetis*, J.-S. Hong and O.H. Viveros, Department of Medicinal Biochemistry, The Wellcome Research Laboratories and Lab. of Behavorial and Neurological Toxicity, NIEHS, Research Triangle Park, NC 27709 U.S.A.

The long-term increase in adrenomedullary TH activity by activation of nicotinic receptors and by agents that elevate cAMP is well established. We have recently shown that catecholamine (CA) depletion increases TH activity by a non-transynaptic mechanism (Wilson S.P. et al. Neuroscience 6:71-79, 1981). To further study the molecular mechanism of long-term TH regulation, BAM cells were exposed to a defined medium containing 2 mM Ca^{++} for 3 days with forskolin (FSK, 50 uM), tetrabenazine (TBZ, 100 uM) or to acetylcholine (ACH, 50 uM) with 10 uM physostigmine. All the treatments increased TH activity (radiometric assay), TH protein (quantitative immunoblot) and TH mRNA (blot hybridization), but TH homospecific activity (HSA) was markedly lower after ACH treatment (Table). The low HSA observed after ACH may result from antibody recognition of inactive newly synthesized enzyme or increased rates of inactivation of TH after ACH. Thus, multiple transcriptional and posttranslational mechanisms appear to participate in the long-term regulation of TH activity.

TREATMENT	TH ACTIVITY	TH PROTEIN	HSA	THmRNA
Control	100 ± 4.8%	100 ± 8.3%	1.00	100%
FSK	224 ± 18.6%	287 ± 59.4%	0.78	259 ± 49%
ACH	128 ± 5.7%	285 ± 28.0%	0.45	156 ± 8%
TBZ	194 ± 15.2%	268 ± 27.6%	0.72	148 ± 4%

322.5 THE REGULATION OF TYROSINE HYDROXYLASE IN PC-18 CELLS: A SUBCLONAL CELL LINE DERIVED FROM RAT PHEOCHROMOCYTOMA PC-12 CELLS. H. Houchi, J.M. Mässerano, J.F. Bowyer, A.W. Tank, E. Dreyer, N. Weiner. University of Colorado Health Science Center, Department of Pharmacology, 4200 E. Ninth Ave, Denver CO 80262

Tyrosine hydroxylase can be activated in situ in rat pheochromocytoma PC-12 cells by cyclic AMP-dependent and calcium-dependent mechanisms. In the present report we have evaluated the regulation of tyrosine hydroxylase by cyclic AMP-dependent and calcium-dependent mechanisms in a new pheochromocytoma PC-18 cell line. The PC-18 cells were isolated by Dr. A.W. Tank from rat pheochromocytoma PC-12 cells. Dr. Tank and co-workers have reported that an induction of tyrosine hydoxylase is produced by either cyclic AMP or glucocorticoid treatments (Mol. Pharmacol. 30: 486-496, and 497-503, 1986).

PC-18 cells were grown in RPMI 1640 media containing 10% heat inactivated horse serum and 5% fetal bovine serum. These cells have a dividing time of approximately 24 hours. Treatment of the PC-18 cells for 15 minutes with either 2 mM dibutyryl cyclic AMP or with 1 µM forskolin, an activator of adenylate cyclase, produced a 90% increase in tyrosine hydroxylase activity. In contrast, treatment of the PC-18 cells with 56 mM potassium, 1 µM of the calcium ionophore, A23187, or with 2 µM of the activator of protein kinase C, phorbol myristate acetate (PMA), had no effect on tyrosine hydroxylase activity. $^{45}Ca^{++}$ uptake studies were performed in an attempt to evaluate whether calcium uptake was deficient in the PC-18 cells which might account of the inability of high potassium, A23187 and PMA to activate tyrosine hydroxylase. $^{45}Ca^{++}$ uptake into the PC-18 cells was increased 290% by A23187 and 110% by PMA. However, there was no change in $^{45}Ca^{++}$ uptake in the presence of 56 mM potassium, dibutyryl cyclic AMP or forskolin. These data suggest that tyrosine hydroxylase in PC-18 cells is regulated by only a cyclic AMP-dependent mechanism. The calcium-dependent mechanisms, calcium-calmodulin-dependent or calcium-phospholipid-dependent protein kinases, may either be deficient in these cells or if present, may not phosphorylate tyrosine hydroxylase. In an attempt to evaluate the phosphorylation component, tyrosine hydroxylase was partially purified from PC-18 cells and incubated in vitro with ATP-^{32}P in the presence of calmodulin-dependent protein kinase purified from rat brain and with cyclic AMP-dependent protein kinase purified from bovine brain. Both calmodulin-dependent protein kinase (stoichiometry = 0.30-0.60 mole ^{32}P/mole TH) and cyclic AMP-dependent protein kinase (stoichiometry = 0.50 -0.80 mole ^{32}P/mole TH) phosphorylated tyrosine hydroxylase purified from these cells. The incorporation of phosphate into PC-18 tyrosine hydroxylase in the presence of these kinases was similar to that which occurs with tyrosine hydroxylase obtained from the PC-12 cells. Additional studies are in progress in PC-18 cells to determine the in situ phosphorylation of tyrosine hydroxylase and the levels of the calcium-dependent and cyclic AMP-dependent protein kinases. Supported by USPHS grants NS07927 and NS09199.

322.6 REGULATION OF TYROSINE HYDROXYLASE ACTIVITY IN RAT PC12 CELLS BY NEUROPEPTIDES OF THE SECRETIN FAMILY. R. Roskoski Jr. Dept. of Biochemistry and Molecular Biology, LSU Medical Center, New Orleans, LA. 70119.

Tyrosine hydroxylase, the rate limiting enzyme in catecholamine biosynthesis, is subject to regulation by the cyclic AMP as well as the calcium and cyclic GMP second messenger systems. Treatment of rat PC12 cells with neuropeptides including secretin and vasoactive intestinal peptide (VIP) resulted in an increase in tyrosine hydroxylase activity measured in vitro. For example, activity increased from 242 ± 18 to 691 ± 41 pmol/min/mg protein after treatment with 10 µM secretin (pH 7.2; 0.125 mM 6-methyltetrahydropterine). Porcine histidine isoleucine peptide (PHI) and glucagon, also members of the secretin family, increased tyrosine hydroxylase activity 30-40%. Neuropeptide Y and substance P, which are not members of the secretin family, failed to alter tyrosine hydroxylase activity even at concentrations of peptides up to 50 µM. The efficacy of secretin and VIP was identical in terms of the degree of stimulation of tyrosine hydroxylase activity at 10 µM concentrations. Secretin, however, was more potent. Concentrations as low as 1 nM secretin stimulated tyrosine hydroxylase activity whereas 1 µM VIP was required to produce a significant increase in tyrosine hydroxylase activity. Both secretin and VIP increased the level of cyclic AMP in the PC12 cells. Both agents, moreover, increased the activity of cyclic AMP-dependent protein kinase as measured in vitro. PHI and glucagon also stimulated cyclic AMP-dependent protein kinase activity but to a lesser extent.

Secretin (5-27), the carboxyl terminal portion of secretin, attenuated the response of tyrosine hydroxylase activation to secretin, but not to VIP or PHI. Secretin (5-27) alone had no effect on either tyrosine hydroxylase or cyclic AMP-dependent protein kinase activity. These experiments suggest that PC12 cells contain a secretin preferring receptor (inhibited by secretin (5-27)) and a VIP-preferring receptor (not inhibited by secretin (5-27)). Secretin and VIP also increased the rate of catecholamine biosynthesis in intact PC12 cells. This work was supported by Grant NS-15994 from the U.S. Public Health Service.

322.7 MULTIPLE STATES OF PHOSPHORYLATION OF TYROSINE HYDROXYLASE IN CULTURED DOPAMINE NEURONS. G. Kapatos Laboratory of Neurochemistry, Center for Cell Biology, Sinai Research Institute, Detroit, MI, 48235, U.S.A.

The 59 KDa subunit of tyrosine hydroxylase (TH) contains 3 phosphorylation sites, two of which are differentially recognized by cAMP-dependent, calcium-calmodulin-dependent, or calcium-phospholipid dependent protein kinases (PKs). The amino acid sequence of the third site is atypical and thus involves an unidentified PK. When examined by 2D-gel electrophoresis and Western blotting with a monoclonal antibody, TH within cultured dopamine-containing neurons derived from the embryonic mouse mesencephalon exists as four isoelectric species exhibiting pI's of 6.5, 6.3, 6.23, and 6.17. In a typical culture these forms represent 28, 38, 28, and 6%, respectively, of the total TH detected. Incubation of cultures for 1 hour in the presence of 200 uCi/ml of 32P-orthophosphate, and subsequent immunoprecipitation and analysis as described above demonstrated an absence of change in the relative abundance of the four species and incorporation of isotope into only the 6.3 and 6.23 forms. These data indicate that under basal conditions: 1) 72% of the TH subunits contain one or more moles of phosphate; 2) phosphate is absent from the most basic species of TH (pI 6.5) and; 3) the most acidic form (pI 6.17) is fully phosphorylated and does not turnover rapidly. We propose that the pI forms of 6.3, 6.23, and 6.17 contain 1, 2, and 3 moles of phosphate, respectively, and that the endogenous PKs mentioned above (including the uncharacterized PK) are operative in these dopamine neurons. In order to investigate this possibility cultures were depolarized with 4-amino-pyridine (4AP) or treated so as to mimic the natural stimulation of the known PKs; with a cAMP analogue, a calcium ionophore (A23187), or an active phorbol ester (PMA). As a result of these treatments the following isoelectric species, expressed as a percentage of total TH, were obtained: 4AP: 8, 24, 44, 24%; 8Br-cAMP: 9, 32, 45, 15%; A23187: 7, 23, 47, 23%; PMA: 10, 30, 45, 15%. All treatments thus resulted in a 3-fold decline in the pI 6.5 form, and a 1.6-fold increase in the pI 6.23 form. In contrast to depolarization or A23187 treatment, incubation with 8Br-cAMP or PMA produced an insignificant change in the pI 6.3 form and only a 2-fold rather than 4-fold increase in the amount of the pI 6.17 species. From these data we conclude that: 1) newly phosphorylated TH is primarily recruited from the unphosphorylated pool of pI 6.5 species; 2) activation of cAMP or calcium-phospholipid-dependent PKs are not as effective as stimuli for phosphorylation of TH as are depolarization and elevated calcium; and 3) under these conditions no more than 25% of the TH pool can make the transition to the fully phosphorylated state.

322.8 INCREASED TRANSCRIPTION OF THE GENE FOR TYROSINE HYDROXYLASE INDUCED BY CYCLIC AMP IN A PHEOCHROMOCYTOMA CELL LINE. L.H.Fossom*, N. Weiner and A.W. Tank. Dept. Pharmacology, Univ. Colorado Health Sciences Center, Denver, CO 80262 and Dept. Pharmacology, Univ.of Rochester Medical Center, Rochester, NY 14642.

Tyrosine hydroxylase (TH) has been shown to be regulated in vivo by stress or catecholamine depleting/blocking drugs. During prolonged stress or reserpine treatment, a slowly developing and long-lasting increase in the enzyme levels of TH is produced. The mechanism responsible for this induction of TH is not completely understood, but recent studies have shown that an increase in TH-RNA precedes the increase in TH protein, suggesting that regulation may be at the level of transcription of the TH gene. Although the intracellular messengers that mediate the stress-related in vivo induction of TH and TH-RNA have not been clearly established, two candidates, cAMP and glucocorticoid, have been extensively investigated. We are using rat pheochromocytoma PC-18 cells (a subclonal cell line derived from PC-12 cells), to study induction of TH enzyme both by cAMP and glucocorticoid. We here report initial results on the time course of the cAMP-mediated induction of TH-RNA levels and the cAMP-mediated effects on rate of transcription of the TH gene.

TH-RNA levels in whole cells or nuclei were quantified by dot-blot and Northern blot analysis, as previously reported (Tank et al, Mol. Pharmacol. 30,497,1986), using as probe the 32P-labelled Pst 1-Kpn 1 restriction fragment of the recombinant plasmid pTH.4, which contains only sequences complementary to TH-RNA (Lewis et al, J.Biol.Chem. 258,14632,1983). Rate of transcription of the TH gene was determined by nuclear transcription run-off assays, followed by hybridization of 32P-RNA run-offs to filters bound with pBR322 plasmid with or without the insert containing sequences complementary to TH-RNA. Treatment of PC18 cells with 1 mM 8-bromocAMP for up to 1 hr failed to alter TH-RNA levels, but by 2 hr of treatment levels were increased approximately 3-fold and remained elevated for at least 12 hr. When the transcription rate for the TH gene was determined in nuclei isolated from cells treated for 1.5-2 hr with or without 1 mM 8-bromocAMP, a 3-fold increase in transcription rate was found with cAMP treatment compared with controls (62+5.5 ppm for controls, 170+17 ppm for treated cells, means+SEM, n=5). Nuclei isolated from a cell line which does not express TH enzyme (GH3 cells, an established rat pituitary cell line) showed no measurable transcription of the TH gene. These results suggest that most if not all of the cAMP-mediated increase in TH-RNA in PC18 cells is due to increased transcription of the TH gene. Supported by USPHS grants NS19749, NS24106, NS09199 and NS07927.

322.9 AN ULTRASTRUCTURAL STUDY OF DOPAMINERGIC TERMINALS AND TARGET CELLS IN REAGGREGATE CELL CULTURE. L. Won, A. Heller, P. C. Hoffmann, B. H. Wainer, S. Price* and P. Greengard[1]. The University of Chicago and [1]The Rockefeller University.

We have previously demonstrated at the light microscopic level that dopaminergic axonal varicosities are associated with clusters of dopaminoceptive target cells (DARPP-32-immunoreactive) in three-dimensional reaggregate cultures composed of mesencephalic and striatal cells (Won et al., Soc. Neurosci. Abstr. 12: 1004, 1986). In the present study, we identified dopaminoceptive cells at the ultrastructural level to determine whether they were synaptically contacted by associated dopaminergic (DA) terminals.

Dissociated fetal murine mesencephalic cells, including DA neurons, were coaggregated with dissociated fetal striatal cells in rotatory culture for 20 days before harvesting for immunocytochemistry. A polyclonal rabbit antibody against tyrosine hydroxylase (TH) was employed to identify dopaminergic axon terminals. A mouse monoclonal antibody was used against the phosphoprotein, DARPP-32, which is present in dopaminoceptive striatal cells expressing D-1 type DA receptors (Ouimet et al., J. Neurosci. 4: 111-124, 1984). Both neural antigens were localized in the same tissue section using a two-color sequential immunoperoxidase staining procedure. TH-immunoreactivity was visualized first with diaminobenzidine (DAB), and then DARPP-32-immunoreactivity was visualized with benzidine dihydrochloride (BDHC). The DAB reaction product (TH), which was brown and diffuse, was easily distinguishable from the BDHC reaction product (DARPP-32), which was blue and granular under the light microscope. At the electron microscopic level these two chromogens remained distinct; the DAB reaction product yielded a diffuse, electron dense cytoplasmic staining whereas the BDHC reaction product consisted of large, electron dense crystalline deposits.

Electron microscopic examination of reaggregate sections was focused on areas which contained patches of TH-positive terminals and DARPP-32-labeled cells and processes, as localized at the light microscopic level. The BDHC crystalline reaction product labeled the nucleus and cytoplasm of cells immunoreactive for DARPP-32. These cells were round or oval in shape, medium-size (9-15 um in diameter) and contained a lightly stained nucleus, which occupied most of the cell. Few cytoplasmic organelles were observed. DARPP-32-immunoreactive cells could be divided into 2 types: 1) neurons containing a smooth, non-indented round or oval nucleus and 2) neurons containing a shallow-indented nucleus. Examination of 35 DARPP-32-labeled neurons revealed that 28 of these cells had a non-indented nucleus. Four DARPP-32-labeled perikarya with non-indented nuclei were contacted by TH-positive boutons. In addition, both types of DARPP-32-immunoreactive cells (those with a non-indented or indented nucleus) received synapses from unlabeled boutons upon their perikarya. Symmetrical synapses were observed between TH-positive boutons (0.5-0.7 um in diameter) and DARPP-32-immunoreactive dendrites. Unlabeled terminals also made symmetrical synapses with DARPP-32-labeled dendrites and perikarya . TH-positive boutons were also observed synaptically contacting an unlabeled, medium size neuron and unlabeled dendrites located within the neuropil.

Based on the presence of TH-immunoreactive boutons contacting the dendrites and perikarya of DARPP-32-labeled cells, we conclude that the association of TH- and DARPP-32-immunoreactivity in reaggregates at the light microscopic level results in identifiable synaptic contacts between dopamine axon terminals and their striatal dopaminergic target cells at the electron microscopic level.

322.10 VOLTAGE-CLAMP ANALYSIS OF EMBRYONIC MESENCEPHALIC NEURONS IN CULTURE. L.A. Chiodo and G. Kapatos, Labs. Neurophysiology and Neurochemistry, Center for Cell Biology, Sinai Research Institute, Detroit,MI 48235.

We have previously demonstrated that DA-containing neurons in mouse mesencephalic cultures derived from embryonic day 13 are flat, multipolar cells characterized by diameters which range between 17-33 um and presence of 3-5 large (approx. 5 um in diameter) proximal dendrites. These morphological characteristics are virtually identical to these observed in vivo for mesencephalic DA neurons. We have recently begun to examine the individual ionic currents present in these morphologically identified neurons using discontinuous single-electrode voltage clamp methods. All cells were studied at a temperature of 20-22^{o}C (with 3M K acetate filled electrodes 20-50 megohm) and, although the ionic composition of the media was varied depending on the requirements of individual experiment, osmolarity was maintained between 320-330 mOsmoles (pH 7.2-7.4), contained 10mM glucose, and was buffered with 5mM HEPES.

To date, we have observed the following currents in these neurons: (1) a very large, transient inward current which is activated by depolarizing voltage steps from the resting potential (-55 to -65 mV) to a level of approx. -42 mV, is dependent on external Na ions, and is blocked by TTX (10 uM) I_{Na}; (2) a slower, smaller inward current which is activated by depolarizations to approx. -45 mV from a conditioning hyperpolarization to a potential of -80 mV, reaches a peak activation at 20-50 mV is inactivated with further depolarizations (50-75% inactivation by 75 mV), and is Ca-dependent (blocked by replacing Ca with Co)-- I_{Ca}; (3) a transient outward current which is activated by depolarizations to approx. -65 mV after a conditioning hyperpolarization to -80 mV, and blocked by 4-AP (1-5 mM) I_{A}; (4) a delayed outward current which is activated on depolarization from rest, 4-AP-resistant. At least one component of this last current is blocked by TEA (5-25 mM) and thus appears to be a K-current (I_{K}). Further analysis of these and other currents are being conducted. (Supportd in part by MH-41557).

322.11 EFFECTS OF CHRONIC ANTIDEPRESSANT TREATMENT ON VOLTAGE DEPENDENT CALCIUM CHANNELS IN CULTURED BOVINE ADRENAL MEDULLARY CELLS. M. Arita*, A. Wada*, Y. Uezono* and F. Izumi. Department of Pharmacology, University of Occupational and Environmental Health, School of Medicine. Iseigaoka 1-1, Yahatanishiku, Kitakyushu 807 Japan.

Prolonged tratment with antidepressants has been shown to modulate the neuronal function and change their therapeutic efficacy. We reported previously that short term treatment of cultured adrenal medullary cells with antidepressants inhibited the influx of Na via voltage dependent Na channels and nicotinic receptor associated ionic channels (Soc. Neurosci, abstr., 275-9, 1986), but not the influx of Ca via voltage dependent Ca channels. In cultured adrenal medullary cells, high concentration of potassium (high K) directly activates the voltage dependent Ca channels without alteration of Na permeability (Neurosci., 15:283-297, 1985). In this study, we examined the change of Ca influx through voltage dependent Ca channels by long term exposure with antidepressants.

(1) Imipramine, imipramine-n-oxide, mianserin and mianserin-n-oxide (1 μM - 100 μM) did not inhibit high K-induced Ca influx when these agents were not pretreated. (2) High K-induced influx of Ca was reduced to 52 % and 34 % of control value by 4 and 6 days exposure to imipramine (100 μM) and remained at this level up to 11 days. (3) Imipramine-n-oxide and mianserin also reduced high K-induced Ca influx after 4 days exposure. However, mianserin-n-oxide which lacks antidepressant effect did not inhibit high K-induced Ca influx.

These observations suggest that long term exposure to antidepressants may affect the voltage dependent Ca channels and reduce the Ca influx in cultured bovine adrenal medullary cells.

SEROTONIN RECEPTORS: RADIOLIGAND BINDING STUDIES

323.1 [^{125}I]DOI: A NEW RADIOLABEL FOR 5-HT2 SEROTONIN SITES. R.A.Glennon,*1 M.R.Seggel,*1 W.H.Soine,*1 K.H.Davis,*2 R.A.Lyon,*2 & M.Titeler.*2 (SPON: L. Harris) (1) Dept of Medicinal Chemistry, Sch of Pharmacy, MCV/VCU, Richmond, VA 23298, and (2) Dept of Pharmacol, Albany Med College, Albany, NY.

Serotonin-2 (i.e. 5-HT2) binding sites are commonly labeled with tritiated ketanserin (KET), a 5-HT antagonist. More recently, we have introduced tritiated DOB, i.e. 1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane, as an agonist ligand for 5-HT2 sites. Tritiated DOB appears to label the agonist high-affinity state of 5-HT2 sites (5-HT2H sites) and as such, antagonists possess similar affinity (Ki) regardless of which radioligand is used to label the sites. Agonists, however, display a ten to 100-fold greater affinity when DOB is used as the radioligand. Because of the low specific activity of tritiated DOB (16 Ci/mmol), we synthesized 125-I DOI - the iodo analog of DOB. The radioiodinated agent was prepared to a specific activity of 1625 Ci/mmol (no carrier added) and a radiochemical purity of 98%. Binding assays were conducted with rat (Zivik-Miller Sprague-Dawley) parieto-frontal cortex homogenates using standard techniques. Binding was saturable and of high affinity; Bmax = 4.5 pmol/g wet wt and Kd = 2.2 nM.

Competition studies (triplicate competition curves) were conducted with several serotonergic agents. All competing agents reduced 125-I DOI-binding to the same extent and produced Hill coefficients of 0.75 to 0.9. Ki values were correlated with those obtained using tritiated DOB as the radioligand.

	Ki (nM)		
Ligand:	[^{3}H]KET	[^{3}H]DOB	[^{125}I]DOI
Serotonin	600	6	10.6
R(-)DOB	25	0.4	1.9
(±)DOI	20	0.7	2.8
Spiperone	0.5	1.8	1.2
Ketanserin	1.2	1.3	2.2
Cinanserin	4.5	3.8	6.3

The results suggest that 125-I DOI labels a subset of 5-HT2 sites in a saturable, displaceable, and selective manner and that the signal is stable and reliable. This radioiodinated ligand should prove useful in subsequent serotonin binding studies. (Supported by DA-01642)

323.2 DIFFERENTIAL DEVELOPMENT OF 5-HT$_1$ AND 5-HT$_2$ RECEPTORS IN FRONTAL CORTEX. Dana Dempsey* and Lynda Uphouse.(SPON. John Hines) Department of Biology, Texas Woman's University, Denton, Texas, 76204.

In addition to their role as neurotransmitters, biogenic amines have often been postulated as chemical messengers involved in the maturation and development of neural tissue . A neurohumoral role for serotonin (5-HT) has been especially emphasized . In support of this concept are reports that serotonin levels and the concentration of tryptophan hydroxylase, the rate-limiting enzyme for synthesis of serotonin, appear relatively early in cerebral ontogenesis. Most studies of the development of serotonin receptors have utilized ^{3}H-serotonin as the ligand for measuring receptor density. Serotonin receptors have been divided into the two major groups of 5-HT$_1$ and 5-HT$_2$ receptors, of which only the first has a high affinity for ^{3}H-serotonin. Consequently most previous studies have restricted their examination to the 5-HT$_1$ receptor population. Although functional roles for the receptors are only beginning to be understood, considerable evidence suggests that some of the 5-HT$_1$ receptor population may exist on the presynaptic membrane, while 5-HT$_2$ receptors may mediate many of the postsynaptic pharmacological actions of serotonin agonists. The development of the 5-HT$_2$ receptor has not been systematically pursued so it remains possible that the capability for serotonin neurotransmission matures earlier than previous examinations of receptor development would suggest. The following study has examined this possibility.

5-HT$_1$ receptors were examined by the binding of ^{3}H-5-HT in the presence of unlabelled 5-HT as competitor. 5-HT$_2$ receptors were examined by the binding of ^{3}H-ketanserin with unlabelled mianserin as competitor. Frontal cortices from male rats, aged 5 to 30 days postnatal were used for preparation of membranes for receptor binding. Binding was performed with various concentrations of the tritiated ligands and the data were evaluated by Scatchard analyses. In agreement with previous reports, there was little ^{3}H-5-HT binding until 15 to 20 days of age when the density of binding sites rapidly approached adult levels. In contrast, ^{3}H-ketanserin binding was readily detectable as early as 10 days of age and was clearly present by 5 days of age. Binding levels then gradually increased to reach adult values by 30 days of age. Although additional studies will be required to substantiate these findings, the present data suggest that the 5-HT$_1$ and 5-HT$_2$ receptors mature at different rates in the developing frontal cortex.

323.3 GUANINE NUCLEOTIDE REGULATION OF THE BOVINE HIPPOCAMPUS $5HT_{1A}$ RECEPTOR. T. B. Kline* and R. Iyengar* (Spon. S. Beck). Department of Pharmacology, Mount Sinai School of Medicine of the City Univeristy of New York, NY 10029

The mammalian hippocampus contains serotonin receptors predominantly of the $5HT_{1A}$ type. Acting via GTP binding proteins (G-protein) the $5HT_{1A}$ receptor is thought to stimulate the opening of the hyperpolarizing K^+ channel and inhibit adenylyl cyclase. The effects of serotonin on the K^+-channel and adenylyl cyclase is attenuated by prior treatment of the system with pertussis toxin. We have used the agonist [^{3}H] 8-hydroxy-2 (di-n-propylamino) tetralin ([^{3}H]DPAT) to study guanine nucleotide regulation of agonist binding to the $5HT_{1A}$ receptor. In the absence of guanine nucleotides [^{3}H]DPAT bound to the receptor with high affinity (K_D=1.7nM). Co-addition of 100uM GMP-P(NH)P resulted in a decrease in affinity (K_D=7nM), without significant decrease in the total number of receptor sites. Competition curves utilizing fixed amounts of [^{3}H]DPAT and varying concentrations of unlabeled DPAT indicate that in the absence of guanine nucleotides there is a single form of high affinity receptors. Upon addition of saturating concentrations of guanine nucleotides there are both high and low affinity forms of the receptor. Formation of the high affinity state of the receptor is not dependent upon added divalent cations (Mg^{2+} or Mn^{2+}). The kact for GTP, guanyl-5'-yl-imidodiphosphate and guanosin-5'-O(2-thiodiphosphate) were 0.19, 0.78 and 0.06 uM respectively.

From these data we conclude that $5HT_{1A}$ receptors directly interact with G-protein(s) that are pertussis toxin substrates, and that high affinity agonist binding arises as a consequence of this interaction. Further, in the presence of saturating concentrations of guanine nucleotides there does not appear to be a complete dissociation of receptor-G protein interactions, as evidenced by high affinity DPAT binding. This is in contrast to other systems such as receptors interacting with G_S (thereby stimulating adenylyl cyclase) in which it is observed that guanine nucleotides completely dissociate G_S from the receptor, thus resulting in exclusively low affinity agonist binding (supported by NIDA grant DA-01875 and NIH grants DK-38761 and CA 44998).

323.4 EVIDENCE FOR DISTINCT SUBTYPES OF SEROTONIN RECEPTORS IN MAMMALIAN RETINA. B. Dvorkin*, X.-C. Qiu*, S.G. Horowitz* and M.H. Makman* (SPON: E.B. Gardner). Departments of Biochemistry and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY 10461

Considerable evidence exists for the presence of pharmacologically distinct serotonin (5HT) receptor subtypes in the CNS. While bovine retina has been shown to contain high affinity ^{3}H-5HT binding sites, these sites were not characterized as to subtype. 5HT and also melatonin have been shown to stimulate adenylate cyclase (AC) activity of rabbit retina. We report here evidence for the presence of $5HT_{1A}$ and $5HT_{1D}$ (Heuring and Peroutka, J. Neurosci., 7:894, 1987) receptor binding sites in mammalian retina. Also we report that 5HT exerts dual effects on retinal AC: an inhibition of transmitter- or forskolin-stimulated activity that is mediated by $5HT_{1A}$ receptors and a stimulation of basal activity that appears to involve another receptor subtype.

Bovine retinal membranes were found to contain high affinity (K_D, 2.7 nM) and saturable (B_{max}, 26 fmoles/mg protein) binding sites for ^{3}H-8-hydroxy-N,N-dipropyl-2-amino tetralin (DPAT), a 5HT receptor agonist with high selectivity for the $5HT_{1A}$ receptor subtype. These receptor sites had high affinity for 5HT itself but not for melatonin, dopamine or norepinephrine. Also they exhibited high affinity for p-aminophenyethyl-m-trifluromethylphenyl piperazine (PAPP), a potent $5HT_{1A}$ agonist, and 2-(2,6-dimethoxyphenoxyethyl)aminomethyl-1,4-benzodioxane (WB-4101), a potent $5HT_{1A}$ antagonist. ^{3}H-DPAT binding sites were also present in rat retina (K_D 1.6nM; B_{max}, 43 fmoles/mg protein). With ^{3}H-5HT itself as ligand, and with use of various selective drugs, bovine retina was found to contain in addition to $5HT_{1A}$ sites, sites that corresponded most closely to $5HT_{1D}$ sites, but no detectable $5HT_{1B}$ or $5HT_{1C}$ sites. We have previously shown that retina contains essentially no $5HT_2$ receptor sites labeled by spiroperidol.

Both rat and rabbit retinal membranes were found to contain AC activity that in the presence of forskolin, a potent activator of AC, was inhibited by 5HT, the selective $5HT_{1A}$ agonists DPAT and PAPP, but not by melatonin. This inhibition could be completely prevented by the antagonist WB-4101. Basal AC was stimulated by 5HT under the same conditions of assay. However, this stimulation involved a receptor as yet not identified, but clearly distinct from the $5HT_{1A}$ receptor based on relative agonist potencies. In addition to inhibition of forskolin stimulated AC, $5HT_{1A}$ agonists were also capable of inhibiting both dopamine- and vasoactive intestinal peptide-stimulated AC activities. These last mentioned findings may provide some indication as to the location and function of $5HT_{1A}$ receptors in retina. Also the retina provides a useful system for elucidating the receptor subtypes mediating stimulation and inhibition of AC by 5HT.

323.5 PARTIAL PURIFICATION OF 5-HYDROXYTRYPTAMINE 1a (5-HT1a) RECEPTOR PROTEIN BY PAPP AFFINITY COLUMN AND ^{3}H-p-azido-PAPP. W. Yang* and J.C. Shih (Spon: Arthur Yuweiler) Division of Biological Sciences, School of Pharmacy, University of Southern California, Los Angeles, CA 90033

We have previously shown that the 5-hydroxytryptamine-1a (5-HT1a) receptor protein was solubilized from bovine hippocampus with 0.3% digitonin and 0.1% Nonident-p40. ^{3}H-5-HT binds to a saturable population of sites in the solubilized fraction with the same high affinity (2-5 nM) as that of the crude membrane. Furthermore, binding of ^{3}H-5-HT to the solubilized receptor is displaceable by a large series of serotonergic agents and the potency of this series corresponds well with the affinity of these agents for the 5-HT1a receptor sites in the crude membranes.

In this report, data was presented to show the partial purification of the 5-HT1a receptor was achieved by using PAPP-affinity column, and ^{3}H-p-azido-PAPP. PAPP has been shown to be a selective ligand for the 5-HT1a receptor (Asarch K, Ransom R, Shih JC, Life Sci 36, 1265-1273 (1985) and ^{3}H-p-azido-PAPP is a selective photoaffinity labeling probe for the 5-HT1a receptor (Shih JC, Asarch K, Ransom R, Psychopharm Bull 22, 818-824, 1986). In these experiments, the solubilized 5-HT1a receptor was effectively bound to the PAPP-affinity column. The bound receptor was eluted by 1 μM ^{3}H-p-azido-PAPP. The eluate was irradiated with a Hanovia 450-W medium-pressure mercury lamp; after the radioligand concentration was reduced to 10 nM using a centricon 30. The photolabeled 5-HT1a receptor protein was then separated by SDS-PAGE. The molecular weight of the labeled protein was 55 KD and 38 KD. When the solubilized fraction was incubated with PAPP affinity gel in the presence of excess 5-HT or PAPP the ^{3}H-p-azido-PAPP elution and labeling of these two polypeptides was significantly decreased. This result suggests that ^{3}H-p-azido-PAPP labeled polypeptides may be related to the 5-HT1a receptor. This notion was supported by the fact that ^{3}H-p-azido-PAPP also photolabeled a 55KD polypeptide in the crude membranes from bovine hippocampus or bovine cortex (Ransom RW, Asarch KB, and Shih, JC J. Neurochem 47:1066-1072, 1986). The nature of the 38KD polypeptide will be discussed. (Supported by NIMH Grant No. 37020 and MH 39085)

Abbreviation used:
PAPP: 1-(2-4-aminophenyl)ethyl)-4-(3-trifluoromethylphenyl) piperazine
p-azido-PAPP: 1-(2-4-azidophenyl)ethyl)-4-(3-trifluoromethylphenyl) piperazine

323.6 ^{3}H-SPIROXATRINE: A NOVEL HIGH AFFINITY RADIOLIGAND FOR BRAIN 5-HT_{1A} SEROTONIN RECEPTORS. M. Titeler and K.H. DAVIS*, Dept. Pharmacol. Toxicol., Albany Medical College, Albany, New York 12208

The 5-HT_{1A} serotonin receptor was originally detected with ^{3}H-5-HT (1). The first specific 5-HT_{1A} radioligand was the 5-HT_{1A} agonist ^{3}H-8-OH-DPAT (2). Recently it was reported that spiroxatrine is a potent, competitive 5-HT_{1A} receptor antagonist in an isolated organ preparation (3). In order to develop the first antagonist radioligand for the 5-HT_{1A} receptor, spiroxatrine was radiolabelled by New England Nuclear. We conducted in vitro radioligand binding studies with ^{3}H-spiroxatrine and ^{3}H-8-OH-DPAT in order to determine if ^{3}H-spiroxatrine would radiolabel the 5-HT_{1A} receptor and also display binding properties generally associated with antagonist radioligands. Table one lists the K_I values of five drugs in competing for ^{3}H-spiroxatrine in rat cortical homogenates.

Drug	KI (nM)
5-HT	3.4
8-OH-DPAT	1.0
Ipsapirone	3.9
(+/-)DOB	7200
Methysergide	8.1
Mesulergine	190

The high affinity of the agonists 5-HT, 8-OH-DPAT and ipsapirone indicate that ^{3}H-spiroxatrine is probably labelling the 5-HT_{1A} receptor. However, it has been noted that antagonist radiolabelled receptors generally display far lower affinities for agonists than agonist radiolabelled receptors (4). Therefore the high affinities displayed by 5-HT, 8-OH-DPAT, and ipsapirone for ^{3}H-spiroxatrine labelled 5-HT_{1A} receptors are somewhat anomalous and may indicate that ^{3}H-spiroxatrine is an agonist radioligand. We will report on further studies examining the in vitro regulation of ^{3}H-spiroxatrine and ^{3}H-8-OH-DPAT labelled 5-HT_{1A} receptors with a view to determing if ^{3}H-spiroxatrine is indeed an antagonist 5-HT_{1A} radioligand.

323.7 LSD AND PHENYLISOPROPYLAMINE HALLUCINOGEN INTERACTIONS WITH MULTIPLE RADIOLABELLED BRAIN SEROTONIN RECEPTORS. R.A. Lyon*, M. Titeler, and R.A. Glennon*. (SPON: J. Popp). Dept. Pharmacol. Toxicol., Albany Medical College, Albany, New York 12208. Dept Med. Chem., Virginia Commonwealth Univ., Richmond, Va. 23298

We recently reported that the potencies of a large series of phenylisopropylamine hallucinogens and LSD strongly correlate with their affinities for the ^{3}H-ketanserin labelled brain 5-HT_2 receptor (1). This observation was consistent with our working hypothesis that brain 5-HT_2 receptor stimulation underlies the psychoactive properties of the hallucinogenic drugs-of-abuse. In order to further investigate the interactions of hallucinogens with brain 5-HT_2 receptors we recently reported the development of ^{3}H-DOB, an hallucinogenic 5-HT_2 radioligand (2). In the present study we investigated the potencies of phenylisopropylamine hallucinogens and LSD in competing for ^{3}H-DOB labelled 5-HT_2 receptors as well as for radiolabelled 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1C} receptors (Table 1).

	K_i (nM)			
Drug	5-HT_2	5-HT_{1A}	5-HT_{1B}	5-HT_{1C}
d-LSD	0.54	0.43	6.6	3.8
(-)DOB	0.39	2332	683	47
(-)DOM	1.80	4004	1840	94
2,5-DMA	268	1131	8435	1217
(-)MDA	198	4167	>10000	2079

LSD displays high affinity for the four 5-HT receptor sub-types assayed (Table 1). However the phenylisopropylamine hallucinogens generally display 10-100 fold higher affinities for the ^{3}H-DOB labelled 5-HT_2 receptors than for the other 5-HT receptor sub-types, implicating the 5-HT_2 receptor as a key site-of-action of the phenylisopropylamine hallucinogens. We are currently investigating the potencies of eleven other hallucinogens for radiolabelled 5-HT_2, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1C} receptors to determine if one or more of these serotonin receptor sub-types may contribute to the psychoactive properties of these drugs.

323.8 CHARACTERIZATION OF SEROTONIN-1B BINDING SITES IN RAT CENTRAL NERVOUS SYSTEM TISSUES USING ^{125}I-IODOCYANOPINDOLOL. P.J. MONROE and D.L. NELSON. Dept. Pharmacology and Toxicology, Univ. of Arizona College of Pharmacy, Tucson, AZ 85721.

It has recently been reported that the radioligand ^{125}I-iodocyanopindolol (ICYP) labels serotonin$_{1B}$ (5HT_{1B}) sites in several mammalian CNS tissues (Eur. J. Pharmacol. 118 (1985), 13-23). The experiments in the current study were undertaken to further examine the characteristics of ICYP binding sites in three rat CNS regions: spinal cord (sc), cortex (ctx), and corpus striatum (cs). Preliminary experiments were performed based on the method described in the above reference. Later experiments were designed to verify that no changes in binding characteristics resulted from altering the assay protocol to that used in ^{3}H-5HT binding assays. Once it had been determined that no differences were observed, all subsequent assays were performed according to standard ^{3}H-5HT binding assay protocol.

Saturation studies using ICYP in a concentration range of 25 pM to 2.5 nM revealed that the ligand was binding to a single population of sites in all three tissues examined. Affinity constant (K_d) values were found to not vary within the three tissues (ANOVA, $p>0.05$), and were calculated to be 0.53, 0.39, and 0.57 nM, respectively, for the sites labeled in the sc, ctx, and cs. The relative proportion of ICYP binding site densities within these tissues agreed with what has previously been reported for 5HT_{1B} sites (sc = ctx < cs). Furthermore, the ability of 5HT to compete for sites labeled by ICYP in the striatum (apparent K_i = 36 nM) is consistent with that seen for striatal 5HT_{1B} sites (by definition, those sites labeled by ^{3}H-5HT in the presence of 100 nM 8-OH-PAT; apparent K_i = 8.2 nM), and also agrees with values which have been previously reported.

The relative affinities of the ICYP binding sites for 8-OH-PAT, quipazine, phenylpiperazine (PP), and TFMPP are indicated by the K_i values shown below:

DRUG	SPINAL CORD	CORTEX	STRIATUM
8-OH-PAT	14.5 uM	15.0 uM	-------
QUIPAZINE	0.44 uM	0.40 uM	0.34 uM
PP	0.55 uM	0.67 uM	0.45 uM
TFMPP	0.04 uM	0.02 uM	0.03 uM

These results are in agreement with the premise that ICYP labels 5HT_{1B} sites in these tissues. However, it should be noted that in the spinal cord, all three piperazine compounds were able to reduce ICYP binding to a greater extent than 10 uM 5HT. Thus in this tissue, ICYP is capable of labeling sites in addition to those which have been designated 5HT_{1B}. Care must therefore be taken when analyzing data from experiments in which this ligand is used to label 5HT binding sites in certain tissues.

Supported by NIH grants NS16605 and NS01009.

323.9 APPARENT ABSENCE OF 5-HT_{1B} BINDING SITES IN HUMAN BRAIN. MEMBRANE BINDING AND AUTORADIOGRAPHIC STUDIES ON CORTICAL BIOPSIES AND POST-MORTEM TISSUES. J. Martial*, C. DeMontigny, A. Olivier*, S. Lal* and R. Quirion (Spon: B. Collier). Douglas Hospital Research Centre and Dept. of Psychiatry, McGill Univ., 6875 Blvd LaSalle, Verdun, Québec H4H 1R3.

At least three distinct sub-types of serotonin (5-HT)$_1$ receptors have been characterized using binding assays namely 5-HT_{1A}, 5-HT_{1B} and 5-HT_{1C} types. The 5-HT_{1B} sub-type is of special interest since it displays nanomolar affinity for 5-HT itself and various well known drugs "classically" classified as beta-blockers such as propranolol and pindolol. Moreover, there is evidence that the 5-HT_{1B} receptor sub-type could act as an autoreceptor on 5-HT neurons. However, there is little evidence for the existence of this 5-HT receptor type in human brain tissues. Thus far, the presence of 5-HT_{1B} receptors have been convincingly demonstrated only in mouse and rat brain. It is possible that the apparent lack of 5-HT_{1B} sites in human brains could be related to the use of post-mortem tissues. Thus, we have studied the possible existence of 5-HT_{1B} receptor binding sites in humans in both fresh cortical biopsies and post-mortem tissues using membrane binding assays and receptor autoradiography. Fresh cortical (temporal, frontal, parietal) biopsied tissues were obtained from patients undergoing surgery for the removal of epileptogenic foci. Only apparently normal (outside foci) tissues were used without delay for binding assays. [^{3}H]5-HT binding to putative 5-HT_{1B} sites were investigated as follows: 200 µl of membrane preparations (3.5-4.0 mg protein/ml) were incubated for 60 min at 25°C in 170 mM Tris.HCl buffer, pH 7.4 containing 4 mM $CaCl_2$, 0.01% ascorbic acid, 10 µM pargyline, 100 nM 8-OHDPAT to block binding to 5-HT_{1A} sites and various concentrations of [^{3}H]5-HT (20.4 Ci/mmol, NEN, Boston) ranging between 0.25 - 10 nM. Specific binding was defined as the difference in ligand bound in absence and presence of 1.0 µM 5-HT. In parallel, autoradiographic studies were also performed using 20 µM sections obtained from fresh cortical biopsies as well as post-mortem tissues (post-mortem delays up to 24 hours). Sections were incubated with 2.0 nM [^{3}H]5-HT as described above or for 120 min with 50 pM [^{125}I](-) cyanopindolol (CYP; 2200 Ci/mmol) in 170 mM Tris.HCl buffer, pH 7.4 at 25°C in presence of 150 mM NaCl and 10 µM (-) isoproterenol to block binding to beta adrenergic receptors. In all preparations studied, only very low specific binding of either [^{3}H]5-HT and [^{125}I]CYP was observed suggesting the apparent absence of 5-HT_{1B} receptor binding sites in human brain tissues. Moreover, the presumed lack of 5-HT_{1B} receptors in human brain does not appear to be related to the use of post-mortem tissues.

323.10 5-HT_{1b} RECEPTORS DO OCCUR IN HUMAN BRAIN: AUTORADIOGRAPHIC AND HOMOGENATE BINDING STUDIES. A. Biegon, and P.M. Whitaker-Azmitia. Weizmann Institute of Science, Rehovot, Israel and Dept. of Psychiatry, SUNY, Stony Brook, NY 11794.

Previous studies, using autoradiographic techniques have failed to detect 5-HT_{1b} receptors in human brain (Hoyer et al., Brain Research, 376:85, 1986). However, there is clinical evidence for their existence (Mueller et al., J. Clin. Endocrin. Metabol. 61:1179, 1985; Heninger and Charney, Soc. for Neurosci., Abst. 11:1256, 1985). We, therefore, decided to re-examine the question, using the direct 5-HT_{1b} label ^{125}I-iodocyanopindolol (^{125}I-CYP) and expanding the study to include brain regions not used by the earlier researchers.

Brains were obtained at autopsy and included three subjects (aged 31, 44 and 66) with no known psychiatric or neurological illnesses. Autoradiographic studies, were performed on 40 micron sections. Sites were labelled directly with ^{125}I-CYP (150 pM) in the presence of 100 µmolar norepinephrine or with ^{3}H-5-HT (2 nM) displaced by 200 nM spiperone. Homogenate binding studies were used to determine pharmacological profiles of the two radioligands in four brain regions: substantia nigra, globus pallidus, cortex and hippocampus. 5-HT displaceable ^{125}I-CYP binding to globus pallidus, in the presence of excess norepinephrine, is saturable with a linear Scatchard plot, a K_D of 98 pM and a B_{max} of 14 fm/mg protein.

Our results show the presence of 5-HT_{1b} sites in human globus pallidus and substantia nigra. This is indicated by the autoradiographic studies which show selective labelling by ^{125}I-CYP which is displaceable by TFMPP (a selective 5-HT_{1b} ligand) but not 8-OH-PAT (a selective $_{1a}$ ligand) and the binding of ^{3}H-5-HT which is not displaceable by spiperone. In homogenate binding studies, the selective $_{1a}$ agonists 8-OH-PAT, LY-165,163 and spiperone have IC_{50} values from 1 to 10 µmolar while TFMPP has a value of less than 100 nM.

This receptor distribution is qualitatively similar to that previously reported in rat.

323.11 DETECTION AND CHARACTERIZATION OF THE PUTATIVE 5-HT1D SEROTONIN RECEPTOR IN RAT, PORCINE, AND BOVINE BRAIN. K.H. DAVIS* AND M. TITELER. (SPON: D. Poulos). Dept. Pharmacol. Toxicol., Albany Medical College, Albany, New York 12208

^{3}H-5-HT (serotonin) binding studies in mammalian brain have revealed the existince of three distinct receptors, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1C} (1). In order to study 5-HT_{1C} receptors in our laboratory we co-incubated 1 uM pindolol, a non-specific blocker of both 5-HT_{1A} and 5-HT_{1B} receptors, with ^{3}H-5-HT. Rather than detecting only 5-HT_{1C} receptors, binding studies revealed evidence for an additional high affinity ^{3}H-5-HT binding site. In order to selectively examine this site we have developed an assay involving 1 uM pindolol, 100 nM mesulergine, and 2 nM ^{3}H-5-HT. Table 1 lists the K_I values for six drugs in competing for the site labelled under these conditions in rat cortex, porcine striatum, and bovine cortex.

	K_I (nM)		
Drug	rat cortex	porcine striatum	bovine cortex
serotonin	2.0	1.7	2.5
8-OH-DPAT	1300	390	300
d-LSD	15	2.6	1.6
TFMPP	330	320	280
methysergide	100	7.4	16
(+/-)DOB	3400	1200	1300

These data indicate that the site is present in at least three species and is present in at least two major brain regions. The pharmacological characteristics reported herein are similar to those reported by Heuring and Peroutka (2), who studied and named a putative "5-HT_{1D}" receptor in bovine caudate. We will report on further pharmacological characterization of the site, on in vitro regulation, and on the development of potent and specific drugs for this putative receptor.

323.12 PERIPHERAL NEURAL SEROTONIN RECEPTORS (5-HT_{1P}): LABELING WITH ^{3}H-5-HYDROXYINDALPINE. T. A. Branchek, G. M. Mawe, and M.D. Gershon. Department of Anatomy & Cell Biology, Columbia University, P & S, New York, NY.10032.

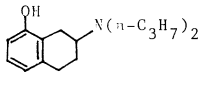
Peripheral neural 5-HT receptors, initially identified in the enteric nervous system (ENS), were first called "M" receptors (Gaddum and Picarelli, 1957). Since these receptors are different from both the 5-HT_1 and 5-HT_2 classes of receptor it has been suggested that they be re-named "5-HT_3" receptors (Bradley et al., 1986). Recently, however, it has been shown that, as in the CNS, there is more than a single type of enteric neural receptor for 5-HT (Mawe et al., 1986). One of these, called 5-HT_{1P}, has a high affinity for ^{3}H-5-HT, initiates a long lasting depolarization of enteric neurons associated with increased input resistance, and is the physiological receptor through which enteric serotoninergic neurons mediate slow epsp's. The other receptor, called 5-HT_{2P}, is not labeled by ^{3}H-5-HT, initiates a brief depolarization with decreased input resistance, but a physiological action of 5-HT mediated by these receptors has not yet been identified. Hydroxylated indalpines (Pharmuka) have been found to be agonists, and dipeptides of 5-hydroxytryptophan (5-HTP-DP) to be antagonists, at 5-HT_{1P} receptors, while 2-methyl-5-HT and ICS 205-930 (Sandoz) have been shown to be, respectively, an agonist and an antagonist at 5-HT_{2P} receptors. We have now examined the possibility that hydroxylated indalpines can be used as probes with which to label 5-HT_{1P} receptors. The action of 5-hydroxyindalpine (5-OHIP) on enteric neurons was determined electrophysiologically and compared with that of 5-HT; the binding of ^{3}H-5-OHIP to isolated enteric membranes was studied by rapid filtration and to frozen sections of tissue by radioautography. ^{3}H-5-OHIP binding was compared with that of ^{3}H-5-HT. 5-OHIP, like 5-HT, induced a triphasic response in most enteric neurons; an intial short-lived depolarization, during which input resistance fell, was followed by recovery, and then a long-lasting depolarization, during which the input resistance increased. 5-OHIP bound saturably, reversibly, and with high affinity to enteric membranes (K_D = 7.6 ± 0.7 nM; B_{max} = 76 ± 14 fmol/mg pr). Binding of ^{3}H-5-OHIP was not inhibited by agents that bind to 5-HT_1 (8-OH-DPAT, D-LSD), 5-HT_2 (ketanserin, spiroperidol, D-LSD, methysergide), or 5-HT_{2P} (ICS 205-930, MDL 72222 [Merrell Dow]) receptors, but was displaced by substances, such as hydroxylated indoles and 5-HTP-DP, which antagonize the binding of ^{3}H-5-HT to enteric membranes or tissue sections. K_i's were: 6-OHIP = 4.4 nM; 5-OHIP = 7.6 nM; 5-HT = 44 nM; 5-HTP-DP = 44 nM; 2-methyl-5-HT > 100 nM. Radioautographs demonstrated enteric ^{3}H-5-OHIP binding sites in the lamina propria of the intestinal mucosa and in the submucosal and myenteric plexuses. Extraenteric sites of ^{3}H-5-OHIP binding were also found in skin, heart, and brain. In pharmacology and in anatomical location peripheral ^{3}H-5-OHIP binding sites were similar to those of ^{3}H-5-HT; therefore, 5-OHIP mimics the effects of 5-HT on 5-HT_{1P} receptors and labels them. On the other hand, 5-OHIP, also has additional effects. Binding of ^{3}H-5-OHIP in the CNS was antagonized by D-LSD and ICS 205-930, as well as by 5-HTP-DP. Moreover, 5-OHIP (and ICS 205-930) inhibited the specific neuronal uptake of ^{3}H-5-HT; however, antagonists of this uptake did not block peripheral ^{3}H-5-OHIP binding. It is concluded that 5-OHIP is a relatively specific agonist at 5-HT_{1P} receptors and that ^{3}H-5-OHIP can be used as a probe for these receptors. Supported by NIH (NS12969, NS22637), Council for Tobacco Res. and the PMAF.

323.13 NEW DERIVATIVES OF 8-HYDROXY-2-(DI-N-PROPYLAMINO)-TETRALIN AND THEIR INTERACTION WITH CENTRAL SEROTONIN RECEPTORS: L. Klaesson[a]*, B. Backlund-Höök[b]*, U. Hacksell[b]* and N.E. Andén[c]* (SPON: J. Engel). [a]Dept.of Med. Pharmacol., [b]Dept. of Org.Pharm. Chem., Biomedical Center, University of Uppsala, [c]Dept. of Pharmacol., Karolinska Institute, Stockholm, Sweden.

8-Hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) is a potent and centrally acting serotonin (5-hydroxytryptamine, 5-HT) receptor agonist with pronounced selectivity for the 5-HT_{1A}-site. It has, however, very low stereoselectivity, the (2R)-enantiomer is only twice as potent as its (2S) antipode.[1)]

We have previously synthesized and tested the C3-methylated derivatives of 8-OH-DPAT. They showed, in contrast to 8-OH-DPAT, clear stereoselectivity, with one stereoisomer acting as an agonist on the 5-HT receptor and the other beeing inactive as a 5-HT receptor agonist. The active isomers appear to be selective for the 5-HT_{1A}-site, but were less potent than 8-OH-DPAT.[2)]

In order to further characterize the structural requirements for the 5-HT receptor activation, a new series of 8-OH-DPAT derivatives has been synthesized and the pharmacological effects have been examined by means of biochemical tests and behavioural studies. The derivatives will be discussed with respect to their potency, specificity and stereoselectivity in the interaction with central 5-HT receptors.



8-OH-DPAT

324.1 DIFFERENTIAL UP- AND DOWN-REGULATION OF TYPE I AND TYPE II ADRENOCORTICOSTEROID RECEPTORS. W.G. Luttge and M.E. Rupp*, Dept. of Neuroscience, Univ. of Florida Coll. of Medicine, Gainesville, Florida 32610.

Previous studies have reported that adrenalectomy and/or treatment with exogenous glucocorticoids can lead to an up- or down-regulation, respectively, of cytosolic Type II adrenocorticosteroid receptors in brain and other tissues. [Type II receptors have a very high affinity for synthetic fluorinated glucocorticoids such as dexamethasone (DEX), a somewhat lower affinity for naturally occuring glucocorticoids such as corticosterone (CORT) and a very low affinity for naturally occuring mineralocorticoids such as aldosterone (ALDO).] In other recent studies it has been claimed that the comparatively low concentration of Type I receptors in brain results in their near total occupancy in adrenally-intact animals, whereas the comparatively high concentration of Type II receptors remain only partially saturated under these same conditions. [Type I receptors have a very high affinity for ALDO and CORT and a very low affinty for DEX.] As a result of this differential occupancy and affinity it has been claimed that, unlike Type II receptors, Type I receptors do not undergo an up- and down-regulation similar to that seen for Type II receptors. The results from our recent studies refute this claim.

In the first study adult female CD-1 mice were adrenalectomized and ovariectomized (Adrex-Ovx) and 0, 1, 3, 6, 12, 24, 48, 96, 192 or 384 h later the concentration of specific Type I and Type II receptors in whole brain, kidney and liver cytosol determined by a 24 h incubation at 0°C with [^{3}H]ALDO (+ RU 26988 to prevent binding to Type II receptors) or [^{3}H]DEX, respectively. Non-specific binding was determined by adding [^{1}H]steroids. Type I receptor binding in brain was found to undergo dramatic up-regulation, with levels 12-14 times those in intact animals by 4-8 days post-Adrex-Ovx. By 16 days, however, Type I specific binding capacity returned to intact levels. Similar, but less dramatic fluctuations were seen in kidney and liver whereas much smaller fluctuations were seen for Type II receptors in all 3 tissues. In a follow-up study with Scatchard analyses we observed a similar transient up-regulation in maximal binding for Type I, and to a lesser extent Type II binding in all 3 tissues. As expected, the apparent binding affinity for both receptors increased after removal of competing endogenous steroids. In the last study we found that exogenous CORT prevented the Adrex-Ovx-induced up-regulation of Type I and Type II receptors in all 3 tissues. Exogenous ALDO was also able to fully prevent Type I receptor up-regulation, however, it was much less effective in preventing Type II receptor up-regulation. Therfore, both Type I and Type II receptors appear to be subject to up- and down-regulation under the influence of both endogenous and exogenous adrenocorticosteroids. (Supported by NS 24404.)

324.2 DIFFERENTIAL INACTIVATION OF TYPE II RECEPTORS FOR ADRENOCORTICOSTEROID HORMONES IN BRAIN: RECOVERY OF INTACT TYPE I RECEPTORS AND DISCOVERY OF A NEW CLASS OF TYPE II RECEPTORS. S.M. Emadian and W.G. Luttge. Dept. of Neuroscience and Center for Neurobiological Sciences, Univ. of Florida Coll. of Medicine, Gainesville, FL 32610.

Recently we reported that whereas Type II receptors for adrenocorticosteroids in brain cytosol preparations required a sulfhydryl reducing reagent for optimal ligand binding, Type I receptors manifested maximal binding capacity in the absence of reducing reagents (Emadian et al., J. Steroid Biochem. 24:953-961, 1986). In this same study we found that removal of endogenous reducing reagents from unlabeled cytosol (prepared in the absence of a reducing reagent) by dextran-coated charcoal (DCC) further reduced the ligand binding capacity of Type II, but not Type I, receptors. As an extention of other observations reported previously from this laboratory (Densmore et al., Life Sci. 35: 2237-2246, 1984), in the experiments outlined below we found that unoccupied Type II, but not Type I, receptors lose their ligand binding capacity in the presence of 300 mM KCl, especially when the unoccupied receptors "aged" at 0°C. In the present study, we sought to use these differences in Type I and Type II receptors to differentially inactivate the latter, in order to facilitate the purfication and further characterization of Type I receptors in future studies.

Brain cytosol prepared in 20 mM HEPES (pH 7.6) was isolated from ovariectomized-adrenalectomized CD-1 mice and subjected to various potentially inactivating treatments prior to assessment of Type I and Type II receptor specific binding capacity by incubation for 24 h at 0°C with [^{3}H]aldosterone (ALDO) (plus [^{1}H]RU 26988 to prevent ALDO binding to Type II receptors) or [^{3}H]dexamethasone (DEX), respectively. Our attempts to selectively inactivate unoccupied Type II receptors revealed that 10% of the DEX binding capacity remained even after extensive and repeated pretreatment with DCC. As expected this treatment had no effect on Type I receptor binding capacity. Further analysis revealed that the DCC-resistant DEX binders do not require endogenous or exogenous sulfhydryl reducing agents to ratain full ligand binding capacity, do not lose their ligand binding capacity when aged at 0°C and remain intact when exposed to buffers with high ionic strength. Noting that these treatments inactivate Type II receptors, but have no effect on Type I receptors, we propose that the DEX binding capacity remaining after treating crude brain cytosol with DCC represents a new class of receptors whose physiological and physicochemical properties remain to be characterized.

Supported by N.I.N.C.D.S. Grant NS 24404

324.3 POTENTIATION OF PHORBOL ESTER-INDUCED UPREGULATION OF ANGIOTENSIN II RECEPTORS IN NEURONAL CULTURES BY A CALCIUM IONOPHORE. C. Sumners, S.M. Rueth*, F.T. Crews and M.K. Raizada*. Depts. of Physiology and of Pharmacology and Experimental Therapeutics, University of Florida, Gainesville, FL 32610.

In previous studies we have shown that phorbol esters, which are agonists of protein kinase C, upregulate angiotensin II (Ang II) receptors in neuronal cultures prepared from the hypothalamus and brainstem of one-day-old rats. The present study was designed to examine the role of Ca^{2+} in phorbol ester-stimulated increases in Ang II receptors, because the activation of C-kinase requires Ca^{2+}. We have studied the effects of a Ca^{2+} ionophore (A23187) on Ang II receptors, alone or in combination with phorbol esters. Treatment of neuronal cultures with the phorbol ester TPA (12-0-tetradecanoylphorbol-13-acetate) at 0.8 μM for 1 hr resulted in significant increases (80-100%) in Ang II binding. This effect was significantly enhanced by co-treatment with the Ca^{2+} ionophore A23187 (0.19-19 μM). A maximum enhancement of 80-90% above TPA stimulation was obtained with 1.9 μM A23187, but higher doses of the ionophore were less effective. Treatment of neuronal cultures with A23187 alone gave the opposite effect, ie 1.9 - 19 μM A23187 caused significant decreases in Ang II binding with a maximum effect at 19 μM of 40-50%. These doses of A23187 had no toxic effects on the cells, as evidenced by Trypan Blue exclusion. Saturation and Scatchard analyses were performed to determine the effects of TPA and A23187 on Ang II receptors, and results are summarized as follows.

Treatment	Kd (nM)	Bmax(fmol/mg protein)
Control	0.82 ± 0.05 (6)	113 ± 17.0 (6)
TPA (0.8 μM, 1hr)	1.31 ± 0.06 (6)*	244 ± 31.4 (6)*
TPA+A23187(0.8μM/1.9μM)	1.54 ± 0.08 (3)*	432 ± 51.2 (3)*
A23187 (1.9 μM, 1hr)	0.85 ± 0.14 (3)	70.4 ± 9.3 (3)*

Data are means ± SEM. Numbers in parentheses = # of experiments.
(*) significantly different from control values.

It is concluded that the TPA induced upregulation of Ang II receptors is greatly enhanced in the presence of A23187 (ie. increased intracellular Ca^{2+}). Conversely, without TPA the ionophore downregulates Ang II receptors. Although the precise mechanisms involved are not established, these results suggest two possibilities of Ang II receptor regulation by Ca^{2+}; (i) via C-kinase and (ii) via influx of Ca^{2+} into the cell.

324.4 HETEROGENEOUS DISTRIBUTION AND UPREGULATION OF MU, DELTA AND KAPPA OPIOID RECEPTORS IN THE AMYGDALA. C.M. Paden, S. Krall* and W.C. Lynch. Depts. of Biology and Psychology, Montana State Univ., Bozeman, MT 59717.

We have undertaken a quantitative autoradiographic study of upregulation of mu, delta and kappa receptors throughout the rat brain in order to provide a data base for investigations of the functional importance of receptor plasticity in specific opioid systems. In this initial report the analysis of four nuclei of the amygdala is presented. While upregulation of mu receptors has been observed in the amygdala (Tempel, A., et al., PNAS, 81:3893, 1984), this phenomenon has not been analyzed within individual nuclei, nor has upregulation of delta or kappa receptors been investigated in this structure.

Adult male Holtzman rats were implanted sc with Alzet osmotic minipumps containing saline (SAL; n=3) or 150 mg/ml naloxone HCl (NAL; n=3), yielding a nominal dosage of 155 µg/kg per hour. Pumps were removed after 14 days, and animals were sacrificed by decapitation 24 hours later. Freeze-dried 30 micron horizontal cryostat sections of whole brain were prepared as described by Herkenham and Pert (J. Neurosci., 2:1129, 1982). Following preincubation in 0.17 M tris containing 120 mM NaCl and 50 µM GTP, sections were incubated for 30 minutes at 25° C in either 1.5 nM ^{3}H-dihydromorphine (mu receptors), 3 nM ^{3}H-DADLE plus 5 nM morphine (delta receptors), or 3.8 nM ^{3}H-bremazocine plus 30 nM morphine and 100 nM DADLE (kappa receptors). Non-saturable binding was estimated by inclusion of 1 µM levallorphan in the incubation. Following a 45 day exposure on LKB Ultrofilm, quantitative autoradiography was performed using a digital image analysis system. Specific binding was estimated by comparison to ^{3}H-Microscale standards after subtraction of background gray values.

A significantly different basal distribution of each receptor subtype was observed, with mu binding greatest in the lateral nucleus (La), delta greatest in the basolateral (Bl), and kappa greatest in the medial (Me). Levels of all three receptors were very low in the central nucleus (Ce). Chronic NAL treatment resulted in statistically significant increases in mu receptors in the Me, Bl and La, while increases in delta and kappa receptors were significant only in the Bl. These results indicate that all three receptor subtypes are subject to upregulation following chronic antagonist treatment, but it is clear that the degree of upregulation varies across different brain regions in a manner which is not predictable solely on the basis of basal receptor distributions.

Supported by MONTS-NSF project ISP-801149 and a grant from the Proctor and Gamble Corp. to WCL, and by a Grant-In-Aid from the Montana Heart Association to CMP.

324.5 INHIBITION OF MEZEREIN- BUT NOT AGONIST-INDUCED LOSS OF VIP RECEPTOR/ADENYLATE CYCLASE ACTIVITY BY AN INHIBITOR OF PROTEIN KINASE C. J. T. Turner, D. W. Bollinger*, and M. L. Toews*, Department of Pharmacology, University of Missouri, Columbia, MO 65212.

Previous studies from our laboratory have indicated both a loss of cell surface receptors for vasoactive intestinal peptide (VIP) and a desensitization of VIP-stimulated adenylate cyclase (AC) activity in HT29 human colonic adenocarcinoma cells following preincubation with either VIP receptor (VIP-R) agonists or activators of protein kinase C (PKC), including phorbol esters and mezerein (MEZ). Differences in the changes induced by PKC activators as compared with VIP-R agonists prompted us to investigate whether inhibition of PKC produced similar effects on agonist- and PKC activator-induced loss of VIP receptors and AC activity.

HT29 cells were treated with the VIP-R agonist peptide histidine isoleucineamide (PHI) or MEZ with or without pretreatment with the PKC inhibitor, 1-(5-isoquinolinesulfonyl)-2-methylpiperazine dihydrochloride (H-7). Changes in the VIP-R/AC system were assessed by three methods: ^{125}I-VIP binding to intact HT29 cells on ice; intact cell cyclic AMP production using the [^{3}H]adenine preloading method; and cell lysate AC assays.

These results were obtained in ^{125}I-VIP binding assays:

Treatment	Specific binding, % of control
None	100
0.1 μM PHI	37 ± 1
300 μM H-7	96 ± 4
PHI + H-7	36 ± 7
1 μM MEZ	62 ± 5
MEZ + H-7	91 ± 10

Similar results were obtained in AC assays. The finding that H-7 reverses MEZ- but not PHI-induced changes in VIP-R/AC activity indicates that the mechanisms through which VIP-R agonists and PKC activators act are different and suggests that PKC is not involved in agonist-mediated regulation of the system. Supported by NIH grant DE05339.

324.6 DOWN REGULATION OF PROTEIN KINASE C IN AtT-20 CELLS: ITS EFFECT ON THE NEUROPEPTIDE SECRETION AND BIOSYNTHESIS. Sheela Vyas*, John Bishop* and Jitendra Patel* (SPON: J. Garcia-Arraras). NIMH, NIH, Bethesda, Maryland 20892, USA

AtT-20 cells were treated with 100 nM phorbol 12 myristate 13 acetate (TPA) for 24-48 hours. It was found that whereas the phospholipid, Ca^{2+} dependent activity of protein kinase C (PKC) virtually disappears in these cells (98% decrease), that of cAMP and Ca^{2+}/Calmodulin dependent kinases remain unchanged. Treatment of cells with TPA at different time intervals showed that the onset of disappearance of PKC activity occurs after 1-2 hours, negligible activity is seen after 8 hours. When the cells were incubated with varying concentrations of TPA (1-100 nM) for 24 hours, higher doses than 10 nM cause a drastic reduction in PKC. In order to see whether the TPA treatment also has an effect on the PKC substrate levels, the phosphorylation of endogeneous substrates was carried out using exogeneous PKC. In TPA treated cells, a time dependent decrease in phosphorylation of proteins with M_r=35 and 50 K_D was seen.

In cells preincubated with TPA for 24 hours, the cAMP-mediated secretion of immunoreactive β-endorphin in response to forskolin or CRF remained unimpaired. However, in these cells, TPA stimulated secretion of β-endorphin was abolished. A homologous desensitization of the secretory response has been previously observed by Zatz and Reisine (P.N.A.S.: 82:1286-1290, 1985). In the absence of TPA preincubation, POMC mRNA levels were increased in response to forskolin, TPA and CRF. After treatment of cells with TPA, the responses to forskolin and CRF remained elevated whilst the TPA induced increase in POMC mRNA levels was abolished. The above finding suggests that multiple regulatory mechanisms are involved in the regulation of POMC mRNA levels and β-endorphin secretion.

324.7 DYNAMIC OF HIGH-AFFINITY VASOACTIVE INTESTINAL PEPTIDE (VIP) BINDING SITES IN SUBCLONES OF A HUMAN NEUROBLASTOMA (SK-N-SH) EXPRESSING VIP: POTENTIAL AUTOCRINE ACTION OF VIP. J.M. Muller*, L. Eiden*, C.-M. Hsu* and J. Waschek* (SPON: P.A. Anderson). Lab. of Cell Biology, National Institute of Mental Health, Md 20892.

Three cell lines (SH-EP, SY5Y and SH-IN) corresponding to subclones isolated from a human neuroblastoma (SK-N-SH) (R.A. Ross, B.A. Spengler, and J.N., Biedler, J. National Cancer Institute, 71:4, 741-747, 1983) appear to be a promising model to study the divergence of transformed neuronal cells originating from the same tissue. For example, SY5Y and SH-IN which contain neuronal markers, possess measurable levels of mRNA encoding VIP and synthesize this peptide. On the other hand, the SH-EP cell line, which appears epithelial in morphology, contains no detectable VIP mRNA (cf. Waschek et al., this volume).

The ability of these different cell lines to specifically bind [3-iodotyrosyl-^{125}I] vasoactive intestinal peptide was investigated. Competitive inhibition of ^{125}I VIP binding on these different cells by unlabeled peptide was analyzed by the mathematical transformation of Scatchard. The results indicate that the three cell lines possess high affinity receptors for VIP. However, SH-EP possess numerous high affinity VIP receptors (7000 sites/cell; Kd = 0.5 nM), while SH-IN and SY5Y have a 7 fold lower binding capacity for radioiodinated VIP with a similar Kd. In addition, in SH-EP cells, VIP induces a rapid and pronounced down regulation of VIP receptors (up to 70% loss of binding capacity compared to control); this process is time and dose dependent (t1/2 = 8 min. in response to 10^{-7} M VIP) and is reversible upon removal of VIP. Dilution of SY5Y and SH-IN in culture medium appears to cause an increase in VIP binding capacity which can be seen within 1 hour. Moreover, the culture medium of SY5Y and SH-IN cells significantly inhibits binding of ^{125}I-VIP on different target cells (HT 29, SY-EP) possessing a high binding capacity for the peptide.

These data are consistent with the possibility that VIP or a related peptide and/or fragments of this peptide secreted by SY5Y and SH-IN cells into their culture medium could act as autocrine factors causing self regulation of the membrane VIP binding capacity of these cells. The differences observed in VIP production and membrane binding capacity among the three cell lines suggest that this autoregulation could be involved in the divergence of these three types of transformed neuronal cells originating from a common precursor. Work is now in progress to check if agents like dibutyryl-cAMP or forskolin which induce changes in the morphology of the SH-EP (epithelial like) cells can also affect their binding capacity for VIP and induce the production of neuron specific markers.

324.8 VASOPRESSIN (AVP) RECEPTOR REGULATION FOLLOWING LESION OF AVP INNERVATION OF VENTRAL SEPTAL AREA OF THE RAT BRAIN. P.Poulin, T. Malkinson, W.L. Veale and Q.J. Pittman. Neuroscience Research Group. University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Recently, immunocytochemical studies have detected AVP cell bodies within the bed nucleus of the stria terminalis (BST) that project to the lateral septal area and the nucleus of the diagonal band and its immediate surroundings, including the ventral septal area (VSA). AVP microinjected into the VSA is known to cause motor disturbances via an interaction with specific receptors. Long term castration (3 months) has been shown to provide a selective "lesion" of AVP fibers projecting to the VSA and lateral septum (LS). Receptors are known to be in a dynamic state of turnover and typically cells respond to a decrease in neurotransmitter levels by increasing their receptor number and/or altering their affinity. We have, therefore, tested the possibility that AVP receptors in the VSA of castrated male rats may be "supersensitive" to the AVP-induced motor disturbances and that changes would occur in AVP receptor numbers or properties. In a behavioral study, when castrated or control animals were challenged with AVP, given into the VSA, no difference in response (motor disturbances) to either a first injection of AVP, or of the characteristic augmented response seen after a second injection was seen. In binding studies, done on synaptic plasma membrane fractions, Scatchard analysis revealed no significant differences in Kd or Bmax in VSA membranes from castrated or control animals (Kd 2.78 nM vs 2.27 nM and Bmax 30 fmol/mg protein vs 28 fmol/mg protein respectively), in LS membranes (Kd 1.7 nM vs 1.3 nM and Bmax 47 fmol/mg protein vs 40 fmol/mg protein), or in hippocampal membranes (Kd 1.3 nM vs 1.3 nM and Bmax 25 fmol/mg protein vs 28 fmol/mg protein). Thus reduction in AVP content of VSA and LS has not altered AVP action in mediating motor disturbances, nor has it caused a change in AVP receptor properties or numbers. Supported by MRC. P.P. is an AHFMR student.

324.9 EFFECT OF SYSTEMICALLY ADMINISTERED CAERULEIN ON RECEPTOR-ADENYLATE CYCLASE COUPLING IN THE RAT BRAIN. T. Saito, Y. Hatta*, F. Tsuchiya*, H. Ikeda* and N. Takahata*. Dept.of Neuropsychiatry, Sapporo Med. Col., S.1, W.16, Chuou-ku, Sapporo 060, Japan.

Caerulein has various central activities similar to those of cholecystokinin octapeptide (CCK-8). Many reports have stated that CCK seems to have a role as a neuromodulator and much interest has been focused on the interaction between CCK and dopamine (DA). Although recent studies have indicated that systemically administered caerulein altered beta-adrenergic receptor function, caerulein's effect on receptor-effector coupling is still unclear. In the current study we examined caerulein's effects on receptor-adenylate cyclase (AC) coupling in the cortex and striatum of the rat brain. Male Wister rats (240-280 g) were used. In the acute caerulein treatment, animals were injected intraperitoneally (i.p.) with caerulein (100 ug/kg) or saline and sacrificed by decapitation at 1 hour after injection. In the chronic treatment, rats were injected with caerulein (200 ug/kg/day, i.p.) or saline twice a day, for 5 days and sacrificed by decapitation at 1 hour after the last injection. After acute injection with caerulein, the concentration of magnesium required for the half-maximal activation of AC (EC_{50}) was decreased slightly from 3.8 mM to 3.1 mM in the cortical membrane. EC_{50} for magnesium in the cortical membrane was shifted significantly from 3.9 mM to 2.8 mM after chronic caerulein treatment. The ^{125}I-pindolol binding to the beta-receptor in the cortical membrane was not altered after acute or chronic caerulein treatment. However, chronic treatment with caerulein resulted in an increase in the IC_{50} for isoproterenol in displacing ^{125}I-pindolol binding to the rat cortical membrane. The EC_{50} for isoproterenol activation of AC in the cortical membrane was also increased after chronic caerulein treatment.

Our data indicate that caerulein treatment in vivo may alter the N-protein function in the rat cerebral cortex. Effect of caerulein on the striatal receptor-AC coupling are currently being investigated.

324.10 CHRONIC MORPHINE TREATMENT INCREASES ADENYLATE CYCLASE ACTIVITY AND PERTUSSIS TOXIN-STIMULATED ADP-RIBOSYLATION OF G-PROTEINS IN A REGION-SPECIFIC MANNER IN RAT BRAIN. J.J. Erdos*, R.S.Duman, J.F.Tallman, and E.J. Nestler, Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508

The molecular changes that occur in neural cells following chronic opioid treatment have not been extensively investigated on a regional basis. Studies on cultured neuroblastoma x glioma cells suggest that the adenylate cyclase complex plays a role in the development of tolerance, dependence, and withdrawal. Few data, however, have been obtained in intact brain on the effects of chronic morphine treatment on adenylate cyclase activity or on the cellular components comprising the adenylate cyclase complex. We have systematically investigated on a regional basis the effects of chronic morphine treatment on adenylate cyclase activity and on levels of pertussis toxin-catalyzed ADP-ribosylation of Gi and Go.

Male Sprague-Dawley rats (150 g) were implanted subcutaneously with one 75 mg morphine pellet daily for 5 days. On day 6 the rats were sacrificed and brain regions isolated by punches taken from coronal cross sections. Punches were sonicated and a particulate fraction obtained by centrifugation for assay of adenylate cyclase activity and of ADP-ribosylation of G proteins.

Chronic morphine treatment was found to enhance basal, as well as GTP- and forskolin-stimulated, adenylate cyclase activity by approximately 30% in the locus coeruleus (LC), but to have no effect on adenylate cyclase activity in the neostriatum (NS) and dorsal raphe (DR), and variable effects in the frontal cortex (FC). In a similar manner, chronic morphine treatment was found to increase the level of pertussis toxin-catalyzed ADP-ribosylation of G-proteins by approximately 25% in the LC, but to have no effect in the NS, and variable effects in the FC. By one dimensional SDS polyacrylamide gel electrophoresis, it was not possible to determine whether the observed increase in the LC occurred in Gi or Go.

These results along with others reported in this volume (Nestler et al., Duman et. al.) indicate that the adenylate cyclase complex and cyclic AMP system can be characterized in discrete brain nuclei, and that regional differences exist in their regulation. Following chronic morphine treatment, there appears in the LC to be a specific increase in adenylate cyclase activity, the level of Gi/Go, and cyclic AMP-dependent protein kinase activity. These increases may contribute to an understanding of the molecular basis of known electrophysiological and behavioral phenomena of opioid tolerance, dependence, and withdrawal.

324.11 CHRONIC MORPHINE TREATMENT INCREASES CYCLIC AMP-DEPENDENT PROTEIN KINASE ACTIVITY IN THE RAT LOCUS COERULEUS. E.J. Nestler and J.F. Tallman. Department of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

The biochemical mechanisms underlying the chronic effects of opiates remain unknown. Studies on cultured neuroblastoma x glioma cells have implicated the enzyme adenylate cyclase in the development of tolerance, dependence, and withdrawal, but it has been difficult to extend these findings to neurons, and steps in the cyclic AMP system other than adenylate cyclase have not been investigated as possible sites of action of opiates. We chose to study the chronic effects of opiates on the cyclic AMP system in the rat locus coeruleus (LC). The LC contains cell bodies of virtually one type of neuron, which develops tolerance, dependence, and withdrawal upon chronic opiate treatment, as shown by electrophysiological studies.

Male Sprague-Dawley rats (150 g) were implanted subcutaneously with one morphine pellet (75 mg) daily for 5 d and were used on day 6. Control rats underwent identical surgery, but were not implanted with pellets. Brain regions were obtained from isolated brains either by gross dissection or by making punches from coronal cross-sections of pons or midbrain. The brain regions were sonicated and particulate and soluble fractions prepared by ultracentrifugation. Cyclic AMP-dependent protein kinase activity was determined in both fractions by use of histone phosphorylation assays.

Chronic morphine treatment was found to increase cyclic AMP-dependent protein kinase activity in both the particulate and soluble fractions of the LC. Study of the time-course by which morphine regulates this protein kinase showed that chronic treatment is required for this effect: no increase in cyclic AMP-dependent protein kinase activity was observed in response to 1 d of treatment, regardless of whether kinase activity was assayed on day 2 or day 6. This increase in protein kinase activity appeared to be specific to the LC. Chronic morphine treatment did not alter cyclic AMP-dependent protein kinase activity in fractions of the frontal cortex, neostriatum, or dorsal raphe. Protein kinase activity was also unaltered in fractions of pons cross-sections from which LC punches were obtained and of punches taken just medial or lateral to the LC.

We have found in related studies (Erdos et al., this volume) that, concomitant with increased AMP-dependent protein kinase activity, chronic morphine treatment increases the level of adenylate cyclase activity and of certain G-proteins, effects also observed specifically in the LC. In addition, we have found (unpublished data) that chronic morphine treatment alters the phosphorylation of a number of individual phosphoprotein substrates for cyclic AMP-dependent protein kinase in the LC. These various effects may represent feedback mechanisms by which LC neurons adapt to chronic opiate exposure and may be part of the molecular basis of tolerance, dependence, and withdrawal.

325.1 EVALUATION OF TOXIN F AS A PROBE FOR NICOTINIC RECEPTORS IN RAT BRAIN. D.W. Schulz and R.E. Zigmond. Department of Pharmacology, Harvard Medical School, Boston, MA 02115.

Toxin F is present along with α-Bungarotoxin (BGT) in the venom of Bungarus multicinctus. Unlike BGT, toxin F (< 100 nM) has been shown to block nicotinic transmission in chick ciliary ganglia and cultured rat sympathetic neurons. In these tissues, toxin F appears to bind to two sites, only one of which is recognized by BGT. Thus it has been suggested that it is the toxin F-selective site that mediates nicotinic responses to acetylcholine.

We have attempted to determine if toxin F is an appropriate compound for studying nicotinic receptors in rat brain. Our studies have focused primarily on the corpus striatum, due to 1) the high concentrations of acetylcholine and choline acetyltransferase in this region, 2) reports of relatively high densities of [^{3}H]-nicotinic agonist binding sites, and 3) evidence that nicotinic receptors that modulate dopamine release are present on the terminals of nigrostriatal neurons.

[^{125}I]-Toxin F bound to striatal membranes with a K_d of 2 nM, a B_{max} of 20 fmol/mg protein, and a Hill coefficient of 0.9. Of 6 brain regions assayed, binding was highest in thalamus, hippocampus, striatum, and hypothalamus, moderate in cortex, and much lower in cerebellum. However, among the first four of these areas, there was considerable variation in the ratio of [^{125}I]-toxin F:[^{125}I]-BGT binding. As is the case with sympathetic neurons, 1 μM BGT competed for only a portion of specific striatal [^{125}I]-toxin F sites (27 + 3%), while unlabeled toxin F completely inhibited [^{125}I]-BGT binding. Kinetic studies revealed that specific binding did not reach equilibrium until after 2 hr at 37° C, and the K_{off} was 0.25/hr. In competition experiments, a variety of nicotinic agonists and antagonists competed for some toxin F-selective sites at appropriate concentrations, but failed to consistently inhibit more than 50% of specific binding. Furthermore, [^{3}H]-nicotine binding in striatum was inhibited only 15% by 1 μM toxin F.

When superfused striatal slices were exposed to the nicotinic agonist DMPP (10μM) for 1 min, a > 100% increase in efflux of endogenous dopamine was observed over the next 3 minutes. This response was reversed over 60% by the nicotinic antagonist mecamylamine (100 μM). However, Toxin F at concentrations up to 1 μM failed to inhibit this augmentation of dopamine release.

In summary, toxin F displays some of the characteristics expected of a nicotinic ligand. However, in view of the lack of convincing pharmacological evidence from binding and release studies that toxin F interacts with striatal nicotinic sites, caution should be exercised when considering this compound as a probe for central nicotinic receptors. Future experiments will utilize other brain regions and other functional assays to address this question. Supported by NS12651 and MH00162.

325.2 **ELECTRON MICROSCOPIC EVALUATION OF INTERNALIZATION OF (125I) ALPHA-BUNGAROTOXIN BINDING INTO RAT HYPOTHALAMIC NEURONS.** **M. M. Miller and E. Antecka.* Departments of Obstetrics and Gynecology and Experimental Medicine and The Center for the Study of Reproduction, McGill University, Montreal, Canada, H3A 1A1.**

The time course of internalization of labeled alpha-bungarotoxin (α-BTX) binding sites was examined by electron microscopic autoradiography in the suprachiasmatic nucleus (SCN) of the adult female rat. (125I) α-BTX was infused into the third ventricle and 4, 8, and 12 hours later animals were perfused percardially with aldehyde fixatives. The dorsal-lateral aspect of the SCN was processed for autoradiography. The ultrastructural distribution of silver grains was studied both by line source and 50% probability circle analysis. The distribution of grains evaluated by 50% probability circle analysis was compared with the distribution of randomly generated hypothetical grains. In electron microscopic autoradiographs, silver grains overlaid either single structures (exclusive grains) or multiple neuronal and/or glial profiles (shared grains). The distribution of real grains was significantly different from that of hypothetical grains at all time points. Non-specific binding was also assessed at 4, 8, and 12 time points in rats infused with (125I) α-BTX in combination with radioinert α-BTX; labeling in these controls was not above background at any time point. Quantification of silver grain localization by 50% probability circle analyses indicated that membrane bound sources were mainly associated with axo-dendritic appositions, regardless of the length of time the tissue was exposed to radioligand. At 4, 8, and 12 hours, the compartment containing synaptic terminals was the most enriched when comparing real to hypothetical grains. Probability circle analysis of exclusive grains indicated that by 8 hours after intracerebroventricular infusion of specifically labeled α-BTX, binding sites were most likely to be within neurons and dendrites. Radiolabel was associated with vesicular structures within the cytoplasm, but not with lysosomal structures. The present study demonstrated that the majority of α-BTX binding sites remain membrane bound with respect to time and may be associated with synaptic transmission. A significant proportion of the silver grains are internalized into soma and dendrites of SCN neurons. Supported by NIH RO1 HD - 19431 and Fonds du Recherche en Santé du Québec.

325.3 TOPOGRAPHIC, NONCOLLATERALIZED BASAL FOREBRAIN PROJECTIONS TO ANTERIOR CINGULATE CORTEX, HIPPOCAMPUS, AND AMYGDALA IN RHESUS MONKEY. V.E. Koliatsos†, L.J. Martin*†, L.C. Walker†, R.T. Richardson§, M.R. DeLong§ and D.L. Price†. †Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Neurophysiology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Although neocortical projections of the magnocellular basal forebrain complex (MBFC) appear to be topographic and not widely collateralized, the possibility of single neurons innervating multiple nonneocortical targets has not been studied in primates. The present study investigates the differential organization of MBFC neurons projecting to anterior cingulate cortex (ACC) and hippocampus (HC), and to amygdala (AM) and HC. All of the above targets receive abundant cholinergic innervation, and each pair of targets receives projections from overlapping sectors of MBFC. However, ACC and HC are interconnected to a minor degree, whereas AM and HC are extensively interconnected. The retrograde tracer Fast Blue was used for HC injections, and Diamidino Yellow was used for injections of AM and ACC. Neurons projecting to ACC were present in rostral septum, vertical limb of diagonal band of Broca (dbB), and dorsal anteromedial nucleus basalis of Meynert (nbM). Cells projecting to AM were widely distributed in anterolateral nbM, intermediate nbM, ventral posterior nbM, and, to a lesser degree, in medial septal nucleus, vertical limb of dbB, and anteromedial nbM. Neurons projecting to HC were situated in almost all sectors of MBFC, clustering most densely in medial septum/dbB/anteromedial nbM and, to a lesser degree, in posterior nbM. In the vertical limb of dbB, neurons projecting to HC mingled with neurons projecting to ACC, which tended to be more laterally and dorsally located, and cells projecting to AM, which were more medially and ventrally located. In anteromedial nbM, neurons projecting to HC were ventral to cingulopetal cells; in anterolateral nbM, they were randomly mixed with amygdalopetal neurons; in posterior nbM, they mingled with amygdalopetal cells but tended to be located more dorsally and laterally. Cells projecting to both ACC and HC were found very rarely in areas of maximum overlap of cingulopetal and amygdalopetal neurons; cells projecting to both AM and HC were approximately 2% of the total number of amygdalopetal and hippocampopetal neurons. These findings indicate that: nonneocortical projections of MBFC neurons are topographically organized; and the degree of interconnectivity and/or functional relatedness of terminal fields does not seem to be related to the degree of collateralization of MBFC axons. Moreover, although separate targets may receive afferents from widely overlapping MBFC regions, the vast majority of these afferents does not originate in the same neurons.

325.4 **THE CHOLINERGIC TELENCEPHALIC SYSTEM OF THE NEW WORLD CEBUS MONKEY: ANALYSIS OF THE PROJECTION TO AMYGDALA.** J.H.Kordower, R.T.Bartus[1], F.F. Marciano*, and D.M. Gash. Dept. Neurobiology and Anatomy, University of Rochester Sch. Med. Rochester N.Y. 14642 and [1] Medical Research Division, Lederle Laboratories, Pearl River N.Y. 10065 USA.

The telecephalic cholinergic system has received considerable attention in recent years due to its putative role in normal cognition and dementing disorders. While cortical projection systems from the basal forebrain have received detailed scrutiny, there have been few and conflicting reports concerning the cells of origin of the cholinergic projection to the amygdala. This study describes the telencephalic cholinergic system of the Cebus monkey and analyzes the pathway and cells of origin for this cholinergic limbic input.

Nine Cebus apella monkeys were anesthetized and perfused with 0.9% saline followed by a 4% paraformaldehyde/0.1% glutaraldehyde fixation. Four animals received an intra-amygdaloid injection of horseradish peroxidase conjugated to wheat germ agglutinin (2.5-5%; 1 ul volume) 48-72 h prior to sacrifice. Sections were processed for choline acetyltransferase (ChAT) immunoreactivity (antibody AB8/dilution 1:20), acetylcholinesterase (ACHE), and Nissl substance. To assess the cells of origin for the projection to amygdala, other sections were processed via cobalt stablized tetramethylbenzidine (TMB) histochemistry either alone, or in combination with ChAT or ACHE staining.

Magnocellular ChAT-immunoreactive neurons were observed in the CH2-CH4 regions of the basal forebrain. These cells were up to 50 μm in diameter, were rounded in shape and often contained an eccentric nucleus. These cells had multipolar processes emanating from their perikarya. ChAT-immunoreactive cells in the CH1 region were oval in shape with their long axis oriented in the vertical direction. Apical and basal processes were observed emanating from these cells. Smaller cells were observed in the striatum and an occasional cell observed in the bed nucleus of the stria terminalis. Cholinergic somata were never observed in the cortex or hippocampus. Many processes from cells in the CH3-4 region were observed to project in apposition to proximal blood vessels.

Double labeled cholinergic cells projecting to amygdala (TMB+/ChAT+ or TMB+/ACHE+) were restricted to the sublenticular portions of the basal forebrain. Most of these cells were found in the anterolateral portion of the CH4 region. Fewer were found in the anteromedial portion of the CH4 and in the CH3 region. No double labeled cells were found in the CH1-2 complex and virtually no double labeled cells were found in the medullary laminae of the globus pallidus. A few double labeled cells were located just caudal to the amygdaloid complex and thus project rostrally to their terminal region.

These data will be discussed in terms of the possible role this cholinergic pathway might play in terms of both experimental studies of cognition and in neurodegenerative diseases in which cognitive dysfunction is a central feature.

325.5 CHOLINE ACETYLTRANSFERASE CONTAINING NEURONS OF RAT AND MONKEY BRAIN. H. Tago*, P.L. McGeer, L.B. Hersh, and G. Bruce* (SPON: P.C.K. Leung). Kinsmen Lab. of Neurol. Res., Dept. of Psychiatry, Univ. B.C., Vancouver, B.C. and Dept. Biochem., Univ. of Texas Health Sci Centre, Dallas, Texas.

We have used a highly sensitive polyclonal anti-human placental choline acetyltransferase (ChAT) rabbit serum, combined with a nickel ammonium sulfate second antibody intensification method, to identify ChAT-containing neurons in rat and monkey brain. The method permitted the identification of a number of new neuronal groups, as well as the confirmation of several other neuronal groups that had formerly been regarded as uncertain. Intense fiber staining permitted the direct tracing of some cholinergic tracts.

The most prominent new ChAT neuronal system was located in the hypothalamus. Small neurons in the infundibular (arcuate) nucleus had fibers extending towards the infundibulum. Other ChAT-positive hypothalamic cells were scattered loosely in the surrounding matrix. A medially distributed group was close to the third ventricle running in a rostro-caudal fashion and a lateral one was distributed principally in the region of the medial forebrain bundle, the lateral dorsal aspect of which contained mainly cholinergic fibers. The identification of these cells helps to account for previous biochemical and pharmacological studies which have strongly indicated the presence of intrinsic cholinergic neurons in the hypothalamus.

Other new neuronal groups include strongly positive cells in the parabigeminal nucleus and a few positive cells in the central gray and near the roof of the aqueduct, and in the cerebellum.

The method permitted confirmation of an extensive system of bipolar neurons in the cerebral cortex of the rat, but not the monkey. A few cholinergic neurons were seen in the amygdala and hippocampus. A strongly positive group was located in the medial habenula. Other, previously reported brainstem groups, were all positive (Kimura et al. in Handbook of Chemical Neuroanatomy, Vol. 3, pp. 51-65, Eds. A. Bjorklund and T. Hokfelt, 1984).

(supported by grants from the Medical Research Council of Canada and the National Institute of Health (A605893))

325.6 DISTRIBUTION OF CHOLINERGIC STRUCTURES IN THE CD-1 MOUSE BRAIN DEMONSTRATED BY IMMUNOCYTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE (ChAT). M.G. Cunningham* and E.J. Mufson (SPON: J. Rogers). Harvard Medical School, Boston, MA 02115 and Institute for Biogerontology Research, Sun City, AZ 85351.

A monoclonal antibody (AB8) (Levey et al., J. Neurosci., 3:1-9, 1983) against ChAT was used to localize central cholinergic structures in the CD-1 mouse brain.

Cholinergic perikarya were observed within five general nuclear groups: 1) striatum, including caudate, putamen, nucleus accumbens, and olfactory tubercle; 2) basal forebrain including the medial septal region (Ch1), vertical limb nucleus of the diagonal band (Ch2), horizontal limb nucleus of the diagonal band (Ch3), and substantia innominata-nucleus basalis complex (Ch4); 3) pontomesencephalic nuclei including the pedunculopontine nucleus (Ch5), lateral dorsal tegmental nucleus (Ch6), and parabigeminal nucleus (Ch8); 4) epithalamus including the medial habenular nucleus (Ch7); and 5) cranial nerve nuclei. Cholinergic cell bodies were also found in the cerebral cortex, hippocampus, nucleus tractus solitarius and medullary reticular formation.

Fiber staining was seen within several axonal tracts including the corpus callosum, cingulum bundle, anterior commissure, fornix, fasciculus retroflexus and portions of the cranial nerves. Fine varicose fibers were found within cortex, striatum, amygdala, hippocampus, thalamus and superior colliculus. ChAT immunoreactive fibers were observed swirling around the densely stained interpeduncular nucleus. Intense ChAT staining was also seen in the lateral amygdala and in the parabigeminal nucleus.

The present study indicates that the distribution and characteristics of cholinergic structures in the CD-1 mouse are similar to those previously reported in the rat and monkey. These factors, combined with our finding of age-related shrinkage of cholinergic basal forebrain neurons in the CD-1 mouse (Mesulam, Mufson, and Rogers, Ann. Neurol., 1987), make this animal a potential model for the investigation of age-associated changes of central cholinergic systems.

Supported by an ADRDA Faculty Scholar Award (EJM) and AG 05134.

325.7 ASCENDING BRAINSTEM PROJECTIONS TO FOREBRAIN CHOLINERGIC NEURONS. L. Zaborszky, W.E. Cullinan, and L. Heimer. Department of Otolaryngology, University of Virginia School of Medicine, Charlottesville, VA 22908.

We have reported previously that following large meso-diencephalic knife cuts, degenerating terminals are found on cholinergic dendrites in the forebrain (Zaborszky et al., Soc. Neurosci. Abst. 12:571, 1986). Furthermore, the specific removal of monoaminergic afferents (6-hydroxydopamine and 5,7 -dihydroxytryptamine) resulted in decreased choline acetyltransferase (ChAT) activity in the forebrain and areas containing the cholinergic projection neurons (Zaborszky and Luine, J. Cell Biochem., Suppl. 11D:187, 1987). In the present study we used the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) in order to determine the areas of origin of brainstem afferents to the cholinergic neurons.

PHA-L was iontophoretically injected in adult rats in the following brainstem areas: ventral tegmental area (A-10 cell group), various portions of the substantia nigra (A-9 cell group), cell groups in the vicinity of the superior cerebellar peduncle (pedunculopontine tegmental nucleus, A-7 cell group, Kolliker-Fuse nucleus, medial and lateral parabrachial nuclei), A-5 cell group, the locus coeruleus (A-6 cell group), subcoeruleus nucleus, Barrington's nucleus, rostroventrolateral reticular nucleus (C-1 cell group), parvocellular reticular nucleus, and the rostral portion of the A-1 cell group. Following 10-day survival periods, brains were fixed via transcardial perfusion, sectioned at 40 um in the coronal plane, and processed for PHA-L immunoreactivity following the conventional avidin-biotin peroxidase (ABC) protocol (Hsu et al., 1981). Another series was processed for the simultaneous visualization of PHA-L labeled fibers and terminals and ChAT containing cell bodies using several different double-labelling techniques. These included the double fluorescence method (FITC/RITC), and the ABC technique utilizing the same (DAB-intensified/DAB; Gorcs et al., 1986) or different chromagens (DAB/BDHC; Levey et al., 1986). Following all successful PHA-L injections, terminal and 'en passant' varicosities surrounding cholinergic cell bodies and dendrites were found in varying amounts in the lateral part of the nucleus of the vertical limb of the diagonal band (DB), the dorsal and medial portions of the horizontal limb of the DB, substantia inominata, ventral pallidum, globus pallidus, and lateral hypothalamus. Since in many cases the PHA-L deposit labeled heterogenous neuronal populations, studies are in progress to determine the neurotransmitter content of these fibers.

325.8 CHOLINERGIC PEDUNCULOPONTINE TEGMENTAL N. PROJECTIONS TO THE FOREBRAIN. A. E. Hallanger and B. H. Wainer. Com. on Neurobiology, The University of Chicago, Chicago, Il 60637.

We have previously demonstrated that the pedunculopontine tegmental nucleus (PPT) in the midbrain provides cholinergic afferents to all thalamic nuclei, including the principal relay nuclei. The laterodorsal tegmental nucleus (LDT) is a major second source of cholinergic afferents to some thalamic nuclei, including the laterodorsal, anteroventral, and mediodorsal nuclei. We have now investigated projections from the PPT and surrounding mesopontine tegmental neurons to other subcortical regions. The anterogradely transported lectin phaseolus vulgaris leukoagglutinin (PHA-L; 2.5%) was iontophoretically injected into the PPT in 10 rats. The tracer was immunohistochemically visualized, with diaminobenzidine as the chromogen, and tissue sections were counterstained with cresyl violet. Anterogradely labelled fibers and varicosities were observed in the thalamic nuclei, confirming the findings of our previous retrograde studies. In addition, PHA-L-labelled fibers and varicosities suggestive of terminal fields were observed in the tuberal and posterior lateral hypothalamic regions, the anterior hypothalamic area, the ventral pallidum in the region of the nucleus baslis of Meynert, the dorsal and lateral septal regions, and in the central and medial nuclei of the amygdala.

To determine whether the cholinergic neurons of the PPT project to these subcortical structures in which axons anterogradely labelled from the region of the PPT are found, the retrograde tracer WGA-HRP was injected into the hypothalamus (n=8), septum (n=7), ventral pallidum (n=5), and amygdala (n=4). Tissue sections were processed for both the retrograde tracer (using TMB) and for ChAT immunohistochemistry (using DAB). Single- (retrograde only) and double- (retrograde + ChAT) labelled neurons in the mesopontine tegmentum were counted in a one of four series of 50 micron sections from these animals. Numerous ChAT-immunoreactive neurons in the PPT and LDT were retrogradely labelled following placement of WGA-HRP into the tuberal and posterior lateral hypothalamus and the anterior hypothalamic area.These retrogradely labelled cholinergic neurons comprised an average of 10% of the total number of retrogradely labelled neurons in the mesopontine tegmentum. Noncholinergic neurons of the central tegmental field, retrorubral field, and cuneiform nucleus were also retrogradely labelled. Following placement of WGA-HRP into dorsal and lateral septal regions, the vast majority of retrogradely labelled neurons were cholinergic neurons of the PPT and LDT, with few noncholinergic retrogradely labelled neurons in the adjacent tegmentum. In contrast, few cholinergic neurons were retrogradely labelled following placement of tracer into the nucleus basalis of Meynert or into the central, medial, and basolateral nuclei of the amygdala. Noncholinergic neurons of the central tegmental field rostral to the PPT and of retrorubral field adjacent to the PPT were retrogradely labelled in these cases. In summary, these anterograde and retrograde studies demonstrate that the cholinergic PPT provides a substantial proportion of mesopontine tegmental afferents to the hypothalamus and lateral septum, while its projections to the nucleus basalis and the amygdala are minimal. 325.9 Changes in the Density of Cortical Cholinergic Innervation in Human Aging and Alzheimer's Disease. Changiz Geula and Marsel Mesulam, Harvard University and Beth Israel Hospital, Boston, MA.

Several lines of evidence indicate that an AChE-rich staining pattern provides a reliable marker for the cholinergic axons of the cerebral cortex. We used a photomontage-based intersect analysis to measure the density of acetylcholinesterase (AChE)-rich fibers in the cerebral cortex (entorhinal area, cingulate gyrus, inferotemporal area TE) of four control subjects (aged 22, 43, 68 and 91 years) with no history of dementia and four confirmed cases of Alzheimer's disease (AD) (aged 78, 88, 88 and 86 years). The AChE-rich fibers were visualized using a modified form of the histological method described by Tago et al. (J. Histochem Cytochem 34:1431, 1986).

In the control subjects, all cortical areas contained a dense net of AChE-rich axons displaying numerous synaptic swellings. Each cortical area had an individual pattern of lamination and density. In keeping with our prior observations in the monkey brain, (Ann. Neurol 19:144, 1986) the entorhinal and cingulate regions contained a denser net of cholinergic axons than inferotemporal visual association cortex. In order to assess the effects of aging and AD, we analyzed "best-stained" areas within comparable sectors of the three architectonic regions under investigation. Our results therefore emphasize changes in the "peak density" of cortical cholinergic innervation in these regions.

Aging was associated with a relatively modest decrease in the density of AChE-rich fibers. With the possible exception of entorhinal cortex, no consistent loss of density could be discerned from 22 to 43 and 68 years of age. When the 91 year old subject was compared to the 22 year old, the reduction in fiber density was in the order of 17-25% (25% in entorhinal cortex, 23% in area TE and 17% in cingulate cortex). The age-dependent reduction in fiber density appeared more pronounced in the deep cortical layers as compared with the superficial layers. In the brains of AD patients, AChE fiber density was markedly and consistently reduced even when compared to the 91 year old control subject. In all AD cases, area TE contained practically no AChE-positive fibers whereas in the cingulate cortex, varying densities of these fibers were detectable in two of the cases (60% and 20% reduction when compared to the 91 year old brain). The entorhinal cortex in AD showed a near-total loss of AChE-rich axons but this was not as complete as in TE. Our results provide the morphological basis for prior neurochemical reports showing a greater loss of cholinergic markers in the temporal lobe than elsewhere in the senile form of AD (Rossor et al. Brain 105:313, 1982). While based on a relatively small sample, these observations also suggest that the age-related alterations of cortical cholinergic innervation are quite modest, becoming established only in the late senium.

325.10 TIME OF ORIGIN OF CHOLINERGIC NEURONS IN THE RAT BASAL FOREBRAIN. K. Semba and H.C. Fibiger. Division of Neurological Sciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C. V6T 2A1 Canada.

The basal forebrain contains a major group of cholinergic neurons which is distributed from the medial septum rostrally to the region of the ventromedial globus pallidus caudally. These cholinergic neurons project to the cerebral cortex, hippocampus, amygdala, and olfactory bulb. In the present study, the development of the basal forebrain cholinergic neurons was investigated using tritiated thymidine autoradiography combined with choline acetyltransferase (ChAT) immunohistochemistry. Tritiated thymidine was injected into timed pregnant rats (conception designated day 0), and the brains of their progeny as young adults were processed for immunohistochemistry followed by autoradiography. The combined techniques permit the determination of the time of final mitotic division of cholinergic neurons.

The first ChAT-immunoreactive neurons to become post-mitotic were located in the caudal globus pallidus and the substantia innominata. In these regions, the peak of final mitotic division of ChAT-immunoreactive neurons occurred on embryomic (E) day 12. In the rostral globus pallidus, the ventral pallidum, and the magnocellular preoptic area, the peak of cholinergic neurogenesis occurred slightly later, on E13. In all the above regions, most ChAT-immunoreactive neurons had left the mitotic cycle by E15. In the horizontal and vertical limbs of the diagonal band, most ChAT-positive neurons became post-mitotic on E13-15. In the medial septum, the peak of final mitotic activity occurred on E15, although some ChAT-positive neurons underwent final mitosis earlier. In all basal forebrain regions, cholinergic neurogenesis was complete by E17.

These results indicate that there is a caudal to rostral gradient in the neurogenesis of cholinergic neurons in the basal forebrain, with peak final mitosis occurring in the caudal cells approximately 3 days earlier than in the rostrally located neurons. It has previously been shown that (1) the cholinergic projection to the cerebral cortex arises in caudal parts of the basal forebrain, whereas that to the hippocampus originates from rostral basal forebrain neurons, and (2) the neurogenesis in the cortex largely preceeds that in the hippocampus. Together, these findings point to a correlation between the gradient of neurogenesis of the cholinergic basal forebrain neurons, and that of their target neurons.

325.11 LOCALIZATION OF mRNA ENCODING THE ENZYME ACETYLCHOLINESTERASE IN THE TORPEDO ELECTROMOTOR SYSTEM BY IN SITU HYBRIDIZATION. M.W. Newton, D. Healy, M. Schumacher* and P. Taylor*. Depts. of Pharmacology, Univ. of Calif., San Diego, CA 92093 and Mt. Sinai Medical School, New York, NY 10029.

The electric organ of Torpedo californica is an abundant source of the asymmetric and globular forms of acetylcholinesterase (AChE). AChE is synthesized in the electrocytes of the electric organ and in the cholinergic neurons of the electromotor nucleus of the brain, from which it is transported along the axons to the electric organ. In situ hybridization is a technique which can potentially localize the cellular sites of biosynthesis of the molecular forms of AChE and which may be useful for studying the regulation of AChE expression. We have used in situ hybridization to analyze the distribution of mRNA coding for AChE at the cellular level in the Torpedo electromotor system. The ^{35}S-labeled RNA probes were prepared by transcription of the AChE cDNA recently isolated in our laboratory with SP6 and T7 RNA polymerases. The presence of large molecular weight RNA species coding for AChE has previously been demonstrated by Northern blot analysis of these tissues.

Frozen tissue sections were cut from fixed or fresh frozen electric organ and electromotor nucleus, fixed onto slides and hybridized with antisense (experimental) or sense (control) strands of the labeled RNA probe encoding AChE. After washes and RNAase treatment, the sections were analyzed by autoradiography.

Autoradiograms of transverse sections through the electric lobe of the brain after hybridization with antisense ^{35}S-RNA revealed dense, punctate labeling in the electromotor nucleus. This pattern was not seen in adjacent sections hybridized with the sense strand. High resolution emulsion autoradiography indicated that the dense punctate labeling was due to the labeling of the large electromotor neurons, whereas the surrounding glial cells were labeled at only low density. Hybridization of the electric organ sections with the antisense ^{35}S-RNA probe resulted in a diffuse pattern of labeling, which was more dense than that observed in sections hybridized with the sense probe. High resolution emulsion autoradiography indicated that the antisense RNA label was frequently associated with the nucleus and perinuclear regions in the electrocytes.

These results indicate that mRNA coding for AChE may be localized at the cellular level by in situ hybridization. Because the catalytic subunits of asymmetric and globular AChE forms may differ in primary structure near the carboxy terminus, specific probes may be developed which can localize expression of the different enzyme forms at the cellular level by in situ hybridization. 325.12 LANDMARKS IN NEUROCHEMISTRY I. HENSING AND THUDICHUM. L.H. Marshall and H.W. Magoun, Brain Research Institute, University of California, Los Angeles, CA 90024.

The earliest systematic analysis of mammalian brain chemistry was carried out by Johann Becker Hensing (1683-1745), a Hessian scholar, physician, and chemist. He looked for, and found, phosphorous in beef brain and published his findings in 1719. His detailed study establishes Hensing as the first modern neurochemist,* but his contributions were largely forgotten.

A century-and-a-half later, another Hessian, Johann Ludwig Wilhelm Thudichum (1829-1901), wrote and published the next important study in brain chemistry and also acknowledged his fellow-countryman's work. After receiving his M.D. from the University of Giessen as had Hensing, Thudichum emigrated to England. In A Treatise on the Chemical Constitution of the Brain (1884), he identified the colloidal nature of the brain "bioplasm" and related it to the phosphatides which he knew occurred in plant as well as animal bioplasm. His findings were assailed and discounted until they were published 17 years later in Germany. Many of the substances he isolated from brain tissue--lecithins, cephalins, and myelins--he identified, classified, and named, and he prepared pure samples that exist today. Thudichum is credited with prophesizing psychochemistry by suggesting that many forms of insanity are due to effects upon the brain-substance of "poisons fermented within the body". Unfortunately, in his treatise he did not discuss any functional aspects of the compounds he discovered.

325.13 LANDMARKS IN NEUROCHEMISTRY II. NEUROTRANSMISSION TO 1940. H.W. Magoun and L.H. Marshall. Brain Research Institute, University of California, Los Angeles, CA 90024.

In the 19th century the roots of functional neurochemistry were gathering evidence not from the central nervous system, but from the periphery with studies of the nerve-muscle preparation. In 1877 Eduard du Bois-Reymond stated that contractile tissue is stimulated at its boundary by "a thin layer of ammonia, lactic acid, or some other powerful stimulating substance. Or the phenomenon must be electrical". This chemical concept stemmed from Fabbrioni's explanation of excitation from contact of dissimilar metals (1792). In 1894 F.S. Locke, in Germany, recognized that calcium ions were necessary to effect neuromuscular transmission. By the early years of the 20th century, his compatriot, Ernest Overton, not only confirmed Locke but showed that sodium ions were required for nerve excitability and suggested a sodium-potassium exchange was involved in conductance. William Howell in the United States and Thomas R. Elliott and John N. Langley in Great Britain published observations that strengthened the idea of the chemical nature of nerve action. Otto Loewi's dual frog heart preparation and its refinement by Kahn were the means of proving that point. Langley in 1905 proposed his receptor theory for a chemical synapse, postulating a "receptive substance" to receive the stimulus from the nerve and pass it on to the postsynaptic cell.

The identification of adrenalin and noradrenalin, involving both British and Swedish investigators, established the concept of adrenergic neurotransmission by the early 1930s. In that same decade David Nachmansohn proposed that acetylcholine, in conjunction with certain enzymes, control bioelectric signals. By the next decade some of the biophysicists and neurochemists had identified themselves as molecular neurobiologists by their concentration on events associated with neural activity.

ACETYLCHOLINE: METABOLISM II

326.1 CHOLINE PROTECTS AGAINST STIMULATION-INDUCED DECREASE IN BRAIN MEMBRANE PHOSPHATIDES. I.H. Ulus, R.J. Wurtman, C. Mauron* and J.K. Blusztajn. Department of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, USA

Rat brain slices continue to make and release large amounts of acetylcholine (Ach) without exhibiting reductions in their contents of free choline or Ach, even when superfused with a choline free medium. This study examines the possibility that the choline in membrane phospholipids is the source of the choline used for Ach synthesis under these conditions.

Male Sprague-Dawley rats, 200-250 g., were decapitated, their striata rapidly dissected, and 300 μm slices prepared using a McIlwain tissue chopper. The slices were superfused (0.6 ml/min. 37°C) with a physiological medium containing (mM): NaCl, 120; KCl, 3.5;$CaCl_2$,1.3;$MgSO_4$, 1.2; NaH_2PO_4, 1.2; $NaHCO_3$, 25; glucose 10 and eserine salicylate, 0.02 (a cholinesterase inhibitor). The medium was continuously bubbled with 95% O_2 and 5% CO_2 (pH = 7.4). After 20 min equilibration, samples of slices were removed for the determination of "initial" tissue contents of phospholipid phosphate. The remaining slices were superfused at rest for 20 min. then electrically stimulated (1 ms pulses: 15 Hz, 30 V amplitude) for 20 min. and then maintained at rest for another 20 min. This stimulation-rest procedure was repeated 8 times. At the end of the 2nd, 4th, 6th and 8th stimulation-rest period, samples of slices were removed for determination of phospholipid. Effluents were collected during every period for determination of Ach.

Total tissue phospholipids were found to have declined from 0.746± 0.014 (μg P/μg DNA: initial) to 0.666 ± 0.040; 0.621 ± 0.02b; 0.576 ± 0.025; and 0.569 ± 0.028 after the 2nd, 4th, 6th and 8th stimulation periods, respectively. Phospholipid levels were inversely related (r = -0.98) to the number of the stimulation period. Addition of choline to the medium (10, 20 or 40 μM) markedly enhanced Ach release, both basal and during stimulation; it completely protected the slices from the phospholipid depletion observed in its absence. Stimulation in the choline-free medium caused proportionate decreases in tissue phosphatidylcholine (PC), phosphatidylethanolamine and phosphatidylserine, so that their ratio to total phosphatides did not decline. Addition of choline to the superfusion medium, while blocking the reduction in phosphatide content, also failed to affect this ratio.

These data support the hypothesis that the phospholipids in brain membranes serve as a reservoir of choline to be used for Ach synthesis. They also indicate that when the supply of free choline is inadequate to sustain Ach synthesis, the cell obtains more choline not by selectively utilizing PC, but by diminishing the total amount of membrane.

326.2 N-METHYLCARBAMYL CHOLINE, A NOVEL NICOTINIC AGONIST, ENHANCES ACETYLCHOLINE RELEASE FROM RAT BRAIN SLICES. D. M. Araujo, P. A. Lapchak, B. Collier and R. Quirion. Douglas Hospital Res. Ctr. and Depts. of Psychiatry and Pharmacology, McGill University, Montreal, Canada H4H 1R3.

[^{3}H]N-methylcarbamyl choline (MCC) binds specifically, saturably, and with high affinity to nicotinic sites in rat cerebral cortex (Abood and Grassi, Biochem. Pharmacol. 35:4199-4202, 1986; Boksa and Quirion, in press). The receptor binding characteristics of [^{3}H]MCC to rat brain are similar to those of [^{3}H]nicotine. The present study attempted to clarify the possible function of the [^{3}H]MCC/nicotinic sites in rat brain. [^{3}H]MCC binding to membranes from rat frontal cortex and hippocampus was characterized as follows: membranes were prepared by homogenizing brain tissue in a Brinkmann Polytron in buffer containing (mM) Tris.HCl 50, NaCl 120, KCl 5, $CaCl_2$ 2, $MgCl_2$ 1, pH 7.4, after which homogenate was centrifuged (49000g/10min/3x). The final membrane pellet was resuspended in fresh buffer and incubated with various concentrations of [^{3}H] MCC (60min, at 4°C), with non-specific binding defined in the presence of 10μM nicotine. The results show that [^{3}H]MCC binds to both frontal cortex (B_{max}=52.4fmol/mg protein, k_d=14.9nM) and hippocampus (B_{max}=21.7fmol/mg protein, k_d=14.0nM) with high affinity and to an apparently single class of sites. The effect of unlabeled MCC on acetylcholine (ACh) release from slices of rat frontal cortex and hippocampus was then tested. Slices were prepared using a McIlwain tissue chopper and pre-incubated in Krebs medium (pH 7.4) containing eserine (30μM) and choline (10μM) for 60min (37°C). Medium was then replaced with fresh buffer and tissue was reincubated for 10min. This incubation was repeated either with or without (controls) various concentrations of MCC. The drug enhanced spontaneous ACh release; this effect was concentration-dependent, with the maximal increase (164 and 74%) evident at concentrations of 1 and 10μM, for hippocampus and frontal cortex, respectively. Similarly, nicotine (1μM) also augmented ACh release from rat brain slices (by 78% in hippocampal slices), although it was not as potent as MCC. The increase in spontaneous ACh release measured in the presence of MCC would appear to be mediated by a nicotinic receptor since it was abolished by the nicotinic antagonists, d-tubocurarine (1μM) and dihydro-β-erythroidine (1μM), but not by the muscarinic antagonist, atropine (1μM). In contrast to its effect on spontaneous ACh release, MCC did not alter evoked ACh release induced by high K^+ (50mM) medium. In summary, the present results are compatible with the idea that presynaptic nicotinic receptors may be involved in the regulation of ACh release in rat brain, at least in the frontal cortex and in the hippocampus. (Supported by MRC, Canda and FRSQ and FCAR, Quebec)

326.3 EFFECTS OF CHOLINERGIC AGENTS ON RAT BRAIN ACETYLCHOLINE METABOLISM: EVIDENCE FOR REGIONAL DIFFERENCES IN METABOLIC REGULATION. A. Enz* (SPON: P.H. Kelly), Preclinical Research, Sandoz Ltd., CH-4002 Basle/Switzerland.

Interest in the metabolism of acetylcholine (ACh) in the brain and the factors that control or modulate it was greatly stimulated by the discovery that an impairment of cholinergic function may play a crucial role in Alzheimer's disease. Muscarinic agonists like oxotremorine, aceclidine and RS86, a spirosuccinimide, increase ACh levels in striatum, cortex and hippocampus of the rat brain in a dose dependent manner, but not in the pons/medulla region. Consistent with these findings, no alteration in ACh turnover is observed after pulse injection of deuterated choline. AChesterase inhibitors (AChE-I) such as tacrine, physostigmine and the miotine derivative RA7 reduce ACh turnover and enhance ACh levels in rat striatum, cortex and hippocampus, but again these drugs exert no influence on pons/medulla. However, the drugs examined stimulate metabolism of dopamine in the striatum, of noradrenaline in the cortex and of serotonin in hippocampus and cortex, whereas no change in noradrenaline metabolism is observed in the pons/medulla region.

The results demonstrate regional differences in the regulation of ACh metabolism. In the forebrain, ACh levels and turnover rates were affected by muscarinic agonists and endogenous ACh, whereas in the pons/medulla these parameters were remarkably constant, suggesting region-specific mechanisms regulating ACh turnover.

326.4 THE RELEASE OF ENDOGENOUS ACETYLCHOLINE FROM RAT TISSUE SLICES PREPARED FROM THE NUCLEUS BASALIS. R.H. Metcalf* and R.J. Boegman (SPON: C. Romero-Sierra). Department of Pharmacology and Toxicology, Queen's University, Kingston, Canada.

Physiological and neuroanatomical studies indicate that there is a cholinergic input to the nucleus basalis (NB) of the rat. It has been proposed that this input arises from the magnocellular cholinergic neurons intrinsic to this region (Kristt et al., Brain Res. 337: 19-39, 1985; Lamour et al., Brain Res. 362: 122-131, 1986). The objective of our study was to measure the release of endogenous ACh from tissue slices of the NB following depolarization with 35 mM K^+ or exposure to 3,4-DAP, a compound known to enhance the release of neurotransmitter from spontaneously active neurons (Thesleff, Neurosci. 5: 1413-1419, 1980). In our study, three strategies were employed to determine the location of the NB. Firstly, choline acetyltransferase (ChAT) activity was determined according to the method of Fonnum (1951). Secondly, quinolinic acid (QUIN), an excitotoxin that produces a 50-60% reduction in cortical ChAT, was stereotaxically injected into the right NB. ChAT activity was measured in both ipsilateral and contralateral regions seven days later. Thirdly, immunohistochemical staining for ChAT-positive neurons was assessed. Having established our dissection, endogenous ACh release from the slices was determined by gas chromatography - mass spectrophotometry (GC-MS). Values were expressed as the mean ± SEM of 6-8 animals unless otherwise stated.

ChAT activity in the NB was 101.84 ± 2.95 nmoles ACh formed/mg protein/hr in the right and 95.37 ± 4.35 nmoles/mg protein/hr in the left. There was no significant difference between the hemispheres. Unilateral injection of 1 µl, 120 mM QUIN into the right NB produced a 66.36% ± 2.82% reduction in ChAT activity at the injection site which was significantly different from control ($p \leq 0.05$). ChAT immunohistochemistry demonstrated the presence of large, sparsely distributed neurons in the tissue slices.

Depolarization (35 mM K^+) of the tissue slices produced a significant increase in the release of ACh. ACh release in the right NB was 1.669 ± 0.088 nmoles/g wet wt/min and in the left was 1.796 ± 0.165 nmoles/g wet wt/min. These values were significantly different from spontaneous release, which varied between 0.168 and 0.225 nmoles/g wet wt/min, but not from each other. The K^+-induced release of ACh was totally dependent on the presence of Ca^{2+} (1.3 mM added to the incubation buffer). 1 mM 3,4-DAP caused the release of 0.448 ± 0.034 nmoles/g wet wt/min ACh (n=4), which was well above spontaneous release. However, it was below that seen in the presence of 35 mM K^+. Our data indicate that ACh can be released from the large cholinergic neurons in the NB by a calcium-dependent process.

Supported by the Medical Research Council of Canada.

326.5 ACTIVATION OF PRESYNAPTIC OPIATE RECEPTORS DECREASES THE RELEASE OF ENDOGENOUS ACETYLCHOLINE FROM RAT AND GUINEA-PIG CORTICAL SLICES. P.A. Lapchak, D.M. Araujo and B. Collier. Dept. Pharm. and Ther., McGill University, Montreal, Quebec, Canada, H3G 1Y6.

There is considerable evidence in the literature suggesting that opiates may have a role in the modulation of neurotransmitter release in the rat brain. Receptor autoradiography has shown that mu, delta and kappa opiate receptors are located in the rat and guinea-pig cortex. However, little direct evidence for a functional link between these opiate receptors and cholinergic function is available. The present study attempted to identify the opiate receptor subtype(s) involved in the regulation of acetylcholine (ACh) release from the cortex of the rat and guinea-pig.

In rat cortical slices, k specific agonists U-50,488H and dynorphin A(1-13) (10 µM) decreased the K^+ evoked release of ACh in the frontal (23.0 ± 5.4% and 24.2 ± 5.9%), parietal (37.5 ± 4.5% and 23.3 ± 4.9%) and occipital cortex (25.2 ± 8.7% and 31.9 ± 4.2%). The µ selective agonists, DAGO and FK-33824 (10 µM), also decreased the release of ACh from the parietal cortex (29.1 ± 4.5% and 29.7 ± 7.3%), but did not have any effect on the evoked release of ACh from either the frontal or occipital cortex. The δ selective agonists DADLE and DSLET (10 µM)were ineffective in altering ACh release from all cortical areas, suggesting that δ opiate receptors appear not to be involved in the regulation of cortical ACh release.

In the guinea-pig, agonists (1 µM) of each of the three opiate receptor subtypes depressed evoked ACh release from the parietal cortex. This decrease was 27% for k (U-50,488H), 22% for δ (DSLET and DADLE) and 24% for µ (FK-33824). In the occipital cortex, k (U-50,488H) and δ (DSLET) agonists (1 µM) inhibited evoked ACh release by 35% and 32%, respectively; µ receptor ligands were ineffective. In the frontal cortex, both k and δ opiate receptor agonists depressed evoked release. However, this effect was much less (16-22%) than in the occipital or parietal cortex, and was apparent only at higher concentrations (10 µM) of these drugs. The opiate agonists were without effect on the basal release of ACh from either rat or guinea-pig cortical slices. The effects of the opiate agonists were reversed by incubation in the presence of 10uM naloxone.

The possible mechanism(s) whereby the opiate receptor agonists tested may alter ACh release is not clear but may be that Ca^{+2} is involved in this effect. This is supported by results which show that none of the opiates which clearly altered evoked release had any effect on basal (non-calcium dependent) ACh release. In conclusion, these results suggest that presynaptic opiate receptors are involved in the regulation of endogenous ACh release from a population of cholinergic neurons in the cortex, but this effect appears to be species dependent. (Supported by MRC, FCAR, Canada).

326.6 A TRANSMEMBRANE SIGNAL IN THE ACETYLCHOLINE STORAGE SYSTEM OF SYNAPTIC VESICLES. K.Nornberg and S.M. Parsons.Department of Chemistry,University of California,Santa Barbara,CA 93106.

The acetylcholine(ACh) storage system of Torpedo electric organ synaptic vesicles is composed of an ATPase,an ACh transporter and a receptor for the inhibitory compound 2-(4-phenylpiperidyl)cyclohexanol (vesamicol).Highly purified synaptic vesicles submitted to hyposmotic shock reseal in isosmotic buffer during20 min incubation at 23°C as measured by [^{14}C]ribitol retention.Some properties of the vesamicol receptor in lysed and resealed synaptic vesicles were studied.Vesicle ghosts exhibit an increase of [^{3}H]vesamicol binding up to 170% compared to that of intact vesicles.[^{3}H]Vesamicol bound to lysed vesicles was displaced in a dose-dependent manner by a nonpermeable analog of vesamicol with potency similar to that in the intact vesicles.Thus, the vesamicol receptor faces the cytoplasmic surface in both intact and lysed vesicles,and some factor on the inside of the intact vesicles controls the vesamicol receptor conformation on the outside.In intact synaptic vesicles ACh added exogenously does not compete with vesamicol binding.In contrast, [^{3}H]vesamicol binding to vesicles ghosts was inhibited by ACh with IC_{50} 5-50 mM,depending on the vesicles preparation.The transport of^{50}[^{14}C]ACh by vesicles ghosts was studied to determine whether the exogenous ACh was acting on the outside of the membrane to displace bound vesamicol.Cholinergic vesicle ghosts rapidly accumulated [^{14}C]ACh in the same amounts under active or passive transport conditions,and the inside concentration of [^{14}C]ACh was the same as that in the incubation buffer.Thus,the question of the sidedness for the ACh effect on vesamicol binding to vesicles ghosts remains to be answered.It also was found that the inhibitory effect of ACh on [^{3}H]vesamicol binding was much less potent (by at least 100 fold) at low vesicles concentration,suggesting that an unknown dissociable factor mediates the ACh effect on vesamicol binding.Taken together, these results suggest that an internal factor,possibly ACh,sends a regulated signal to the vesamicol receptor which reports about the internal status of the vesicles.

326.7 INHIBITION OF HIGH AFFINITY CHOLINE TRANSPORT WITH A-4 ATTENUATES THE EFFECT OF ETHYLCHOLINE MUSTARD AZIRIDINIUM (AF64A) ON BOTH CHOLINERGIC AND SEROTONERGIC PARAMETERS. P.E. Potter*, C.E. Tedford*, G.H. Kindel* and I. Hanin (SPON. A. Karczmar). Department of Pharmacology and Experimental Therapeutics, Loyola University Stritch School of Medicine, 2160 S. First Ave., Maywood, IL 60153, U.S.A.

Intraventricular (i.c.v.) administration of AF64A in rats leads to a marked and longlasting reduction in indices of hippocampal cholinergic function, such as acetylcholine (ACh) levels and release, high affinity choline transport (HAChT), and the activities of choline acetyltransferase and acetylcholinesterase[1,2]. We have also found decreases in 5-hydroxytryptamine (5-HT) levels after i.c.v. injection of 2 nmoles of AF64A into each lateral ventricle[1,3]. However, in contrast to the changes in cholinergic parameters, this reduction was transient, with a maximal effect at 4 days after treatment, followed by eventual recovery to control levels. This suggests that, rather than being due to a direct toxic action of AF64A on serotonergic neurons, the changes might result from increased 5-HT release as a consequence of removal of inhibitory cholinergic input. If so, decreasing the effect of AF64A on cholinergic neurons by blocking the HAChT site should also prevent the decrease in 5-HT, whereas if the changes were due to direct toxicity of AF64A, this treatment should not protect serotonergic neurons.

In the present study, A-4, a specific inhibitor of HAChT[4], was given i.p. (20 mg/kg) one hour before bilateral i.c.v. administration of 2 nmoles AF64A. The rats were killed 4 days after treatment by head focussed microwave irradiation and hippocampal content of ACh, choline, 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) were determined by HPLC with electrochemical detection. AF64A treatment reduced ACh content from 198.5 ± 11.7 to 112.3 ± 21.1 pmoles/mg protein ($p < 0.01$) and decreased 5-HT by from 2.96 ± 0.18 to 2.19 ± 0.24 pmoles/mg tissue ($p < 0.05$). The content of 5-HIAA was not changed at this time. Pretreatment with A-4 markedly attenuated the effect on ACh and completely prevented the decrease in 5-HT. These results strongly support the hypothesis that the changes observed in serotonergic parameters after AF64A treatment are related to the loss of cholinergic input to these neurons.

326.8 LACK OF GABAERGIC MODULATION OF ACETYLCHOLINE TURNOVER IN THE RAT THALAMUS. C. Cosi* and P.L. Wood (SPON: E. Snowhill). Neuroscience Res. Dept., Pharmaceuticals Div., CIBA - GEIGY Corp., Summit, N.J. 07901 U.S.A.

Electrophysiological, radioenzymatic and immunohistochemical studies (see Fibiger, Brain Res. Rev. 4:327, 1982) describe the existence of cholinergic projections from the midbrain and pons to the thalamus. However, the modulation of this projection by other neurotransmitter systems has not been defined. A GABAergic innervation of thalamic nuclei has been described (Fagg and Foster, Neuroscience 9:701, 1983). Since a GABAergic modulation of other central cholinergic systems, including the septohippocampal and substantia innominata-cortical pathways, is known (Wood, Can. J. Physiol. Pharmacol. 64: 325, 1986), the present study investigated the effects of GABAergic drugs on acetylcholine (ACH) turnover in the thalamus.

ACH turnover was measured in the thalamus, frontal cortex and parietal cortex after the intraperitoneal injection of THIP, a GABAergic agonist, and the benzodiazepine receptor agonist, diazepam. Animals were infused intravenously with deuterated phosphorylcholine for 9 min, 21 min after the administration of drug. The percentage of deuterium incorporated into regional brain choline and acetylcholine, was monitored by gas chromatography-mass spectrometry in positive chemical ionization mode (Wood and Peloquin, Neuropharmacology 21:349. 1981).

THIP (20 mg/kg) reduced ACh turnover in the frontal cortex and in the parietal cortex to 53 % and 48 % of control, respectively ($p < 0.05$) while not affecting ACh turnover in the thalamus of the same animals. Diazepam (5 mg/kg) decreased ACh turnover in the frontal cortex and in the parietal cortex to 65 % and 48 % of control, respectively ($p < 0.05$), but did not affect ACh turnover rate in the thalamus in the same animals.

This study confirms the previous finding of a GABAergic inhibition of the cortical cholinergic system (Wood, 1986) and indicates that the thalamic cholinergic projection does not appear to be modulated by GABAergic inputs.

326.9 EVIDENCE FOR CARRIER-MEDIATED SPONTANEOUS RELEASE OF ACETYLCHOLINE FROM RAT HIPPOCAMPAL TISSUE. Michael T. Ivy* and Paul T. Carroll. Department of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Spontaneous release of acetylcholine (ACh) from brain tissue differs from evoked release in that it appears to occur from the nerve terminal cytosol rather than from vesicles; also it is not calcium (Ca^{++})-dependent (Carroll, P.T. and Aspry, J.M., Neurosci., 6: 2555, 1981; Carroll, P.T., Neurochem. Res., 8: 1271, 1983). Recent evidence suggests that the spontaneous release of ACh from brain tissue may be carrier-mediated; 2-(4-phenylpiperidino) cyclohexanol (AH 5183), a drug which blocks vesicular ACh transport, reduces the spontaneous release of ACh from both mouse forebrain and rat striatum (Carroll, P.T., Brain Res., 358: 200, 1985; Ricny, J. and Collier, B., J. Neurochem., 47: 1627, 1986) at low concentrations. In the present study, the inhibitory effects of the L- and D-stereoisomers of AH 5183 on the spontaneous ACh release from rat brain hippocampal tissue were compared. The temperature and energy-dependence of spontaneous ACh release were also studied. The results indicated that both of the stereoisomers inhibited spontaneous ACh release in a concentration dependent fashion to produce parallel responses. The L-stereoisomer of AH 5183 had a half-maximal inhibitory concentration (IC_{50}) of 263 nM, whereas the D-isomer had an IC_{50} of 25.2 µM. The L-isomer of AH 5183 reduced the spontaneous release of ACh in both the presence and absence of extracellular Ca^{++}. Spontaneous ACh release was also temperature-dependent; a Q_{10} of approximately 3.2 was obtained. It did not, however, appear to be energy-dependent; 2, 4-dinitrophenol did not significantly reduce it. These results suggest that the spontaneous release of ACh from rat hippocampal tissue is carrier-mediated (supported in part by a Tarbox postdoctoral Fellowship to MTI and NINCDS 212189-03 to PTC).

326.10 IS THE VERATRIDINE INDUCED RELEASE OF ACh FROM RAT HIPPOCAMPAL TISSUE LINKED WITH AN ACTIVATION OF CHOLINE-O-ACETYLTRANSFERASE ACTIVITY? Paul T. Carroll and Michael T. Ivy* (SPON: J.B. Lombardini), Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

It is well established that K^+ and veratridine depolarization of rat striatal tissue in vitro augment the calcium dependent activity of a water soluble fraction of tyrosine hydroxylase (El Mestikawy et al, Nature, 302: 830, 1983; El Mestikawy et al, J. Neurochem, 45: 173, 1985; Knorr et al, Biochem. Pharmacol. 35: 1929, 1986). To ascertain whether depolarization of rat hippocampal tissue might similarly activate choline-O-acetyltransferase (E.C. 2.3.1.6; ChAT) activity, the effect of varying concentrations of veratridine on both ACh release and on the activity of various ChAT fractions, isolated from rat hippocampal tissue according to the procedure of Benishin, C.G. and Carroll, P.T., J. Neurochem. 41: 1030, 1983, was determined. The results indicated that veratridine treatment stimulated the activity of water and detergent soluble ChAT fractions over the same concentration range as it stimulated ACh release. Conversely, it did not augment or reduce the activity of the major ChAT fraction, the pH 7.4 salt soluble fraction, at any of those concentrations which stimulated ACh release. Those treatments which decreased the amount of ACh released in response to veratridine depolarization such as tetrodotoxin, Ca^{2+} omission, and the ACh transport blocking drug 2-(4-phenylpiperidino) cyclohexanol (AH 5183) - 75 nM, also decreased the veratridine induced activation of the detergent soluble ChAT fraction. In contrast, L-AH 5183 (75 nM) did not block the veratridine induced activation of the water soluble ChAT fraction. When hippocampal minces were loaded with [^{14}C]choline and then depolarized with veratridine in the presence of hemicholinium, veratridine augmented the synthesis and release of [^{14}C]ACh. Both of these increases were abolished by L-AH 5183 (75 nM). When subcellular fractions containing occluded ACh were prepared by sucrose density gradient centrifugation, ChAT, but not lactate dehydrogenase (EC 1.1.1.27; LDH), could be solubilized from organelles in the 0.4 M sucrose fraction upon addition of detergents. Veratridine depolarization of hippocampal minces doubled the activity of the detergent soluble ChAT fraction in the 0.4 M sucrose layer and this increase was blocked by L-AH 5183 (75 nM). These results suggest that the evoked release of ACh from rat hippocampal nerve terminals may be linked with an activation of a detergent soluble ChAT fraction associated with synaptic vesicles (Supported in part by NINCDS 1 RO1 NS2-1289-03, 2 RO1 NS2-1289-04).

326.11 REVERSAL BY ANESTHETICS OF CARDIORESPIRATORY EFFECTS OF ACETYLCHOLINE ACCUMULATION. A.S. Foutz*, M.P. Morin-Surun*, J. Champagnat* and M. Denavit-Saubié. Laboratoire de Physiologie Nerveuse, C.N.R.S. 91190 Gif-sur-Yvette, France.

We have shown that the proportion of medullary respiratory neurons inhibited by iontophoretic application of ACh was much higher in pentobarbital anesthetized cats than in decerebrate cats (Morin-Surun et al., Naunyn Schmiedeb. Arch. Pharmacol. 1984, 325 : 205). We have now extended these results to the functional level by using different types of preparations : (1) Local intracerebroventricular administration of the anticholinesterase paraoxon (3 mg) in the 4th ventricle of chronic cats stimulated respiration (frequency and minute volume) in the conscious state but depressed respiration in the same animals anesthetized with pentobarbital. Decerebrated cats after recovery from halothane anesthesia responded to paraoxon by an increased ventilation. (2) In cats pretreated with methylatropine (0,2 mg/kg), paralyzed and artificially ventilated, paraoxon (3 mg/kg i.v.) induced an immediate and long lasting arrest of phrenic nerve respiratory discharges during anesthesia with pentobarbital, alpha-chloralose or halothane but did not suppress central respiratory activity in cats decerebrated or ventilated with nitrous oxide/oxygen. (3) Blood pressure was increased by paraoxon (i.v.) in cats which were either awake (chronic), decerebrated or ventilated with nitrous oxide/oxygen, but it was decreased in all anesthetized animals. It is concluded that anesthetics may reverse the action of ACh at both cellular and functional levels and thus may considerably alter the normal functioning of cardiorespiratory cholinergic mechanisms.

326.12 MEMBRANE PEROXIDATION, ALUMINUM AND CHOLINERGIC FUNCTION. J. Judkins*, M.K. Raizada, and E.M. Meyer. Depts. of Pharmacology and Physiology, Univ. of Florida School of Medicine, Gainesville, FL.

Aging reduces the calcium-dependent release of brain acetylcholine (ACh) apparently by reducing the potency of calcium ions for triggering release. Since membrane lipid peroxides may accumulate with age, we studied the effects of artificially induced lipid peroxidation on a variety of cholinergic processes. Adding ferrous (0-200 uM) and ascorbate (0-10 uM) ions together (inducing the Fenton reaction) in creasing concentrations to cerebral cortical synaptosomes induced a biphasic degree of lipid peroxidation as measured by malonaldehyde production. A similar biphasic effect was observed on ACh release. Low levels of peroxidation induced a reduction in calcium-dependent release, while higher levels increased both ACh and choline efflux via a non-physiological process. Higher levels of peroxidation were also associated with a reduction in high affinity choline uptake and ACh synthesis, without affecting low affinity uptake.

Since the permeability to cations such as choline seemed to be increased with membrane peroxidation, we attempted to increase the accumulation of aluminum ions by primary rat brain neuronal cultures with the Fenton reaction. Combined, the Fenton reaction plus aluminum (at pH 5.5) blocked ACh synthesis after an overnight incubation. Individually, each treatment reduced synthesis by about 20%. A surprising result in this preliminary study was that protein levels increased by 140% after the overnight treatment compared to controls, suggesting a large increase in protein synthesis induced by the combined treatment. Together, these results suggest that impairment of membrane function with the Fenton reaction may be a model for studying age-related changes in transmitter release as well as aluminum-sensitivity.

326.13 EFFECTS OF HALOTHANE ON CENTRAL CHOLINERGIC SYNAPSES. C.W. Bazil and K.P. Minneman*, Department of Pharmacology, Emory Univ. School of Medicine, Atlanta, GA 30322

We reproduced anesthetic concentrations of halothane in rat brain tissue in vitro and examined aspects of cholinergic functioning. Halothane was introduced into Krebs Ringer bicarbonate buffer in 95% O_2/5% CO_2, and an equilibrating atmosphere maintained throughout. We found previously (Bazil et al, J. Neurochem. in press) that equilibration with approximately 1.0% halothane containing buffer in vitro results in brain tissue concentrations similar to those associated with complete anesthesia in vivo.

Previous reports showed that high concentrations of halothane lock muscarinic receptors into a high affinity state for agonist binding (Aronstam et al, Biochem. Pharm., 35:667, 1986). We prepared membranes from rat midbrain, and found no effect on the displacement of ^{3}H-N-methylscopolamine by carbachol (K_i or Hill coefficient) or on the shift in displacement curves induced by Gpp(NH)p in the presence of 1.25% halothane. Carbachol-induced increases in inositol phosphate accumulation were examined in slices of rat cerebral cortex. There was no difference in maximal stimulation in the presence of 1.25% halothane. These results suggest that anesthetic concentrations of halothane do not alter muscarinic receptor binding affinity or coupling to inositol phospholipid metabolism.

High concentrations of halothane have also been shown to depress ^{3}H-acetylcholine release from synaptosomes (Johnson and Hartzell, J. Neurochem. 44:1838, 1985). Basal and potassium-evoked release were examined using superfused slices of rat cerebral cortex preloaded with ^{3}H-choline. The slices were perfused with Krebs-Ringer bicarbonate buffer for 1 hr, and the perfusate discarded. The perfusate was then collected in 4 minute fractions. Control pulses of high K^+ buffer (52 mM) for 4 min were given to all slices. Various concentrations of halothane were then introduced into the perfusing buffer of some chambers and further pulses of high K^+ buffer given to all chambers. Depolarization-evoked release of acetylcholine was markedly reduced by equilibration with as little as 0.75% halothane, which gives tissue concentrations comparable to in vivo concentrations in anesthetized animals.

These results suggest that clinically relevant concentrations of volatile anesthetics do not indiscriminantly affect membrane-associated proteins such as receptors and transducer proteins, but may be more specific in their actions. However, acetylcholine release is reduced substantially at concentrations of halothane found in the anesthetized brain. The relevance of this phenomenon to the production of anesthesia remains to be determined.

327.1 ^{3}H-CHOLINE MUSTARD AZIRIDINIUM ION UPTAKE AND BINDING IN RAT BRAIN SYNAPTOSOMES. R.Jane Rylett and E.H. Colhoun . Departments of Physiology and Pharmacology, Univ. Western Ontario, London, Canada.

Choline used as substrate for the synthesis of acetylcholine (ACh) must be transported into the nerve ending by a specialized transmembrane carrier localized almost exclusively in cholinergic presynaptic terminals. We determined that choline mustard (ChM Az) and ethylcholine mustard aziridinium ion (ECM Az) are irreversible ligands specific for the high-affinity choline carrier in rat brain synaptosomes (Rylett and Colhoun, 1980, 1984) and may be useful tools as inhibitors of choline transport in in vitro studies and as ligands for labelling and isolating the carrier protein (Rylett and Whittaker, 1987). ECM Az has also been used as a potential neurotoxin to produce deficits in central cholinergic neuron function (Hanin and Fisher, 1986). The interaction of ChM Az or ECM Az with the choline carrier in rat brain synaptosomes has not been characterized fully, nor have the mechanism(s) of action of these compounds as putative in vivo cholinotoxins been elucidated.

In the present study, the uptake and binding of ^{3}H-ChM Az was investigated in purified synaptosomes prepared from hippocampus and striatum of rat brain. ^{3}H-ChM Az bound to synaptosomal membranes was separated from that transported into synaptosomes by lysing the nerve endings and collecting the TCA-precipitated membranes onto filters. ^{3}H-ChM Az was transported into the nerve endings by a HC-sensitive mechanism, but at a rate much slower than ^{3}H-choline; uptake of ^{3}H-ChM Az was only 18.4% compared to uptake of ^{3}H-choline after 5 min and fell to only 10.6% of ^{3}H-choline uptake by 30 min. Kinetic analysis of ^{3}H-ChM Az (0.2-8 µM) transport at 5 min (linear uptake) revealed a K_m of 2.14 ± 0.98 µM and V_{max} of 2.54 ± 0.75 pmol/mg/min compared to a K_m of 1.44 ±0.15 µM and V_{max} of 13.0 ± 2.7 pmol/mg/min for ^{3}H-choline. Following 30 min incubation with 0.2 - 1 µM ^{3}H-ChM Az, approximately 50% of the ^{3}H-label associated with the nerve endings was membrane-bound (about half of which was bound specifically demonstrated by HC-3), 30% was taken up by a HC-sensitive carrier and 15-20% was taken into the synaptosomes by some other mechanism; the latter amount could represent accumulation of ^{3}H-labelled breakdown products of the mustard. In summary, ^{3}H-ChM Az could be accumulated into cholinergic nerve endings, but this uptake was only a fraction of ^{3}H-choline transport measured under the same conditions.

327.2 SELECTIVE REDUCTION IN HIGH AFFINITY CHOLINE UPTAKE AFTER SYSTEMIC ADMINISTRATION OF A-4, A CENTRALLY-ACTING HEMICHOLINIUM-3 ANALOG. C.E. Tedford*, E. Wulfert*, J.G. Cannon*, J.P. Long* and I. Hanin. Dept. of Pharmacology, Loyola Univ., Stritch School of Medicine, Maywood, IL 60153 and UCB s.a. Pharmaceutical Sector, Brussels, Belgium.

A-4, a tertiary amine 4-methyl piperidine analog of hemicholinium-3, has been shown to produce a selective reduction in cholinergic function (Tedford et al., 1986 and 1987). Diminished cholinergic function was indicated by inhibition of neuromuscular transmission, reduction in ACh synthesis in rat striatal slices, and decreased ACh content in various rat brain regions after i.p. administration of A-4. It has been postulated that the effects of A-4 are due to inhibition of high affinity choline uptake (HAChT). In the present study the effect of systemic administration of A-4 (40 mg/kg), on several central cholinergic indices was investigated. These include HAChT, low affinity choline uptake (LAChT), choline acetyltransferase (ChAT) activity, acetylcholinesterase (AChE) activity and QNB binding.

Male Sprague-Dawley rats (200-300 grams) were given 40 mg/kg of A-4 or saline i.p. and killed 60 minutes later by decapitation. Sodium-dependent high affinity and sodium-independent low affinity choline uptake, as well as QNB binding were assessed in synaptosomes prepared from the hippocampus, cerebral cortex and striatum. ChAT and AChE activities were determined in brain homogenates from the hippocampus, cerebral cortex and striatum.

A selective reduction in HAChT was seen 60 minutes after administration of A-4. Hippocampal HAChT was reduced by 45% (from 6.7 ± 0.3 to 3.7 ± 0.3 pmoles/mg protein/8 min). Similar reductions were seen in the striatum and the cortex. Striatal HAChT was reduced by 54% (from 17.6 ± 2.6 to 8.1 ± 0.9 pmoles/mg protein/8 min) and cortical HAChT was reduced by 62% (from 4.0 ± 0.2 to 1.5 ± 0.1 pmoles/mg protein/8 min). A-4 did not affect LAChT in any of the brain regions examined, moreover, no differences were seen in ChAT activity, AChE activity, or total QNB binding in the control versus A-4 treated rats in any of the brain regions examined.

In summary, the results indicate a selective reduction in HAChT after systemic administration of A-4, which is consistent with the decrease in central ACh content seen 60 minutes after i.p. administration of 40 mg/kg of A-4 (Tedford et al., 1987). Therefore, it appears that reduced central cholinergic function can be produced after acute i.p. administration of A-4 and, furthermore, reduction in central cholinergic function is produced by selective impairment in HAChT.

Tedford et al.,1986, Eur. J. Pharmacol. 128, 231-239.

327.3 DEMONSTRATION OF A REVERSIBLE AND REPEATABLE IN VITRO ACTIVATION OF THE HIGH AFFINITY CHOLINE UPTAKE SYSTEM IN BRAIN. I. Vincent and J.R. Simon. Depts. of Biochemistry and Psychiatry, Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46223.

The in vitro approach most frequently used to activate high-affinity choline uptake (HACU) involves a pre-exposure to elevated potassium ion (K^+) concentrations. This pretreatment results in a subsequent increase in HACU when measured under conditions of normal potassium. In previous studies we examined the effects of elevated K^+ on HACU using rat brain hippocampal and striatal synaptosomes, and observed an approximate two-fold increase in HACU in the hippocampus, while the uptake in the striatum exhibited an increase of 20%. It was also observed that these effects were dependent on the concentration of potassium in the preincubation buffer, and that maximal activation in both regions was achieved at the same concentration, i.e., 48 mM K^+. In the present study, the effect of preincubation time on the K^+-induced activation of HACU has been investigated. Our results indicate that the "activation" of HACU appears to be due to a time-dependent decrease in the control uptake, and that the presence of high concentrations of potassium in the preincubation medium prevent such a decrease. This was found to be the case for both hippocampal and striatal preparations. Based on these findings, a new protocol has been adopted, which involves "equilibrating" synaptosomes in normal Krebs buffer for 30 min at 30°C prior to any additional preincubations. Using this approach, we have re-examined the time course for K^+-activation and its dependence on the K^+ concentration using equilibrated preparations obtained from hippocampus and striatum. Maximal activation in both regions was observed following a 10 min exposure and occurred at a concentration of 48 mM K^+. In addition, we have investigated the reversibility and the repeatability of the activation of HACU. To reverse the stimulated uptake, activated synaptosomes were reincubated in normal Krebs for various times, thereby establishing a deactivation time course. These studies indicated that complete reversal of activation in both regions could be achieved by reincubation for 20 min. Thus, one complete cycle of activation and deactivation could be accomplished by a 10 min exposure to elevated K^+ followed by a 20 min reincubation in normal Krebs. When synaptosomal preparations were subjected to 3 such cycles, the activation in HACU was found to be repeatable as well as reproducible in magnitude. The plasticity of HACU demonstrated in the present study, utilizing in vitro depolarization, resembles closely the well documented alterations in uptake that have been observed following various in vivo treatments. Furthermore, the results validate the use of this in vitro paradigm in studying mechanisms involved in the modulation of HACU.

327.4 HIGH AFFINITY CHOLINE UPTAKE IN SYNAPTOSOMAL FRACTIONS FOLLOWING POTASSIUM-DEPOLARIZATION OF HIPPOCAMPAL SLICES. J.R. Simon and S.K. DiMicco,* Depts. of Psychiatry and Biochemistry, Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46223.

Alterations in cholinergic neuronal activity in vivo have been shown to result in parallel changes in high affinity choline uptake (HACU) measured in vitro. Since the mechanisms underlying the modulation of the HACU system are not known, several attempts have been made to reproduce the in vivo-induced activation by utilizing in vitro models. Most of these models employ a pre-incubation of synaptosomes under various test conditions followed by uptake measured in normal buffer. In the present study, synaptosomal HACU has been measured following preincubation of hippocampal slices, thereby providing a system in which the time delay from treatment to uptake assay more closely approximates that which exists following in vivo treatments. Initial time course experiments indicated that a significant decrease in synaptosomal HACU occurred over the first 30 min of incubation of the slice. Similar time course experiments conducted in the presence of elevated concentrations of K^+ failed to show such a time-dependent decrease in uptake. Thus, it appears that elevated concentrations of K^+ prevent the decrease in HACU rather than actually stimulating transport. Based on these observations, we have taken the approach of allowing the hippocampal slices to equilibrate for 30 min at 30°C prior to any further perturbations. Using this protocol, HACU was found to be activated by elevated concentrations of K^+ in a time- and concentration-dependent manner. Maximal activation was achieved following a 30 min exposure to 48mM K^+. The activation elicited by 24mM K^+ and 36mM K^+ was not calcium-dependent, whereas that produced by 48mM K^+ and 62mM K^+ was attenuated but not abolished in the absence of external calcium. Similar studies involving the effects of magnesium indicated that the activation produced by all elevated concentrations of K^+ (24mM-62mM) was less in the presence of 12mM magnesium. Nonetheless, the uptake under these conditions still remained significantly activated relative to control. These results suggest that the inhibitions of K^+-stimulated HACU caused by calcium omission and by elevated magnesium are qualitatively different and that these alterations may affect different components of the cholinergic nerve terminal. The results suggest further that the activation in uptake produced by K^+ concentrations above 36mM may involve mechanisms consistent with transmitter release whereas the HACU stimulated by K^+ concentrations below 36mM appear to involve a separate mechanism.

327.5 CHOLINE CSF LEVELS ARE INCREASED IN ALZHEIMER PATIENTS. C. Higgins*, R. Elble and E. Giacobini (SPON: H.B. Clark). Depts. Medicine and Pharmacology, Southern Illinois University School of Medicine, P.O. Box 3926, Springfield, IL 62708 USA

Several authors (see for review Greenwald, B.S. et al., Biol. Psychiatry, 20:367-374, 1985; Sherman, K.S. and Friedman, E., Advances in Behavioral Biology, 30:291-301, 1986) have reported that plasma and red blood cell (RBC) choline levels do not differ between Alzheimer patients and age-matched controls. We measured lumbar cerebrospinal fluid (CSF) choline levels with a radiometric method in 20 controls (mean + SD = 1.91 + 0.60 nmole/ml), 19 mildly demented patients (2.58 + 0.83 nmole/ml) and 24 severely demented patients (2.81 + 1.02 nmole/ml). The CSF choline values of our Alzheimer patients were significantly different from controls ($p < 0.005$). Our patients have undergone serial lumbar punctures over time intervals as long as 30 months, but thus far, we have been able to demonstrate only a statistically insignificant trend for increasing choline values with time. Given the lack of change in plasma and RBC levels, the changes in CSF choline may reflect changes in brain phospholipid metabolism which could relate to the cholinergic deficit of Alzheimer disease. Furthermore, the mechanism of this pathologic rise in CSF choline may have important bearing on the clinical ineffectiveness of choline precursor therapy in Alzheimer disease. Of particular interest is the significant elevation of CSF choline in young adults with Down syndrome (Schapiro, M.B. et al., Neurobiology of Aging, In Press, 1987) and the lack of change in patients with Parkinson disease and Huntington disease (Welch, M.J. et al., J. Neurol. Neurosurg. Psych., 39:367-374, 1976; Aquilonius, S.M. et al., J. Neurol. Neurosurg. Psych., 35:720-725, 1972) and other CNS disorders (Flentge, F. et al., J. Neurol. Neurosurg. Psych., 47:207-209, 1984; Haber, B. and Grossman, R.G., Neurobiology of Cerebrospinal Fluid, 26:345-350, 1983). The rise in CSF choline may, therefore, be a useful marker of the cholinergic deficit in Alzheimer patients. (Supported by NIA grant #AG05416-01A1).

327.6 BRAIN CHOLINERGIC PARAMETERS DIFFERENTIATE INBRED STRAINS OF MICE J.I. Nurnberger, Jr., J.R. Simon, J.N. Hingtgen. Institute of Psychiatric Research and the Departments of Psychiatry and Biochemistry, Indiana University School of Medicine, Indianapolis, IN 46223.

Bailey (1971) introduced a method by which a number of genetically distinct but very similar strains may be studied and compared. His recombinant inbred strains are the result of continued brother-sister matings among the descendants of the F2 generation following a cross between two initial inbred strains. At least seven strains resulting from an initial cross between BALB/cBy and C57BL/6BJ have been described. The continued brother-sister matings result in animals that are essentially homozygous at all loci. The resultant strains may then be backcrossed with one of the parental strains for genetic analyses. Genetic markers with known chromosomal locations have been analyzed in the seven strains, so that each marker may be said to display a "strain-distribution pattern." A pharmacologic response or other biologic characteristic displaying the same "strain distribution pattern" as the marker may be presumed to be linked to that marker.

In the present study, we have investigated the high affinity choline uptake (HACU) and choline acetyltransferase activity (ChAT) in three brain regions of the C57BL/6J and DBA/6J inbred strains of mice. These are ancestor strains for a set of recombinant inbred strains produced by Jackson Laboratories. HACU was determined in crude synaptosomal preparations of the cerebral cortex, striatum and hippocampus using 0.5 uM choline as the substrate. ChAT activity was assayed from the same samples by a radiometric assay employing 0.1 mM acetylcoenzyme A and 10 mM choline. No significant difference between strains were found for either cholinergic parameter in cerebral cortical tissue. On the other hand, HACU was significantly greater in striatal (34%) and hippocampal (17%) preparations from C57BL/6J than from DBA/6J mice. The activity of ChAT was found to be somewhat greater (23%) in striatal synaptosomes obtained from the DBA/6J strain than that found in similar preparations from C57BL/6J mice. No statistically significant difference was found for ChAT activity in hippocampal preparations.

Behavioral studies are in progress to assess possible relationships between neurochemical parameters and ambulatory/rearing responses in an open-field maze. Promising differences will be followed into the recombinant lines.

This work is partially funded by Indiana Department of Mental Health grant #47-869-36.

327.7 ARACHIDONIC ACID INHIBITS CHOLINE UPTAKE AND DEPLETES ACETYLCHOLINE CONTENT IN CEREBRAL CORTICAL SYNAPTOSOMES. P. Boksa, S. Mykita* and B. Collier. Douglas Hosp. Res. Ctr., Depts. Psychiatry and Pharmacology, McGill Univ., Montreal, Canada, H4H 1R3

During cerebral ischemia, hypoxia and some other conditions, there is a rapid liberation of free fatty acids, particularly arachidonic acid, in brain. The cholinergic system is known to be particularly sensitive to impairment by even mild hypoxia. In the present study we have examined the effects of arachidonic acid on choline uptake and acetylcholine (ACh) content and release in rat cerebral cortical synaptosomes. Arachidonic acid (10-150 μM) produced a dose-dependent inhibition of high affinity [^{3}H]choline uptake. Low affinity [^{3}H]choline uptake was inhibited to the same degree. Free fatty acids inhibited high affinity [^{3}H]choline uptake with an order of potency: arachidonic>palmitoleic>oleic>lauric; stearic acid had no effect. Arachidonic acid inhibition of high affinity [^{3}H]choline uptake was reversed by the fatty acid binding protein, bovine serum albumin. To test the possibility that arachidonic acid may have produced a generalized disruption of synaptosomes, the integrity of the synaptosomes was monitored by measurement of a cytosolic marker, choline acetyltransferase. Arachidonic acid had no effect on the recovery of choline acetyltransferase with the synaptosomes. Medium choline was increased by arachidonic acid, however the resulting dilution of radiolabelled choline could not account for the observed inhibition of [^{3}H]choline uptake.

In synaptosomes incubated with [^{3}H]choline, arachidonic acid (150 μM) produced an 87% depletion of [^{3}H]ACh content. This decrease in [^{3}H]ACh content was equal in magnitude to the inhibition of high affinity [^{3}H]choline uptake produced by the same concentration of the fatty acid. A depolarization-induced increase in [^{3}H]ACh content was also completely inhibited by 150 μM arachidonic acid. Arachidonic acid (150 μM) depleted the endogenous ACh content of the synaptosomes by 71%. In the presence of eserine, 150 μM arachidonic acid had no effect on release of endogenous ACh; however depletion of ACh content by arachidonic acid was minimal in the presence of eserine, indicating that eserine may have interfered with the actions of arachidonic acid. The results suggest that arachidonic acid may deplete ACh content by inhibiting high affinity choline uptake and subsequent ACh synthesis. This raises the possibility that arachidonic acid may play a role in the impairment of cholinergic transmission seen in cerebral ischemia. Supported by the Medical Research Council of Canada.

327.8 DIETARY REPLACEMENT OF CHOLINE BY N-AMINODEANOL IN RATS, MEASURED BY HPLC. B. Knusel*, S.D. Lauretz*, R.A. Booth* and D.J. Jenden (SPON: F.J. Ehlert). Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

N-Amino-N,N-Dimethylaminoethanol (N-Aminodeanol, NADe) is a precursor of a cholinergic false transmitter (Newton & Jenden, TIPS 7:316-320 (1986)). In the present study rats at age 29 days were put on a controlled choline free diet, to which either choline (Ch) or NADe was added at a concentration of 5 gm kg^{-1}. Free and lipid-bound choline and NADe were measured in blood at various times during the first 87 days and Ch, NADe, and their acetate esters were determined in tissues after 120 days of diet. The compounds were separated and quantitated by HPLC. In the blood of controls lipid-bound Ch was constant from days 0 to 87 with a mean of 2.1 mM in plasma and 3.0 mM in cells. Free Ch, in plasma and cells respectively, increased from 20.1 and 25.6 μM at weaning to 38.5 and 42.2 μM on day 10 and then decreased steadily to 22.3 and 19.8 μM on day 87. In NADe-treated animals free and bound Ch decreased to a plateau, which was reached after 10 to 38 days. The final levels in plasma and cells were 300 and 900 μM (bound) and 5 and 4 μM (free). The totals (NADe + Ch) of free and bound compounds in cells and free compounds in plasma followed the pattern of free and bound Ch in controls, being mostly equal to or higher than the respective levels of Ch in controls. The total of bound compounds in plasma after day 10 was only 33% of control. After 120 days the animals were sacrificed. Bound Ch in the NADe group was reduced in cortex, myenteric plexus and liver to 22.5 - 32.4% of control. Free Ch was reduced in liver to 73.3%, in cortex, hippocampus, striatum, heart, diaphragm and myenteric plexus to 17.7 - 30.5% of control. ACh in the same tissues was reduced to 34.9 - 49.0% of control. The total of bound compounds in NADe-treated animals was in all tissues equal, the total of free NADe and Ch was higher and the total of acetyl esters was lower than in controls. As these results show, NADe replaces Ch in all known metabolic pathways, but the degree of replacement, as expressed by the ratio NADe:Ch decreases from the precursor in blood to the transmitter in tissues. Lipid-bound NADe replaces lipid-bound Ch as an element of cell membranes in a 1:1 manner, whereas the kinetics of replacement of the free compounds and of lipid-bound Ch in plasma seem more complex.

Supported by USPHS Grant MH-17691.

328.1 IN VIVO DOPAMINE RECEPTOR PROFILE OF NEUROLEPTICS

Peter H. Andersen, Department of Pharmacology, NOVO INDUSTRI A/S, Pharmaceuticals R&D, Novo Allé DK-2880 Bagsvaerd, Denmark.

Using binding in vivo to mouse brain tissue of the D2-selective benzamide ^{3}H-Raclopride and the D1-selective benzazepine ^{3}H-SCH 23390, the dopamine receptor profile of a variety of neuroleptics and dopaminergic agonists were investigated. Compounds exhibiting receptor selectivity in vitro retained this selectivity in vivo, thus the butyrophenones (e.g. spiroperidol and haloperidol), benzamides (e.g. sulpiride, clebopride and raclopride), (-)-NPA and LY 171555 were D2-selective whereas the benzazepines (e.g. SCH 23390, SKF 38393 and SKF 75670) were D1-selective.

Most compounds with a dual dopamine D1-D2 receptor profile in vitro retained this profile in vivo i.e. the thioxantenes (e.g. cis-flupentixol), the phenothiazines (e.g. chlorpromazine), the dibenzepines (e.g. clozapine, tilozepine and loxapine) and butaclamol. However, some compounds changed receptor profile in vivo as compared to in vitro. Thus, fluperlapine and fluphenazine, which in vitro were non-selective (D1:D2; 1:3 and 5:1, respectively) and pergolide which in vitro were D2-selective (D1:D2; 50:1) exhibited in vivo D1-selectivity, D2-selectivity and non-selectivity (D1:D2; 1:15, 54:1 and 1.9:1), respectively.

In conclusion, these data indicate that the dopamine D1 receptor is an important target for several different types of neuroleptics, and it is tempting to speculate that blockade of brain dopamine D1 receptors convey the antipsychotic efficacy of some of these compounds.

The generous gift of ^{3}H-Raclopride from Dr. H. Hall, Astra Alab, Sweden, is appreciated.

328.2 IN VIVO LABELING OF BRAIN D-1 AND D-2 DOPAMINE RECEPTORS. C.A. Leslie[1]* and J.P. Bennett, Jr.[1,2,3]. Departments of (1) Behavioral Medicine and Psychiatry, (2) Neurology, and (3) Pharmacology, University of Virginia Medical School, Charlottesville, VA 22908.

Mammalian brain dopamine (DA) receptors appear to exist in two major classes; D-1 DA receptors are positively linked to stimulation of adenylate cyclase activity, and D-2 DA receptors are not linked or negatively linked to adenylate cyclase. Radiolabeled spiperone and spiperone derivatives have been extensively utilized to examine D-2 DA receptors in vitro and in vivo; radiolabeled SCH 23390, a benzazepine neuroleptic, is currently the ligand of choice for examining D-1 DA receptors.

We have characterized in detail the kinetic, saturation, and pharmacological properties of in vivo binding to rat brain of ^{3}H-spiperone and ^{3}H-SCH 23390 and compared these in vitro properties to these occurring in vitro in striatal homogenates.

250-300 gram male rats received tail vein injections of 25-50 µCi ^{3}H-spiperone (s.a. 17-23 Ci/mmol) or 10 µCi ^{3}H-SCH 23390 (s.a. 85-90 Ci/mmol), with or without unlabeled D-1 or D-2 drugs, and were decapitated at varying times thereafter. Brains were removed, chilled on ice, dissected in regions, and homogenized in 50 volumes cold 0.05 M Tris buffer. 0.5 ml alqiuots of homogenate were rapidly vacuum filtered through GFB filters, washed 3X with Tris buffer, and assayed with liquid scintillation spectrometry.

Our data indicate that ^{3}H-SPIP and ^{3}H-SCH bind in vivo to striatal sites having pharmacological characteristics similar to D-2 and D-1 sites, respectively, labeled in vitro. The in vivo kinetic rate constants for association and dissociation for both ligands are reduced compared to in vitro. The estimated binding dissociation constants, measured in saturation experiments, are increased 120-200-fold (i.e., lower affinity) compared to in vitro.

Our data indicate that striatal D-1 and D-2 DA receptors can be labeled in vivo with ^{3}H-SCH and ^{3}H-SPIP, respectively, but that homogenization of tissue induces alterations in the kinetic properties of these ligands.

328.3 **^{3}H-SCH-23390 AND ^{125}I-SCH-23982 LABEL BOTH SEROTONIN AND DOPAMINE RECEPTORS IN THE CHOROID PLEXUS.** K. J. Nicklaus*, P. McGonigle, D. Lau* and P. B. Molinoff. Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104-6084.

^{3}H-SCH-23390 and, more recently, ^{125}I-SCH-23982, have been used to label the D-1 subtype of dopamine receptors. These ligands have been reported to show high selectivity for the D-1 receptor. Quantitative autoradiographic studies with ^{3}H-SCH-23390 have revealed high levels of saturable binding in many brain regions including the caudate-putamen, nucleus accumbens, substantia nigra, and choroid plexus. The binding of ^{3}H-SCH-23390 was further characterized in homogenates of dog choroid plexus. Inhibition of the binding of ^{3}H-SCH-23390 (5 nM) by serotonin resulted in markedly biphasic curves that were best fit by a two-site model. The high-affinity site had a nanomolar affinity for serotonin, consistent with the properties of the 5-HT$_{1c}$ site previously found to be present in high density in choroid plexus. The low-affinity site had a micromolar affinity for serotonin. Scatchard analysis of the binding of ^{3}H-SCH-23390 (0.3-9 nM) resulted in a curvilinear plot when 5 µM (+)-butaclamol was used to define nonspecific binding. Nonlinear regression analysis of untransformed saturation data suggested the existence of two distinct classes of binding sites. The high-affinity site (K_d = 0.5 nM) had the properties expected of the D-1 receptor. The low-affinity site (K_d = 9 nM) was present at an equal or greater density. Quantitative autoradiography of ^{3}H-SCH-23390 and ^{125}I-SCH-23982 binding was also performed. Serial sections of rat brain (20 µ) were labeled with either 1 nM ^{3}H-SCH-23390 or ^{125}I-SCH-23982. Approximately 50% of total binding of either ligand was displaced by 100 nM serotonin in the choroid plexus, while over 95% of total binding was displaced by 1 µM (+)-butaclamol. These findings demonstrate that dog and rat choroid plexus contain both dopamine and serotonin receptors, and both of these classes of receptors are labeled by ^{3}H-SCH-23390 and ^{125}I-SCH-23982. These ligands may label 5-HT$_{1c}$ receptors as well as D-1 receptors in various brain regions. (Supported by USPHS Grant GM 34781 and an NSF predoctoral fellowship to K.J.N.)

328.4 **DOPAMINE D_2 RECEPTORS: EFFECTS OF IONS ON [^{3}H]NEUROLEPTIC BINDING.** K.R. Jarvie, H.B. Niznik and P. Seeman. Dept. Pharmacology, University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

Dopamine D_2 receptors are selectively labeled in a sodium-sensitive manner by the benzamide ligand [^{3}H]YM-09151-2. In the presence of 120 mM NaCl, [^{3}H]YM-09151-2 had a dissociation constant of 55 pM and a maximal binding capacity of 34 pmol/g of tissue (canine striatum). In the absence of NaCl, the dissociation constant was 440 pM with no change in the binding capacity. The binding of [^{3}H]YM-09151-2 (52 pM) was increased by 700% with 150 mM Na^+, 440% with 500 mM Li^+, and 290% with 500 mM K^+. The ion concentrations producing half-maximal increases in binding were 4 mM Na^+, 8.5 mM Li^+, and 115 mM K^+. The ionic strength control N-methyl-D-glucamine (NMG) (0.5-500 mM) did not increase [^{3}H]YM-09151-2 binding. [^{3}H]Spiperone binding was much less affected by monovalent cations. Analysis of saturable binding showed that these changes were due to changes in binding affinity, independent of changes in binding capacity.

The sulfhydryl alkylating agent N-ethylmaleimide inactivates [^{3}H]YM-09151-2 binding. The sodium ion at a concentration of 120 mM can protect approximately 40% of the susceptible sites while lithium and potassium ions (120 mM) do not.

The anion exchange blocker 4,4' diisothiocyano-2,2'-stilbene disulfonic acid (DIDS) has been shown to be capable of blocking the effect of Na^+ on the binding of agonists to alpha$_2$-adrenoceptors. Pretreatment with DIDS had no effect on the ability of Na^+ to alter [^{3}H]YM-09151-2 binding (120 mM NaCl: DIDS pretreated, K_D = 69 pM; Control, K_D = 53 pM).

Consistent with their actions on other benzamide ligands, monovalent cations are capable of affecting the interactions of the potent benzamide [^{3}H]YM-09151-2 with the dopamine D_2 receptor. The insensitivity to NMG and extent of stimulation by low millimolar Na^+ concentrations indicate that this effect is not solely due to ion strength.

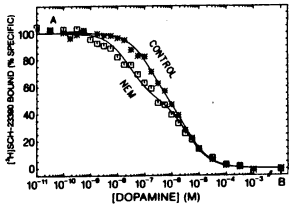
328.5 **DOPAMINE D_1 RECEPTORS: EFFECTS OF THIOL MODIFYING REAGENTS**
Natalie H. BZOWEJ*, Hyman B. NIZNIK, Dimitri E. GRIGORIADIS and Philip SEEMAN. Dept. of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

In this study we detail the effects of N-ethylmaleimide (NEM), a sulfhydryl group alkylating agent and of dithiothreitol (DTT), a disulfide bond reducing agent, on [^{3}H]SCHERING 23390 binding to canine striatal D_1 receptors. Pretreatment of striatal membrane preparations with increasing concentrations of NEM (100 nM to 100 mM) and of DTT (100 nM to 100 mM) for 20 min at 37°C reduced [^{3}H]SCH 23390 binding by about 90% with IC_{50}'s of 40 µM and 3 mM, respectively. This apparent reduction in binding was shown to be a result of a decrease in the number of binding sites with only a 3-fold decrease in the affinity of the remaining sites, as determined by [^{3}H]SCH 23390 saturation curves. Pretreatment of membranes with increasing concentrations of various dopaminergic antagonists (100 pM to 10 µM) and agonists (1 pM to 10 µM) prior to the incubation with 200 µM NEM or 10 mM DTT afforded protection against the reduction in binding by these agents.

NEM has been found to mimic the effect of guanine nucleotides on agonist binding of the D_2 dopamine receptor, with a loss of the agonist high-affinity form of the receptor. In marked contrast, the high-affinity form of the D_1 receptor is not abolished by pretreatment with 200 µM NEM. Moreover, competition of dopamine for [^{3}H]SCH 23390 binding resulted in an apparent 5-fold leftward shift in the affinity of dopamine for the high-affinity state (figure below). Pretreatment with 10 mM DTT did not significantly alter either the affinity or the proportion of high- and low-affinity states of the D_1 dopamine receptor as detected by dopamine/[^{3}H]SCH 23390 competition. Furthermore, pretreatment of membranes with either NEM or DTT had no effect on guanine nucleotide regulation of the high-affinity state. Further effects of NEM and DTT on the regulation of the D_1 receptor will be discussed.



This work was supported by The Medical Research Council of Canada (MRC) and the Ontario Mental Health Foundation (OMHF). N.H.B. and D.E.G. are supported by OMHF Student- ships. H.B.N. is a recipient of an MRC post-doctoral Fellowship.

328.6 ALTERATIONS IN MUSCARINIC M-2 AND DOPAMINE D-2 RECEPTORS IN THE RAT BRAIN FOLLOWING INTRASTRIATAL INJECTION OF THE CHOLINOTOXIN, AF64A: AN AUTORADIOGRAPHIC STUDY.
V.L. Dawson, J.K. Wamsley, F.M. Filloux and T.M. Dawson. Dept. Psych., Pharm., Univ. Utah Sch. Med., SLC, UT 84132.

The aziridinium ion of ethylcholine (AF64A) has been shown to produce a selective decrement in Na^+-dependent high affinity choline transport sites (HAChT), choline acetyltransferase activity and acetylcholine levels without affecting other neurotransmitter systems. These results suggest that AF64A is a neurotoxin selective for the cholinergic nerve. Although, nonselective cell destruction can be observed at the site of injection, adjacent to this site, the toxin appears to be selective for cholinergic cells. By means of in vitro quantitative autoradiography, the effect of stereotaxic intrastriatal lesions with AF64A on muscarinic receptors, labeled with [^{3}H]-Quinuclidinyl benzilate (QNB), and [^{3}H]-Pirenzepine (PZ); Na^+-dependent HAChT, labeled with [^{3}H]-Hemicholinium-3 (HC-3); and dopamine D-1 and D-2 receptors, labeled with [^{3}H]-SCH 23390 and [^{3}H]-Sulpiride respectively, has been examined.

Unilateral stereotaxic lesions of rat caudate-putamen (CPu) with AF64A were performed. Control animals were stereotaxically injected with vehicle. Ten micron thick, slide-mounted, serial tissue sections of rat forebrain were incubated in radiolabeled ligand. Dopamine D-1 and D-2 receptors were labeled with 1.0 nM [^{3}H]-SCH 23390 and 20 nM [^{3}H]-Sulpiride respectively, under previously described conditions. Total muscarinic receptors were labeled with [^{3}H]-QNB and M-2 receptors were identified as the residual after displacement with pirenzepine. M-1 receptors were labeled with [^{3}H]-PZ. In order to determine the efficacy of the lesions, Na+-dependent HAChT were labeled with [^{3}H]-HC3. Three areas within the CPu were quantitated, a site near the lesion (zone #1), an area farthest away from the lesion (zone #3) and an intermediate site (zone #2).

The results showed a significant decrease of HAChT of 62% and 20% at zones #1 and #2 respectively, and no decrease of binding sites at zone #3. Total muscarinic receptors and the M-2 subtype were also decreased at zones #1 and #2. The M-1 subtype showed no change. There were no observable changes in the dopamine D-1 receptors, but a significant decrease in D-2 receptors at zone #1 was observed.

These results provide evidence that, under the conditions used, AF64A is a selective cholinergic neurotoxin. Furthermore, a population of D-2 receptors are postsynaptic and a population of M-2 receptors are presynaptic on cholinergic interneurons within the CPu.

328.7 PURIFICATION OF RAT STRIATAL DOPAMINE (DA) RECEPTORS BY FAST PROTEIN LIQUID CHROMATOGRAPHY (FPLC).
J.Y. Lew* and M. Goldstein. (SPON: C. Adler) Department of Psychiatry, Neurochemistry Research Labs, New York University Medical Center, New York, NY 10016.

We have investigated whether FPLC might be a useful procedure for purification of rat striatal DA receptors. The CHAPSO solubilized striatal DA receptors were prelabeled with 2 nM ^{3}H-spiroperidol (^{3}H-Spi) and the protein-bound radioactivity was separated from the unbound by passing through a Sephadex G-25 column. Samples were then applied on a Mono Q anion exchange column. The column was preequilibrated with 0.05 M Tris-HCl buffer, pH 7.0, containing 0.1% digitonin (Buffer A). The proteins were eluted from the Mono Q column with a linear gradient from 0 to 2.0 M NaCl in Buffer A. The ^{3}H-Spi protein-bound radioactivity was associated with two peaks and their DA receptor binding properties are now under investigation.

In another experiment we covalently labeled the striatal membrane-bound DA receptors with the photoaffinity ligand ^{3}H-7-azidofluphenazine (^{3}H-7-AF) (J.Y. Lew, E. Meller and M. Goldstein, Eur. J. Pharmacol. 113:145, 1985), and following solubilization with CHAPSO the labeled proteins were submitted to FPLC. Elution with the linear gradient from 0 to 2 M NaCl in Buffer A showed that the radioactivity is associated with two peaks. The two ^{3}H-7-AF labeled protein peaks separated by FPLC on the Mono Q column are now being further characterized on SDS-gel electrophoresis. Following SDS-gel electrophoresis of the glycoproteins isolated from the rat striatum, ^{3}H-7-AF covalently labels one major peptide (92 KDa) and a minor peptide (72 KDa). The incorporation of radioactivity into the 92 KDa peptide is reduced by approximately 70-80% in presence of 10^{-6}M butaclamol, suggesting that this peptide represents the D-2 DA receptor binding protein.
These studies were supported in part by NINCDS 06801 and NIMH 02717.

328.8 **AFFINITY CHROMATOGRAPHY FOR SELECTIVE PURIFICATION OF D_1 DOPAMINE RECEPTORS: SYNTHESIS AND USE OF (R,S)-7-CHLORO-8-HYDROXY-1[4-(3-AMINOPROPYL)PHENYL]-2,3,4,5-TETRAHYDRO-3-METHYL-1H-3-BENZAZEPINE.**
D. Wray*, S. Wyrick*, J. Petitto* and R.B. Mailman. (Spon: D. Janowsky). Depts. of Psychiatry and Pharmacology, Biol. Sci. Res. Ctr., School of Med., and Dept. of Med. Chem, School of Pharmacy, Univ. of North Carolina, Chapel Hill, NC 27514.

Basic biochemical and molecular biological studies of the dopamine receptor require isolation and purification of important subclasses. To perform such studies, we synthesized (R,S)-7-chloro-8-hydroxy-1[4-(3-aminopropyl)phenyl]-2,3,4,5-tetrahydro-3-methyl-1H-3-benzazepine [*PropylSCH*], an analog of the drug SCH23390, for use as a possible affinity ligand for the D_1 dopamine receptor. N-methyl-3-chloro-4-methoxyphenethylamine and 4-(2-cyanoethyl)phenacyl bromide were synthesized as starting materials, and key intermediates included N-methyl-N-[4-(2-cyanoethyl)phenacyl]-N-(3-chloro-4-methoxyphenethyl)-amine; N-methyl-N-(3-chloro-4-methoxyphenethyl)-N-[2-(4-(3-aminopropyl)phenyl)-2-hydroxyethyl]amine; and (R,S)-7-chloro-8-methoxy-1-[4-(3-aminopropyl)phenyl]-2,3,4,5-tetrahydro-3-methyl-1H-3-benzazepine.

Competition studies in striatal membranes indicated that the racemate of propylSCH was about one-third the potency of SCH23390 in competing for [^{3}H]-SCH23390 binding sites, with IC_{50}s of 3.6 nM for propylSCH and 1.0 for SCH23390 (n_H equal to 1.00 ± 0.05 for both). A similar ratio of potencies for both compounds was found for inhibiting dopamine-sensitive adenylate cyclase. Neither compound had significant potency in competing for the D_2 dopamine receptor as labeled by [^{3}H]-spiperone. These data indicate that propylSCH, like SCH23390, is a potent and selective D_1 antagonist. The propylSCH was then coupled to cyanogen bromide-activated Sepharose. To verify that the affinity gel retained pharmacological activity, the ability of the Sepharose to compete for [^{3}H]-SCH23390 binding sites in striatal membranes was determined. PropylSCH-linked Sepharose, or soluble SCH23390, competed for [^{3}H]-SCH23390 binding sites, whereas glycine-linked Sepharose had minimal effect. These data indicate that propylSCH-linked Sepharose is capable of binding even crude striatal membranes having SCH23390 recognition sites. The affinity support was then used with crude striatal membranes solubilized with cholate. Initial studies with this soluble membrane preparation indicated that D_1 recognition sites were recoverable after removal of detergent with Biobeads. However, the ability to detect binding activity from the soluble preparation correlated with formation of insoluble membrane vesicles, suggesting that this cholate soluble form may not be active.

Supported by PHS Grant MH40537 and Center Grants HD03110 and MH33127.

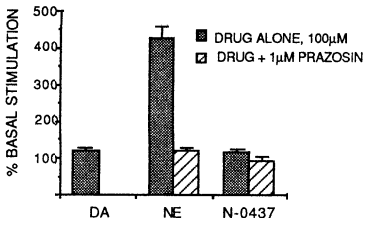
328.9 EFFECT OF THE CA^{2+} ANTAGONIST PN-200-100 ON GBL-ELICITED ENHANCED STRIATAL L-DOPA SYNTHESIS. Y. Namba, E. Meller and M. Goldstein. (SPON: R. Margolis). Department of Psychiatry, New York University Medical Center, New York, NY 10016.

To determine whether presynaptic dopamine (DA) receptors (autoreceptors) which regulate dopa biosynthesis are linked to Ca^{2+} channels, we have investigated the effects of a known Ca^{2+} antagonist, PN-200-100 (PN), on the GBL enhanced striatal L-dopa synthesis. Rats were divided into four treatment groups: (a) NSD 1015 (NSD) alone (100 mg/kg, i.p.); (b) PN (10 mg/kg, s.c.) 25 min before NSD; (c) GBL (750 mg/kg, i.p.) 5 min before NSD; and (d) PN 25 min and GBL 5 min before NSD. All animals were sacrificed 30 min after treatment with the dopa decarboxylase inhibitor (NSD). Treatment of rats with GBL resulted in an enhanced accumulation of L-dopa in the striatum. In animals treated with NSD, pretreatment with PN resulted in a decrease in striatal L-dopa accumulation of approximately 25%. In animals treated with both GBL and NSD, pretreatment with PN reduced the GBL-enhanced L-dopa accumulation by approximately 55-60%. These results show that the increased synthesis of L-dopa which occurs following GBL-induced cessation of dopaminergic impulse flow is inhibited by PN, analogous to the effect produced by DA agonists. This suggests that presynaptic striatal DA receptors, like the D-2 DA receptors of rat anterior pituitary (M. Memo et al., J. Neurochem. 47:1689, 1986) may be functionally linked, in part, to Ca^{2+} channels. However, other mechanisms directly involving Ca^{2+}-dependent protein kinases, cannot be excluded. These studies were supported in part by NIMH Grant 02717, NIH Grant 06801, and the Leon Lowenstein Foundation.

328.10 **DOPAMINE D2 RECEPTOR ACTIVATION FAILS TO STIMULATE PHOSPHATIDYLINOSITOL TURNOVER** J. Black, J.D. Belluzzi, and L. Stein, Dept. of Pharmacology, University of California, Irvine, CA 92717

The dopamine D2 receptor has been implicated in positive reinforcement, both at the behavioral (Gallistel and Davis, 1983) and cellular (Stein and Belluzzi, 1986) levels. To investigate the hypothesis (Stein and Belluzzi, 1986) that phosphatidylinositol (PI) metabolism may underlie DA-mediated positive reinforcement, we attempted to stimulate PI turnover by D2 receptor activation. Previous investigations of the effect of D2 receptor activation on PI metabolism have used D1/D2 agonists, such as DA itself, in conjunction with specific D2 antagonists. These investigations suggest that the D2 receptor does not activate, and even may inhibit, PI turnover; however, the concurrent activation of D1 receptors which interact with D2 receptors in many systems to might have confounded the PI measurements. If so, a specific D2 agonist might reveal an otherwise masked DA-activated increase in PI turnover. The availability of N-0437, a potent and specific D2 receptor agonist, made this test feasible.

The rat hippocampus was used in most experiments because cellular reinforcement has been demonstrated in this tissue, and because the ratio of D2 to D1 receptors in hippocampus is second highest in the brain. The method used was a slight modification of that of Berridge et al., 1982. Briefly, chopped tissue was incubated in oxygenated artificial cerebrospinal fluid, to which was added LiCl, ^{3}H-myo-inositol, and test drugs. Agonist-stimulated PI turnover would result in the appearance of radiolabelled inositol phosphates, which could be collected on an anion exchange column and counted on a liquid scintillation counter. As seen in the Figure, 100μM norepinephrine stimulated PI turnover, an effect antagonized by the α-adrenergic antagonist prazosin but not by the β-antagonist propranolol. This supports findings of other investigators by showing an α-adrenergic stimulation of PI turnover. Although we saw no effect of DA alone at doses up to 5mM, the specific D2 agonist N-0437 at a dose of 100μM resulted in a slight but significant increase (114% of basal, $p \leq 0.025$) in PI turnover. However, addition of 1μM prazosin abolished this increase, though prazosin alone had no effect.



These results indicate that the stimulatory action of N-0437 on PI turnover is mediated via α-adrenergic receptors. Similar results in rat striatum furthermore suggest that our negative findings in hippocampus are not due to low DA receptor density. (Supported by AFOSR grant 84-0325)

PAIN: CENTRAL PATHWAYS IV

329.1 PARCELLATION OF HUMAN THALAMIC NUCLEI BASED ON HISTOCHEMICAL STAINING AND SUBSTANCE P INNERVATION. T. Hirai*, S.H.C. Hendry and E.G. Jones. (SPON: H.D. Schwark). Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Seven human thalami from neurologically normal subjects and from patients suffering from Alzheimer's disease (ages 62 to 78 years), were fixed by immersion in 4%, phosphate-buffered paraformaldehyde and sectioned frozen in horizontal, sagittal or frontal planes. Four out of every five sections were cut at 60 um and one of each was stained for acetylcholinesterase, cytochrome oxidase, with thionin or with a myelin stain. The fifth was cut at 20 um and stained immunocytochemically for tachykinin immunoreactivity, using a rat monoclonal antibody made against Substance P (Sera Labs) and the avidin-biotin method.

Re-evaluation of human thalamic cytoarchitecture indicates a close correlation with the macaque monkey thalamus and nuclei have been renamed accordingly. The subdivisions of the ventral nuclei are particularly clear in man, in acetylcholinesterase (AChE) stained material. The VLa nucleus, corresponding to the nucleus innervated by the globus pallidus, is particularly large and strongly AChE positive. The VLp nucleus, corresponding to the cerebellar relay nucleus and including the so-called Vim nucleus, is AChE negative, while the lemniscal relay nuclei, VPL and VLPM, are strongly positive. VPL in Nissl preparations shows two clear divisions that probably correspond to relays for deep and cutaneous afferents.

The densest concentrations of fiber plexuses showing tachykinin-like immunoreactivity are in the central medial, paracentral, central lateral and limitans nuclei and in a small region postero-inferior to the centre médian nucleus, provisionally identified as the human nucleus submedius. Moderate densities appear in the anteroventral, mediodorsal and reticular nuclei and in parts of the posterior complex. Low densities appear in the pulvinar and ventral anterior nuclei. The major relay nuclei are virtually devoid of immunoreactive fibers.

The major densities of tachykinin immunoreactive fibers are with certain notable exceptions, such as the VLa and lateral geniculate nucleus, coincident with the major densities of acetylcholinesterase staining. These, in turn, tend to correlate negatively with cytochrome oxidase staining patterns.

Supported by NIH grant NS 22317 and by the Alzheimer's consortium of Southern California.

329.2 MORPHOLOGY OF GOLGI-IMPREGNATED NEURONS IN THE CAT AND RAT NUCLEUS SUBMEDIUS. V. Miletic and H.-J. Tan*, Dept. of Comparative Biosciences, School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

The nucleus submedius (SM) of the medial thalamus might contain neurons that play an important role in nociceptive information processing. Since little is known about this nucleus, we have used the Golgi impregnation technique to examine the morphology of SM cells.

Cats (n=4) and rats (n=6) were deeply anesthetized, and perfused with buffered 1% paraformaldehyde and 1% glutaraldehyde. Thalami were cut into 2-3mm blocks and processed with the Golgi method (1% osmium tetroxide for 30 min, 5% potassium dichromate for 4-5 days at 4°C with agitation, and 0.5% silver nitrate for 16-24 hrs). Blocks were then cut into coronal or parasagittal sections (100μm), and the sections were dehydrated, mounted, and examined with a light microscope.

Preliminary analysis of the Golgi-impregnated material reveals no clear morphological grouping of the cat and rat SM neurons with respect to soma size (range 7-50μm), area of dendritic spread, or presence and number of dendritic spines. A noticeable difference among SM neurons is seen only with respect to the number of primary dendrites. Most of the impregnated neurons had three primary dendrites emanating from an oval cell body. Two of these dendrites exited the soma at opposite poles, while the third emanated from the midregion. On occasion, this third dendrite branched more extensively than the other two, especially in those neurons located close to the SM borders. In such cases the numerous daughter branches were directed at the center of the SM neuropil. The remainder of the impregnated neurons were either multipolar (4-6 primary dendrites emanating in different directions) or bipolar (two primary dendrites exiting the soma at opposite poles). The multipolar neurons appeared to be somewhat more numerous in the inner half of the nucleus, while the bipolar were frequently found along the SM borders.

The present analysis indicates that, apart from the number of primary dendrites, there are no clearly observable morphological differences among neurons in both the cat and rat SM. It remains to be established whether this morphological similarity suggests a uniformity of function for the SM neurons involved in medial thalamic nociceptive processes.

329.3 NOCICEPTIVE RESPONSES IN NUCLEUS SUBMEDIUS OF THE RAT. J. O. Dostrovsky, G. Guilbaud* and M. Gautron*. Dept. of Physiology, University of Toronto, Toronto, Ontario, and INSERM, u161, 2 rue d'Alesia, Paris 75014, France.

Recent anatomical studies by Craig and others have revealed the existence of a direct projection from the spinal cord to nucleus submedius in medial thalamus of the rat, cat and monkey. In the cat it has been shown anatomically and confirmed electrophysiologically that the projection neurons are located exclusively in lamina I of the spinal and medullary dorsal horns thus suggesting that Sm is involved in pain and/or temperature mechanisms. Most of the neurons in Sm project to ventrolateral orbital cortex. In the present study we have investigated the response characteristics of Sm neurons in the rat.

Experiments were performed on 17 rats anesthetized with 0.5% fluothane in a mixture of 1/3 O_2 2/3 N_2O. Adequate and stable anesthesia and a good brain condition were maintained as assessed on the basis of the EEG. Single unit recordings were obtained from neurons in medial thalamus using glass microelectrodes filled with pontamine dye. Every neuron was tested to determine whether its activity could be altered by innocuous and noxious mechanical and sometimes thermal stimuli applied to various body regions. All recording sites were reconstructed on the basis of dye marks.

Of the 66 neurons recorded in Sm, 29 were excited and 3 inhibited by nociceptive stimulation, whereas the remainder did not respond to any cutaneous stimuli including cold and warm stimuli. The responses could be elicited in most cases by stimuli applied to the tail and bilaterally to the posterior paws. In many cases the neurons responded also to stimulation of the forepaws and face. In almost all cases the responses persisted for the entire duration of the standard 15 second stimulus used and frequently persisted for periods of 5 to 60 seconds after termination of the stimulus. For 8 of the neurons responding to mechanical stimulation, noxious thermal stimulation (46 - 50°C) of the hindlimb or tail was tested and in all but one case excitation was observed. No topographic organization was noted and responsive neurons were found in all parts of the nucleus at all anterior-posterior levels. These results are similar to those we have recently reported for Sm of arthritic rats except that in the former group responses could be obtained also by low intensity mechanical stimuli applied to the inflamed joints and by joint movements.

These findings indicate that Sm may be involved in the processing and relay of pain related sensory information to frontal cortex.

329.4 INTRATHECAL ADMINISTRATION OF PHENTOLAMINE, METHYSERGIDE OR NALOXONE: EFFECTS ON HYPOTENSION, BRADYCARDIA, AND ANTINOCICEPTION INDUCED BY INTRAVENOUS ADMINISTRATION OF D-ALA^2-METHIONINE ENKEPHALINAMIDE IN THE RAT. S.A. Aicher and A. Randich. Department of Psychology, University of Iowa, Iowa City, IA 52242

Two experiments examined the effects of intrathecally administered receptor antagonists on the hypotension, bradycardia, and inhibition of the tail-flick reflex evoked by noxious radiant heat induced by intravenously (IV) administered D-Ala^2-Methionine enkephalinamide (DALA). The receptor antagonists studied were phentolamine, naloxone and methysergide. Awake, restrained rats showed no systematic effects for any of the receptor antagonists on the hypotensive, bradycardic or antinociceptive effects of DALA. However, there was a significant effect of the order of IV administration of the saline vehicle or DALA on these response measures. Specifically, a 5-minute delay between the intrathecal administration of any of these antagonists or saline vehicle and the IV DALA injection, resulted in an attenuation of the antinociception produced by DALA. The arterial blood pressure responses to DALA also were attenuated or reversed by all of the intrathecal injectates, including the saline vehicle with a 5-minute delay. However, at a 20-minute delay between the intrathecal injections and IV administration of DALA, the tail-flick and cardiovascular responses were both similar to those seen in animals without intrathecal catheters and unaffected by the receptor antagonists. Using a single dose (30 µg) of each receptor antagonist and the lightly-anesthetized rat preparation, intrathecal administration of phentolamine produced a significant attenuation of the antinociception induced by IV administration of DALA compared to controls. There were no systematic effects of any of the antagonists on either the arterial blood pressure or the heart rate response to IV administration of DALA in lightly-anesthetized rats.

329.5 **CROSS INTERACTION BETWEEN THE LATERAL RETICULAR NUCLEUS AND THE PERIAQUEDUCTAL GRAY. M.E. Clement and M.M. Behbehani (SPON: A. Mathieu). Department of Physiology and Biophysics, University of Cincinnati College of Medicine, Cincinnati, OH 46267-0576.**

Recent experiments have shown that electrical and chemical stimulation of the lateral reticular nucleus(LRN) produces analgesia. There is evidence that lesion of the LRN alters pain perception. Anatomical studies have shown that there is a cross innervation between PAG and LRN.

Adult male rats were used in these experiments. In one series of experiments animals were anesthetized with sodium pentobarbital and after surgery, were maintained under methohexital anesthesia by continuous infusion at a rate of 15mg/Kg/Hr. Under these conditions, heating of the tail produced a reliable tail flick (TF). The second group of animals were maintained under chloral hydrate anesthesia throughout the experiment. Single unit recordings were made from the LRN. The response of the LRN neurons to PAG stimulation, to peripheral stimulation and to norepinephrine applied iontophoretically was measured. In methohexital anesthetized animals, electrical stimulation of LRN produced an increase in TF latency that lasted as long as the stimulus was applied. Injection of 100 to 200 nl of glutamic acid into the LRN produced an increase in the tail flick latency that outlasted the injection time by several minutes.

The activity of 112 cells in 24 animals was recorded. Of these, 30.8% showed a five to ten-fold increase in firing rate and in 48.9% the firing rate was decreased. The majority of these latter cells were completely inhibited for as long as the noxious stimulation was applied. The latency to onset of response of PAG stimulation was variable with a range of 3 to 10 milliseconds and a mean latency of 4.8 msec with a standard deviation of 1.2 msec, with antidromically activated cells showing a latency of 3.9 ms. The response of each cell to 10 seconds 100 Hz electrical stimulation of PAG was recorded. An excitatory response was observed in 47.8% cells. Fourteen cells were excited only during PAG stimulation. Twenty-nine cells responded with an extended excitation with a mean duration of 35.4 seconds. 40.2% of the cells were inhibited by electrical stimulation. Thirty-three cells responded only during PAG stimulation, the majority of these cells were completely inhibited. Only four cells showed an extended inhibition with a mean duration of 16.50 seconds. The response of 20 LRN neurons to iontophoretically applied norepinephrine was measured and compared to their response to peripheral and to PAG stimulation. The most consistent effect of NE was inhibition of the baseline firing rate. There was no significant correlation between the response to PAG stimulation and to NE. The effect of NE could be blocked by phentolamine while yohimbine had a predominantly excitatory effect. It is concluded that 1) the majority of LRN neurons are inhibited by noxious stimulation. 2) There is a fast conducting pathway that connects the LRN region with the PAG that is likely to be monosynaptic. 3) It is possible that analgesia produced by LRN stimulation is mediated through the activation of PAG-rostral ventral medulla- spinal cord pathway.

329.6 CORRELATION OF OPIOID RECEPTOR BINDING WITH ENK AND 5HT IMMUNOCYTOCHEMISTRY IN THE MEDULLARY RAPHE AND RETICULAR NUCLEI. Robert M. Bowker and Roger P. Dilts, Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520

The nucleus raphe magnus and nucleus gigantocellularis are known to be important participants in the descending control of nociception, while the nucleus raphe pallidus and the nucleus raphe obscurus have roles in autonomic and motor control systems. Opiate mechanisms mediate, in part, many of the spinal cord effects produced by these nuclei. The anatomical localization of mu and delta opioid receptors within these cell groups was assessed by quantitative autoradiography, and the resulting distribution correlated with enkephalin-like and serotonin-like immunoreactivity.

Adjacent brainstem sections from guinea pigs and rats were processed for receptor autoradiography, using ^{125}I-Tyr-D-Ala-Gly-N-MePhe-Gly-ol-enkephalin (DAGO) and ^{125}I-D-Ala-D-Leu-enkephalin (DADL) in the presence of 10 nM DAGO to localize mu and delta receptors, respectively (Mankowitz and Goodman, 1982). Other sections were processed for ENK and 5HT immunocytochemistry, using antisera raised to either leucine- or methionine-ENK and to 5HT. The immunocytochemically stained sections were examined and correlated with opioid receptor autoradiography.

Dense DAGO and DADL binding was observed in the NTS, DMV and spinal trigeminal nucleus, consistent with most studies. In addition, moderately intense staining was located within the NRM and the NGC. The specific binding pattern formed a horizontally directed band in the NGC with less binding caudally in the NRO and NRP. The distribution of leucine- and methionine-ENK immunoreactivity was closely correlated with the localization pattern of opioid receptors. In double labeling studies, ENK terminals appeared to make contact with both 5HT and non-5HT neurons in the NRM and NGC, with fewer in the NRO and NRP. These observations provide anatomical evidence for the localization of opioid receptor binding in the medullary raphe and reticular nuclei and a close correlation between the opioid receptors and the ENK- and 5HT-immunoreactive elements. Thus the raphe-spinal and reticulospinal pathways from these nuclei may be modulated, in part, by opioid receptor mechanisms. (Supported by NS22321 and NS24388.)

329.7 MORPHOLOGICAL CHARACTERISTICS OF PHYSIOLOGICALLY IDENTIFIED CELLS IN THE ROSTRAL VENTRAL MEDULLA OF THE RAT. A.M. Williamson, P.T. Ohara and H.L. Fields. Departments of Anatomy and Neurology, University of California, San Francisco, CA 94143.

Within RVM (nucleus raphe magnus and immediately adjacent areas of the medulla) there are neurons whose firing rate increases (on-) decreases (off-) or remains unchanged (neutral) just prior to withdrawal from a noxious stimulus. Since systemic opiate administration elicits specific alterations in the firing of both on- and off-cells, and since electrical stimulation of RVM produces behavioural analgesia, RVM has been postulated as a significant link in a descending system specifically designed to inhibit pain transmission. This study was conducted to determine whether or not electrophysiologically identified cells in RVM exhibit specific morphological differences that might help in understanding the mechanism through which behavioural analgesia is mediated.

The experiments were performed on lightly barbiturate-anesthetized rats. Areas containing on- and off-cells were identified by extracellular recording with metal electrodes, and then the area was searched with high impedance glass electrodes filled with the fluorescent marker, ethidium bromide (1% in 2.0 M K-acetate). Cells were characterized as on-, off- or neutral by the change in their firing pattern immediately preceeding withdrawal from either noxious heat applied to the tail or pinch applied to the paw or ear. At the conclusion of the recording session, the animals were perfused with fixative, and 20 μm thin sections were cut on a freezing vibratome. The sections were viewed with a fluorescent microscope. The filled cells were then identified, photographed and drawn. All cells were found in RVM within 1.0 mM of the midline, and no more than 1.5 mM from the pyramids in the dorsoventral plane. All filled cells were within RVM and were centered on the rostrocaudal plane of the nucleus of the seventh cranial nerve. Off-cell somata have an area of 758 ± 113 μM^2 (mean ± SEM,n=5). On-cell somata are smaller and have an area of 447 ± 145 μM^2 (n=4).

No consistent morphological differences between on- and off-cells were found. Most cells of both classes have triangular cell bodies which give rise to at least three principal dendrites which bifurcate into smaller secondary dendrites within 20-50 μM of the cell body. The orientation of most dendrites is roughly mediolateral, but dorsoventral orientations were seen in two cells.

This work was supported by PHS grants NS 07265 and NS 21445.

329.8 PHYSIOLOGY AND MORPHOLOGY OF PONTOMEDULLARY RAPHE AND RETICULAR NEURONS IN CAT BRAINSTEM: AN INTRACELLULAR HRP STUDY J. F. Whitney, C. E. Poletti and W. E. Foote Depts. of Psychiat. and Neurosurg., Mass. Gen. Hosp. and Harvard Med. School, Boston, Mass. 02114

We have been examining the connections and morphology of pontomedullary raphe and reticular neurons in an attempt to better understand the role these nuclei play in antinociception. One interest involves correlating the morphology and physiology of brainstem neurons located in n. raphe magnus (NRM), n. gigantocellularis (NGC), n. paragigantocellularis (NPGD), and n. magnocellularis (NMC).

Preliminary results indicate that cells with spinal efferents as determined by antidromic invasion from stimulation of the dorsolateral fasiculis exhibited a consistent pattern of dendritic branching. The ratio of dendritic terminal branches to dendritic trunks is less variable for these cells than for neurons not antidromically activated from the spinal cord (Bartlett's test for homogeneity of variance, $X^2(1) = 7.739$, $p < 0.01$). Cells with spinal efferents varied in size (from < 850 μm^2 to < 3,500 μm^2) and location (NGC, NPGD, and NMC). These cells all received rostral input from one or more of the following: periaqueductal grey (PAG), amygdala, and hypothalamus and none were influenced by tooth pulp stimulation.

Other cells were influenced by tooth pulp stimulation with latencies suggesting polysynaptic input. Cells with shorter latencies received excitatory input while the longest latency cell received inhibitory input. These tooth pulp responders exhibited nearly spherical dendritic trees which were found to differ significantly from the other cells (n=14) taken as a group which had more oval shaped dendritic fields that were flattened in the mediolateral direction ($t_{(12)} = 2.327$, $p < 0.05$). All tooth responders were located in the NGC which, as a group (n=7), also had significantly more spherical dendritic trees than the other cells ($t_{(12)} = 6.87$, $p < 0.001$). Tooth responders all received excitatory spinal input and all responded to diverse rostral inputs.

As opposed to NGC cells, cells with oval dendritic fields were found in the NPGD which differed significantly on this measure from the other cells ($t_{(12)} = 2.707$, $p < 0.02$). Unlike NGC, NMC, & NRM cells, NPGD cells did not receive PAG input.

329.9 THE ROLE OF SPINAL CORD MONOAMINES IN THE PRODUCTION OF OPIOID AND NONOPIOID STRESS-INDUCED ANALGESIA. L. A. Yuva* and S. F. Maier. Dept. of Psychology, University of Colorado, Boulder, CO 80309.

Numerous studies have demonstrated that environmental events can activate endogenous pain inhibitory systems within the central nervous system. The antinociceptive response which follows exposure to such environmental events (e.g., electric shocks, cold water, rotation, etc), called "stress-induced analgesia" (SIA), is not produced by a single mechanism. Rather, it is produced by multiple mechanisms whose pattern of activation depends on the nature of the environmental event. These mechanisms are still only poorly understood.

Spinal cord monoamines play a key role in the analgesia produced by opiates (Yaksh, T. L., Pharm. Biochem. Behav, 22:845, 1985), but little is known concerning their importance in SIA. The data which do exist are largely contradictory, possibly because different studies have used SIA paradigms which activate different pain inhibitory systems. The present studies explored the role of spinal cord monoamines using a SIA procedure which produces sequential nonopioid and opioid analgesias in the same subject. Thus we were able to assess the importance of the monoamines with regard to two major classes of SIA simultaneously.

Rats were implanted with intrathecal cannulae in the lumbosacral enlargement. Some rats then received intrathecal (i.t.) administration of 5,7 dihydroxytryptamine (5,7-DHT) to deplete 5-HT and NE from the lumbar spinal cord, others received intraperitoneal (i.p.) desipramine in combination with i.t. 5,7,-DHT to selectively deplete 5-HT, while the remaining rats received i.t. saline as a control. 7 days later all rats were restrained in Plexiglas tubes and received a series of 60 inescapable 5 sec 1.0 mA shocks delivered to the tail via fixed electrodes. Tail-flick to radiant heat was measured after 1, 5, 10, 20, 40 and 60 shocks. Testing was conducted without disturbing the subjects or removing them from the tubes. Half of the animals that had initially received i.t. saline received naltrexone (14 mg/kg) before the shock session, while the remaining controls received i.p. saline.

Naltrexone reduced the analgesia seen after 1 shock, but had no effect on the analgesia occurring after 5, 10, and 20 shocks. It again reduced the analgesia after 40 and 60 shocks, suggesting a pattern of a very brief opioid analgesia, followed by a nonopioid and then another opioid analgesia. 5-HT depletion reduced the analgesia observed after 1 shock, but had no effect on the analgesia after 5, 10, and 20 shocks. It again reduced analgesia after 40 and 60 shocks. In contrast 5-HT+ NE depletion reduced the analgesia seen after all shocks. Thus, 5-HT depletion reduced analgesia at all points at which naltrexone had been effective, but had no effect where naltrexone was without impact. The addition of NE depletion, on the other hand, reduced analgesia at the points at which naltrexone had been ineffective. This pattern suggests that spinal cord 5-HT plays a role in opioid forms of SIA and that NE plays a role in nonopioid SIA.

330.1 PRODUCTION OF AMYLOID-LIKE MATERIAL BY CULTURED MICROGLIA. C. A. Colton, T. Behar*, J. S. Colton*, M. Simon*, and D. L. Gilbert. (SPON: S. L. Pocotte). Dept. of Physiol. Biophys., Georgetown Univ. Med. Sch., Washington, D.C. 20007 & Lab. of Molecular Genetics and Lab. of Biophysics, NINCDS, NIH, Bethesda, MD 20892.

The role of microglia in inflammatory and non-inflammatory pathological processes in the CNS is not clear. Evidence has suggested that microglia share morphological and functional properties with other tissue macrophages. Since Kupffer cells, the resident macrophages in the liver, have been shown to produce amyloid in response to casein and also to endotoxin injection and since microglia are frequently seen at the site of amyloid plaques in the CNS, the ability of microglia to produce amyloid-like material was tested directly using cultured microglia. Primary glial cell cultures were prepared from 2 day old rat cerebral hemispheres. Cultures were grown for 10 to 14 days at 37 C in a 10% CO_2, 90% air environment using Dulbecco's medium (DMEM) containing 10% fetal calf serum. After selective replating, a microglia enriched culture was obtained. Cells were plated on poly d lysine coated cover slips in 24 well culture dishes and allowed to adhere overnight. The cells were then exposed to casein or endotoxin by addition of the agent to the DMEM. After a variable time of exposure, the cells were fixed with formalin and stained with either Congo Red or thioflavin S. After 48 hours of exposure to casein and endotoxin, green yellow birefringence under polarized light was seen within many microglial cells for the Congo Red stained cells and a yellow florescence for the thioflavin S stained cells. Stain was seen only intracellularly and appeared to be in vesicles. No stain was seen in either control cells from the same time period or in cells exposed for 48 hours to opsonized zymosan or arachidonic acid.

330.2 TRUE MICROGLIA PROLIFERATION INDUCED BY BLOCK OF AXOPLASMIC FLOW AND INHIBITED BY ADRIAMYCIN TRANSPORT: A CELL UNRELATED TO THE MACROPHAGE. R.L. Schelper, R. Miyazaki, Univ. Iowa, Iowa City, IA 52242

It has been well documented that true reactive microglia (TRM) are unrelated to monocyte derived brain macrophages (MΦ). Unlike TRM, brain MΦ have monocyte esterases, react with anti-macrophage antibody and specific lectins, are labeled by non-reusable DNA precursors, and have Fc receptors. Brain MΦ appear only after direct traumatic injury. TRM appear after injury to a neuronal cell process and are seen in a nerve nucleus after axotomy or around neurons adjacent to areas of direct trauma. The neuron may perceive that it has been injured when it no longer receives a retrogradely transported trophic factor from the innervated structure. To test this hypothesis we blocked axonal transport with colchicine and monitored TRM proliferation by thymidine uptake. Hypoglossal or sciatic nerves of mice were exposed to saline or to colchicine (60 μM) for 30 minutes. They were subsequently given three intraperitoneal injections of ^{3}H-thymidine (2 μCi/gm body wt) per day and were killed 2 days after colchicine treatment. Carnoy's fixed, paraffin embedded sections were cut and coated with Kodak NTB2 emulsion. Saline treated animals showed no evidence of cellular proliferation in the spinal cord or hypoglossal nucleus. Colchicine treated animals showed a TRM response identical to that seen in animals after hypoglossal or sciatic axotomy. Thus, colchicine disruption of axonal transport appears to play a role in the TRM response, supporting the hypothesis that loss of a peripherally produced trophic factor is the signal to the neuron that it has been injured.

Because TRM are so intimately associated with neurons injured by axotomy or colchicine, we reasoned that the neurons must release a factor that stimulates the TRM response. In an attempt to block local TRM proliferation, we injected the tongue with 80-160 μgm Adriamycin (ADM). ADM, which is autofluorescent and carried by retrograde transport, blocks both DNA-RNA transcription and DNA replication by becoming intercalated between the DNA strands. ADM leaks out of neurons and is taken up by glia. In our study ADM was detected by fluorescence as early as 4 hours after injection in cell nuclei of neurons and glia of the hypoglossal nucleus, but not elsewhere. One day after ADM injection the hypoglossal nerve was cut and mice were given ^{3}H-thymidine for 2 days before being killed. No labeled cells were found after axotomy in ADM treated mice. Controls injected with saline showed the usual TRM response. Thus, inhibition of local DNA transcription and replication by ADM blocks the TRM response. This is probably a direct effect of ADM on the TRM but might also be explained by an inhibition of neuronal synthesis of a TRM mitogenic/chemotactic factor.

330.3 SECRETION OF SUPEROXIDE BY CNS MICROGLIA. D. L. Gilbert and C. A. Colton. (SPON: B. G. Szaro). Lab. of Biophysics, NINCDS, NIH, Bethesda, MD 20892 and Dept. of Physiol. and Biophys., Georgetown Univ. Med. Sch., Washington, DC 20007.

Microglia have been implicated in both physiological and patholgical processes in the brain. Since microglai share many of the same surface antigens as blood macrophages, they have been considered to be resident CNS macrophages. Thus, it is possible that microglia can kill invading organisms by secreting oxygen radicals. To test this possibility, superoxide secretion of microglia in tissue culture was studied. Primary glial cell cultures were prepared from 2 day old rat cerebral cortices and grown in Dulbecco's medium (DMEM) with 10% fetal calf serum at 37 C in a gas mixture containing 10% CO_2 and 90% air. Selective replating of the cells after 10 to 14 days of growth produced two cell fractions; one enriched in microglia and the remaining adherent fraction, rich in astrocytes. Both fractions were assayed for superoxide production using a microcytochrome C reduction assay. Specificity for superoxide was provided by comparing the amount of cytochrome C reduction in the presence and absence of superoxide dismutase (SOD), the enzyme which degrades the superoxide radical ion.

Superoxide production was shown to increase over 2 hours at a rate of 3.7 nmoles/mg protein per minute in the microglia enriched fraction when stimulated with opsonized zymosan. In contrast, no superoxide production was seen in the astrocyte fraction when stimulated with opsonized zymosan. Also, no superoxide production was seen in either fraction in non-stimulated conditions. This production of superoxide was dependent on the dose of the opsonized zymosan and on the cell density. In addition the microglia were responsive to stimulation by phorbol myristate acetate in a dose dependent fashion. This ability to secrete free radicals may implicate the microglia in pathological states.

330.4 CALCIUM CHANNEL AND SUPEROXIDE SECRETION IN MICROGLIA. M. Jia*, C. A. Colton, and D. L. Gilbert. Lab. of Biophysics, NINCDS, NIH, Bethesda, MD 20892 and Dept. of Physiol. Biophys., Georgetown Univ. Med. Sch., Washington, D.C. 20007.

CNS microglia have been shown to be similar functionally and anatomically to blood and other tissue macrophages. These cells do secrete the superoxide radical ion. Since calcium has been implicated in the superoxide secretory mechanism of macrophages, we decided to determine if calcium has any influence on superoxide secretion by CNS microglia. Cultured microglia cells were examined for 1) calcium dependent channels and 2) the effect of calcium in the external medium on superoxide secretion.

A primary culture of microglia was obtained from 2 day old rat cerebral hemispheres. The cells were grown at 37 C in a 10% CO_2, 90% air environment using Dulbecco's modified essential medium (DMEM) containing 10% fetal calf serum. After 10 to 14 days, a microglia enriched culture was obtained by using the differential adherence properties of microglia and astrocytes. Microglia were then seeded into either 96 well culture dishes for the superoxide assay and to 15 cm^2 petri dishes for patch clamping.

Superoxide secretion, as measured by a microcytochrome C reduction assay, in the presence and absence of superoxide dismutase, was increased within 30 minutes when calcium concentration of the medium was increased from 2.5 mM to 20 mM. Addition of the calcium ionophore, A23187, to the media produced a similar increase in superoxide production.

Single calcium channel currents were observed from cell attached patch recordings. The bath medium contained 140 mM KCl, 1 mM $CaCl_2$, 1.8 mM $MgCl_2$, and 10 mM HEPES buffered solution to pH 7.35. The pipette was filled with 110 mM $BaCl_2$ and 10 mM HEPES buffered to pH 7.35. A non-inactivating inward current was noticed at resting and at hyperpolarized membrane potentials (i.e., -60 mV to -100 mV). The single channel conductance is about 10 pS with the barium in the pipette. This channel has the same functional properties as the B type calcium channel previously described (Rosenberg, R. L. and Tsien, R. W., Biophys. J. 51:29a, 1987). Using these results, we estimated that the calcium concentration in the cell could possibly be doubled in 10 minutes when the cell is exposed to 20 mM calcium. This increase in calcium concentration could be a factor in the superoxide secretion.

330.5 EFFECTS OF ANTICONVULSANTS ON CALCIUM, CALMODULIN DEPENDENT PROTEIN KINASE IN PRIMARY ASTROCYTE CULTURES. E. Babcock-Atkinson*, L.O.B. Norenberg*, M.D. Norenberg, and J.T. Neary. Laboratory of Neuropathology, Vet. Admin. Med. Center and Univ. of Miami School of Medicine, Miami, FL 33101.

Calcium-regulated processes have been implicated in epileptogenesis; for example, calcium, calmodulin-dependent protein phosphorylation is altered in kindling (Wasterlain and Farber: Proc Natl Acad Sci USA, 81: 1253, 1984), and anticonvulsants such as diazepam and phenytoin inhibit rat brain calcium, calmodulin-dependent protein kinase (Ca/CaMK) (DeLorenzo et al: Science 213: 546, 1981). To evaluate the potential contribution of astrocytes to calcium-dependent mechanisms related to epilepsy, we have investigated the effect of anti-convulsants on Ca/CaMK activity in astrocytes in primary culture.

Astrocytes were derived from neonatal rat cortices and were at least 95% pure (J Neuropath Exp Neurol 44: 397, 1985). Cells from 3 to 6 week old cultures were homogenized in calcium-free buffer containing protease inhibitors. Supernatant and membrane fractions were prepared by centrifugation at 23,000 x g for 30 min at 4°C. Membranes were resuspended in homogenizing buffer supplemented with 0.1% Triton X-100. Ca/CaMK activity was measured by phosphorylation of (a) endogenous substrates by SDS gel electrophoresis, autoradiography, and densitometry and (b) casein by a slight modification of the method of Kuret and Schulman (Biochemistry 23: 5495, 1984).

We found that diazepam inhibited phosphorylation of several endogenous substrates for Ca/CaMK, including two major phosphoproteins (59 and 53 kDa) present in supernatant and membrane fractions. Little to no inhibition was observed with phenytoin or valproic acid (50-500 µM). Preliminary results indicated that 50% inhibition in these crude preparations was attained at about 100 µM diazepam. Since astrocyte cultures treated with dibutyryl cyclic AMP (dBcAMP) have some properties of reactive astrocytes (Fedoroff, et al: J Neurosci Res, 12: 15, 1984) which are frequently found in epileptic foci, we investigated the effect of anticonvulsants on Ca/CaMK activity in cultures treated with dBcAMP. These cells showed a 4-fold increase in calmodulin-dependent phosphorylation in the major phosphoprotein (59 kDa) present in the supernatant fraction. This band was particularly sensitive to inhibition by diazepam, but not by phenytoin or valproic acid.

Our results indicate that diazepam is capable of inhibiting Ca/CaMK activity in astrocytes. These findings suggest a possible site of diazepam action and a potential mechanism for a role of astrocytes in epileptogenesis.

330.6 PHOSPHORYLATION OF AN ACIDIC 80 kDa PROTEIN BY PROTEIN KINASE-C IN ASTROCYTES. P.L. Mobley and B.C. Harrison*. Dept. of Pharmacology, Univ. of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Studies indicate that a calcium/phospholipid dependent protein kinase (protein kinase-C) is present in astrocytes and activation of this kinase by the tumor promoter phorbol myristate acetate (PMA) can induce morphological changes in these cells (Brain Res. 398:366-369). Because of the important role this kinase may play in cell function, studies were conducted to identify phospho-protein substrates in astrocytes for this kinase.

Astrocyte cultures were prepared from the neocortex of newborn Sprague-Dawley rats. Cells were grown to confluency, then contaminating cells were removed, and astrocytes were replated (30,000/sq.cm.). After cells again reached confluency, they were labeled in phosphate-free medium containing approximately 0.5 mCi/ml of ^{32}P-orthophosphate. Cells were incubated with ^{32}P for 2 hours then treated as indicated. Following treatment the medium was removed and cells were then dissolved in 1% SDS and subjected to 2-D gel electrophoresis. From the resulting gels autoradiograms were prepared and the amount of ^{32}P incorporation into various phosphoproteins estimated.

Using this technique several apparent phosphoproteins have been identified in astrocytes which appear to be phosphorylated by protein kinase-C. The most prominent of these is an acidic protein (pI value 4.0-4.5) with a molecular weight of approximately 80 kDa. The ^{32}P content of this protein was increased by a 15 minute treatment with 300 nM PMA. In contrast, treatment of astrocytes with 2 mM dibutyryl cyclic AMP for 15 minutes did not increase the ^{32}P content of this protein although this treatment did increase the ^{32}P content of other phosphoproteins. The effects of PMA on the ^{32}P content of the 80 kDa protein appear to be mediated by protein kinase-C since no effects were observed with PMA in cells depleted of protein kinase-C by pretreatment with PMA 24 hrs earlier.

While the role of this 80 kDa protein in astrocyte function is unknown, it is likely that this phosphoprotein is identical to an acidic protein of similar molecular weight identified in several other tissues and which appears to be a substrate only for protein kinase-C. Therefore the phosphorylation of this protein may serve as a useful marker for the activation of protein kinase-C in astrocyte cultures.

Supported in part by an institutional research grant funded by the American Cancer Society.

330.7 PHORBOL ESTER DOWN-REGULATES PROTEIN KINASE C ACTIVITY IN PRIMARY CEREBELLAR NEURONAL AND ASTROCYTE CULTURES. R.A. Philibert*, K.L. Rogers and G.R. Dutton, Dept. of Pharmacology, College of Medicine, University of Iowa, Iowa City, IA 52242

We have studied the effects of chronic treatment of primary rat cerebellar neuronal and astrocyte cultures with phorbol 12, 13-dibutyrate (PDBU). Neuronal and astrocyte cell cultures were prepared from 7-9 day old rat cerebella according to the method of Dutton et al. [J. Neurosci. Methods, (1981) 3: 421-427] and grown in poly-d-lysine coated T-flasks. At 7-9 and 16-18 days in vitro for neuronal and glial cultures, respectively, studies using appropriate antibodies revealed that neuronal cultures consisted of 92-95% granule cells, 5-7% inhibitory interneurons and <1% astrocytes, while astrocyte cultures consisted of approximately 95% type I astrocytes, <1% oligodendrocytes, 4% macrophages, fibroblasts, smooth muscle and endothelial cells. Cultures were incubated with PDBU or vehicle (0.2% DMSO) for 18 hours, and then homogenized in a Tris-based buffer. Homogenates were applied to a DEAE-cellulose column and Protein Kinase C (PKC) was eluted with a 0-300 mM NaCl gradient. PKC activity was assayed by determining the rate of transfer of ^{32}P from [γ^{32}P]-ATP to histone by the method of McArdle and Conn [Mol. Pharm. (1986) 29: 570-576].

After 18 hours, PKC down-regulation in neuronal cultures was dose-dependent and produced nearly complete loss of enzyme activity at 1 µM PDBU (EC_{50} approximately 5 nM). Time-course studies showed that the down-regulation of neuronal PKC activity reached backround levels after 6 hours of incubation with 1 µM PDBU. Following removal of of the phorbol ester by repeated washing, PKC activity recovered significantly within only 6 hours. After 18 hours of incubation with PDBU, down-regulation of astrocyte PKC activity was also dose-dependent, with complete loss of activity at 1 µM PDBU (EC_{50} approximately 15 nM).

In other studies with neuronal cultures, preliminary results indicate that a 12.5 minute preincubation with 0.1 µM PDBU attenuates the release of the neurotransmitters normally seen in response to stimulation with 50 µM kainic acid.

These results demonstrate that PKC activity is present in cultures of neurons and astrocytes from the cerebellum, and that this enzyme can be down-regulated by phorbol ester in a way which is reversible and perhaps related to neurotransmitter release.

330.8 FORSKOLIN AND PHORBOL ESTERS MODULATE THE SAME K^+ CONDUCTANCE IN CULTURED OLIGODENDROCYTES. B. Soliven,* S. Szuchet,* B.G.W. Arnason, D.J. Nelson.* (SPON: P. Hoffmann) Dept. of Neurology, The Univ. of Chicago, Chicago, IL 60637.

Cultured ovine oligodendrocytes (OLG) express a number of voltage-dependent potassium currents as they attach and develop processes. At 24-48 hours following plating, a potassium outward current can be identified that represents a composite response of a rapidly inactivating component and a slowly or noninactivating component. After 4-7 days in culture, OLG also develop an inward rectifier current. We studied the effects of forskolin and 4-phorbol-12 myristate -13 acetate (PMA), compounds known to modulate the myelinogenic metabolism in these cells, on OLG outward currents. PMA, an activator of protein kinase C (PK-C), has been shown to enhance myelin basic protein phosphorylation while forskolin acting on adenylate cyclase increasing cAMP, inhibits it. Both forskolin and PMA increase the phosphorylation of 2' 3' cyclic nucleotide phosphodiesterase, an OLG/myelin protein. We have found that forskolin decreased the steady state outward current at 120 mV by 10% at 1 nM, and by 72% at 25 uM (n=6), from a holding potential of -80 mV. The time course of inactivation of the peak currents was decreased affecting both the fast and slow time constants. There was no significant change in the steady state parameters of current activation and inactivation. A reduction in the inward rectifier current was also observed. The effect of forskolin was attenuated when the adenylate cyclase inhibitor adenosine (2mM) was present in the intracellular/pipette filling solution. The results of PMA experiments (n=9) were similar to those obtained with forskolin. Whereas the amplitude of the currents in the presence of PMA was reduced by 30% at 1.5 nM and 60-70% at 600 nM, the decay phase of the peak currents was less affected. The PMA effect could still be seen when the intracellular Ca++ was reduced to 10^{-9}M with 5 mM BAPTA, but was inhibited partially when the cells were preexposed to 10 uM sphingosine, a PK-C inhibitor. We postulate that the potassium currents in OLG could be physiologically modulated by two distinct second messenger systems, perhaps converging at the level of a common phosphorylating enzyme or regulatory protein.

330.9 PHORBOL ESTER INDUCED SPONTANEOUS AND RHYTHMIC OSCILLATIONS IN ASTROCYTES IN VITRO B.A. MacVicar, S.A. Crichton,* D.M. Burnard, and F.W. Tse*. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada T2N 4N1

Glial cells of the mammalian central nervous have complex functions which are difficult to decipher because of the intimate intertwining of glial cells with neurons. Recent electrophysiological studies on pure glial preparations in primary tissue culture have identified voltage activated conductances to calcium, sodium, potassium and chloride, as well as calcium activated potassium conductances. To investigate the properties of astrocytes that have not been cultured we have developed an essentially neuron free preparation of CNS astrocytes in the kainic acid (KA) lesioned hippocampal slice. Following KA injection into the lateral ventricles, glial cells proliferated and neurons degenerated in the CA3 region thus allowing electrophysiological analysis of glial properties without neurons present. Histological examination of the hippocampus indicated that the CA3 region after KA injection was a gliotic area free of neurons as has been previously reported by many other investigators. With this preparation we have examined the effect of activating protein kinase C in astrocytes with a phorbol ester, TPA (12-O-tetradecanoyl-phorbol-13-acetate). Intracellular impalements were obtained from glial cells in KA lesioned hippocampal slices. Following TPA application (50nM) we observed that 60% of the cells (n=26) showed rhythmic oscillations which were 5-10 mV in amplitude and were associated with large changes in whole cell input resistance. An inactive phorbol ester, 4-α-PMA, did not induce oscillations. These oscillations were characterized by the following: rhythmicity, spontaneity, increased resistance during the depolarizing phase, sudden transitions from a high to a low resistance state, a waxing and waning of the phenomenon, reversability of the wave form around membrane resting potential, and lastly voltage sensitivity (whereby depolarization can decrease the frequency of oscillation). We postulate that the oscillations are due to sudden changes in potassium conductance that are evoked by oscillating intracellular calcium levels. These rhythmic oscillations in astrocytes could have profound effects in generating neuronal rhythmic activity in widespread areas of the CNS and perhaps also seizures.

330.10 CARBACHOL STIMULATES RHYTHMIC OSCILLATIONS IN ASTROCYTES S.A. Crichton* and B.A. MacVicar, (SPON: R. Berdan). University of Calgary, Calgary, Alberta, Canada T2N 4N1

Protein kinase C activation by phorbol esters induces spontaneous and rhythmic oscillations in astrocytes (see MacVicar et al.this meeting). These oscillations appear to be due to rhythmic changes in potassium permeability of astrocytes. Muscarinic receptors have been reported in glial cells in culture and in glioma cell lines. Activation of these receptors causes increased inositol phospholipid metabolism. This should, therefore, lead to protein kinase C activation. We have tested the effects of muscarinic activation in astrocytes in kainate (KA) lesioned hippocampal slices to see if the effects are similar to phorbol ester activation of protein kinase C.

Intracellular recordings were obtained from astrocytes in CA3 and CA4 region of KA lesioned hippocampi. The average resting potential was -76mV and the average input resistance was 10.5MΩ. These properties are similar to cells which we have stained with lucifer yellow and have shown to be astrocytes. Neurones were never impaled in the CA3 region of lesioned hippocampi. Following perfusion of carbachol (50-100μM), input resistance increased by an average of 9.35MΩ and a gradual depolarization, reversible in wash, was seen. In 8 out of 15 cells rhythmic changes in input resistance and membrane potential were observed 4 - 10 minutes following carbachol application. The behavior of these oscillations was quite variable in these cells, sometimes the rhythmicity lasted up to 30 minutes and sometimes for only a few minutes. The characteristics of these oscillations appeared to be the same as those induced by phorbol ester application. The depolarizing phase was associated with an increased input resistance and the sudden hyperpolarizing phase was associated with a decreased input resistance. The wave form reversed polarity around the estimated equilibrium potential for potassium. To ensure that these effects were mediated through a muscarinic receptor, carbachol was applied in the presence of atropine (a muscarinic antagonist). Atropine (10μM) blocked the depolarizing phase and the change in input resistance induced by carbachol; oscillations were not observed. Therefore, muscarinic activation in astrocytes induces an increase in input resistance and oscillations of membrane potential. Possibly this is due to activation of the phosphatidyl inositol pathway because activation of protein kinase C by phorbol esters also induces spontaneous and rhythmic oscillations. These rhythmic oscillations could have profound effects in generating neuronal rhythmic activity in widespread areas of the CNS and may play a role in generating the theta rhythm of the EEG.

330.11 PENTYLENETETRAZOL HAS DIRECT ACTIONS ON ASTROCYTES. D.M. Burnard and B.A. MacVicar. Department of Medical Physiology, Univ. of Calgary, Calgary, Alberta, T2N 4N1.

The electrophysiological properties of astrocytes are currently being investigated in a relatively neuron-free preparation, the kainic acid lesioned hippocampal slice. Recent work indicates that activation of protein kinase C in astrocytes with a phorbol ester results in spontaneous and rhythmic oscillations of membrane potential. The depolarizing phase of these oscillations is accompanied by an increase in input resistance (MacVicar et al., this meeting). Similar oscillations have been observed in astrocytes exposed to carbachol (Crichton and MacVicar, this meeting). It is hypothesized that these oscillations are due to rhythmic changes in the potassium permeability of astrocytes, which may be related to oscillating intracellular calcium concentrations. Such oscillations may cause rhythmic increases in extracellular potassium and thus rhythmically excite surrounding neurons. This could be a basic mechanism for seizure discharge. We have therefore investigated the action of a convulsant, pentylenetetrazol (PTZ), on the electrophysiological properties of astrocytes. PTZ causes bursting activity in neurons, profound displacements of intracellular calcium, and protein kinase activation.

Male Sprague Dawley rats (150 - 200 g.) received a bilateral intracerebroventricular injection of 1.0 μg kainic acid a minimum of two weeks prior to hippocampal slice preparation. Intracellular recordings of glia were reliably obtained in the intensely gliotic CA3/CA4 region of the hippocampus. Astrocytes were identified by their high resting membrane potentials, low input resistances and the absence of action potentials. Lucifer yellow (8%) injections confirmed that recordings were obtained from astrocytes, not neurons. PTZ (50 mM) was perfused into the bath for 5 to 15 min and changes in glial input resistance and membrane potential were recorded intracellularly.

The average resting membrane potential of astrocytes was 82.1 ± 2.7 mV. In the presence of PTZ (50 mM), glial membrane potential depolarized (3-9 mV) and in 60% of the astrocytes studied, spontaneous oscillations in input resistance and membrane potential were observed. There were both low and high frequency oscillations, and the increases in input resistance (25 - 50%) were typically associated with membrane depolarization.

These findings suggest that PTZ induces oscillations of membrane potential and input resistance in some glial cells. The mechanism underlying these oscillations remains to be determined, however it may be similar to the mechanism underlying phorbol ester induced oscillations. We are currently investigating whether or not these oscillations can be blocked by phenytoin, a widely used anticonvulsant drug.

330.12 ISOPROTERENOL ENHANCES CALCIUM CURRENT IN CULTURED ASTROCYTES F.W. Tse,* and B.A. MacVicar (SPON: Fred Quandt). Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada T2N 4N1

Astrocytes in tissue culture have voltage activated calcium channels and calcium activated potassium channels as well as voltage activated sodium, chloride and potassium currents. Receptors for several neurotransmitters such as norepinephrine, GABA, excitory amino acids and adenosine have also been found in glial cells and in some cases have been shown to regulate glial cAMP levels. In other cell types properties of the calcium channels are altered by neurotransmitters via cAMP. Therefore we have examined the effects of cAMP and isoproterenol (a beta-noradrenergic agonist which is known to increase cAMP in glial cells) on barium spikes and calcium currents in cultured astrocytes. Primary cultures of astrocytes were prepared from neonatal rats as described by MacVicar (Science 226: 133). Two microelectrodes (20 to 100MΩ) were used to impale the astrocytes to perform two electrode current and voltage clamping. Cells were impaled while superfused with artificial cerebral spinal fluid. Then a solution containing barium (10mM) TEA (10mM) 4-aminopyridine (0.2mM) and apamin (10nM) was superfused to enhance calcium currents and decrease potassium currents. In this solution injection of depolarizing current in some cells evoked barium spikes. Two electrode voltage clamping indicated that these cells had an inward current that was not blocked by TTX but was blocked by cobalt, cadmium or nifedipine. This inward current was reduced by lowering [Ba^{++}] in the solution; therefore, it is a barium current entering through calcium channels. In two electrode voltage clamp this current could be stable for up to two hours. Addition of isoproterenol (100μM) increased the barium current. This increase in barium current was mimicked by 0.5 mM dibutyryl cAMP (a membrane permeable form of cAMP). Therefore increasing cAMP intracellularly either by the addition of a cAMP analog or isoproterenol enhances calcium currents in cultured astrocytes. This agrees with a previous report (Chun et al.Soc. Neurosci. Abs. 12: (1986) 1346) that calcium currents could only be observed in cultured astrocytes that had been treated with cAMP. The function of this calcium current is unknown, although we have evidence that the morphological differentiation of astrocytes induced by cAMP or isoproterenol in tissue culture can be blocked by blocking calcium entry.

330.13 COMPARATIVE STUDIES OF BETA-ADRENERGIC RECEPTOR IN THE NEURON AND ASTROCYTE GLIA OF CEREBELLAR GRANULE CELLS. Y.Watanabe[1,2,3], T.Shibuya[1,2], S.Culp[3], C.Rabe[3] and B.Tabakoff[1,3] 1) Dept. of Biomed. Sci., Univ. of Ill. Sch. of Med. at Rockford, 1601 Parkview Ave., Rockford, IL 61107 2) Dept. of Pharmacol., Tokyo Medical College, Japan 3) Lab of Physiol. and Pharmacol., NIAAA, 12501 Washington Ave., Rockville, MD 20852

Primary culture of granule cells, prepared from cerebellum of 8 day old neonatal rats, were utilized in the characterization of Beta-adrenergic receptors on neurons and glia. The following assays were performed in cells cultured for 8 days in vitro (DIV): cyclic AMP (cAMP) radioimmunoassay; immunochemistry for determining the number of neurons and glia; radioreceptor assay for determining the characteristics of Beta-receptor. Isoproterenol (Iso) administration produced a dose dependent increase in the cAMP levels with a dose as low as 1 nM resulting in a significant change. The time course for stimulation of cyclase by isoproterenol was dose-dependent, with maximal accumulation within 5 min and this rate of formation was maintained for 30 min. Accumulation of Iso-induced cAMP was completely blocked by Beta-adrenergic antagonists but not Alpha-adrenergic antagonists. The binding to Beta-receptors of the 8DIV granule cell was characterized with ^{125}I-iodo-cyanopindolol (^{125}ICYP). For this membrane preparation, the affinity (K_D) and maximum binding sites (B_{max}) were 90.4 ± 9.4 pM and 32.0 ± 1.8 fmol/mg protein, respectively. The above results, like those of previous reports, are not sufficient to localize the binding sites to neurons. There is a slight contamination of this culture with glia (95.8 ± 1.0% neurons and 4.2 ± 0.6% glia). To determine if Beta-receptors exist on glia, a second set of cultures was prepared in which cytosine arabinoside, which prevents replication of non-neuronal cell, was not included in the culture media on 2DIV. The resulting glia rich culture was 49.9 ± 1.6% neurons and 50.1 ± 1.6% glia. ^{125}ICYP binding to membranes from this culture exhibit a K_D of 64.5 ± 13.8 pM and a B_{max} of 66.3 ± 6.7 fmol/mg protein. The glia rich 8DIV culture possessed approximately 2 times as many sites as the neuron rich 8DIV culture, reflecting a doubling of the total cell population when glia are allowed to replicate. Furthermore, Iso increased cAMP levels in the glia rich culture suggesting functional receptor sites. In summary, Beta-receptor is localized in both neuron and astroglia on 8DIV cerebellar granule cells. Moreover, the Beta-receptor appears to be more prevalent in glia than in neuron.

330.14 **GLIA CULTURED FROM DIFFERENT BRAIN REGIONS ARE HETEROGENEOUS WITH RESPECT TO ADRENERGIC RECEPTOR DENSITY.** *L. Lyandvert*, L. Iacovitti, P. Ernsberger, and D. J. Reis,* (SPON: D.H. Park). Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

It is generally believed that glia represent a homogeneous group of cells exhibiting no distinguishing features from one brain region to another. In this study, we examined the possibility that glia are regionally specialized with respect to their density of neurotransmitter receptor sites.

Mixed glial cell cultures were generated from a variety of brain regions from 1-2 day old rats (McCarthy & DeVellis, *J. Cyc. Nucl. Res.* 4:15-26 1978). Cells were trypsin-dissociated, plated onto plastic dishes at a density of 4 x 10^5 cells/cm^2, fed media containing 15% fetal calf serum, and maintained in a humidified atmosphere of 97% air and 3% CO_2. The complete absence of immunoreactivity for neuron-specific enolase (NSE) and the presence of immunoreactivity for glial fibrillary acidic protein in the vast majority of cells (> 95%), indicated that the cultures contained nearly pure populations of glial astrocytes. Two to three weeks after plating, the cells were harvested, homogenized in a teflon-glass homogenizer, and membranes (P_2 fraction) were prepared and washed for radioligand binding assays for α_2- and β-adrenergic and muscarinic acetylcholine receptors (Ernsberger & U'Prichard, *Life Sci.* 38:1557, 1986). α_2- and β-adrenergic and muscarinic receptors were assayed by incubating membranes with ^{3}H-*p*-aminoclonidine (1 nM), ^{3}H-dihydroalprenolol (0.4 nM), or ^{3}H-quinuclidinyl benzylate (0.4 nM), respectively, for 20-60 min at 25° C. Nonspecific binding was defined in the presence of either guanabenz (10 μM), (±)-propranolol (1 μM), or atropine (1 μM). Muscarinic receptors could not be detected in glial membranes, indicating that not all neurotransmitter receptors are present in glia. Shown below is specific adrenergic receptor binding to glial membranes from each region expressed as sites per cell (n=3 to 11):

	Cortex	Caudate	Midbrain	Sup. Col.	Hypothal.	Hippocampus
α_2	14±1	5±1	8±2	17±2	12±1	8±1
β	60±6	24±3	37±6	16±4	16±4	28±2

The number of receptors detected per cell varied 3-fold from the highest to lowest regions for both adrenergic subtypes. It is unlikely that this variation is due to contamination with neurons, since a) the cultures are devoid of cells containing NSE immunoreactivity and b) the regional distribution of receptors in glia was unrelated to the distribution in whole tissue as previously determined by receptor autoradiography (rank-order correlation = -0.54 for α_2 and 0.29 for β-receptors). There was no significant tendency for regions enriched in one adrenergic subtype to be enriched in the other (r = 0.53 for the correlation between α_2 and β-receptor density, p > 0.10). We conclude that (a) muscarinic receptors appear to be absent in cultured glia, and (b) adrenergic receptors in glia are regionally distributed. Therefore, the anatomical mapping of receptors may reflect variations in glial as well as neuronal function since glia may also be heterogeneous with respect to their expression of neurotransmitter receptors. (Supported by NIH grant 18974, N.Y. Heart Assoc. Postdoctoral Fellowship to P.E.)

330.15 GLIAL CELL PROLIFERATION AND ION CHANNELS: A POSSIBLE LINK Donald G. Puro. Bascom Palmer Eye Institute, University of Miami, Miami, FL 33101.

A variety of pathophysiological conditions in the adult CNS are associated with the proliferation of glial cells. For example, in the mammalian retina, glial cell proliferation may occur under abnormal conditions such as inflammation, ischemia and diabetes. Since a breakdown of the retina-blood barrier is a feature often found in retinal disorders associated with glial cell proliferation, an hypothesis is that certain plasma-derived molecules are mitogenic for retinal glial cells. At present, the regulation of glial cell proliferation is poorly understood. In this report, I began to examine the possibility that the activity of certain ion channels play a role in the response of retinal glial cells to mitogens.

Experiments were performed on glial cells dissociated from adult rat retinas and maintained in cell culture. The cells stained positively by immunocytochemistry with antibodies specific for glial fibrillary acidic protein and with Muller cells of the rat retina. Patch clamp studies of these glial cells previously demonstrated a diversity of ion channels including a calcium-activated potassium channel with a high conductance (124pS, SD=37) and a sensitivity to tetraethylammonium. In this study, the activity of this class of potassium channel was assessed prior to and after exposure to a conditioned medium that is obtained from spleen cells and is mitogenic for cultured retinal glial cells. Within one hour of exposure to the conditioned medium, ion channels having outward currents and conductances >100pS at 32° demonstrated an increase in the percent of time that they were opened at various depolarizing potentials. Another indication of a possible link between the activity of potassium channels and the action of mitogens was suggested by the finding that tetraethylammonium (20mM) virtually eliminated the proliferative effect of the conditioned medium on retinal glial cells. These experiments are consistent with the notion that the activity of certain potassium channels may play a role in the proliferative response of retinal glial cells to mitogens produced by the immune system in the course of intraocular inflammation.

330.16 **A CABLE MODEL OF THE ELECTRICAL PROPERTIES OF RETINAL MULLER CELLS.** R. L. Winslow*, R. F. Miller, and P. A. Coleman* (SPON: C. Blazynski). Inst. Biomed. Comp. and Dept. Opth., Washington Univ. Sch. Med., St. Louis, MO, 63130.

The membrane resistance of retinal (Muller) glial cells is highly non-uniform, with roughly 95% of the cell membrane conductance localized to the endfoot region (Newman, J. Neurosci. 5(8):2225). The charging curves of isolated Muller cells also exhibit an exceptionally fast rise-time (Newman, J. Neurosci. 5(8):2225). We have attempted to relate these two observations by formulating a simple cable model of the Muller cell. In this model, the distal end, cell body, and stalk is represented by an equivalent cylinder. The highly localized conductance of the the endfoot region is modeled by terminating the cylinder with a resistor. We have derived an expression specifying membrane potential in response to a current pulse injected into the cylinder. Simulation results show that a current pulse injected at the distal end produces changes in voltage at the site of current injection with a rise time which can be significantly faster than that of a semi-infinite cable. Decreases in the electrotonic length of the cylinder or increases of the value of the terminating conductance produce monotonic decreases in the rise time of model charging curves.

The model is completely specified by three parameters: A) the electrotonic length L of the cylinder; B) the percentage P of input conductance accounted for by the endfoot; C) the membrane time constant τ. We have derived an algorithm for generating estimates of these parameters given an experimentally measured charging curve and estimated values of the exponents of the first two terms of the series representation of this response. Performance of the algorithm has been tested using simulated data. We have used the algorithm to estimate parameter values that yield best fits to charging curves obtained from both dissociated tiger salamander (*Ambystoma tigrinum mavortium*) Muller cells as well as Muller cells in the intact retina eyecup preparation. Estimated parameter values obtained from measurements in dissociated cells are $L \approx .38$, $\tau \approx .9$msec, and $P \approx 95\%$. Muller cell charging curves obtained using measurements from the eyecup preparation exhibit rise-times which are clearly slower than those recorded from dissociated cells. Parameter values estimated using these data are $L \approx 2$, $\tau \approx 1.0$ msec, and $P \approx 98\%$. These two sets of data support the finding that a significant fraction of Muller cell membrane conductance is localized to the proximal face of the endfoot region. These data differ significantly in the rise time of the charging curves, and in the estimated values of electrotonic length. These differences may result from an alteration of the physical dimensions of Muller cells due to the dissociation procedure. We consistently noted that dissociated Muller cells become less elongated and more spheroidal after dissociation, a distortion which may tend to decrease L. Simulations have shown that a decrease in L results in charging curves with faster rise time.

An extreme non-uniformity of membrane conductance may be common to all astrocytes, and may play an important role in the spatial buffering of extracellular K^+. The development of simple procedures for estimating the degree of this non-uniformity should have important implications for the analysis of glial function in a variety of normal and abnormal states.

330.17 ELECTROPHYSIOLOGY AND MORPHOLOGY OF EPENDYMAL CELLS AND TANYCYTES IN RAT HYPOTHALAMUS. C.R. Jarvis and R.D. Andrew. Anatomy Dept., Queen's University, Kingston, Ontario K7L 3N6.

The ependyma lines the ventricular system of the vertebrate brain and spinal cord. Although its embryology and morphology have been studied extensively, little is known of its physiological properties, particularly in mammals. Tanycytes are modified ependymal cells that are found predominently lining the floor of the third ventricle, overlying the median eminence (ME). Their processes accompany and enwrap neuroendocrine axons that course from hypothalamic nuclei to terminals in the ME but the significance of this interaction is not yet understood.

Intracellular recording and injection techniques were used to study ependymal cells and tanycytes of the rat in the hypothalamic slice preparation after differentiating their respective regions morphologically. At rest, the mean membrane potential $\pm$ SD for common ependyma was 79.9 $\pm$ 1.40 mV (n=30) and for tanycytes 79.5 $\pm$ 1.77 mV (n=46). From the Nernst equation, these values indicate that K^+ is the primary ion determining Vm, considering $[K^+]_o$=6.24 mM. Input resistances (Rin) were very low (<< 1 Mohm). Single cell injection of Lucifer Yellow, a fluorescent dye of low molecular weight, revealed dye coupling among 2-70 ependymal cells or 5-48 tanycytes. In both freeze-fractured replicas and thin sections, large numbers of gap junctions were found between adjacent ependymal cells or between adjacent tanycytes. The observations of numerous gap junctions, extensive dye coupling, and low input resistance, demonstrated that both ependymal cell and tanycyte populations in mammals are strongly coupled networks. Perhaps for this reason, attempts to uncouple these cells using sodium propionate, chlorpromazine or CO_2 were unsuccessful.

Electrical stimulation of the arcuate nucleus did not elicit any synaptic response in impaled tanycytes, so that the functional significance of synaptoid contacts between neuroendocrine neurons and the postsynaptic tanycytes is not yet apparent.

Ependymal cells and tanycytes demonstrated a near Nernstian response to changes in extracellular $[K^+]$ between 3 and 20 mM. This finding, as well as their high negative resting potential, low Rin, electrical inexcitability, and extensive coupling demonstrate that ependymal cells possess numerous glial characteristics and therefore may have similar functions. The high K^+ permeability of tanycyte cell bodies suggests that their processes may buffer the extracellular [K+] by taking up K+ released from adjacent neurons and shunting it to the ventricular space.

REGENERATION: PNS

331.1 LOCALIZATION AND AXONAL TRANSPORT OF B50 (GAP43) IN REGENERATING RAT PERIPHERAL NERVES: ASSOCIATION WITH OUTGROWING AXONS AND SCHWANN CELLS. M.A.Bisby, H. Zwiers* and W. Tetzlaff* (SPON: H.B. Sarnat). Dept. Med. Physiology, Univ. of Calgary, Calgary, Alta, T2N 4N1, Canada.

The synaptic phosphoprotein B50 has been shown, by several laboratories, to be identical to growth-associated protein (GAP) 43, whose synthesis and axonal transport is greatly increased in regenerating peripheral axons. We have used an affinity-purified rabbit antibody to rat brain B50 to investigate the localization and axonal transport of B50/GAP43 in regenerating peripheral nerve.

Nerve segments were processed for one-dimensional SDS-PAGE and Western blots were probed with antibodies to B50, then labelled with alkaline phosphatase-conjugated goat anti-rabbit immunoglobulins. The greatest amount of B50-like immunoreactivity occurred within newly-regenerated axons, approximately midway between the site of injury and the point of maximum outgrowth.

Immunocytochemistry, using rhodamine-conjugated goat anti-rabbit immunoglobulins as secondary antibody, revealed intra-axonal B50-like immunoreactivity in the nerve proximal to the injury, as well as in newly regenerated axons close to the point of maximum outgrowth. However, in the zone of greatest immunoreactivity, label was associated not primarily with axons but with apparent Schwann Cell profiles of the bands of Büngner, enclosing neurofilament-containing axons.

Conventional ligature techniques were used to measure anterograde and retrograde transport of B50-like immunoreactivity in regenerating sciatic nerve proximal to the injury. Only about 1/6 of the B50 appeared mobile, and 3-4 times as much was transported in the anterograde direction as in the retrograde direction. Anterograde velocity was 6.3 mm/hr, consistent with previous data for fast transport of GAP43.

As expected, B50-like immunoreactivity was increased in regenerating nerve. The association of immunoreactivity with structures other than axons was unexpected, and raises the possibility that B50/GAP43 can be secreted from regenerating axons.

331.2 TIME DEPENDENT CHANGE IN ACTIVITY OF RAT MEDULLARY RESPIRATORY NEURONS REGENERATING AXONS INTO PERIPHERAL NERVE GRAFTS. P. Gauthier* and M. Rasminsky. Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Quebec, Canada H3G 1A4.

Autologous segments of peroneal nerve were implanted into the medulla oblongata of young adult rats. To investigate activity of medullary respiratory neurons regenerating axons into these grafts, unitary recording from single fibers was performed on small strands teased from the grafts in anesthetized, curarized and artificially ventilated rats. Central respiratory rhythm was monitored by recording phrenic nerve activity.

Spontaneous respiratory related activity was observed in teased fibers in 5 of 9 grafts recorded 2 to 5 months after graft implantation. All but one of 42 respiratory related units were identified as efferent inspiratory or expiratory units because of their persistent respiratory related activity during arrest of artificial ventilation. Medullary respiratory neurons include both intrinsic neurons having their axonal projections entirely within the CNS and cranial motoneurons projecting their axons towards the periphery. Patterns of spontaneous activity of some recorded units were characteristic of intrinsic brainstem respiratory neurons rather than of cranial motoneurons. The persistence of activity with deepening level of anesthesia seen in most units was also characteristic of intrinsic brainstem respiratory neurons. In the 2 to 5-month grafts, the integrity of the input connections to the neurons that had regenerated axons was manifested not only by normal patterns of activity but also by the responsiveness of firing patterns to lung hyperinflation and by the interruption of inspiratory discharge of graft units by vagal stimulation (inspiratory off-switch effect).

Ten grafts were studied 9 to 11 months after implantation. Five were blind-ended, as in the 2 to 5-month grafts; the distal ends of five other grafts were implanted into the left C4 ventral horn. No spontaneous respiratory activity was found in fibers teased from any of the 9 to 11-month grafts inserted into the brainstem.

These results suggest that there may be only a limited period of time following graft implantation during which a peripheral nerve graft can exert a supportive effect on function and/or survival of the CNS neurons innervating the graft with regenerated axons. In our small preliminary sample of bridge grafts, recordings from the left phrenic nerve revealed no physiologic evidence of functional connection between electrically stimulated graft fibers and phrenic motoneurons. It remains to be established whether interaction between appropriately placed terminals of fibers regenerating in the grafts and target neurons will have a stabilizing effect on the function and/or survival of neurons regenerating axons into peripheral nerve grafts.

331.3 CHOLINERGIC NEURONES IN THE VAGAL AFFERENT FIBRES. J.P. Ternaux*, B. Palouzier*, M. Falempin*, C. Simon*, P. Portalier* and M-C. Chamoin-Barrit* (SPON: J.P. VEDEL). INSERM-U.6 and CNRS-UA634, 280 Bd Sainte-Marguerite, 13009 Marseille, France.

In various mammalian species the anastomosis of vagal afferent fibres, cut above the nodose ganglion, with the fibres of the peripheral end of the spinal nerve is followed, several months after, by a functional reinnervation of the sterno-cleido-mastoïd muscle (SCM). This heterogeneous suture allows, in chronic sheep and rabbit, the characterization of various interoceptors located in the upper part of the digestive tract, by simply recording the EMG activities of the reinnervated SCM muscle.

Since muscular fibres are reinnervated by vagal afferent neurones, it can be assumed that some of these fibres contain acetylcholine (ACh) or may be that some afferent neurones are able to express cholinergic potentialities when sutured with the spinal nerve.

Various biochemical results indicate the presence of an ACh neuronal system in the vagal afferent fibres of both rat and rabbit. In the nodose ganglion, which contains all the cell bodies of the vagal afferent fibres, choline acetyl transferase (ChAc) as well as acetylcholine esterase (AChE) activities can be detected. An uptake of choline is also measured and seems to be related to a high affinity transport of the precursor. Finally, ACh endogenous content as well as release can be detected in the nodose ganglion. Release from cell bodies is sodium- and calcium-dependent and indicates that afferent messages can be controlled at nodose level.

Presence of a cholinergic pool in afferent vagal fibres is also confirmed by the immunohistochemical determination of ChAc in some cell bodies of the nodose ganglion.

In the sutured nodose ganglion of the rabbit, ChAc activity as well as ACh content decrease until four months. Five months after the suture when electrophysiological activities can be recorded from the SCM muscle, the amount of ACh detected in the sutured ganglion is higher compared to four months. In the non sutured ganglion the endogenous ACh is first enhanced and then decreases suggesting the involvement of a compensatory mechanism.

331.4 $pp60^{c\text{-}src}$ PROTEIN-TYROSINE KINASE IS STRONGLY INDUCED IN REGENERATING SCIATIC NERVE. J.M. Le Beau and G. Walter*, Department of Pathology, University of California, San Diego, La Jolla, California 92093.

$pp60^{c\text{-}src}$, the cellular homolog of the transforming protein of the Rous sarcoma virus oncogene, $pp60^{v\text{-}src}$, is a phosphoprotein with a high tyrosine kinase activity in the nervous system. Recent findings have implicated the expression of $pp60^{c\text{-}src}$ with CNS neuronal differentiation and function. In the present study we asked whether $pp60^{c\text{-}src}$ was associated with Schwann cell and axonal differentiation during peripheral nerve regeneration. To examine this, a model of regeneration was used in which the proximal and distal stumps of a severed rat sciatic nerve were sutured into a 14 mm long silicone tube. Regeneration across the 10 mm gap was accomplished by 35-42 days following nerve-transection. Segments of regenerated nerve as well as other associated tissues were extracted at various times following nerve transection and analyzed for c-src activity by in vitro kinase assays. An induction of c-src kinase activity occurred at 7 days following nerve transection in segments of regenerated nerve. This activity increased with post-transectional time, reaching a level that was 10-15 fold greater than control nerve at 21-28 days following nerve transection. Significant changes in kinase activity were not observed in other tissues associated with regenerated sciatic nerve (i.e. spinal cord and dorsal root ganglia). Western blotting experiments showed results similar to those of in vitro kinase assays suggesting that the altered expression of $pp60^{c\text{-}src}$ was due to an increase in protein synthesis rather than specific activity. Since the increased expression of $pp60^{c\text{-}src}$ in regenerated nerve segments coincided with both axonal sprouting and myelination, c-src may play a role in these events during nerve regeneration. Cellular and sub-cellular localization of $pp60^{c\text{-}src}$ in regenerated nerve segments are currently in progress.

331.5 IMMOBILIZED FIBROBLAST GROWTH FACTOR AFFECTS PERIPHERAL NERVE REGENERATION IN A SILICONE CHAMBER MODEL. N. Danielsen*, H.L. Vahlsing*, B. Pettmann*, M. Manthorpe and S. Varon (SPON: H. Muller). Dept. of Biology, Univ. California San Diego, La Jolla, CA 92093.

The silicone chamber model allows the investigation of the cellular and molecular events underlying successful regeneration of a peripheral nerve. We report here a modification of the standard silicone chamber into a two-compartment model which also allows the investigation of the effects on nerve regeneration of initially immobilized growth factors. Two opposing longitudinal grooves were cut into the interior surface of a silicone tube (1.8 mm I.D., 14 mm long). A strip of nitrocellulose paper was then inserted into the grooves, thus dividing the chamber into two compartments. Before insertion, the nitrocellulose strip was soaked overnight in saline (control) or saline containing purified basic Fibroblast Growth Factor (FGF). The chambers were used to entubate a 10 mm gap between the proximal and distal stumps of the rat sciatic nerve as done in previous studies. The rats were sacrificed 16 days after chamber implantation and the nerve regenerates were processed for light microscopy. Macroscopic observations revealed that in both control (n=8) and FGF (n=4) chambers, regenerates formed on each side of the nitrocellulose partition and adjacent to it. The migration of the cellular elements (perineurial-like cells, vasculature and Schwann cells) into control chambers was restricted to 1-3 mm from the proximal and distal nerve stumps. At mid-chamber level (5 mm) control chambers still displayed "blood-lakes" within a fibrin matrix. In contrast, FGF-containing chambers showed a vascularized cellular structure across the gap in 3 out of 4 chambers. Statistically significant differences were observed between control and FGF chambers in the spatial progress of migrating perineurial-like cells, vasculature and Schwann cells, while the differences in axonal elongation were not significant in this limited series. Thus, initially immobilized FGF promotes both the vascularization of the nerve regenerate and the migration of perineurial-like and Schwann cells into the regenerate.

331.6 MOTONEURON--MUSCLE UNIT MISMATCHES IN REINNERVATED SOLEUS MUSCLE. GW Sypert, RC Foehring & JB Munson Univ of Florida, Gainesville.

When a fast muscle is cross-innervated by a nerve formerly innervating a slow muscle, the fast muscle fully acquires slow-muscle properties. In the reverse cross, however, the formerly slow muscle partly retains slow properties (1). In normal or self-reinnervated MG motor units (2), and in LG muscle units cross-innervated by MG motoneurons (3), a close correspondence exists between electrical properties of motoneurons and contractile properties of their innervated muscle units (5). When MG motoneurons cross-innervate soleus muscle [a slow muscle which resists conversion by fast motoneurons (1)], most motor units consist of either slow motoneurons (electrical properties) innervating slow muscle units (contractile properties) or fast motoneurons innervating fast muscle units (as above) (3). In a few cases, however (6 of 44), there are apparent mismatches; i.e. fast motoneurons innervating slow muscle units.

We further investigated this apparent anomoly in 4 cats by self-anastomosing the LG-soleus nerve and analyzing the properties of reinnervated soleus motor units 6 mos later. Of 69 motoneurons studied, 47 innervated LG and 22, soleus. These percentages (68% and 32%) mirror the 2:1 proportions of alpha motoneurons in each muscle and suggest that, as in the rat (4), neither muscle has an advantage in recapturing motor axons, despite the fact that axons destined for soleus must first traverse LG. Analysis of contractile properties of motor units in soleus showed 16 slow-twitch and 3 fast-twitch units (the latter all type FR; 3 others not fully analyzed). As with cross-innervated MG-->soleus (3), the motor units of 5 of the 16 slow-twitch units had motoneurons with "fast" properties, in particular AHP half-decay time <30 ms (5). Other properties of these motor units (rheobase, input resistance, conduction velocity, twitch time-to-peak) were also consistent with their being former (probably LG) fast motoneurons now innervating soleus muscle units classified as slow on the basis of their contractile properties (cf 2).

We conclude that regenerating LG and soleus motor axons express no preference to regenerate through endoneurial tubes of their former type or muscle, nor to reinnervate their former muscle (cf 4). Some fast motoneurons respecify the contractile properties of their innervated soleus muscle units, but others do not. Enduring motoneuron-muscle unit mismatches are the result.

331.7 IMPAIRMENT OF SCIATIC NERVE REGENERATION BY PROTEASE INHIBITOR TREATMENT: INHIBITION OF SCHWANN CELL MIGRATION. N. Kalderon, J.P. Kirk*, and A. Juhasz*. The Rockefeller Univ. New York, NY 10021.

The Schwann cell is an essential component in support of the repair process of an injured nerve. The present study is focused on the elucidation of one of the biochemical processes which is elaborated by the Schwann cell and is instrumental in successful nerve regeneration. Schwann cells, the proliferating populations, express high levels of plasminogen activator activity (Kalderon, PNAS, 81:7216, 1984). During nerve regeneration the Schwann cells seem to precede the regenerating axons. The temporal sequence of events in peripheral nerve regeneration in a model system, through a 10mm silicone chamber, has been established: (a) within one week postsurgery, an acellular fibrin bridge is formed between the nerve stumps; and (b) in the second week, extensive migration within this bridge of Schwann cells and other cells takes place, while the regenerating axons lag by 1-2 days behind the Schwann cells (Williams et al., J. Comp. Neurol., 218:460, 1983). The experiments described in this report examine the idea that Schwann cells utilize proteolysis to invade, paving the way for the regenerating axons. For this purpose we are studying the effects of protease inhibitors on rat sciatic nerve regeneration through a 10mm silicone chamber and herein describe the effects of the plasmin inhibitor, E-aminocaproic acid. The sciatic nerve was cut and the stumps were sutured to a silicone tubing which was filled with a physiological salt solution. The inhibitor was injected into the chamber (final concentration of 0.5 mg/ml) at seven days postsurgery, at which time a massive cell migration was about to occur, and its effect on nerve regeneration was examined a week later. Samples were processed for cryostat sectioning, sectioned through their horizontal axis and then were analysed in parallel for: cell content, regenerating axons, morphology, etc. The effect of the inhibitor was unambiguously clear: it inhibited the cell migration into the chamber. Analysis with thionin staining revealed that while cells filled up the entire bridge between the nerve stumps in the control samples, cell migration was impaired by the presence of the inhibitor leaving a gap of 2-5mm without any cells. Analysis of the extent of axonal elongation by immunocytochemistry with antibodies against neurofilaments revealed that the neurites advanced for 7-8mm in the control, and only for 2-4mm in the presence of the inhibitor. It is concluded that in the process of nerve regeneration, Schwann cells utilize proteolytic activity to invade/migrate, since inhibition of this activity prevented cell migration; accordingly, axonal regrowth was delayed.

Supported by NIH (NS23064) and Spinal Cord Research Foundation.

331.8 **EARLY DIFFERENCES IN PNS AXONAL REGENERATION WITHIN TUBULAR PROSTHESES FILLED WITH LAMININ VS. COLLAGEN MATRICES.** I.J. Kljavin*, R. Madison, and R.L. Sidman. (Spon:Brooke Seckel). Depts. of Neuropathology and Neuroscience, Harvard Medical School and Children's Hospital, Boston, MA. 02115

Entubulation repair experiments have shown that modification of the local environment within the tube can change the rate of axonal regeneration. At 2 to 4 weeks post-section more axons cross a 4mm nerve gap within laminin-containing than collagen containing tubes. The present study examines cellular relationships in the first 12 days post-section that may account for the differences in axonal regeneration noted at later times in the laminin and collagen matrices.

One sciatic nerve in adult male C57BL/6J mice was transected at midthigh level. Proximal and distal nerve stumps were sutured into the ends of a 6mm long Tygon tube, maintaining a 4mm gap between stumps. The tube lumens were filled either with a laminin-rich gel (gift of Drs. Kleinman and Martin, NIH), or a collagen matrix (Vitrogen-100, Flow Laboratories). Three animals from each group were killed at 1,3,5,7,10 and 12 days after implantation, tissues processed for light and electron microscopy, and examined in longitudinal sections.

Up to 3 days post-implantation, both laminin-rich and collagen samples showed a distinct cellular border, composed mostly of RBC's and macrophages, between the stumps and matrix. No cells entered either matrix until 5 days, at which time axonal sprouts were still confined to the stump. By 7-12 days, putative Schwann cells, fibroblasts, and endothelial cells had migrated even further into the matrices, and the first morphological differences in outgrowth within laminin and collagen were seen. Outgrowth from the proximal and distal stumps extended up to 1.0mm in laminin and up to 0.5mm in collagen at 7 days. The cellular density was less in the laminin-rich matrix (11 cells/0.1mm), compared to collagen (25 cells/0.1mm). This difference became more obvious at 10 and 12 days, when cells extended across the entire gap. The extent of axonal growth was independent of nonneuronal cell density, and matched the distribution of putative Schwann cells furthest from the proximal stump. Thus, axons typically had extended further from the proximal stump in the laminin samples. Reconstructions from serial sections revealed that in the laminin matrix, some axonal portions were free from cell contacts, (naked), whereas in the collagen samples the complete axonal surface was associated with Schwann cells. Axonal numbers appeared similar in both matrices.

The greater length of axons in the laminin-rich matrices thus appeared related to the faster outgrowth of supporting cells, probably Schwann cells, but did not correlate with the concentration of nonneuronal cells.

331.9 ANTIBODIES TO THE NEURAL CELL ADHESION MOLECULE DISRUPT CELL INTERACTIONS IN REGENERATING ISCHIATIC NERVES. L.G. Remsen,* G.M. Strain, A.A. Smith,* and J.K. Daniloff, Veterinary Anatomy & Fine Structure, and Physiology, Pharmacology & Toxicology, LSU School of Veterinary Medicine, Baton Rouge, LA 70803

The neural cell adhesion molecule (N-CAM) mediates homophilic binding between neurons; although also present on Schwann cells, its function there is unknown. Previous studies suggested that modulation of N-CAM is critical for regrowth of nerve fibers (Daniloff et al., 1986, J. Cell Biol. 103:929). The aim of the present study was to elucidate the contributions of N-CAM to regeneration by using antibodies to N-CAM to disrupt it.

Monoclonal antibodies (Ab) were raised against major polypeptide components of rat and chicken N-CAM. Ab or their Fab' fragments were concentrated (100 ug/ml) into a solid collagen gel (Vitrogen; Collagen Corp) within pieces of inert, sterile silastic tubing. Control tubes contained nonspecific Ab isolated from nonimmune mice, or Ab to Thy-1. A 4-mm section of one ischiatic nerve was removed from adult rats and chickens. Gel containing tubes were then surgically attached to the nerve stumps with epineurial sutures. After 10 or 30 days, muscle and somatosensory evoked potentials were recorded to assess the return of function. Animals were then killed and their nerves were prepared for light and electron microscopy and immunoblot analysis.

In short-term survivors, Ab disrupted interactions between both neural and nonneural cells within the tubes and produced abnormal gaps between them. At 30 days after implantation, regenerating fibers and nonneural cells had grown out and around the tubes to join the distal stumps. No such growth was observed in controls. Minimal responses to stimulation returned in some experimental animals after 30 days, although no significant differences were observed at that survival time. Physiological data recorded from long-term survivors (45 and 90 days) were used to compare the return of function in all experimental conditions. The number of nerve cells/unit area was measured in sections of nerves labeled with Ab to neurofilament protein. Relative number and position of Schwann cells and fibroblasts were analyzed in sections labeled with Ab to S100 protein and fibronectin, respectively. Results are discussed relative to potential contributions of N-CAM to regeneration of the peripheral nervous system.

331.10 CYTOSKELETAL CHANGES IN AXOTOMIZED HAMSTER CORTICOSPINAL NEURONS: SIMILARITIES AND DIFFERENCES TO THE METABOLIC RESPONSE EXHIBITED BY PERIPHERAL NEURONS. M.M. Oblinger, M. Vanefsky* and J. Pickett*. Dept. Biol. Chemistry & Structure, Chicago Medical School, North Chicago, IL 60064.

Aspects of the axotomy response in peripheral neurons have been well characterized but little is known about the molecular response of central mammalian neurons to injury. Among the prominent changes that ensue after axon injury in the peripheral nervous system are a decrease in the synthesis and axonal transport of neurofilament (NF) proteins and a corresponding increase in tubulin (TUB) and actin (Oblinger and Lasek, 1985). Recent studies using specific cDNA probes have revealed that mRNA levels for major cytoskeletal proteins in peripheral neurons change after axotomy (Hoffman et al., 1987). In this study we have examined whether the axotomy response of a class of CNS neurons is similar to that exhibited by mammalian PNS neurons. Corticospinal neurons were studied because these long projection neurons are easily axotomized in the spinal cord and because slow transport and other aspects of the cytoskeleton in normal axons has been well characterized (Oblinger, 1987).

Hemisections of the upper cervical spinal cord (C4) were made in adult male Golden hamsters. In one series of experiments, animals were sacrificed 1d to several weeks later and the brains and spinal cords were removed and frozen. Samples of motor cortex, corticospinal tracts and spinal cord on the lesioned and normal side were homogenized in phosphate buffer, assayed for total protein, diluted with an equal volume of 2% SDS, 16M urea, 4% BME .2M Tris, pH 6.8 and subjected to SDS-PAGE. Immunoblotting of this material using various monoclonal antibodies (phosphorylated and nonphosphorylated NF proteins, beta tubulin, microtubule associated proteins) revealed that marked changes in the levels of cytoskeletal proteins resulted after injury. These changes included a reduction in NF proteins that became quite prominent 5-14 days after injury. The magnitude of change in tubulin levels in injured corticospinal axons was much less marked. Preliminary results obtained on corticospinal neurons in the motor cortex using NF and TUB specific probes are consistent with the changes observed in the axons by immunoblotting. Thus, the axotomy response of these CNS neurons is both similar to (NF) and different from (TUB) the response of PNS neurons to injury.

Supported by NIH grant NS-21571.

331.11 BYPASSING SPINAL CORD LESIONS USING PERIPHERAL NERVE GRAFTS.
V. M. Romano*, S. J. Blair* and R. D. Wurster. (SPON:C. Robinson) Departments of Orthopaedics and Physiology, Loyola University Medical Center, Maywood, IL 60153 and Rehab. Research & Development Center, Hines Veterans Adm. Medical Center, Hines, IL 60141.

Following spinal cord lesion, voluntary function below the lesion is permanently lost. Many attempts to "bridge" these lesions, spinal cord to spinal cord, have met with limited success. In this pilot study, we have successfully "bypassed" a spinal cord lesion by anastomosing a peripheral nerve above the lesion to a peripheral nerve below the lesion.

In Group A (sham surgery, N-12), the femoral and tibial nerves, innervated by L3-4 and L4-6, respectively, were exposed on one side, but left intact. In three other groups, these two nerves were transected. In Group B (fem-tib BP, N=12), the distal tibial nerve was anastomosed to the proximal femoral nerve by tunnelling it under the adductor muscles. In Group C (tibial reanast., N=12), the tibial nerve was reanastomosed to itself. In Group D (cut tibial, N=12), the nerves were left divided. Periodically, the rats were tested for recovery of lower hind limb motor function using the twitch-tension method (i.e., transcutaneously stimulating the spinal cord and recording the strength of foot flexor contrastion via a transducer attached to the middle toe).

After 4-6 months, motor recovery was 99, 72, 54, and 31% for Groups A-D, respectively ($p<.05$ for all combinations). HRP studies confirmed that innervation to the operated lower hind limb of Group B was higher in the spinal cord (L3-4 level) than in Groups A and C (L4-6) and absent in Group D (except in two animals where some reinnervation occurred because of close approximation of the nerve stumps). Furthermore, after an L4 spinal transection, motor function remained only in the operated side of Group B and was absent in the unoperated side of Group B and both sides of the remaining groups; thereby "bypassing" the spinal lesion to retain function by re-routing the peripheral nerves.

In the hope of some day being able to return useful function to spinal patients via peripheral nerve bypassing, further studies using more proximal peripheral nerves along with nerve grafts for length are necessary.

331.12 FIBRIN GLUE VS BIORESORBABLE TUBING VS CONVENTIONAL ANASTOMOSIS IN PERIPHERAL NERVE REPAIR: A FUNCTIONAL COMPARISON.
R. D. Wurster, V. M. Romano*, S. J. Blair* and J. M. Kerns. (SPON: C. L. Webber, Jr.) Departments of Physiology and Orthopaedics, Loyola University Medical Center, Maywood, IL 60153, Rehab. Research Development Center, Hines Veterans Adm. Medical Center, Hines, IL 60141, and Anatomy Department, Rush Medical College, Chicago, IL 60612.

Many techniques are available for peripheral nerve repair, but few have shown clear functional superiority. The results of nerve reanastomosis using fibrin glue have been variable, most likely because of the lack of consistency of the glue. Nerve guide tubes have been used to span gaps; but are they better than conventional repair when length is not a problem?

In 18 adult male rats, the tibial nerves were exposed bilaterally at mid-thigh and, via random assignment, either crushed (CRUSH, N=9) or divided and reanastomosed using: conventional epineural repair with two 10-0 sutures (SUTURE, N=9); a two-component fibrin seal (GLUE, N=9); or a 1 mm internal diameter, 6 mm length, bioresorbable nerve guide tube with a 1-2 mm nerve gap (TUBE, N=9). Recovery of tibial nerve motor function was assessed at weekly intervals by the twitch tension method (i.e., percutaneously and supramaximally stimulating the sciatic nerve and recording the tension developed by the digital flexors via a transducer attached to the middle toe). By transecting only the tibial nerve and leaving the sural and peroneal branches of the sciatic nerve intact, toe chewing was not a problem.

After 28 days post-op, the CRUSH group was at its preoperative function, while the remaining three groups had little motor recovery ($p<.001$). Motor recovery began in these groups at around 35 days post-op. By 56 days post-op, recovery had plateaued. There was no significant difference in the mean motor recovery indices (EXP/CONTR amplitudes X 100%) among the three repair groups: SUTURE 63% (5, S.E.M.), GLUE 60% (5) and TUBE 63% (5). Histological and HRP studies to confirm these results will follow.

In conclusion, although nerve guide tubes and fibrin glue technically may facilitate nerve repair, we presently cannot offer proof that they will improve recovery of motor function over conventional anastomosis alone.

331.13 ANALYSIS OF PROTEINS MODIFIED BY AMINO ACID ADDITION DURING REGENERATION OF THE RAT SCIATIC NERVE.
G. Chakraborty, M.J. Yu*, J. Sturman, and N. Ingoglia. Dep't. of Physiology, New Jersey Medical School, Newark, N.J., 07103 and Instit. for Develop. Disabil. Staten Island, New York.

Rat sciatic nerves were crushed and allowed to regenerate for 13 days. Nerve segments containing the leading edge of regenerating fibers were isolated, homogenized, centrifuged at 150k xg, and the supernatant was passed through a Sephacryl S-200 column. The void volume fraction was then incubated with a mixture of 3H amino acids (ICN) for 20' at 37° C after which samples were immediately frozen and stored. In one fraction of the stored sample proteins were precipitated with TCA and unincorporated amino acids were removed by successive washes in TCA. The radioactive precipitated product was hydrolyzed in 6N HCl and a portion of the hydrolyzate was applied to an amino acid analyzer. Radioactivity which eluted from the analyzer comigrated with threonine/ serine (5%), proline/glycine (11%), alanine (6%), valine (6%), leucine/isoleucine (30%), phenylalanine (3%), lysine (20%), and arginine (19%) standards. Less than one percent of the total radioactivity was associated with aspartic and glutamic acid, and tyrosine and histidine.

Another portion of the stored sample was applied to a 10% SDS polyacrylamide slab gel. Following electrophoresis, the gel was cut into 1 mm sections and radioactivity was removed from the gel by incubation overnight in H_2O_2. Radioactivity was found associated with molecular weight markers of approximately 88,82,66,53,32 and 17 kD.

A third portion of the stored sample has been applied to an HPLC gel filtration column and labeled product is being separated and collected according to molecular size for further analysis.

These experiments show that specific amino acids are incorporated posttranslationally into proteins of regenerating sciatic nerves and that they label a specific subset of the total nerve proteins. The labeled proteins are similar to those labeled at 6 days post crush suggesting that similar proteins are targets for modification at different points in nerve regeneration. Supported by grants NS19148 and EY06728 from NIH.

331.14 PIEZOELECTRIC GUIDANCE CHANNELS ENHANCE REGENERATION IN THE MOUSE SCIATIC NERVE AFTER AXOTOMY
R. F. Valentini *, P. Aebischer *, P. Dario *, C. Domenici *, V. Guenard *, S.R. Winn *, P. M. Galletti * (SPON: J. T. McIlwain). Artificial Organ Laboratory, Brown University, Providence, RI 02912 and Centro "E. Piaggio", University of Pisa, 56100 Pisa.

Synthetic tubular guidance channels have been used experimentally to support the regeneration of transected peripheral nerves. We have previously reported that the permeability characteristics of the guidance channel play a major role in the regeneration process. Since in vitro neurite outgrowth has been shown to be influenced by electrical activity it is possible that piezoelectric guidance channels, which generate transient electrical charges upon slight mechanical deformation, may enhance peripheral nerve regeneration.

Polyvinylidene fluoride (PVDF), a biocompatible polymer, displays one of the highest piezoelectric activities of any synthetic polymer known. Tubes of PVDF can be rendered piezoelectric by stretching them along their longitudinal axis and then poling them under a high intensity electrical field. The sign of the generated charge can be controlled by the poling procedure. Minute mechanical deformations, such as those induced by natural movements of an experimental animal, lead to the generation of transient electrical charges. The tubes used in this study generated a positive charge on the order of 350 picoCoulomb on their luminal surface for a 1 mm vertical deflection along their longitudinal length. After resecting 4 mm of mouse sciatic nerve, the proximal and distal nerve stumps were secured 4 mm apart within a 6 mm long, 0.85 mm ID channel. Positively poled PVDF channels were compared to unpoled, but stretched PVDF channels. All tubes were cleaned and sterilized identically prior to implantation. Cohorts of 5 animals were implanted for each tube type for periods of 4 and 12 weeks. Upon retrieval, all tubes contained a regenerated nerve cable bridging the proximal and distal nerve stumps. The regenerated cables were round, free from attachment to the inner wall and surrounded by an acellular gel. Transverse sections taken at the midpoint of the guidance channel revealed that nerves regenerated in positively poled channels contained a significantly higher number of myelinated axons at both 4 weeks (2,179 ± 177 versus 1,456 ± 398) and 12 weeks (3,183 ± 224 versus 2,163 ± 210) than those regenerated in unpoled channels.

These results indicate that a guidance channel which generates transient positive charges on its luminal surface significantly promotes peripheral nerve regeneration.

331.15 BLIND-ENDED PERMSELECTIVE GUIDANCE CHANNELS ALLOW PERIPHERAL NERVE REGENERATION IN THE ABSENCE OF A DISTAL NERVE STUMP

P. Aebischer *, V. Guenard *, S.R. Winn *, R.F. Valentini *, P.M. Galletti *
(SPON: K. M. Chapman). Artificial Organ Laboratory, Brown University, Providence, RI 02912

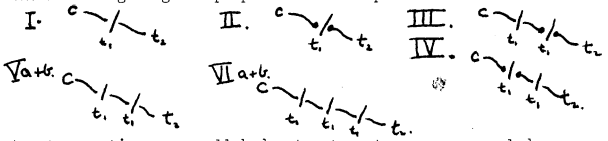
Guidance channels serve as tools for elucidating the cellular and molecular processes underlying peripheral nerve regeneration. The importance of the distal nerve stump in promoting regeneration in synthetic, impermeable tubes has been stressed by several authors. When the distal end of an impermeable channel is plugged and the distal nerve stump avulsed, no regeneration from the proximal nerve stump occurs. We have previously reported that permselective guidance channels support the regeneration of nerves with thinner epineurium, fewer blood vessels and more myelinated axons than impermeable channels. In order to determine whether a channel which allows controlled exchange across its wall will allow regeneration in the absence of a distal stump, the following procedures were performed. In this series of experiments only the proximal stump of a transected mouse sciatic nerve was positioned within a 6 mm long channel; the distal nerve was fully resected and discarded. In some animal the distal channel end was left open and in others it was capped with a polymer plug. Permselective acrylic copolymer (AC) channels were compared to impermeable silicone elastomer (SE) channels. Cohorts of 3 animals were implanted with capped and uncapped AC and SE channels for 8 weeks. All capped AC channels contained large regenerated nerve cables which extended to the distal end of the channel. The nerve cables contained over 1,000 myelinated axons with no significant decrease up to the cap level. Two of 3 uncapped AC channels contained small regenerated cables extending from the proximal stump to the open distal end but contained fewer axons than those regenerated in capped AC channels. The capped SE channels contained only fine threads of connective tissue extending for less than 2 mm and not containing any myelinated axons. Two uncapped SE channels contained small 2-3 mm long tissue cables containing fewer than 100 myelinated axons.

These results suggest that metabolic support and growth factors from the external wound environment and/or the proximal nerve segment are capable of supporting nerve regeneration. The enhanced regeneration observed in capped versus uncapped AC channels may be due to increased maintenance of growth factors within the regenerating environment.

331.16 POSSIBLE SOURCES OF INFLUENCE ON EARLY RECONNECTION OF TRANSECTED RAT SCIATIC NERVE. K. Harman, J.C. de la Torre, Dept. of Anatomy, Univ. of Ottawa Health Sciences, Ottawa K1H 8M5

Successful mammalian peripheral nerve regeneration depends upon a number of factors which have recently been the focus of investigation by many researchers. Neurites have been stimulated to extend by different substrates, exogenously applied substances and electrical stimulation. It has been found that regenerative growth across a nerve gap begins with a fibrin matrix connecting the proximal and distal stumps. Schwann and epineurial cells then migrate in from both stumps forming a cellular bridge, succeeded by axonal extension into the region (Williams et. al., '84). A study was performed to examine possible sources of influence upon the establishment of the acellular (fibrin) bridge after transection of the sciatic nerve of Long-Evans hooded rats.

Using a polyethylene tube to surround the transected nerve, the following surgical preparations were performed:



t_1 = transection c = cell body t_2 = target = sealed

In all preparations, open ends of the catheter were plugged with petroleum jelly. In an attempt to exclude the external environment more completely, another triple transection (VIb) was performed, sealing the open ends with plastic. At nine days, under anaesthesia, the nerves were removed, measured for growth, frozen or fixed for histology, and then the rats were killed.

It was found that the two nerve stumps reconnected with a fibrin matrix, containing a small number of cells. This matrix spanned the gap averaging 3.5 mm. Reconnection was observed in 63%, 78%, 100%, 60% and 0%, of I, Va, Vb, VIa and VIb respectively. When the cell bodies' and/or target's influence is removed, there is still reconnection.

These results suggest that initial proximal/distal reconnection after transection is a locally mediated event.

331.17 REGENERATION OF SPINAL MOTOR AXONS INTO CUTANEOUS SENSORY PATHWAYS. Paul B. Farel. Dept. of Physiology, Univ. of N. Carolina Sch. of Med., Chapel Hill, NC 27514.

In the bullfrog (Rana catesbeiana), axons of spinal motoneurons regenerate to their appropriate hindlimb regions only during the first third of larval life. Regeneration of motor axons is not specific during the balance of larval life or in postmetamorphic frogs (J. Comp. Neurol. 254:125-132, 1986). Although regenerating motor axons in older animals cannot select the pathway leading to the muscle they previously innervated, they nevertheless may be capable of distinguishing between purely sensory (cutaneous) and motor nerve branches. A mechanism that could place regenerating motor axons at a competitive disadvantage in reinnervating purely sensory nerve branches has recently been identified. Taniuchi et al. (PNAS 83:4094-4098, 1986) found that denervated Schwann cells express low-affinity receptors for NGF which, they suggest, may make NGF available for the support and guidance of regenerating axons of NGF-sensitive (e.g., sensory) neurons.

The ability of motoneurons to regenerate their axons into a purely sensory nerve branch was examined in juvenile bullfrogs. In 6 experimental frogs, the three spinal nerves that innervate the hindlimb were transected on one side slightly rostral to the sciatic plexus. After 6-8 weeks recovery, the medial cutaneous femoral nerve (MCFN, which innervates skin of the posterior thigh) was dissected free and prepared for electrical stimulation through suction electrodes. The spinal cord was removed and responses were recorded from the cut distal stumps of dorsal and ventral roots. Stimulation of the MCFN elicited responses in recordings from dorsal roots, but never from ventral roots, in 13 control frogs and on the unoperated side of experimental frogs. However, on the operated side, MCFN stimulation produced ventral root responses in 5 of 6 preparations. These ventral root responses were similar in size to those recorded from dorsal roots, indicating no significant selectivity of the pathway for sensory axons.

HRP was placed on the MCFN in 10 additional frogs (4 unoperated, 6 experimental). No retrogradely labeled motoneurons were found in the spinal cords of unoperated frogs; however, labeled motoneurons were found in the spinal cords of 3 of the 6 previously operated frogs.

These results show that regenerating motor axons are not excluded from purely sensory pathways. Further, the similarity in the size of responses recorded from dorsal and ventral roots in experimental frogs indicates that a mechanism favoring reinnervation of previously sensory pathways by sensory neurons is likely not sufficiently selective to be of significant importance during regeneration.

331.18 DISTRIBUTION OF ALBUMIN-LIKE IMMUNOREACTIVITY IN RAT SCIATIC NERVE AFTER NERVE CRUSH INJURY. M. Mata, J. Staple*, and D. Fink, Neurology Research Laboratory, University of Michigan and VA Medical Center, Ann Arbor, MI 48105.

In order to better understand the role of local factors in the response of peripheral nerve to crush injury, we studied the distribution of albumin-like immunoreactivity (A-LI) in the rat sciatic nerve from 1 day to 8 weeks after a crush using electron microscopic immunocytochemistry.

Male Sprague Dawley rats 200-250 grams were anesthetized with choral hydrate, the sciatic nerve exposed in the gluteal region, and crushed 1 min with a jewelers forceps. At 1 day, 1 week, 2 weeks, 4 weeks or 8 weeks after injury, the animals were sacrificed by perfusion through the heart with 75-100 mM phosphate buffer, followed by 0.5% glutaraldehyde and 4% paraformaldehyde. The sciatic nerve was removed and embedded in LR white. Ultrathin sections were exposed to goat anti-rat serum albumin antibody at dilutions of 1:1500 or 1:2000 for 1.5-2 hrs, followed by rabbit anti-goat IgG bound to 15 nm colloidal gold (1:10) for 1 hr and then stained with uranyl acetate. The specificity of the anti-RSA antibody was tested by immunodiffusion; it precipitated RSA but not bovine serum albumin, ovalbumin or phosphorylase A. Controls for the immunohistochemical reaction included deleting the anti-RSA antibody and blocking the anti-RSA antibody with RSA.

In the nerve distal to the crush degenerating areas demonstrated intraaxonal A-LI early. These axonal contents subsequently disappeared. By 1 week most of the Schwann cells in the distal nerve also demonstrated A-LI. As regenerating sprouts entered the distal nerve, those Schwann cells in contact with sprouts lost their A-LI, while those cells not in contact with axons retained immunoreactivity up to 8 weeks after injury.

Proximal to the nerve crush many axons showed intra-axonal A-LI from 1 to 2 weeks after injury, despite appearing normal ultrastructurally. This immunoreactivity diminished as the distance from the crush site increased. Many Schwann cells proximal to the crush also showed A-LI from 1 to 4 weeks after injury, some more proximal than the most proximal distribution of axonal A-LI.

Recent studies have emphasized the role of the microenvironment at the tip of regenerating axons in determining the success or failure of regeneration, and the complex interaction of regenerating axons with Schwann cells in controlling Schwann cell protein synthesis and secretion. The results of this study describe a previously unknown aspect of this interaction which may be important in the process of peripheral nerve regeneration.

331.19 **INSULINLIKE GROWTH FACTOR-II GENE EXPRESSION IN MUSCLE: RELATIONSHIP TO SYNAPSE ELIMINATION AND NERVE REGENERATION.** D. N. Ishii. Physiology Department, Colorado State University, Fort Collins, CO 80523.

During development individual immature muscle fibers become innervated by axons from several motor neurons (Redfern, J. Physiol. 209: 701, 1970). Superfluous synapses are later eliminated so that a mature muscle fiber retains innervation from only a single motor neuron. Denervated and immature muscles share a biochemical "state" receptive to innervation, whereas mature muscle is unreceptive. The potential involvement of insulinlike growth factor-II (IGF-II) is suggested, in part because it can induce neurites and support neuron survival, and IGF-II mRNA is present in muscle and the CNS (discussed in Recio-Pinto et al, J. Neurosci. 6: 1211, 1986; Ishii and Mill, Curr. Topics Membrane Transport, in press, 1987. Is the level of IGF-II gene expression correlated with synapse elimination and the muscle state receptive to innervation? This hypothesis was tested. The expression of the IGF-II gene was studied in calf muscles from rat littermates. Purified RNA was analyzed by the Northern blot method using rat cDNA clone 27, which contains the IGF-II coding region (Soares et al., J. Mol. Biol. 192: 737, 1986). Transcript levels were high in muscles from pre and early postnatal rats. A profound decline in transcript abundance began in the second week of life and followed exactly the time course for the elimination of multiple synapses in muscle (Brown et al., J. Physiol. 261: 387, 1976). Transcript levels were very low in rats older than 15-days. Following unilateral transection of the sciatic nerve, IGF-II mRNA levels transiently continued the developmental decline for 2-4 days, then became elevated in muscles from the operated but not the unoperated side. Sham operation was without effect. Following bilateral transection, transcripts were elevated in muscles from both sides in 24-day-old rats (10 days postoperative). The differences had a high level of significance: 6.84 $\pm$ 3.04, N = 7 intact muscles; 14.65 $\pm$ 3.83, N = 9 denervated muscles (means $\pm$ S.D., relative areas under the curve of the densitometric scans from the autoradiograms of Northern blots). These results suggest a) the abundant IGF-II transcripts in immature muscles may predispose to polyinnervation, b) the decline in transcript abundance may modulate the elimination of superfluous synapses, c) IGF-II gene expression in muscle is regulated by innervation, and d) the up regulation of IGF-II gene activity in denervated muscle may contribute to nerve regeneration. (Supported in part by grants ROl NS 24787 from the NINCDS and ROlNS 24327 from the NIDDKD).

331.20 SENSITIVITY OF REGENERATED SCIATIC NERVE TO 4-AMINOPYRIDINE AND TETRAETHYLAMMONIUM FOLLOWING INJURY AT BIRTH AND LATE MATURATION. C.M.Bowe AND C.H.Yu* Dept. of Pediatrics and Section of Neurobiology, Brown University, Providence, RI 02912

Morphological and physiological properties of regenerated mammalian nerves differ following lesions at various postnatal ages. The enhanced sensitivity to potassium channel blockade by 4-AP reported for regenerated nerves following injury during adulthood is less evident in nerves lesioned between 2-3 weeks of age (Bowe, Devel Brain Res, in press) suggesting that ongoing maturational processes influence regeneration. The recent identification of the presence of a second, pharmacologically distinct tetraethylammonium (TEA)-sensitive potassium channel on immature mammalian axons prompted this examination of the physiological properties of regenerated rat sciatic nerve in the presence of 4-AP and TEA.

Sciatic crush lesions were performed on 1 day and 10 week old rats. Following a recovery period of 9-16 months, contralateral control and regenerated nerves were excised and studied in vitro during superfusion with a physiological solution (NS) and NS containing 4-AP (.5-1.0 mM), TEA (2.5-10 mM), or 4-AP+TEA. Compound action potential (CAP) waveform characteristics, recovery cycle properties, and ability to follow trains of stimuli at fast frequencies were compared for control and the two lesion-age groups. Control and regenerated nerve recordings were comparable during superfusion with NS with the exception of prolonged latency to peak amplitude noted for both groups of regenerated nerves. Minimal changes were observed for control nerves during 4-AP, but application of TEA resulted in an appreciable CAP amplitude decrement and delayed recovery of conditioned CAP amplitude during paired stimulation. More marked sensitivity to 4-AP was observed for all regenerated nerves associated with the development of a prominent, delayed negativity and prolongation of recovery cycles during paired stimulation. Distinctive CAP waveform alterations, previously described following adult lesions, were noted only for the older lesion-age group. Application of TEA or TEA+4-AP to regenerated nerves resulted in significant amplitude reduction and loss of 4-AP effects on waveform. Recovery cycles were prolonged for all regenerated nerves with most marked delays observed in nerves from the younger lesion-age group.

Physiological effects of both 4-AP and TEA differ for normal and regenerated nerves. Furthermore, the relative magnitude of sensitivity to 4-AP and TEA varies for regenerated nerves following lesions at different maturational ages.

331.21 MOTOR NERVE TERMINALS CAN PRODUCE SYNAPTIC ACETYLCHOLINESTERASE AT NEUROMUSCULAR JUNCTIONS. L. Anglister. Dept. of Anatomy and Embryology, Hebrew Univ.-Hadassah Med. Sch., Jerusalem, Israel.

Acetylcholinesterase (AChE) in skeletal muscle is concentrated at neuromuscular junctions where it is found in the synaptic cleft between muscle and nerve. This raises the question of whether the synaptic enzyme is produced by muscle, nerve or both. Studies on denervated and regenerating muscles show that myofibers can produce synaptic AChE (Anglister & McMahan, J. Cell Biol. 101:735, 1985). The motor nerve may play an indirect role: By inducing activity in the myofibers it triggers them to produce synaptic AChE (Weinberg & Hall, Dev. Biol. 68:631, 1978). The aim of the following study was to determine whether or not some of the AChE that is made and transported by the motor nerve contributes directly to synaptic cleft enzyme.

The experiments were carried out on operated cutaneus pectoris (CP) muscles of frog in which muscle fibers had been removed from the basal lamina sheaths, while leaving intact motor axons, nerve terminals and synaptic basal lamina sheaths. In these preparations nerve terminals persist at almost all the synaptic sites on the sheaths for a year in the absence of myofibers and show no discernible differences in structural features from normal (Yao & McMahan, Soc. Neurosci. Abs. 10:1085, 1984). At the time of operation muscles were exposed to DFP or MSF, which block irreversibly and inactivate all AChE activity detected by either histochemical or biochemical assays. Five weeks later the preparations were examined for the appearance of newly formed AChE. Histochemical staining revealed an arborized pattern, characteristic of neuromuscular junctions, which co-localized with the staining for nerve terminals. AChE reaction product was concentrated adjacent to the nerve terminals, obscuring synaptic basal lamina. No staining appeared at denervated sites. Since all original AChE had been inactivated and myofibers had been removed, the newly formed AChE at synaptic sites must have been produced by the persisting axon terminals. These results demonstrate that motor nerves are capable of producing some of the synaptic AChE at the neuromuscular junctions.

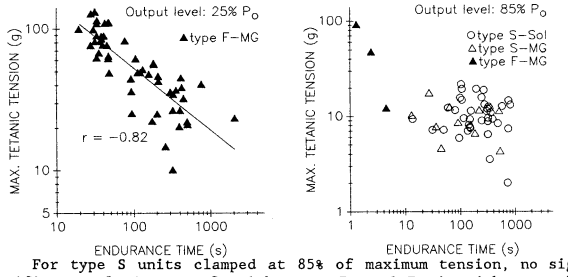
332.1 ENDURANCE OF SLOW-TWITCH MOTOR UNITS AT SUB-MAXIMAL CONTRACTIONS OF CONSTANT TENSION. C. B. Webb*, T. C. Cope and B. R. Botterman. Dept. of Cell Biology and Anatomy, Univ. Texas Health Sci. Ctr., Dallas, TX 75235.

Recent work from our laboratory has shown that among type F motor units there is a significant relationship between maximum tetanic tension (P_o) and the length of time (endurance time, E_t) that a unit can maintain tension at 25% of maximum (left panel, below). Whether a similar relationship exists for type S units is not known. For the few type S units studied at this level (n=5), the pattern of activation indicated that the contraction would be maintained well in excess of our arbitrary limit of 3000s. Because of the impracticality of studying type S units for this length of time, we chose instead to test for the relationship at a higher output level.

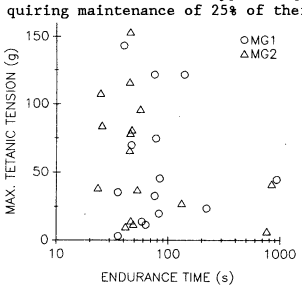
In 6 cats, motor axons to either soleus (SOL; n=38) or medial gastrocnemius (MG; n=13) muscles were isolated from ventral root filaments. Motor-unit tension was 'clamped' at 85% of maximum by altering the activation rate of a unit's motor axon through computer feedback control.



For type S units clamped at 85% of maximum tension, no significant relation was found between P_o and E_t in either muscle (right panel, above). This was true despite the fact that the absolute range for E_t was comparable to that found for type F units at 25% of maximum tension. For both type F and S groups, the relative range for P_o was similar as well (~10-fold). The lack of a relation for type S units may simply be due to the higher output level studied. Alternatively, there may be fundamental differences between type S and F units with regard to the P_o-E_t relation. In the latter case, a recruitment scheme based on tension would result in a random activation of units with respect to endurance. (NIH grants NS17683 to B.R.B and NS21023 to T.C.C.)

332.2 TENSION AND ENDURANCE ARE UNCOUPLED FOR MOTOR UNITS IN SELF REINNERVATED MUSCLE T.C. Cope, C.B. Webb* and B.R. Botterman Dept. of Cell Biology and Anatomy, Univ. of Texas Hlth. Sci. Ctr., Dallas, TX 75235.

Fast-twitch motor units in reinnervated muscle regain their normal relative differences in both tension and fatigue when grouped by type. Our recent finding that tension and endurance are precisely ranked in normal muscles enabled us to determine the recoverability of this relationship after reinnervation irrespective of unit type. Isometric contractile properties of motor units in self-reinnervated medial gastrocnemius (MG) muscles were studied more than 2 years after nerve-section in 2 adult cats. Single motor axons were functionally isolated and electrically stimulated in ventral root filaments for characterization of each unit's type and performance under conditions requiring maintenance of 25% of their maximum tension (P_o) achieved by modulating motor axon stimulation rate through computer feedback control. Under this condition, fast-twitch units in normal muscles, including MG, have a continuous inverse relation between P_o and the duration that the sustained contraction can be maintained, defined as endurance time (E_t; see Webb, Cope and Botterman in this volume).



This figure plots P_o vs. log E_t for 30 reconstituted type F units in reinnervated MG muscles. The range in E_t for these units (24-937s) overlapped with that for essentially all normal type F MG units (n=52; 20-767s), meaning that it can recover in reinnervated muscle. With regard to P_o, we confirm other studies in showing that approximately normal values were recovered, although the range was greater than normal. In face of the recovery of these parameters, the figure shows that for neither pooled nor individual samples were P_o and E_t related after reinnervation, as they are normally. Expressed quantitatively, Spearman rank order correlation coefficients for P_o vs. E_t were 0.13 and -0.34 for MG1 and MG2, respectively. These values were not significant ($p>0.1$) and were less than half those found for type F units sampled in normal MG muscles (smallest value -0.83). We conclude that two important functional properties of motor units, namely tension and endurance, cannot act synergistically after self-reinnervation. (Supported by NIH grants NS21023 to TCC and NS17683 to BRB)

332.3 FORCE HYSTERESIS OF SINGLE MOTOR UNITS DURING FREQUENCY-VARYING STIMULATION S.A. Binder-Macleod and H.P. Clamann. Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

The force output of single motor units in cat soleus muscle was studied in response to stimulus trains of continuously varying frequency. Although a sigmoid relation between frequency and force is well known in whole muscles and single motor units, this relationship is determined during stimulus trains of constant frequency and fails to explain a number of features of rate coding.

Single soleus motor units were isolated in cats deeply anesthetized with sodium pentobarbital. Each unit was stimulated with a continuous train whose frequency varied linearly from 0 to 20% above the unit's fusion frequency and back to 0. The period of this cycle was 1, 2.5, 5, 10 or 20 seconds, and was repeated 2 to 5 times.

As we previously reported for medial gastroc-nemius (MG) motor units (Clamann and Binder-Macleod, Neuroscience Abstracts, 1985) a marked hysteresis was seen in all motor units during frequency-varying stimulation. That is, a motor unit produced more force at any given stimulus frequency if frequency was decreasing than if frequency was increasing. The MG data suggested that motor unit slowing and potentiation could be contributing to the hysteresis. A time delay in force production and a catch-like property may also be contributing. The contribution of these last two factors should depend on the rate of change of frequency (cycle period).

Because soleus units showed no potentiation or contractile slowing during stimulation, these factors could not contribute to the hysteresis seen here. The use of longer cycle periods did decrease the hysteresis. Therefore, the soleus unit hysteresis appear to depend on the rate of change of frequency. Mathematical modelling suggests that a time delay in force production and a catch-like property may contribute to the hysteresis.

The force-frequency relation during decreasing frequency was quite stable. In voluntary or reflex movement, CNS control of force output can be made predictable by the use of a discharge pattern in which frequency is initially high and then decreases. Such a discharge pattern is typical of many movements in intact animals and man.

332.4 FIRING RATE CHANGES STUDIED USING CLOSED-LOOP CONTROL OF ISOLATED SINGLE MOTOR UNITS IN RAT EDL. G.P. Rovai* and T.G. Sandercock*. (SPON: E. Polley). Bioengineering Dept., Univ. of Ill. at Chicago, Chicago, IL 60680.

Research on human adductor pollicis muscle has shown that when a subject sustains a maximal voluntary contraction a fall in muscle tension is accompanied by a fall in motor unit firing frequency (Bigland-Ritchie, et al., J. Physiol. London. 340:335-346,1983). Artificial stimulation of the muscle at higher frequencies fails to produce more tension. It has been hypothesized that as a motor unit fatigues its contractile properties change so full tension can be achieved with lower firing rates. Because of the difficulty in recording motor unit contractile properties in humans we chose to study isolated motor units in the extensor digitorum longus(EDL) muscle of rats. The goal of the study was to test the hypothesis that during a prolonged contraction of rat EDL motor units there is a decline in the stimulating frequency needed to maintain maximum tetanic tension(Po).

Rats were anesthetized with sodium pentobarbital. The hindlimb was mounted in a rigid frame, and the EDL tendon was cut and attached to a force transducer. Single motor units were isolated and stimulated through the ventral roots. Two computer-controlled stimulus paradigms were developed to maintain tension at a constant percentage of Po by modulating the stimulation frequency. The paradigms are described:

1) Tension control. Tension was used as the feedback variable and the stimulating frequency was adjusted to maintain tension at the desired setpoint. We used a setpoint of 80% of Po. To compensate for muscle fatigue, Po was periodically remeasured, and the setpoint was adjusted accordingly.

2) Ripple control. This control strategy used a percentage of ripple for the setpoint. Ripple is defined as the amount of fluctuation in the unfused portion of tetanus. The stimulation frequency was modulated to maintain ripple at 5% of the average tension. Preliminary experiments showed that in rat EDL this control paradigm kept tension above 80% of Po without the need to remeasure Po.

Both paradigms showed that even though Po fell over time, Po could be achieved using a lower activation rate. Most of the change in the firing rate was observed in the first 20 seconds of the experiment. Results from 10 motor units studied with the tension control paradigm showed the average stimulation frequency decreased by 20.4 Hz during the first 20 seconds. An average decrease of 14.9 Hz in 20 seconds was determined from 6 motor units studied with the ripple control strategy.

332.5 THE DEPENDENCE OF THE EMG-FORCE RELATIONSHIPS ON THE MUSCLES CONTROL STRATEGY AND PREDOMINANT FIBER TYPE. M. Solomonow, R. Baratta*, B. Zhou*, H. Shoji* and R. D'Ambrosia*. Bioengineering Laboratory, Louisiana State University Medical Center, New Orleans, LA 70112.

The impact of various action potentials firing rate and motor unit recruitment control strategies on the EMG-Force relationships of a predominant fast (m. gastrocnemius) and slow (soleus) twitch muscles was determined with a recently developed electrical nerve stimulation system (Zhou, B. et al, IEEE trans. BME, 34: 128-139, 1987). The system consisted of dual stimuli delivered to the muscle nerve of nine adult cats via two electrodes. The first electrode induced action potential of increasing rate while the second electrode allowed motor units to be concurrently recruited according to their size. The simultaneous stimuli could be calibrated to recruit all the motor units any time during the firing rate increase phase such that control strategies similar to that known to exist in various skeletal muscles could be duplicated.

It was shown, for the soleus muscle, that strategies which recruited all the motor units by the time 30% or 40% of the maximal muscle force was reached and firing rate complimented the generation of the final force segment, the EMG-Force relationships were linear. Progressive increase in non-linearity was evident as total recruitment was allowed to occur from 50% and up to 70% of the maximal force. No statistically significant difference ($p < .05$) was observed in the relationships for strategies employing recruitment ranges from 70% to 100% MVC.

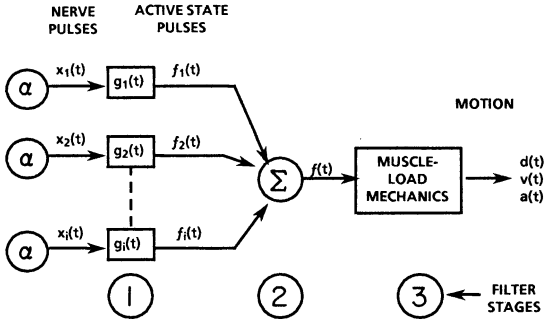
Linear relationships were evident in the m. gastroc for a strategy of 50% recruitment range, with progressive increase in non-linearity for strategies of 60% to 80% recruitment range.

It was concluded that the EMG-Force relationships are strongly dependent on the control strategy employed by the muscle as well as on its motor unit architecture. The fact that a specific muscle responded physiologically to a wide range of control strategies is importantly noted.

332.6 THREE STAGES OF LOW-PASS FILTERING BY A MUSCLE-LOAD SYSTEM. R. N. Stiles, Department of Physiology and Biophysics, University of Tennessee, Memphis, Memphis, TN 38163.

Low-pass filtering is a major step in frequency demodulation of pulse trains (Bayly, *IEEE Trans. BME*: 15, 1968). Also, motor unit (MU) fibers of skeletal muscle are normally stimulated by frequency-modulated pulse trains, and a muscle-load system behaves as a low-pass filter. How the total low-pass filter effect is divided between the active state process and muscle-load mechanics is unclear. Also unclear is the *in situ* contribution of a third stage of low-pass filtering, spatial summation of asynchronous MU pulses. Of particular interest is the possibility that the cut-off frequency of each filter is under CNS control. These three stages are illustrated below.

The frequency response of a muscle-load system (treated as a single MU) can be obtained using a constant low-rate (2-4 pps), constant-amplitude pulse-train stimulus. In this study, frequency response plots were obtained for hamster (and rat) gastrocnemius-plantaris lever-preload systems, using both an accelerometer to detect load kinematics and spectral analysis of the acceleration record. Mechanical measurements from these same systems indicate that the third-order low-pass behavior of a typical frequency response could be attributed primarily to muscle-load mechanics. These results suggest that the equivalent width (treated as a rectangular pulse) of the active state pulse was less than about 10 ms. This value compares well with certain estimates of the duration of the active state pulse.



332.7 **PHYSIOLOGICAL AND HISTOCHEMICAL CHARACTERIZATION OF THE RECTUS FEMORIS MUSCLE IN THE CAT.** B.G. Samojla, P.J. Rebeta*, L.L. Glenn. *Department of Physiology, Ohio College of Podiatric Medicine, Cleveland, Ohio, 44106-3082*

Although neuromuscular compartments have been identified in various muscles of the hindlimb of the cat, none have been described in the quadriceps. It was the purpose of this study to identify and characterize (physiologically and histochemically) the muscle compartments that comprise the rectus femoris m. (RF) in the cat.

Innervation patterns, fiber angles, lengths, and volumes were determined from fixed animals. It can be difficult to define a region within a muscle using glycogen depletion and PAS stain, so a modified method to enhance the contrast between depleted and non-depleted regions was used. Nicotinic acid (NA) was injected i.v., followed by stimulation of first order nerve branches at 40 Hz/333 ms/second at 15 minutes; epinepherine was injected i.v. followed by an additional 5 minutes of stimulation. The muscle was excised and frozen in isobutane cooled by liquid nitrogen. Every 3 mm, a 10 μm section was taken and stained for glycogen with PAS. Fiber types were determined on additional sections stained for ATPase (acid and alkaline) and NADH-TR. Contraction properties were studied using standard procedures that were uniform for each compartment identified by dissection and glycogen depletion.

RF is a bipennate muscle which is innervated by three, occasionally four, primary nerve branches from the femoral nerve; however, only three compartments are consistent in their morphology. The proximal half of RF is divided into a lateral (PL) and a medial (PM) compartment, and the distal (D) half is itself a single compartment. The percentages of muscle fibers (SO : FOG : FI : FG) within the PL compartment was 3.9 : 39.1 : 2.0 : 49.8; PM was 7.4 : 32.7 : 1.1 : 53.2; D was 28.2 : 31.4 : 4.3 : 31.9. Glycogen depleted muscles using NA, when compared to control slides, showed identical staining patterns and intensities for ATPase and NADH-TR. The fiber angles (22.6°) and lengths (15.5 mm) were constant throughout the muscle. The physiological cross-sections follow: whole muscle, 5.4 cm^2; compartments PL and PM, 2.7 cm^2; D 5.0 cm^2. The maximum tetanic tensions were 33.9 N (PM), 31.1 N (PL), and 89.2 N (D). Summation coefficients (SC) were 0.283 (PM), 0.199 (PL), 0.313 (D). Specific tensions were 11.5 N/cm2 (PL), 12.6 N/cm2 (PM), 17.8 N/cm2 (D).

RF is composed of three compartments defined by innervation patterns and glycogen depletion. The two proximal compartments are similar in all respects, appearing like mirror images with respect to the central RF tendon. The distal compartment differs from the proximal by having a larger cross sectional area, MTT, specific tension, and more even proportion of muscle fiber types. These proximal-to-distal differences can be associated with the function of RF during locomotion. The proximal compartments may be the major contributor to the muscles ability to flex the hip. While, the distal compartment by virtue of the larger cross sectional area and may be responsible for tension production during deceleration and antigravity functions. [Supported by Ohio Board of Regents Research Challenge Program]

332.8 **MUSCLE FIBER LENGTHS WITHIN SINGLE MOTOR UNITS IN THE CAT TIBIALIS ANTERIOR MUSCLES.** **M. Qunjian, R.R. Roy, E. Eldred, and V.R. Edgerton. Dept. of Kinesiology and Brain Research Institute, UCLA, Los Angeles, CA 90024.**

The length of a muscle fiber, the number of sarcomeres arranged in series, relates closely to the maximum shortening velocity potential of a fiber. Based on whole muscle acid digestion and maceration techniques for determining muscle fiber lengths, there appears to be conflicting results regarding the range in lengths of fibers in cat skeletal muscles. In this study, the lengths of fibers belonging to a single motor unit (MU) and located within a single fascicle were measured in 4 tibialis anterior muscles of adult cats. To identify fibers of a MU, ventral root filaments were split until a single MU response was obtained. After having measured routine contractile properties, the muscle fibers were depleted of glycogen by repetitive stimulation (*e.g.*, 75 Hz trains each lasting ~ 100 ms and each train repeated at 5 Hz) of the split ventral root. A periodic acid-Schiff (PAS) reaction was used to stain for glycogen. In order to maintain the physiological optimal muscle length during quick freezing, the whole muscle was secured at its physiological resting length. The frozen muscle was cut into ~ 18-20 blocks of 4.0-8.0 mm segments. Every block of each of the 4 muscles was sectioned serially into 20 μm slices. Approximately 10-20 fibers within a fascicle that were depleted of glycogen were traced throughout their lengths by examining each 20 μm thick section. The results from these 4 units are summarized in the following table:

MOTOR UNIT NUMBER	1	2	3	4
Physiological Type	Fast Fatigable	Fast Intermediate	Fast Fatigable	Fast Fatigue Resistant
ATPase Type	Fast	Fast	Fast	Fast
Contraction Time (ms)	22	20	25	21
Tetanic Tension (g)	21.6	16.0	40.3	10.1
Mean Fiber Length (mm)	8.86	19.83	48.04	36.07
SD	± 0.08	± 3.51	± 7.31	± 8.42
Number of Fibers	12	20	11	8
Muscle + Tendon Lengths (mm)	N/A	106	114	125
Fiber Length: Muscle Length (%)	N/A	19	42	29
Location of MU in Muscle (% of Muscle Length)	0-10	0-30	20-70	50-80
No. of Fibers Tapering				
Proximal End of Fibers	0	0	9	3
Distal End of Fibers	0	0	4	3
Body Weight (kg)	2.49	3.60	4.50	3.20

These results illustrate that fiber lengths can vary widely from one MU to another. Further, it appears that the fiber lengths of a MU within the same fascicle are similar. In one case, one fiber (MU No. 4) appeared to divide into two fibers. This fiber's total length was 22.8 mm and appeared to split 7.63 mm from its most proximal end. The cross-sectional area of a number of fibers changed progressively towards their ends (tapered). No tapering occurred in the proximal ends of fibers of MUs 1 and 2 which were located in the most proximal part of the muscle. However, some tapering was apparent in some or all of the fibers of each of the 3 units located more distally in the muscle. This progressive tapering usually occurred over a distance of about 2 mm.

332.9 CHRONIC IMMOBILIZATION-INDUCED CHANGES IN CAT MUSCLE-UNIT POPULATIONS. G.A. Robinson, R.M. Enoka, C.R. Kirby* and D.G. Stuart. Dept. of Physiology, Univ. of Arizona, Tucson, AZ 85724.

The properties of individual tibialis posterior muscle units were evaluated after a 3-week period of hindlimb immobilization in 6 adult male cats (3.2-4.5 kg). All cats were conditioned for 3 weeks prior to immobilization in a large communal environment. Splinting the right hindlimb (with the ankle extended and the knee flexed) reduced the mobility of the limb and produced an average decrease of 19% in test-muscle weights (n = 5) relative to contralateral muscles. Muscle units were characterized into one of four types (FF, FI, FR, or S) based on conduction velocity (CV), twitch contraction time (CT), a progressive fatigue index (PFI), tetanic force (Po), and a test for sag as described previously for normal, tibialis posterior muscle units (McDonagh et al., J. Neurophysiol., 44: 696, 1980). Immobilization results were then compared to these normal data. In general, both nonfatigable (FR + S) and fatigable (FF + FI) units were altered by immobilization. Specifically, type FR and S units had PFI values significantly greater than those found in normals, whereas values for Po and CT were unchanged. Fatigable units exhibited a trend for slower CVs than in normals, which was significant for type FI units. The population distribution of different unit types was also changed from normal. The population of fatigable units was reduced by one half whereas the proportion of nonfatigable units remained unchanged. Furthermore, of the 102 units studied, 21 could not be classified into one of the four types. These units had CVs consistent with other fast units but produced tetanic forces below the resolution of the measurement system (0.5 mN). The absence of such units in the sampling of normal muscle, combined with the reduced populations of type FF and FI units after immobilization, suggests that these altered units (AU) may represent type FF and FI units which have undergone preferential and severe atrophy.

MUSCLE-UNIT POPULATIONS

Type	% Distribution	
	Normal	Immobilized
FF	30.1	14.7*
FI	8.7	3.9
FR	19.4	29.4
S	41.8	31.4
AU	---	20.6*

332.10 MUSCLE FIBRES SHORTEN WHEN THE WHOLE MUSCLE IS BEING STRETCHED IN THE 'YIELD' PHASE OF THE FREELY WALKING CAT. R.I. Griffiths* and J.A. Hoffer. (SPON: F.T. Hambrecht), Depts. Medical Physiology and Clinical Neurosciences, Univ. of Calgary, Calgary, Alberta, T2N 4N1, Canada.

During the E2 phase of the step cycle, the ankle extensor muscles are stretched by the weight of the animal. By measuring force and length changes in the medial head of gastrocnemius muscle (MG) in the wallaby, and by subtracting expected length changes in the tendon (calculated from isolated tendon measurements), Griffiths (Ph.D. thesis 1984) predicted that the muscle fibres would actually shorten during this period.

In the cat MG the tendon is about five times longer than the muscle fibres, and this represents a significant series elasticity. Using the ultrasound transit-time technique, Griffiths (J. Neurosci. Meth. in press) measured 25% shortening of the muscle fibres in 'isometric' tetanic contractions. This occurred due to stretch of the compliant tendon.

MG muscle fibre length has now been measured directly in the conscious freely walking cat (See Figure). MG EMG begins prior to footfall (↓) and increases during the E1 phase of the step cycle. It results in shortening of the muscle fibres, and since there is no load during E1, the whole muscle also shortens. When the foot is placed on the ground (E2 phase), **the whole muscle is stretched, but the active muscle fibres continue to shorten.**

The lengthening of the whole muscle is due to the compliance of the tendon, which is stretched from both ends, and to any decrease occurring in the pennation angle of the muscle fibres. This compliance may act as a shock absorber to prevent sudden, possibly damaging jerks to the muscle fibres. The tendon stretch will contribute to the storage of elastic energy and will also provide for a greater range of movement in the muscle than would be available from the muscle fibres alone.

Since whole muscle length and muscle fibre (and therefore muscle spindle) length are not always correlated, spindle discharge patterns must be analized with respect to the muscle fibre length rather than whole muscle length. For example, the lack of stretch of the muscle fibres during E2 implies that previously observed increases in muscle spindle firing must be controlled by fusimotor activation and to a greater extent than was previously thought (eg. Prochazka et al., 1976, J. Neurophysiol. 39: 1090).

332.11 QUADRICEPS CONTRACTILITY CHANGES WITH BRIEF MAXIMAL EFFORTS. A.V. Sirin and A.E. Patla, Neural Control Lab, Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, N2L 3G1.

This study was conducted to determine the effect of maximal voluntary contraction (MVC) on the contractility of individual as well as the overall quadriceps muscle group. The subjects (n=11, 10 female, 1 male) were seated on the experimental bench with the right leg in full extension and tightly coupled with the force transducer. Copper plate electrodes 2 cm in diameter were used for stimulating vastus lateralis (VL), rectus femoris (RF), and vastus medialis (VM). Furthermore, large plate electrodes were placed on the quadriceps group (Q) just below the hip joint (anode), and just above the knee joint (cathode) for whole muscle group stimulation. The stimulation equipment consisted of Grass Instruments S44 stimulator, isolation unit, and constant current unit. Square wave pulses of 5 msec duration were used for cutaneous stimulation. The voltage was adjusted such that the stimulus was as high as possible without the excitation spreading into adjacent muscles. This was verified through manual palpation. This was further confirmed by viewing the distinct twitch profile for each muscle on the oscilloscope prior to testing. The stimulus intensity was held constant throughout the experiment.

Individual muscle and whole muscle group submaximal stimulations were done prior to and immediately following a ten second MVC. Force records were converted to digital format (sampling rate 100 Hz) and stored onto floppy disks for later analysis.

Table 1: Peak Twitch Torque (N.m)

	Pre	Post	P
VL	1.2 (± .5)	1.6 (± .7)	< .01
RF	1.7 (± .7)	1.8 (± .7)	NS
VM	2.2 (± 1.1)	2.8 (± 1.8)	< .05
Q	10.9 (± 1.9)	13.3 (± 3.0)	< .005

These peak twitch results indicate that although the quadriceps group as a whole exhibits a 22% potentiation in the peak twitch torque, the contribution to this potentiation appears to be from the vastii muscles and not from the rectus femoris. Twitch potentiation is highly correlated with increased phophorylation of myosin light chains in type II fibres. In fact three types of phosphorylated light chains were reported in the VL which increased their phosphorylation level following a similar protocol (Stuart D. Msc. thesis, University of Waterloo, 1986). The fibre type of the VL is generally used to estimate the fibre type of the quadriceps group. However, the current results indirectly indicate that this may not be appropriate since RF does not appear to undergo potentiation and therefore may be much lower in type II content than either VL or VM. Supported by NSERC grant (A#0070).

332.12 MOTOR UNIT FIRING RATE CHANGES DURING FATIGUE INDUCED BY SUBMAXIMAL, INTERMITTENT, ISOMETRIC, VOLUNTARY CONTRACTIONS OF QUADRICEPS. B. Bigland-Ritchie, F. Furbush*, D. Karrmann*, J. Woods* and C. Thomas, J.B. Pierce Foundation Lab. & Quinnipiac College, New Haven, CT 06519.

Motor unit discharge rates were examined in the quadriceps muscle using an intermittent, submaximal voluntary contraction protocol described previously (Bigland-Ritchie, B. et al., J. Appl. Physiol. 61: 421, 1986). It involved repeated 6s contractions at 50% of the maximum voluntary contraction (MVC) force followed by 4s rest until the maximum force generating capacity had declined by 50%. At this point in time (Tlim), the original target force was now the best force the subject could generate. During all of the target force contractions up to and at Tlim, discharge rates were recorded from single muscle fibers using tungsten microelectrodes. They were compared with those recorded during brief non-fatigued MVCs and target force contractions. Changes in force generating capacity were assessed using a "fatigue" test interjected every minute during the contraction protocol. It included both tetanic and single shock stimulation and an MVC during the last three seconds of a target force contraction.

The time taken for a 50% MVC force loss (Tlim) averaged 7.7 ± 2.1 (SE) min. During this time, the decline in voluntary force was paralleled by a proportional decline in the response to tetanic muscle stimulation. Initially, the mean target force firing rates were approximately 50% of the mean MVC firing rates. At Tlim, MVC firing rates had declined by 30% on average while those recorded during target force contractions had increased so that they were not significantly different from fatigued MVC rates. Surface integrated EMG (IEMG) activity followed similar trends (i.e. target force contraction IEMG increased to match the maximal IEMG). These results suggest that a decline in mean maximal motor unit firing rates is apparent whether fatigue is induced by intermittent, submaximal contractions or by sustained, maximal efforts as reported in our earlier work. However, a decrease in contractile speed remains to be documented for this intermittent form of fatiguing exercise. This work was supported by NIH grants NS 14756 and HL 30026.

332.13 CORRELATION ANALYSIS OF MULTIUNIT MOTOR UNIT TRAINS TO REVEAL COMMON INPUTS TO DIFFERENT MOTONEURON POOLS IN MAN. RK Powers, S Vanden Noven, D Bourbonnais, J Gemperline* and WZ Rymer. Dept. Physiol., Northwestern Univ. Med. Sch. and Sensory-Motor Performance Prog., Rehabilitation Inst. of Chicago, Chicago, IL 60611.

In order to assess the prevalence of common inputs to different motoneuron pools, we are investigating synchrony in the discharge of paired groups of motoneurons (Sears and Stagg, 1976, J.Physiol. 263:357-381), based on multiunit motor unit records from different upper limb muscles. Short-term synchronization of the discharge from different motoneurons, manifested as a narrow, central peak in the crosscorrelation histogram, has been attributed to the joint arrival of unitary EPSPs from branches of the same presynaptic fiber (Sears and Stagg, 1976). Such synchronization has been found previously in humans for pairs of single motor units from the same muscle (e.g., Datta and Stephens, 1980, J.Physiol. 308:19-20P). However, if shared inputs make up a relatively small proportion of the total input to different motoneuron pools, then the detection of synchrony will be more difficult, requiring the examination of a large number of pairs of single motor units as well as long periods of simultaneous discharge. Alternatively, the chance of detecting synchrony should be improved be examining simultaneous activity in paired groups of motoneurons.

Motor unit activity was recorded from two synergist muscles via needle electrodes while subjects performed steady, low level, isometric contractions. The motor unit recordings were amplified (1- 10K), bandpass filtered (0.5 - 10Khz) and recorded on magnetic tape for off-line analysis. Using window discriminators, the recorded motor unit spikes were converted to a series of TTL pulses to trigger programmable clock-counters which measured the interspike intervals with a resolution of 0.1 msec. Cross-correlation histograms (lags of -100 to 100 msec, bin width 1 or 2 msec) were calculated from these two interspike interval records. The amplitude and statistical significance of peaks in the histogram were determined as described by Sears and Stagg (1976).

Preliminary results support the existence of common inputs to different elbow flexor muscles. Crosscorrelation histograms were constructed by correlating the discharge of single motor units in the brachioradialis muscle with multiple motor units in either the brachialis or the long head of the biceps. Although these histograms were generally flat, significant central peaks of 12 - 20 msec duration were obtained in several instances where large numbers of spikes were analyzed (giving mean bin counts of at least 200). In these examples, spike-triggered averages from the single unit in brachioradialis into the raw, multiunit record from the other muscle showed that remote pickup from the triggering motor unit was insignificant. However, under certain recording conditions these remote potentials could lead to spurious peaks in the cross-correlogram. We are currently applying this technique to other synergist muscles of the upper limb in both normal and spastic, hemiparetic subjects.

332.14 EFFECTS OF SAMPLING RATE AND RECTIFICATION ON THE POWER SPECTRUM OF THE ELECTROMYOGRAM N. L. Suresh*, G. C. Agarwal, G. L. Gottlieb, Dept. of Physiology, Rush Medical College, Chicago IL 60612.

The purpose of this study was to investigate the effects of sampling rate and rectification on the power spectrum of the electromyogram (EMG).

The EMG from the biceps of three normal subjects was recorded from three channels (ch 1 - raw, ch 2 - full-wave rectified, ch 3 - full wave rectified and filtered) while the subject sat comfortably in a chair next to an elbow device with the elbow flexed 90 degrees. A DC torque motor was used to put out a constant torque against which the subject was asked to contract for 60 seconds. A computer was utilized to digitize the data at a 1000 Hz sampling rate (on each channel), which was then stored for later analysis. Filtering was done through a third order Paynter filter with a 10 ms averaging time. For analysis, data was sampled through a computer program by retaining every nth point (n = 1,2,4,8) yielding 1000,500,250 and 125 Hz sampling rates respectively. The power spectrum was calculated by using blocks of 1024 points (with the first and last 10% cosine tapered).

The power spectrum of the raw EMG, sampled at 1000 Hz, contained a peak spanning the range from 50 - 145 Hz after which the magnitude rapidly decreased. The results indicate that 500 Hz is the lowest rate at which the raw and full wave rectified signal can be sampled, while retaining the correct frequency information. For the full-wave rectified and filtered signal, 250 Hz is allowable.

Rectification of the EMG considerably altered the frequency spectrum, producing a major peak to the left (0 - 50 Hz) and a relative peak to the right(80 - 150 Hz) of that in the raw signal spectrum (sampled at 500 and 1000 Hz). The rectified and raw signal spectra did look identical beyond 170 Hz, although there is little energy in the original signal at these frequencies. Digital rectification of the raw signal (1000 Hz) produced a spectrum almost identical to that of the analog rectified signal in the low frequency region but differed from it in the higher frequency portion.

332.15 CONDUCTION VELOCITY OF MOTOR UNIT ACTION POTENTIALS IN HUMAN ANTERIOR TIBIAL MUSCLE AS A NEW SIZE PRINCIPLE PARAMETER. S. Andreassen* and L. Arendt-Nielsen*,(SPON: R.B. Stein) Dept. of Medical Informatics, Aalborg University, Strandvejen 19, DK-9000 Aalborg, Denmark.

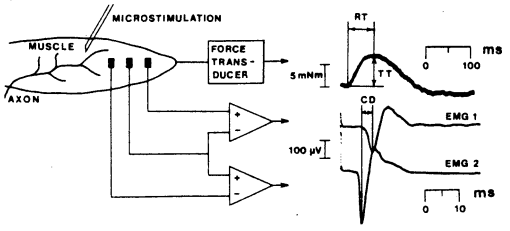

Fig. 1

Single motor units in human anterior tibial muscle were stimulated intramuscularly by a bipolar needle electrode.

The contractile properties of the motor units were obtained by averaging the torque developed around the ankle joint. Twitch torques (TT) ranged from less than 10^{-3} Newton·meter (Nm) to $16 \cdot 10^{-3}$ Nm, with a mean of $5.7 \cdot 10^{-3}$ Nm. Rise times (RT) ranged from 47-80 ms with a mean of 61 ms. The correlation coefficient R between rise times and twitch torques was -0.81 (N = 27, fig. 2a.).

The conduction velocity of motor unit action potentials was calculated from the conduction delay (CD) and the distance between the surface electrodes (see fig. 1). Conduction velocities ranged from 2.6-5.3 m/s with a mean of 3.7 m/s.

For individual motor units conduction velocity was highly correlated to twitch torque (R = 0.87, N = 29, fig 2b.) and to rise time (R = -0.75, N = 27, fig 2c.). This suggests that conduction velocity of motor unit action potentials is a member of the family of interrelated "size principle parameters".

This material has been submitted for publication in J. Physiol.

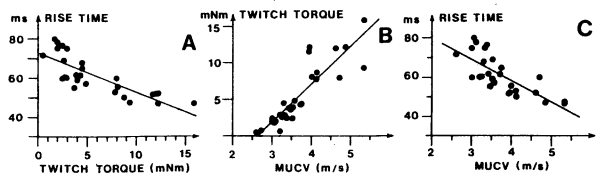

Fig. 2

332.16 A FAST, ACCURATE, ON-LINE SYSTEM FOR DISCRIMINATING ACTION POTENTIALS, BASED ON A TEMPLATE MATCHING ALGORITHM. T.S. Miles*, N. Smith*, K.S. Türker* and M.A. Nordstrom* (SPON: A. MACKAY-SIM). Department of Physiology, University of Adelaide, AUSTRALIA 5001.

In a multi-unit recording in nerves or muscles, the action potentials of individual neurones are recognized by their distinctive waveforms. However, most attempts to discriminate individual units are based on simply the amplitude of the waveform, or its amplitude at a particular time. A new system is now described, based on the ubiquitous IBM-compatible personal computer, which uses a sophisticated template-matching algorithm to discriminate simultaneously up to 3 units in real time. The system consists of a special-purpose printed circuit board which is plugged into an expansion socket in the computer, together with the operating software. The incoming multi-unit signal is digitized by an 8-bit analog-to-digital converter at up to 90 kHz sampling rate, and is stored by direct memory access. When an action potential exceeds an adjustable voltage threshold, a specifiable number of samples is collected and compared with stored templates of the waveforms of 3 unit potentials. The templates themselves are records of the unit potentials previously selected by the operator. When the waveform of an action potential in the incoming signal matches one of the templates, on analog acceptance pulse is output through one of three digital-to-analog ports. At the same time, the waveform of that action potential is displayed briefly on the computer screen alongside the image of the template to which it was matched to check the reliability of the discrimination. The instantanous firing frequencies of each unit are also displayed on the screen, and are available analog outputs from the circuit board. To deal with the situation in which a unit potential changes slowly in amplitude or waveform over time, the templates can be made adaptive; i.e., progressive changes in the unit potential are reflected by similar changes in the template. This is achieved by a continuous, weighted averaging of the incoming matched waveforms and the template. Waveforms which fail to be matched to a template are stored in memory and can be viewed one-at-a-time after a run. Inspection of the "rejected" waveforms is helpful in verifying the appropriateness of the discrimination settings. The reject file also contains the superimposed waveforms of pairs of units which occasionally fire simultaneously. To optimize the speed of the system, the program is written entirely in assembler language, utilizing scaled, fixed-point arithmetic. The user is able to vary all important operating parameters through a simply-learned set of keyboard commands. In practice, the system has been found to discriminate reliably between pairs of units which, because of similar amplitude action potentials, could not be separated by conventional window discriminators.

333.1 EFFECTS OF TEMPERATURE AND COLD ACCLIMATION ON NEUROMUSCULAR PROPERTIES OF CHELAE OF DECAPOD CRUSTACEAN SPECIES FROM TEMPERATE AND TROPICAL POPULATIONS. J.A. Blundon* (SPON: P.J. Stephens). Department of Zoology, Univ. MD, College Park, MD 20742.

This study tests the hypothesis that populations within a latitudinally dispersed species that experience different ranges of environmental temperatures will have different physiological responses to changes in temperature. Excitatory postsynaptic potential (EPSP) amplitude, summation, and facilitation as well as muscle stress and muscle fiber cable properties were measured in the chela closer neuromuscular system of temperate and tropical stone crabs Menippe mercenaria and blue crabs Callinectes sapidus. Northern populations of both crab species experience year round temperatures from < 5°C to 30°C, while the southern populations are exposed to a narrower range of temperatures as low as 15 to 20°C and as high as 30°C. No differences were found in neuromuscular performance of the northern and southern populations of both species when tested at summer temperatures common to both (30°C). Both northern and southern blue crabs were capable of acclimating from 30°C to 8°C in 4 weeks and showed similar levels of muscle stress at the two temperature extremes. Cold acclimated blue crabs from both populations had higher specific muscle fiber membrane resistance at 8°C than warm acclimated crabs. Neither stone crab population was capable of acclimating to 8°C over a 7 week period in the laboratory. However, when tropical stone crabs were transported to temperate waters in the summer and retested in the winter (at 8 °C), they showed similar neuromuscular properties as winter temperate crabs. There was a significant difference in specific muscle fiber membrane resistance between stone crabs naturally acclimated to 8°C and those that failed to acclimate in the laboratory. In all crabs, muscle performance was enhanced at cold temperatures due to increased muscle fiber membrane resistance which resulted in a broadening of EPSPs which enhanced EPSP summation and muscle fiber depolarization. The difference in acclimation ability of blue crabs and stone crabs is reflected in their natural environment. Blue crabs live in estuarine environments where large short term temperature fluctuations are much more common than in the marine subtidal environment of stone crabs.

333.2 DYNAMICS OF MUSCLE STIFFNESS IN A CRUSTACEAN SLOW MUSCLE. William D. Chapple, Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06268.

Although information has long been available about the dynamic properties of vertebrate muscle, little is known about the variations in dynamic stiffness in crustacean slow muscles with stretch amplitude and level of activation. Hoyle (1983) has suggested that decay after stretch has a time constant composed of two exponential terms, fast and slow.

To examine this in more detail, a decapod slow muscle, the right superficial ventral muscle of the fourth abdominal segment of the hermit crab, Pagurus pollicarus, was subjected to ramp stretches (36 mm/s, 3.2 muscle lengths/s) with amplitudes ranging from 0.5 to 1.6 mm. (4% to 14% of optimal length). Decays from peak force, sampled at 1KHz, were fit with a non linear least squares routine to an equation of the form $A_0 + A_1e^{-B_1t} + A_2e^{-B_2t}$. A third exponential term did not improve the fit of the equation. The slow time constant (B_1 = 0.214 s + 6%, n=18) did not vary with stretch length or level of isometric force prior to stretch. The fast time constant (B_2 = 0.013 s + 21%,n=18) decreased slightly (0.011s to 0.016s) but significantly ($p < 0.01$) with increasing isometric force but did not vary as a function of stretch length. All three coefficients (A_0,A_1,A_2) increased as a function of stretch length multiplied by the level of isometric force. At one stretch amplitude, A_1 was about 25% of A_0, but A_2 ranged from 50% of A_0 in passive muscle to 30% of A_0 in muscles stretched at higher levels (0.15 N) of isometric force.

Calculation of the parameters for active stiffness (coefficients of activated muscle minus the coefficients for passive muscle) suggests that muscle activation (over the ranges produced by the stretch reflex) does not alter substantially the dynamics of muscle stiffness, but multiplies it by a constant determined by the level of activation.

333.3 EFFECTS OF EXTERNAL Ca^{2+} ON CAFFEINE AND THEOPHYLLINE CONTRACTURES IN TONIC MUSCLE FIBERS OF THE FROG. J. Muñiz*, J. Dueñas* & M. Huerta. Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Apdo. Postal 199, Colima, Col. 28000 México.

To further investigate the role of extracellular Ca^{2+} on contractile activation in tonic muscle fibers, we have made a study of the ionic dependence of caffeine and theophylline contractures. Tension was isometrically recorded from bundles of cruralis muscle of Rana pipiens. Fibers of the cruralis muscle were current-clamped. The membrane potential corresponds to the values measured immediately after the insertion of the micropipette. Tonic muscle fibers were identified according to their passive electrical properties. Experiments were done at room temperature (20-22°C). Control solution was (mM): NaCl 117.5, KCl 2.5, $CaCl_2$ 1.8. pH was adjusted to 7.4 with imidazole-chloride. Caffeine and theophylline were added from concentrated aqueous solution. To reduce possible changes of the surface potential, $CaCl_2$ was replaced by $MgCl_2$ (3mM) or $NiCl_2$ (0.5mM). Contractures were elicited when caffeine or theophylline (0.5 - 14mM) was added to the control solution. The tension was sustained and the muscle fibers relaxed after caffeine or theophylline withdrawal. In both, the threshold concentration to elicited tension was about 0.5mM. With larger concentration (1-14mM) tension clearly rose to a peak and then relaxed to a low sustained level and it reached the maximum at about 14mM. The membrane potential of tonic muscle fibers was not modified by caffeine or theophylline. The membrane potential in control solution was -74 ± 8 mV (20), with caffeine (4mM) and theophylline (4mM) added they were -76± 9 mV (11) and -75 ± 6 mV (5) respectively.

We found that caffeine and theophylline contractures were highly Ca^{2+} -dependent. When external Ca^{2+} was omitted from the contracture fluid the caffeine and theophylline (0.5 , 1, 6mM) elicited a very small tension. This effect was reversible. The results suggest that external Ca^{2+} has to be continuously present to maintain the tension during caffeine or theophylline contracture.

333.4 MECHANICAL RESTITUTION IN NORMAL AND CARDIOMYOPATHIC HAMSTER HEARTS. S.E. Howlett and T. Gordon. Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2H7.

Cardiomyopathy (CM) in the hamster may be secondary to an increase in intracellular calcium (Ca) which may arise from defective Ca sequestration by the sarcoplasmic reticulum (SR). Ca distribution in the heart is dynamic, cycling between uptake, release and exchange compartments. The amount of Ca in these compartments may be systematically varied in isolated, stimulated (0.2 Hz, 1 Hz) left atria (2.5 mM Ca) and papillary muscles (1.0 mM Ca) from normal and CM hamsters by comparing the effects of interposing varying test intervals on steady state muscle force (mechanical restitution). The force produced by the heart is a function of the amount of Ca released by the SR release compartment. At short test intervals (≈ 1 s) there was a small peak in the force-interval curve which reflects Ca movement from SR uptake to release compartments; this was similar in normal and CM muscles. At longer test intervals (≈ 25 s) a large peak, related to Ca movement from exchange to release compartments, was also similar in normal and CM tissues. When stimulation was interrupted for very long intervals (>10 min) there was a marked decrease in force in both normal and CM muscles which reflects Ca loss from the release compartment. Normal and CM hearts differed only in that the rate of recovery of force following long test intervals was greatly slowed in CM atria (Figure 1). The mechanical restitution data shows that 1) the dynamic Ca movement between uptake, release and exchange compartments is similar in normal and CM hearts and 2) the recovery of force is slowed following long test intervals and is consistent with less Ca in the uptake compartment. The slowed recovery of force is consistent with 1) less Ca influx, which is unlikely as there is no change in the number of Ca channels in normal and CM hearts (Howlett & Gordon, Biochem. Pharmacol., in press), 2) reduced Ca sequestration by the SR or 3) a decrease in the Ca storage capacity of the SR and may account for Ca overload in CM hearts.

333.5 ACTIVATION OF SINGLE MUSCLE FIBERS REVEALED BY 2-DEOXYGLUCOSE-6-PHOSPHATE (2DG6P). D.A. Gordon, R.M. Enoka, D.G. Stuart, B.J. Norris*, P.M. Nemeth and O.H. Lowry*. Depts. of Neurology and of Anatomy and Neurobiology and of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110. Dept. of Physiology, Arizona Cen. for Health Sci., Univ. of Arizona, Tucson, AZ 85724.

In skeletal muscle cells, carbohydrate substrates for energy metabolism arise from endogenous glycogen breakdown and exogenous glucose uptake. Both of these processed are operative during muscle fiber activation. In the past, depletion of glycogen has been used as an indicator of activity in single fibers, however, the adequacy of this technique has recently been questioned (J. Neurosci. 6:892, 1986). In the present work, the relation between glycogen depletion and glucose uptake was investigated in fibers of cat tibialis anterior muscle activated in situ by electrical stimulation of single motor axons. 2-deoxyglucose, which has the same intercellular transport mechanism as glucose, was intraveneously administered and provided the substrate for the cellular accumulation of 2DG6P. Following activation, the muscle was removed and single fibers were examined for qualitative glycogen depletion using the glycogen-specific periodic acid Schiff reagent (PAS), and for quantitative levels of 2DG6P. In muscles exhibiting the typical motor unit mosaic pattern of PAS-negative fibers, glycogen depletion and increased 2DG6P coexisted, with few exceptions. The 2DG6P was about 20 times higher in PAS-negative fibers compared to the PAS-positive, presumably inactive, control fibers. In contrast, there was a dissociation between glycogen depletion and 2DG6P in fibers which did not exhibit the typical motor unit depletion pattern, in particular, where entire fascicles contained PAS-negative fibers. In these fascicles, none of the glycogen depleted fibers had elevated levels of 2DG6P. This suggests that there may be differential activation of the glycogen breakdown and glucose uptake processes. Local ischemia can induce glycogen breakdown in muscle fibers, but not increase glucose uptake. Thus, glycogen depletion is not always a reliabale indicator of muscle fiber activation. In such instances, the uptake of glucose, as measured by the accumulation of 2DG6P, can be used to verify acute activity of muscle cells.

333.6 GLYCOSPHINGOLIPID SYNTHESIS IN VITRO BY FUSION COMPETENT (C-2) AND FUSION DEFECTIVE (BC3H1) MURINE MUSCLE CELLS. K.C. Leskawa* and E.L. Hogan (SPON: D.A. Cotanche). Department of Neurology, The Medical University of South Carolina, Charleston, SC 29425.

We have previously reported that ganglioside synthesis by rat L6 muscle cells in culture transiently doubles when myoblasts achieve contact and begin fusing, while neutral glycosphingolipid (GSL) synthesis gradually decreases as myotubes form (Leskawa et al., Soc. Neurosci., 1986). Such a transient increase in the synthesis of either gangliosides, neutral GSLs or both has also been observed with the murine G-7 and G-8 lines and primary cultures of chick embryo pectoral muscle (Leskawa et al., Int. Soc. Neurochem., 1987). Here, we report a comparison of a murine muscle cell line, C-2, and a nonfusing varient, BC3H-1.

Both cell types were cultivated for 9 days in complete medium, and harvested at days 2, 3, 4, 7 and 9, after addition of [3H]-galactose 12 hr prior. Gangliosides and neutral GSLs were purified by extraction, saponification, and column chromatography on silicic acid, C18 and DEAE-Sephadex. Both cell types reached confluency at day 3, when C-2 cells began fusing (over 75% total nuclei within myotubes by day 7). Creatine kinase activity gradually rose with time in culture in both cell types.

Labeling of gangliosides by C-2 cells increased significantly on day 3 (approximately twice day 2 values) and then decreased. Neutral GSL labeling decreased during this period, with day 3 values being one-half those at day 2, and then remained constant. The decrease was greatest with nLcOse4Cer, which comprised 83% of labeled neutral GSLs on day 2, but 51-31% days 3-9. Labeling of both gangliosides and neutral GSLs by BC3H1 cells during this period did not vary significantly. BC3H1 cells synthesized LacCer, GbOse3Cer and a GSL tentatively identified as the Forssman hapten, with no changes during time in culture. GM3 was the major ganglioside synthesized by both cell types, with little change in ganglioside distribution with time in culture.

These results support our observations of a transient increase in GSL synthesis during myogenesis, and suggest that this response is lacking in fusion-defective myoblasts. While BC3H1 cells do not fuse to form myotubes, others have shown that they aquire many other biochemical aspects of differentiated muscle, including shifts in creatine kinase isoenzymes, expression of acetylcholine and insulin receptors and N-CAM. Therefore, the present results further suggest that increased synthesis of glycolipids may be integral to development of the morphological phenotype, i.e., the fusion of myoblast membranes to form multinucleated myotubes.

333.7 CHONDROITIN SULFATE COMPONENT IN MEMBRANES (EXTERNAL LAMINAE) SURROUNDING INDIVIDUAL AVIAN INTRAFUSAL FIBERS. A Maier and R. Mayne. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

Serial cross sections of muscle spindles from eight-week old chick tibialis anterior muscle spindles were incubated with monoclonal antibodies against O-sulfated (IB5), 4-sulfated (2B6) and 6-sulfated (3B3) chondroitin sulfate. These antibodies have been shown to combine with a residue of the glycosaminoglycan portion of the proteoglycan after it has been incubated with chondroitinase, and they do not react with the intact molecule (Couchman et al., Nature 307:650-652, 1984). Other sections were incubated with a monoclonal antibody (CS-56) (Avnur and Geiger, Cell 38:811-822, 1984) which reacts with intact, undigested chondroitin sulfate chains. The location of the immunohistochemical staining was verified by inspecting sections with phase contrast microscopy. Chondroitinase did not affect the immunohistochemical appearance of heparan sulfate proteoglycan. In the muscle spindle the presence of immunohistochemical reaction product was essentially limited to the external (basal) lamina that is associated with intrafusal fibers. No staining was apparent in the periaxial space or the outer spindle capsule. The antibody against the O-sulfated compound (IB5) produced no reaction product, even after pretreatment with chondroitinase. At the equator after incubation with 2B6 or 3B3 staining was limited to a narrow band. It coincided in location with the external lamina that is interposed between sensory terminals and the collagenous sheath that covers the sensory terminals. Staining around entire intrafusal fibers and along the external surface of the collagenous sheath was apparent at the equator after incubation with CS-56. At the polar region 2B6 gave a very weak reaction or no reaction at all, but 3B3 and CS-56 produced a staining pattern around extrafusal and intrafusal fibers that was reminiscent of the location of the external lamina. Results of this study show that subspecies of chondroitin sulfate in which the position of the sulfate group differs may be selectively distributed along excitable cells. With this arrangement the negatively charged chondroitin sulfate conceivably could impart specific electrical properties to intrafusal fibers. In this context it should be noted that at the equator the location of the 4-sulfated and 6-sulfated variants is limited to that portion of the external lamina which overlies the sensory terminals, the sites where the afferent signals originate. Alternately, proteoglycans may act to attach collagen to basal (external) laminae (Koda et al., J. Biol. Chem. 260:8157-8162, 1985). This view is supported by the presence of chondroitin sulfate immediately adjacent to the collagenous sheath.

333.8 CLASSIFICATION OF FIBER TYPES IN TURTLE NECK MUSCLE. R.J. Callister, R. Callister, and E.H. Peterson. Dept. Zoological & Biomedical Sciences and College of Osteopathic Medicine, Ohio University, Athens, Ohio, 45701.

As part of a study aimed at understanding the control of head movement in a turtle, Pseudemys scripta we have characterized its neck muscle fiber types using histochemical markers which are known to have functional significance. We reacted serial sections with markers for contraction speed (Myosin ATPase), oxidative metabolism (NADH-diaphorase) and two glycolysis associated markers (alpha-glycerophosphate dehydrogenase [GPDH] and glycogen phosphorylase A [GPA]). We used microphotometry to quantify the intensity (optical density) of the reaction deposit in each fiber, and we subjected the resulting optical density measurements to a cluster analysis to assign fibers to groups (fiber types). For comparison we processed turtle hindlimb muscle ambiens and rat sternomastoid simultaneously.

Our results suggest that in turtle muscle, as in mammals, slow (Type I) and fast (Type II) contracting fibers can be distinguished by reversal of the routine ATPase staining pattern (generated at pH 9.4; or with preincubation at pH 10.4) after acid preincubation, but the pH at which reversal occurs is higher (pH 4.5) than in mammals (pH 4.2). In both neck and limb turtle muscle an intermediate staining fiber type (IIb) can be demonstrated following preincubation at pH 4.7; this is higher than the pH needed to demonstrate intermediate fibers in rat (pH 4.5). Furthermore, intermediate fibers demonstrated by ATPase staining differ in the two species: turtle IIb fibers have higher oxidative capacity and GPA activity than IIa fibers (fibers with low myosin ATPase activity after acid preincubation), but in rat muscle this condition is reversed.

Cluster analysis results suggest that turtle (like rat) muscle can be grouped into three fiber classes: slow oxidative (SO), fast oxidative glycolytic (FOG) and fast glycolytic (FG). A discriminant function analysis of the groups generated by the cluster analysis suggests that a fiber classification based on both ATPase and metabolic markers yields more accurate group assignments than a scheme based on ATPase staining alone, and that these two classification schemes yield somewhat different group assignments. This analysis also revealed that the histochemical markers which best differentiate muscle fiber types differ in turtle and rat.

Our results suggest that turtle muscle can usefully be grouped into three fiber types (SO, FOG, FG), but these types differ from like-named fiber types in rat muscle both in the pH lability of their myosins and in their metabolic profiles.

333.9 NEONATAL SOLEUS MUSCLE FIBERS ARE HETEROGENEOUS IN THEIR MYOSIN HEAVY AND LIGHT CHAIN COMPOSITIONS. H. L. Sweeney*, L. A. Sutton* and W. J. Thompson. Depts. of Zoology and Physical & Health Education, University of Texas, Austin, TX 78712.

Myofibrillar ATPase histochemistry of neonatal rat soleus suggests the muscle contains two types of fibers 16-18 days after birth. By use of glycogen depletion it has been shown that single motor units in these muscles are comprised mostly of one or the other of these two fiber types (Nature 309: 709), suggesting that the muscle contains two distinct types of motor units. Measurements of the contractile characteristics of single units in these muscles showed, however, that these units had a wide range of unloaded velocities of shortening, distributed apparently unimodally (Soc. Neurosci. Abs. 11: 1287). Since the unloaded shortening velocities were determined using the "slack test" (J. Physiol. 291: 143) and since the slack test gives the velocity of shortening of the fastest contracting fibers in each unit, this result was interpreted to mean that motor units in the muscle are comprised of a non-random assortment of fibers. A random innervation would be expected to result in units each of which should contain some of the fastest fibers present in the muscle. However, this result also suggests that myofibrillar ATPase histochemistry underestimates the diversity of fiber types present in the muscle. We have attempted to test this prediction by examining the myosin heavy and light chain composition of single muscle fibers in 16-18 day old rat soleus muscles.

Single fibers were mechanically teased from 16-18 day old muscles treated overnight with a skinning solution (Tissue & Cell 11: 143). The proteins in each fiber were extracted in 2 µl of SDS sample buffer and analyzed on SDS polyacrylamide gels. Myosin heavy chains (MHC's) and light chains (MLC's) were detected following silver-staining. Electrophoresis on 5% gels (Biochem. Biophys. Res. Comm. 116: 793) resolves two clear bands representing the MHC's in these muscles: the faster migrating band moves to the same position in the gel as adult slow MHC whereas the slower migrating band moves to the same position as adult fast MHC. Since additional bands corresponding to embryonic and neonatal MHC's do not clearly resolve as extra bands on these gels, we cannot positively identify the MHC's comprising the bands. Nevertheless, more than three patterns of MHC's are seen in individual fibers: either of the two bands by itself or both of the bands in varying relative intensities. Electrophoresis on 13% gels resolves at least two patterns of myosin light chains in the individual fibers. The first pattern consists of $LC1_S$, $LC2_S$, and $LC2_F$. The second pattern consists of the three LC's in the first pattern together with two additional LC's: $LC1_F$ and a fifth LC of mobility intermediate between that of $LC1_S$ and $LC1_F$. Each of these two patterns of light chains was observed in fibers having each pattern of MHC. This heterogeneity of myosin among single fibers is consistent with the previously observed broad distribution of velocities of unloaded shortening measured in single motor units. Thus, the histochemically derived notion of only two fiber types existing at this developmental stage is an oversimplification.

333.10 CORRELATION OF FIBER SIZE AND NECROSIS IN SKELETAL MUSCLE OF C57BL/6J DY2J/DY2J DYSTROPHIC MICE. H.L. Davis, G. Desypris and S.L. Lui*, Department of Anatomy, and School of Physical and Occupational Therapy, McGill University, Montreal, Canada, H3A 2B2; and Department of Physiology, University of Ottawa, Ottawa, Canada, K1H 5A3.

The muscular dystrophies have long been considered as inherited diseases of muscle (myogenic theory) because of the widespread changes in the muscle, however the basic biochemical defect has yet to be elucidated. The currently popular myogenic theory is that of a sarcolemmal abnormality, and it has been proposed by G. Karpati and colleagues that muscle fibers must obtain a certain diameter before the dystrophic phenotype (necrosis) is expressed, possibly due to factors related to contraction-related strains per unit surface area. The considerable evidence which supports this theory has been obtained from studies on human (Duchenne), hamster and MDX murine dystrophic muscle, in which it was shown that fibers with large diameters were severely affected while those of smaller caliber (e.g. developing, denervated while young) did not show signs of necrosis. The present study examined the relationship between fiber size and severity of necrosis in C57BL/6J dy2j/dy2j male dystrophic mice.

The extensor carpi radialis longus (ECRL) and brevis (ECRB) muscles from normal (+/+) and dystrophic (dy2j/dy2j) mice at 4 wk or approximately 1 yr of age were used for this study (n=5 per age group). Cross-sections from the mid-belly regions of the muscles were stained with haematoxylin and eosin, for activity of myofibrillar ATPase, and by immunohistochemistry for localization of specific isoforms of heavy chain myosin. The two muscles were found to have similar fiber type composition and there were no differences between mean cross-sectional areas of type II fibers (stained for activity of ATPase) of ECRL and ECRB muscles of either normal or dystrophic mice in either age group. Dystrophic ECRL muscles, however did exhibit significantly more necrosis, as determined by percentage of total fibers with centronucleation, than ECRB muscles ($\bar{x} \pm$ SEM = 28 + 2% and 18 $\pm$ 2 % respectively for 1 yr old animals). Since the ECRL and the ECRB muscles occupy a similar environment and work together functionally, the results from the present investigation do not support the hypothesis that phenotypic expression of the dystrophic gene is dependent on the caliber of the skeletal muscle fibers in dy2j/dy2j mice.

This work was supported by a grant from the Medical Research Council of Canada to H.L.D. The antibodies were a generous gift of Dr. S. Schiaffino, Padua, Italy.

333.11 HISTOPATHOLOGY OF SKELETAL MUSCLES IS SIMILAR IN AGED DYSTROPHIC CHICKENS AND HUMAN DUCHENNE DYSTROPHY. R.K. Entrikin, R.T. Abresch*, D.B. Larson*, R.B. Sharman*, and W.M. Fowler*. Dept. of Physical Medicine & Rehab., Univ. of Calif., Davis, CA 95616.

Although hereditary muscular dystrophy of the chicken (HMDC) has been widely used as an animal model of human Duchenne muscular dystrophy (DMD), its validity has been questioned due in part to less severe histopathological changes in comparison to DMD muscle. Since previous histological analyses of muscles in HMDC have involved relatively young animals (usually about 8 weeks of age), we have tested the hypothesis that progression of the dystrophy might lead to more severe changes in older, adult birds.

Histopathology was analyzed qualitatively and quantitatively (computer-based image analysis system) in pectoralis major muscles from 2 genetic lines of normal (03 & 412) and dystrophic (433 & 413) chickens at early (6 weeks) and advanced (18 months) stages of the disease. At 18 months muscles from both lines of dystrophic chickens exhibited severe histopathological changes that were strikingly similar to those observed in human biopsy slides. In fact, 3 "blinded" clinicians could not distinguish between hematoxylin-eosin stained cross-sections of dystrophic chicken and human DMD muscles, except for internal nuclei typical of avian muscles. Both HMDC and DMD muscles exhibited a significant increase in fiber size variability, proliferation of connective tissue, phagocytosis, and degeneration. Avian sections also revealed extensive splitting of large muscle fibers, one possible origin of the many small fibers in late stages of avian dystrophy. Fiber size (cross-sectional area in square microns) and percent connective tissue in muscles from one normal and one dystrophic line of chickens are shown below (N: number of muscles; values: mean $\pm$ SEM):

	AGE	LINE	N	FIBER SIZE	CONNECTIVE TISSUE
Normal	6 Wk	03	4	332 $\pm$ 16	31% $\pm$ 3%
Normal	18 Mo	03	8	1447 $\pm$ 64	22% $\pm$ 1%
Dystrophic	6 Wk	433	6	424 $\pm$ 20	34% $\pm$ 2%
Dystrophic	18 Mo	433	10	896 $\pm$ 79	73% $\pm$ 3%

In addition to the histopathological similarities between HMDC and DMD, recent reports have shown that a single drug that improved muscle function in avian dystrophy has now produced positive effects in DMD patients. These observations strongly support use of the dystrophic chicken to advance knowledge of human neuromuscular diseases. (Supported by NIDDR Grant #G008300078.)

333.12 ANALYSIS OF HIGH MOLECULAR WEIGHT PROTEINS IN DUCHENNE AND BECKER MUSCULAR DYSTROPHY. R MEDORI*, R WATERSTON*, M BROOKE*, Washington University School of Medicine, St. Louis, MO.

We analysed muscles from biopsies of patients with Duchenne and Becker muscular dystrophy using polyacrylamide gel electrophoresis. Total muscle homogenates and myofibril preparations were processed for separation by polyacrylamide electrophoresis using 4% gels. Patients with neurogenic atrophy and different forms of myopathies other than dystrophy as well as normal fetal and mature muscles were used as controls. In preliminary work, muscle biopsies from patients with Duchenne and Becker muscular dystrophy show the absence of an approximately 500 KD polypeptide in the patients with muscular dystrophy. This high molecular weight protein may correspond to nebulin, which has been suggested to be the Duchenne dystrophy gene product. Efforts are underway to establish the relationship of the 500 KD protein to nebulin. The extra doublet of polypeptides in fetal and Duchenne muscle has been characterized as spectrin in Western blots. In the muscle affected with congenital dystrophy both the extra doublet of bands and the 500 KD polypeptide are present. A study of the Duchenne muscular dystrophy patients from this clinic is planned to determine if these preliminary findings can be generalized. Patients with an alteration in size of the putative nebulin band would be of particular interest. These findings open a new approach to the study of the pathogenetic mechanisms of Duchenne and Becker muscular dystrophy.

ANALYSIS OF HIGH MOLECULAR WEIGHT PROTEINS IN DUCHENNE AND BECKER MUSCULAR DYSTROPHY. R MEDORI*, R WATERSTON*, M BROOKE*,(SPON: R. Wilkinson) Dept. of Cell Biology & Physiology, Washington University Med. Ctr, St. Louis, MO 63110.

333.13 FIBER TYPE SPECIFIC ENZYMATIC TRANSFORMATION IN NEWLY FORMED HUMAN MOTOR UNITS. W.R. Turk* and L.A. Wargowski* (SPON: N.J. Lenn). Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908

In mammalian skeletal muscle the motoneuron has a significant influence on the metabolic characteristics of the fibers it innervates. We have studied whether human skeletal muscle fibers within newly formed motor units acquire biochemical similarity following innervation by a common motoneuron.

Serial sections were obtained from the gastrocnemius muscle of a patient with motoneuron disease. Histochemical staining with myosin ATPase (pre-incubation pH 4.6) demonstrated a loss of the normal fiber type mosaic pattern and areas of fiber type grouping, which identify fibers that have been denervated and subsequentially reinnervated by a common motoneuron (Karpati G. & Engel W., Neurol. 18:447, 1968). Individual fibers within four regions of fiber type grouping were isolated and quantitatively assayed to determine their activity for lactate dehydrogenase (LDH) and adenylokinase (AK).

	Fiber Type	n	LDH*		AK*	
I	Motor Unit A	12	20.79 ± 3.30	15%	44.94 ± 5.62	13%
	Motor Unit B	10	7.30 ± 1.88	26%	24.99 ± 3.38	14%
	Random Fibers	18	9.30 ± 3.57	38%	29.77 ± 7.49	25%
	Total	40	12.30 ± 6.53	53%	33.11 ± 10.05	30%
IIA	Motor Unit C	13	39.80 ± 4.32	11%	82.13 ± 6.79	8%
	Random Fibers	20	37.14 ± 5.96	16%	85.87 ± 13.79	16%
	Total	33	39.19 ± 5.46	14%	84.70 ± 11.77	14%
IIB	Motor Unit D	7	42.29 ± 2.99	7%	103.37 ± 9.64	9%
	Random Fibers	20	44.66 ± 9.27	21%	113.45 ± 16.36	14%
	Total	27	44.10 ± 8.12	18%	110.84 ± 15.40	14%

*Enzyme activities are moles/kg dry wt/hr from duplicate samples expressed as mean ± S.D. and coefficient of variation. n=number of fibers.

The results demonstrate that fibers within newly formed motor units are enzymatically homogeneous when compared to randomly selected fibers of each fiber type. The variability within motor units composed of type IIA or IIB fibers approached the experimental error of the method (determined by multiple measures on individual fibers to be 5.9%). Within type I motor units there was greater variability than within type IIA and IIB motor units. This is in contrast to our previous examination of newly formed motor units in the rat using a nerve crush model where the extent of variability within newly formed motor units was identical regardless of fiber type (Nemeth P. & Turk W., J. Physiol. 355:547, 1984). These findings suggest a divergence with respect to the direction and extent of motoneuron directed fiber type transformation. Type II to type I transformation appears enzymatically less complete than type I to II transformation in human skeletal muscle. (Supported by NIH grant NS00957)

333.14 INCLUSION BODY MYOSITIS: A LIGHT MICROSCOPIC AND ULTRASTRUCTURAL ANALYSIS. M.J. Winger* and R.I. Roelofs* (SPON: D. Knopman). Dept. of Neurology, University of Minnesota, Minneapolis, MN 55455.

Inclusion body myositis (IBM) is thought to be a distinctive but rare myopathic disease of skeletal muscle. It is characterized by intramuscular rimmed vacuoles that stain basophilic with H&E, red on modified Gomori's trichrome and are acid phosphatase negative on cryostat sections. Final diagnosis depends on EM demonstration of intranuclear and/or sarcoplasmic fibrillary inclusions, 15-18 nm in diameter. Typically these patients develop painless extremity paresis in their sixth and seventh decades that is slowly progressive and involves proximal more than distal muscles. Serum creatine kinase may be normal or modestly elevated. The disease tends to be refractory to immunosuppressive therapy compared to polymyositis and dermatomyositis. Fewer than 60 cases have been reported in the literature. We report analysis of 686 consecutive muscle biopsies; 138 (20%) had features of an inflammatory myopathy and 38 of these had the characteristic light microscopic features of IBM. This latter group represented 5.5% of the total and 28% of the idiopathic inflammatory myopathies. To qualify for the diagnosis of probable IBM, at least 1% of muscle fibers had to contain the typical vacuoles on cryostat sections. None of the cases were felt to have any of the other rare conditions associated with a myopathy having rimmed inclusions. Seventeen of the 38 cases had ultrastructural evaluation; 9 demonstrated the pathognomic sarcoplasmic fibrillary inclusions, while 8 had sarcomembranous inclusions commonly seen in IBM but not considered diagnostic of the condition. All of these 8 cases had a low percentage (1-3%) of fibers containing rimmed vacuoles on light microscopy. Sampling error could account for the negative EM results. There was no light microscopic difference between the 9 proven cases of IBM, the 8 cases with only sarcomembranous inclusions and the remaining cases not studied with EM. It is likely that most of the 38 cases do in fact represent IBM, at least pathologically. As a tertiary referral center, our patient population is biased with cases that pose diagnostic or therapeutic dilemmas. However our high proportion and absolute numbers of cases with a pathologic diagnosis of IBM seem excessive. IBM may be a more common clinical pathologic disorder than previously recognized or conversely the histologic and ultrastructural features of IBM are less specific than generally appreciated.

SPECIAL LECTURE

334 SPECIAL LECTURE. NEUROETHOLOGY OF ELECTRIC FISH: THE ROLES OF ANALOGIES VS MODELS IN COMPREHENDING NEURAL SYSTEMS. Theodore H. Bullock, University of California, San Diego.

Loose, graphic analogies and formal models have distinct, mainly heuristic values as well as serious inadequacies. Nothing substitutes for specific anatomy and physiology of actual neural systems including the comparison of similar but contrasting systems. Nature often uses different solutions to common problems. Seven general neurobiological issues will be illustrated, mainly with examples from gymnotiform and mormyriform electric fish.

(1) The parliamentary analogy for control of graded behavior grades into oligarchy for switching of either-or behavior. The orchestra analogy of spatiotemporal pattern coding grades into a corporation or university analogy for decision and control.

(2) Corollary discharge is used in some taxa but not others, and at its best shows rapid learning of the reafference to be expected. (3) Special mechanisms act in some species to regularize pacemaker units, greatly reducing the variance of intervals, and others act to deregularize; some modulate pacemaker firing for social signaling. (4) Receptors and central neurons are tuned to respond best to a certain band of input signals, a frequency band in the cases here considered; the tuning may be more or less plastic if the internal milieu is conducive. (5) Multiple maps present several kinds of problems. One is the distinction between projection maps that preserve neighbor relationships and computed maps that extract parameters from converging afferents. Another is the distinction between maps that represent two equivalent dimensions of the input (e.g. somatotopic) and those represent only one or else 2 or 3 nonequivalent dimensions intersecting at some angle.

(6) The cerebellum presents an opportunity to compare functional organization in a conservative organ, highly developed in some fishes, with that in mammals and other classes. Apparent differences are a challenge to interpretation.

(7) Processing in afferent pathways, serial and parallel, from medullary input through midbrain, diencephalon and telencephalon, presents opportunity and challenge in other ways. Among the aspects to be discussed will be the meaning of the contrast between mammalian and fish telencephalon, the former showing responses readily and at high repetition rates, the latter only within a fractional mm of the hot spot and at extremely long intervals. The relation between unit and population responses, spikes and evoked potentials, exogenous and relatively endogenous event related potentials may give clues to the nature of evolution of neuronal cooperativity.

335 SYMPOSIUM. STIMULANT-INDUCED SENSITIZATION; BEHAVIOR AND NEUROPHARMACOLOGY. W.H. Riffee, University of Texas at Austin (Chairperson); B.A. McMillen, East Carolina University; G.V. Rebec, Indiana University; T.E. Robinson, University of Michigan.

Striatal dopamine (DA) exists in a large storage pool and a readily releasable pool, but the other monoamines do not. This distinction is important for both the acute effects of amphetamines and non-amphetamines and for the long term effects of stimulant or antipsychotic drugs on the dopaminergic system compared to the other monoaminergic systems. DA appears to be very much involved in the phenomenon of stimulant-induced sensitization. Many of the processes involved in the availability of DA within the dopaminergic neuron (transmitter synthesis, autoreceptor sensitivity, receptor-mediated control of synthesis and release as well as frequency of cell firing) have been studied and characterized as to their potential role in sensitization while other processes are yet to be explored in sufficient detail. Now, there are indications that certain drugs may interfere with the ability of central nervous system stimulants to induce sensitization.

One of the most important aspects of stimulant-induced sensitization is the effects that these drugs have on processes within the neuron which are not restricted to the nerve ending itself but extend to the cell body and its associated structures. Single-unit recording techniques have been used to investigate pre- and postsynaptic changes in monoaminergic systems during long-term amphetamine treatment. Such treatment increases impulse flow in dopaminergic and serotonergic neurones, and this effect is mediated in part by subsensitive autoreceptors. In sites downstream from monoaminergic terminals, including the neostriatum and substantia nigra pars reticulata, multiple amphetamine injections also accelerate neuronal activity. In these sites, however, the actions of amphetamine appear to reflect a complex interaction between monoaminergic mechanisms and other neurochemical systems.

Finally, the symposium will look at an overview of various stimulant drugs as well as stress and their enduring effects on brain dopamine systems and behavior. Additional information will be presented which discusses factors that are known to contribute to individual variation in sensitization and sucseptibility to the phenomenon.

336 SYMPOSIUM. A HEART-BRAIN PEPTIDE: THE ATRIAL NATRIURETIC FACTOR. J.M. Saavedra, NIMH (Chairperson); A. de Bold* Heart Institute, Ottawa; T. Inagami, Vanderbilt Univ.; C. Glembotski, San Diego St. Univ.; C. Saper, Univ. of Chicago; R. Quirion, Douglas Hosp., Quebec; A. Negro-Vilar, NIEHS, NC.

The atrial natriuretic factor (ANF) is a potent diuretic and natriuretic hormone released by the heart atria to the circulation. Peripherally, it inhibits renin and aldosterone secretion. In addition, circulating ANF has central actions, and the brain contains an endogenous ANF system and ANF receptors.

Dr. de Bold will define ANF biochemically and will analyze its production, storage and processing in the brain and peripheral tissues.

Dr. Inagami will describe the ANF forms in hypothalamus and other brain areas, its mechanism of secretion from neuronal tissues and its central antagonism of angiotensin II-induced hypertension.

Dr. Glembotski will compare the atrial and brain ANF molecular forms, and the molecular characteristics and the brain and peripheral ANF receptors using chemical crosslinking techniques, which demonstrate tissue-specific receptor heterogeneity.

Dr. Saper will describe the immunohistochemical evidence for the ANF system of neurons in the brain and will demonstrate that centrally administered ANF can inhibit baroresponsive vasopressin neurons.

Dr. Quirion will describe the characterization and distribution of brain ANF binding sites, including in human brain, their differences and similarities with peripheral sites, their alterations in disease states and their coupling to second messengers and other neurotransmitter systems.

Dr. Negro-Vilar will present evidence for a physiological antagonism between ANF and angiotensin in the central nervous system, with special emphasis on their interactions in relation to water intake.

The localization of brain ANF and its receptors, their brain-specific molecular forms, the central actions of ANF to decrease drinking, to lower blood pressure in hypertensive animals and to inhibit vasopressin secretion and saline preference, together with the very low numbers of brain ANF receptors in genetically hypertensive rats, and the presence of ANF receptors in the choroid plexus indicate that this peptide has important actions in central fluid and cardiovascular regulation and in the production of cerebrospinal fluid.

PROCESS OUTGROWTH IV

337.1 TIME-LAPSE STUDIES OF ENCOUNTERS BETWEEN SENSORY NEURON GROWTH CONES AND MOTONEURONS. M. G. Honig. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109

In the chick hindlimb, sensory neurons grow along the appropriate pathways from the outset during normal development, but sensory neuron pathway selection is aberrant in the absence of motoneurons (Landmesser and Honig, Dev. Biol. 118:511). This result suggests that motoneuron (MN) axons guide outgrowing sensory neuron (SN) axons. To further address this possibility, I have begun to examine how the growth cones of SNs respond when they encounter the processes of MNs in dissociated cell cultures.

MNs and SNs were distinguished from one another and from other spinal cord neurons by labeling with highly fluorescent carbocyanine dyes (Honig and Hume, J. Cell Biol. 103:171). Prior to culturing, MNs from St. 25-27 embryos were retrogradely labeled by injection of the red dye, diI, into the lumbosacral spinal nerves. SNs were labeled green by dissociating lumbosacral dorsal root ganglia from St. 28-31 embryos in the presence of a second dye, diO. The cells were plated onto glass which had been coated first with polyornithine and then with laminin. The processes of the neurons were brightly labeled for the first few days in culture, during which time their interactions (in regions not complicated by the presence of other cells and processes) were assessed by videotaping. In most cases, the MN neurite under examination appeared to be an axon in that it ran a fairly long distance before branching.

A variety of behaviors have been seen. In some cases, the SN growth cone crossed the MN process. In other cases, the growth cone reoriented after its filopodia contacted the neurite, and instead of crossing, the growth cone grew roughly parallel to the neurite, typically separated by a distance of 5 - 20 μm, making repeated filopodial contact as it progressed. SN growth cones fasciculated only very rarely and for only short distances before diverging when they encountered MNs. This is likely to reflect, at least in part, the highly adhesive nature of the substrate, since fasciculation was also rare and brief when SNs encountered other SNs.

Finally, a common response was that the SN growth cone retracted from the MN. Sometimes this was followed by one of the behaviors described above or by growth in a direction away from the MN; in other cases the growth cone failed to progress any further for up to several hours. This last result is similar to the finding of Raper and Kapfhammer (Neurosci. Abst. 12:1335) that the growth cones of neurons originating from the peripheral nervous system (e.g. sympathetic neurons) tend to retract after they contact neurites of CNS origin (e.g. retinal neurons). However, the interactions between SN growth cones and MN processes (which normally encounter one another in the developing embryo) appear to be more varied and complex than those reported to occur between the more disparate sets of neurons. (Supported by NS21043 to R. Hume)

337.2 **STEREOTYPED PATHFINDING BY IDENTIFIED GROWTH CONES IN THE EMBRYONIC SPINAL CORD.** J.Y.Kuwada, A.Chitnis, & L.A.Lindamer. Dept. Biology & Institute of Gerontology, University of Michigan, Ann Arbor, MI 48109.

We are investigating how growth cones get to their targets in the simple spinal cords of zebrafish embryos by injecting dyes into individual neurons, backfilling neurons with axons in a single spinal tract with dyes, and by applying a monoclonal antibody (MAb ON1) we have generated that appears to recognize a subset of neurons in the embryonic CNS. MAb ON1 was generated by injecting membranes from optic nerves of adult carp into mice. It recognizes some of the axons in the early (up to 30 hr) embryonic CNS including the reticulo-spinal interneurons, neurons in the nucleus of the median longitudinal fasciculus (MLF), the C1 commissural neurons, and the Rohon-Beard neurons, but not the primary motor neurons nor any of the retinal neurons. By 52 hr MAb ON1 recognizes the segmental motor nerves, and in young adults many axonal tracts and nerves, including the optic nerve, are recognized.

Recent studies of axonal outgrowth in the embryonic fish (Eisen, et al., Nature, 1986; Kuwada, Science, 1986) demonstrated that the growth cones of identified neurons in the fish cord grow along precise routes to reach their targets. Likewise, we report that other embryonic growth cones extend in the embryonic CNS in a stereotyped fashion. The MLF contains the axons of a number of identified neurons in the fish CNS (Kimmel, et al., J.Comp. Neurol. 1982). Many of these neurons grow directly into the MLF. One of the most conspicuous hindbrain neurons, the M cell, projects its growth cone following approximately 18 hours of development at 29° C. In the next few hours it extends posteriorly and medially to cross the midline before proceeding posteriorly into the ventral portion of the spinal cord. Other large identified hindbrain neurons (RoL2, MiD1c, & MiD2c) grow into the MLF several hours after the M cell. These cells are followed by the neurons of the nucleus of the MLF found in the midbrain. Likewise, embryonic cord neurons project growth cones in a stereotyped fashion into their correct tracts. There are a set of large commissural interneurons that appear to be homologous to the C1 interneurons found in the embryonic cord of the Japanese medaka fish. These neurons appear not to be distributed in a strict segmental fashion: one is found every 1 or 2 hemi-segments and one does not always have a bilateral homologue in the same segment. By 22 hours of development the C1 neurons in anterior segments have projected growth cones that have extended ventrally and circumferentially, crossed the ventral midline and begun to grow anteriorly and dorsally on the other side. In the next several hours these growth cones extend into the mid-dorsal tract just ventral to the dorso-lateral fasciculus, the dorsal most spinal tract.

We are presently using the single cell techniques and generating more MAbs to learn more about how growth cones reach their targets in the vertebrate CNS.

Supported by research grants from NIH and the U of M.

337.3 INTRINSIC CELL POLARITY AND ORIENTATION OF AFFERENT PIONEER AXON OUTGROWTH IN THE GRASSHOPPER EMBRYO. Frances Lefcort and David Bentley. Neurobiology Group and Department of Zoology, University of California, Berkeley, CA, 94720.

In vitro, the site of growth cone emergence from neuroblastoma cells has been shown to be associated with microtubule organizing centers (Spiegelman et al, Cell 16, 253; 1979). What role, if any, might cellular control of the site of growth cone emergence play in the orientation of axon outgrowth in vivo? The pair of Ti1 pioneers are the first afferent neurons to initiate axonogenesis in grasshopper limb buds (Bate, Nature 260,54;1976). They are the progeny of an ectodermal mother cell situated at the distal tip of the limb, and extending from the apical to the basal surface of the epithelium (Keshishian, Dev.Bio. 80, 388; 1980). The mitotic spindle of this cell is aligned with the limb axis when it divides to produce the two pioneers, which thus have mirror image symmetry. In over 99% of limbs, the growth cone of the proximal pioneer emerges from the cell pole and is aligned with the former axis of the mitotic spindle (as indicated by the alignment of the pioneer nuclei). Therefore, while various extrinsic cues appear to orient these growth cones, it is possible that the initial orientation of axon outgrowth is due to intrinsic information (Bentley and Caudy, CSH Symp. Quant. Biol. 48, 573; 1983).

In most limbs, the distal pioneer extends its growth cone in close apposition to that of the proximal pioneer. In the minority of cases where this does not occur, the growth cone of the distal cell emerges from its distal pole and is also aligned with the former axis of the mitotic spindle, so that the two pioneers have mirror image configuration. This also suggests that growth cone emergence is initially determined by internal features of the cell.

How important might this internal information be in directing initial axon outgrowth from the pioneers toward their proximally located target, the CNS? To test this, we exposed grasshopper embryos to a pulse of 0.1 ug/ml cytochalasin D for 0.5 to 3 hours after the pioneer mother cell had divided, but before the initiation of pioneer axonogenesis, and then cultured the embryos for an additional twenty-four hours. Following cytochalasin treatment, some pioneer neurons initiated axonogenesis in non-proximal directions. In most cases, these growth cones reoriented proximally within 50 micrometers. Therefore, if internal information does control the direction of axon emergence (at least from the proximal pioneer), this factor is not essential for guidance of the axon in a proximal direction. On the other hand, it seems likely that internal information does control the site and direction of initial axon outgrowth, and that this underlies the very high incidence of proximally oriented axonogenesis.

337.4 THREE GENES ACT TOGETHER TO GUIDE SOME MIGRATING CELLS AND AXONS IN *CAENORHABDITIS ELEGANS*. B.D. Stern*, N. Ishii*, E.M. Hedgecock*, J. Culotti, and D.H. Hall. Department of Cell Biology, Roche Institute of Molecular Biology, Nutley, NJ 07110, Mount Sinai Hospital Research Institute, Toronto, Ontario, and Albert Einstein College of Medicine, Bronx, NY.

Over fifty mutations in the genes *unc-5, unc-6, and unc-40,* disrupt the dorsalward or ventralward migrations of neuron growth cones, and other cells, along the epidermis in the nematode *Caenorhabditis elegans*. Mutations in the *unc-5* gene selectively disrupt dorsalward migrations, which include migrations of the axons of ventral nerve motorneurons, and of the excretory canals, the head mesodermal cell, the hermaphrodite distal tip cells, and the male linker cell. Mutations in the *unc-6* gene selectively disrupt these dorsalward migrations as well as ventralward migrations, which include migrations of the axons of lateral sensory neurons, and of the hermaphrodite anchor cell, and the male linker cell. In *unc-5* and *unc-6* mutant animals the axons of ventral nerve motorneurons which normally grow along the epidermis to the dorsal nerve are instead found in lateral positions. Mutations in the *unc-40* gene disrupt primarily the abovementioned ventralward migrations. In *unc-6* and and *unc-40* mutants the axons of the lateral sensory cells which normally grow ventrally into the ventral nerve are instead found to wander about and only sometimes reach the ventral nerve. Thus, in large part, the defects found in *unc-5* and *unc-40* mutants are each a subset of the defects found in *unc-6* mutants. Interestingly, certain *unc-6* hypomorphic mutations preferentially disrupt either the dorsalward or ventralward migrations mentioned above.

These mutants suggest that neuron growth cones and migrating mesodermal cells share some guidance cues provided by the epidermis. Nerve growth cones migrate between the epidermal cell membrane and the epidermal basal lamina, while the migrating mesodermal cells have direct contact with only the basal lamina. Thus, it seems likely that some of the guidance molecules coded for by these genes are located within the epidermal basal lamina.

One model to explain the functioning of these guidance genes is that the wild type*unc-6* gene product is a core molecule produced by all the epidermal cells. This molecule is modified by graded expression of the wild type *unc-5* (dorsal > lateral > ventral) and *unc-40* (ventral > lateral > dorsal) gene products. An alternative model is that the wild type *unc-5, unc-6,* and *unc-40* gene products are selectively expressed in the dorsal, lateral, and ventral epidermal cells, respectively. Using the technique of mosaic analysis we are attempting to determine the sites of expression of these genes.

We are currently attempting to molecularly clone these genes by the method of transposon-tagging. We have identified transposon-containing bands in *unc-5* and *unc-6* mutants, by Southern blot, which are presumed to be within these genes. A molecular understanding of these gene products should add to our current knowledge of the mutant phenotypes and help to understand how these genes function in cell guidance.

337.5 PEPTIDE MAPPING DEMONSTRATES THE EXISTENCE OF A FAMILY OF SENSORY NEURON AND GLIAL CELLS SPECIFIC 130 KD LEECH GLYCOPROTEINS. M.L. BAJT AND B. ZIPSER. DEPT. PHYSIOLOGY, MICHIGAN STATE UNIVERSITY, EAST LANSING, MI 48824.

Cell surface glycoproteins play important roles in the formation of brain patterns. The modulation hypothesis, advanced by Edelman, postulates that a small number of very ubiquitous adhesion molecules, among them N-CAM, can mediate pattern formation provided that their binding activities are epigenetically modulated. More restrictively distributed surface glycoproteins of 130 kD molecular weight were isolated from the leech (Haemopis, Hirudo) nervous system through monoclonal antibodies. In the adult leech, they a) define the system of sensory afferents (Lan3-2) and b) divide the system into three progressively smaller subsets (Laz2-369, Laz6-212, Laz7-79). Evidence consistent with the hypothesis that these surface glycoproteins play a role in specific axon tract formation comes from regeneration studies. A fifth glycoprotein of similar molecular weight, expressed by glial cells enveloping axons (Laz6-297), may provide a general permissive substrate for axonal growth.

We have begun a structural analysis of the group of 130 kD proteins asking whether they constitute a protein family in which individual members share a common protein core but differ in their oligosaccharides. Here, we are characterizing the protein cores in peptide mapping studies, using as probes our 5 mabs which appear to be directed against carbohydrate epitopes. Peptide mapping studies in SDS-PAGE gels using limited proteolysis with Staphylococcus aureus V8 Protease (0.2 to 2.0 ug/ml) demonstrate that the 130 kD band can be digested into several distinct smaller molecular weight fragments as analyzed by Western blotting. Proteolytic digestion of the 130 kD glycoprotein expressed by the full set of sensory afferents (Lan3-2), resulted in fragments centered around 92, 80, 45, and 40 kD. Proteolytic digestion of the 130 kD glycoprotein expressed by largest subset (Laz2-369) revealed similar molecular weight fragments: 90, 79, and 45 kD. The glial cell protein has a slightly lower molecular weight, about 125 kD, and proportionately its proteolytic fragments also have a slightly lower molecular weight which may arise from less glycosylation. Proteolysis of the 125 kD glial cell glycoprotein include 76, 36, and 33 kD fragments. Thus, the different neuronal and glial 130 kD glycoproteins are cleaved into similar peptide fragments when exposed to limited proteolysis. These results provide evidence in favor of a 130 kD protein family with a common, differentially glycosylated, core protein.

Our studies suggest that recognition molecules may come as epigenetically modified protein family which reduces the number of gene products necessary for creating specific brain patterns.

337.6 DEVELOPMENTALLY REGULATED APPEARANCE AND MODIFICATION OF SURFACE GLYCOPROTEINS LOCALIZED TO SPECIFIC CELLS IN THE LEECH EMBRYO. E.K. McGlade-McCulloh* and B. Zipser (Spon:K.J. Muller) Dept. Physiol. & Biophys., Univ. of Miami, Miami, FL 33101 and Dept. Physiol., Michigan State Univ., East Lansing, MI 48824

The development and regeneration of neurons relies upon cell-cell interactions which may be mediated by surface glycoproteins functioning as recognition/adhesion molecules. We have characterized the spatial and temporal expression of cell-type specific glycoproteins recognized by the monoclonal antibody (Mab) Lan3-2 during neuronal development in the leech, Hirudo medicinalis.

Fusiform cells located along the midline between primordial hemiganglia are the first cells during development of the CNS which are recognized by Mab Lan3-2. The midline cells are first found in anterior segments by day 7 and gradually appear more posteriorly forming a rostral-caudal chain over the course of 2 to 4 days. These midline cells occupy a landmark position toward which primordial ganglion cells move from their early bilateral positions. Shortly after the bilateral hemiganglia join, the midline cells cease to express antigen and may disappear. The midline cell's location and the timing of its transient existence suggest that it may have a role in the movement and fusion of primordial ganglia. Mab Lan3-2 later recognizes growing sensory afferent axons which continue to be recognized by the Mab into adulthood. Thus, within the nervous system of the embryonic leech the glycoproteins are expressed by two different cell types: 1) early, presumably transient cells and 2) sensory afferents which differentiate at a slightly later stage.

On immunoblots, embryonic (day 8) glycoproteins recognized by Mab Lan3-2 were of a higher molecular weight than those from adults. Adult neuronal glycoproteins occur as a major broad band centered at 130 kD and minor bands at 103 and 95 kD. In contrast, the embryonic forms of these glycoproteins occur as a major broad band centered at 160 kD and two minor bands at 140 and 130 kD. Additionally, there is a 240 kD glycoprotein species expressed by embryonic cells. Other surface glycoproteins (e.g. NCAM) undergo a molecular weight conversion during development which is postulated to play a role in brain pattern formation. In other systems, surface glycoproteins play a role in cell-cell or cell-matrix interactions and may serve as receptors for recognition molecules such as nerve growth factor, fibronectin and/or laminin. Perhaps transiently expressed glycoproteins of the fusiform midline cells in the leech play a role in gangliogenesis. (Supported by NIH grants RO1-NS20607 & 5T32-NS07044-11.)

337.7 Labelling of Subsets of Early Forming Axon Tracts in the Rat by a Monoclonal Antibody to the Limbic System-Associated Membrane Protein (LAMP). H. L. Horton* and P. Levitt, Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, Pa. 19129.

Unique cell surface molecules may play a role in the formation of specific neuronal connections by serving as recognition molecules in the processes of pathfinding and synaptogenesis. Such a molecule would be distributed on functionally and anatomically related neurons, as is the Limbic System Associated Membrane Protein (LAMP) (P. Levitt, Science 223:299, 1984). In the present study, we found an early and selective expression of LAMP on neurons and developing axon pathways. Dot-blot assays demonstrate the presence of LAMP-immunoreactivity by E13, followed by a substantial increase during fetal development. Immunocytochemical staining of fetal brains reveals that LAMP is expressed in both cellular areas and on certain fiber tracts during development, including the fimbria/fornix, stria terminalis, internal capsule and corpus callosum. Neurons which will express LAMP in adulthood appear to express the antigen shortly after they are born. For example, in the thalamus the earliest staining occurs by embryonic day 15, about 24 hours after the earliest birthdates (J. Altman and S. A. Bayer, JCN 188:473, 1979). At this time, subsets of fibers of the internal capsule are also immunoreactive. These appear to originate from the newly generated LAMP-immunoreactive thalamic neurons. The selective expression of LAMP on subsets of the internal capsule fiber bundles can readily be seen by comparing cresyl violet and LAMP-stained sections. This is being confirmed by double labeling of frozen sections with antibodies to LAMP and neurofilament protein and by electron microscopic analysis. The LAMP-immunoreactive fibers can be traced during fetal development to specific cortical areas that also express the cell surface protein. Similar patterns of staining, on subsets of LAMP-immunoreactive fibers originating from LAMP-immunoreactive cells, also occur within the corpus callosum and fimbria/fornix. The presence of a common epitope on related neurons and fibers suggests that LAMP may be a model target and pathway recognition molecule in the developing vertebrate brain. Supported by NSF BNS-8645272 and March of Dimes Basic Research Grant 1-919.

337.8 **CHARACTERIZATION AND CLONING OF FASCICLIN II IN GRASSHOPPER** A. Harrelson, K. Zinn*, P.M. Snow*, M. Bastiani, J. Schilling*,[1], and C.S. Goodman. Dept. Biol. Sci., Stanford University, Stanford CA 94305, and [1]California Biotechnology.

One important form of neuronal recognition during development is the selective affinity that growth cones display for specific axon pathways. Previous cellular studies using insect embryos gave rise to the labeled pathways hypothesis which predicts that axon fascicles in the embryonic neuropil are differentially labeled by surface recognition molecules. To identify candidates for such molecules, we generated monoclonal antibodies (MAbs) which recognize surface antigens expressed on subsets of axon fascicles in the grasshopper and Drosophila embryos. We used these MAbs to identify and purify three different surface glycoproteins which meet these criteria: two in grasshopper (fasciclin I and II; Cell 48:745, 1987) and one in Drosophila (fasciclin III; Cell 48:975, 1987). We are using molecular genetic approaches to determine the structure of these proteins and to study their function.

The fasciclin II (FII) protein is localized primarily on longitudinal axon bundles in the developing grasshopper CNS. At an early stage of development it is expressed on the growth cones and transiently on the cell bodies of only a few neurons. The protein first appears on the most medial of the three major longitudinal tracts, soon thereafter on the middle tract, and finally on the most lateral tract. After 50% of development, the protein is localized on all of the longitudinal tracts but on none of the commissural pathways. Thus FII is regionally expressed on only certain portions of the neurons. For example, axons express FII where they run in longitudinal tracts, but do not express it where they run in commissural bundles.

FII was purified and the amino acid sequences of portions of two proteolytic fragments were determined. This information was used to design oligonucleotide probes which were used to isolate clones encoding FII from grasshopper genomic and cDNA libraries. We also isolated a FII cDNA clone by screening a cDNA expression library with an antiserum against FII; this clone also hybridizes to the oligonucleotide probe. We are presently determining the structure of FII by cDNA sequence analysis, and searching for the homologous gene in Drosophila.

337.9 **MOLECULAR GENETIC ANALYSIS OF FASCICLIN I FROM GRASSHOPPER AND DROSOPHILA: SEQUENCES OF cDNA CLONES ENCODING MULTIPLE FORMS OF THE PROTEIN** L. McAllister*, K. Zinn*, P.M. Snow*, T. Elkins, J. Schilling*,[1], G. Makk*,[2], and C.S. Goodman (SPON: M.J. Bastiani). Dept. Biol. Sci. and [2]Dept. Psychiatry, Stanford University, Stanford CA 94305, and [1]California Biotechnology.

We previously reported the purification and characterization of fasciclin I (FI), a 70 kD cell-surface glycoprotein which is expressed on a subset of axon pathways in the grasshopper embryo (Cell 48:745, 1987). We have since identified a second, 37 kD form of FI. Both forms of FI are membrane-associated, but neither is an integral membrane protein, as both can be stripped from membranes by high pH treatment. We have determined the amino acid sequence of the N-terminus and of portions of two fragments from the 70 kD FI. This information was used to design oligonucleotide probes which were used to isolate clones encoding FI from grasshopper genomic and cDNA libraries.

Northern blot analysis indicates that there are at least three FI mRNAs (~3.6, 3.2, and 1.8 kb in length). We have isolated full-length cDNA clones corresponding to each of these size classes, and have determined the sequences of a 3.2 and 1.8 kb clone. These two cDNAs encode proteins of 70 kD and 37 kD, respectively. The 70 kD protein consists of a signal sequence, three imperfect copies of a 37 amino acid sequence spaced at 150 a.a. intervals (suggesting three structural domains), and no transmembrane region. The third copy of the repeat is truncated and is immediately followed by a very basic C-terminal sequence. The 37 kD protein corresponds to the N-terminal half of the larger protein (containing only the first of the three domains), followed by a short unique C-terminal peptide. We are generating antibodies against the unique C-terminal portions of the two forms of FI in order to study their localization in the grasshopper embryo.

We have used the grasshopper cDNA to isolate homologous cDNAs from Drosophila. These also exist in multiple forms. Limited sequence analysis indicates that the Drosophila sequence is 60-70% homologous to grasshopper FI. The Drosophila FI gene maps to position 49F on the polytene chromosomes. We are currently generating antibodies to Drosophila FI for localization studies, and making deletion mutatations to determine its function during neuronal development.

337.10 **GENETIC ANALYSIS OF FASCICLIN III IN DROSOPHILA: DELETION OF THE GENE LEADS TO ABNORMAL AXON FASCICULATION** J. R. Jacobs, N. H. Patel*, T. Elkins and C. S. Goodman. Dept. Biol. Sci., Stanford University, Stanford CA 94305.

We previously reported the characterization and cloning of fasciclin III (FIII), a group of highly related surface glycoproteins which are expressed on a subset of neurons and axon pathways in the Drosophila embryo (Cell 48:975, 1987). Here we report on genetic and ultrastructural studies aimed at determining the function of FIII.

In each segment of the CNS at hr 11, FIII is expressed on the surface of 52 of the 153 axons in the two commissures; these axons are fasciculated in 5 bundles (3 in the anterior and 2 in the posterior commissure). In addition, FIII is expressed on the continuation of one of these fascicles as it turns posteriorly and laterally toward the intersegmental nerve, and on the medial nerve. FIII is also expressed on parts of glial cells which contact these labeled axons. FIII is regionally expressed on only certain portions of the neurons. For example, axons express FIII where they run in a labeled commissural fascicle, but then cease to express it where they turn longitudinally.

The FIII gene maps to position 36E1 on chromosome 2L. The gene is deleted in embryos which are trans-heterozygous for the deficiencies VA18 and H20. These embryos show a clear but subtle abnormal phenotype in the developing CNS. In contrast, other deficiencies which delete flanking genes but not the FIII gene, do not show this phenotype.

At the ultrastructural level, the mutant phenotype fits the predictions based on normal FIII expression. The anterior commissure in particular is broader in the mutants due to abnormal trajectories of many commissural axons. The RP1/RP2 neurons (which normally express FIII) fail to complete their normal migration towards the midline. The trajectory of the RP1 axon is often abnormal and variable from segment to segment. Other axons which normally express FIII are also abnormal in their trajectory. These results suggest that fasciclin III is a neuronal recognition molecule involved with selective fasciculation and other specific cell interactions. We are presently screening for lethal point mutations in the FIII gene, and reconstructing the CNS in mutant vs. wild type embryos.

337.11 **MOLECULAR ANALYSIS OF FASCICLIN III IN DROSOPHILA: SEQUENCES OF cDNA CLONES ENCODING MULTIPLE FORMS OF THE PROTEIN.** P.M. Snow*, N.H. Patel*, and C.S. Goodman. Dept. Biol. Sci., Stanford University, Stanford CA 94305.

In the previous abstract we reported on genetic and ultrastructural studies aimed at determining the function of fasciclin III (FIII), a group of highly related surface glycoproteins which are expressed on a subset of neurons and axon pathways in the Drosophila embryo (Cell 48:975, 1987). Here we report on a molecular genetic analysis of FIII cDNA clones aimed at determining the sequence and structural domains of the different forms of the protein.

Immunoprecipitation experiments indicate that FIII consists of at least four distinct but related proteins (80, 66, 59 and 46 kD). Two dimensional peptide maps indicate that the proteins are highly related at the level of their primary structure. The proteins were purified by immunoaffinity chromatography and antisera generated against each of the four forms. The antisera were used for cDNA expression cloning to identify a single gene. That this gene encodes FII was confirmed by in situ hybridization and genetic deficiency analysis. Northern blot analysis identified at least four mRNAs, suggesting that different mRNAs might encode the different forms of the protein.

In order to identify full length cDNA clones encoding the different forms of the protein, several other cDNA libraries were screened with one of the initial cDNA inserts. These screens resulted in the isolation of 50 cDNA clones which fell into at least two classes based on Eco R1 restriction sites. The longest representatives of each class were subcloned and sequenced. The two cDNAs encode proteins which are identical at the N-terminus (apparent extracellular domain), but which diverge at the C-terminus. At least one of the two possesses a transmembrane region characteristic of integral membrane proteins. Antisera against peptides specific for each of the two forms are being generated in order to study their tissue distribution in greater detail. In addition, the cDNA clones are being used to screen for other genes encoding potentially related proteins.

337.12 THE 5B4 ANTIGEN EXPRESSED ON SPROUTING NEURONS IS A MEMBER OF THE NCAM FAMILY. Leland Ellis[1], Purita Ramos[1,*], Roohangiz Safaei[2,*] and Celik Kayalar[2,*]. Howard Hughes Medical Institute and Department of Biochemistry, University of Texas Health Science Center, Dallas, Tx. 75235-9050[1]; Department of Chemistry, University of California, Berkeley, Ca. 94720[2].

Monoclonal antibody (mAb) 5B4 recognizes a developmentally regulated membrane glycoprotein whose expression on neurons is coincident with neuronal sprouting (Ellis et al., J. Cell Biol. 101 1977-1989, 1985; Wallis et al., J. Cell Biol. 101 1990-1998, 1985). In fetal rat brain, mAb 5B4 identifies a diffuse antigen of ~ 185-255 kDa, while the antigens recognized in adult rat brain are of ~ 180 and 140 kDa. Furthermore, the 5B4 antigen expressed in fetal brain carries the unusual carbohydrate moiety α-2,8-linked polysialic acid (Rosenberg et al., Dev. Brain Res. 30 262-267, 1986), which is a characteristic of neural cell adhesion molecules (NCAMS; Rutishauser, Nature 310549-554, 1984; Edelman, Ann. Rev. Biochem. 54135-169, 1985).

To further explore the relationship of the 5B4 antigen to the NCAM family, we utilized mAb 5B4 to screen a λgt11 library prepared from mRNA of postnatal week two rat brain. λ5B4.1 contains a cDNA insert of ~ 500 bp, and encodes a β-galactosidase fusion protein of ~ 130 kDa which reacts on a Western blot with mAb 5B4. The DNA sequence of this insert reveals an open reading frame of 95 amino acids, whose sequence is ~ 70% homologous with the carboxy terminus of chicken NCAM (Hemperly et al., PNAS 83 3037-3041, 1986). The localization of the 5B4 epitope to the cytoplasmic domain of the molecule is consistant with previous results of indirect immunofluorescence studies of cultured neurons with mAb 5B4, where visualization of staining required prior permeabilization of the cultures with the nonionic detergent saponin (see above refs.). Rescreening of the library with the λ5B4.1 insert yielded an additional clone with an insert of ~ 1700 bp. Characterization of this insert by restriction enzyme mapping demonstrates that λ5B4.1 is contained within the 3' end of λ5B4.2. DNA sequencing reveals that the more 5' sequences of λ5B4.2 continues the open reading frame amino proximal. This deduced amino acid sequence shares significant homology with chicken NCAM extending from the end of the extracellular domain through the transmembrane and cytoplasmic (the so-called long form; see above reviews) domains.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: VESTIBULAR SYSTEM II

338.1 SENSORY CODING BY THE VESTIBULAR LABYRINTH OF THE LARVAL FROG. S.L. Cochran and J.T. Hackett. Dept. Physiology, Univ. of Virginia Med. School, Charlottesville, VA 22908.

Tadpoles (Rana catesbeiana, premetamorphic) exhibit a prominent ocular counter-rolling in response to tilt of the animal. The gain of this static reflex is approximately one. The head of these tadpoles can be maintained in vitro with the brain exposed (forebrain removed) and shows spontaneous and light-aroused eye movements and swimming-like contractions of the neck muscles. The compensatory response of the eyes to head tilt persists in the in vitro head preparation for several days following isolation, facilitating elucidation of the neuronal networks mediating these reflexes. Bilateral section of the optic nerves does not affect the static gravitationo-ocular reflexes, while lesions of the VIIIth nerves abolish them. Examination of the labyrinth reveals that the inner ear end organs are structurally and functionally similar to those of the adult frog. Hair cells and VIIIth nerve afferents are well-developed in the amphibian papilla, lagena, sacculus, utriculus, and the three canals. Synaptic profiles between the hair cells and the afferents show the same specializations at the electronmicroscopic level (i.e.--chemical, Type I) as are found in the adult. Efferent terminals also contact the hair cells. In the isolated labyrinth, intracellular recordings from individual afferents (at their exit from the end organs) reveal the presence of spontaneously-occurring EPSP's that often provoke action potential generation. Kynurenic acid (bath-applied), a glutamate receptor antagonist, reversibly reduces the amplitude of these EPSP's, indicating that the pharmacology of this synapse is glutamatergic, as is that of the adult. Intracranial recordings from these afferents in the isolated head suggest that the tadpole brain receives similar sensory information as its adult counterpart. Some cells respond selectively to rotation about specific axes (yaw, pitch, roll) in a phasic manner with no apparent response to static head position per se. These dynamic units most likely arise from the canals. Other axons respond to vibration and probably are saccular in origin. Within the anterior portion of the VIIIth nerve, there are units (apparently small), whose tonic discharge rate is related to head angle with respect to the horizontal plane implying these fibers communicate gravity sensing information and most likely arise from the utriculus. Most of these axons respond phasically to tilt as well. These preliminary studies of the vestibulo-ocular reflex in vitro suggest that the vestibular labyrinth in the tadpole conveys similar specialized sensory information as it does in the adult. The decrease in the gain of this reflex as the tadpole develops into a frog is thus more likely due to central than to peripheral reorganization of the neuronal networks involved in this reflex.

338.2 THREE-NEURON VESTIBULO-OCULAR REFLEX ARC IN THE ADULT FLATFISH: EXCLUSIVE ROLE OF SECOND-ORDER VESTIBULAR NEURONS FOR THE ADAPTATION OF COMPENSATORY EYE MOVEMENTS. W. Graf and R. Baker. The Rockefeller University, New York, NY 10021, and Dept. Physiol. & Biophysics, New York University Med. Ctr., New York, NY 10016.

Flatfish offer a natural paradigm for studying adaptive changes in the vestibulo-ocular reflex (VOR) because of the 90 deg relative displacement of vestibular versus extraocular muscle coordinates after metamorphosis. Structurally, this arrangement requires a neuronal pathway from the horizontal semicircular canals to muscles that move the eye vertically (J. Neurophysiol. 54: 887-889, 900-916, 1985). The present study in the winter flounder, Pseudopleuronectes americanus, extends the previous work to include the entire three-neuron reflex arc of the VOR. We have focused on the bilateral symmetry of the vestibular system, especially the projections of primary vestibular afferents, and on the trajectories of axons ascending in the MLF. Single cell morphology of second-order vestibular neurons linked to the right or left horizontal canal, visualized with the intracellular HRP injection method, revealed a qualitatively bilaterally symmetric distribution of neurons with terminals in either both superior rectus and inferior oblique motoneuron pools or with the antagonists to these muscles, the inferior recti and superior obliques (trochlear nuclei). Surprisingly, all second-order neurons had contralaterally ascending main axons, and even some cell somata of stained neurons were found contralateral to the stimulated horizontal canal. The latter organization, in particular, has never been observed in any other vertebrate VOR system. Vertical canal related second-order neurons were not different from that described in other vertebrates. Visualized by extra- and intracellular HRP methods, primary afferents from the semicircular canals terminated in the five subnuclei of the vestibular complex (anterior, magnocellular, descending, tangential, posterior), and also in the eminentia granularis and the medial reticular formation, as described in other teleost fishes. The intracellular HRP data of primary vestibular afferents showed that no axon collaterals crossed the midline, and thus offered little explanation for the peculiar contralateral location of vestibular nucleus neurons.

In summary, our data indicate a thoroughly bilateral symmetric distribution of post-metamorphic second-order VOR neurons for both excitation and inhibition linking the horizontal canals to vertical eye muscles. In light of normal primary vestibular afferent, second-order vertical vestibular neuron, and oculomotor organization, the species-specific horizontal vestibular neurons are both necessary and sufficient for adaptation of the VOR in the adult flatfish. - Supported by NIH grant NS20358.

338.3 **GABA-IMMUNOCYTOCHEMISTRY OF THE VESTIBULAR COMPLEX IN WEAVER AND PCD MUTANT MICE.** U. Grüsser-Cornehls* and B.G. Grover* (SPON: European Neuroscience Association) Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1000 Berlin 33 (Germany).

In the mutant mouse Weaver (B6CBA) almost all cerebellar granular cells die in the first postnatal weeks, while in the PCD mutant (C57BL6J) almost all Purkinje cells die in the first postnatal month. Cerebellar processing is disrupted in both mutants but they differ in the way in which the malfunction is able to affect downstream structures such as the vestibular complex, as indeed electrophysiological experiments have demonstrated (Grüsser-Cornehls, U., *Soc. Neurosci.*, 8: 524, 1983; Helmchen, Ch. et al., *Pflüg. Arch. Suppl.*, 405: R56, 1985). The present investigation was undertaken to determine whether changes in GABA-immunocyto-chemistry occur in the vestibular nuclei of these mutants and whether they can be related to plasticity mechanisms which might underly normal cerebellar function in relation to motor learning.

In material immuno-reacted for GABA using the PAP method, experiments started with K.-P. Hoffmann and A. Horn in Ulm, stained boutons may be identified in apposition to somata and dendrites. In normal mice GABA positive boutons in the superior and lateral vestibular nuclei range in size from 0.3 to 2 µ in diameter and may be roughly categorized as small, medium and large. The large boutons are comparable in size to those identified in the lateral vestibular nucleus of cats as Purkinje-cell terminals using EM-degeneration methods (Mugnani, E. and Walberg, F., *Exp. Brain Res.*, 4: 212-236, 1967). The fact that in the PCD mutants only small- and medium-sized terminals are found in the lateral and superior nuclei also suggests that the large boutons are of Purkinje-cell origin. In Weaver mutants, stained boutons in these nuclei are almost all of the large size and there is no obvious increase in the number of terminals per unit area. It is not yet clear whether the increase in large GABA terminals in Weavers represents an increase in the number of Purkinje cell terminals at the expense of interneuron terminals or an increase in size of existing terminals.

In contrast, cytoplasmic staining of GABA positive cells, in the vestibular nuclei only, is consistently weaker in Weaver mutants than in normals or PCD mutants, suggesting either a depletion of intracellular GABA stores due to higher release rate or a turning off of GABA production in vestibular nuclei GABA-ergic neurons in Weavers.

The immunocytochemical results suggest that the derangement of cerebellar function in Weaver (in which the anatomical integrity of the output channels is preserved) results in a cascade of compensatory mechanisms located extrinsicly to the cerebellum (profusion of large terminals and changes in cytoplasmic GABA levels in the vestibular nuclei). Such mechanisms, on a smaller scale, could partially underlie the 'cerebellar' contribution to motor learning.

338.4 CONVERGENCE OF NECK AND VESTIBULAR INFLUENCES ON NEURONS IN THE VESTIBULAR NUCLEI OF THE DECEREBRATE CAT. J. Kasper*, R.H. Schor, and V.J. Wilson. The Rockefeller University, New York, NY 10021.

When the head moves on the body, the tonic neck and vestibular reflexes interact to produce a coordinated postural response in the limbs. Part of this convergence takes place in the vestibular nuclei (Boyle and Pompeiano, J. Neurophysiol. 45, 1981). We examined the spatial and temporal properties of this interaction by recording the responses of neurons in the lateral and inferior vestibular nuclei. Stimuli consisted of combinations of sinusoidal rotations in vertical planes (roll, pitch, intermediate planes) delivered to the whole animal (vestibular stimulus), body with stationary head (neck stimulus), and head with stationary body (combined).

We found 44 cells which responded to both neck and vestibular stimuli, 15 of them identified as vestibulospinal neurons. The vestibular input to these cells originated in vertical semicircular canals and utricle. All but five neurons responded better to roll than to pitch, with the majority excited by ipsilateral side down tilt. From their response orientations and dynamics, 7 cells appeared to receive input from a single vertical canal, 10 from the utricle, 6 from both vertical canals, and 12 from canal and utricle.

The dynamics of the response to neck stimulation shows, on average, a gain increase (about 3-fold per decade) and phase lead of 30 to 60 degrees over a frequency range of 0.02 to 1 Hz. This response is similar to that seen in neck spindle afferents excited by neck rotation (Chan et al., J. Neurophysiol. 57, 1987).

We determined the orientations of the neck and vestibular response vector (the stimulus direction producing the maximal response) in 33 of these cells. In 21 cells, the vector orientations pointed in opposite directions (within 30 degrees). Only a single cell with vectors in the same direction was observed.

In response to head rotation on a stationary body, neck and vestibular contributions often opposed each other, resulting in no net neural modulation. Such cancellation was observed in 12 neurons, all with opposite neck and vestibular vector orientations and similar response gain and phase to these two stimuli. In 7 neurons, the interaction of these inputs produced a response during head rotation which had fairly flat gain and phase near position at all frequencies, despite the fact that the neck or vestibular signal often showed a considerable dynamic response. Such neurons appear to be encoding head position in space.

338.5 OPTOKINETIC RESPONSES OF SECOND-ORDER VESTIBULAR NEURONS IN THE RABBIT. J.F. McGurk and W. Graf. The Rockefeller University, New York, NY 10021.

Direction selective retinal ganglion cells provide an important sensory input for the performance of compensatory eye movements. While there have been a number of studies on visual-vestibular interaction in the horizontal system, no information is available regarding the spatial organization of the optokinetic input to vestibular nucleus neurons in the vertical systems.

We recorded intracellularly from second-order vestibular neurons linked to the vertical canals projecting to the oculomotor/trochlear nuclei in the rabbit. Axons of contralaterally (excitatory) and ipsilaterally (inhibitory) ascending neurons were penetrated with micropipettes filled with 2 M KCl in the MLF caudal to the trochlear nucleus. Neurons were identified by their monosynaptic potentials following electrical stimulation via labyrinth implants. Neurons were first characterized with hand-held visual patterns to establish their receptive field properties, and later by a planetarium projector to determine the axis of visual field rotation producing the best response. The planetarium projector could be oriented in any direction in space via a gimble system. Typically, data were taken at nine orientations for binocular and monocular stimulations each.

All recorded vestibular neurons received binocular visual input. Excitatory anterior canal (AC) neurons were excited by upward and backward movement of the hand-held patterns in the anterior three quadrants of the ipsilateral hemifield, and by downward and backward movement in the posterior three quandrants of the contralateral hemifield. This response was consistent with rotation of the entire visual world about an axis passing from approximately 135 deg ipsilateral to 45 deg contralateral (0 deg represents an axis pointing rostrally). Excitatory posterior canal (PC) neurons were excited by upward and forward movement in the ipsilateral posterior three quadrants, and by downward and forward movement in the contralateral anterior three quadrants of the visual field. This response was consistent with rotation about an axis passing from 45 deg ipsilateral to 135 deg contralateral. Ipsilaterally projecting neurons could be driven from any portion of the visual field consistent with rotation about their respective canal axis. Quantitative analysis of fully characterized neurons showed that on average, AC neurons (n=4) responded best to rotation about an ipsilateral axis of 136 deg (AC axis = 135 deg; vertical recti axis = 151 deg), and PC neurons (n=3) responded best at an ipsilateral axis of 43 deg (PC axis = 32 deg; obliques axis = 43 deg). These results demonstrate that the optokinetic input to second-order vestibular neurons is coded in coordinates comparable to the vestibular and/or extraocular muscle sensory and motor axes.

Supported by NIH grant EY04613.

338.6 **SINGLE UNIT RESPONSES IN THE VESTIBULAR CORTEX OF SQUIRREL MONKEYS.** W.O. Guldin* and O.-J. Grüsser (SPON: European Neuroscience Organization). Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, Germany.

A new vestibular cortical area is described in Squirrel monkeys (Saimiri sciureus). This area is situated in the fundus of the Fissura lateralis in area ritp (Pandya and Sanides, *Z.Anat.Entwickl.-Gesch.*,139:127,1973) or Ri according to Jones and Burton (*J.Comp.Neurol.*,168:197,1976). A comparable vestibular area was described by Grüsser, Pause and Schreiter (Roucoux and Crommelinck [eds.], *Physiological and Pathological Aspects of Eye Movements*, 251,1982) in the Macaque monkey as the parieto-insular vestibular cortex (PIVC).

About fifty percent of the PIVC neurons recorded in Squirrel monkeys were responsive to vestibular stimulation (sinusoidal pitch, roll or jaw) as well as to large-field visual stimulation. Most units also showed activation during stimulation of neck receptors. A few units also reacted to stimulation of other parts of the body such as limbs or back.

Nearly all recorded vestibularly activated cells responded to rotation in more than one of the semicircular canal planes. Each unit appeared to have a "preferential plane" of rotation in space for which the response is maximal. The data collected suggest that all possible preferential planes are represented in the PIVC. As a rule, PIVC units respond to angular acceleration and not to steady tilt in darkness.

There is some indication in the present data that units with similar preferential planes were located close to one another suggesting the existence of a barrel- or cluster-like organization of the PIVC.

The parieto-insular vestibular cortex seems to be a high-order center for vestibular somatosensory and visual integration that processes information about the localization of the body and head in space.

Supported by a grant of the Deutsche Forschungsgemeinschaft (Gr 161).

338.7 BIOMECHANICAL CONSTRAINTS LIMIT THE NUMBER OF DEGREES OF FREEDOM OF THE VERTEBRATE HEAD-NECK ENSEMBLE: ITS CONSEQUENCES FOR THE POSTURAL SYNDROME FOLLOWING HEMILABYRINTHECTOMY. C. de Waele*, W. Graf, and P.P. Vidal (Sponsor: E.E. Brink). Lab. Physiologie Neurosensorielle du C.N.R.S., 75270 Paris Cedex 06, France, and The Rockefeller University, New York, NY 10021, USA.

In a previous study we demonstrated a stereotyped resting posture of the head-neck arrangement in a number of vertebrates: the cervical vertebral column is oriented vertically, and the horizontal semicircular canals are tilted upward from earth horizontal (Exp. Brain Res. 61: 549-559, 1986).

The present investigation first quantified the range of motion of the different articulations of the head-neck ensemble in monkey, cat, rabbit and guinea-pig by x-ray photography and dissection. Our data indicate that biomechanical constraints limit the number of possible solutions how an animal can perform a given orienting movement. For example, in the sagittal plane, the upper cervical vertebrae allow only flexion, whereas the lower cervical and upper thoracic vertebrae only allow extension of the vertebral column. Although there is about a 90-100 deg range of motion in the atlanto-occipital joint, the head cannot be flexed beyond a certain limit. By comparing these constraints to the head-neck posture of alert unrestrained animals, we conclude that, when at rest, assuming a vertically oriented cervical vertebral column, animals hold their heads at the extreme point of flexion in the atlanto-occipital articulation. Similarly, the cervical and upper thoracic vertebrae are locked into the limits of their range of extension. At this position, mechanical constraints almost exclusively provide the biomechanical means of maintaining resting position with minimum energy expenditure (Soc. Neurosci. Abst. 11, 25.25, 1985). Furthermore, at this position the horizontal semicircular canals will appear tilted upward from earth horizontal. From that resting position, lowering of the head is only possible by moving the C6-Th3 vertebrae out of their extreme extension into the flexion direction. Secondly, a radiological study was performed on the postural syndrome following hemilabyrinthectomy in guinea pigs. X-ray photographs from lateral and from above were taken every 30 minutes during the first 72 hours following surgery. Head position in space resulted from a) lateral head deviation by rotation mainly at C1/C2, b) longitudinal twist of the vertebral column via rotation about C6-Th3, c) crossed extension of the legs. Compensation for each of these deficits followed different time courses.

In conclusion, our results suggest that during normal and pathological motor activity, biomechanical constraints limit the degrees of freedom of the skeleton. These constraints are thought to simplify neuronal operations subserving motor control and plasticity.

338.8 HEAD AND EYE MOVEMENTS DURING CIRCULAR LOCOMOTION. D. Solomon* and B. Cohen, Dept. of Neurology, Mt. Sinai Sch. of Med. NY, NY 10029

The gain of visual, vestibular and somatosensory inputs on gaze velocity (eye velocity + head velocity) was determined during circular locomotion for two monkeys. Animals wore a harness tethered to a .3 meter radial arm fixed to a freely rotating center post and walked or ran around the perimeter of a circular platform. The platform and post were mounted on a motorized rate table, so that the running animal's velocity in space could be reduced or nulled. Horizontal and vertical eye position in the head was measured with electro-oculography (EOG), and differentiated to obtain eye velocity. An angular velocity sensor (Watson Industries) measured head velocity in the yaw plane. A similar device mounted on the center post measured the animal's net angular velocity re earth. Head on body velocity was determined by subtracting post velocity from yaw head velocity. The animal's gait velocity re the platform was obtained by subtracting platform angular velocity from the animal's angular velocity re earth. One monkey spontaneously circled to the left in his cage, and had asymmetrical responses to passive rotation and optokinetic stimulation. It ran equally well in either direction on the platform, however, with velocities in excess of 300 deg/sec. A second animal had no directional bias. While running in light at a constant velocity, compensatory slow phase gaze velocities were maintained in excess of 200 deg/sec at around unity gain. Phase plots of head vs. eye velocity indicated that both eye and head movement contributed to the slow phase velocity seen during any beat of nystagmus. Eye velocity developed earlier in the slow phase but declined as head velocity increased. Synchronous fast head and eye movements constituted the fast phases. Continuous gaze velocity during running in darkness occurred in directions in which there was substantial velocity storage on passive rotation or during OKN and OKAN. The gain of the steady state slow phase gaze movements during running in darkness was 0.6. In contrast, during passive rotation with the head fixed, slow phase velocities decayed to zero over the dominant time constant of the VOR. When the animal stopped running, attenuated post rotatory nystagmus occurred only in the eyes. The platform was counter-rotated during running to decrease or eliminate angular velocity re earth and linear acceleration. Eye and head nystagmus still occured without vestibular stimulation during stationary running in darkness, and after-nystagmus was observed in the same direction after stopping, as in stepping around in humans, described by Bles (1981). These studies show that combined head and eye velocity is affected by vision, vestibular sensation and somatosensory information. The maintenance of gaze velocity during stationary running in darkness indicates a role for proprioceptive and motor signals in the generation of velocity storage.

338.9 EFFECTS OF GRAVITY ON THE PRINCIPAL AXES OF VELOCITY STORAGE IN THREE DIMENSIONS. Theodore Raphan and Bernard Cohen. Dept. of Computer and Information Science, Brooklyn College of CUNY, Brooklyn, New York, and Depts. of Neurology and Neurophysiology, Mount Sinai School of Medicine, New York, New York.

Rotation of the visual surround that induces horizontal optokinetic nystagmus (OKN) excites the velocity storage integrator and induces horizontal optokinetic after-nystagmus (OKAN). If horizontal OKN is induced while monkeys are tilted with regard to gravity, then the OKAN which follows has a vertical component; if monkeys are supine or prone then the OKAN has a roll component (Raphan & Cohen, 1987). The cross coupled components of the nystagmus do not appear immediately but build up and decay slowly with dynamics consistent with those associated with velocity storage. This indicates that the principal axes of the velocity storage integrator in three dimensions i.e those axes along which velocity storage is maximal are dependent on the orientation of the head with regard to gravity. The purpose of this study was to determine the orientation of these axes as a function of angle of head tilt in response to optokinetic stimulation. To this end, oblique optokinetic stimuli were given with monkeys upright as well as on their sides. If monkeys were upright when they received an oblique stimulus at any angle, the direction of the OKN was oblique and followed the stimulus but only horizontal OKAN was induced and the vertical component was essentially absent. This is consistent with the fact that that pure vertical OKN with subjects upright is associated with little vertical OKAN (Matsuo & Cohen, 1974). It indicates that the animal's vertical is the principal axes for storage in the upright position. When animals are on their sides, vertical OKAN tends to be stronger and is asymmetrical, being weaker for downward than for upward nystagmus (Matsuo & Cohen, 1974). If subjects were given an oblique optokinetic stimulus such that the cross coupling would tend to produce a vertical component in the same direction as that of the stimulus, the vertical component of both upward and downward OKN and OKAN were stronger. If the oblique stimulus was such that the cross coupling would tend to produce a vertical component opposite to the direction of that component induced by the stimulus, then the vertical component of the OKAN was cancelled. The vertical cross coupling was stronger with greater angles of tilt. Consequently, the angle of the stimulus relative to the animal that augmented or cancelled the vertical component increased becoming more oblique. This tended to maintain the principal oblique axes for velocity storage constant in space. The data suggest that gravity orients the principal axes of the velocity storage integrator towards the space vertical and attempts to maintain them spatially invariant regardless of head orientation.

338.10 **EFFECTS OF ROTATION ECCENTRICITY & TARGET DISTANCE ON VISUAL SUPPRESSION OF VESTIBULO-OCULAR REFLEX.** J. Goldberg & C. Cox*. Department of Otorhinolaryngology and Clayton Neurotology Laboratory, Baylor College of Medicine, Houston, TX 77030

Body rotation about a vertical axis positioned behind the eyes imparts a linear as well as angular acceleration to the eyes relative to a stationary visual target. We have previously shown that vestibulo-ocular reflex (VOR) gain, measured as the ratio of eye to head angular velocity, exceeds 1.0 in human subjects during such eccentric rotations. Visual suppression of the high-gain VOR can be expected to increase in difficulty with increasing rotation eccentricity and target distance, since VOR gain increases as a function of these kinematic parameters. Alternately suppression could be independent of the kinematics.

Eight normal subjects were rotated sinusoidally at 0.2 Hz, 120°/s amplitude in a servo-driven chair while fixating a small target light attached to the chair. They were seated so that the rotation axis passed near the midpoint of the inter-ocular distance ('concentric rotation') or about 20 cm behind it ('eccentric rotation'). Target position was varied along the midline in a randomized sequence of viewing distances from about 65 cm to the near point of accomodation/convergence of each subject. Every subject could fixate the target at least as close as 20 cm without difficulty. Smooth eye velocity was computed from digitized left eye position measured by electro-oculography. Statistical analysis was carried out on data obtained from each subject for 50 and 25 cm distances during concentric and eccentric rotations.

Suppression of VOR during concentric rotation resulted in mean eye velocity amplitudes of 5.7°/s (range: 0.7-21.9) for the 50 cm distance and 6.5°/s (1.0-26.6) for the 25 cm distance. During eccentric rotation eye velocity increased to 7.2°/s (0.9-27.4) for the 50 cm distance and 8.9°/s (1.9-29.6) for the 25 cm distance. While suppression performance was quite variable between subjects, the effects of rotation eccentricity and target distance on eye velocity were consistent and statistically significant within subjects (two-way ANOVA on repeated measures, $p<0.05$).

Our results show that slow-phase eye velocity increases with rotation eccentricity and visual target proximity during visual suppression of VOR as it does during VOR. The single kinematic factor that differs between the two situations - target rotation in space - does not appear to change this relationship.

338.11 MODIFICATION OF THE VESTIBULOOCULAR REFLEX AND OPTOKINETIC RESPONSE. H.Cohen, B.Cohen, T.Raphan, Depts. of Neurology, Mount Sinai School of Medicine, N.Y., N.Y. 10029, and Computer and Information Sciences, Brooklyn College, Brooklyn, N.Y. 11210

Habituation and adaptation of the vestibuloocular reflex (VOR) optokinetic nystagmus (OKN), and optokinetic after-nystagmus (OKAN) were studied in rhesus monkeys. Habituation is a relatively permanent decrement in the time constant after repeated testing; adaptation is a temporary incremental or decremental modification of the gain, in response to a change in the stimulus. The goal was to determine the time course of these processes and establish whether either or both are controlled by the cerebellar nodulus and uvula. Animals were tested with steps of velocity about the vertical axis, at velocities varying from 30 to 150 deg/sec while eye movements were recorded with a scleral search coil system. First, the animal was tested repeatedly to habituate the time constant of the VOR to a stable level. Then, the animal wore magnifying lenses (x 2.0) and reducing lenses (x .5) for varying time periods to manipulate the gain. The animal also wore control lenses (x1.0) for 24 hours. The lenses were bolted to the head and the animal was free to move about her cage. The gain of the VOR and OKAN, tested in darkness, adapted approximately 30% after wearing magnifying or reducing lenses for up to 120 hours although substantial adaptation occurred within 4 hours, and most adaptation took place within 24 hours. OKN and OKAN gains were more variable than VOR gains. Time constants changed inversely with changes in gain, decreasing as initial eye velocity increased, and vice versa. This is similar to findings in normal monkeys. Therefore adaptation of the VOR gain does not affect the VOR time constant directly. Upon removal of the lenses the gain returned to preadapted levels. Continued testing, including adaptation trials, reduced the time constants further. The asymptote for habituation of the OKAN time constant was 2-3 sec, and of the VOR time constant was near the cupular time constant. Thus, velocity storage was essentially eliminated in the fully habituated animal.

After adaptation training the nodulus and uvula were surgically ablated in one monkey. Post-operatively, VOR and OKAN gains were affected little. The VOR and OKAN time constants rose immediately to the pre-habituation level and were unaffected by repeated testing. The ability to adapt the VOR gain, however, remained intact. These data suggest that the VOR gain and time constant are controlled separately. Habituation is due to decreased ability to store activity related to slow phase velocity. The nodulus and uvula are involved in control of the VOR time constant, but are not primarily involved in control of its gain.

338.12 CONDITIONAL ADAPTATION OF VESTIBULOOCULAR REFLEX (VOR) DIRECTION S.I. Perlmutter*, S.A. Rude*, B.W. Peterson, F.R. Robinson, and J.F. Baker. Dept. Physiology, Northwestern University Medical Ctr., Chicago, IL 60611; and Dept. Physiology and Biophysics, University of Washington, Seattle, WA, 98195.

Although adaptation of the VOR has been well studied, it is not clear whether such plasticity generalizes or is specific to the exact conditions of adaptation. We are examining the specificity of adaptation of VOR direction.

The VOR rapidly adapts the direction of its compensatory eye movements when whole-body rotations are paired with orthogonal optokinetic motion. After adaptation, VOR eye movements are seen in the optokinetic direction (cross-axis gain ~=0.3 at 120 min.) when the animal is rotated in darkness.

We tested for specificity of VOR direction adaptation by exposing cats to combined vestibular and optokinetic stimulation in two body postures. The direction of optokinetic motion was reversed when body orientation was changed so that VOR adaptation in opposite directions was required for the two body orientations. Each animal was trained while lying on both its left and right sides to make horizontal eye movements (earth-vertical) in response to pitch (earth-horizontal) whole-body rotations. For example, during training on the left side, when the head was moved in the ventral direction (clockwise as seen from above), the visual world moved to the cat's right (upward relative to earth); during training on the right side, when the head was moved ventrally the visual world moved to the cat's left. Ten minute adaptation sessions on the left and right sides were interleaved for two hours of training on each side. Horizontal and vertical electro-oculographic recordings during 0.25 Hz rotations on the left and right in the dark were made before, during, and after the four hour adaptation period. Saccades were removed from the records, and the adaptation was measured as the vectorial difference between pre- and post- adaptation gain and phase of cross-axis VOR.

In all five experiments on three cats, we observed adaptation specific to training posture. Cross-axis eye movements during rotation in the dark while the animal was lying on one side attained gains (slow phase eye velocity / rotation velocity) of 0.1-0.35 after 120 minutes of training on that side. The adaptive movements on the two sides were in opposite directions relative to the same whole-body rotation; that is, they were in phase with the optokinetic training stimulus experienced on each side.

These results suggest that VOR directional adaptation occurs through plastic changes in highly specific neural pathways which are dependent on animal orientation. It seems likely that static signals from the otoliths relay information about body orientation and provide conditioning cues that differentiate these pathways.

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT III

339.1 FUNCTIONAL GABA AND GLYCINE RECEPTORS PRECEDE GLUTAMATE RECEPTORS DURING THE DEVELOPMENT OF THE RAT SPINAL CORD. R.N.Mandler, A.E.Schaffner, E.A.Novotny*, G.D.Lange and J.L.Barker. Lab. of Neurophysiology, NINCDS, NIH, Bethesda, MD 20892.

We have utilized voltage-sensitive dyes in conjunction with flow cytometry to study the functional effects of putative aminoacid transmitters on embryonic rat spinal cord cells. This strategy allows sampling of relative membrane potential for large cell populations with single cell resolution. Rat embryos at embryonic (E) days 12 to 20 were used. Spinal cords were dissected and treated with papain for 45 min. Cellular suspensions were stained with acridine orange and ethidium bromide, to assess viability or with anionic voltage-sensitive dyes, to assess changes in membrane potential. Stained suspensions were studied in a flow cytometer for their fluorescence and light scatter properties under control and experimental conditions. Over 90% of cells obtained throughout the entire embryonic period were viable. GABA, muscimol or glycine did not change the membrane potential distribution at resting conditions (physiological medium). However, incubation with GABA and glycine in low-Cl^- saline revealed depolarizing responses that were detected early (E12). Furthermore, incubation with GABA and glycine in high K^+ or in batrachotoxin revealed hyperpolarizing responses that were also detected early. Bicuculline and strychnine blocked GABA and glycine responses, respectively. Depolarizing responses to glutamate, aspartate, kainate and quisqualate in physiological saline, and to NMDA in low Mg^{++} were detected at E14-15. Dose-response treatments starting at nanomolar concentrations up to high micromolar were done for inhibitory and excitatory aminoacids at all ages; detectable effects were seen with submicromolar concentrations for inhibitory and excitatory agonists, indicating that this strategy is a sensitive assay of receptor coupled changes in membrane excitability. The results suggest that GABA and glycine activate Cl^- conductance mechanisms relatively early in the development of the rat spinal cord, and that physiological responses to excitatory aminoacids appear later in embryogenesis.

339.2 FLOW CYTOMETRIC ANALYSIS OF A VENTRAL-DORSAL GRADIENT IN THE DEVELOPMENT OF BATRACHOTOXIN AND KAINATE SENSITIVITIES IN EMBRYONIC RAT SPINAL CORD. A.E. Schaffner, R.N. Mandler, E.A. Novotny*, G.D. Lange and J.L. Barker. LNP, NINCDS, NIH, Bethesda, MD 20892.

We have used flow cytometry in conjunction with voltage-sensitive dyes to examine the development of Na^+ channels and glutamate receptors in embryonic spinal cord cells. There is evidence for a rostral-caudal and ventral-dorsal gradient in the production and maturation of spinal cord cells. We were interested in determining if the development of pharmacological responses would follow a similar pattern. Pieces of spinal cords corresponding to cervical, thoracic and lumbo-sacral segments were removed from 15-day rat embryos and hemisected into dorsal (DH) and ventral halves (VH). Cells were dissociated after 45 min in papain and stained with either acridine orange (AO) to assess cell viability or the oxonol dye $DiBaC_4(3)$ to assess changes in resting membrane fluorescence properties after various pharmacological manipulations. AO staining revealed that 95% of the cells in the preparation were viable. Over the length of the cord, cells from the VH scattered more light than cells from the DH, presumably due to the presence of large motoneurons in the VH. Cells were incubated with micromolar batrachotoxin (BTX), a sodium channel agent. Both DH and VH contained cells which were relatively insensitive to BTX and cells which were depolarized in the presence of BTX. The BTX responses were blocked by TTX. The extent of the depolarization was greater in cells from the VH. Within each segment, cells from the VH but not the DH were depolarized in the presence of 50 μM kainic acid, a glutamate receptor agonist. Although we could not demonstrate marked rostral-caudal gradients in the development of these sensitivities, gradients may be more apparent in either younger or older embryos. In contrast to the rostral-caudal axis, there are clear differences in the ventral-dorsal direction at all spinal levels with regard to kainate and BTX sensitivity. This is in agreement with previous studies that indicate that cells in the VH, specifically motoneurons, differentiate before cells in the DH. The results suggest that functional forms of electrical and chemical excitability are not expressed uniformly throughout the rat spinal cord at this time in development. The application of indicator dyes and flow cytometry to anatomically discrete areas in spinal cord and brain throughout development should allow a systematic study of the developmental appearance of specific aspects of electrophysiological function.

339.3 SYMPATHETIC PREGANGLIONIC NEURONS IN CULTURE DISPLAY RECEPTORS TO MULTIPLE NEUROTRANSMITTERS. B. Clendening * and R.I. Hume. (SPON: S.S. Easter). Dept. Biology, Univ. of Michigan, Ann Arbor, MI 48109

Most mature CNS neurons express receptors for several different neurotransmitters. We wondered whether, during development, the different receptors on a single cell might be regulated independently, or in a co-ordinated manner. We have approached this issue by characterizing the transmitter sensitivity of an identified class of CNS neurons in cell culture.

We used methods developed by Honig and Hume (J. Cell Biol. 103:171) for labelling sympathetic preganglionic neurons (SPN) in embryonic chick spinal cords, and then maintaining them in dissociated cell culture. Whole cell recordings were used to characterize the responses of SPN to a battery of neurotransmitters which are generally believed to be released from terminals presynaptic to SPN in mature animals in vivo. We studied responses to serotonin, norepinephrine, gaba, glycine and glutamate. All were applied by pressure ejection from puffer pipettes, and each transmitter was tested at 10 μM.

Serotonin and norepinephrine both produced relatively small hyperpolarizations from resting potential and under voltage clamp they produced small outward currents (< 100 pA) at rest. Glutamate produced relatively large depolarizations from rest, often eliciting long trains of action potentials. Under voltage clamp glutamate produced relatively large inward currents (>100 pA) at rest. As has been noted by others these inward currents got larger as the cells were depolarized over the range of -45 to -20 mV. Under our recording conditions, with relatively high intracellular chloride (E_{Cl} = -5 mV), gaba and glycine produced depolarizations from rest, and under voltage clamp they produced currents that reversed at E_{Cl}. Only two neurotransmitters were tested on any one cell, however since almost all SPN responded to each transmitter, we conclude that SPN in culture are sensitive to at least 5 different transmitters.

We have made two interesting observations concerning the regulation of transmitter sensitivity. First, application of a transmitter is sometimes much more effective if applied to a region other than the cell body. Furthermore, the site of maximal sensitivity is not necessarily at the same location for different transmitters. Second, in some cultures the gaba sensitivity was 10 times higher than usual, whereas in these same cultures the sensitivities to glycine, serotonin and norepinephine were not atypically high. Thus it seems likely that receptors for different neurotransmitters on the same cell can be regulated by relatively independent mechanisms.

339.4 TRANSFERRIN IMMUNOCYTOCHEMISTRY REVEALS CHANGING PATTERNS DURING RETINAL DEVELOPMENT. G.D.Zeevalk & A.G.Hyndman. Rutgers Univ. Dept. Biol.Sci., Piscataway N.J. 08855

The serum glycoprotein transferrin is the major transporter of iron to cells. In recent years, evidence has accumulated to suggest that transferrin might be functioning in unique roles in the nervous system, possibly involving neurite outgrowth, synaptogenesis, target cell differentiation and behavior modulation. Transferrin or its receptors have been found in central neurons in chick, sheep and mouse and peripheral neurons in chick. None of the work on the brain distribution of transferrin or its receptor has included the retina. In this study we have looked for the presence of transferrin in the developing chick retina, as well as, its pattern of distribution and any changes in distribution that may occur with development. Sites of iron stores in the retina also were examined to determine if these correlated with regions of transferrin distribution. Immunocytochemical examination of retinas from embryonic day 6 to 3 weeks post hatching revealed that transferrin was differentially distributed in retinal layers. Furthermore, the pattern of transferrin distribution changed with developmental age. At day E6, transferrin was found in 2 distinct bands which were located in the area of the Muller cell endfeet. By day E9, additional regions of transferrin immunoreactivity could be found in the inner and outer plexiform layers (IPL,OPL) and the nerve fiber layer (NFL). These latter three bands became more prominent from E9 until E17 as the synaptic layers and nerve fiber layer increased in size, density and maturation. Perikarya in the nuclear layers were negative. At day E17 and later, the newly forming outer segments of photoreceptor cells were strongly reactive for transferrin while somas of the photoreceptor cells, in the ONL, were negative. Retinas from chicks 1 day to 3 weeks post hatching retained strong immunoreactivity for transferrin in the photoreceptor cell outer segments and OPL, lessened immunoreactivity in the IPL and loss of immunoreactivity in the NFL. Iron distribution at all ages showed only 2 bands that locally corresponded to the Muller cell endfeet. Iron stores were not found in the synaptic layers or photoreceptor cell outer segments. These studies suggest an iron storage function for retinal glia and a role for transferrin in neuronal development and differentiation.

339.5 TRANSFERRIN CAN ALTER ELECTROPHYSIOLOGICAL AND NEUROTRANSMITTER PROPERTIES OF RETINAL NEURONS A.G. Hyndman, P.E. Hockberger, G.D.Zeevalk & J.A. Conner, Dept of Biol. Sci., Rutgers Univ., Piscataway N.J. 08855 & Dept of Molec. Biophysics, Bell Labs, Murray Hill, NJ 07974

Transferrin, an iron transport protein, may be important in the regulation of neural differentiation. During synaptogenesis in the chick retina, transferrin has been localized within the plexiform & optic nerve layers (Zeevalk & Hyndman, this issue). These unique locations suggest a possible role for transferrin in synaptogenesis and led us to examine the effects of transferrin on the electrophysiological properties of retinal neurons and on the development of glutamate binding, uptake and stimulated release in vitro. Retinal neurons from 8 day chick embryos were grown in basal medium supplemented with catalase (5.6U/ml) and insulin (0.83uM) plus or minus transferrin (62.5nM). Cultures used in whole cell patch recordings were supplemented with 10% fetal bovine serum. Using whole cell patch recording, we examined the influence of transferrin on the electrophysiological properties of neurons with a bipolar morphology after 6 days in vitro. Pressure application of transferrin evoked an inward current in most cells recorded from under voltage clamp conditions. In normal saline, the amplitude of the evoked current was larger at a holding potential of -40mV compared to -80mV. This response was identical to the response evoked by glutamate applied iontophoretically. Both responses showed less voltage sensitivity in Mg++ free PBS and on many occasions were found on the same cell. Coupled with these observations, we found that K+ stimulated release of preloaded 3H-glutamate in cultures maintained for 6 days in vitro occurred only when cultures were maintained in transferrin or when transferrin was present during the assay. Glutamate binding & uptake in retinal cultures increased between 2 and 5 days in vitro. This change was mainly due to an increase in the number of neurons which developed specific glutamate binding or high affinity uptake in vitro. The presence of transferrin during the culturing period did not alter these properties. These studies indicate that transferrin may have neurotransmitter like actions of its own, and may function as a neuromodulator in the developing retina. This work was funded by AFOSR, Grant # F49620-85-C-0009 to JC & PHS RR 07058-21 to AH.

339.6 IDENTIFICATION AND PURIFICATION OF AN AXONALLY SECRETED PROTEIN THAT IS DEPOSITED ON THE SURFACE OF NEURONAL SOMAS AND PROCESSES. P. Sonderegger, E.T. Stöckli*, M.A. Rüegg*, P.F. Lemkin*§, P. Streit**, T.B. Kuhn*, and M. Heller*, Institute of Biochemistry and *Brain Research Institute, University of Zurich, CH-8057 Zurich, Switzerland, and §Image Processing Section, DCBD, NIH, Frederick, MD 21701.

Proteins secreted from axons have been suggested to contribute to axon growth and synapse formation and might be involved in the transmission of a variety of axon-derived regulatory signals during neurogenesis. In order to identify axonally secreted proteins, dorsal root ganglia neurons from chicken embryos were cultured in a compartmented cell culture system that allows separate access to neuronal cell somas and axons. The proteins synthesized by the neurons were metabolically labeled by addition of [^{35}S] methionine to the compartment containing the cell somas; the proteins released from the axons were harvested from the culture medium of the axonal compartment. Two-dimensional SDS- PAGE/fluorography, followed by computerized gel-image analysis, revealed two axonally secreted proteins (ASPs) with apparent molecular weights of 54-60 kD and 132-140 kD; they were termed ASP54-60 and ASP132-140, respectively. Both ASPs were found to be secreted from a variety of neuronal cell cultures, but not from any of the non- neuronal cultures investigated, and hence, might be neuron-specific. Virtual absence of these proteins from the axonal protein pattern suggests constitutive secretion. Using coordinates and spot morphology in two-dimensional SDS-PAGE as a means for identification, one of these proteins, ASP132-140, was subsequently purified from chick embryonic vitreous fluid by a four step chromatographic procedure. Polyclonal antibodies were raised. The identity of the purified protein and the in vitro identified axonally secreted protein was confirmed by immunoprecipitation. Immunoblotting experiments revealed that ASP132-140 is exclusively present in vitreous fluid of the embryo but not of the adolescent or adult chicken. The tissue localization of this protein was investigated by light and electron microscopy. Light microscopic localization by indirect immunofluorescence or indirect immunoperoxidase on embryonic spinal cord cultures revealed circumscribed, extracellular depositions of ASP132-140 on neuronal somas and processes, but not on nonneuronal cells. In immuno-electron microscopy these extracellular depositions of ASP132-140 were prevalently between the membranes of adjacent neuronal elements; most frequently they were encountered in the neuropil.

The distinct localization and the occurrence during development suggest a role for ASP132-140 in the organisation of intercellular contacts between neurons during neurogenesis.

339.7 MONOCLONAL ANTIBODY CAT-301 RECOGNIZES A PROTEOGLYCAN SPECIFIC TO THE SURFACE OF SUBSETS OF MAMMALIAN CNS NEURONS. S. Zaremba* and S. Hockfield (SPON: M. DeSantis). Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

A proteoglycan unique to subsets of mammalian CNS neurons is shown here to react specifically with monoclonal antibody Cat-301. Previous immunohistological studies with Cat-301 have shown that the antigen (1) is associated with subsets of neurons, (2) is localized on the surfaces of neuron cell bodies, (3) is expressed relatively late in nervous system development, and (4) requires normal neuronal activity early in development in order to be expressed. The present work shows that antigens reacting specifically with Cat-301 can be purified from urea/CHAPS (3-[(3-cholamidopropyl)dimethylammonio]1-propanesulfonate) extracts of membrane preparations from either hamster or guinea pig CNS. Two pools of immunoreactive material are isolated by DEAE (diethylaminoethyl) ion-exchange column chromatography from extracts of either species; within each species, the two pools are apparently distinguishable only by the ionic strength at which they elute from the column. On Western blots, specific Cat-301 immunoreactivity appears as a broadly migrating species in the stacking gel. Protease treatment totally abolishes immunoreactivity. In contrast, Cat-301 staining on Western blots is altered by incubation with chondroitinase ABC or hyaluronidase, enzymes that degrade glycosaminoglycan chains. The characteristic, broadly migrating species disappears and a sharply defined immunoreactive band is generated that runs just inside the resolving gel and is larger than the 400,000 dalton subunit of laminin. Further incubation of the chondroitinase-treated pools with endoglycosidase F has no effect on Cat-301 immunoreactivity. These biochemical data indicate that the Cat-301 antigens are proteoglycans and suggest, but do not prove, that the Cat-301 epitope is a polypeptide. This raises the possibility that discrete subsets of mammalian CNS neurons may express characteristic cell surface proteoglycans through a mechanism of selective gene expression.

Supported by grants EY-06511 (S.H.), the Klingenstein Foundation (S.H.) and EY-05855 (S.Z.).

339.8 MOLECULAR EVIDENCE FOR EXPERIENCE-DEPENDENT DEVELOPMENT OF MOTORNEURONS. R. Kalb* and S. Hockfield (SPON: S. Gobel). Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT.

Monoclonal antibody Cat-301 recognizes a surface antigen on subsets of neurons in many areas of the mammalian CNS, including Y-cells in the cat dorsal lateral geniculate nucleus (LGN) and spinal motorneurons in several species. We have shown previously that the Cat-301 antigen is expressed relatively late in postnatal development with a time course that matches that of late developmental features of both LGN and spinal cord neurons. In the visual system of cats and primates the anatomy and physiology of neurons can be profoundly altered by depriving an animal of normal visual experience early in life (Hubel and Weisel, J. Physiol. 206: 419). The developmental time course of the expression of the Cat-301 antigen in the LGN correlates with the period during which visual deprivation can alter LGN Y-cells. Neonatal visual deprivation (by monocular lid suture or dark rearing) suppresses Cat-301 expression on Y-cells while deprivation in adult animals has no effect on antigen expression. These results suggested that the onset of Cat-301 immunoreactivity provides a positive molecular marker for the end of a critical period in cat visual system development.

To determine if Cat-301 might be a general marker for experience-dependent development in other areas of the CNS we have examined antigen expression on hamster spinal cord motorneurons. Here we report that Cat-301 antigen expression on motorneurons is tied to early neuromuscular experience. Cat-301 immunoreactivity develops on hamster motorneurons between postnatal days 7 and 14. Altering neuromuscular activity by sciatic nerve crush or thoracic hemicordotomy inhibits Cat-301 expression on motorneurons if performed at postnatal day 5, before the normal onset of Cat-301 immunoreactivity. The loss of Cat-301 is relatively selective as other motorneuron antigens are unaffected. In adult animals nerve crush or cordotomy has no effect on Cat-301 immunoreactivity, demonstrating that Cat-301 expression is not simply dependent on ongoing neural activity. These observations suggest that motorneurons, like LGN neurons, require some pattern of neuronal activity during a critical period in development and, further, that the phenotypic changes in neurons consequent to early experience are reflected by the expression of specific molecules. The identification and characterization of such molecules may yield a description of the molecular mechanisms of experience-dependent development. (Supported by BNS-8544681 and the Klingenstein Foundation).

339.9 BRAIN OPIOID RECEPTOR REGULATION IN THE DEVELOPING ANIMAL. J. Habas[1], A. Tempel[2] and G.A. Barr[3] (SPON: A.B. Johnson[2]). [2]Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461, USA, [1]Dept. of Medicine, SUNY/Downstate Medical Center, Brooklyn, NY 11203, USA, [3]Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, NY 10461, USA.

Chronic treatment with opiate agonists and antagonists have been shown to induce changes in brain opioid receptor density in adult rats. The development of these receptors and their regulation by exogenously administered opioids in perinatal pups has been less well characterized. We examined opioid receptor regulation in brains of neonatal rats after chronic agonist and antagonist treatment. Two regimens of drug treatment were used: naltrexone or morphine was administered to 1) dams or 2) pups of non-treated mothers starting on day of birth. Pups (ages 0-28 days) from each treatment group were sacrificed and brains assayed for specific opioid receptor types. The highly specific ligands used were [^{3}H]D-Ala^2,N-Me-Phe^4,Gly-ol^5-enkephalin for u receptor assays and [^{3}H]D-Pen^2-D-Pen^5-enkephalin for delta assays. Scatchard analysis revealed a 115% increase in brain u opioid receptors on the day of birth in offspring of naltrexone-treated mothers. Daily naltrexone administration to offspring of non-treated mothers induced a 78% increase in brain u opioid receptors. In a separate series of experiments, dams were treated chronically with morphine sulfate for 1 week prior to parturition. Chronic agonist treatment produced a 35% decrease in brain u opioid receptors of pups at postnatal day 0. Daily morphine administration (8 days) to offspring of non-treated mothers also induced a 30% decrease in brain u opioid receptor density. Subsequently, the number of receptors increased to control levels. The observation of a pronounced up- and downregulation of u opioid receptors following chronic pre- and/or postnatal treatment of opioid antagonist and agonist raised the question as to the behavioral consequences of these changes. In order to address this issue, morphine-induced forepaw analgesia was measured in pups treated either prenatally or postnatally with either morphine or naltrexone. Chronic morphine treatment of pregnant rats produced a statistically significant decrease in the morphine-induced analgesic response or tolerance in offspring. Conversely, chronic naltrexone treatment of pregnant rats resulted in an enhancement of the morphine-induced forepaw analgesic response. These data show a behavioral correlate for the observed changes in u opioid receptor numbers following postnatal treatment with morphine or naltrexone as the time course for the induced changes are well-correlated with the behavioral data. (This work is supported by NIH grant No. NS21973).

339.10 CHARACTERIZATION OF A TYPE II CALCIUM/CALMODULIN-DEPENDENT KINASE FROM NEUROBLASTOMA/GLIOMA CELLS. M.L. Vallano and C.M. Beaman-Hall* Dept. of Pharmacology, SUNY/Health Science Center, Syracuse, NY 13210.

A type II calcium/calmodulin-dependent protein kinase (CaM Kinase II) is a proposed regulator of a variety of cellular events, including cytoskeletal protein function. In order to elucidate the role of this kinase in cytoskeletal function, a neuroblastoma/glioma hybrid cell (NG-108CC15) that elaborates cytoskeletal-filled neurites under specific conditions of cell culture (treatment with dibutyryl cAMP) was selected as a model. Initial studies were directed towards the partial purification and biochemical characterization of CaM Kinase II in these cells. A combination of differential centrifugation, ion-exchange chromatography, and calmodulin-affinity chromatography were employed to partially purify CaM Kinase II activity from whole cell homogenates. The putative kinase in NG-108CC15 cells was compared with authentic CaM Kinase II purified from rat brain cytosol. Based upon subunit molecular weight, calmodulin-binding properties, calmodulin-dependent autophosphorylation, time course, substrate specificity, requirement for divalent cations, ATP and calmodulin, CaM Kinase II was identified in these cells. In addition to the autophosphorylated subunits of CaM Kinase II, several other endogenous proteins whose identity remains to be determined served as substrates for the kinase.

In a second series of experiments, cell differentiation was induced by addition of 1 mM dibutyryl cAMP to the culture medium. A combination of morphological, biochemical and electrophysiological criteria were applied to establish that differentiation had occurred. After several days in culture, CaM Kinase II activity was measured in control cells versus treated cells and a significant increase in activity was observed in differentiated cells. Using a combination of gel electrophoresis and scanning densitometry, a significant increase in the staining of several proteins was observed in the treated cells compared to control cells. We suggest that there is an increase in the amount of CaM Kinase II associated with the cytoskeleton in treated cells and that this enzyme may play an important role in regulating cytoskeletal function in these cells.

339.11 NEUROTENSIN IS PRESENT IN LARGE AMOUNTS IN THE PRINCIPAL INFERIOR MEDULLARY OLIVARY COMPLEX OF THE HUMAN YOUNG INFANT. J.-J. Vanderhaeghen and P. Mailleux* laboratories of Neuropathology and Neuropeptide Research and of Pathology and Electron Microscopy, Brugmann and Erasme Hospitals, Université Libre de Bruxelles,808 route de Lennik,B-1070,Brussels,Belgium.

Human brains were obtained at autopsy less than ten hours post mortem from adults, fetuses and young infants (therapeutic abortus, sudden death syndrome, non neurological diseases). Medulla was processed for immunohistochemistry (10 to 50 micrometers thick, 4 % paraformaldehyde fixed-sucrose, cryostats sections), radioimmunoassays (supernatants of 10 % freshly dissected inferior medullary olivary complex homogenized in 0.06 M potassium phosphate buffer, 0.01 M EDTA, Ph 7.2 and boiled for 10 minutes) or receptors autoradiographies (25 micrometers thick, unfixed, cryostat sections). Neurotensin 1-13 (NT) radioimmunoassay was performed with iodinated I^{125} Neurotensin (Amersham). Antiserum was raised in rabbit by injection of NT coupled to thyroglobulin (Sigma) or to albumin (kindly from L. Jennes). Immunohistochemistry was performed using the PAP technique of Sternberger.

In infants from birth to one year, an intense labelling of nerve terminals was present in all parts of the principal medullary olivary complex (principal oliva) but not in the accessory oliva. The labelling disappeared around 8 years of age and was completely absent in the adult. In the 6 months infant or in 75 year old adult, respectively 582 +/- 106 and 5 +/- 0.1 picomoles of NT equivalent (+/- SEM) per g wet weight (n=3) of medullary olivary complex was present. This material eluted as one main peak together with NT on a sephadex G25 column equilibrated with ammonium acetate buffer. Using autoradiography after binding of iodinated NT I^{125}, high levels of displaceable binding sites were present in the principal oliva of a six months old infant but not in an adult .

The presence of NT in nerve terminals of the infant principal oliva but not in the accesory paroliva suggests that they belong to a descending pathway. The accessory paroliva receive they afferences from the spinal cord but the principal oliva receive them from the cerebral cortex, the basal ganglia and the mesencephalic tegmentum. Several NT containing nerve cell bodies have been found in colchicinised rat in the mesencephalic tegmentum where we observed numerous NT nerve fibers but no NT cell bodies during the first year of age. NT neurons, in the human hippocampus (Brain research, 375, 351, 1986), have been shown to be present in the young child but to disappear in adult age.

Data supporting the implication of trophic factors including neuropeptides (Nature, 325, 617, 1987) in the development of the nervous system are rapidly accumulating. NT nerve terminals in principal oliva especially during the first year of age, may play a role in the development of that nucleus projecting to the cerebellum which also completes its development during that year. 339.12 TEMPERATURE AND LIGHT INDUCED CHANGES IN NEONATAL RAT PINEAL GLAND N-ACETYLTRANSFERASE ACTIVITY. G. Torres*, K.A. Haak*, and L.D. Lytle. Department of Psychology, University of California, Santa Barbara, CA 93106.

The activity of N-acetyltransferase (NAT), a pineal gland enzyme important for the synthesis of the methoxyindoleamine endocrine hormone, melatonin, varies diurnally. Interestingly, the high nocturnal activity of the enzyme can be rapidly suppressed by exposing animals to brief presentations of light (Klein and Weller, 1972). Nocturnal light inhibits adult rat pineal gland NAT activity via a circuit that involves portions of the retina, brain, spinal cord, and sympathetic nervous system. Changes in other environmental stimuli [e.g., long-term exposure to high ambient temperatures (Nir and Hirschmann, 1978)] also affect adult pineal gland NAT activity, but the mechanisms involved in these changes are unknown.

We initially determined whether changes in environmental temperature might differentially affect NAT activity in the pineal glands of newborn animals whose sense organs and nervous systems were incompletely developed. Neonatal male or female albino rats were exposed to different temperatures (22 °C or 35 °C) for a 4 hr period during the middle of the light phase of a 12:12 hr day:night cycle (17 ft candle fluorescent lights on at 0700 hr). Unlike animals older than 12 days of age, 4 day old rats showed large increases in NAT activity following exposure to the 22 °C vs. 35 °C ambient temperature. Interestingly, animals pretreated with 6-hydroxydopamine (to destroy the sympathetic nervous system) failed to show cold-induced elevations in pineal gland enzyme activity.

We also studied possible maturational changes in light-induced inhibition of nocturnal pineal gland NAT activity. Four day-old animals maintained at 35 °C were exposed briefly (1 min) or for longer (4 hr) periods of time to nocturnal light (17 ft candles) 2 hr after the onset of darkness. The long (but not short) light exposure significantly reduced pineal gland NAT activity, indicating that photic stimuli may affect the enzyme at an earlier age than thought previously. Whether this light induced inhibition of enzyme activity in 4 day old animals depends on mechanisms different from those involved in the retina-pineal gland circuit remains to be determined.

GABA AND BENZODIAZEPINE: RECEPTORS

340.1 ISOLATION AND PURIFICATION OF ENDOGENOUS LIGAND FOR BENZODIAZEPINE RECEPTOR FROM PIG BRAIN. H.S. Lin*, C.T. Lin and J.-Y. Wu. Dept. of Physiol., Penn State Univ. Col. of Med., Hershey, PA 17033.

The purification of endogenous ligand for benzodiazepine (BZ) receptor was performed by homogenizing pig brain gray matter in distilled water to make a 10% homogenate, followed by ultracentrifugation at 100,000 X g for 1 hr. The supernatant liquid obtained was filtrated through Amicon membrane which has an exclusion limit of 10,000-dalton. The filtrate was concentrated by heating to about one seven hundredth of the original volume. The concentrated sample was extracted by a mixture of chloroform/methanol (2:1) for overnight. The supernatant solution obtained after brief centrifugation was completely air dried. The dried sample which was resuspended in minimal amount of distilled water was reextracted with petroleum ether in a water bath at 37°C for 3 hrs. The organic phase and aqueous phase were separated after brief centrifugation. The ligand activity which was determined by binding assay was found to be mainly in the aqueous phase. The active fraction was further purified by HPLC using C-18 column which was eluted with a linear gradient of buffer A (25 mM ammonium acetate) and buffer B (40%, 50 mM ammonium acetate and 60% acetonitrite). The ligand activity was found to be eluted at 70% buffer B. The HPLC purified ligand preparation was eluted as a single, symmetrical peak at 220 nm on a second HPLC column. The purified preparation had an absorption maximum at 215 nm (between 200-340 nm) which is different from any BZ endogenous ligands that had been reported. The purified ligand preparation inhibited the binding of flunitrazepam (FNZP) and RO5-1788 in a competitive manner; whereas, no effect was observed on the binding of RO5-4864 to the peripheral BZ receptor in both pig and rat preparations. The competitive nature between the isolated ligand and FNZP was further demonstrated in autoradiographic experiments in which the binding of [^{3}H]FNZP to BZ receptor in the hippocampus and cerebral cortex was greatly reduced in the presence of either unlabeled FNZP or purified endogenous ligand. However, the nature of the endogenous ligand whether it is an agonist, antagonist or inversed agonist has not been determined yet. (Supported by NIH grants #NS20978, #NS20922 and #EY05385.)

340.2 THE BRAIN GABA RECEPTOR: CLONING AND FUNCTIONAL EXPRESSION OF THE cDNAs ENCODING ITS SUBUNITS AND LOCALIZATION BY IN SITU HYBRIDIZATION. P.R. Schofield*, B.D. Shivers, H. Rodriguez*, L. Rhee*, J. Ramachandran*, M. Darlison*, N. Fujita*, D. Burt*, A. Stephenson*, T. Glencorse*, V. Reale*, E. Barnard* and P.H. Seeburg* (SPON: C. Cusick) ZMBH, University of Heidelberg, Im Neuenheimer Feld 282, D-6900 Heidelberg, FRG; Genentech Inc., 460 Point San Bruno Boulevard, South San Francisco, CA 94080, USA and MRC Molecular Neurobiology Unit, Hills Road, Cambridge, CB2 2QB, UK.

Gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the vertebrate brain, produces neuronal hyperpolarization by activating a chloride channel that forms an integral component of the GABA receptor. The channel activity of this receptor is modulated allosterically by a variety of clinically significant drugs because of anxiolytic (e.g. benzodiazepines, barbiturates) anxiogenic (e.g. ß-carbolines) or convulsant (e.g. picrotoxin) activities.

We have used affinity-purified bovine GABA receptor to generate peptide sequences and have thus cloned bovine cDNAs encoding both subunits, and ß, of the GABA receptor. The GABA receptor subunits are homologous in both primary sequence (35% identity between and ß subunits) and transmembrane topology. Homology is also seen with subunits of the nicotinic acetylcholine receptor suggesting the existence of a superfamily of chemically-gated ion channels.

Co-expression of both and ß RNA's in Xenopus oocytes produces a functional receptor and chloride ion channel which is potentiated by benzodiazepines and barbiturates and blocked by picrotoxin and bicuculline.

We have used these bovine sequences to isolate the corresponding rat and human cDNA's. The former have been used to map the tissue and cellular distribution of GABA receptor in the rat brain. The latter have been used for directed mutagenesis and electrophysiological analysis of these mutants.

340.3 MOLECULAR CLONING OF THE LIGAND-BINDING SUBUNIT OF THE GLYCINE RECEPTOR. H. Betz, G. Grenningloh*, A. Rientiz*, B. Schmitt*, E.D. Gundelfinger*, C. Methfessel*, M. Zensen* and K. Beyreuther*. ZMBH, Universität Heidelberg, FRG, Max-Planck-Institut für Biophysikalische Chemie, D-3400 Göttingen, FRG, and Institut für Genetik, D-5000 Köln, FRG.

Glycine is a major inhibitory neurotransmitter in the CNS of vertebrates and invertebrates. The glycine receptor was purified by affinity chromatography and shown to be a heterooligomeric glycoprotein containing three polypeptides of 48, 58 and 93 K. The 48 K polypeptide contains the ligand-binding site of the receptor. The 93 K polypeptide is a cytoplasmically localized peripheral membrane protein of the postsynaptic glycine receptor complex. Using microsequencing and oligonucleotide screening approaches, cDNA clones encoding the strychnine-binding 48 K-polypeptide were isolated and analysed. The deduced protein exhibits the same structural organization and significant sequence homology to neuronal and muscle acetylcholine receptor polypeptide. In particular, two invariant cysteines of the extracellular region and the putative transmembrane regions M1 to M4 are all found at equal positions in these receptors. Our data suggest that the glycine and the nicotinic acetylcholine receptors, and possibly other receptors as well, are structurally related products of a family of genes encoding neurotransmitter-gated ionic channels.

Supported by the Deutsche Forschungsgemeinschaft (SFB 317) and the Bundesministerium für Forschung und Technologie (BCT 381-S).

340.4 PREFERENTIAL AFFINITY OF ^{3}H-2-OXO-QUAZEPAM FOR TYPE I BENZODIAZEPINE RECOGNITION SITES IN THE HUMAN BRAIN

M.G. Corda, O. Giorgi, B. Longoni*, E. Ongini[2], S. Montaldo*[1] and G. Biggio

Department of Experimental Biology and [1]Institute of Forensic Medicine, University of Cagliari, Italy

Quazepam and its active metabolite 2-oxo-quazepam (2-oxo-quaz.) are two benzodiazepine (BZ) hypnotics containing a trifluoroethyl mojety on the ring nitrogen at position 1, characterized by their preferential affinity for Type I BZ recognition sites. In the present study we characterized the binding of ^{3}H-2-oxo-quaz. in discrete areas of the human brain. Saturation analysis demonstrated specific and saturable binding of ^{3}H-2-oxo-quaz. to membrane preparations from human cerebellum. Scatchard plots of saturation data indicated a single population of binding sites in this brain area. Hill plot analysis of displacement curves of ^{3}H-Flunitrazepam (^{3}H-FNT) binding by 2-oxo-quaz. yelded Hill coefficients significantly less than unity in the cerebral cortex, hippocampus, caudate nucleus, thalamus and pons suggesting the presence of more than one binding site for 2-oxo-quaz. in these brain areas. Self and cross displacement curves for ^{3}H-FNT and ^{3}H-2-oxo-quaz. bindings in these brain areas indicated that 2-oxo-quaz. binds with different affinities to two population of binding sites. High affinity binding sites were more abundant in the cerebellum (96% of total sites), cerebral cortex and thalamus, whereas low affinity sites were predominant in the caudate nucleus and pons. Competition studies of ^{3}H-2-oxo-quaz. (2nM) and ^{3}H-FNT (0.5 nM) using unlabelled ligands indicated that compounds which preferentially bind to Type I sites, such as ethyl-ß-carboline-3-carboxylate, quazepam, 2-oxo-quaz. and halazepam were more potent at displacing ^{3}H-2-oxo-quaz. than ^{3}H-FNT from cerebral cortex membrane preparations. On the other hand, flurazepam, temazepam and nitrazepam, compounds which have similar affinity for Type I and Type II sites displaced ^{3}H-2-oxo-quaz. and ^{3}H-FNT with similar Ki values. The results suggest that ^{3}H-2-oxo-quaz. may be used for selectively studying Type I BZ recognition sites in the human brain. We also studied the modulation by ɣ-aminobutyric acid (GABA) of ^{3}H-2-oxo-quaz. binding to well-washed cerebral cortex membrane preparations. The "in vitro" addition of GABA concentration-dependently (10^{-8} - 10^{-4} M) enhanced the specific binding of ^{3}H-2-oxo-quaz. This effect was potentiated by the presence of chloride ions in the incubation buffer. Scatchard analysis of saturation curves indicated that GABA decreased the apparent dissociation constant (K_D) while did not modify the maximum number of binding sites (Bmax).

340.5 ASTROCYTIC BENZODIAZEPINE RECEPTOR - PHARMACOLOGICAL EVIDENCE THAT IT MAY BE INVOLVED IN CONVULSANT AND ANXIETY STATES. L. Hertz* and A.S. Bender* (SPON: J.S.Richardson), Dept. of Pharmacol., Univ. of Saskatchewan, Saskatoon, Sask. S7N 0W0 Canada

It is now well established that astrocytes possess receptors for not only the "peripheral-type" benzodiazepine ligand PO 5-4864 but also such clinically relevant drugs as diazepam and flunitrazepam and that the pharmacological profile for the astrocytic and the neuronal benzodiazepine receptor are profoundly different (Bender and Hertz, J. Neurochem., 43, 1319, 1984; J. Neurosci. Res. in press). The astrocytic benzodiazepine receptor may be correlated with a voltage-dependent calcium channel (Bender and Hertz, Europ. J. Pharmacol. 110, 287, 1985), and atrial natriuretic peptide, 8-bromo 3',5'cyclic GMP and phorbol-ester, compounds which may be involved in modulation of calcium channels, all displace astrocytic diazepam binding potently.

The anti-anxiety, anticonvulsant and/or sedative effects by benzodiazepines might equally well be mediated by the astrocytic and the neuronal benzodiazepine receptor. We have therefore compared potencies of several convulsant and anticonvulsant drugs as well as of anxiogenic and anxiolytic compounds in displacing [^{3}H]diazepam binding in primary cultures of either astrocytes or neurons. The two convulsants picrotoxinin and pentylenetetrazole inhibited diazepam binding in astrocytes with IC_{50} values in the low nanomolar range but had much less effect on neuronal binding. The excitatory barbiturates CHEB and DMBB were also more potent on astrocytic than on neuronal binding. The anticonvulsant drugs carbamazepine and phenobarbital were ten times more potent in displacing astrocytic benzodiazepine binding than in displacing neuronal binding, whereas phenytoin was equipotent. Valproic acid, trimethadione and ethosuximide were also more active at the astrocytic than at the neuronal binding site. For all of the anticonvulsant drugs the IC_{50} values in the astrocytes were comparable to the therapeutic plasma levels. The endogenous anxiogenic compound octadecaneuropeptide (ODN; anxiety peptide) was much more potent in inhibiting astrocytic (IC_{50} 140 nM) than neuronal (IC_{50} value 7 µM) binding (Bender and Hertz, Europ. J. Pharmacol. 132, 335, 1986). Classical anxiolytic drugs like diazepam had relatively similar IC_{50} values (approximately 10 nM) in astrocytes and in neurons. A novel group of drugs, the thienotriazolodiazepines WE 973 and WE 1008, which have pronounced effects on conflict behavior and are potent anticonvulsants, were, however, less potent in astrocytes (IC_{50} values > 100 nM) than in neurons. Brotizolam which, in addition, has sedative effects displaced both astrocytic and neuronal binding potently whereas the convulsant KW 1937 was much more potent in astrocytes (IC_{50} value 5 nM) than in neurons.

340.6 INTERACTIONS OF PYRETHROID INSECTICIDES WITH THE PERIPHERAL-TYPE BENZODIAZEPINE RECEPTOR. L. Devaud* and T.F. Murray (Spon: J.E. Morris), College of Pharmacy, Oregon State University, Corvallis, OR 97331.

The neurotoxic effects of pyrethroids have been well characterized. Investigating the results of low dose administration of pyrethroids on seizure susceptibility we have previously reported that pyrethroids exert potent proconvulsant effects when tested in the pentylenetetrazol (PTZ) seizure threshold model. (Devaud et al, Europ. J. of Pharmacol., 120: 269 (1986)). This effect is stereoselective with 1RcisαS cypermethrin and 1Rcis permethrin (insecticidally active) each causing a dose dependent reduction in seizure thresholds while their insecticidally inactive isomers were devoid of proconvulsant activity. 1RcisαScypermethrin was the most potent pyrethroid tested, producing a maximal 33% reduction in mg/kg PTZ required to elicit the first myoclonic twitch. The peripheral-type benzodiazepine receptor (PTBR) has been implicated as a site of action for pyrethroids. Pretreatment with PK11195, an antagonist of the PTBR, blocked the proconvulsant effects of deltamethrin, permethrin and cismethrin. Having established the proconvulsant activity of both Type I and Type II pyrethroids, the interactions of pyrethroids with the PTBR were investigated using radioligand binding techniques. We now report that the results of competition binding studies were in agreement with published reports in that Ro5-4864 and PK11195 were potent displacers of [^{3}H]Ro5-4864 from a rat olfactory bulb membrane preparation. The IC50 for this effect was 2.9 ± 0.33 nM for Ro5-4864 and 2.8 ± 0.28 nM for PK11195. Deltamethrin effectively displaced [^{3}H]Ro5-4864 binding with an IC50 of 40.3 ± 8.7 nM and a maximal displacement of 85-90% of specific binding. 1RcisαS cypermethrin was equipotent with deltamethrin as an inhibitor of [^{3}H]Ro5-4864 with an IC50 of 43.1 ± 6.1 nM. The 1ScisαR isomer of cypermethrin, which lacked proconvulsant activity was 350 fold less potent than the 1RcisαS isomer as an inhibitor of [^{3}H]Ro5-4864 binding. In addition, the maximal inhibition of [^{3}H]Ro5-4864 produced by the 1ScisαR isomer of cypermethrin was 47% whereas the maximal displacement produced by the 1RcisαS isomer was 88-95% of specific binding. Type I pyrethroids also interact with the PTBR. The insecticidally active 1Rcis permethrin (but not the insecticidally inactive 1Scis isomer) displaced [^{3}H]Ro5-4864 with an IC50 of 1.50 ± 0.01µM. Other Type I pyrethroids, such as allethrin and cismethrin, also inhibited [^{3}H]Ro5-4864 binding, with an IC50 values of 2.3 ± 0.3 µM and 7.2 ± 3.3 µM, respectively. These indicate a general correlation between proconvulsant activity of pyrethroids and in vitro affinity as inhibitors of binding to the PTBR. Moreover, these results provide additional evidence for this site as a locus of a neurotoxic action of pyrethroid insecticides. (Supported in part by a grant from the Oregon State University Environmental Health Sciences Center.)

340.7 MICROSCOPIC ANALYSIS AND ALLOSTERIC MODULATION OF [^{3}H]-SR 95531 BINDING TO GABA$_A$ RECEPTORS IN THE RAT BRAIN. R.T. McCabe, James K. Wamsley, J.P. Yezuita* and R.W. Olsen[1]. Depts. of Pharmacology and Toxicology and Psychiatry, Univ. of Utah, SLC, UT 84132, and [1]Dept. of Pharmacology and the BRI, UCLA, LA, CA 90024.

One of the two GABA receptor subtypes, the GABA$_A$ receptor, is coupled to a chloride ionophore and exists in both high- and low-affinity conformations. A pyridazinyl-GABA derivative, SR 95531 [2-(3'-carbethoxy-2'-propyl)-3-amino-6-paramethoxy-phenyl-pyridazinium bromide], has recently been reported to have selective GABA$_A$ antagonist properties. In the present study, we investigated the binding of [^{3}H]-SR 95531 using autoradiographic techniques. Furthermore, based on experiments showing allosteric interactions at the GABA receptor, modulation of [^{3}H]-SR 95531 binding by various benzodiazepine (BZ) and barbiturate receptor ligands was examined in several brain areas.

For autoradiography, tissue sections from rat brain were prepared for assay. Dissociation, association, saturation and displacement studies were performed to determine the optimal binding conditions. In all subsequent experiments, tissue sections were incubated for 15 min in ice-cold 10 mM K_2HPO_4/KH_2PO_4 buffer (pH 7.5) containing 100 mM KCl and [^{3}H]-SR 95531, and then rinsed (3x5 min) in buffer alone before drying. Nonspecific binding was defined by 10^{-4} M GABA or 10^{-4} M SR 95531. For homogenate studies, membranes were prepared from whole brain or regions representing cortex, striatum, hippocampus, midbrain-thalamus, medulla-pons and cerebellum. Tissues were immersed for 30 min in ice-cold buffer containing [^{3}H]-SR 95531 and separation of bound from free ligand was performed by centrifugation or filtration. Nonspecific binding was identified with 10^{-4} M GABA. Microscopic analysis indicates that intermediate to high densities of [^{3}H]-SR 95531 binding were found in areas which also contain intermediate to high densities of low-affinity GABA$_A$ sites. A K_d of 42.4 nM and B_{max} of 105.8 fmol/mg tissue was obtained from Scatchard analysis of saturation data. The binding of [^{3}H]-SR 95531 to membranes occurred at low-affinity GABA$_A$ receptor sites. Results from displacement studies, to determine pharmacological specificity, demonstrate that [^{3}H]-SR 95531 is displaceable by GABA$_A$ ligands and preferentially inhibited by GABA$_A$ antagonists. Allosteric modulation data indicate that [^{3}H]-SR 95531 binding is inhibited by barbiturates and several BZ receptor ligands that varied with brain region. Numerous barbiturates exhibited a stereoselective inhibition of [^{3}H]-SR 95531 binding in whole brain.

The binding of [^{3}H]-SR 95531 selectively identifies GABA$_A$ receptors which correspond to the low-affinity sites previously reported in homogenate assays. Our results show that this agent is a new probe for obtaining specific labeling of the low-affinity GABA$_A$ receptor.

340.8 THE LOCALIZATION OF GABA$_A$ RECEPTOR-LIKE IMMUNOREACTIVITY IN RAT CEREBELLUM: A LIGHT AND ELECTRON MICROSCOPIC STUDY. D.L. Meinecke, J. Tallman, and P. Rakic. Section of Neuroanatomy, Yale U. School of Medicine. 333 Cedar Street New Haven, CT 06510-8001.

The inhibitory action of GABA appears to be mediated mainly through a GABA$_A$ receptor complex which gates chloride channels. Therefore, knowledge of the precise location of these receptors in normal and disease states may provide insight into inhibitory synaptic mechanisms in the CNS. Sensitive and high resolution localization of GABA$_A$ receptors can be achieved with immunocytochemical techniques using monoclonal antibodies against proteins of the GABA$_A$ receptor complex. The present study examines the distribution and ultrastructural localization of GABA$_A$ receptor-like immunoreactivity in rat cerebellum with a monoclonal antibody (E9) to a 50KD subunit of the GABA$_A$/benzodiazepine receptor complex (Sweetnam et al., 1986 Psychopharm. Bull. 22).

Cerebellar hemispheres were excised from rats after cardiac perfusion with 4% paraformaldehyde and 0.1% glutaraldehyde in 0.1M PO_4 buffer. Sections of cerebellum were cut at 20um with a Vibratome and incubated in buffered dilutions of E9 and control sera overnight. Sections were next immunoreacted with the ABC-peroxidase system and 0.08% DAB, post-fixed in osmium ferricyanide, and flat embedded in epoxy resin.

Light and electron microscopy showed that GABA$_A$ receptor-like immunoreactivity was located in all three layers and the five neuronal types of the cerebellar cortex and in neurons of the deep nuclei. Glial cells and white matter were not immunoreactive. Immunoreactivity was most intense in the neuronal cell bodies and dendrites where reaction product was localized mostly over free ribosomes and rough endoplasmic reticulum, but not in the nucleus, while axonal shafts and synaptic terminals were not reactive. In the molecular layer stellate and basket cells, small diameter dendrites belonging to these cells, and large Purkinje cell dendrites were immunoreactive. However, reaction product was not present in Purkinje dendritic spines, nor axon terminals forming synapses with these spines. Purkinje cell bodies were strongly immunoreactive but synaptic terminals on their somas were unreactive. In the granule layer reaction product was located in the perikaryal cytoplasm and dendrites of granule and Golgi II cells, as well as in mossy fiber terminals. In contrast, GABAergic axon terminals of Golgi II cells forming synapses with mossy fiber terminals were free of reaction product. Consequently, E9 antibody was differentially distributed over cerebellar cells and their subcellular compartments. These data indicate that GABA$_A$ receptors may be located in the post-synaptic elements of cell bodies and their processes known to form synapses with GABA-containing axon terminals.

340.9 IN VITRO AND IN VIVO BINDING CHARACTERISTICS OF BENZODIAZEPINE RECEPTOR LIGANDS IN THE CNS: QUANTITATIVE AUTORADIOGRAPHY AND IMAGE ANALYSIS. J.G. Richards, J.M. Séquier*, R. Glinz* and H. Möhler*, Pharma Res. Dept., F. Hoffmann-La Roche & Co., Ltd., CH-4002 Basle, Switzerland.

The therapeutic effects of benzodiazepine minor tranquillizers are triggered by their selective interaction with allosteric binding sites on GABA$_A$ receptors which regulate the gating function of chloride channels in the CNS. Although the cellular and subcellular distribution of benzodiazepine receptors can be resolved immunohistochemically using monoclonal antibodies (Richards et al., J. Neurosci., in press), a quantitative analysis of receptor numbers, their affinity and regulation in microscopic regions of the CNS is only possible using radiohistochemical techniques.

We determined the regional affinity and GABA-shift of receptor ligands (agonists and partial agonists) in ^{3}H-meclonazepam and ^{3}H-flumazenil binding respectively (to rat brain sections) in vitro. Moreover, in order to further characterize drug-receptor interactions in discrete brain regions under more physiological conditions, the regional affinity and time-course of binding inhibition by agonists and partial agonists were determined in ^{3}H-flumazenil binding (to mouse brain) in vivo. For the measurement of binding data by quantitative autoradiography, we used tritium brain paste calibration standards and an image analyser (ASBA^R, Wild-Leitz, Zürich). The influence of the variable lipid content of brain regions on tritium absorbance (quench effect) was investigated by comparing the in vitro binding of a benzodiazepine receptor ligand (Ro 16-0154) radiolabelled with either ^{3}H or ^{125}I.

The findings reveal, 1) the need for re-calibration of commercially available standards, 2) the absence of a quench effect with tritium, 3) the absence of a correlation between the pharmacological profile (agonist, partial agonist) of a drug and its regional affinity for benzodiazepine binding sites in vitro or in vivo, 4) a correlation between the pharmacological characteristics of a drug and its GABA-shift in vitro as well as its duration of binding inhibition in vivo.

340.10 **DISTRIBUTION AND LATERAL MOBILITY OF BENZODIAZEPINE RECEPTORS ON SPINAL CORD AND CEREBRAL NEURONS**
K.J. Angelides*, C.L. Thompson*, J.R. Velazquez*, and E.M. Barnes, Jr. (SPON: D, Bridges). Depts. of Physiology and Molecular Biophysics and Biochemistry, Baylor College of Medicine, Houston, TX 77030

GABA is the most abundant inhibitory neurotransmitter in the central nervous system and appears to exert its main effects via a GABA receptor that gates a Cl^- channel in the subsynaptic membrane. These receptors contain a modulatory unit, the benzodiazepine receptor, which potentiates GABA-gated channel openings.

To determine the topography and mechanisms governing the distribution of these receptors on neurons, microfluorimetry and fluorescence recovery after photobleaching (FRAP) were used to measure the density and lateral mobility of fluorescently labeled benzodiazepine receptors on neuronal cells in culture. We have synthesized several fluorescent benzodiazepine derivatives. One of these, 7-nitroben-2-oxa-1,3-diazole-1012S (NBD-1012S) was synthesized, purified to homogeneity, and tested in equilibrium binding. Competitive binding of NBD-1012S with [^{3}H]-flunitrazepam on adult chick brain membranes, membranes prepared from chick neuronal cultures, or on neuronal cultures yields K_is of 30 pM, 29 pM, and 46 pM respectively. By microfluorimetry neurons could be specifically labeled by NBD-1012S; the cell soma was predominately labeled and 85 % of the labeling could be displaced by 300 nM unlabeled 1012S or by 300 nM clonazepam. In some neurons, hotspots were observed on the cell body. FRAP experiments on chick neurons indicate that 30 % of the labeled receptors on the same are immobile ($D \leq 10^{-12}$ cm^2/s). The mobile fraction had an average lateral diffusion coefficient of 2×10^{-10} cm^2/s, while those receptors on processes were completely immobilized. On rat spinal cord motoneurons, a significantly greater fraction of receptors were immobilized on the soma (63 %). In contrast, voltage-dependent Na^+ channels and tetramethyrhodamine-phosphatidylethanolamine were very mobile on the cell soma ($D = 10^{-9}$ cm^2/s). General glycoproteins identified by tetramethylrhodamine-succinylConcanavalin A were diffusely distributed with 60% of these sites having only moderate mobility (5×10^{-10} cm^2/s). The results indicate that benzodiazepines are largely restricted to the neuronal soma and are immobilized there. Hence, the forces which restrict benzodiazepine receptor diffusion and allow Na^+ channels to move freely must have some measure of molecular specificity (Supported by NIH grants DK 17436, NS 11535, and NS 24606).

340.11 BICUCULLINE-INSENSITIVE [^{3}H]GABA BINDING TO HOMOGENATES OF CATFISH CENTRAL NERVOUS SYSTEM. G. Tunnicliff*and J.M. Myers* (SPON: H.C. Stanton). Laboratory of Neurochemistry, Indiana University School of Medicine, Evansville, IN 47712.

At least 2 subtypes of GABA receptors have been described in the mammalian central nervous system. $GABA_A$ receptors are linked to Cl^- flux whereas evidence exists that $GABA_B$ receptors are associated with both Ca^{2+} and K^+ currents. In catfish brain it has previously been shown that [^{3}H]GABA binding occurs (Mathis, C.A. and Tunnicliff, G., Comp. Biochem. Physiol. 78C:479,1984.) that has properties similar to $GABA_A$ binding in rat brain. The present study has revealed that a second, and possibly a third, type of GABA binding site exists in catfish brain, both of which are sodium ion independent. One of these sites resembles the $GABA_B$ binding site in mammalian brain since it requires Ca^{2+} and can be inhibited by baclofen. However, this inhibition was not very potent and even at high baclofen concentrations maximum inhibition was only 43%. Moreover, the dissociation constant (Kd) for GABA binding was 4 µM, a value that is about 40 times higher than that measured in rodent brain. At high concentrations isoguvacine was able to substantially increase the inhibition of [^{3}H]GABA brought about by baclofen. This suggests a third GABA binding site exists in catfish brain that is sensitive to high isoguvacine. Neither of the binding sites described is able to be inhibited by bicuculline.

340.12 MODULATION OF FLUNITRAZEPAM BINDING IN INTACT PRIMARY CULTURED SPINAL CORD NEURONS BY GABAergic DRUGS. A.K. Mehta* and M.K. Ticku. Division of Molecular Pharmacology, Department of Pharmacology, Univ. of TX Hlth. Sci. Ctr., San Antonio, TX 78284-7764.

[^{3}H]Flunitrazepam binding and its modulation by $GABA_A$ergic drugs was studied in intact primary cultured spinal cord neurons. The specific benzodiazepine binding to intact cells was rapid, exhibiting high affinity and saturability, with an apparent K_D of 6 nM and B_{max} of 822 fmol/mg protein. The association as well as dissociation of [^{3}H]flunitrazepam binding exhibited monoexponential kinetics. Benzodiazepines such as flunitrazepam, clonazepam, diazepam and RO 15-1788, as well as β-carbolines such as methyl-6, 7-dimethoxy-4-ethyl-β-carboline-3'-carboxylate (DMCM) displaced specifically-bound [^{3}H]flunitrazepam in a concentration-dependent manner. In intact cells, RO15-1788 (K_i = 1.7 nM) was the most potent displacing agent, followed by DMCM (K_i = 4.7 nM) and RO5-4864 (K_i > 5,000 nM) was the least potent. Conversely, specific [^{3}H]flunitrazepam-binding to intact cells was enhanced in a concentration-dependent manner by GABA agonists like muscimol (EC_{50} = 2.6 µM) and GABA (EC_{50} = 14 µM). The EC_{50} values of muscimol and GABA are similar to their K_m values for increased ^{36}Cl-influx in these neurons (Lehoullier and Ticku, Neurosci. Abst. 12:186(#533.3), 1986). The enhancing effect of GABA agonists was susceptible to reversal by bicuculline and picrotoxinin. Specific [^{3}H]flunitrazepam binding was also enhanced by drugs which facilitate GABAergic transmission, like etazolate (EC_{50} = 2.4 µM), (+)etomidate (EC_{50} = 11 µM) and pentobarbital (EC_{50} = 200 µM). These results suggest that the intact cultured spinal cord neurons exhibit the properties of benzodiazepine-GABA receptor-ionophore complex thereby probably providing an ideal in vitro assay preparation to study GABA synaptic pharmacology.

NEURAL PLASTICITY IN ADULT ANIMALS II

341.1 DL-AMINOPHOSPHONOVALERATE (APV) BLOCKADE OF HIPPOCAMPAL LONG-TERM POTENTIATION (LTP) PREVENTS AN LTP-ASSOCIATED INCREASE IN PROTEIN F1 PHOSPHORYLATION. D.J. Linden*, F-S. Sheu, and A. Routtenberg. (SPON: Z. Iqbal). Cresap Neurosci. Lab., Northwestern Univ., Evanston, IL, 60201.

Previous work from this laboratory has shown a selective increase in the phosphorylation of protein F1 (47K, 4.5pI) measured in vitro following induction of hippocampal LTP. Protein F1 phosphorylation is also positively correlated with the persistence of the potentiated response measured 1 hour or 3 days after LTP induction [Br. Res.(1985) 343:137,(1986) 399:205]. Application of APV, an antagonist of the NMDA class of glutamate receptor reversibly blocks initiation of hippocampal LTP, while leaving low-frequency synaptic transmission unimpaired. However, APV blocks only the initiation of LTP, as APV has no effect on a response once potentiated [J. Physiol.(1982)334:33]. If increased phosphorylation of protein F1 were critical for the persistence of LTP and were a consequence of LTP initiation, then blockade of LTP initiation by APV should prevent an LTP-induced increase in protein F1 phosphorylation.

Rats were implanted with a stimulating electrode in the perforant path and a multi-barrelled micropipette to record field potentials and deliver drugs in the dentate hilus. APV (192 pmol) and vehicle control solutions were applied by micropressure ejection over a 2 min period; high-frequency stimulation (HFS) to induce LTP was provided by 8 stimulus trains (400 Hz, 8 pulses, .4 msec pulse width); 60 min following HFS, the hippocampus was rapidly frozen for study of protein phosphorylation.

Three groups (n=8/group) received either APV immediately before HFS (potentiated response completely blocked, 101% of baseline), APV immediately after HFS, or vehicle before HFS (responses 147% and 149% of baseline respectively). Significant and selective increases in protein F1 phosphorylation of the APV-post HFS (10.21% of total) and vehicle-pre HFS (10.01%) groups relative to the APV-pre HFS group (7.53%; overall difference p<.005 by ANOVA) were observed. Protein F1 phosphorylation was positively correlated with the magnitude of potentiation observed immediately (+.859) and 60 min (+.903) following HFS.

The result herein, that blockade of LTP prevents the associated increase in protein F1 phosphorylation, indicates that protein F1 phosphorylation may be critical for the persistence of the LTP response, and furthermore that phosphorylation of protein F1 is a consequence of the activation of APV-sensitive initiation mechanisms (supported by MH25281-13 and AFOSR87-0042 to A.R.).

341.2 INDUCTION, ENHANCEMENT AND BLOCKADE OF HIPPOCAMPAL SYNAPTIC POTENTIATION: DOSE-DEPENDENT EFFECTS OF PHORBOL 12,13-DIBUTYRATE (PDBu) P. Colley* and A. Routtenberg (SPON: R. Sekuler). Cresap Neuroscience Laboratory, Northwestern Univ., Evanston, Ill 60201

Protein kinase C (PKC), in synergism with a calcium signal, plays a central role in signal transduction and transmembrane signalling in nervous tissue [Science (1984) 225 1365]. Such a mechanism may underlie synaptic potentiation in brain. Phorbol ester, a PKC activator by translocating the kinase to the membrane, enhanced dentate gyrus synaptic responses only in combination with 2 trains of 400 Hz afferent stimulation (2TP) in the intact hippocampus [Br. Res. (1986) 374 378]. In contrast, induction of synaptic potentiation has been observed by others [J. Neurosci. (1986) 8 475]. To clarify this issue, we explored a range of PDBu dosages on PKC regulation of synaptic potentiation.

PDBu, diluted in a 10% ethanol/TRIS vehicle (Veh), was applied iontophoretically in dosages of 6, 12 or 20 pmol, as determined by ejection of 3H-PDBu into test tube. A low dose of PDBu (6 pmol) given alone without 2TP had no effect on synaptic activation, yet in synergism with 2TP induced a growth of the initial potentiation (126% at T=120 min) similar to that seen in the dentate hilus using 32 pmol of phorbol (TPA). If the synergistic enhancement of low dosages of PDBu and 2TP were mediated by PKC activation as proposed, then one would expect an increase in membrane PKC activity. Using lysine-rich histone as substrate to measure PKC activity [Science (1986) 231 587], animals who showed growth of the response over two hours regardless of the magnitude of the initial potentiation after 2TP had 32% more membrane PKC activity compared to animals receiving 12 pmol of PDBu or Veh which showed near baseline responses.

12 and 20 pmol of PDBu delivered alone enhanced the baseline population EPSP slope (twoway ANOVA at T=120 min: df=3,108 p<.001) in a way similar to that seen in the CA1 region of hippocampal slice. Surprisingly, doses which produced this enhancement blocked initial potentiation by 70% when applied just prior to 2TP in a second experiment (oneway ANOVA at T=0 min: F=16.41 df=3,12 p<.001). Whether this block of initiation is mediated by direct activation of PKC, a modulatory role of PKC, or by a non-PKC mediated mechanism can not yet be determined. PKC does appear to have an essential role, however, in the maintenance of synaptic potentiation induced with high frequency stimulation. (Supported by MH25281-13, and AFOSR87-0042 to A.R.)

341.3 PROTEIN KINASE C (PKC) INHIBITORS PREVENT MAINTENANCE OF HIPPOCAMPAL LONG-TERM POTENTIATION (LTP) D. Lovinger*, K. Wong*, K. Murakami*, and A. Routtenberg. (SPON: J.P. Rosenfeld). Cresap Neurosci. Lab., Northwestern Univ., Evanston, IL 60201.

If PKC activation were crucial for maintenance of potentiation, as we have proposed [Prog. Br. Res., 69, 1987, p. 411], then PKC inhibitors should decrease the endurance of potentiation. The failure to observe such a result would be strong evidence against our proposal. We applied PKC inhibitors [mellitin (MEL), polymyxin B (PMB) or H-7] by micropressure ejection to the perforant path synaptic zone in the dentate gyrus 10 min after LTP. Each of the 3 inhibitors induced decay of potentiation in contrast to the persistence observed in Tris-ejected or no ejection controls ($F=21.44$, $df=2,117$, $p<.001$ using MEL, $F=156.61$, $df=1,150$, $p<.001$ using PMB). Synaptic responses returned to baseline within 50 min of MEL or PMB application, and potentiation induced at this time did not differ from that seen in controls. Given the differing effects of the 3 inhibitors on protein kinases other than PKC, their elimination of potentiation likely resulted from actions on PKC. To assay PKC subcellular distribution we measured phosphorylation of exogenous histone H-1 using hippocampal cytosol and membrane from animals given PMB or Tris 10 min after LTP. PMB-treated animals exhibited a decreased percentage of membrane-associated PKC activity relative to animals given Tris (PMB = 68.75±4.29%, Tris=85 ± 4.95%). Thus inhibitors may act by reducing membrane association of PKC following LTP.

MEL treatment 1 hr after LTP produced decay of potentiation, but not to pre-LTP baseline levels ($F=45.53$, $df=2,225$, $p<.001$). MEL treatment 4 hr after LTP was without effect. Thus the importance of PKC activity for LTP maintenance might peak within the first hour after potentiation and decrease thereafter. Alternatively, PKC translocated to the membrane following the onset of potentiation may become resistant to inhibitor action.

MEL or PMB given 15 min before LTP did not affect initial potentiation, but decreased its persistence ($F=19.81$, $df=2, 171$, $p<.001$). The effect of PKC inhibitors on potentiation contrasts with that of the NMDA receptor antagonist APV which does not affect maintenance when given after LTP, but blocks initiation [Trends Pharm. Sci., 6, 407, 1985, p. 407] and PKC substrate phosphorylation when given before LTP [see Linden et al., this meeting]. These data suggest that initiation and maintenance of potentiation constitute separable molecular processes. (Supported by MH25281-13, and AFOSR87-0042 to A.R.)

341.4 TWO GROWTH CONE-ENRICHED C-KINASE SUBSTRATES AND TWO VESICLE-ASSOCIATED PHOSPHOPROTEINS ARE DIRECTLY CORRELATED WITH PERSISTENCE OF LONG-TERM POTENTIATION: A QUANTITATIVE ANALYSIS OF TWO-DIMENSIONAL GELS. R.B. Nelson*, D.J. Linden*, A. Routtenberg (SPON: T. Bleck). Cresap Neuroscience Laboratory, Northwestern University, Evanston, IL 60201.

Translocation of protein kinase C (PKC) from cytosol to membrane and increased phosphorylation of protein F1 (47 kDa, pI 4.5) are correlated with long-term potentiation (LTP; Akers et al., Science, 231:587, 1986; Lovinger et al., Brain Res., 399:205, 1986). Although protein F1 alone was related to LTP persistence in previous studies, not all phosphoproteins can be analyzed by one-dimensional SDS-PAGE, in particular co-migrating phosphoproteins and minor phosphoproteins competing against background label. We therefore used quantitative analysis of two-dimensional gels to relate individual phosphoproteins to measures of LTP, after inducing LTP in the intact dorsal hippocampal formation. Of 15 protein spots analyzed, the phosphorylation of 4, including protein F1, were directly correlated to persistence of LTP over 10 min (measured as growth or decay of the potentiated population spike amplitude), but not to the spike amplitudes themselves. Two of these phosphoproteins, protein F1 and an acidic 80 kDa protein (Albert et al., PNAS, 83:2822, 1986) are PKC substrates and the major phosphoproteins seen in a purified fraction of neural growth cones (Nelson et al., Soc. Neurosci., 11:927, 1985; Katz et al., J. Neurosci., 5:1402, 1985). The other two phosphoproteins are relatively minor species stimulated by cAMP, and to a lesser extent, by phorbol esters and calmodulin. The molecular weight, isoelectric point, charge heterogeneity, and phosphorylation dependencies of these latter two proteins suggest they are the immunologically-related synaptic vesicle proteins IIIa and IIIb (Browning and Greengard, Soc. Neurosci., 10:196, 1984). The synaptic vesicle proteins Ia and Ib were not correlated to persistence of LTP. The present findings suggest that multiple PKC substrates and a specific subset of synaptic vesicle phosphoproteins may be important in the mechanism underlying persistence of LTP. All four of these proteins appear to be heavily or exclusively represented in the pre-synaptic terminal. The enrichment of both protein F1 and 80k in growth cones is consistent with our proposal that a common molecular mechanism involving PKC substrate phosphorylation may underlie both normal neurite growth in developing brain and neural plasticity at adult synapses (Routtenberg, Prog. Brain Res., Vol. 69, 1986). Supported by MH25281-13 and AFSOR87-0042 to A.R.

341.5 **LEUPEPTIN, A THIOL-PROTEINASE INHIBITOR, BLOCKS HIPPOCAMPAL LONG-TERM POTENTIATION IN CHRONICALLY IMPLANTED RATS.** U. Staubli, M. Baudry & G. Lynch, Center for Neurobiology of Learning and Memory, U. of Calif. Irvine, CA 92717.

We recently reported that stimulation applied in a pattern that mimics the naturally occurring theta rhythm induces a potentiation (LTP) of hippocampal field potentials that is stable for one to several weeks (Staubli & Lynch, in press). It has been proposed that partial degradation of submembraneous cytoskeletal proteins, in particular brain spectrin, by a calcium-activated protease is a crucial step in the translation of intense physiological activity into the morphological changes that accompany LTP (Lynch & Baudry, 1984). If so, then drugs that inhibit calpain would be expected to interfere with the induction of LTP. Leupeptin is a reasonably potent antagonist of purified calpain but does not freely enter intact cells. However, intraventricular perfusion of the drug for several days does produce a selective impairment of some forms of learning and causes at least a partial inhibition of calpain activity (Staubli *et al.*, 1985). Accordingly, we have used the chronic perfusion technique to test if leupeptin also affects LTP.

Animals were implanted bilaterally with stimulating electrodes in the Schaffer-commissural system and with one recording electrode in the apical dendrites of field CA1. Osmotic pumps containing either leupeptin (20 mg/ml) or saline and that infused 0.5 *u*l/hr into the lateral ventricle were used. In some rats the pumps were inserted at the same time as the electrodes and in others only after several days of physiological recording. Rats that did not exhibit stable physiological responses for 3 days were dropped from the study. Baseline testing was begun after at least 3 days of infusion and continued for 3 days. "Theta bursting" stimulation (Larson & Lynch, 1986) was used to induce LTP. The control group (n=11) exhibited an immediate and robust LTP effect that remained in place 24 and 48-72 hrs later. Only three of the thirteen leupeptin treated rats exhibited evidence of LTP and in only one of these was a sizeable effect recorded over several days. The difference in amount of LTP between the 2 groups was highly significant. The leupeptin filled pumps were disconnected in seven rats and testing was resumed after a delay of 5-8 days. Potentiation was observed in all of these animals immediately after bursting stimulation and in five for several days thereafter. Thus, elimination of leupeptin removed the block on LTP induction.

Two lines of evidence indicate that leupeptin did not substantially affect baseline physiology: 1) the evoked responses were unchanged from the drug-free condition in the rats in which this analysis was conducted; 2) disconnecting the pumps did not affect the size of the response from that recorded during infusion. Accordingly, it is not likely that the striking blockade of LTP induction caused by leupeptin is due to a generalized disturbance in the physiological properties of the hippocampus. (Supported by AFOSR grant #86-0099.)

341.6 MULTIPLICATIVE INTERACTION BETWEEN LONG-TERM POTENTIATION AND SHORT-TERM FACILITATION IN CRAYFISH NEUROMUSCULAR SYNAPSES. C.L. Keenan, D.A. Baxter, & T.H. Brown, Division of Neurosciences, Beckman Research Institute, City of Hope, Duarte, CA 91010.

We investigated the interaction between long-term potentiation (LTP) and short-term facilitation (STF) in crayfish opener-excitor (OE) neuromuscular synapses. At the same time, we also began to explore the optimal patterns of stimulations for LTP induction.

In each experiment, an attempt was made to induce LTP by stimulating the OE axon 300 times within 30 s. A constant stimulation rate appeared to be more effective in inducing LTP than a sequence of brief but high-frequency stimulations. In 27 of 34 preparations, stimulating the OE at a constant frequency of 10 Hz (300 stimulations in 30 s) induced LTP (72% mean increase above the control level 30 min after the stimulation). In contrast, in 10 of 10 preparations, a series of short bursts of tetanic stimulations (also a total of 300 stimulations in 30 s) failed to induce LTP (9% mean increase). Subsequent stimulation at a constant rate of 10 Hz (for 30 s) induced LTP in all 10 preparations (63% mean increase).

Several characteristics of STF, including the magnitude (F_e) and accumulation (F_n) of STF during short trains of stimuli and tonic stimulation (Bittner and Sewell, J. Comp. Physiol. 109:287, 1976), were monitored before and at least 30 min after LTP induction. The results indicated that the LTP-induced increase in transmitter release (Baxter, Bittner and Brown, Proc. Natl. Acad. Sci. 82: 5978, 1985) had a multiplicative (not additive) effect on STF. The parameters F_e and F_n were not altered by LTP.

The expression of STF and LTP may therefore be mediated through independent processes. McNaughton (J. Physiol.324:249, 1982) observed a similar multiplicative interaction between LTP and STF in the hippocampal formation. He noted that a simple multiplicative interaction could arise if LTP increased the mean quantal size $\bar{q}$ and STF increased the mean quantal content m. However, in the OE synapses LTP, is accompanied by an increase in m but not $\bar{q}$ (Baxter, et al., 1985). Alternatively, it is possible that STF and LTP selectively and differentially increase the binomial release parameters (Brown, Perkel and Feldman, Proc. Natl. Acad. Sci. 73: 2913, 1976) $\bar{n}$ and $\bar{p}$ (whose product is m), a possibility that appears testable in this system (Keenan and Brown, Soc. Neurosci. Abstr. 12: 605a, 1986).

We are now studying the biophysical mechanisms underlying the multiplicative interaction between STF and LTP in OE synapses. We are also exploring the possible behavioral role of LTP in fine tuning the motor system that controls the claw, the operation of which depends on the development of STF. (Supported by NIH grant NS21561, AFOSR contract F49620 and a McKnight Foundation Award.

341.7 TRANSITION FROM LONG-TERM POTENTIATION TO KINDLING IN THE PYRIFORM CORTEX. J. S. Stripling and D. K. Patneau. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Electrical stimulation of the olfactory bulb (OB) elicits a potential in the pyriform cortex (PC) consisting of an initial wave (period 1) encompassing both a mono- and di-synaptic population EPSP, followed by period 2, which is temporally associated with inhibition of PC pyramidal cells. Repeated high-frequency trains of OB stimulation too brief (10 pulses each) to trigger a seizure produce a selective long-term potentiation of period 2 in the PC (Soc. Neurosci. Abstr. 10:76, 1984). In contrast, a single long (100 pulse) high-frequency train at the same current intensity triggers a focal electrographic seizure and produces a distinctly different pattern of effects. An increase in period 2 is seen, as with stimulation below seizure threshold, but in addition a long-term increase in period 1 occurs (Brain Res. 361:61-69, 1985). This pattern of effects suggests that long-term potentiation in the PC involves enhancement of inhibitory mechanisms, and that kindling superimposes upon this effect an increase in excitatory input to PC pyramidal cells. This contrasts sharply with the hippocampus, where potentiation of the population EPSP is a prominent effect of high-frequency stimulation below seizure threshold. The present experiment examined whether it is possible to produce an increase in period 1 in the PC without triggering a seizure.

Male Long-Evans rats were chronically implanted with electrodes in the OB and PC. Animals received high-frequency stimulation of the OB (100 pulses at 100 Hz) at increasing current intensities until a focal electrographic seizure was triggered. Test potentials were evoked in the PC by OB stimulation before and after each stimulation train. Potentiation of period 1 was reliably seen not only following a seizure, but also following stimulation trains 1-2 current steps below seizure threshold.

These results indicate that the occurrence of a seizure is not essential for the potentiation of period 1, but that stimulation close to seizure threshold is needed. Whether this potentiation is due to an increased output from the OB or to increased transmission at the synapses between lateral olfactory tract fibers and PC pyramidal cells is currently under investigation. Potentiation of period 2 can be produced by much briefer trains which are far below seizure threshold and cause no long-term alterations in period 1, even with extensive repetition. Thus the potentiation of period 2 in the PC appears to involve a separate mechanism which is more likely to be activated by naturally occurring patterns of neural activity than the mechanism responsible for potentiation of period 1.

341.8 RECOVERY OF FUNCTION AFTER UNILATERAL SENSORIMOTOR CORTEX LESIONS: CONTRIBUTION OF THE CONTRALATERAL CORTEX. T.M. Barth, T.A. Jones*, and T. Schallert. Dept. of Psychology Univ. of Texas at Austin, TX 78712

Unilateral damage to the sensorimotor cortex in rats causes a somatosensory asymmetry ipsilateral to the lesion that is readily quantified using bilateral tactile extinction tests (T. Schallert et al., *Pharm. Biochem Behav.*, 19:753, 1983; T.M. Barth et al., *Neurosci. Abstr.*, 10:1146, 1984). Previous work has shown that recovery (a gradual reduction in the magnitude of sensory asymmetry) occurs even after hemidecortication (T.Schallert & I. Q. Whishaw, *Behav. Neurosci.*, 98:518, 1984). These data suggest that cortex ipsilateral to the lesion is not necessary for recovery to occur, and that the contralateral cortex and/or subcortical brain areas may be involved. In the present study we examined the effects of lesions in the homotopic contralateral cortex following recovery from unilateral brain damage.

Unilateral lesions were placed in three different areas of the rat cortex: 1) the anteromedial cortex; 2) the caudal forelimb sensory + motor area; 3) the rostral forelimb motor area. An ipsilateral sensory asymmetry and subsequent recovery were observed in each of the lesion groups. After recovery (i.e. two consecutive postoperative tests in which an animal showed no sensory asymmetry) half of the rats in each unilateral lesion group received a second lesion in the homotopic contralateral cortex (i.e. two-stage bilateral lesion) and the other half were given a sham surgery (i.e. lesion + sham). For comparison, additional groups of rats were given simultaneous bilateral lesions (i.e. one-stage bilateral lesion).

The results showed that rats receiving two-stage bilateral lesions in either the caudal or rostral forelimb area exhibited a sensory asymmetry ipsilateral to the ***second*** lesion that was comparable in magnitude to that observed after the initial unilateral lesion. No change in sensory asymmetry was observed in the respective lesion + sham or one-stage bilateral lesion groups. In contrast, rats with two-stage bilateral lesions in the anteromedial cortex did not exhibit a sensory asymmetry after the second lesion and were not different from the lesion + sham or one-stage bilateral groups.

These data suggest that subareas of the rat cortex may be distinguished by comparing the effects of two-stage bilateral lesions and that the role of the homotopic contralateral cortex in recovery may differ depending on the area damaged.

341.9 CHRONIC STABILITY OF RECEPTIVE FIELDS AT LOCI IN NORMAL, ADULT SOMATOSENSORY CORTEX. M.B. Calford, Neuroscience Laboratory, Department of Physiology and Pharmacology, University of Queensland, St Lucia, Queensland, 4067, Australia.

Somatosensory cortex of adult mammals is known to be capable of dramatic reorganization following peripheral nerve damage, or amputation (Wall, J.T. and Kaas, J.H., in *Synaptic Plasticity*, Cotman, C.E., ed., Guildford Press, 1985). An unresolved issue is the extent to which the ability of cortex to quickly adapt to a changed afferent input, maintaining responsiveness and topography, is reflected in plasticity of somatotopy in normal animals.

Chronic (2 to 6 weeks) multiunit recordings were obtained through implanted, floating electrodes (teflon-coated, stainless steel; 24 μm diameter) from somatosensory cortex of the little red flying fox. Previous studies of flying fox somatosensory cortex (Calford *et al.*, *Nature*, 313: 477-479, 1985) revealed a normal mammalian pattern with at least three somatotopic fields. No check on the physical stability of the floating electrodes was possible. However cutaneous receptive fields on the head, snout, back, chest, arm or pro-wing of 25 electrodes from 6 animals recorded over periods of 2 to 6 weeks were remarkably stable. This suggests that the electrodes were fixed in position and that somatosensory cortex does not show plasticity in normal animals. This result contrasts with plasticity demonstrated acutely in the same species following amputation of the thumb. Loci that once represented the digit are immediately responsive to adjacent regions. These new receptive fields (on the arm and wing) are larger than fields found in this region of normal animals and always extend to some part of the wound. The acute result demonstrates that connections exist to supply a locus in somatosensory cortex with input from an area far larger that its receptive field. The chronic result indicates that the subset of this input that forms the receptive field is stable over time in normal animals.

341.10 TOPOGRAPHICAL REORGANIZATION IN THE SECOND SOMATOSENSORY AREA (SII) AFTER REMOVAL OF SELECTED PORTIONS OF POSTCENTRAL CORTEX T.P. Pons, P.E. Garraghty, and M. Mishkin, Lab Neuropsychology, NIMH, Bethesda, MD 20892, and Dept of Brain Sciences, MIT, Cambridge, MA 02139.

We used electrophysiological recordings to assess the fate of the SII body representation following lesions of selected portions of the postcentral strip (areas 3a, 3b, 1, and 2). Six to eight weeks following the cortical lesions, single or multiunit activity elicited by peripheral somatic stimulation was recorded with tungsten microelectrodes in the SII region of 9 hemispheres in 5 adult macaques (4 Macaca mulatta and 1 M. fascicularis) anesthetized with a mixture of nitrous oxide and halothane. Our results yielded two major findings.

First, as previously reported, elimination of the representations of any body part in the postcentral strip eliminated that, and only that, representation in SII (5 hemispheres). Second, six weeks after removal of the postcentral hand representations, a procedure that functionally deafferented the SII hand representation, the cortical space in SII previously representing the hand was not silent. Instead, the normally adjacent representations of the body expanded into this vacated region. The expansion was most obvious for the representation of the foot, which occupied only 5-12% of SII in each of five unoperated hemispheres, but occupied 55-80% of SII in each of three hemispheres that received lesions of the postcentral hand representations. This massive reorganization extended over half of SII in the rostral caudal dimension, for a distance up to 7mm. In three additional cases we recorded from the SII region of adult macaques (M. mulatta) 24 hours after removal of the postcentral hand representations. In these cases there appeared to be no expansion of the foot or trunk representation. Instead there was a large "silent" zone in the expected location of the SII hand representation. Thus the results obtained at 6-8 weeks after the lesions are not completely attributable to a simple "unmasking" of preexisting inputs.

These findings provide evidence for a previously unrecognized degree of cortical plasticity in adult primates in that the reorganizational changes occur over 5 or more millimeters of cortex. The results require major revisions of current theories which tend to confer static properties on cortical maps.

342.1 SEROTONIN RECEPTOR BINDING AND AGONIST PROPERTIES OF 6-CARBOXAMIDO-4-DIPROPYLAMINOTETRAHYDROBENZINDOLE. N. R. Mason, R. W. Fuller and M. E. Flaugh*. Lilly Research Laboratories, Lilly Corporate Center, Indianapolis, IN 46285.

Several analogs of the ABC tricyclic partial ergoline, 4-dipropylaminotetrahydrobenzindole (DATB), were synthesized with a protophilic group at position 6 and were tested as serotonin agonists based on their structural similarity to serotonin. The 6-methoxy, 6-nitro, 6-cyano and 6-carboxamido derivatives all inhibited binding of tritiated serotonin (^{3}H-5HT) to 5HT1 sites in membranes from rat frontal cortex with IC-50 values of approximately 100 nM or less. The 6-bromo derivative and the parent compound with no substituent at the 6 position were slightly less potent. The methoxy, carboxamido and bromo derivatives had much lower affinity for 5HT2 receptors labeled in frontal cortex membranes with ^{3}H-spiperone (IC-50 values greater than 1000 nM) and for dopamine D2 receptors labeled in striatal membranes with ^{3}H-spiperone.

Competition curves for inhibition of ^{3}H-5HT binding by 6-carboxamido-DATB were biphasic, indicating differential affinity for different binding sites. Experiments in the presence and absence of 1 μM spiperone to block binding of ^{3}H-5HT to 5HT1A sites revealed that 6-carboxamido-DATB had high affinity for the 5HT1A site (IC50=1 nM) and low affinity for the 5HT1B site (IC50 >1000 nM). The (+) and (-) enantiomers of 6-carboxamido-DATB had similar affinities for 5HT1A sites as the racemate. The racemate and the enantiomers showed similarly high affinity for 5HT1A sites when ^{3}H-8-hydroxy-2-dipropyl-aminotetralin was used as the radioligand.

6-Carboxamido-DATB given to rats at doses of 0.03 mg/kg s.c. and higher decreased hypothalamic concentrations of 5-hydroxy-indoleacetic acid, indicating a decreased serotonin turnover presumably secondary to activation of synaptic receptors for serotonin. The two enantiomers were equipotent in producing this effect and in decreasing the accumulation of 5-hydroxy-tryptophan in hypothalamus following decarboxylase inhibition by NSD 1015. The racemate and enantiomers also increased serum corticosterone concentration in the same dose range, an effect produced by other 5HT1A agonists including 8-hydroxy-2-dipropyl-aminotetralin, buspirone and ipsapirone.

These data indicate that both enantiomers of 6-carboxamido-DATB are potent serotonin agonists with selectivity for the 5HT1A receptor subtype.

342.2 STRUCTURE-ACTIVITY RELATIONSHIPS OF NITRO AND AMINO PHENYLPIPERAZINES ON [^{3}H]SEROTONIN BINDING. S.G. Britt*, G.T. Redpath*, S.R. VandenBerg, Dept. of Path., Univ. of Virginia Sch. of Med., Charlottesville, VA 22908

The multiple specific binding sites for serotonin (5-HT) in the CNS may mediate the variety of its effects, but there is currently limited information on the structural correlates of receptor agonist/ antagonist activities and the functional significance of the various binding sites. Trifluoromethylphenyl piperazine (TFMPP), an agonist at the high affinity [^{3}H]5-HT binding site(s), and a number of other non-indoleamine ligands have been recently used to study populations of these binding sites (Glennon, R.A., J. Med. Chem. 30: 1-12, 1987). The majority of phenyl piperazines which have been used are halogenated compounds and comprise a relatively limited group with respect to polarity and electronic character. We have synthesized a series of mono- and disubstituted nitro and amino phenyl piperazines, which differ significantly in structure from the original halogenated compounds, to further elucidate the structure-activity relationships of this class of compounds.

The nitro phenyl piperazines (NO_2PP) were prepared by dehaloamination of a substituted fluoronitrobenzene with piperazine, or by a reaction involving ring closure of bis (chloroethyl) amine with a substituted aniline. The amino phenyl piperazines (NH_2PP) were prepared by catalytic hydrogenation of the nitro precursors. The pure compounds were characterized by TLC, NMR, mass spectrometry and elemental analysis. Radioligand displacement studies in a 50mM TrisHCl, 6mM $CaCl_2$, 10μM pargyline HCl buffer (pH 7.4) supplemented with antioxidants were done with 2nM [^{3}H]5-HT (New England Nuclear, 24-30 Ci/mmol) using 5μM d-LSD to define non-specific binding, in a lysed P2 membrane fraction prepared from bovine cerebral cortex.

The rank order of affinity for some of these compounds in comparison to previously characterized phenyl piperazine analogues was TFMPP > $2NO_2$PP > PP > $3NO_2$PP ≈ mianserin > $2NH_2$PP > $2NO_2$-$4NH_2$PP > $4NO_2$PP > $4NH_2$PP and affinity constants derived from computer analysis (McPherson adaptation of "LIGAND") ranged from 110 nM to 93,000 nM. Change in the position of nitro substitution was accompanied by a 3-18 fold reduction of the affinity while change from nitro to amino substitution at a given position reduced the affinity 8-10 fold. This rank order could also be demonstrated with human cortical membranes. These substituted phenyl piperazines will be useful in subsequent studies to more clearly establish the structural correlates of serotonin agonist interaction with receptor binding site(s).

Supported by grants NS22455 and NS00854 from the NINCDS, and J-80 from the Jeffress Memorial Trust.

342.3 **ASCORBATE EFFECTS ON REVERSIBLE [^{3}H] SEROTONIN BINDING TO BOVINE FRONTAL CORTEX MEMBRANES.**
P. A. Bauer and R. D. Todd (SPONSOR: E. Robins) Department Psychiatry, Washington University School of Medicine, St. Louis, MO 63110

There has been controversy over the use of ascorbate as an antioxidant in [^{3}H] serotonin binding assays. Both beneficial and deleterious effects have been reported. Ascorbate is also present in the brain in concentrations approaching those used in binding assays. It seems possible that ascorbate could have both antioxidant and physiologically meaningful effects in binding assays. To test for non-antioxidant effects of ascorbate, however, conditions must be established where [^{3}H] serotonin binding is reversible without exogenous antioxidants. We have utilized the endogenous antioxidant capacity of membranes (Kovachich and Mishra Neurosi.Letts. 52, 153-158, 1984: Todd and Ciaranello Brain Res., 400, 245-258, 1987) to study the effects of ascorbate on reversible binding.

Conditions for [^{3}H] serotonin binding to bovine frontal cortex membranes were established where binding was reversible and saturable in the absence of ascorbic acid. Membranes were added to assay tubes first and binding was initiated by the addition of [^{3}H] serotonin. Greater than 95 percent of binding was dissociable under our conditions. There were two components of binding with kds of 1.33 ±0.26 nM (5-HT_1) and 124.8 ±56.9 nM (5-HT_2) and Bmaxs of 0.16 ±0.02 fmoles/ug and 0.80 ± 0.24 fmoles/ug, respectively (mean ± standard deviation, n = 3). At pH 7.4, increasing ascorbate (0 to 5.7 mM) significantly enhanced binding affinities (0.90 ± 0.04 nM and 29.6 ±17.3 nM, mean ± standard deviation, n = 3, at 5.7 mM ascorbate) without changing Bmaxs. At lower pHs (pH 6.6 to pH 7.1) 5-HT_1 binding was reduced in the presence of ascorbate while 5-HT_2 binding was not affected.

These results confirm that ascorbate is not necessary for reversibility of [^{3}H] serotonin binding in vitro. In addition, conditions were found where combinations of ascorbate and hydrogen ion concentrations could enhance or decrease [^{3}H] serotonin to different binding site subtypes. The hydrogen ion and ascorbate concentrations used here are in the physiological range. It is possible that changes in ascorbate and pH could potentiate or attenuate serotonergic responses in either normal or extreme metabolic circumstances.

342.4 [^{3}H]-DIHYDROERGOTAMINE: VALIDATION AS A RADIOLIGAND FOR SEROTONERGIC 5-HT_{1B} BINDING SITES IN RAT BRAIN AND DEMONSTRATION OF 5-HT_{1B} GUANINE NUCLEOTIDE SENSITIVITY. Mark W. Hamblin, Kayvan Ariani*, Peter I. Adriaenssens*, and Roland D. Ciaranello. Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305.

The 5-HT_{1B} binding site is a putative 5-HT receptor subtype that may represent a cerebral cortical presynaptic autoreceptor in rats. The only 5-HT_{1B} radioligands available to date, [^{3}H]-5-HT and [^{125}I]-iodocyanopindolol, both suffer from lack of specificity and relatively high non-specific binding. We now describe the binding characteristics of [^{3}H]-dihydroergotamine ([^{3}H]-DE) to 5-HT_{1B} type binding sites. The high affinity and low non-specific binding seen with this compound may make it the preferred radioligand in many studies.

[^{3}H]-DE labels a population of sites in rat cerebral cortex and hippocampus membranes with high (K_d<0.1nM) affinity. This binding is both saturable and reversible. Kinetic and competition studies indicate heterogeneity of binding sites, with significant contributions to binding made by alpha adrenergic and 5-HT_{1A} serotonergic sites, as well as 5-HT_{1B} sites. When phentolamine (500nM) and spiroxatrine (500nM) are included to mask alpha and 5-HT_{1A} binding, all remaining specific binding shows affinities (K_i's) for other drugs characteristic of 5-HT_{1B} sites: 5-HT, 29nM; RU 24969, 2.4nM; ±21-009, 0.75nM; ±cyanopindolol, 1.6nM; DPAT, 4100nM; and mesulergine, 4500nM. Under these 5-HT_{1B} specific conditions, [^{3}H]-DE binding is typically about 90% specific and has a K_d of approximately 50pM. The B_{max} is 96 fmol/mg protein in hippocampus membranes and 77 fmol/mg protein in cortex membranes. [^{3}H]-DE dissociation from 5-HT_{1B} sites is slow, with a dissociation $t_{1/2}$ of 2.1 hours at 37° C, 17 hours at 25° C, and >48 hours at 4° C, a feature that may make [^{3}H]-DE useful in the study of solubilized 5-HT_{1B} site proteins.

[^{3}H]-DE 5-HT_{1B} specific binding is weakly inhibited by the addition of GTP or Gpp(NH)p. In contrast, addition of guanine nucleotides lowers the affinities of the 5-HT_{1B} agonists 5-HT and RU 24969 7-fold in [^{3}H]-DE competition studies. This suggests that the 5-HT_{1B} site has a G-protein effector-linkage and that [^{3}H]-DE is a weak partial agonist at this receptor.

342.5 STRUCTURE-ACTIVITY RELATIONSHIPS OF A SERIES OF TETRAHYDROPYRIDYL-INDOLES AT SEROTONIN$_{1A}$ AND SEROTONIN$_2$ RECEPTORS. D.L. Nelson, A.L. Killam*, G. Lambert*, S.S. Nikam*, B. Weck*, and A.R. Martin*. College of Pharmacy, Univ. of Arizona, Tucson, AZ 85721.

Based on findings that the tetrahydropyridylindole RU 24969 is an agonist at serotonergic receptors, a series of 22 analogs of this compound was synthesized to carry out a systematic study of the structural features that determine high potency and selectivity between subtypes of serotonin (5-hydroxytryptamine, 5-HT) receptors. The compounds were evaluated at 5-HT$_{1A}$ sites, measured by the binding of [^{3}H]8-OH-DPAT, and 5-HT$_2$ sites, measured by [^{3}H]ketanserin binding. In addition, certain compounds were also tested at functional 5-HT$_2$ receptors found in the vasculature. The starting compound for all structural modifications was 3-(1-methyl-1,2,3,6-tetrahydropyridin-4-yl)-indole (MTHPI). MTHPI itself showed little discrimination between the two binding sites, while substitution at position 5 of the indole generally resulted in increased potency at 5-HT$_{1A}$ sites with either no change or decreased potency at 5-HT$_2$ sites (see examples below).

Substitution at C-5	Apparent K_i, nM 5-HT$_{1A}$	5-HT$_2$
H	146	67
OCH_3	21	897
OH	62	356
F	68	45
Cl	26	51
Br	15	48
CO_2CH_3	19	3,665

In contrast to substitution at position 5, addition of a benzyl group at position 1 resulted in almost complete loss of affinity for the 5-HT$_{1A}$ site (K_i> 10,000 nM) with an increased affinity for the 5-HT$_2$ site (K_i= 15 nM). Studies of selected compounds at peripheral vascular models of 5-HT2 receptors produced unexpected results. In the rabbit femoral artery the compounds tested acted as agonists, while in the rat aorta they acted as antagonists. As an example, RU 24969 produced contractions in the rabbit femoral artery ($EC_{50} \simeq$ 100 nM) that appeared to be antagonized by the 5-HT$_2$ antagonist ketanserin. In the rat aorta RU 24969 itself antagonized the actions of 5-HT. The data from these studies show that structural modifications of a simple, partially rigid analog of 5-HT can produce compounds that have relatively high potency and that can discriminate between 5-HT receptor subtypes. Such compounds should aid in defining the nature of the ligand recognition sites of these receptors. (Supported by NIH grants NS16605 and NS01009).

342.6 DIFFERENTIAL EFFECTS OF SULFHYDRYL REAGENTS ON BINDING TO BRAIN SEROTONIN (5-HT) RECEPTOR SUBTYPES. C.A. Stratford, G.L. Tan*, M.W. Hamblin, and R.D. Ciaranello. Dept. of Psychiatry and Behavioral Sciences, Stanford Univ. Stanford, CA 94305

The sulfhydryl reagents N-ethylmaleimide (NEM) and para-chloromercuribenzoate (PCMB) reduce binding of [^{3}H]8-hydroxy-2-(di-propylamino)tetralin (DPAT) to 5-HT$_{1A}$ and of [^{3}H]5-HT to 5-HT$_{1B}$ and 5-HT$_{1D}$ binding sites in rat cortex and bovine frontal cortex. IC_{50}'s for NEM and PCMB on binding to these subtypes range from 20 to 40 micromolar. Binding of [^{3}H]mesulergine to 5-HT$_{1C}$ binding sites and of [^{3}H]ketanserin to 5-HT$_2$ sites is reduced only at much higher concentrations of either NEM or PCMB (20-50,000 and 500 micromolar, respectively). Binding of [^{3}H]dihydroergotamine (DE) to 5-HT$_{1B}$ sites is not as sensitive to NEM as is binding of [^{3}H]5-HT to this site. The rank order of NEM sensitivity of the binding sites is as follows (compound listed in parentheses indicates tritiated ligand used to define the site):
5HT$_{1A}$(*DPAT) $\approx$ 5HT$_{1B}$(*5-HT) $\approx$ 5HT$_{1D}$(*5-HT) >> 5HT$_{1B}$(*DE) $\geq$ 5HT$_2$(*Ketanserin) $\approx$ 5HT$_{1C}$(*Mesulergine).
These data suggest that the determination of sulfhydryl sensitivity may not be intrinisic to the receptor subtype, but rather to the type of ligand (agonist or antagonist) used to label specific sites.

The effects of the sulfhydryl reagents on [^{3}H]5-HT binding are prevented by pre-incubation of membranes with dithiothreitol, indicating sulfhydryl specificity of the effect. Prior and concommitant incubation of membranes with serotonin or other serotonergic agents (DPAT, mesulergine, spiperone) does not appear to protect the sites from the effects of NEM, suggesting that the sensitive sulfhydryl groups are not at the ligand binding sites.

5-HT competes with [^{3}H]DE for binding to rat 5-HT$_{1B}$ binding sites with an IC_{50}-derived $K_{D(app)}$ of 16nM. Addition of either GppNHp or NEM to the assay shifts the 5-HT competition curve to the right. When incubated together, the effects of these agents are not additive. In other receptor systems, such as the bovine brain GABA-B receptor, NEM sensitivity of agonist binding has been shown to be attributable to sulfhydril groups present on receptor-associated G-proteins (Asano, T. and Ogasawara, N., Mol. Pharmacol., 29:244, 1986). In such systems, non-additivity between GppNHp or GTP and NEM was also observed. Work is in progress to determine the extent and nature of linkage of each of the 5-HT receptor subtypes to G-protein(s).

342.7 **CHARACTERIZATION OF 5-HT2 RECEPTORS IN A CELL LINE DERIVED FROM THE 7315a ANTERIOR PITUITARY TUMOR.** **P. McGonigle, K. Nicklaus, K. A. Neve, N. Cocero and P. B. Molinoff. (SPON: R.B. Murray). Dept. of Pharmacology, University of Pennsylvania, Phila., PA 19104.**

Dispersed cells from 7315a transplantable anterior pituitary tumors were plated on protamine-coated plates in Dulbecco's modified Eagle's medium (DMEM) enriched with horse serum, fetal bovine serum (FBS) and rat hypothalamic extract. After 3 weeks, hypothalamic extract was removed and the concentration of horse serum was reduced. Cells that attached to protamine-coated plates were subcultured repeatedly. Cells were cloned by limiting dilution after plating at a theoretical density of 0.1 cell/well and are presently being maintained on uncoated tissue culture plates in DMEM with FBS supplemented with penicillin G (100 μg/ml) and streptomycin (100 μg/ml). This cell line was selected for further study on the basis of a high density of specific binding sites for ^{125}I-NAPS and ^{3}H-spiroperidol. A preliminary saturation experiment with ^{3}H-spiroperidol yielded a linear Scatchard plot and a K_d of 1 nM. Nonspecific binding was defined with 2 μM (+)-butaclamol. The binding of ^{3}H-spiroperidol was inhibited by ketanserin and pipamperone, but was not inhibited by the D-2 antagonist sulpiride. These data are consistent with the presence of 5-HT2 receptors that are labelled with ^{3}H-spiroperidol.

These sites were further characterized in binding assays with ^{125}I-LSD. Nonspecific binding was defined in the presence of 100 nM ketanserin. At 37^{o}C, the binding of ^{125}I-LSD (0.25 nM) reached equilibrium in 45 min and remained stable for at least an additional 45 min. Scatchard analysis of the equilibrium binding of ^{125}I-LSD (.05-2.5 nM) resulted in linear plots and yielded a K_d of 0.53 $\pm$ .02 nM and a B_{max} of 90 $\pm$ 29 fmol/mg protein. Studies of the inhibition of the binding were performed with a number of competing ligands including ketanserin, pipamperone, domperidone and sulpiride. The inhibition curves for the competing ligands had Hill coefficients close to 1.0 suggesting that ^{125}I-LSD is labelling only a single class of receptors in this cell. The order of potency for these competing ligands, ketanserin > pipamperone > domperidone > sulpiride, was consistent with an interaction at the 5-HT2 receptor. Thus, this clonal line of cells appears to contain a relatively high density of 5-HT2 receptors. (Supported by NS 18591 and GM 34781)

342.8 ACTIVATION AND REGULATION OF THE SEROTONIN 5-HT$_{1C}$ RECEPTOR ON THE CHOROID PLEXUS BY CSF-BORNE SEROTONIN. James Giordano and Paul R. Hartig. Environmental Neurobiology Program, Johns Hopkins School of Hygiene and Public Health, Baltimore, MD 21205.

The serotonin 5-HT$_{1C}$ receptor is found at high densities on epithelial cells of the choroid plexus. This tissue forms an interface between the CSF and the blood circulation, forming an important component of the blood-CSF barrier. Since the epithelial cell layer of the choroid plexus does not receive significant direct innervation by serotonergic fibers, it has been suggested that the 5-HT$_{1C}$ receptor is activated by serotonin contained in fluids which bathe this tissue. An unresolved question has been whether this receptor is located on the apical surface of this cell layer, where it may be activated by serotonin from the ventricular CSF, or whether it is located on the basal or lateral surfaces, where it may be activated by serotonin in blood serum. In the present study we investigated the source of activation of the 5-HT$_{1C}$ receptor by measuring in vivo labeling of the choroid plexus following intravenous (iv) and intracerebroventricular (icv) injections of ^{3}H-5-HT. Following iv injection, we observed a slow labeling of choroid plexus sites that were four-fold more abundant than the total 5-HT$_{1C}$ site density in this tissue. The amine transport inhibitor hexamethonium reduced choroid plexus labeling by 95% following iv injection of doses that do not block the serotonin 5-HT$_{1C}$ receptor. We conclude that blood-borne ^{3}H-5-HT does not label the choroid plexus 5-HT$_{1C}$ site but may label a transport site in this tissue. In contrast, icv injection of ^{3}H-5-HT labels a saturable site in the choroid plexus that was relatively unaffected by co-administration of hexamethonium. In vivo saturation labeling studies of this site revealed a site density (apparent B_{max} = 3060 fmol/mg protein), binding affinity (apparent K_d = 72 nM), and antagonist binding properties in good agreement with previous in vitro homogenate binding studies on the 5-HT$_{1C}$ receptor. We conclude that the 5-HT$_{1C}$ receptor can be labeled by CSF-borne, but not by blood-borne, serotonin. These data suggest that the 5-HT$_{1C}$ receptor is located on the apical surface of the epithelial cell layer, in direct contact with ventricular CSF.

The most likely candidate for the source of CSF serotonin activating the choroid plexus 5-HT$_{1C}$ receptor is the network of supraependymal serotonergic fibers lining the ventricular walls. We are currently testing whether denervation of these fibers by icv injections of 5,7 dihydroxytryptamine will promote regulatory changes in the levels of 5-HT$_{1C}$ receptors in the choroid plexus. Recent studies by Conn et al. (Brain Res. 400, 396 (87)) report supersensitivity of the 5-HT$_{1C}$-mediated phosphoinositide response following such treatments. The current studies will determine if this is accompanied by changes in 5-HT$_{1C}$ receptor levels.

342.9 2,5-DIMETHOXY-4-BROMOAMPHETAMINE (DOB) INTERACTIONS WITH 5-HT RECEPTOR SUBTYPES. S.S. Wang and S.J. Peroutka. Departments of Neurology and Pharmacology, Stanford University, Stanford, CA 94305.

2,5-dimethoxy-4-bromoamphetamine (DOB), a potent hallucinogen, has been suggested to be a highly specific ligand for the 5-HT_2 receptor through radioligand binding studies. Moreover, ^{3}H-DOB has been hypothesized to label a "high-affinity" form of the 5-HT_2 receptor (Lyon et al, Mol. Pharmacol. 31:194-199, 1987). The present study attempted to further characterize the interactions of DOB with brain 5-HT receptor subtypes.

Radioligand binding studies were carried out in rat brain membrane preparations with enantiomers of DOB and various serotonergic drugs. Both enantiomers of DOB display K_i values of approximately 3,000 nM for 3H-5-HT binding sites. No competition for 2 nM ^{3}H-5-HT binding could be detected at DOB concentrations below 100 nM.

Specific ^{3}H-spiperone binding in rat brain membranes is displaced by nM concentrations of DOB with Hill slopes of approximately 0.5-0.7. However, (+) and (-)DOB continue to compete for specific ^{3}H-spiperone binding below the level of "non-specific" binding as defined by 1 uM cinanserin. Similar data have been reported with agents which compete for the "spirodecanone" site labeled by ^{3}H-spiperone (Leysen and Gommeren, Life Sci. 23:447-452, 1978). These data show that DOB has complex interactions with ^{3}H-spiperone binding sites.

^{3}H-DOB was also used to label putative 5-HT_2 sites in rat frontal cortex. In agreement with the results of Lyon et al (1987), 5-HT, (+)DOB, (-)DOB, and d-LSD were all found to display nanomolar potency for these recognition sites. These results are not necessarily consistent with ^{3}H-DOB binding to a high-affinity form of the 5-HT_2 binding site. In addition, it is unlikely that ^{3}H-DOB binding sites represent a "hallucinogen" receptor since d-LSD, (-)DOB, and (+)DOB vary by two orders of magnitude in their human hallucinogenic activity, yet are equipotent agents at the ^{3}H-DOB binding site. Studies are currently under way to further characterize hallucinogenic radioligand binding in rat and human brain tissues.

342.10 **QUANTITATIVE AUTORADIOGRAPHIC MAPPING OF 5-HT_1 AND 5-HT_2 RECEPTORS IN FRONTAL, PARIETAL AND OCCIPITAL CORTEX OF ADULT RHESUS MONKEYS.**

P.S. Goldman-Rakic, M.S. Lidow, D.W. Gallager and P. Rakic.
Yale University, School of Medicine, Section of Neuroanatomy, New Haven, CT 06510

Serotonin receptors are present in the cerebral cortex and determination of their precise localization in different cytoarchitectonic areas may aid in the analysis of their role in cortical function. In the present study, the *in vitro* receptor autoradiographic technique was used to characterize the distribution of 5-HT_1 and 5-HT_2 receptors in Walker's areas 46, 9, 12, 25 and 4 and Brodmann's areas 1-2, 3, 5, 7, 17 and 18 of cerebral cortex in three adult rhesus monkeys. 5-HT_1 receptors were labeled with [^{3}H]5-HT while 5-HT_2 receptors were labeled with [^{3}H]ketanserin. Non-specific binding for [^{3}H]5-HT was determined using 8-OH-DPAT while methysergide was used as a non-specific displacer for [^{3}H]ketanserin. Total and non-specific binding were quantitatively analyzed on adjacent tissue sections by computer-aided image analysis. Evaluation of K_d values indicated that the affinity of each ligand for its receptor was uniform across the layers and sublayers and between cortical regions.

Both 5-HT_1 and 5-HT_2 receptors were present in all cortical layers in each cytoarchitectonic area. B_{max} for 5-HT_1 receptors varied from 55 200 fmol/mg of tissue and B_{max} for 5-HT_2 varied from 35 - 350 fmol/mg of tissue depending on area and layer. The pattern of 5-HT_1 receptors was similar in all areas except area 17. The basic pattern was that of high density in cortical layers I, II and in the most superficial part of layer III. In area 17, however, 5-HT_1 receptors were more uniformly distributed across the layers. The distribution of 5-HT_2 receptors was complimentary to that of 5-HT_1 receptors in all regions except areas 4 and 17. In areas 46, 9 and 12, the 5-HT_2 receptors were more dense throughout layers III and IV; in area 25 - throughout layer IV and sublayer Va and in areas 1-2, 3, 5, 7 and 18 - throughout layer III. In area 4, the 5-HT_2 receptors were prominent in layers I, II and in the most superficial part of layer III while in area 17, sublayer IVC_β contained the most label.

The high density of 5-HT_1 and 5-HT_2 receptors within the granular and supragranular layers, which contain the cells of origin and termination of cortico-cortical projections, implicates both types of receptors in the associative functions of the cerebral cortex. However, their complimentarity within these layers implies a differential contribution of each to these functions.

342.11 1-(m-CHLOROPHENYL)PIPERAZINE (mCPP) INTERACTIONS WITH NEUROTRANSMITTER RECEPTORS IN HUMAN BRAIN. A. Hamik* and S.J. Peroutka. (SPON: P.B. Hicks) Departments of Neurology and Pharmacology; Stanford University Medical Center; Stanford, CA 94305.

1-(m-Chlorophenyl)piperazine (mCPP) is a breakdown product of the anti-depressant trazodone which elicits unique neuroendocrinological and behavioral effects in man. mCPP causes an increase in prolactin and cortisol levels in animals and humans. In humans, mCPP causes decreased self-rated scores for happiness and calmness, and increased scores for drowsiness, anxiousness, and feeling "high". Low doses do not cause hallucinations, but higher doses result in transient perceptual distortions and feelings of derealization (Mueller, E.A. et al, J. Clin. Endocrinol. Metab., 61: 1179, 1985; Charney, D.S. et al, Arch. Gen. Psych., in press, 1987). In general, mCPP has been considered an agonist at central 5-HT recptors, perhaps specifically with the 5-HT_{1B} subtype.

We determined the affinity of mCPP at 11 neurotransmitter receptor sites in human brain. mCPP is essentially equipotent at all 5-HT receptor subtypes (K_i values ranging from 250 - 870 nM). The drug displays similar affinity (K_i = 360 nM) for alpha2-adrenergic receptors and is only slightly less potent at $alpha_1$- and beta-adrenergic, dopamine, and muscarinic cholinergic receptors (K_i values = 1,1000 - 24,000 nM). mCPP is inactive at both benzodiazepine receptors and the 5-HT uptake sites at concentrations below 100,000 nM.

These data demonstrate that mCPP displays similar potency for multiple neurotransmitter receptors in human brain. The unique effects of mCPP cannot be attributed to interactions with a single receptor subtype. The differential neuroendocrine and psychological effects shown at different doses may be due to the affinity of mCPP for various neurotransmitter receptor sites. Low doses may selectively activate 5-HT and $alpha_2$-adrenergic sites, while slightly higher doses may interact with $alpha_1$-adrenergic, beta-adrenergic, dopamine and muscarinic cholinergic sites.

342.12 ULTRASTRUCTURAL RELATIONSHIPS OF SEROTONIN NERVE TERMINALS IN ADULT RAT FRONTAL CORTEX. Philippe Séguéla, Kenneth C. Watkins* and Laurent Descarries. Centre de recherche en sciences neurologiques (Dép. physiologie), Université de Montréal, Montréal (Qué.), Canada H3C 3J7.

To further elucidate the fine structural features and cellular relationships of serotonin (5-HT) afferents in adult rat cerebral cortex, an antiserum directed against 5-HT-glutaraldehyde-lysyl-protein complex (Patel et al., Histochemistry 85: 259, 1986) was used for immunocytochemical examination of identified 5-HT axon terminals (varicosities) in the superficial layers (I-II) of the frontal cortex (areas Fr1 and Fr2, according to Zilles, 1985). Tissue from 2 animals was fixed by perfusion with 3.5% glutaraldehyde, reduced with Na borohydride, immunostained using the peroxidase-anti-peroxidase technique, postfixed with osmium tetroxide, embedded in Epon, serially thin sectioned, stained with lead citrate and photographed at a magnification of X 14 500. More than 50 immunostained varicosities were analyzed for size and content, frequency and type of junctional complex, identity of synaptic targets and of other juxtaposed processes (microenvironment), and relative length of the different membrane appositions. The 5-HT immunoreactive varicosities measured 0.65 ± 0.17 µm (mean ± SEM) in average diameter. They usually exhibited small, round, clear synaptic vesicles associated with a few larger clear vesicles and mitochondria. In the whole population of 54 varicosities examined in series of 5 to 12 adjacent thin sections (mean of 7.3 sections per varicosity), the observed frequency of synaptic junction was 26%. The linear relationship between junctional frequency and the number of adjacent thin sections available for examination allowed to estimate the actual synaptic incidence at 35 to 40% of total. Most synaptic 5-HT varicosities (86%) showed symmetrical junctional complexes which were exclusively made with dendritic branchlets (57%) and spines (43%). The length of these synaptic contacts averaged 0.23 ± 0.06 µm. Preliminary quantitative comparisons between the microenvironments of synaptic and non synaptic 5-HT varicosities showed no significant difference in the identity and apposed lengths of surrounding processes. Thus, the cortical serotoninergic innervation appeared predominantly non junctional (60-65%) in the molecular layer of rat frontal cortex. It will be of interest to determine whether this synaptic incidence is different in other layers and other regions of rat cerebral cortex. Further analysis of the microenvironment of junctional versus non junctional 5-HT varicosities should provide clues as to possible determinants of their cellular relationships. (Supported by FRSQ and MRC grant MT-3544).

343.1 **ASSESSMENT OF CYTOSOLIC-FREE CALCIUM IN SYNAPTOSOMES WITH FURA-2 IN THE PRESENCE OF FURA-2AM: EFFECTS OF HYPOGLYCEMIA AND AGING.** T. Manger*, J. Bowers* and G. Gibson. Cornell Univ. Med. Coll. at the Burke Rehab. Ctr., White Plains, NY 10605.

Cytosolic-free calcium (Ca_i) is a regulator of many cellular processes. The development of calcium sensitive fluorescent probes has made Ca_i measurements feasible in intact cells. However, incomplete hydrolysis of the ester that was used in loading the cells leads to erroneous estimates of Ca_i. The described method estimates Ca_i with fura-2 even in the presence of varying amounts of the incompletely hydrolyzed fura-2-acetoxymethyl ester (FAM) that was used for loading. The method is based on the observation that in the presence of high calcium concentrations, the fluorescence ratio (excitation 340/380, emission 510 nm) predicts the mole fraction of FAM in the sample. With the appropriate fluorescence coefficients, this ratio allows the contribution of FAM to be subtracted from the signal. The subsequent calculation to estimate Ca_i paralliels the standard ratio method. With this approach, depolarization of synaptosomes from young CD-1 mice with 60 mM-KCl increased Ca_i from 179.4 $\pm$ 8.9 to 304.7 $\pm$ 26.4 nM.

Neuronal damage and increased spontaneous glutamate release accompany hypoxia, aging (Freeman and Gibson, 1987) and hypoglycemia (Wieloch, 1985). Elevated Ca_i possibly mediates the increase in glutamate release in each of these conditions. In histotoxic hypoxia, we previously demonstrated increased Ca_i (Gibson, Manger, Bowers, 1987). To see if alterations in Ca_i may also underlie the glutamate changes in aging and hypoglycemia, their effects on cytosolic calcium were determined. With decreased glucose, Ca_i (nM; mean $\pm$ SEM; n=7) increased from 190 $\pm$ 16 (1.5 mM-glucose) to 198 $\pm$ 17 (0.75 mM-glucose) to 286 $\pm$ 23 (0 glucose; $p<0.05$). With whole brain synaptosomes from BALB/C mice, no effect of aging on Ca_i was apparent. The basal concentration (nM; mean $\pm$ SEM, n=7) was 171 $\pm$ 7 (3 months), 164 $\pm$ 9 (10 months) and 163 $\pm$ 4 (30 months). The percent increase with potassium stimulation (15 mM and 60 mM) were similar at 3 months (46% and 70%), 10 months (46% and 54%) and 30 months (49% and 66%). Thus, increased Ca_i may underlie the elevated glutamate release in hypoxia and hypoglycemia, but does not appear to be altered during aging.

343.2 MEASUREMENT OF FREE INTRACELLULAR CALCIUM IN APLYSIA SENSORY NEURONS USING Fura-2. M.E. Spira*, H. Blumenfeld*, S. Schacher and S.A. Siegelbaum. (SPON: C. Kaufmann). HHMI, Columbia Univ., NY, NY 10032; and Dept. of Neurobiology, Hebrew University, Jerusalem, Israel.

Serotonin facilitates transmitter release from Aplysia sensory neuron terminals. This involves a closure of serotonin-sensitive K^+ channels, and is associated with an increase in the free intracellular Ca^{++} transient in response to long (0.5-1 sec) depolarizing voltage-clamp steps as measured by the transient Arsenazo signal (Boyle et al., PNAS 81, 7642, 1984). Here, we report experiments using the more sensitive Ca^{++} indicator, Fura-2, to investigate whether 5-HT 1) alters resting Ca^{++} levels in the cell bodies of sensory neurons, and 2) produces changes in Ca^{++} transients in response to more physiological stimuli.

Sensory neurons in culture were loaded with 100 uM Fura-2 using iontophoretic injection from microelectrodes containing 10 mM Fura-2 and 0.5 M KCl. For stimulation and recording from neurons, a 2.5 M KCl filled microelectrode was used. Fluorescence images of free Ca^{++} levels were obtained by digital video imaging using 350 nm and 380 nm excitation wave lengths (Williams et al., Nature, 318:558, 1985). Transient changes were monitored by a photomultiplier.

The resting level of free Ca^{++} in the sensory neurons is 90-100 nM. The region of the cell body corresponding to the nucleus showed a somewhat lower concentration. Short trains of 5-20 action potentials at 10-20 Hz produced a transient increase in the free Ca^{++} of about 20-40 nM, which lasts for 10-20 sec. Repeated trains of action potentials at intervals of 2-3 min did not change the steady state Ca^{++} levels and were not associated with changes in the recovery time course of the signal, indicating that under these conditions the Ca^{++} buffering systems are not affected. In some experiments, the Ca^{++} signal continued to increase even after termination of the train. This, and the observation of asynchronous Ca^{++} transients that sometimes occur after termination of the action potential train, raises the possibility that a component of the Ca^{++} transient may involve release of Ca^{++} from intracellular stores.

Serotonin (1-10 uM) did not produce marked changes in the steady state Ca^{++} level. In experiments in which serotonin application (1-10 uM) induced typical increases in sensory neuron excitability, the Ca^{++} transient (measured by the 380 nm Fura-2 signal) in response to an identical train of spikes (10-20 Hz) increased by 50-200% over the control Ca^{++} transient. However, as in the earlier study of Boyle et al., the increase in the Ca^{++} transient was delayed in respect to the onset of the increase in excitability, appeared gradually, and reached a maximum only 2-8 min after the onset of the membrane excitability changes. These experiments demonstrate that under conditions which do not involve overloading of the cell by Ca^{++}, 5-HT application increases the transient Ca^{++} concentration evoked by short trains of action potentials.

343.3 IONIC CURRENTS AT THE LIZARD NEUROMUSCULAR JUNCTION. C. A. Lindgren & J. W. Moore. Dept. of Physiology, Duke Univ. Med. Cntr., Durham, NC 27710.

We are interested in the role of calcium in synaptic transmission; its entry, its sub-membrane concentration transient and its effect on transmitter release. We have found the neuromuscular junction of the *ceratomandibularis* muscle in the lizard (*Anolis carolinensis*) to be a potentially useful preparation for studying these phenomena. The muscle is easy to dissect and is very thin and flat, making it possible to visualize the nerve endings with either Nomarski optics or by staining with the dye 4-(4-diethylaminostyryl)-N-methylpyridinium iodide (Magrassi, Lichtman & Purves, 1987, *J. Neuroscience 7* 1207). Sodium, potassium, calcium and calcium-activated potassium currents can be detected in the presynaptic nerve terminals with an extracellular electrode. The ability to isolate the calcium and calcium-activated potassium currents from the sodium and potassium currents, as described below, offers the possibility of elucidating calcium's role in activating transmitter release.

Ionic currents induced by nerve stimulation were measured at different positions along the motor nerve terminal by careful positioning of the heat-polished tip (~5 μm i.d.) of an extracellular electrode. Similar to what was observed at motor nerve endings of the mouse (Brigant & Mallart, 1982, *J. Physiol. 333*, 619), the net current flow is predominantly inward just distal to the end of the myelin, a region we refer to as "heminode", and outward over the remainder of the terminal. This shows that, as has been demonstrated in the mouse, the sodium and potassium channels are separated, with sodium the dominant current in the heminode and potassium in the terminal branches and boutons.

In all of the current patterns recorded, independent of the position of the electrode, there is an initial, brief outward current due to the discharging of the membrane capacitance as the action potential invades the terminal. In the heminode this initial positive phase is followed by two inward peaks. We think that the first of these represent active sodium current in the heminode membrane and the second a sodium sink (or return path) for the potassium current generated in the terminal branches and boutons. In contrast, we do not observe inward sodium current in distal portions of the terminal. Rather, the initial capacitative peak is followed immediately by an outward current, which was identified as potassium since it was reduced by increasing the potassium ion concentration in the bath ($[K]_o$) and blocked by adding 8 mM tetraethylammonium (TEA) or 0.1 mM 3,4-diaminopyridine (DAP).

Along with blocking the potassium current, application of TEA unmasked a small, prolonged current which was identified as a calcium current because it increased with increasing calcium concentration and was abolished when cobalt was substituted for calcium. In contrast, application of DAP revealed a slow, delayed current which was identified as a calcium-activated potassium current because it could be reduced by increasing $[K]_o$ and blocked by (a) replacing the calcium with cobalt, or adding (b) 8 mM TEA or (c) 50 nM Charybdotoxin.

343.4 CORRELATION OF Ca, Ba, AND Sr ENTRY WITH 5-HT RELEASE AT RETZIUS - P SYNAPSES IN CULTURE. R.R. Stewart, J.G. Nicholls, W.B. Adams and R.J. Bookman*. Dept. of Pharmacology, Biocenter, CH-4056 Basel, Switzerland.

Pairs of Retzius cells and P sensory cells dissected from leech ganglia form chemical synapses in culture. The aim of these experiments is to determine the relationship between entry of divalent cations into the presynaptic Retzius cell and transmitter release. Cells were plated on poly-L-lysine, a substrate upon which synapses form without profuse outgrowth of neurites. Under voltage-clamp with Na and K currents reduced or blocked, depolarization of the Retzius cell gave rise to an inward current. This inward current carried by Ca, Ba or Sr was followed after a delay by release, as assessed by the synaptic potential recorded in the postsynaptic P cell. Fig. 1 shows an experiment in which a depolarizing pulse from -50mV to + 20 mV led to an inward Ba current of 13 nA (peak) and a synaptic potential of 1.5 mV (peak) in the P cell. These synaptic potentials were mediated by an increase in chloride conductance and were unaffected by low Na or high TEA in the bathing fluid. The amplitudes of the synaptic potentials were steeply dependent on the amplitudes and durations of the inward Ca-channel current. The efficacy of Ca, Ba and Sr in effecting release has been compared. Moreover by applying voltage clamp pulses of varying amplitude, duration and frequency, a quantitative analysis has been made of the relation between Ca currents and 5-HT release during facilitation and depression.

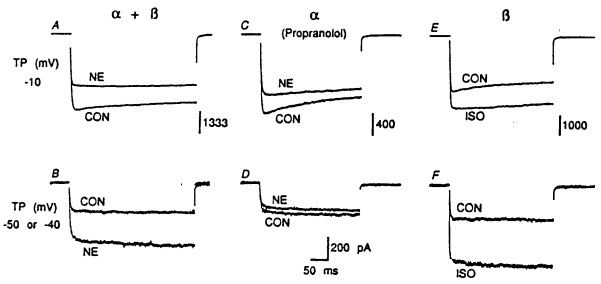
343.5 **α-ADRENERGIC INHIBITION OF N-TYPE Ca CHANNELS AND ß-ADRENERGIC STIMULATION OF L-TYPE Ca CHANNELS IN FROG SYMPATHETIC NEURONS.** **D. Lipscombe* & R.W. Tsien, Department of Physiology, Yale University School of Medicine, New Haven, CT 06510.**

When norepinephrine (NE) is released from sympathetic neurons it affects its own release through negative feedback via presynaptic α-receptors and positive feedback via presynaptic ß-receptors. To determine which type(s) of Ca channel NE modulates, we have carried out whole cell and single channel recordings from frog sympathetic neurons. We found two types of Ca channels somewhat similar to L and N-type channels in chick DRG and rat sympathetic neurons. In whole cell recordings (2 mM Ba or 2-10 mM Ca, HP= -80 or -90 mV), nifedipine-sensitive L-type channels generated a sustained Ca current that was activated with weak depolarizations (*B,D,F*) and remained available even at relatively depolarized HPs. N-type Ca channels produced a slowly decaying current (*A,C,E*) that required negative holding potentials for repriming. Application of 1 μM NE inhibited Ca channel current evoked by strong depolarization (*A*) while it often increased the current produced by weak test pulses (*B*). The inhibition is due to α-adrenergic block of N current, since it is abolished by the α-blocker phentolamine or by depolarized HPs that inactivate N current (Lipscombe & Tsien, J. Physiol., in press). With the ß-blocker propranolol present, NE failed to enhance L current at weak test potentials (*D*), although it still inhibited the N current evoked by strong depolarizations (*C*). Conversely, selective ß-stimulation by isoproterenol increased Ca current seen with either strong (*E*) or weak test pulses (*F*). This whole cell response was paralleled by stimulation of unitary L-type Ca channel activity following application of NE or 8-bromocyclic AMP. Thus, it appears that NE inhibits N-type Ca channels via α-receptors and stimulates L-type Ca channels via ß-receptors. These actions may account for the opposing effects of NE on its own release.



343.6 INHIBITION BY SYNAPSIN I OF MEMBRANOUS ORGANELLE MOVEMENT IN ISOLATED SQUID AXOPLASM. T.L. McGuinness*, S.T. Brady, J.A. Gruner, M. Sugimori, R. Llinás, and P.Greengard (SPON: J.A. Grebb). Rockefeller Univ., New York, NY 10021; Dept. of Cell Biol., Univ. of Texas Health Science Ctr., Dallas, TX 75235; Dept. of Physiol. Biophys., New York Univ. Med. Ctr., New York, NY 10016; and Marine Biological Laboratory, Woods Hole, MA 02543.

Synapsin I, a synaptic vesicle-associated phosphoprotein, is thought to play an important role in synaptic vesicle function. Indeed, recent studies have shown that injection of synapsin I into the preterminal digit of the squid giant synapse inhibits neurotransmitter release in a phosphorylation-dependent manner (Llinás et al., PNAS, 82:3035, 1985). We considered the possibility that dephospho-synapsin I (d-synapsin I) might regulate release by restricting the ability of synaptic vesicles to move to or fuse with the plasma membrane. To test the possibility that d-synapsin I restricts synaptic vesicle mobility, we have begun using extruded axoplasm from the squid giant axon with video-enhanced contrast-differential interference contrast (VEC-DIC) microscopy. Axoplasm was extruded from the giant axon of the squid (Loligo pealii) onto a coverslip for viewing by VEC-DIC microscopy as previously described (Brady et al., Cell Motility 5:81, 1985) and was then bathed in buffer A (10 mM Hepes, pH 7.2/5 mM $MgCl_2$/150 mM K^+-aspartate/1 mM ATP) containing 0.1 mg/ml or 1.0 mg/ml d-synapsin I. D-synapsin I produced a dramatic decrease in the amount and rates of organelle movement along microtubules within the interior of the axoplasm. This inhibition was not observed along microtubules protruding from the edges of the axoplasm into the surrounding buffer, suggesting that d-synapsin I does not directly affect the fast axonal transport mechanism itself. Stoichiometric phosphorylation of synapsin I by either Ca^{2+}/calmodulin-dependent protein kinase II (CaM kinase II) or cAMP-dependent protein kinase abolished the inhibitory effect of the protein. Fluorescence monitoring of Texas Red-labeled synapsin I ensured that the difference between phospho- and dephospho-synapsin I was not due to differential penetration of the proteins into the axoplasm. Furthermore, when CaM kinase II was microinjected into a small region of the axoplasm, followed by bathing the axoplasm with buffer A containing d-synapsin I, Ca^{2+}, and CaM, organelle movement was inhibited in all regions except in the vicinity around the kinase injection. These results show that synapsin I inhibits directed organelle movement within axoplasm in a phosphorylation-dependent manner. In summary, these data are consistent with the possibility that d-synapsin I crosslinks synaptic vesicles to some component(s) of the cytoskeleton, thereby indirectly restricting the movement of all organelles within the axoplasm.

343.7 INTERACTION OF SYNAPSIN I WITH PHOSPHOLIPID VESICLES. F. Benfenati*, R. Jahn*, M. Bahler* and Paul Greengard. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

Synapsin I, a major neuron specific phosphoprotein, is localized on the cytoplasmic surface of brain small synaptic vesicles, to which it binds with a Kd of 10nM (at 40mM NaCl) and with a Bmax of approximately 750 fmol/μg vesicle protein or 250 fmol/μg vesicle phospholipid (PL). To characterize the binding of synapsin I to synaptic vesicles, we have analyzed the binding to integral vesicle proteins reconstituted into liposomes as well as to pure lipid vesicles. When lipid vesicles were prepared from cholesterol and PLs using a lipid composition (w/w) similar to that found in the native vesicle membrane (41% phosphatidylcholine [PC], 32% phosphatidylethanolamine [PE], 11% phosphatidylserine [PS], 6% phosphatidylinositol [PI] and 10% cholesterol), synapsin I bound with a Kd of 10 nM and a Bmax of about 180 fmol synapsin I/μg PL, corresponding to about 60 molecules of synapsin I/vesicle. As with native synaptic vesicles, increasing the ionic strength decreased the affinity without greatly affecting the maximal amount of synapsin I bound. In contrast to the data observed using native synaptic vesicles, changes in the phosphorylation state of synapsin I seemed not to affect its binding to PL vesicles. When pure PC or PC-PE vesicles were tested, it was not possible to detect a significant binding under any conditions tested. On the other hand, PC-PS and PC-PI liposomes bearing a net surface negative charge strongly interacted with synapsin I. The amount of synapsin I maximally bound was directly proportional to the percentage of acidic PL present in the liposome bilayer, whereas the Kd was not affected by varying the composition of the liposomes. The binding was virtually independent of the liposome size, since similar results were obtained using cholate-formed liposomes (mean diameter 30 nm) or octylglucoside-formed liposomes (mean diameter 300 nm). PC liposomes negatively charged by the inclusion of 10% (w/w) dicetyl phosphate bound synapsin I to a lesser extent and with a very low affinity (0.5-1 μM), providing evidence for the specificity of synapsin I binding to PS and PI. However the binding of synapsin I to small synaptic vesicles cannot be explained only as an interaction with endogenous acidic PLs. Synapsin I bound with high affinity to liposomes prepared from endogenous vesicle PLs. Nevertheless when more than 98% of the endogenous PLs were removed from detergent solubilized synaptic vesicles, over 50% of the synaptic vesicle binding was retained by the protein fraction reconstituted into pure PC liposomes. Thus, acidic PLs and specific protein(s) in the small synaptic vesicle membrane may both be involved in the specific association of synapsin I with small synaptic vesicles in vivo.

343.8 **DECREASE IN AVAILABLE QUANTA BY DEPHOSPHOSYNAPSIN I INJECTED PRESYNAPTICALLY INTO THE GOLDFISH MAUTHNER AXON.** **J.T. Hackett, S.L. Cochran, L.J. Greenfield, Jr., and T. Ueda. Dept. Physiol., Univ. Virginia Med. School, Charlottesville, VA 22908 and Univ. Mich. Mental Health Institute, Ann Arbor, MI 48109.**

Synapsin I is a neuron specific phosphoprotein (Ueda, Maeno, Greengard, 1973) associated with presynaptic vesicles (De Camilli et al., 1983; Hutter et al., 1983). Dephosphorylated synapsin I (dSI) has a high affinity for presynaptic vesicles and decreases synaptic transmission when injected into the squid presynaptic terminal (Llinás et al., 1985). The purpose of our investigation was to extend these observations to a vertebrate CNS synapse which can be analyzed at the quantal level.

Two microelectrodes were used to record simultaneously from pairs of neurons (presynaptic Mauthner axon, postsynaptic cranial relay neuron). The postsynaptic electrode was placed within 50 μm of the synapse and the presynaptic electrode then impaled the Mauthner axon 50 to 200 μm from the first electrode. Spontaneous (mEPSP) and evoked postsynaptic potentials were digitized and analysed by computer and their variance was calculated. Evoked release was triggered by action potentials at 2 to 5 Hz. Values of quantal content ("m"), available store ("n"), release probability ("p") and quantal size ("q") were obtained at steady states before and after dSI (0.2 mg/ml in 2 M K-acetate, about 100 picoliters, pH 7.2) or a control protein was pressure-injected into the presynaptic Mauthner axon.

In 6 experiments there was a reduction in the EPSP amplitude attributed to the action of dSI. The decrease in transmission began about 30 sec. after the injection, reached a plateau within 10 min., was reversible, and was dose dependent. Injection of dSI did not affect the frequency or the amplitude of mEPSPs, hence the decrease in transmission is due to a decrease in "m" with no effect on postsynaptic receptor sensitivity or the amount of transmitter per quanta. Further analysis based on the binomial model for quantal release revealed that dSI reduced the "n" without affecting "p". Other proteins injected in control experiments were found to be ineffective.

The most likely mechanism for the action of dSI is that it binds to presynaptic vesicles and removes transmitter quanta from a releaseable pool. The protein apparently does not affect the spontaneous mEPSPs or the probability that a quantum in the available pool will be released by an action potential. Since fatigue of transmission produced by repetitive stimulation at this synapse is also the result of a decrease in the store of available quanta, it is tempting to suggest that the phosphorylation of dSI and the resulting increase in available quanta is a rate limiting step important in the regulation of nerve terminal function.

343.9 RECYCLING OF A SYNAPTIC VESICLE PROTEIN (P38)
F.Valtorta*, R.Fesce*, R.Jahn*, P.Greengard and B.Ceccarelli*
(SPON: J.Wang) The Rockefeller University, New York; Dept. of Medical Pharmacology, Univ. of Milan, Italy; and Max Planck Institut, Munich, FRG

Protein p38 (also called synaptophysin) has been shown to be an integral protein of the synaptic vesicle membrane (R.Jahn et al., PNAS 82:4137-4141, 1985; B,Wiedenmann and W.Franke, Cell 41:1017-1028, 1985). Using monoclonal antibodies raised against rat brain p38, we affinity purified p38 from frog brain. The frog protein appears to have a higher molecular weight than the mammalian protein and, like mammalian p38, can also exist in a dimeric form. The purified frog brain p38 was used to raise rabbit antisera and the specificity of the antisera obtained was verified by immunoblotting. When these antisera were used to stain frog nerve-muscle preparations by immunofluorescence, a bright specific signal was observed in the nerve-terminal region. The fluorescent image resembled that obtained using antisera against synapsin I, a phosphoprotein associated with the outer (cytoplasmic) side of the synaptic vesicle membrane. In both cases, permeabilization of the plasma membrane with detergent was required. Fluorescent end-plate images could be observed with p38 antisera without previous permeabilization in preparations treated for one hour with a low dose (0.2-0.4 μg/ml) of α-latrotoxin (αLTx) in Ca-free medium. Under this condition, α-LTx caused depletion of the quantal store of ACh and of synaptic vesicles, and swelling of the nerve terminal was observed as a result of the permanent incorporation of the vesicle membrane into the axolemma. These results support the validity of the vesicle hypothesis of neurotransmitter release and indicate that exocytosis leads to the exposure of antigenic determinants of p38 on the outer surface of the axolemma. After one hour treatment with the same doses of α-LTx in the presence of 1.8 mM Ca, immunofluorescent images were obtained only after permeabilization with detergents, and no swelling of the terminal was evident. Under this condition, the vesicle population was maintained by an active process of recycling and more than three times the initial store of quanta was secreted. Thus it seems that, in spite of the active vesicle and neurotransmitter turnover, no extensive intermixing occurs between vesicle and axolemma components.

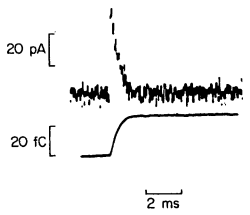
343.10 CURRENTS THROUGH THE FUSION PORE THAT FORMS DURING EXOCYTOSIS OF A SECRETORY VESICLE.
W. Almers and L.J. Breckenridge*. Dept. Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195.

Early events in exocytosis of single secretory vesicles were captured by patch clamp measurements on mast cells of beige mice, a murine mutant with giant secretory vesicles. When exocytosis is induced by cytoplasmic $GTP_\gamma S$, membrane capacitance (C_m) is seen to increase in steps, each reporting the fusion of a single vesicle with the cell membrane or, more precisely, the making of an electric connection between vesicle lumen and cell exterior. Through this connection, termed the fusion pore, a capacitative current transient must flow to equalize the membrane potentials of vesicle and cell membranes. Indeed, the increase in C_m is preceded by current transients with a mean reversal potential (E_r) of -76 mV. The Fig. shows an example, recorded at 30 mV, along with its time integral. The transients have these properties: (1) They decline monotonically and (2) carry a charge Q that is linearly related to the final amplitude (^C) of the C_m step. (3) The ratio Q/^C depends linearly on holding potential with a slope of one, and intercepts the abscissa at E_r = -76 mV. (4) FCCP, a H^+-ionophore, shifts E_r to 0 mV. (1)-(4) are strong evidence that the current transients serve to charge the vesicle membrane through the fusion pore. E_r gives the membrane potential of the vesicle, 76 mV lumen positive to cytosol. The initial conductance of the fusion pore, g, is obtained either from the amplitude (I_o) of the transient ($g = I_o*^C/Q$) or from the time constant of decline ($g = \tau/^C$). Mean value is 230 pS, corresponding to a probable pore diameter of < 2 nm. Once the transient has declined, the further time course of g was reconstructed from the admittance (800 Hz voltage sinusoid) contributed by the fusing vesicle. Real and imaginary components of the admittance were sampled at 800 Hz with a synchronous-integration lock-in amplifier. We find that g rapidly grows to about 1 nS, as if the fusion pore rapidly dilated. The dilated fusion pore may persist for hundreds of ms and can repeatedly close and open again (C_m flicker) or expand further to complete membrane fusion. We conclude that membrane fusion starts with the sudden formation of an aqueous channel that connects the lumen of the exocytosing vesicle to the cell exterior. Its conductance is similar to that of a gap junction, the only other ion channel that spans two membranes. Supported by NIH AR-17803.



343.11 DISTRIBUTION OF SYNAPTIC NOISE IS A PREDICTABLE SUM OF PRESYNAPTIC BINOMIAL RELEASE FUNCTIONS.
H. Korn, Y. Burnod* D.S. Faber & J.R. Martin* Laboratoire de Neurobiologie Cellulaire, INSERM U261, Institut Pasteur, Paris, France, and SUNYAB, Buffalo, NY, USA.

We recently reported (H. Korn, et al., Proc. Natl. Acad. Sci. USA, in press) that quantal currents can be extracted from spontaneous synaptic noise in the voltage-clamped teleost Mauthner (M-) cell. Inhibitory postsynaptic currents, due to background firing of a well-defined population of presynaptic cells, were collected during depolarizing steps, to isolate them from excitatory ones. Their amplitude histograms exhibited multiple peaks, separated by a constant increment comparable to the basic quantal units derived by the simple binomial analysis of unitary postsynaptic potentials (H. Korn, et al., J. Neurophysiol. 1982, 48:679-707). However, the overall response distributions differed from binomial functions, with a predominance of single events and a regular sigmoidal-like decrease in the frequency of occurrence in successive peaks. This result is not surprizing since, unless parameters n and p are the same, one does not expect several binomial curves to sum up as a single one. Assuming the 42 presynaptic cells previously analyzed (H. Korn, et al., J. Neurophysiol. 1986, 55:402-421) were representative of the inhibitory network, the statistical behavior of responses to asynchronous activity in these neurons was modeled by 1) adding their corresponding binomial distributions (with n ranging from 3 to 52 and p from 0.17 to 0.65 for 1 Hz stimulation) and, 2) scaling all their release probabilities (ps) according to an exponentially decreasing function of presynaptic firing rate (H. Korn, et al., J. Neurosci. 1984, 4:125-130). In 8 experiments, the observed amplitude histograms, each of which included from 1200 to over 3000 events, were adequately fit by the predicted population curves, with the p values equal to 38±0.05% of their controls such as would occur when the presynaptic firing rate is superior to 33 Hz, and p reaches a minimum. Accordingly, with simultaneous recordings, high frequency presynaptic discharges have been observed in some inhibitory interneurons during depolarizing steps in the M-cells possibly due to accompanying outward currents. Therefore, synaptic noise brought about by activity in a given pool of presynaptic interneurons can be isolated and characterized by a unique function, which is here a limited series of single binomials, where the distribution of n (corresponding to the number of active sites) remains constant and p is the variable parameter.

343.12 A COMPARISON OF THE ACTIONS OF THE CLOSTRIDIUM BOTULINUM BINARY TOXIN ON THE STRUCTURE AND FUNCTION OF ADRENAL Y-1 CELLS AND MOUSE NEUROBLASTOMA N1E-115 CELLS.
Lance L. Simpson and Kevin S. Chinn*. Departments of Medicine and Pharmacology, Jefferson Medical College, Philadelphia, PA 19107.

The botulinum binary toxin is composed of two separate and independent polypeptide chains (Mr ~ 50,000 and 100,000). The heavy chain is a binding component that interacts with the plasma membrane of vulnerable cells; the light chain is an enzyme that possesses mono(ADP-ribosyl)ating activity. The intracellular substrate for the catalytic chain is G-actin. When studied on adrenal Y-1 cells, the toxin produces dose-dependent (10^{-11} to 10^{-9} M) morphological changes. These are characterized by rounding of the cell and by disruption of the cytoskeleton. The morphological changes do not lead to cell death, as indicated by: a) exclusion of impermeant ions, b.) continued incorporation of tritiated amino acids into protein, and c.) continued incorporation of purines into nucleic acids. The toxin does not alter basal levels of cyclic-AMP or cyclic-GMP, but it does produce a modest increase in steroid secretion. Equivalent studies were done on mouse neuroblastoma N1E-115 cells, with the addition of intracellular dialysis via patch clamp electrodes. When applied to the outside of cells, the holotoxin was needed to produce characteristic changes. When dialysed into individual cells, only the light chain was necessary. Morphological changes could be obtained prior to changes in leakage current. While morphological changes required approximately 30-45 minutes to occur when the holotoxin was bath applied (10^{-9} M), such changes occurred within 15-20 minutes after beginning cell dialysis (10^{-11} M light chain in the electrode). During the dialysis studies, a shrinking of the cell processes occurred before rounding of the cell soma. The data suggest that the binary toxin may be a powerful tool for studying the relationship between actin and various aspects of cell structure and function.

343.13 MOVEMENT OF Cl THROUGH DOUBLY RECTIFYING ELECTRICAL JUNCTIONS BETWEEN TOUCH CELLS IN THE CNS OF THE LEECH. S.E. Acklin* and J.G. Nicholls. Dept. of Pharmacology, Biocenter, CH-4056 Basel, Switzerland.

An unusual type of rectification occurs in the spread of current between touch (T) sensory neurons in the CNS of the leech. Depolarization spreads from one T cell to another in both directions, whereas hyperpolarization spreads in neither direction (Baylor, D.A. and Nicholls, J.G., J. Physiol. 203:591, 1969.) In principle such characteristics could be due to the properties of the electrical junctions themselves or to rectifying properties of membranes interposed between the cell somas and the junctions within the neuropil. The aim of the present experiments was to distinguish between these mechanisms and to characterize the permeability of the junctions to small ions. In one test, the membrane resistance and length constants of T cells were increased by substituting sucrose for Na. Under these conditions double rectification was still apparent, even though current spread through processes within the neuropil was increased. A more direct test was to stimulate one T cell repetitively. This activates the Na pump and gives rise to a hyperpolarization that spreads throughout the fine processes of the neuropil and the axons of the T cell (Van Essen, D.C., J. Physiol. 230:509, 1973). When one T cell was hyperpolarized in this way the IPSP's recorded in it became reversed. The other T cell showed no hyperpolarization and the IPSP's continued to be hyperpolarizing. These results indicate that hyperpolarization does not cross the electrical junctions. IPSP's also provided a reliable and sensitive assay for intracellular Cl. When Cl was injected into one T cell the IPSP's in it reversed within one minute. After a few minutes the IPSP's in the coupled T cell also became reversed, indicating that Cl can cross the junctions. (Supported by grants from the Swiss Nationalfonds and the US Navy).

VISUAL SYSTEM: DEVELOPMENT AND PLASTICITY IV

344.1 A CELLULAR ANALOG OF DEVELOPMENTAL VISUAL CORTICAL PLASTICITY. Y. Frégnac* and D. Shulz* (SPON: European Neuroscience Association). Lab. de Neuropharmacologie et Neurobiologie du Dévelopment. Univ. Paris XI, Bat 440, 91405, Orsay Cedex, France.

An electrophysiological paradigm has been developed to reproduce, during the time of recording, functional changes similar to those described during epigenesis of visual cortex. Ionophoretic pairing was used to control the temporal correlation between postsynaptic firing and given characteristics of the visual stimulus (Frégnac et al. Soc. Neurosc. Abstr. 10: 1078 (1984)). Four types of differential pairing procedures were applied: two test stimuli which could differ in 1) position within the receptive field (R.F.), 2) orientation, 3) ocular dominance or 4) interocular orientation disparity (I.O.D.), were paired respectively with an imposed increase and decrease in visual response. Generalisation effects for stimuli other than those used during pairing were looked for when possible.

429 cells were recorded in kitten area 17: 275 were used for control (including invariance of R.F. properties during non-differential pairing) and 154 were submitted to differential pairings. Significant changes in R.F. profile, orientation selectivity, ocular dominance and I.O.D., were found in 30 to 40% of "paired" neurones. They were largest in kittens between 4-8 weeks of age, but could be produced in the adult as well. Cells often retained the pattern of firing imposed during pairing. Extinction was eventually observed after several tens of minutes. Changes induced by I.O.D. pairing (using dichoptic stimulation) affected mainly binocular responses, and were not explainable by summed monocular responses. In spite of occasional global excitability changes, most modifications were interpretable in terms of competitive changes in responsiveness. Relative preference between the two test stimuli was displaced towards the stimulus paired with imposed increased visual responsiveness.

These changes were associative : no modifications were observed following ionophoretic action uncorrelated with visual stimulation (pseudopairing), or when control of activity was uneffective during pairing. Both imposed increases and decreases in postsynaptic activity appeared to be equally effective. If subsequent increase in synaptic efficiency is predicted by Hebbian schemes of plasticity (Hebb, 1949), forced repetitive failure of a given stimulus to evoke postsynaptic activation could result per se in a long-lasting decreased responsiveness for this stimulus. In favor of selective changes in synaptic efficiency is the finding that separate zones in the R.F. can be modified differentially. These data suggest that only sets of synapses active during control of postsynaptic firing will be susceptible of undergoing plastic changes.

344.2 **A NOVEL EXPRESSION OF PLASTICITY IN KITTEN VISUAL CORTEX IN THE ABSENCE OF POSTSYNAPTIC SPIKE ACTIVITY.**
H.O. Reiter and M.P. Stryker. Division of Neurosciences and Department of Physiology, University of California, San Francisco, 94143-0444, USA.

Models of synaptic plasticity in the nervous system have conventionally assumed that spike activity in the postsynaptic cell enhances the efficacy of recently active presynaptic inputs. This contrasts with purely presynaptic models like those of classical conditioning in *Aplysia*, in which responses of cells were facilitated even while their somata were hyperpolarized by an intracellular microelectrode. The aim of the present experiments was to reveal whether, as postulated by Hebb, postsynaptic spike activity regulates the efficacy of synaptic transmission in cortex. We made use of the prompt and dramatic response of the visual cortex to occlusion of one eye during the critical period to test the requirement for postsynaptic discharges in ocular dominance plasticity. If postsynaptic spike activity were crucial, our expectation was that selectively blocking it should prevent plasticity.

We selectively blocked cortical cell discharges in 4 27-32-day old kittens with a continuous intracortical infusion of muscimol (10 mM, 0.5 µl/hr) during a 5-7 day period of monocular deprivation. Muscimol, an agonist of the principal inhibitory neurotransmitter in cerebral cortex, GABA, completely blocks cortical cell discharges with no apparent effect on the activity of their presynaptic inputs. The selective inhibition produced by muscimol was verified by microelectrode recordings. When the cortex was allowed to recover from muscimol-induced blockade, recordings from single cells revealed a consistent shift in the responsiveness of the visual cortex in favor of the less-active, **closed** eye. This surprising result was confirmed using a blind procedure in additional 4 kittens. Such an inhibition-coupled expression of plasticity in favor of the less-active, closed eye has never previously been reported and cannot be explained by a non-specific disruption of cortical function. The normal shift in favor of the more-active open eye was evident in control regions unaffected by muscimol treatment, as well as in border regions in which spike activity was profoundly attenuated.

The fact that identical presynaptic input activities can result in expressions of plasticity favoring either the less-active, closed eye or the more-active, open eye indicates (1) that the postsynaptic cell is crucially involved in plasticity of the visual cortex, (2) that the direction of cortical plasticity depends solely on postsynaptic membrane conductance or polarization and (3) that at least this novel expression of plasticity can occur in the absence of postsynaptic spike activity. The normal ocular dominance shift found in the border regions is consistent with the idea that excitation-coupled plasticity also does not require postsynaptic spikes. While these data provide direct evidence for Hebb's postulate of a crucial role for the postsynaptic element, they suggest that local responses rather than action potentials govern cortical plasticity.

344.3 OCULAR DOMINANCE SHIFT AFTER MONOCULAR EXPOSURE IN ANESTHETIZED AND IMMOBILIZED KITTENS: EFFECTS OF NORADRENALINE (NA) INFUSION.

K. Imamura and T. Kasamatsu. The Smith-Kettlewell Eye Research Foundation, 2232 Webster Street, San Francisco, CA 94115.

Monocular deprivation in early life induces profound changes in functional connection in the kitten visual cortex. At the peak of the sensitive period around 4-5 weeks of age, short-term deprivation for a day or less is sufficient to induce shift in ocular dominance towards the open eye. However, the changes do not occur if a kitten has been anesthetized and paralyzed during monocular exposure, suggesting that in addition to imbalance of visual input to the cortex, nonvisual afferent is necessary for inducing such modification. Recently we showed that in acutely anesthetized and paralyzed adult cats the ocular dominance distribution was arbitrarily altered in the NA-infused visual cortex by optical manipulations of the alignment of the visual axes. In the present study, we wanted to show that cortical NA infusion was sufficient to induce the shift in ocular dominance in response to brief monocular exposure in anestetized and paralyzed animals.

Five to seven week old kittens were used. Throughout the experiments, anesthesia was maintained with nitrous oxide (75% N_2O,22.5% O_2, 2.5% CO_2), supplemented with thiamylal sodium (1 mg/kg/hr or more), and paralysis was maintained with continous i.v. infusion of gallamine triethiodide (Flaxedil, 10 mg/kg/hr). Cut wounds and pressure points were infiltrated with 2% Xylocaine. One hemisphere of the visual cortex was locally infused with 0.5 mM NA using a cannula-osmotic minipump system. The contralateral eye was sutured shut and animals were continuously exposed to TV shows for 24 hr concommitantly with the NA infusion. The implanted cannula and minipump assembly was removed at the beginning of recordings. Single-unit recordings were carried out following the standard procedures in our laboratory. Thirty visually active cells were recorded, along a single recording track which was started near the cannulation site, with an intercellular spacing of about 100um. We obtained the shift in ocular dominance (binocularity, B=0.38; proprotion of group-7 cells, G7=0.47) in the NA-infused hemisphere, while no change was found, as expected, in the control hemisphere (B=0.63, G7=0.17) which do not receive the NA infusion. The difference was statistically significant. We conclude that in acutely anesthetized and paralyzed kittens the NA infusion was a sufficient condition to induce ocular dominance shift after brief monocular exposure.

(Supported by USPHS Grant EYO-5549).

344.4 **EFFECTS OF INTRACORTICAL INFUSION OF APV ON SYNAPTIC MODIFICATIONS IN KITTEN STRIATE CORTEX.**

M.F. Bear, C. Gu*, A. Kleinschmidt* and W. Singer. Max-Planck-Institute für Hirnforschung, 6000 Frankfurt 71 (FRG) and Brown University, Providence, RI 02912.

Depletion of cortical ACh and NE retards the ocular dominance (OD) shift in striate cortex that normally results from 10 days of monocular deprivation (MD, Bear and Singer, Nature 320: 172-176, 1986) Other visual response properties seem to be unaffected, suggesting that this treatment simply slows or prevents the process of synaptic modification. We have found that continuous intracortical infusion of 50 mM D,L-2-amino-5-phosphonovaleric acid (APV), a selective NMDA receptor antagonist, also prevents the OD shift (Kleinschmidt, Bear and Singer, Neurosci Lett. Suppl. 26:S58, 1986). However, unlike ACh + NE depletion, APV treatment also results in a striking loss of orientation selectivity and an overall reduction in visual responsiveness. Thus, it appears that synaptic modifications do occur under the influence of APV, although they may no longer be guided by retinal activity. To test this idea further, we asked whether APV infusion would prevent the recovery of cortical binocularity that normally occurs when a kitten is allowed binocular visual experience (BE) after a brief period of MD. Kittens were monocularly deprived by lid suture at approximately 4 weeks of age for 8-14 days. After this period of MD, the sutured eyelid was opened and the animals were given 7-13 days of BE, followed by a standard physiological assay of cortical OD. Most of the BE occured as one hemisphere was infused continuously with 50 mM APV at a rate of 1 µl per hour. We found no evidence of an ocular dominance shift in the experimental hemispheres even though they had received only 3-4 days of binocular vision without APV. This recovery of binocular connections is another example of plasticity in the presence of APV, and suggests that NMDA receptor activation is not a necessary condition for all synaptic modifications in striate cortex. The available data rather suggest that NMDA receptors may be involved specifically in the competitive strengthening/weakening of synapses that occurs during an OD shift or during the acquisition of orientation selectivity.

344.5 KETAMINE BUT NOT XYLAZINE IMPAIRS CONSOLIDATION OF PLASTIC CHANGES IN KITTEN VISUAL CORTEX.

A. Kossel*, U. Egert* and J.P. Rauschecker* (SPON: European Neuroscience Association).Max-Planck-Institut für biologische Kybernetik, D-7400 Tübingen, West Germany.

We have reported recently that ketamine-xylazine anaesthesia given to young kittens immediately after each of a series of 30 monocular exposures reliably prevents an ocular dominance shift in visual cortex (Rauschecker and Hahn, Nature, 326: 183-185, 1987). Using the same experimental protocol we have now tested the two drugs separately in order to find out whether ketamine, or xylazine, or both are responsible for the 'retrograde' impairment of cortical plasticity.

Nine kittens were reared in a totally dark room from three weeks of age. Every day they were taken out into the light for 20 minutes with one eye covered by a black contact occluder. During this time the kittens were alert and viewed a high-contrast visual environment. At the end of each exposure session they received an intramuscular injection of either ketamine (25 mg/kg; four kittens) or xylazine (10 mg/kg; five kittens) and were returned into the dark. Two of the xylazine-treated animals were given only single shots leading to a brief anaesthetic state of 15-20 minutes duration, in three xylazine kittens anaesthesia was prolonged to 60 minutes by increasing the dosage and/or giving additional injections. After 30 exposures, leading to a total of 10 hours monocular experience, a recording experiment in area 17 was performed.

All of the xylazine-treated kittens consistently showed a clear ocular dominance shift. In the ketamine-treated animals such a shift was absent or grossly reduced. In addition, the orientation tuning of cortical units in the ketamine kittens was broader than in the xylazine group, while responsiveness was the same. These results show that an impairment of synaptic consolidation in the visual cortex cannot be induced by any kind of reduced arousal. Since ketamine is known as a blocker of NMDA receptors for excitatory amino acids (Thomson et al., Nature, 313: 479-481, 1985), our results rather suggest that this type of receptor may be involved in cortical plasticity.

344.6 ENHANCED PHYSIOLOGICAL RECOVERY IN THE VISUAL CORTEX OF MONOCULARLY DEPRIVED KITTENS PROMOTED BY CERTAIN REGIMENS OF PART-TIME REVERSE OCCLUSION.

D.E. Mitchell and M. Cynader. Psychology Dept., Dalhousie University, Halifax, N.S., Canada.

After several weeks of monocular deprivation (MD) imposed on kittens, most cells in the visual cortex can be excited only by visual stimulation of the nondeprived eye. Such animals also appear blind when forced to use their deprived eye. Some recovery occurs subsequently if visual input is restored to the deprived eye sufficiently early. Until recently, only two conditions of recovery have been investigated, namely reverse occlusion where the nondeprived eye is occluded during recovery, and binocular recovery where both eyes are open during this period. However, neither of these conditions produces a satisfactory outcome for vision since the recovery is neither complete nor permanent, and frequently occurs at the expense of the vision of the nondeprived eye. We have found (Mitchell et al. Clin. Vis. Sci. 1:173, 1986) that certain regimens of part-time reverse occlusion could promote complete and seemingly permanent recovery of the vision of the deprived eye. We now report on the extent of physiological recovery in area 17 of 4 of these kittens.

After MD to 6 weeks of age the nondeprived eye was occluded for part of each day for 6 weeks by an opaque mask for either 3.5 (N=2) or 5 (N=2) hours each day after which the mask was removed to allow binocular visual input for the remainder of the short (7 hr) daily period of visual exposure. All 4 kittens eventually developed normal contrast sensitivity functions as well as vernier acuities in both eyes. Single cell recordings (478 cells) were made from area 17 of both hemispheres by conventional qualitative procedures. Quantitative measurements were made of the tuning for retinal disparity of about 20 of these cells in each animal. The animals that received 5 hrs of daily occlusion showed considerable physiological recovery with a substantial proportion (about 1/3) of cells dominated by the deprived eye. For one of these animals the proportion of binocular cells (80%) was similar to that observed in normal animals, but in the other animal the proportion was much lower, a finding that may be related to the presence of a strabismus in this animal. The physiological recovery observed in the 2 animals that received 3.5 hrs of daily occlusion was less impressive; only about 10% of cells were dominated by the deprived eye and less than half (45%) could be excited by both eyes. A number of the cells that were examined quantitatively in each animal exhibited reasonable tuning for retinal disparity, but most cells were quite unselective. Nevertheless it is possible that the former cells may be sufficient to provide a neural substrate for local stereopsis. These findings show that a relatively small proportion of cortical neurons may be sufficient to mediate behavioral recovery.

344.7 SPATIAL RECEPTIVE FIELD PROPERTIES OF STRIATE CORTICAL NEURONS IN CATS REARED WITH SURGICALLY INDUCED ESOTROPIA PAIRED WITH SAGITTAL TRANSECTION OF THE OPTIC CHIASM, Y.M. Chino, B. Timmney, W.L. Salinger, H. Wada*, G.A. Lesher*. Illinois College of Optometry, Chicago, IL 60616, University of North Carolina, Greensboro, NC 27412, and University of Western Ontario, London, Canada.

We have previously shown that rearing kittens with esotropia, surgically induced shortly after birth, leads to amblyopia of striate cortical neurons, i.e., a loss of spatial resolution and reduced contrast sensitivity (Chino et al. J. Neurophysiol. 50, 265-286, 1983). Our electrophysiological findings are corroborated with comparable results from behavioral testing performed on the same strabismic animals prior to our recordings (Holopigian and Blake, J. Neurophysiol. 50, 287-296, 1983). In an attempt to identify factors that may contribute to such deficits of our strabismic cats, we have raised strabismic kittens paired with a sagittal transection of the optic chiasm, thus eliminating direct binocular competition in the retino-geniculo-striate pathway during postnatal development. Surgeries were performed between the third and fourth postnatal week. Kittens' visual acuity was behaviorally measured with a jumping stand prior to electrophysiological recording. Extracellular single-cell recordings were made in the striate cortex with conventional methods.

We find that receptive fields of striate cortical neurons receiving inputs from the deviating eye were significantly enlarged as compared to those from the non-deviating eye or normally reared cats. Spatial modulation transfer functions, obtained with drifting high contrast sinusoidal gratings, show that the optimal spatial frequency and spatial resolutions of those units controlled by the deviating eye were significantly lower than those driven by the non-deviating eye. Interestingly, these values obtained with the non-deviating eye are slightly lower, but similar to optimal frequencies and resolutions measured in normal cats. In addition, the contrast threshold of the cells driven by the deviating eye was elevated as compared to the non-deviating eye. The threshold value for the non-deviating eye, however, was also higher than that of normal controls. These physiological findings are supported by our behavioral data; the acuity of the deviating eye was consistently lower than that of the non-deviating eye. Possible factors that may contribute to the present results will be discussed including a possible binocular competition through the corpus callosum.

344.8 THE EFFECT OF NEONATAL VISUAL CORTEX DAMAGE ON VERNIER ACUITY AND RESOLUTION ACUITY IN CATS. S. Belleville and F. Wilkinson. Dept. of Psychology, McGill University, 1205 Dr. Penfield, Montreal, Que., CANADA H3A 1B1

The present study investigates the effect of neonatal lesions of visual cortex on two types of acuity: spatial resolution and vernier acuity. Eight kittens served as subjects in this study. In four, visual cortex (areas 17-18-19) was ablated bilateraly during the neonatal period (day 1-8); the remaining four animals served as littermate controls. Histological work and examination of the lesion extent have been completed in the four lesioned animals.Histological verification was based on the reconstructed borders of the lesion and the pattern of cell loss in the lateral geniculate nucleus and medial interlaminar nucleus. The lesions included most of area 17 and 18 and part of area 19.

Both types of threshold measurements were made using a two-choice discrimination procedure on a jumping-stand. Vernier acuity (detection of offsets in square-wave gratings) was tracked developmentally until asymptotic levels had been reached. Spatial acuity was then measured in adulthood in three of the lesioned animals and three littermate controls.

In the normal kittens, vernier acuity developed rapidly reaching asymptote at 3-5' by 90 days of age. At very early ages, vernier thresholds for the lesioned kittens were comparable to those of their normal littermates. However, their thresholds remained at that level (22-35' of arc) into adulthood.

Spatial resolution thresholds for the three normal cats tested on this task in adulthood were 3.6 c/deg, 4.1 c/deg and 4.5 c/deg. Thresholds in the lesioned animals were reduced only slightly (3.6 c/deg, 3.0 c/deg, 3.6 c/deg) in comparison to their respective littermates. These values all fall within the range of spatial acuities measured in this laboratory in intact adults cats. Consequently, whereas vernier acuity is severely decreased by neonatal damage to the visual cortex, resolution acuity remains relatively preserved. This provides further evidence that the sparing of function which has been claimed to occur following early brain damage is task-specific.

This research was supported by NSERC grant # 7551 to F.W.

344.9 OPTICAL STUDIES OF MACAQUE STRIATE CORTEX DURING DEVELOPMENT. L. Kiorpes* and G. Blasdel (SPON: J.A. Movshon). Dept. of Psychology and Center for Neural Science, New York University, New York, New York; Dept. of Medical Physiology, The University of Calgary, Calgary, Alberta, Canada.

As shown previously, optical techniques offer a powerful approach to the study of the functional organization of monkey striate cortex (Blasdel and Salama, 1986). Two features of these techniques make them particularly attractive for use in developmental studies: first, it is possible to study repeatedly the same cortical region in an individual animal; and second, it is thought that the optical signal derives from the upper cortical layers (laminae 2,3) where many of the neurons with projections to extrastriate cortex are located. Thus, the postnatal development of cortical organization in the upper layers, which remains largely unexplored, can be studied directly with these methods.

We have adapted one optical approach using the voltage sensitive dye NK2367 in conjunction with video imaging techniques to follow changes in the functional organization of striate cortex in individual infant monkeys during periods of normal and abnormal development. Our results to date show that high resolution optical images of neuronal activity can be obtained in animals as young as 7.5 weeks, and that the same patch of cortex can be studied at weekly intervals for at least 4 weeks in young monkeys. Results from one monkey, studied after 7.5 weeks of normal development reveal patterns of ocular dominance and orientation selectivity that are highly remeniscent of those in the adult. Visual stimulation with sine wave gratings of differing spatial frequencies, presented at all orientations, reveals a pattern of spots selective for low spatial frequencies that populate ocular dominance column centers and probably correspond to the cytochrome oxidase blobs seen histochemically (Tootell and Blasdel, 1987).

Monocular deprivation for 2 weeks following the period of initial study clearly altered the pattern of ocular dominance in the cortex. However, the topography of the ocular dominance pattern at this stage was not easily related to the normal topography. The ocular dominance pattern following a subsequent 2 week recovery period, during which the monkey was allowed binocular vision, revealed a shrinkage of the ocular dominance columns corresponding to the deprived eye, however, in addition, there appeared to be a break-up along the lengths of the columns as well.

344.10 ASSESSMENT OF SPATIAL VISION IN MONKEYS WITH EXPERIMENTALLY INDUCED APHAKIA. M. W. Quick*, C. D. O'Dell*, J. A. Gammon*, J. Wilson, M. Tigges, A. Fernandes*, and R. G. Boothe. Yerkes Regional Primate Research Center, Departments of Psychology, Ophthalmology, Anatomy and Cell Biology, Emory University, Atlanta, GA 30322.

To evaluate treatments of infantile monocular cataracts, neonatal monkeys were lensectomized unilaterally under conditions of general anesthesia and sterile surgery. Some animals were then optically corrected to a near point in the aphakic eye using extended-wear contact lenses. Visual input to the unoperated eye was either normal or blocked (part-time or full-time) using an occluder lens. Lens wear was monitored every 2 hours for compliance and lens power adjusted when necessary. Forced choice preferential looking (FPL) was used to assess acuity in the infants (O'Dell et al., IOVS Suppl. 28:216, 1987). Operant testing was used after 6 months, and final acuity was determined after 1 year of age. Final mean data for the various treatment groups were as follows: 1) uncorrected aphakia/no occlusion: .81 cpd/26.2 cpd; 2) corrected aphakia/no occlusion: 8.9 cpd/20.0 cpd; 3) corrected aphakia/full-time occlusion: 24.0 cpd/.025 cpd. One monkey did not wear any type of lens for one year after initial testing. When retested under original conditions no change in acuity was observed in either eye, indicating no acuity loss with lens removal after one year of age.

As evident in the above data, good vision is not maintained in the aphakic eye without occlusion of the unoperated eye. With occlusion, good acuity can be maintained (range 20-60 cpd). However, in the fully occluded eye, only one of six monkeys showed any pattern vision (.15 cpd); the others could distinguish only light-dark. We measured contrast sensitivity in the aphakic eye of one monkey from this group and found normal sensitivity across the entire spatial frequency range.

We are currently rearing several animals under conditions of corrected aphakia/part-time (6 hours) daily occlusion in an attempt to maintain good vision in both eyes. At 11 months, FPL measurements of acuity were the same in both eyes (14.2 cpd). One animal initially assigned to the corrected aphakia/full-time occlusion group learned to intermittently displace the occluder from in front of his pupil and maintained vision of 30 cpd in the unoperated eye; acuity in the aphakic eye was 20 cpd. Measures of contrast sensitivity in this animal showed an average sensitivity loss of 35% over the range of 1 cpd to the acuity point in the aphakic eye, and was normal in the unoperated eye. Furthermore, in a spatial phase discrimination task, threshold was normal in the unoperated eye but no phase discrimination ability was evident in the aphakic eye. We are currently measuring these and other (Landolt C acuity, vernier acuity) components of spatial vision to determine other possible deficits. NIH grants RR-00165 and EY-05975.

344.11 EFFECT OF PRENATAL MONOCULAR ENUCLEATION ON VERNIER HYPERACUITY IN RHESUS MONKEYS.

Martha G. MacAvoy*, Charles J. Bruce, and Pasko Rakic(SPON: M.S. Schwartz). Section Neuroanatomy, Yale University School of Medicine, New Haven CT 06510.

Prenatal enucleation of one eye causes a set of dramatic changes in the pattern and number of neuronal connections in the primate visual system (Rakic, Science, **214**:928, 1981; Rakic & Riley, Nature, **305**:135, 1983). The remaining optic nerve has 30-40% more fibers than a normal optic nerve. Both lateral geniculate nuclei have normal numbers of neurons but only two layers (a magno- and a parvocellular layer). Striate cortex has a normal size and a normal complement of layers; however, it is uniformly innervated by the remaining eye, in marked contrast to the interdigitating ocular dominance columns of the normal striate cortex. To begin to understand how visual function is affected by these anatomical changes, we measured the vernier acuity in two adult (3-5 yrs) rhesus monkeys that were enucleated on embryonic days E63 and E91, respectively and were delivered at term (E165). The vernier task was chosen because it has been hypothesized that the hyperacuity ability assessed by this task depends critically upon the grain of the visual field representation on the granule cells of layer IVc (Barlow, Nature, **279**: 189, 1979) and thus might be improved by having all of the IVc granule cells devoted to only one eye.

Each experimental monkey was paired with an age and sex matched normal control and all subjects were tested on a detection version of the classic vernier acuity task in which they were rewarded for responding when two nearly abutting vertical lines were horizontally displaced. The method of constant stimuli was used. Threshold was taken as the displacement with 50% detection after correcting for guessing and fitting with a sigmoid curve. The detection thresholds for the two experimental monkeys were 0.002° and 0.0024° (e.g., 7.2 & 8.6 sec of arc), which were slightly better than the thresholds of 0.003° obtained for the two control monkeys tested binocularly. One control monkey was also tested monocularly; detection thresholds were 0.0032° and 0.0044° in the left and right eyes, respectively. One experimental monkey and one control were also tested in a forced-choice version of the vernier acuity task in which they had to indicate the direction of the vernier displacement. Their thresholds were approximately the same as in the detection version. We also tested three human subjects in this forced-choice version: their binocular thresholds were 0.001°, 0.0018°, and 0.002°.

We conclude that early monocular enucleation does not adversely affect vernier hyperacuity; in fact, acuity of the enucleated monkeys was slightly better than the acuity of the control monkeys. We further conclude that rhesus monkeys have hyperacuity abilities that are nearly as fine as those of humans.

344.12 **"VISUAL" CORTEX OF HUMAN EARLY BLIND SUBJECTS MAPPED WITH POSITRON-EMISSION TOMOGRAPHY.**

C. Veraart, M.C. Wanet-Defalque* and A. De Volder*. Lab. de Neurophysiol. Univ. Louvain, Brussels, Belgium.

We studied glucose metabolism in the striate and prestriate cortex of 4 early blind and 4 normal sighted volunteers. The regional cerebral metabolic rate for glucose (rCMRGlc) was measured by positron emission tomography (PET) with [^{18}F]-2-deoxy-2-fluoro-D-glucose (^{18}FDG). In all experimental conditions, the sighted subjects were blindfolded. Each subject was involved in a tactile or in an auditory task during a PET study. The tactile task consisted either in silent braille reading or in manipulation of objects; the ears were plugged. The auditory task consisted in the mental localization of a sound source. The subjects remained seated during all these tasks. Furthermore, two blind and one control subjects took part in a second PET study performed in the resting state with the ears plugged. For each PET study, nine slices were collected at 10 mm interval, parallel to, and starting 20 mm above the suborbito-meatal plane. Neuroanatomic localization was performed by matching PET images with Magnetic Resonance Imaging (MRI) data obtained in the same planes, and by reference to a brain atlas. Relative rCMRGlc were calculated as the percentage of mean gray matter glucose metabolism defined over all gray structures in the forebrain.

MRI examinations revealed that the striate and prestriate cortices had a similar, normal appearance in blind as well as in normal subjects. In four PET studies of early blind volunteers performing auditory or tactile tasks, the maximal rCMRGlc was consistently found in striate or prestriate regions, irrespective of the type of task. When performing the same task, the relative rCMRGlc in the striate and prestriate cortices were always higher for the early blind subjects than for the blindfolded control subjects. In order to assess whether the high metabolic activity of the Blind's occipital cortex was induced by the task, two blind subjects were also studied in the resting state. As a result, rCMRGlc measured in striate and prestriate areas at rest or during tactile or auditory stimulation were just so high. A quantitative evaluation revealed that the relative rCMRGlc in the striate and prestriate cortices were significantly higher in the blind subjects than in the blindfolded sighted ones.

CARDIOVASCULAR REGULATION: CNS PATHWAYS V

345.1 SPECIFICITY OF CONNECTIONS IN BRAIN STEM RETICULAR FORMATION: SYMPATHETIC CIRCUITS.

G.L. Gebber, S.M. Barman and S.F. Morrison. Depts. of Pharmacol. and Physiol., Michigan State Univ., East Lansing, MI 48824.

A critical question concerning the organization of the brain stem reticular formation is whether its plan of connectivity is specific or nonspecific. The classic view is one of indiscriminate interconnnection of reticular neurons with axons directed to different targets. In this case, the reticular formation would exert uniform actions on all of its outputs under all conditions. An alternative view is that the plan of connectivity is highly ordered so that the discharges of reticular neurons with the same target are preferentially synchronized. In this case, the reticular formation would be comprised of a number of functionally distinct modules. The current study was designed to test these alternative views.

Crosscorrelation analysis was used to determine whether the discharges of adjacent neurons in the cat brain stem were synchronized on a time scale of a few milliseconds. Unit recordings were made in three regions of the brain stem reticular formation - lateral tegmental field (LTF) of dorsal medulla, rostral ventrolateral medulla (RVLM) and raphe (R) of medulla. Unit recordings also were made in the lateral hypothalamus (LH), a region whose architectonic design is similar to that of the LTF. Neuronal pairs were chosen so that at least one member had spontaneous activity temporally related to inferior cardiac postganglionic sympathetic nerve discharge (as demonstrated with spike-triggered averaging). When both members of a pair had sympathetic nerve-related activity, the pair was designated S-S. When only one member had sympathetic nerve-related activity, the pair was designated S-NS. Short time scale (a few milliseconds) interactions were demonstrated for 58, 65, 25 and 69% of S-S pairs in the LTF, RVLM, R and LH, respectively. The crosscorrelograms for these neuronal pairs contained either a sharp paracentral peak or a pericentral peak. The percentages of S-NS pairs showing short time scale interactions were considerably lower than for S-S pairs. They were 36, 17, 0 and 38% for S-NS pairs in the LTF, RVLM, R and LH, respectively. The data clearly point to a specific rather than a nonspecific plan of connectivity among the neurons in the regions studied. That is, our results support the view that the medullary reticular formation and LH are organized into functionally distinct modules, some of which direct their influences to sympathetic nerves. Short time scale synchronization of the discharges of members of some S-NS pairs may reflect weak coupling between sympathetic and nonsympathetic modules. The predominance of short time scale interactions for S-S pairs, however, clearly indicates that intramodular coupling was stronger than intermodular coupling under the conditions of our experiments. (Supported by HL13187 and HL33266.)

345.2 RAPHESPINAL SYMPATHOINHIBITORY NEURONS EMIT BRANCHES IN THE CERVICAL SPINAL CORD IN CATS.

Susan M. Barman and Gerard L. Gebber. Depts. Pharmacol./Physiol., Mich. St. Univ., E. Lansing, MI 48824.

Morrison and Gebber (J. Neurophysiol. 53: 759-772, 1985) and Barman and Gebber (J. Neurophysiol. 53: 1551-1566, 1985) characterized cat raphe (R) and rostral ventrolateral medullary (VLM) neurons in sympathetic pathways. Spike-triggered averaging showed that the spontaneous activity of these neurons is temporally related to inferior cardiac postganglionic sympathetic nerve discharge (SND). Antidromic mapping of the upper thoracic spinal cord revealed that the axons of these neurons innervate the intermediolateral nucleus (IML). Since the firing rate of the R-spinal neurons increased during baroreceptor reflex activation, they likely subserve a sympathoinhibitory function. VLM-spinal neurons are considered to be sympathoexcitatory since their firing rate decreased during baroreceptor reflex activation. The current investigation was designed to test the hypothesis that the axons of R- and VLM-spinal sympathetic neurons emit branches in the cervical spinal cord. This hypothesis was considered since the studies of Kirchner et al. (Pfluegers Archiv. 357: 349-360, 1975) and Schramm and Livingston (Am. J. Physiol. 252: R514-R525, 1987) support the existence of cervical propriospinal neurons in sympathetic pathways. Such neurons may receive input from the same groups of medullospinal neurons that project directly to the thoracic IML. We microstimulated the third thoracic (T3) IML to antidromically activate 47 R-spinal sympathoinhibitory neurons and 15 VLM-spinal sympathoexcitatory neurons neurons in 22 cats. A second stimulating microelectrode was positioned in the gray matter of the cervical spinal cord (C3-C5). When a neuron was antidromically activated from both sites, we used a collision test to determine whether stimuli applied at C3-C5 activated an axonal branch or the main axon by current spread to the white matter. Specifically, we determined the maximum interval after a C3-C5 stimulus at which a T3 stimulus failed to elicit an antidromic response at the recording site. If the main axon is activated by C3-C5 stimulus, this collision interval (CI) equals the difference between the onset latencies of the antidromic responses elicited by thoracic and cervical stimuli ($L_T - L_C$) plus the axonal refractory period at the thoracic site (R_T); $CI = L_T - L_T + R_T$. When a cervical axonal branch is activated, $CI > L_T - L_C + R_T$. Conduction time in the axonal branch (t_B) = $1/2(CI - L_T + L_C - R_T)$. None of the 15 VLM neurons antidromically activated by stimulation of both C3-C5 and T3 IML emitted a branch in the cervical region. In contrast, stimulation of the C3-C5 gray matter activated an axonal branch of 12 of 47 R-spinal neurons. Conduction time in the axonal branch averaged 8.2±2.0 ms. The conduction velocity in the main axons of these R-spinal neurons averaged 2.9±0.4 m/s. Antidromic mapping revealed that the longest latency antidromic response was elicited with the least stimulus current when the microelectrode was positioned in lamina VII. It remains to be determined whether these cervical branches of R-spinal neurons innervate descending propriospinal neurons in sympathetic pathways. If so, R neurons may control SND by both an indirect and direct projection to the IML. (Supported by NIH grants HL13187 and HL33266.)

345.3 MIDLINE MEDULLA MEDIATES TONIC SYMPATHOINHIBITION AT THE LEVEL OF THE ROSTRAL VENTROLATERAL MEDULLA. Robert B. McCall. Cardiovascular Diseases Research, The Upjohn Company, Kalamazoo, MI. 49001.

Previous studies in our laboratory indicate that the midline medulla is heterogenous with respect to autonomic function containing both sympathoexcitatory and sympathoinhibitory elements. Sympathoexcitatory responses elicited by stimulation of the midline medulla are mediated by serotonin, while sympathoinhibitory responses are mediated by GABA. The purpose of the present study was to further characterize the nature of the sympathoinhibition elicited by stimulation of the midline medulla. Lesions of the midline medulla extending 2 to 7 mm rostral to the obex significantly increased inferior cardiac spontaneous sympathetic nerve discharge (SND) by 54± 11% in chloralose anesthetized cats (n=25). Lesions failed to affect baroreceptor-mediated inhibition of sympathetic activity. These data indicate that neuronal elements in the midline medulla tonically inhibit SND by a non-baroreceptor mechanism. The effects of midline stimulation on the discharge of sympathetic neurons in the rostral ventrolateral medulla were determined in order to test the hypothesis that the tonic sympathoinhibition was mediated at the level of sympathoexcitatory medullospinal neurons located in this area of the brain stem. Neurons in the rostral ventrolateral medulla were recorded extracellularly and classified as sympathoexcitatory if 1) they could be antidromically activated from the spinal cord, 2) they were inhibited during baroreceptor reflex activation and 3) their discharge was temporally correlated to SND. Electrical stimulation of the midline medulla (100 μA, 0.5 ms; 0.5 Hz) inhibited the discharges of sympathoexcitatory neurons in the rostral ventrolateral medulla. The mean onset latency of inhibition was 22 ms and the mean duration of inhibition was 175 ms. The onset of the raphe elicited sympathoinhibitory response recorded from the inferior cardiac nerve was equal to the sum of the onset latency of the sympathoexcitatory response elicited from the rostral ventrolateral medulla (76 ms) plus the conduction time (22 ms) in the raphe to rostral ventrolateral sympathoinhibitory pathway. A second group of neurons located in the immediate vicinity of the sympathoexcitatory neurons were excited by single shocks applied to the midline medulla. The onset latency of activation of these neurons ranged from 12 to 32 ms. These neurons fired spontaneously with a bursting pattern of discharge, were not affected during baroreceptor reflex activation and did not fire with a pattern that was obviously related to SND. Finally, bilateral microinjections of the GABA antagonist picrotoxin into the rostral ventrolateral medulla increased SND to an amount comparable to that observed following midline lesions. Baroreceptor inhibition of SND was not affected by the microinjection. These data are consistent with the possibility that non-baroreceptor neuronal elements in the midline medulla tonically inhibit sympathoexcitatory medullospinal neurons in the rostral ventrolateral medulla by activating closely adjacent GABAergic interneurons.

345.4 Non-adrenergic pace-maker neurons of rat rostral ventrolateral medulla. Miao-Kun Sun, John T. Hackett and Patrice G. Guyenet. Dept. Pharmacology, University of Virginia, Charlottesville, VA 22908.

Coronal slices of the rat rostral ventrolateral medulla (Sprague-Dawley, 100g) maintained "in vitro" (500 μm thick, interface method, temperature 31° or 37°C) were explored to characterize the properties of tonically active neurons. The majority of the latter consisted of cells with non-bursting rhythmic discharges (9 ± 0.3 spikes/sec N=84 at 31°C; 21.3 ± 2 spikes/sec, N=9 at 37°C) and positive going extracellular spikes. Stable intracellular recordings were obtained in 30 cases. All these cells displayed a typical pace-maker potential decreasing from -63 ± 0.2mV (N=18) after each action potential to -49 ± 1.1 mV (N=18) representing threshold for spike initiation. EPSP's were not detected even during negative current injection which resulted in a 10 ± 5 mV (N=15) hyperpolarization and complete silencing of the cell. Current-voltage relationship indicated a mean apparent resistance of 138 ± 10 MΩ (N=18) when measured around -60mV. Lucifer Yellow was iontophoresed into 15 pace-maker cells with resting potentials of -53mV or better and the tissue was processed for PNMT-immunohistochemistry (Texas-red labelled secondary AB). Ten cells were recovered in 40 μm sections, none of which contained PNMT-immunoreactivity. All ten cells were surrounded by adrenergic cells and were located in the retrofacial portion of nucleus paragigantocellularis lateralis (PGCL). Cells with similar characteristics were also extracellularly recorded within retrofacial PGCL in an "in vitro" preparation consisting of the entire medulla plus C_1 spinal segment (vascularly perfused through basilar artery, 31°C). Twenty-three neurons with pace-maker like discharges were recorded in this area (8 ± 2 s/sec mean firing rate). In four cases, the presence of a spinal axon could be detected. The rhythmic firing pattern of these neurons could be reset by orthodromic activation produced by focal stimulation of the caudal ventrolateral medulla. The rhythmic firing pattern of these cells was unaffected by 0.5-1mM of the glutamate-receptor antagonist kynurenic acid in the medium. This drug, however, completely abolished the excitatory effect produced by focal stimulation (N=6).

It is concluded that the rostral ventrolateral "pressor" area contains non-adrenergic pace-maker reticulospinal neurons. (HL 28785).

345.5 Sympathoexcitatory reticulospinal neurons of rostral ventrolateral medulla have intrinsic pace-maker properties. P.G. Guyenet and M.-K. Sun. University of Virginia, Dept. of Pharmacology, Charlottesville, VA.

The preceeding abstract described the presence of reticulospinal non-adrenergic pace-maker neurons in the retrofacial portion of nuc paragigantocellularis lateralis "in vitro" (PGCL, so called "ventrolateral medulla pressor" or "C_1" area). The aim of this second study is to provide evidence that these pace-maker neurons represent the reticulospinal sympathoexcitatory neurons previously recorded by us "in vivo" in the same brain area (PGCL-SE neurons, see Brown & Guyenet 1985, Circ. Res. 56: 359).

Single-unit recordings of PGCL-SE neurons were obtained in halothane-anesthetized 350 g Sprague-Dawley rats ventilated with room air. The lumbar sympathetic discharge (LSND) was recorded with bipolar electrodes (30-3000 Hz), full wave rectified, integrated and quantified with a 1 sec reset-time. The following sympathetic reflexes were investigated; baroreflex, vagal inhibitory and sympathoexcitatory responses, somatosympathetic reflexes, mixed excitatory-inhibitory responses produced by lateral hypothalamus stimulation.

Intracisternal injection of the glutamate-receptor antagonist kynurenic acid (KYN, 5 μmole) produced a sustained increase in AP and LSND provided that access of the drug to the spinal cord was minimized by head-down tilt. Under these conditions all sympathetic reflexes were abolished (N= 5-10) except somatosympathetic reflexes (75% reduction only, N=5). The inactive analog 8-OH kynurenic acid produced no effect. Following KYN, the discharge rate of PGCL-SE neurons stabilized around 22 spikes/second (N=22;SEM 1.6) and the cells became insensitive to arterial pressure. KYN had no effect on action potential size and configuration. After KYN the discharge rate of PGCL-SE neurons became extremely regular and pace-maker like. Antidromic activation by stimulating their spinal axon at T_3-T_4 resetted their rhythmic discharge (N=8) except when the spinal stimulus was triggered within the critical latency for collision extinction. When cord stimulation was delivered at random with regard to spontaneous spikes and below threshold for antidromic activation post-stimulus spike histograms were uniformly flat (N=8). Thus, after synaptic blockade with KYN, PGCL-SE neurons are the only tonically active cells of the rostral ventrolateral medulla and display a firing rate characteristic of pace-maker neurons which cannot be explained by the activity of recurrent or collateral networks. Since the spike configuration, location, discharge rate of PGCL-SE neurons after KYN is identical to that of the pace-maker cells recorded "in vitro", we conclude that they belong to the same non-adrenergic cell population. (HL 28785).

345.6 PARABRACHIAL STIMULATION INHIBITS CAROTID SINUS AFFERENT INPUT TO NUCLEUS TRACTUS SOLITARIUS. R.B. Felder, S.W. Mifflin* (SPON: E.A. Anderson). Cardiovascular Center, Department of Internal Medicine, University of Iowa, Iowa City, IA 52242.

The parabrachial nucleus (PBN) is a major projection nucleus for efferent neurons leaving nucleus tractus solitarius (NTS), the termination site for primary afferent fibers innervating reflexogenic areas of the circulation. We recently reported excitation of single neurons recorded extracellularly in and around NTS by electrical stimulation of PBN and ipsilateral or contralateral carotid sinus nerve (CSN), and demonstrated a potent inhibitory influence of the PBN stimulus on CSN input to the same neuron whether evoked by electrical or selective baroreceptor stimulation. The reciprocol interaction, though less pronounced, was also observed. In the present studies, we utilized intracellular recording techniques to further investigate the mechanisms underlying these inhibitory interactions.

In chloralose anesthetized, mechanically ventilated and paralyzed cats, we recorded in right NTS region from 37 neurons, which responded to electrical stimulation of both ipsilateral CSN and PBN. CSN stimulation evoked an EPSP in 19 units, an EPSP/IPSP in 14, and an IPSP in 4. The latency ranges for these PSPs were 3.5-26.4 msec, 3.1-10.0 msec and 10.9-15.3 msec, respectively. In these 37 cells the PBN stimulus (50-300 μA, 1-4 pulses) uniformly evoked an IPSP, which ranged in amplitude from 2.1 to 5.8 mV (mean 3.3±0.2 mV, x̄±SE) and in duration from 65 to 270 msec (mean 160±9 msec). The IPSP was reversed using negative DC current injection in 5 units. In 29 of the 37 cells the PBN evoked IPSP was preceded by an EPSP (onset latency 2.3-29.6 msec, < 5 msec in 16 cells). The latency of the PBN evoked EPSP was less than the CSN evoked PSP in 20 of 29 neurons. When CSN stimulation was preceded by PBN stimulation at a 50 to 70 msec interval (n=12), the CSN evoked PSP (EPSP or IPSP) was reduced in amplitude. In 5 cells tested, inhibition of the CSN PSP lasted for the duration of the PBN evoked IPSP. In contrast, the PBN evoked EPSP was inhibited by a prior CSN stimulus for intervals up to 150 msec with no change in membrane potential in 3 of 6 cells tested.

These findings demonstrate that parabrachial stimulation causes an early excitation followed by prolonged post-synaptic inhibition of NTS neurons also activated by CSN stimulation. This suggests a potential role for PBN in enhancing or inhibiting the responses of NTS neurons to sinus nerve input.

345.7 TIME DEPENDENT INHIBITORY INTERACTIONS BETWEEN CAROTID SINUS NERVE (CSN) AFFERENT INPUTS TO NUCLEUS TRACTUS SOLITARIUS (NTS).
S.W. Mifflin* and R.B. Felder (SPON: C.V. Gisolfi).
Cardiovascular Center, Dept. of Internal Medicine, Univ. of Iowa, Iowa City, IA 52242.

Previous studies have demonstrated inhibitory interactions between carotid sinus baro- and chemoreflexes and between ipsilaterally and contralaterally evoked carotid sinus baroreflexes. An earlier report from this laboratory demonstrated time dependent inhibitory interactions between CSN afferent inputs which independently excited neurons in NTS, the primary site of termination of CSN afferent fibers. Using a conditioning test paradigm, we electrically stimulated the CSNs to examine the mechanism for this phenomenon.

Intracellular recordings were made from cells in the NTS region in chloralose anesthetized, mechanically ventilated, paralyzed cats. Electrical stimulation of ipsilateral CSN evoked an epsp in 20 cells, an epsp/ipsp in 16 cells and an ipsp in 13 cells. In all cells, the CSN evoked psp was abolished or reduced in amplitude and duration by a conditioning stimulus consisting of a single pulse or train of pulses (2-5 at 200-500 Hz) to the same nerve at intervals of 50-70 msec. The inhibition could be graded by varying the number of conditioning stimuli and persisted for 150-450 msec in 19 cells tested. In cells receiving convergent input from both CSNs, the epsp (5 of 7 cells tested), epsp/ipsp (5 of 5), or ipsp (5 of 5) evoked by ipsilateral CSN was inhibited by conditioning stimuli to the opposite CSN. Similar inhibition was noted when the order for stimulating the two nerves was reversed. The inhibition occurred in the absence of changes in membrane potential or input resistance and persisted beyond the duration of CSN evoked ipsps (cells receiving an epsp/ipsp or an ipsp). These observations suggest distal dendritic inhibition and/or disfacilitation (epsps) or disinhibition (ipsps) as potential mechanisms for this phenomenon.

We conclude that the temporal pattern of converging inputs may profoundly influence cardiovascular afferent integration at NTS level.

345.8 POTASSIUM CURRENTS IN NEURONS ISOLATED FROM ADULT RAT SOLITARY TRACT NUCLEI INVOLVED IN CARDIOVASCULAR CONTROL
J.P. Moak* and D.L. Kunze, Department of Pediatrics* and Department of Physiology and Molecular Biophysics, Baylor College of Medicine, Houston, TX 77030.

Cardiovascular afferent fibers terminate in the the medial and dorsal medial nuclei of the solitary tract. A group of morphologically similar neurons from these nuclei has been enzymatically isolated for the purpose of characterization of the ionic currents which are responsible for their spontaneous activity and response to putative transmitters. A TTX sensitive sodium current and a calcium current with two distinct components have already been identified in all cells studied in this group (Kunze, D.L., AJP, 252:H867,1987). The present study examined the potassium currents in these cells. The gigaseal technique for whole cell recording was used for a voltage clamp analysis. To isolate potassium currents a bathing solution containing in mM 137 NaCl, 5.4 KCl, 1 $MgCl_2$, 10 Glucose, 10 Hepes, 10-5 TTX and 2x10-6 $CaCl_2$ was used. The pipette contained 140mM KAsp, 10mM Hepes, 5mM EGTA and 3 mM $MgCl_2$. Under these conditions an outwardly rectifying potassium current was present in all cells. This current was present at potentials more positive than -40mV, was slowly developing (20msec) and noninactivating during a 250msec depolarizing pulse. A transiently activated potassium current was also present in approximately 40% of the cells studied. When present it was seen with depolarizing steps to potentials positive to -40mV, it activated rapidly (<5 msec) and its inactivation was voltage dependent. It was inactivated at holding potentials more positive than -50mV. Of the ionic currents studied thus far, only this transient potassium current has been restricted to a subpopulation of cells from these nuclei. An inwardly rectifying potassium current was not present in any of the cells studied. These results will serve as a basis for examining the role of putative transmitters in modifying potassium currents and for interpreting the mechanism of spontaneous activity in this group of neurons.

345.9 MECHANISMS OF CARDIOVASCULAR AND ANTINOCICEPTIVE ACTIONS OF INTRATHECAL CLONIDINE.
R.E. Solomon, M.J. Brody and G.F. Gebhart.
Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242.

The α_2-adrenoceptor agonist clonidine produces antinociceptive effects following systemic or central administration and complex effects on blood pressure, including a transient pressor response followed by a prolonged depressor effect after bolus systemic administration, and depressor (at lesser doses) or pressor (at greater doses) effects after central administration. The present study was designed to characterize these effects of clonidine upon its intrathecal (i.t.) administration to the level of the lumbar enlargement. Rats were initially deeply anesthetized with pentobarbital (45 mg/kg i.p.) for placement of femoral arterial and venous and 7.5-8 cm i.t. catheters. Under light pentobarbital anesthesia (3-6 mg/kg/hr i.v.), the nociceptive tail-flick (TF) reflex was evoked by radiant heating of the tail. Mean arterial pressure (MAP) and heart rate (HR) were continuously recorded, and TF latencies were determined at 1-60 min after i.t. administration of single doses of clonidine (1-32 µg/7.5 µl). The effects of i.t. clonidine on MAP were also determined in conscious, freely-behaving rats. In both lightly anesthetized and conscious rats, lesser doses of clonidine (1-3.2 µg) decreased MAP, while greater doses (10-32 µg) produced marked pressor effects. In lightly anesthetized rats, antinociceptive and depressor effects produced by 3.2 µg clonidine were significantly attenuated by pretreatment with the α_2-adrenoceptor antagonist yohimbine (30 µg i.t.) but not by the α_1-adrenoceptor antagonist prazosin (30 µg i.t.) or by i.v. yohimbine (0.1 mg/kg). Thus, these effects of i.t. clonidine are mediated by spinal α_2-adrenoceptors. In contrast, the cardiovascular effects of the greatest dose of i.t. clonidine (32 µg; maximal ↑ in MAP of 53.3±3.3 mm Hg within 5 min, maximal ↓ in HR of -72±8 bpm) were similar to those effects observed upon injection of this dose either i.v., or i.t. to the cervical level, and were not significantly altered by pretreatment with yohimbine (30 µg i.t. or 0.1 mg/kg i.v.), prazosin (30 µg i.t. or 0.1 mg/kg i.v.) or the vasopressin antagonist [1-(β-mercapto-β,β-cyclopentamethylene propionic acid), 2-(o-methyl) tyrosine] Arg^8-vasopressin (10 µg/kg i.v.), nor by adrenal demedullation. The ganglionic blocking agent chlorisondamine (2.5 mg/kg i.v.) significantly attenuated the bradycardia, but potentiated the pressor response, whereas the non-selective α-adrenoceptor antagonist phentolamine (2 mg/kg i.v.) abolished the pressor response but had no significant effect on the bradycardia. Thus, the pressor effects of i.t. clonidine are not mediated by activation of spinal α-adrenoceptors or spinal sympathetic preganglionic neurons. Rather, these effects appear to result from activation of peripheral α-adrenoceptors, suggesting a rapid systemic redistribution of large doses of i.t. clonidine. Supported by T32 GM 07069 and DA 02879.

345.10 **TONIC CONTROL OF ARTERIAL PRESSURE AND REGIONAL HEMODYNAMICS BY PONTINE REGIONS.**
B. F. Cox and M. J. Brody. Dept. of Pharmacol. and Cardiovascular Center, Univ. of Iowa, Iowa City IA. 52242.

We have previously reported on the role of the rostral ventrolateral medulla (RVLM) in the maintenance of vasomotor tone in rats. In earlier studies, the microinjection of lidocaine (LIDO) into the lateral aspect of the RVLM resulted in a depressor response and a fall in resistance in the renal, mesenteric, and hindquarter vascular beds. Reduction of tidal volume (TV) from 2.5cc to 1.5cc resulted in an attenuation of the depressor response and the fall in resistance in the three vascular beds. However, under conditions of reduced TV, the level of sympathetic nerve activity remained the same or was slightly elevated. Thus, some other region must assume the role of maintaining vasomotor tone under conditions of reduced TV.

In this study, we examined the role of pontine sites in the tonic control of vasomotor tone. 200nl of a 4% solution of LIDO was microinjected into the pons at the level of the Kolliker-Fuse nucleus (KFN). These injections were made 0.9 and 2.5mm lateral to midline and 6,7,8 and 9mm below dura. For reference, the injection 2.5mm lateral to midline and 7mm below dura centered on the KFN nucleus. First, the inactivation of the region 2.5mm lateral to midline and 6mm below dura resulted in an insignificant (-4±7mmHg) fall in arterial pressure when the animal was respired at a 2.5cc TV. A significant depressor response to LIDO was seen when TV was reduced to 1.5cc (-14±3mmHg). Resistance was lower in each vascular bed. No significant effects were noted with LIDO injection at the site 0.9mm lateral to midline. The injection of LIDO into the site 2.5mm lateral to midline and 7mm below dura (i.e. in KFN) resulted in a depressor effect at 2.5cc (-14±4mmHg) and at 1.5cc (-14±4mmHg) TVs. These effects were mediated primarily by a fall in hindquarter vascular resistance. Injection of LIDO 0.9mm lateral to midline (in the region of the ventral tegmental nucleus) resulted in a slight increase in arterial pressure at both TVs. Injection of LIDO into the region 1mm below KFN yielded similar results. At the lateral site, depressor responses were seen at both the 2.5 and 1.5cc TVs (-17±4 and -13±3mmHg respectively). Again, these effects were mediated primarily by a fall in resistance in the hindquarter vascular bed. LIDO in the medial site produced a pressor response at both the 2.5 and 1.5cc TVs (14±4 and 14±4mmHg respectively). These increases in arterial pressure were mediated by an increase in resistance in all three vascular beds. Injection of LIDO 9mm below dura (most rostral pole of the A_5 region) had no significant effect on arterial pressure regardless of site or TV. This work illustrates a role for supra-medullary cell bodies or fibers of passage in the tonic control of vasomotor tone. (Supported by HLB-14388 and GM-07069.)

345.11 SPINAL CORD ADMINISTRATION OF A THYROTROPIN-RELEASING HORMONE (TRH) ANALOG, MK-771, INCREASES SYMPATHETIC OUTFLOW TO THE CARDIOVASCULAR SYSTEM. C.J. Helke and E.T. Phillips*, Dept. of Pharmacology Uniformed Services Univ. of the Health Sciences, Bethesda, MD 20814.

TRH increased mean arterial pressure (MAP) and sympathetic activity when administered into the brain ventricles (J. Pharmacol. Exp. Ther. 238:232, 1986), however sympathetically mediated spinal cord actions of TRH have not been investigated. This is of interest because TRH binding sites and TRH-immunoreactive nerve terminals are present in the intermediolateral cell column (IML), the origin of sympathetic preganglionic neurons. Recent studies showed that the TRH innervation of the IML arises from a region in the ventral medulla (Brain Res. 381:1, 1986) which plays an important role in regulating sympathetic activity to the cardiovascular system. We studied the effects of intrathecal (i.t.) administration of the stable TRH analog, MK-771, on mean arterial blood pressure (MAP) and heart rate (HR) in chloralose/urethane anesthetized, artificially ventilated rats. MK-771 (0.01-5.0 µg i.t.) caused dose-related increases in MAP and HR. A 1 µg dose of MK-771 increased MAP 33±5 mmHg and HR 80±21 bpm. The onset of action was rapid and the peak response occurred 5-10 min after administration. Similar doses of MK-771 administered i.v. were without effect. TRH (i.t.) produced cardiovascular effects similar to those seen with MK-771 but was less potent. TRH-free acid produced no cardiovascular effects in doses up to 1000 µg (i.t.) That the MK-771 effects were due to activiation of the sympathetic nervous system was shown by blockade of the MAP effects of MK-771 (5 µg i.t.) with phentolamine (10 mg/kg i.v.) and both MAP and HR effects with pentolinium (10 mg/kg i.v.). Assessment of changes in regional blood flow and vascular resistance caused by MK-771 (1 µg i.t.) were done with the radioactive microsphere technique. MK-771 increased total peripheral resistance due to vasoconstriction in cutaneous, skeletal muscle, and renal vascular beds. MK-771 had no effect on vascular resistance locally, in the spinal cord region of the i.t. injection. Cardiac output was also unchanged by MK-771 (1 µg i.t.).

These data show that TRH receptor activation in the thoracic spinal cord, presumably in the IML, increases sympathetic activity to the peripheral vasculature. Assessment of the role of TRH-innervation of the IML on maintenance of sympathetic tone to the vasculature awaits development of TRH receptor antagonists. (Supported by NIH grant #NS24876).

OPIATES, ENDORPHINS AND ENKEPHALINS: ANATOMY AND CHEMISTRY II

346.1 IDENTIFICATION OF PRO-DYNORPHIN HIGH MOLECULAR WEIGHT INTERMEDIATES IN THE RAT ANTERIOR PITUITARY. R. Day* and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan, 48109.

The post-translational processing of pro-dynorphin (Pro-DYN) is not well understood. The anterior pituitary is an interesting tissue to examine this question since it is well known that dynorphin-immunoreactivity (DYN-ir) is contained in high molecular weight intermediates and not as free products such as DYN A 1-17 (1). A 6 Kd product containing DYN A and DYN B was identified as well as an 8 Kd product containing alpha-neo-endorphin (α-NE). The aim of this study is to fully characterize these products with the aid of a series of antibodies directed to various regions of Pro-DYN including non-opioid regions. These included antibodies to DYN A 1-17, DYN B, α-NE, Bridge peptide (the amino acid sequence between α-NE and DYN A), C-peptide (the carboxyl terminal region of Pro-DYN), and Pro-DYN mid-amino terminal peptide (an 11 amino acid sequence midway between the amino terminal of Pro-DYN and α-NE). Rat anterior pituitary extracts were submitted to G-50 gel filtration chromatography. Fractions were analyzed by radioimmunoassay. Various fractions were pooled and submitted to HPLC analysis. Also immunoaffinity columns were used to complement the above information. Four major products containing Dyn A-ir were observed with MWs ranging from 4 Kd to 9 Kd. Two of these products contained C-peptide-ir while the other two contained only DYN B-ir. Furthermore two high MW α-NE-ir products were observed with respective masses of 16 Kd and 4 Kd. The 16 Kd molecule was also immunoreactive for Pro-DYN mid-amino terminal peptide. Based on these data we conclude that Pro-DYN post-translational processing in the anterior pituitary can occur by multiple pathways. A scheme for the processing of Pro-DYN will be proposed.

346.2 DEVELOPMENTAL CHANGES IN STEADY STATE LEVELS OF FORMS OF PRO-DYNORPHIN IN THE RAT SUBSTANTIA NIGRA. C.A. Sei and R.M. Dores, Department of Biological Sciences, University of Denver, Denver, CO 80208.

In the rat brain the substantia nigra is a rich terminal field area for the pro-dynorphin end products: dynorphin A, dynorphin B, and alpha-neo-endorphin. Although there have been extensive studies on the pro-dynorphin system in the substantia nigra of the adult rat, there is relatively little information on the forms of pro-dynorphin end products in this terminal field during post-natal development. In this study the steady state levels of pro-dynorphin end products were analyzed in the substantia nigra of post-natal day 0, post-natal day 7, and adult animals.

Acid extracts of pools of tissue were separately fractionated by gel filtration chromatography on a Sephadex G-50 column and analyzed with radioimmunoassays specific for dynorphin A(1-17) and dynorphin A(1-8). The identity of each immunoreactive peak was confirmed by reverse phase HPLC analysis. In the adult substantia nigra the molar ratio of dynorphin A(1-17) to dynorphin A(1-8) is approximately 1:15. However, at post-natal day 0 the molar ratio of these forms in the substantia nigra is approximately 0.6:1. By post-natal day 7 the adult ratio of dynorphin A(1-17) to dynorphin A(1-8) has been reached. These observations for the substantia nigra are in contrast to the ontogeny of the pro-dynorphin system in the posterior pituitary as reported by Seizinger et al. (Neuroendocrinology, 39: 414-422, 1984). In the latter terminal field the adult molar ratio of dynorphin A-related products is not reached until post-natal day 21.

Experiments are currently in progress to determine the steady state levels of pro-dynorphin end products at pre-natal time points. Additionally, a parallel study is being conducted on pro-dynorphin products in the striatum. This research was supported by NIMH Grant MH41000 and BRSG Grant RR07138 from the NIH.

346.3 PHOSPHORYLATION OF PROENKEPHALIN-DERIVED PEPTIDES. N.B.D' Souza* and I. Lindberg, Dept. of Biochemistry and Molecular Biology, L.S.U. Medical Center, New Orleans, LA 70112

The opioid peptide precursor proopiomelanocortin has been shown to undergo several biologically important posttranslational modifications during processing, such as phosphorylation, glycosylation, acetylation, and amidation. We are currently studying the biosynthesis of peptides derived from another opioid peptide precursor, proenkephalin. In an effort to determine whether similar post-translational modifications occur within the proenkephalin system, we have investigated the phosphorylation of proenkephalin-derived peptides in bovine adrenal medulla.

Cultured chromaffin cells were incubated with (^{32}P)orthophosphate for 24 h. Cells were then washed and extracted with acid. The acid extract was dried, resuspended in buffer, and centrifuged. Labelled peptides were immunoprecipitated from the supernatant using antiserum to Peptide B (the carboxyl terminal fragment of proenkephalin) and subjected to SDS polyacrylamide electrophoresis in a 15% gel. Two labelled bands of M_r 30 kDa (minor) and 4-6 kDa (major) were observed following autoradiography. Thin layer electrophoresis of the hydrolysis products of labelled peptides (immunoprecipitated and then size-fractionated) demonstrated the presence of labelled phosphoserine rather than phosphotyrosine or phosphothreonine.

We have also analyzed size-fractionated extracts of bovine adrenal medulla using thin layer isoelectric focusing (IEF; pH range 2.5-5.0) in order to detect possible charge differences in endogenous Peptide B-immunoreactive peptides. More than half of total Peptide B-ir peptides were present as more acidic species than Peptide B. Treatment of the adrenal extract with alkaline phosphatase prior to IEF resulted in a shift of immunoreactivity of more acidic to less acidic immunoreactive peptides. Multiple peaks of immunoreactive Peptide B were also observed following HPLC of size-fractionated medullary extracts.

Taken together, the above results provide strong evidence that proenkephalin is phosphorylated at serine residue(s) within its carboxyl terminal portion, Peptide B. Given the importance of phosphorylation as a regulatory event in a large number of biochemical processes, it will be extremely interesting to investigate the control of the phosphorylation of this opioid peptide precursor. (Supported by DK 35199)

346.4 RAT ADRENAL MEDULLARY ENKEPHALINS AND mRNA ARE INCREASED BY DEXAMETHASONE. C.E. Inturrisi, R.D. Howells, S.O. Franklin*, J.R. Shapiro*, S.E. Calvano* and B.C. Yoburn. Dept. of Pharmacology, Cornell Univ. Med. Coll., New York, NY 10021.

The rat adrenal medulla contains low levels of enkephalin-containing (EC) peptides. However, if depolarizing influences are removed by surgical or pharmacological denervation or by culturing medullary explants, there is a dramatic increase in prepro-enkephalin mRNA and EC peptide biosynthesis. In a previous study (Yoburn et al., Life Sci. in press 1987) we found that the denervation-induced rise in rat adrenal medullary EC peptides is blocked by hypophysectomy and partially reinstated by corticosterone, dexamethasone or ACTH treatment. We now report the effect of dexamethasone on EC peptides and preproenkephalin mRNA in adrenal medullary explants (glands) from sham and hypophysectomized (hypox) rats. Culture for 4 days in serum-free medium without dexamethasone resulted in a 13 and 4-fold increase in EC peptide levels in sham and hypox glands, respectively. The addition of dexamethasone (10^{-5}M) produced a 20-26 fold increase in EC peptides in sham and hypox glands to approximately 9 pmole/gland. In serum free medium, hypox glands show a concentration dependent increase in EC peptides with the ED50 for dexamethasone equal to 5.7×10^{-7}M. Since the glucocorticoid antagonist RU486 partially blocked the rise in EC peptides in sham glands, it appears that the increase in EC peptides in sham glands in the absence of dexamethasone is a result of the higher concentration of endogenous corticosterone in sham (27 ng/gld) compared to hypox glands (0.2 ng/gld). Dexamethasone results in an increase in preproenkephalin mRNA in hypox glands after 2 days in culture that is approximately proportional to the increase in EC peptides seen at 4 days. In serum free medium progesterone, testosterone and the mineralcorticoid, deoxycorticosterone failed to increase EC peptides. Enzymatic digestion (trypsin and carboxypeptidase B) and size exclusion chromatography of the extracts from rat adrenal medullary explants indicate that a high molecular weight (18,000) peptide with a (Met)/(Leu)-enkephalin ratio of approximately 6 (i.e., proenkephalin) is the major component of the glucocorticoid-induced increase in EC peptides. These results indicate that a loss of depolarizing stimuli initiates a pretranslational event wich requires glucocorticoid for proenkephalin gene expression and EC peptide biosynthesis. The physiological response of the adrenal medulla to stress includes increases in both transsynaptic impulse activity and glucocorticoid levels. The recognition that both of these factors are capable of regulating EC peptides adds significantly to our understanding of the physiological response to stress and may point the way to the sites of action and therapeutic utility of EC peptides. Supported in part by NIDA Grant DA-01457 and NIGMS Grant GM-34021.

346.5 LOCALIZATION OF POMC mRNA AND β-ENDORPHIN IN THE PRIMATE PINEAL ORGAN. O.K. Ronnekleiv, J. Douglass*, J.P. Adelman*, I. Maslar*. Dept. of Physiology and IABR, OHSU, and Oregon Regional Primate Research Center, Portland, OR 97201

Previous studies have described the presence of α-MSH immunoreactivity in rat pineal extracts (Eskay et al., Brain Res. 178:55, 1979). Recently, we have observed nerve fibers containing vasopressin in the macaque pineal, but we were unable to find nerve fibers containing α-MSH. This would indicate that α-MSH is synthesized in the pineal organ. Therefore, initial studies were designed to determine if the precursor to α-MSH, proopiomelanocortin (POMC), is synthesized in the primate pineal. Pineals from rhesus macaques (N=3) and baboons (N=2), obtained at necropsy, were fixed in 4% paraformaldehyde, sectioned at 10 μm and mounted on poly-L-lysine coated slides. Six additional pineals (4 rhesus and 2 baboons) were enzymatically dispersed and the cells cultured for 3-6 days, at which time the cells were fixed in paraformaldehyde. Tissue sections and cultured pinealocytes were first reacted immunohistochemically for β-endorphin (β-End) using the Avidin Biotin method. Next, cells and tissue sections were hybridized with ^{35}S-labelled POMC mRNA full length probe for 20 h at 55°C and then washed to a final stringency of 0.25 X SSC at 55°C. Emulsion autoradiography revealed specific hybridization of the probe to POMC mRNA in the cytoplasm of cultured pinealocytes. The same cells were also immunoreactive to β-End. On pineal tissue sections clusters of cells had high concentrations of silver grains over the cytoplasm indicating the presence of POMC mRNA. These studies indicate that a subpopulation of pinealocytes within the pineal organ of primates contains mRNA coding for POMC. We are investigating the processing of POMC in the primate pineal.

346.6 REGULATION OF ENKEPHALIN AND SUBSTANCE P mRNA'S BY EXOGENOUS OPIOIDS A. Tempel, J.A. Kessler and R.S. Zukin. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Long-term blockade of brain opioid receptors by the opiate antagonist naltrexone produces marked increases in Met-enkephalin in the striatum and nucleus accumbens (94% and 45%, respectively). We determined by RNA blot analysis that these changes in peptide levels were the result of increased peptide synthesis. Levels of proenkephalin mRNA in striata of chronic antagonist-treated rats were increased approximately 25-fold relative to that of control animals. In order to determine the regional specificity of this increase, levels of proenkephalin mRNA in antagonist-treated and control rat brain regions were determined by RNA blot analysis. The mRNA corresponding to preproenkephalin was identified using a riboprobe made using the rat cDNA hybridization probe complementary to preproenkephalin mRNA (J. Roberts, Columbia Univ.) and RNA blot analysis. The level of proenkepahlin mRNA in the hypothalamus of chronic antagonist-treated rats was increased approximately 3-fold relative to that of control animals. No significant changes were found in the hippocampus or frontal cortex. The time course of the increase in proenkephalin mRNA levels was examined. Large increases in message levels were seen as early as 24 hours following antagonist treatment. This is in contrast to changes in opioid receptor density which take 3-4 days to reach half maximal upregulation following chronic antagonist treatment. Recent evidence has suggested that substance P is regulated by opioid peptides. In order to determine substance P mRNA levels in striata of control and drug-treated animals, the mRNA corresponding to the precursor for substance P was identified using a probe for exon-7 of the preprotachykinin gene (T. Bonner, NIMH). The level of substance P mRNA in the striatum was increased 14-fold after chronic antagonist treatment relative to that in the striatum of control animals. By contrast, no statistically significant change was observed in striatal mRNA for actin. In summary, these data suggest that chronic blockade of brain opioid receptors leads to the increased synthesis of both enkephalin and substance P in the striatum, and that these changes are relatively specific. The finding of a significant change in substance P levels supports the concept of a role for enkephalin in the regulation of substance P. (Supported by NSF grant BNS 8308634; NIH grants DA01843, DA00069, and NS21973).

346.7 DISTRIBUTION OF OPIOID PEPTIDES AND mRNA IN GUINEA PIG ADRENAL MEDULLA. K.L. Valentino, J. Hunter*, L. Tecott, C.J. Evans and J.D. Barchas. Nancy Pritzker Laboratory, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California 94305.

Peptides from both proenkephalin and prodynorphin precursors have been shown to coexist at the cellular level in guinea pig adrenal medulla. The two precursors are differentially regulated by dexamethasone treatment: proenkephalin mRNA levels increased two-fold, with a slight increase in peptide levels, and prodynorphin mRNA and peptide levels showed no change (Eberwine et al., Soc. Neurosci. Abstr. 11:857, 1985).

We decided to further investigate this system using the techniques of immuno-electron microscopy and in situ hybridization. Adrenals from either normal or dexamethasone treated (100 mcg/kg i.p.) male Hartley Albino guinea pigs were removed, fixed by immersion and either processed through LR White or Epon resins for electron microscopy or frozen and sectioned on a cryostat for in situ hybridization and immunohistochemistry. Antibodies were raised in rabbits and mice against the proenkephalin peptide met-enk-arg-gly-leu (MeRGL) and the prodynorphin peptide dynorphin B. Secondary antibodies were conjugated to 5 nm and 15 nm gold (Janssen Pharmaceutica). Oligonucleotide probes for proenkephalin and prodynorphin mRNAs were synthesized (BioSearch) and labeled with ^{32}P or ^{35}S.

The distribution of the two peptides in normal adrenal medulla was as follows: dynorphin B immunoreactivity was present in the vast majority of medullary cells, whereas MeRGL immunoreactivity was found in a smaller proportion of cells. MeRGL cells usually contained dynorphin B as well, and this colocalization occurred at the secretory granule level. We then set about answering the following questions: Does the distribution of proenkephalin and prodynorphin mRNA parallel the distribution of the peptides and does this distribution change after dexamethasone treatment? Is there any change in the ultrastructural localization of MeRGL following dexamethasone treatment?

Preliminary EM experiments have shown ultrastructural changes in the dexamethasone-treated adrenal medulla. Some cells appear to be depleted of granules and contain large membrane-bound structures. Other cells seem to have larger amounts of MeRGL in secretory granules than normal, although the number of MeRGL containing cells appears the same. Amounts of dynorphin B immunoreactivity appear similar to normal. A small percentage of cells have very dark, condensed cytoplasm and appear to be dying. Further EM studies and in situ hybridization experiments are in progress to confirm these results.

Supported by NIDA grant DA 01207.

346.8 PROOPIOMELANOCORTIN GENE EXPRESSION IN RAT PITUITARY DURING DEVELOPMENT: AN IN SITU HYBRIDIZATION STUDY. H. Khachaturian[1], S.P. Kwak*, M.K.-H. Schafer*, and S.J. Watson. Mental Health Res. Inst., Univ. Michigan, Ann Arbor, MI 48109; [1]Dept. Anatomy & Neurobiology, Univ. Tennessee, Health Sci. Ctr., Memphis, TN 38163.

Proopiomelanocortin (POMC) codes for several bioactive peptides which are important not only in the adult neuroendocrine function, but also during development. Specifically, during embryogenesis POMC peptide immunoreactivity can be detected in pituitary corticotrophs from day E15 and in intermediate lobe cells from E16. The existence of POMC mRNA has also been shown in rat pituitary as early as E17 (Lugo and Pintar, Soc. Neurosci. Abstr. 11:142, 1985). In the present study, we have further addressed the question of early POMC mRNA detection in rat pituitary during pre- and postnatal development.

Embryonic (E) and postnatal (P) rats from days E14, E15, E17, E19, P1, P7, P14 and P21 were decapitated and the pituitaries were postfixed in 4% formaldehyde. All tissues were frozen in liquid nitrogen. Ten micron cryostat sections were mounted onto polylysine-coated slides. Some sections were processed for PAP immunocytochemistry using an antiserum to ACTH. Other sections were processed for in situ hybridization. Riboprobes for mouse POMC (cRNA, a generous gift from J. Roberts, Columbia Univ.) were prepared in SP6 plasmid. The plasmid was transcribed in the presence of [^{35}S]UTP yielding a probe length of 460 bases, which was used for in situ hybridization and autoradiography as described (Lewis et al., Proc. Natl. Acad. Sci. 83:5419, 1986).

The results were as follows: no autoradiographic labelling was observed on day E14, but grains were seen over anterior lobe corticotrophs on E15. This observation corresponds well with the earliest detection of ACTH immunoreactivity in anterior lobe corticotrophs on E15. At E17 and E19 labelling was seen in both the anterior and intermediate lobes of the pituitary corresponding with the pattern of ACTH immunoreactivity in both lobes. From P1 to P21, labelling was progressively "diluted" in both lobes of the pituitary, and ACTH staining was likewise progressively weaker in later postnatal stages. This progressive diminution can best be explained by the fact that the pituitary expands rapidly during development, and thus labelling per unit area drops as a result of expansion. Finally, the observation that both in situ hybridization and immunocytochemistry detect mRNA and peptide labelling, respectively, on the same day (i.e., E15), suggests that POMC gene transcription and subsequent translation occur within a very short time in the pituitary during embryogenesis.

Supported by NIMH grant MH422251 to S.J.W. and NIADDK grant AM34933 to S.J.W. and H.K.

BLOOD-BRAIN BARRIER II

347.1 CENTRAL NERVOUS SYSTEM UPTAKE OF Ca-45 IN RATS FED CALCIUM DEFICIENT DIET. V. A. Murphy and S. I. Rapoport. Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20892.

Brain and cerebrospinal fluid (CSF) [Ca]'s decrease far less than concurrent decreases in plasma [Ca]'s in developing rats fed Ca deficient diets (Murphy, V.A. et al., J. Neurochem., 47:1735, 1986). Because plasma [Ca] is reduced for at least 4 weeks in such animals, stability of central nervous system [Ca] suggests an active regulatory mechanism. We therefore decided to measure the unidirectional transfer coefficients for Ca-45 from plasma to brain and to CSF, to see if regulation of Ca transfer into the central nervous system is responsible for Ca homeostasis.

Male Fischer-344 rats, 3 weeks old, were divided into 3 groups: (1), fed diet containing 0.01% w/w Ca (LOCA); (2), fed diet containing 0.67% Ca (CONT); and (3), fed reduced amounts of CONT diet to match the diet intake of anorexic LOCA rats (RCONT). After 8 weeks on the diets, mean weights were LOCA, 105 g; CONT, 221 g; and RCONT, 114 g. Plasma ionized [Ca] was significantly less in LOCA rats (0.80 mmol/l), than in CONT (1.32) or RCONT (1.28) rats.

The right femoral artery and vein were catheterized under ketamine anesthesia and the rats were allowed to recover for 5 h under partial restraint. Ca-45 and Cl-36 were injected i.v. and allowed to circulate for 10 min before killing the animal. H-3 raffinose was injected i.v. 3 min before death to determine blood volume. Serial blood samples were taken over the 10 min period and centrifuged. Transfer coefficients were calculated by dividing dpm/g CSF or brain (corrected for residual blood) by integrated plasma radioactivity times ionized fraction of isotope in plasma.

CSF transfer coefficients for both Ca-45 and Cl-36 in LOCA (419 and 528 nl/g/s) and RCONT (274 and 474) rats were significantly higher than CONT (226 and 412) rats ($p<0.05$). The LOCA value for Ca-45 was also significantly above the RCONT value. Brain regions close to the ventricles (eg, hippocampus) had elevated transfer coefficents for Ca-45 in LOCA (48.0) compared to CONT (34.3) and RCONT (29.1) rats, but more distant brain regions (eg, parietal cortex) had transfer coefficients that were not significantly different among the groups (8.3, 8.3, and 9.0, respectively). Brain transfer coefficients for Cl-36 did not differ among the groups.

The results indicate that the transfer coefficient for Ca-45 into CSF is elevated in LOCA, and that this elevation contributes to stability of both CSF and brain [Ca]'s. The increased transfer coefficient for Cl-36 into CSF was probably due to diminution of CSF volume rather than to increased uptake because only very small volumes (about 0.015 ml) could be obtained from LOCA animals. It thus appears that the choroid plexus is the major site contributing to Ca homeostasis of the central nervous system during chronic hypocalcemia.

347.2 THE GLUCOSE TRANSPORTER OF THE BLOOD-BRAIN BARRIER IN EXPERIMENTAL DIABETES MELLITUS. S.I. Harik, S.A. Gravina* and R.N. Kalaria, Department of Neurology, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Recent evidence suggests that hyperglycemia has deleterious effects on ischemic brain injury in man and experimental animals, possibly due to the production of high levels of brain lactic acid and the resultant tissue acidosis. However, there is controversy as to whether sustained hyperglycemia in man or animals is associated with a change in the transport capacity (Tmax) or affinity (Km) of blood-to-brain glucose transport. We assessed this question directly by measuring the number of glucose transporter molecules in the endothelium of brain microvessels, which constitutes the blood-brain barrier, using specific [3H]cytochalasin B binding to cerebral microvessels obtained from streptozotocin-treated rats and from normoglycemic controls.

Male Wistar rats were used in all studies. Diabetes mellitus was induced in the experimental group by intravenous injection of 60 mg/kg of streptozotocin. Control rats received the vehicle solution. The streptozotocin-treated rats developed polyuria and hyperglycemia (mean plasma glucose ~ 32 mM) and they failed to gain weight. Control rats had mean plasma glucose of ~ 9 mM. Rats were killed 2 weeks later and their cerebral microvessels harvested from the cortical mantles by bulk separation. Specific [3H]cytochalasin B binding to brain microvessels was estimated by subtracting nonspecific binding in the presence of 0.3 M D-glucose from total binding in the presence of 0.3 M L-glucose. D-glucose-displaceable [3H]cytochalasin B binding to microvessels from both groups was saturable. Scatchard analyses yielded linear plots indicating a single class of binding sites. The maximal number of binding sites (Bmax) in the control group was 61 pmol/mg protein while that of streptozotocin-treated diabetic rats was 76 pmol/mg protein; a 20 % increase in the number of glucose transporters in brain microvessels of diabetic rats. The dissociation constant of binding (Kd) was similar in both groups at ~ 0.7 μM.

These results support our earlier in vivo findings that blood-to-brain glucose transport is not decreased in chronic hyperglycemia (Harik S.I. et al., Soc. Neurosci. Abstr. 12:1260, 1986).

Supported by US PHS grants HL-35617, NS-18150 and by the David S. Ingalls, Sr. Fund.

347.3 THE GLUCOSE TRANSPORTER OF THE HUMAN BLOOD-BRAIN BARRIER.
R.N. Kalaria, S.A. Gravina*, J.W. Schmidley* and S.I. Harik, Dept. of Neurology, Case Western Reserve University, School of Medicine, Cleveland, Ohio 44106.

We used cytochalasin B as a ligand to identify and characterize the glucose transporter moiety in preparations of human cerebral microvessels, choroid plexus and P2 fractions of the frontal cerebral cortex. Tissues were obtained at autopsy from victims of motor accidents, and microvessels obtained by bulk isolation. Specific [3H]cytochalasin B binding to tissues was estimated by subtracting non-specific binding in the presence of 300 mM D-glucose from total binding in the presence of 300 mM L-glucose. D-glucose-displaceable [3H]cytochalasin B binding was saturable. Scatchard analysis yielded linear plots indicating a single class of noninteracting binding sites. Maximal binding (Bmax) of microvessels, choroid plexus and P2 fractions were 42.3 ± 4.2, 26.7 ± 2.6 and 7.0 ± 0.8 pmol/mg of tissue protein (means ± SEM). The dissociation constant of binding (Kd) to all tissues was similar at about 0.4 μM. Irreversible D-glucose-displaceable [3H]cytochalasin B binding after UV photoactivation, followed by SDS-PAGE enabled us to estimate the apparent molecular weight of the glucose transporter. The peak of radioactivity appeared between 55-50,000 daltons.

We also used monoclonal antibodies (IgM) to the glucose transporter of human erythrocyte ghosts to localize the glucose transporter in human frontal cerebral cortex. These immunocytochemical studies corroborated our binding studies by revealing a very high density of the reaction product in brain capillaries and larger blood vessels, with only little background reaction. In separate studies, we also demonstrated that the monoclonal antibody abolished specific cytochalasin B binding to cerebral microvessels by more than 90 %. Studies are now in progress to localize the glucose transporter in brain microvessels at the ultrastructural level.

These studies corroborate and extend our previous findings in experimental animals which showed that brain capillary endothelium, which consistutes the blood-brain barrier, is richly endowed with the glucose transporter (Dick, A.P.K. et al, PNAS 81:7233-7237, 1984; Dick, A.P.K. and Harik, S.I., J. Neurochem. 46:1406-1411, 1986.). This is reasonable in view of the fact that endothelial cells, which constitute less than 0.1 % of the brain weight, have to transport glucose for the whole brain.

Supported by US PHS grants HL-35617 and by the David S. Ingalls, Sr. Fund.

347.4 RECOVERY OF $5HT_2$ BINDING SITES IN AGED BRAIN BY EXPOSURE OF HUMAN BRAIN MEMBRANE FRAGMENTS TO 0.1 M GLYCINE.
A.C. Andorn and M.A. Pappolla* Dept. of Psychiatry, Case Western Reserve Univ. Schl. Med., Cleve. Metro. Gen. Hosp., Cleve. OH 44109 and Dept. of Pathology, FDR Veterans Admin. Hosp., New York Medical College, Montrose, N.Y. 10548.

Serotonin$_2$ ($5HT_2$) receptor density is decreased in aged human brain (Reynolds, G.P. et al., Neurosci. Letts. 44:47, 1984). We reported that serum proteins inhibit ligand binding at human brain cortical neurotransmitter binding sites including $5HT_2$ as labeled with [^{3}H]spiroperidol (SP) (Andorn, A.C., Synapse, 1:82, 1986). We also showed that serum proteins can be seen immunocytochemically in aged, but not young, brain (ibid). We hypothesized that the decrease in receptor density observed in aging was secondary to leakage of serum proteins through a compromised blood brain barrier (BBB). As a first test of this hypothesis, we exposed tissue sections of brain staining positive for serum proteins, to 0.1 M glycine (ph 2.5 at 40C) for up to 3 hrs at room temperature (RT). Immunocytochemical studies showed that serum proteins were effectively removed from the tissue sections by this method (not shown). This method is also valid for the removal of proteins bound with high affinity L(antibody reactions). We also exposed membrane fragment preparations (MFP) from young and aged brain to the glycine buffer for 60 min at RT prior to use in the standard assay of [^{3}H]SP (0.2 nM) binding in cortex (Andorn, A.C., Life Sci., 38:1251, 1986). Specific binding (SB) in MFP preincubated in glycine was compared to SB in MFP preincubated in assay buffer for 60 min at RT. Cortical MFP from 4 brains (aged 18-41) preincubated in assay buffer had 80.8 +/-9.9 fmol/mg protein SB (N=5). The SB in the companion MFP preincubated in the glycine buffer was 38.6 +/- 18.7 fmol/mg. The decrease in SB was accounted for by both an increase in non-specific binding (NSB) as determined in the presence of 10 uM haloperidol, and by a decrease in total binding. In contrast, 3 aged brains (ages 78-80) demonstrated 49.8 +/- 18.1 fmol/mg SB after exposure to assay buffer in 71..9 +/- 39.0 fmol/mg SB after exposure to glycine buffer (N=8). NSB in young and aged brain was the same, as determined by Student's t-test, within each condition. The statistically significant increase in SB in aged brain ($p=0.05$) was most likely due to an increased B_{max} since the K_D of the multiple [^{3}H]SP binding sites in cortex are not affected by age or glycine preincubation (not shown). These findings are consistent with the hypothesis that the apparent decline in receptor density seen in aging may be due in part, to a masking effect of putative serum or other proteins which are abnormally present in aged brains due to a compromise of the BBB.

347.5 ALLOGRAFTS OF CNS TISSUE DO EXHIBIT A BLOOD-BRAIN BARRIER TO PROTEIN.
R. Broadwell, M. Charlton*, M. Salcman, and R. Schlegel*. University of Maryland School of Medicine, Balto., MD, 21201.

A recent article in **SCIENCE** (235:772, 1987) suggested that neonatal rat cortex transplanted into the IVth ventricle or near the cortical surface of adult rats failed to exhibit a blood-brain barrier (BBB) to blood-borne endogenous and exogenous proteins. If this observation is correct, absence of a BBB in transplanted brain tissue, coupled with a host immune response for tissue rejection, could complicate potential clinical application of CNS transplants in the treatment of neuro-degenerative disorders. Although the mammalian BBB is not absolute to circulating, non-lipid soluble macromolecules, results from our laboratory strongly advocate the presence of a BBB to blood-borne protein within intracerebral allografts of the mammalian CNS. Brains of fetal day 13 to term mice possess a well-developed blood supply and a BBB to intravenously injected HRP. Blocks of the parietal cortex or basal forebrain from fetal/neonatal mice were placed stereotaxically into the IIIrd ventricle or basal ganglia deep to the cortical surface of adult mice for 1 day to 6 months. Systemically administered HRP failed to enter the parenchyma of CNS allografts or that of the host brain from blood vessels within allografts. Blood-borne HRP exiting fenestrated vessels supplying the hypothalamic median eminence of the host spread extracellularly into the ventralmost portion of all allografts positioned within the IIIrd ventricle. Blood vessels intrinsic to the CNS allografts were sustained and anastomosed with host blood vessels at the allograft-host interface for perfusion with host blood (red cells) and blood-borne HRP between 7-10 days post-transplantation. Ultrastructural inspection of allograft blood vessels at all post-transplantation times confirmed that the endothelial cells exhibit BBB characteristics (e.g, interendothelial tight junctions, absence of transendothelial vesicular transport, lysosomes, etc.). Adult pituitary tissue, which contains fenestrated capillaries that normally are leaky to blood-borne HRP, transplanted intracerebrally in our animals did not develop a BBB and permitted HRP delivered systemically to the host to enter the pituitary allograft and surrounding host brain parenchyma. The results suggest that blood vessels indigenous to solid allografts of fetal, neonatal, or adult mammalian tissue, whether neural or non-neural, sustain their normal characteristics and eventually connect with host blood vessels. The mammalian CNS can be expected to possess a BBB to circulating protein when grafted as solid tissue within or outside the CNS. Supported by NIH/NINCDS Grant #NS 18030.

347.6 TRANSCYTOSIS OF PROTEIN THROUGH THE CEREBRAL ENDOTHELIUM AND CHOROID PLEXUS EPITHELIUM.
B. Balin*, R. Broadwell, M. Salcman. University of Maryland School of Medicine, Balto., MD, 21201.

Transcytosis (endocytosis,transport, exocytosis) of protein through cerebral endothelia and choroid plexus epithelia was investigated in mice injected intravenously or into the cerebral ventricles with native HRP or HRP conjugated to the lectin wheat germ agglutinin (WGA); post-injection survival times were 5mins-24hrs. Native HRP enters cells indiscriminately by fluid phase endocytosis, whereas WGA-HRP binds to oligosaccharides on the cell surface and is internalized by adsorptive endocytosis. Blood vessels throughout the cerebral vascular tree were visible with the blood-borne tracers at 5mins. Native HRP-labeled organelles within the endothelium included endocytic vesicles, endosomes, tubules, multivesicular and dense bodies. Acid phosphatase cytochemistry revealed that a population of the tubules, multivesicular and dense bodies are representative of secondary lysosomes. Transcytosis of native HRP from luminal to abluminal sides of the endothelium did not occur, and the peroxidase-positive tubules did not form para-junctional channels. Blood-borne WGA-HRP, in addition to labeling the same organelles as those seen with native HRP, appeared within the Golgi complex at 3hrs. By 6-24hrs, WGA-HRP was observed on the abluminal surface of the endothelium and within the perivascular clefts and pericytes. Pericyte organelles sequestering WGA-HRP were identical to those in the endothelium. Cerebral endothelia exposed abluminally to native HRP and WGA-HRP delivered into the ventricles failed to internalize the tracer proteins significantly through 24hrs, suggesting that endocytosis at the abluminal plasmalemma is not demonstrable. Choroid plexus epithelia exposed to blood-borne native HRP and WGA-HRP for 5mins-24hrs contained peroxidase-positive endocytic vesicles, endosomes, tubules, multivesicular and dense bodies; the latter three types of organelles were acid phosphatase-positive cytochemically. Transcytosis of the two blood-borne tracers through the choroid epithelia was not observed. Similar results were obtained with native peroxidase injected intraventricularly. Conversely, transcytosis of cerebrospinal fluid-borne WGA-HRP through the choroid epithelia from the microvillus border to the basolateral surfaces occurred within 10mins post-injection. This transcytosis of WGA-HRP appeared at a time prior to WGA-HRP labeling of the Golgi complex. The results suggest that blood-borne protein entering the endothelium by the process of adsorptive endocytosis can undergo transcytosis through the intact blood-brain barrier without compromising the integrity of this barrier; the cerebral endothelium appears to be polarized with regard to the internalization of its cell surface membrane. Whether or not the choroid epithelium is polarized concerning the transcytosis of protein entering the cell by adsorptive endocytosis remains equivocal at this time. Supported by NINCDS #NS 18030.

347.7 FREE FATTY ACIDS EFFECT ON CEREBROMICROVASCULAR ENDOTHELIAL AND SMOOTH MUSCLE CELL PERMEABILITY: IN VITRO STUDIES. A. Villacara, O. Kempski, J. Bembry and M. Spatz. LNNS, NIH, Bethesda, Md. 20892

The release of free fatty acids from cellular membranes has been implicated in attenuating the blood-brain barrier (BBB) permeability under pathological conditions. Recently we adopted a new in vitro system consisting of cerebromicrovascular endothelium grown on dextran microcarriers to study their properties related to the function of BBB under controlled conditions (Kempski and Spatz in press 1987). This method utilizes the fact that cell covered beads prevent accumulation of dyes like trypan blue(TB) in the microcarriers. Any increase in cellular permeability to TB results in reduced level of TB in the supernatant since TB that passes through the cellular layer binds tightly to the dextran beads.

The aim of this investigation has been to use this model for evaluating the effects of free fatty acids on the permeability of separately cultured endothelial and smooth muscle cells derived from cerebral microvessels (Spatz et al Brain Res, 191:577-582, 1980; 280:387-391, 1983).

Washed samples of endothelium or smooth muscle cells grown on microcarriers as well as empty beads were incubated with various concentration of palmitic, linoleic or arachidonic acid (20-100μM) in phosphate buffer (PBS) containing serum albumin and glucose (0.1%) while the controls were exposed to the solvent solution in the same buffer at pH 7.4 for 30 min at 37°C. Thereafter each sample was equilibrated with TB albumin [serum albumin fatty acid free (0.2% TB)] phosphate buffer and glucose (0.1%) at pH 7.4. Aliquots of supernatant were removed at short intervals (15 sec - 19 min). The TB concentration in the supernatant was measured with the use of spectrophotometer at a wavelength of 580nm.

Both cell types excluded TB equally. There were no significantly different changes between the TB permeability of endothelium and smooth muscle cells exposed to either arachidonic or linoleic acid. Arachidonic acid leads to a 5-fold while linoleic acid leads to a 4-fold increase in cellular permeability to TB. On the other hand, palmitic acid caused little change but TB permeability of the smooth muscle appeared greater than that of the endothelial cells. Each of these changes could be reversed when the cells were washed after their incubation with free fatty acids but prior to the trypan blue albumin exposure.

These results support the contention that free fatty acids can alter the permeability of cerebromicrovascular cellular elements and thus the function of BBB.

347.8 ALKALINE PHOSPHATASE STAINING OF LEAKY BLOOD VESSELS IN HUMAN POST MORTEM AREA POSTREMA AND CHOROID PLEXUS. M.A. BELL, D.M. MOODY‡ J.N. ANGELO‡ V.R. CHALLA* AND T.C. JOHNSTON‡ Departments of Radiology and Pathology, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

In a study of post mortem human brain sections (100-500 um celloidin and 2 um glycol methacrylate) we have observed strong Gomori alkaline phosphatase staining of the endothelial lining of area postrema and choroid plexus vessels. Alkaline phosphatase is thought to assist transmural transport of nutrients, metabolites or ions. It appears in small exchanging vessels (arterioles and capillaries) throughout the brain, so its appearance in these two areas would not be remarkable except for previous postulates that the enzyme is associated with blood-brain barrier (BBB) functions; the absence of a BBB in these two specialized (leaky) vascular beds distinguishes them from the tight junction vessels characteristic of most other brain regions.

Our observation and other arguments suggest that endothelial BBB and alkaline phosphatase functions may coexist, but are not strongly interdependent or identically distributed along the microvasculature, to wit: 1) alkaline phosphatase activity has here been demonstrated in leaky area postrema and choroid plexus vessels; 2) it has been demonstrated (by one of us, MB, and others) in human or mammalian capillaries of peripheral nerve (a less restrictive barrier system than the brain's), skeletal muscle (no specialized barrier), and dorsal root ganglia (leaky fenestrated vessels); 3) most brain venules, while possessed of a BBB, do not stain for alkaline phosphatase; 4) rabbit brain vessels, while presumably tight, do not stain for alkaline phosphatase at all. Perhaps barrier and phosphatase transport functions are cooperatively rather than intrinsically related.

The discrepancy between our phosphatase positive vessels in area postrema and choroid plexus and the phosphatase negative ones reported there in detailed EM studies by Vorbrodt et al (Acta neuropathol. (Berl.), Suppl. VIII: 43, 1983; Dev. Neurosci., 8:1, 1986) is puzzling. Species differences, pathological conditions, post mortem effects, or methodological differences might be invoked.

347.9 WIDESPREAD DISTRIBUTION OF TRANSFERRIN IMMUNOREACTIVITY IN HUMAN BRAIN. A.J. Dwork*, E.A. Schon*, and J. Herbert* (SPON: S. DiMauro). College of Physicians and Surgeons of Columbia Univ., New York, NY 10032

Non-pathological sections from five adult autopsy brains were examined immunohistochemically for transferrin (Tf) using the avidin-biotin-peroxidase complex technique. Specificity of primary antibody was confirmed by immunoblot. Intensity of staining and number of stained cells varied from case to case, but the anatomical distribution was similar in all cases. Neuropil stained most heavily in iron-rich areas: globus pallidus, substantia nigra, dentate nucleus, and to a lesser extent, corpus striatum. Virtually all neurons of cranial nerve nuclei, substantia nigra, locus ceruleus, and nucleus basalis were intensely positive for Tf, compared to a moderate number in hippocampus and few or none in neocortical areas. Staining of Purkinje cells was quite common. Selected astrocytes, oligodendrocytes, ependymal cells, and choriod plexus epithelial cells were strongly immunoreactive. Subependymal astrocytes stained with particular frequency and intensity. Staining of neurons and glia generally involved cell bodies and processes, but not nuclei. Whether this widespread distribution of Tf represents local synthesis or uptake from plasma or CSF remains to be determined.

Our results show immunoreactivity that is more abundant and involves more cell types than that which has been reported in fetal and newborn humans and that differs in cellular distribution from that reported in adult rat. Ontogenetic and phylogenetic differences evidently exist.

347.10 ANIMAL SUSCEPTIBILITY TO 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE NEUROTOXICITY VARIES INVERSELY WITH MONOAMINE OXIDASE ACTIVITY IN THEIR BRAIN MICROVESSELS. N. J. Riachi*, S. I. Harik, R. N. Kalaria and L. M. Sayre* (SPON: R. B. Daroff), Departments of Neurology and Chemistry, Case Western Reserve University, Cleveland, OH 44106.

Systemic 1-methyl-4-phenyl-1,2,3,6,-tetrahydropyridine (MPTP) causes parkinsonism in man and other primates, but not in rats; while mice are intermediate in their susceptibility which varies among strains. Since MPTP selectively lesions dopamine neurons when infused directly into rat substantia nigra (Harik, S. I. et al, JPET, 1987), we suspected that the rat's resistance to systemic MPTP is due to inability of MPTP to reach the brain, possibly because of unique capability of the rat "biochemical" blood-brain barrier (BBB). We then discovered that rat brain microvessels, which constitute the BBB, have unusually high monoamine oxidase (MAO) activity while human brain microvessels were deficient and mice microvessels had intermediate MAO activity (Kalaria, R. N. et al, PNAS, 1987). We therefore hypothesized that the rat's resistance to systemic MPTP toxicity is likely due to the rapid metabolism in brain capillaries of MPTP to MPP+, a water-soluble cation that would have difficulty in traversing biological membranes.

We tested this hypothesis by: (i) studying MPTP metabolism, in vitro, by human, rat and mouse brain microvessels, and (ii) following MPTP metabolism, in vivo, in the brain and liver of Wistar rats and 2 strains of mice known to react differently to systemic MPTP. We find that rat brain microvessels are extremely efficient at converting MPTP to MPP+ and that this conversion is totally inhibited by pargyline. Microvessels from C57 black mice, which are more sensitive to MPTP toxicity than white CFl mice, were less capable of metabolizing MPTP to MPP+. Human microvessels were least capable of producing MPP+.

In vivo metabolism of MPTP in Wistar rats and the 2 strains of mice showed that 1 hour after MPTP injection, rats had the least amount of MPTP and its metabolites in their striata and that white mice were intermediate between rats and black mice, with black mice having the highest concentration of MPTP and its metabolites. On the other hand, liver metabolism of MPTP by the 3 groups showed highest levels of MPTP metabolites in rats and lowest levels in black mice.

These results correlate differences in susceptibility to systemic MPTP neurotoxicity to the ability of the BBB and other tissues like the liver to metabolize MPTP and prevent it from reaching its sites of toxicity within the brain.

348.1 ABNORMAL NEURONAL MORPHOLOGY IN THE BRAIN OF AN AIDS-INFECTED CHILD: A GOLGI STUDY. Ronald F. Mervis[1], Carl Boesel*[1], Marc Rosenblum*[2], and Richard W. Price*[2] (SPON: A.J. Yates). [1]Div. of Neuropathology, The Ohio State Univ. Med. Ctr., Columbus, OH 43210, and [2]Memorial Sloan-Kettering Med. Ctr., New York, NY 10021.

Infants and adults with the acquired immune deficiency syndrome (AIDS) frequently develop a progressive encephalopathy which is accompanied by neurological, motor, and behavioral dysfunction. Although secondary opportunistic infections accompanying AIDS may be responsible for some of the findings, there is substantial evidence that HTLV-III infection of the CNS is a causative agent. The neuroanatomical basis of the disorder is poorly understood. The virus itself has not been clearly shown to infect neurons directly, and only on rare occasion has evidence implicated its presence in astrocytes or oligodendroglia. Here, we report the effects of confirmed AIDS infection of the CNS on the neuronal morphology of a two year-old infant with severe developmental disabilities who died of the disorder.

He was born full term and was initially normal until 7 months-old when he failed to reach normal developmental milestones. At two years he was shown by CT scan to have cerebral atrophy. At autopsy, neuropathology tissue sections stained with Nissl and hematoxylin and eosin showed gliosis and multinucleated giant cells in the brain. Golgi staining of cerebellum showed Purkinje cells that were generally poorly branched and sparsely spined. Purkinje cells that were atrophic or had distorted soma were frequently seen. In the neocortex, the dentritic trees and soma of pyramidal cells were similarly affected. Dendritic branches were swollen or otherwise distorted with varicosities. Spines were generally fewer in number and often grossly enlarged or misshapen. These observations suggest that neurological and behavioral dysfunction in this AIDS-infected infant are accompanied by widespread abnormalities of neuronal structure. In view of the apparent absence of secondary opportunistic infection, the findings described here could be attributed to AIDS infection of the brain.

348.2 Gamma-Interferon (G-IFN) May Mediate Central Nervous System (CNS) Disease in HIV-1 Infection

Sheremata WA, Bohn N,* Resnick L,* Berger J,* Sazant A.*

The pathogenesis of CNS disease complicating HIV-1 infection is not explained. As alternative to direct infection of CNS cells, we have hypothesized that g-IFN may mediate such disease. G-IFN (an immuno-modulatory lymphokine) is a potent activator of macrophages, can induce Class I and II MHC antigens and enhance a variety of immune responses. We studied paired serum and CSF of 8 normals, 10 with HIV sero-conversion, and 10 other CNS disorders including 4 with myelopathies. Using a double antibody assay radio-immune assay (RIA) modified for detection of very low g-IFN levels we found very low level serum antibody in 7/10 HIV sero-converters (confirmed by Western blot) and 1/2 tropical spastic paraplegia patients, but failed to find detectable levels in normals serum. Low cerebrospinal (CSF) levels were found in all subjects, however. Values ranged from 0.18 to 0.42 U/ml in normals and from 0.24 to 1.40 U/ml in HIV + patients. Values were higher in those with absent or minimal neurological disease. Two HIV + patients had increased levels of serum alpha-IFN and 2 others had increased alpha in CSF as compared with normals and controls. This study provides preliminary evidence that CNS disease with HIV infection may be mediated by inappropriate g-IFN production early in disease. However, a prospective longitudinal study of sero-negative subjects and early sero-converters will be needed to further evaluate the role of g-IFN in HIV related CNS disease.

348.3 GLYCOLIPID MODIFICATION OF THE SCRAPIE PRION PROTEIN. N. Stahl*, D. R. Borchelt*, K. K. Hsiao, and S. B. Prusiner (SPON: B. Libet). Dept. of Neurology, University of California, San Francisco, CA 94143-0518.

We are investigating posttranslational modifications of the scrapie prion protein that may play a role in scrapie pathogenesis and explain the differences in physical properties between PrP^{C} and PrP^{Sc}. Several lines of evidence indicate that the scrapie prion protein is posttranslationally modified with a phosphatidylinositol-containing glycolipid that shares many properties with the glycolipids found on the carboxy termini of trypanosome variant surface glycoprotein (VSG), Thy-1, and acetylcholinesterase. We have used GC/MS to identify ethanolamine, P_i, inositol, and stearic acid in acid hydrolysates of purified PrP 27-30, the protein that is derived from PrP^{Sc} by limited proteolysis. These compounds are found associated with PrP 27-30 despite boiling the protein in SDS followed by repeated extraction with chloroform/methanol, or purification of PrP 27-30 from gel slices after SDS-PAGE. Gel-purified PrP 27-30 contains 2-3 moles of ethanolamine per mole of protein when analyzed by reverse-phase HPLC of acid hydrolysates after derivatization with phenyl isothiocyanate. GC analysis of trimethylsilylated fatty acids released from purified PrP 27-30 by 1 N NaOH at 65°C after extraction with chloroform/methanol indicates the presence of 5 different species of fatty acids dominated by palmitate. However, gel-purified PrP 27-30 contains mostly stearic acid, suggesting that the other fatty acid species are attached to a contaminating component that purifies with PrP 27-30. Furthermore, the amount of stearic acid observed decreases after digestion of purified PrP 27-30 with a bacterial phosphatidylinositol-specific phospholipase C (PI-PLC), while the amount of palmitate does not change. This suggests that the PrP glycolipid contains only stearic acid. After PI-PLC digestion, PrP 27-30 crossreacts on Western blots with antisera raised against the PI-PLC treated glycolipid present on VSG. Exposure of primary cell cultures derived from neonatal hamster brain to PI-PLC results in the release of >90% of their PrP^{C} into the media when measured by Western blotting or immunoprecipitation of [^{35}S]-labeled protein. This release by PI-PLC is not proteolytic because the media contains less than 10 [^{35}S]-labeled bands by SDS-PAGE. Upon release by PI-PLC, PrP^{C} migrates more slowly in SDS-PAGE; similar results have been observed previously with other glycolipidated proteins. Incubation of neuroblastoma N2a cells with PI-PLC also results in a substantial decrease in cell surface indirect immunofluorescence when the cells are stained with PrP antisera. These results show that nearly all of the PrP^{C} present in primary cell cultures are anchored to the cell surface by a glycolipid.

348.4 C-11-METHIONINE ACCUMULATION IN NORMAL AND TUMOR-CONTAINING HUMAN BRAIN: QUANTITATIVE IMAGING -- COMPARISON OF LINEAR AND NON-LINEAR MODELS. L.A. O'Tuama*, K.H. Douglass*, R.F. Dannals*, N.D. LaFrance* and H.N. Wagner, Jr.* (SPON: E. Matthew). Division of Nuclear Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Several groups (e.g., Huebner et al., 1982; Bergstrom et al., 1987) have shown that 11-C-L-Methionine (MET) accumulation is a sensitive method for detection and delineation of extent of brain tumors. Further development of this technique will require improved quantification of data. We have compared two mathematical models for evaluation of k (accumulation rate constant). Patients were injected with 11-C-L-MET (18 to 21 mCi) with or without a pre-tracer dose of L-phenylalanine (100 mgs/kg) to separate saturable transport from diffusion. Dynamic PET imaging was performed for up to 25 minutes after tracer injection. Input functions to the model consisted of (1) the "arterialized" plasma time-radioactivity curve, and (2) the time-activity curve of 11-C-L-MET assessed in regions of interest (15-20 pixels of.08 cm^2 per pixel) placed over normal brain or center of the tumor, respectively. In the linear method, k was defined as the slope of the graph of the regional brain activity/plasma activity versus integrated plasma activity/plasma activity. In the non-linear least squares method, a sum of convolution integrals, equivalent to a three compartment model, was fitted to the data. When the linear method was restricted to the later data points, and the non-linear method included an estimate for k-4, the rate constants agreed (R=.99). Agreement between the models for other stages of the acquisition was in the range of R=.75 to .8. We conclude that there are complementary advantages and disadvantages to the linear and non-linear methods of analysis, and that best results are obtained when both are used.

348.5 SUSTAINED SPONTANEOUS ACTIVITY IN COMPRESSED SCIATIC NERVE OF CATS AND RATS. M.H. Bennett. Dept. Neurosurgery, Univ. of Pittsburgh Sch. of Med. Pittsburgh, PA 15261.

It has long been thought that static compression of nerve is ineffective in producing sustained activity. In contrast, compression of nerve has been implicated in many pathological states in which sustained activity has been hypothesized. It was thought that the different findings might be due to the mode of force application experimentally. In attempting to mimic the clinical situation, low-level forces were slowly applied to the nerve and maintained for hours. Due to the viscoelastic properties of nerve a diminishing rate of advance of the compressor was required. Nerve function was tested by measurement of compound action potentials in response to nerve or foot stimulation. EMG monitoring was performed with pre- and postaxial needle electrodes placed at mid-tibial levels. Exposed nerve was covered with oil or saline soaked cotton pledgets. Uncompressed nerve was maintained in the experimental arrangement for up to 4 hrs. with no sign of spontaneous activity.

Spontaneous EMG activity was first seen with a force of 4-10 gr. Maintenance of this level of compression produced an increase of activity over the next 30 to 60 min. Prior to this increase, removal of compression resulted in a loss of spontaneous activity. Once activity was well established, compressor advance was stopped and spontaneous activity was seen for up to 12 hrs. After 2 to 3 hrs. of activity, removal of compression produced a declining level of activity which disappeared within 30 to 40 min. After 6 hrs. of activity, removal of compression produced a slightly lower leve of activity which continued for the remaining 4 hrs. of the experiment. At times, waxing and waning of activity was seen with both silent periods and bursting activity. These findings were repeated in experiments in which the spinal cord was transected at T6 and/or the sciatic nerve was transected at the notch. Xylocaine applied to the nerve just distal to the compressor reversibly abolished spontaneous activity but the site of xylocaine effect moved distally with time.

Direct nerve recording in paralyzed animals also demonstrated compression induced activity. With compression, a decreased threshold at the compressor site was also seen. Evidence of ephaptic action at the compressor site was obtained using action potential collision techniques.

Further descriptions of methods and results, suggestions of possible mechanisms and a discussion of clinical implications of these findings will be presented.

348.6 MEASUREMENT OF SERIAL CHANGES IN LACTATE AND PYRUVATE IN SPINAL CORD ISCHEMIA AND REPERFUSION USING MICRODIALYSIS AND HIGH PERFORMANCE LIQUID CHROMATOGRAPHY. J.C. Goodman, C.S. Robertson*, and R.G Grossman. Departments of Pathology and Neurosurgery, Baylor College of Medicine, Houston, Tx 77030

Measurement of changes in metabolites in central nervous system tissue during ischemia and reperfusion has classically required the sacrifice of animals at discrete times during the experiment, measurement of the metabolites, and collation of results of many experiments to reconstruct the time course of metabolic changes. We have developed a method of measuring serial changes in lactate and pyruvate in the extracellular space of the spinal cord in an individual rabbit with spinal cord ischemia caused by intra-aortic balloon inflation. Prior to inflation of the balloon, a microdialysis probe is placed in the spinal cord at the level of the fifth lumbar vertebra and perfused with artificial CSF at a rate of 10 µl/min. Specimens are collected every 15 minutes for 1 hour. The balloon is then inflated, and metabolic failure of the cord is confirmed by abolition of spinal sensory evoked potentials (Cheng M.K., et al, J.Neurosurg. 60:786, 1984). Ischemia is maintained for 20 minutes during which time dialysate is collected every 5 minutes. The balloon is then deflated restoring circulation to the cord, and dialysate is collected every 15 minutes for 3 hours. The animal is sacrificed and the dialysate is stored at -70° C. until analysis.

The dialysate is analyzed for lactate and pyruvate by direct injection of 25 µl onto a BioRad Aminex HPX-87H cation exchange column with 5 mmol/L sulfuric acid mobile phase, and detection by absorbance at 210 nm at 0.005 AUFS. Excellent baseline separation of the organic acids is obtained, and quantitation by peak height measurement is linear over the applicable range. In vitro studies reveal an 8% recovery of organic acids in the dialysate relative to calibration solution at the flow rate used.

During ischemia the lactate levels increase and pyruvate levels decrease resulting in marked elevations of the lactate/pyruvate ratio reflecting increased anaerobic metabolism. During reperfusion, the pyruvate level rebounds dramatically, lactate levels decline though not to baseline levels, and the lactate/pyruvate ratio drops toward normal. These changes in extracellular concentrations of these metabolites parallel changes in tissue levels determined by classical methods.

This method of measuring metabolites during experimental manipulation of the spinal cord requires far fewer animals to acquire comparable data, and adds a new dimension to studies of therapeutic agents for CNS ischemia. Biochemical studies are by no means confined to organic acids; indeed, analysis of amino acids and neurotransmitters is extensively described in the microdialysis literature. Additionally, sample acquistion by microdialysis often results in a sample suitable for direct injection into the the liquid chromatograph, raising the possibility of directly coupled on-line microdialysis HPLC analysis.

348.7 INCREASED VULNERABILITY OF THE MILDLY TRAUMATIZED RAT BRAIN TO CEREBRAL ISCHEMIA: THE USE OF A CONTROLLED SECOND INSULT AS A RESEARCH TOOL. L. W. Jenkins*, W. Lewelt*, K. Moszynski*, B. G. Lyeth, R. L. Hayes, D. S. DeWitt*, S. E. Robinson, A. Allen*, J. Opoku*, A. Marmarou* and H. F. Young* (SPON: Richard J. Krieg). Div. of Neurosurgery, Medical College of Virginia/Virginia Commonwealth University, Richmond, VA 23298-0001.

Mild mechanical brain injury alone does not usually result in overt cell death. However, we hypothesized that certain pathophysiological mechanisms initiated during mechanical injury may ultimately result in cell death when post-traumatic steady state conditions are challenged. The present study compared the response of rodent brains, initially subjected to mild mechanical injury, and subsequently challenged with a "subletha1" ischemic insult, to the response of the normal untraumatized brain subjected to an identical ischemic insult. The ultimate goal of this approach is to describe in detail common, or different, pathophysiological mechanisms accompanying mechanical and ischemic brain injury.

Fasted male Wistar rats were intubated and maintained under halothane/nitrous oxide anesthesia and subjected to either: a 1.0 ATM fluid pulse (Group 1, N=6), 6 minutes of transient forebrain ischemia (Group 2, N=5), or a 1.0 ATM fluid pulse followed 1 hour later by 6 minutes of forebrain ischemia (Group 3, N=6). EEG and evoked potentials were recorded prior to, during, 1 hour after, and 7 days after injury. Morphological analysis was performed on all rats after 7 days post-injury survival.

All animals survived 7 days post-insult and in all three groups complete qualitative recovery of electrical activity was observed. No overt neuronal cell loss was seen in either trauma alone or ischemia alone, but bilateral CA1 pyramidal cell loss was found in the rostral third of the dorsal hippocampi in the combined insult group.

Employing neuronal death as an endpoint in the present paradigm, we conclude that mild mechanical injury potentiates ischemic selective vulnerability rather than ischemia potentiating typical traumatic brainstem vulnerability. Acute studies in the cat also support this conclusion (Mechanisms of Secondary Brain Damage, A. Baethmann (Ed.), Plenum Press, 1986, p. 273). These data suggest that mild mechanical trauma decreases the threshold of the brain to lethal ischemic injury. Delayed ischemic hippocampal neuronal death has been linked to an excitotoxic induced pathological calcium signal. A similar but sublethal excitotoxic process after mild trauma may occur, which is then potentiated to lethality by a second excitotoxic induced pathological calcium signal. (Supported by NS19550.)

348.8 ENDURING SHORT-TERM MEMORY DEFICITS IN THE ABSENCE OF HIPPOCAMPAL CELL DEATH FOLLOWING MODERATE HEAD INJURY IN THE RAT. B. G. Lyeth, L. W. Jenkins, R. J. Hamm, S. E. Robinson, C. E. Dixon, M. L. Geibel,* A. Allen,* M. Schaeffer,* L. Oleniak,* J. Opoku,* R. G. Chapouris,* A. Marmarou,* H. F. Young* and R. L. Hayes. Division of Neurosurgery, Medical College of Virginia/Virginia Commonwealth University, Richmond, VA 23298-0001.

Enduring neurological dysfunction that results from an insult to the brain is often equated with irreversible structural CNS damage such as loss of neurons or axonal degeneration. Following diffuse cerebral ischemia, the loss of CA_1 hippocampal neurons has been directly associated with enduring deficits in radial maze memory performance (Stroke 15:558, 1984). The present study examined the relationship between hippocampal cell death and enduring memory deficits resulting from concussive mechanical brain injury.

Male Sprague-Dawley rats (300-400g) were maintained at 85% of their free-feeding weight and trained to criteria on an 8-arm radial maze prior to sham injury or moderate fluid percussion brain injury (2.1-2.3 atm). After daily assessments for 25 days, animals were perfusion fixed, processed for paraffin, and serially sectioned at 8 µm. Cell counts from consistent coronal sections of the rostral-dorsal hippocampus were made and all other brain regions were assessed qualitatively. Sham-injured controls were compared to injured animals with enduring maze deficits.

Animals manifesting maze deficits at sacrifice averaged 2.4 short-term errors/session compared to 1.1 errors/session for sham-injured animals. No overt evidence of cell death was observed in any brain region. Preliminary cell counts were expressed as the number of pyramidal or granule neurons per unit area for the intrinsic rostral third of the dorsal hippocampus as follows: 1) the dentate gyrus, 2) sectors CA_2-CA_4, and 3) CA_1-subiculum). Mean sham control values for region 1 (3704.5 neurons/10^6 µm^2), region 2 (1296.9 neurons/10^6 µm^2) and region 3 (1748 neurons/10^6 µm^2) were not significantly different from means in region 1 (3457.6 neurons/10^6 µm^2), region 2 (1206.2 neurons/10^6 µm^2) or region 3 (1842 neurons/10^6 µm^2) from injured animals with maze deficits.

These data suggest that enduring short-term memory deficits may exist in the rodent following moderate head injury without quantitative neuronal cell death within representative samples of the intrinsic hippocampi or overt cell death in other associated brain regions. While axonal and/or dendritic field injury cannot yet be eliminated, a sublethal neurochemical basis for these persisting deficits appears probable.

Supported by NIH grants NS21458 and NS19550 and the Richard Roland Reynolds Neurosurgical Research Laboratories.

348.9 PRETREATMENT WITH PHENCYCLIDINE (PCP) ATTENUATES LONG-TERM BEHAVIORAL DEFICITS FOLLOWING CONCUSSIVE BRAIN INJURY IN THE RAT. R. L. Hayes, R. Chapouris*, B. G. Lyeth, L. Jenkins*, S. E. Robinson, H. F. Young* and A. Marmarou*. Div. of Neurosurgery and Department of Pharmacology and Toxicology, Medical College of Virginia/Virginia Commonwealth University, Richmond, VA 23298-0001.

A number of lines of evidence suggest that excitatory information flow pathways participate in injury processes associated with CNS insults such as seizures, hypoxia/ischemia and hypoglycemia. These brain injuries may share information flow abnormalities mediated by agonist-receptor interactions at excitatory amino acid/NMDA receptors. The present study examined the possibility that similar processes may contribute to behavior deficits following mechanical brain injury. We administered varying doses of PCP, an NMDA receptor antagonist, and evaluated the drug's effects on durations of transient behavior suppression (i.e. "unconsciousness") and longer-term behavioral deficits.

Rats were surgically prepared under Nembutal 24 hours prior to injury by placing a hollow tube epidurally over a central craniotomy. Rats were administered either saline or PCP (1.0, 2.0 or 4.0 mg/kg, i.p.) 15 minutes, and methoxyflurane, 5 minutes prior to 2.35-2.45 atm fluid percussion injury. Rats were ventilated as necessary following injury. The duration of acute suppression of several reflexes (pinna, corneal, righting, and flexion) and responses (escape, head support, and spontaneous locomotion) was recorded for up to 60 minutes after trauma. Longer-term behavioral assessments (beam walking, spontaneous activity and body weight) were made for up to 10 days after trauma. PCP did not significantly alter the duration of acute behavioral suppression. Rats pretreated with 1.0 mg/kg PCP lost significantly ($p<.05$) less weight than saline-treated rats through the first eight days after injury. Saline-treated rats showed significant ($p<.05$) decreases in spontaneous locomotion for 10 days after injury while no significant changes were seen in rats pretreated with 1.0 mg/kg of PCP. In contrast, while PCP significantly ($p<.05$) reduced deficits in the beam-walking task, maximal protection was provided by the 4.0 mg/kg dose. Sixty-five percent of saline-treated animals died within 10 days after injury. For rats pretreated with 1.0, 2.0 and 4.0 mg/kg of PCP, 40%, 20%, and 33% died, respectively.

While the possibility of effects mediated by other neurotransmitter systems cannot be excluded, these data suggest that NMDA agonist-receptor interactions contribute to the pathophysiology of brain injury. In addition, neural mechanisms mediating transient unconsciousness following moderate levels of head injury may differ from mechanisms mediating more persistent neurological deficits. (Supported by NIH Grant #NS21458.)

349.10 THE EFFECT OF NALOXONE PRETREATMENT ON BEHAVIORAL RESPONSES TO CONCUSSIVE BRAIN INJURY IN THE RAT. S.E. Robinson, B.G. Lyeth, L.W. Jenkins*, T.K. McIntosh, H.F. Young*, R.G. Chapouris* and R.L. Hayes. Department of Pharmacology and Toxicology and Division of Neurosurgery, Medical College of Virginia, Richmond, VA 23298

Data from our laboratory suggest that endogenous opiates may contribute to certain physiological responses observed after experimental brain injury (Hayes et al. J. Neurosurg. 58: 720, 1983). The present study examined the effect of naloxone pretreatment on transient behavioral suppression (e.e. "unconsciousness") and more enduring behavioral deficits associated with experimental concussion in the rat.

Rats (male Sprague-Dawley, 300-350g, n = 10 per group) were surgically prepared under Nembutal 24 hours prior to injury by placing a hollow tube epidurally over a central craniotomy. Rats were administered either saline or naloxone (0.1, 1 or 20 mg/kg, i.p.) 15 min and methoxyflurane 5 min prior to 2.15-2.25 atm fluid percussion injury. Rats were ventilated as necessary following injury. The duration of suppression of several reflexes (pinna, corneal, righting, and flexion) and responses (escape, head support, and spontaneous locomotion) was recorded for up to 60 min after trauma. Longer-term behavioral measures (beam balance, beam walking, and body weight) were measured up to 10 days after trauma. The lower doses of naloxone tended to exacerbate the transient behavioral suppression produced by experimental head trauma, with the lowest dose (0.1 mg/kg) significantly increasing the duration of suppression of the righting, corneal and escape reflexes. The two lower doses of naloxone (0.1 mg/k/g and 1 mg/kg) significantly exacerbated deficits in beam balance and beam walking. On the other hand, the highest dose of naloxone (20 mg/kg) tended to reduce the deficits in beam balance and beam walking.

In low concentrations naloxone preferentially binds to mu receptors; however, at higher concentrations it also binds to additional opiate receptors (Wood, Neuromethods Vol. 4, p. 329, Humana Press, 1986). These findings suggest that endogenous opiates acting on mu receptors may attenuate transient behavioral suppression and exert a protective effect on longer term behavioral deficits observed after brain injury. On the other hand, endogenous opiates, possibly acting at additional receptors, may contribute to the production of longer-term behavioral deficits. It is possible that the high dose of naloxone will be found to significantly protect against long term behavioral deficits after higher levels of injury. Future research will include studies with higher injury levels and will include measurement of additional physiological parameters. (Supported by NIH Grants #NS 21458 and NS24413).

349.11 SYSTEMIC PHYSIOLOGICAL AND CINE-RADIOGRAPHIC CHARACTERIZATION OF A NEW FLUID-PERCUSSION BRAIN INJURY TECHNIQUE IN RATS. C.E. Dixon, J.W. Lighthall, and T.E. Anderson. General Motors Research Labs, Biomedical Science Dept., Warren, MI 48090.

The fluid-percussion (FP) technique produces brain injury through brief deformation of neural tissue associated with injection of small volumes of saline. We have developed a new FP technique that may assist in delineating biomechanical components of brain injury. This report demonstrates comparability with previous techniques at comparable pressure pulse parameters and characterizes: 1) systemic physiologic and histopathologic responses, and 2) the fluid dynamics associated with FP brain injury through use of cine-radiography.

For physiological characterization, rats (n=14) were anesthetized with Ketamine (87mg/kg) plus Xylazine (13mg/kg), tracheostomized and ventilated. A tube was fastened over a central craniotomy. Blood pressure, ECG, EEG, and blood gases were recorded for 60 minutes post injury. Offline, EEG magnitude (μV) was computed for Delta (1-4 Hz), Theta (5-8 Hz), Alpha (9-14 Hz), and Beta (15-25 Hz) frequency bands. The FP device consists of a gas accelerated piston which drives a chambered valve spool through a valve body to rapidly open and close a connection between a pressurized saline reservoir and the intracranial cavity. Rats received either a low (1.5 atm) or high (3.1 atm) severity fluid pressure pulse, both with 20msec duration. The new technique produces changes in blood pressure similar to previous techniques; however bradycardia was not observed. Increases in heart rate were produced by both injury levels, and were more prolonged at the high level of injury severity. Both magnitudes of injury produced decreases in EEG amplitude immediately post-injury, but high severity injury produced a greater decrease in delta activity than did low severity injury. Both levels produced hemorrhage at the site of injury, thalamus, corpus collosum, hippocampus and fimbria hippocampus similar to previous techniques. Higher severities produced more extensive cerebral hemorrhage and greater spinal involvement. This data demonstrates that our new FP technique is comparable to other techniques for comparable pressure pulse parameters, while providing full control of pulse parameters to enable biomechanical characterization.

For biomechanical characterization, cine-radiographic images were made in a separate group of rats (n=7) at coronal and sagittal orientations during the fluid pressure pulse. Intracranial fluid movement was characterized by rapid lateral and anterior/posterior epidural flow. This suggests that the distributed nature of FP induced pathology and dysfunction reflects, in part, a diffuse mechanical loading of brain tissue.

349.12 CONTROLLED CORTICAL IMPACT: A NEW MECHANICAL BRAIN INJURY MODEL. James W. Lighthall, Biomedical Science, General Motors Research Laboratories, Warren MI, 48090-9055.

A new experimental model of mechanical brain injury was produced in the laboratory ferret using a stroke-constrained pneumatic impactor. This model for the first time allows the independent control of the impact contact velocity and the level of forced compression used to produce the brain injury. The purpose of this study was to design a model which reliably produced graded cortical contusion and subcortical injury by precisely controlled brain deformations. Ferrets were anesthetized with Ketamine HCL (25mg/kg) and Xylazine (2mg/kg) I.M. Changes in blood pressure (BP), heart rate (HR) and respiration were monitored continuously. Cortical impacts were performed through a craniotomy centered between bregma and lambda with contact velocities of 2.0 to 4.0 m/s and deformation levels of 2.0 to 5.0 mm. The impactor tip measured 1.25cm in diameter with a spherical interface. Stability of the skull and level of deformation were verified radiographically. Low velocity (2.0 m/s) impacts at deformations <3.5mm produced no discernible morphologic changes. Medium velocity (3.0 m/s) impacts produced a range of morphopathologic alterations including immediate subdural hematoma, extensive subarachnoid hemorrhage, and production of graded cortical contusion. High velocity (4.0 m/s) impacts consistently produced contusion of the cerebellum, brainstem and spinal cord. High velocity impacts at deformations >3.5mm were fatal. Histologic examination revealed graded severity injury including petechial and intraparenchymal hemorrhage in the cortex, subcortical white matter, hippocampus, cerebellum, brainstem and spinal cord. Axonal beading and retraction balls were observed in the subcortical white matter underlying the impact site when survival times were 10-12hrs. Cortical impact produced changes in the HR, SABP and respiration similar to those described in published mechanical brain injury models. The severity of the injury response was dependent on both contact velocity and the level of cortical deformation. Several aspects of the new model are unique: a) graded severity cortical contusions can be produced in conjunction with subcortical reactive axonal injury and vascular damage; b) independent control of the impact contact velocity and level of cortical deformation is possible, thus allowing physical and analytical modelling of the impact dynamics to be performed; c) this model utilizes a colony-bred laboratory mammal which possesses a convoluted cerebral cortex.

The model described here will form the basis for further studies which address the influence of velocity and forced deformation on the severity of brain injury.

349.1 **BODYWALL MUSCLE FIBERS OF *DROSOPHILA* LARVAE ARE INNERVATED BY BOTH GLUTAMATE AND ASPARTATE IMMUNOREACTIVE NERVE TERMINALS.** J. Johansen, M.E. Halpern*, K.M. Johansen*, and H. Keshishian, Department of Biology, Yale University, New Haven, CT 06511.

Glutamate, classically, has been thought of as the principal excitatory transmitter at the neuromuscular junction in dipteran larvae (Jan & Jan, *J. Physiol.*, 1976). However, physiological evidence suggests that aspartate may play a role as well (Irving & Miller, *J. Comp. Physiol.*, 1980). We have investigated bodywall muscle innervation in *Drosophila* third instar larvae by applying immunocytochemical techniques. Using polyclonal antisera (Toomim et al., *Soc. Neurosci. Abstr.*, 1986) we have mapped the distribution and characterized the morphology of glutamate and aspartate immunoreactive nerve terminals on the bodywall muscles. Immunoblot analysis and preincubation experiments with BSA-conjugated aspartate and glutamate showed that the two antibodies used were specific for the respective transmitters and that they did not have any cross-reactivity.

The bodywall of *Drosophila* larvae is a particularly favorable preparation for analysis of motor innervation since each hemisegment is composed of less than 30 discrete muscle fibers which are segmentally repeated in a stereotyped pattern. Immunocytochemical staining with the two antibodies revealed that every bodywall muscle fiber was innervated by both aspartate and glutamate positive nerve fibers. The innervation was in most cases initiated at the middle of each individual muscle fiber from where multiple axons branched over the inner surface of the muscle fibers. However, in some instances, as exemplified by the longitudinal muscles 6 and 7, two muscle fibers were innervated simultaneously by the same axon. These axons were running longitudinally in the cleft between the muscles giving off alternating terminals to the two muscle fibers. Consequently, muscle 6 and 7 may constitute a functional unit. The innervating axons were beaded in appearance with regularly spaced varicosities of from 1-5 μm in diameter. Immuno-electron microscopy with peroxidase labeled second antibody showed that the varicosities were surrounded by a subsynaptic reticulum, that they contained immunoreactive vesicles of about 30-50 nm, and thus probably represent synaptic release sites.

We could not discern any differences in the innervation pattern and morphology between the glutamate and aspartate positive nerve fibers. However, double labeling experiments with the aspartate and glutamate antibodies using different fluorescent conjugated second antibodies showed that the aspartate and glutamate positive nerve terminals were separate and belonged to different axons. Thus, our experiments suggest that every larval bodywall muscle fiber in *Drosophila* is dually innervated by at least one aspartatergic and one glutamatergic axon. A direct physiological excitatory transmitter role for aspartate, in addition to that of glutamate, has been demonstrated in *Musca* (Irving & Miller, *J. Comp. Physiol.*, 1980) and similar experiments to detemine whether this is also the case for aspartate in *Drosophila* are in progress.

We thank Drs. C. Toomim and P. Petrusz for their generous gift of glutamate and aspartate antibodies.

349.2 PHARMACOLOGICAL STUDIES OF AN IDENTIFIED MONOSYNAPTIC CHOLINERGIC SENSORY-TO-MOTOR CONNECTION IN THE NICOTINE-RESISTANT INSECT MANDUCA SEXTA. B.A. Trimmer* and J.C. Weeks (SPON: D. Bentley). Dept. of Entomological Sci. Univ. of California, Berkeley, CA 94720

Sensory hair afferents on the prolegs of the tobacco hornworm Manduca sexta make monosynaptic excitatory connections with an identified motorneuron, PPR. This motorneuron forms the efferent part of a reflex arc which results in proleg withdrawal. As in other insect sensory systems, the afferents appear to release acetylcholine (ACh) (Weeks & Jacobs, J. comp. Physiol. 160:315, 1987). This synapse provides a unique system in which to study the pharmacological basis of Manduca's remarkable tolerance to the ACh agonist nicotine, which is present in high levels in its natural diet.

Single sensory neurons were stimulated at 1 Hz by current pulses through a suction electrode applied to the epidermal surface of a hair socket. The responses of PPR were recorded intracellularly while perfusing the desheathed ganglion with various cholinergic agents. The evoked unitary EPSP was found to be relatively stable over the course of a two hour experiment. PPR's resting potential, input resistance and signal-averaged EPSP were measured during drug application. The potent nicotinic antagonist mecamylamine reversibly blocked the EPSP with the half maximal effect (V_{50}) at 5 x 10^{-5}M. Higher concentrations of tubocurarine and atropine also blocked the synapse. During perfusion with the agonists carbachol or tetramethylammonium, PPR rapidly and reversibly depolarized with a corresponding decrease in input resistance. The potency of these effects is equivalent to that seen in the cockroach (David & Sattelle, J. exp. Biol. 108:119, 1984). Nicotine, which also depolarized PPR, is much less potent than on cockroach motorneurons (V_{50} = 1 x 10^{-4}M compared to V_{50} = 2.3 x 10^{-6}M). The rapidity and reversibility of these agonists' actions would suggest that in addition to the cellular protection mechanisms described previously (Morris, J. Insect. Physiol. 29:807, 1983) Manduca's insensitivity to nicotine results from a specific resistance of the ACh receptors themselves.

We have also observed potent effects of several muscarinic agents. Oxotremorine completely suppress the EPSP at doses as low as 2 x 10^{-8}M. In addition it caused long-lasting oscillations of the resting potential and evoked bursts of activity in the ganglion. These effects were antagonized by atropine. At low concentrations, atropine and scopolamine-methyl-bromide caused a potentiation of the EPSP and a slight hyperpolarization of PPR. In insects there is no known role for the numerous muscarinic binding sites identified with radioligands. We are at present using physiological methods to determine if some of these muscarinic effects are mediated by receptors presynaptic to PPR. Supported by a research grant from the Whitehall Foundation.

349.3 REGULATION OF BEHAVIORAL SENSITIVITY TO THE NEUROPEPTIDE, ECLOSION HORMONE, IS DIFFERENT IN THE ADULT AND PUPAL STAGES OF THE TOBACCO HORNWORM, MANDUCA SEXTA. D.B. Morton and J.W. Truman (SPON. K.A. Mesce), Department of Zoology, University of Washington, Seattle, WA 98195.

The neuropeptide, eclosion hormone (EH), triggers ecdysis behavior at the end of each molt in the tobacco hornworm, Manduca sexta. Previous studies have shown that at pupal ecdysis, EH acts directly on the CNS via cGMP to phosphorylate two proteins, termed the EGPs (Eclosion hormone and cGMP regulated Phosphoproteins).

At each developmental stage, the animals will only respond to EH during the 6-8 hrs immediately preceding the expected time of ecdysis. We have previously shown, for pupal ecdysis, that the onset of this window of behavioral sensitivity coincides with, and is believed to be due to, the appearance of the EGPs in the CNS.

The present report describes the presence of the EGPs in the CNS of both larvae and adults. During the last larval molt, the EGPs are first seen 6 hrs before the expected time of ecdysis, the same time as when behavioral sensitivity is first seen. Immediately after ecdysis, the EGPs will no longer accept ^{32}P from ATP, most probably because they have already been phosphorylated by unlabeled phosphate as a result of the action of endogenously released EH. Thus, larval ecdysis is similar to pupal ecdysis in that EH acts via the phosphorylation of the EGPs. Also, the appearance of the EGPs at larval ecdysis coincides with the appearance of sensitivity to EH.

The EGPs are also present prior to adult ecdysis and, as with the larval and pupal ecdyses, will no longer accept labeled phosphate after ecdysis. This suggests that EH acts via the EGPs at each ecdysis. Unlike larval and pupal ecdysis, however, the EGPs are first present 6 days before the animals will first respond to EH. Furthermore, they can also be phosphorylated by the action of EH prior to behavioral sensitivity. This implies that at adult ecdysis, the regulation of sensitivity to EH is at a step distal to the phosphorylation of the EGPs.

Supported by NIH grant NS-13079.

349.4 CLONALLY RELATED NEURONS IN MANDUCA SEXTA EXPRESS DIFFERENT PUTATIVE TRANSMITTERS. J.L. Witten and J.W. Truman. Dept. of Zoology, U. Washington, Seattle, WA 98195.

We have been studying the neurochemical differentiation of identified clusters of neurons born during the larval life of the moth, Manduca sexta. Using immunohistochemical methods, we have mapped the distribution of gamma-aminobutyric acid (GABA), an octopamine-like compound and a peptide that is similar to molluscan small cardioactive peptide$_b$ (SCP$_b$) in the segmental ganglia of this insect. We have localized these three putative neurotransmitters to one identified cluster of clonally related postembryonic neurons (PEN's).

During the larval stages arrays of identifiable neuroblasts generate discrete clusters of neurons. These nests are in stereotypic positions in the ganglia and can be studied as identified neuron clusters. After birth the cells in each cluster are arrested at an early stage of differentiation. At the onset of metamorphosis, ecdysone triggers the resumption of their development. The strength of this system is that each cluster represents a unique, identified lineage of a single stem cell and we can follow its neurochemical differentiation throughout the postembryonic development of the insect.

Antisera to each putative transmitter stains a distinctive subpopulation of the PEN clusters. The SCP$_b$-like and octopamine-like immunoreactivity (IR) are restricted to 2 of the 22 paired clusters in the thoracic ganglia. The subpopulation of PEN's that show GABA-IR is the largest (80% of the clusters staining). Only a subgroup of the neurons within each cluster are immunoreactive for each antigen. This heterogeneity in phenotype may indicate that both lineage position and extrinsic factors are involved in regulating transmitter expression. All three antisera stain subsets of neurons within one identifiable cluster in the thoracic ganglia (F cluster). Birth-dating and cell lesion techniques are being applied to neurons of the F cluster to investigate the interaction of cell lineage with steroid hormones in the regulation of transmitter expression.

Supported by grants NS-07936 (JLW) and NS-13079 (JWT).

349.5 NEUROPEPTIDE BIOSYNTHESIS: MODEL SYSTEM IN AN INSECT

S. Hekimi* and M. O'Shea. Lab. of Neurobiology, Univ. of Geneva. CH-1211 Geneva 4, Switzerland

We have investigated the biosynthesis of two homologous neuropeptides in the insect Schistocerca gregaria (Desert locust). The two neuropeptides are adipokinetic hormones called AKH I (pGlu-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-Thr-NH_2, Stone et al., Nature 263, 1976) and AKH II (pGlu-Leu-Asn-Phe-Ser-Thr-Gly-Trp-NH_2, Siegert et al., Biol. Chem. Hoppe Seyler 366, 1985). We have shown (Hekimi and O'Shea, 1987, J. Neurosci. in press) that both are synthesised by the neurosecretory cells of the glandular lobe of the corpus cardiacum (CC), a major neurosecretory structure in the insect head. The AKH peptides regulate a variety of physiological processes during long-duration (migratory) flight.

Using an in vitro organ culture system we are able to study the biosynthesis of AKH I and II by monitoring the incorporation of ^{3}H-labeled Trp into proteins and peptides. The products of the neurosecretory cells are purified by size exclusion and reverse-phase HPLC and can be identified by radioimmunoassay (RIA). To achieve the latter, analogs of AKH I and II were designed for the production of antisera which discriminate between AKH I and II. We have also generated, using a non-amidated analog of AKH I, an antiserum which recognises the two primary precursor polypeptides, P1 and P2, of the AKH peptides (Hekimi and O'Shea, 1987, J. Neurosci. in press). Using the in vitro system and by combining HPLC purification with RIA detection we have identified polypeptides intermediate in size between P1/P2 and the two hormones. We believe these peptides are intermediates in AKH biosynthesis. In order to characterize enzymatic steps involved in precursor processing we incubated the neurosecretory cells with two non-protein amino acids, L-canavanin (analog of arginine) and S^2-amino-ethyl cystein (an analog of lysine). These analogs are incorporated into the P1 and P2 precursors in place of Arg and Lys. Processing of the newly made precursors (P1 and P2) is inhibited, suggesting trypsin-like enzymes are involved in precursor processing. The culture system we have developed also has allowed us to study the regulation of AKH biosynthesis during postembryonic development. This study shows that the rate of synthesis of both precursors and neuropeptides increases dramatically in late postembryonic development and during adult maturation, just prior to the first appearance of flight behavior. We are currently investigating whether this increase in synthesis rate is hormonally induced.

(Research supported by SNF No 3.181.0.85. We thank T. Barkas for help in design of the analogs.)

349.6 **PURIFICATION AND CHARACTERIZATION OF THE FMRFamide RELATED PEPTIDE OF DROSOPHILA MELANOGASTER.**

John R. Nambu[1], Philip C. Andrews*[2], Gottfried J. Feistner*[3], and Richard H. Scheller[1]. [1]Dept. of Biol. Sci., Stanford Univ., Stanford, CA 94305, [2]Dept. of Biochem., Purdue Univ., West Lafayette, IN 47907, [3]Dept. of Psychiatry and Behav. Sci., Stanford Medical Center, Stanford, CA 94305.

The amidated tetrapeptide FMRFamide has been shown to exhibit a wide range of activities on target neurons and muscle cells in both vertebrate and invertebrate preparations. In addition, FMRFamide immunoreactivity has been observed in a variety of organisms and several structurally related peptides have been identified. The FMRFamide gene has been cloned from Aplysia californica, and encodes a precursor which contains 28 copies of FMRFamide and a single copy of FLRFamide. In Drosophila melanogaster, K. White et al. (J. Comp. Neurol., 247:430-438, 1986) have demonstrated that a stereotypic pattern of neurons and processes in the larval and adult CNS stain specifically with FMRFamide antibodies, implying a neurosecretory function for this material. Interestingly, FMRFamide staining was observed to overlap the staining patterns of antisera against two other neuropeptides, CCK and Substance P.

In order to determine the precise nature of the FMRFamide immunoreactive material, we employed ion exchange chromatography, gel filtration, and HPLC techniques in conjunction with a FMRFamide radioimmunoassay to purify the FMRFamide immunoreactive substance from adult Drosophila melanogaster. Amino acid composition analysis as well as FAB mass spectrometry, and protein sequencing methods indicated that the most abundant immunoreactive substance is a 9 amino acid peptide with a molecular weight of 1182, and a sequence of DPKQDFMRFamide. The peptide thus contains a FMRFamide core but is extended amino-terminally and is distinct from all other known FMRFamide related peptides. Studies are currently in progress to determine the physiological activities of this peptide, and also, to isolate the corresponding gene sequences. It is hoped that application of the powerful molecular and genetic techniques available in Drosophila will permit evaluation of the actions and importance of this molecule in the fly's physiology and development.

349.7 RFamide NEUROPEPTIDES IN THE HYDROMEDUSA POLYORCHIS PENICILLATUS; LOCALIZATION, ISOLATION AND ELECTROPHYSIOLOGY.

A.N. Spencer, C.J.P. Grimmelikhuijzen*, M. Hahn* and J. Przysiezniak. Department of Zoology, University of Alberta, Edmonton, Alberta, Canada T6G 2E9 and Zoological Institute, University of Heidelberg, Im Neuenheimer Feld 230, 6900 Heidelberg, Federal Republic of Germany.

Within the nervous systems of all cnidarians, examined to date, there are populations of neurons which are immunoreactive to antisera raised against RFamide and FMRFamide. These immunoreactive neuronal populations share several characteristics. They form diffuse nerve-nets closely associated with smooth muscles and many somas have a neurosensory appearance. In addition they may be found close to regions of neuronal condensation, such as the nerve-rings of medusae.

Using a radioimmunoassay for RFamide, large quantities (3.4 nmol/g wet weight) of immunoreactive material were found in an acetic acid extract of the bell margins of the hydromedusa, Polyorchis penicillatus. After desalting and partial purification using Sep-pak cartridges, further purification using cation-exchange chromatography on CM-Sephadex C-25 and reversed-phase HPLC, gave a peptide which was subsequently analysed and sequenced. This Polyorchis peptide has the sequence <Glu-Leu-Leu-Gly-Gly-Arg-Phe-NH_2. The chromatographic behavior of the purified peptide was compared with that of synthetic peptide produced by Bachem Ltd. (Switzerland). No differences were found. Antisera raised against this peptide gave strong neuronal staining, particularly of a nerve-net in the manubrium, with lighter staining of neurons in tentacles and the marginal nerve-rings.

Applications of RFamide, FMRFamide, FLRFamide and <Glu-Gly-Arg-Phe-amide (an anthozoan neuropeptide) to the partially isolated motor nerve-net (SMN network) of Polyorchis produced long duration (2 min.) depolarizations with an associated increase in firing frequency. The anthozoan peptide was active at the lowest concentration (approx. 10^{-7}M). Unlike the above peptides, the Polyorchis RFamide peptide does not appear to produce electrophysiological effects in the swimming motor nerve-net. Preliminary data on the effect of the Polyorchis RFamide peptide on other identified neurons and epitheliomuscular cells in primary cultures will be described. Primary cultures are produced by exposing the marginal nerve-ring to hypotonic shock (20% ASW) to remove the epithelium and then subsequent treatment in divalent-cation free seawater followed by digestion in 1000 U/ml collagenase.

The purification and sequencing of the Polyorchis RFamide peptide were carried out by CJPG and MH in Heidelberg; electrophysiological experiments were performed by ANS and JP in Edmonton and the Bamfield Marine Station. Supported in part by the Deutsche Forschungsgemeinschaft (Gr 762/4-3, Gr 76217-1) and NSERC, Canada (A0419).

349.8 FMRFAMIDE AND RELATED PEPTIDES SWITCH A CRUSTACEAN MUSCLE INTO AN OSCILLATORY MODE.

P. Meyrand*, J. Golowasch, and E. Marder. Biology Department, Brandeis University, Waltham, MA 02254.

The pyloric dilator (cpv) muscles of the shrimp, Palaemon serratus, are capable of producing myogenic contractions, which can be entrained by rhythmic excitatory synaptic input from the Pyloric Dilator (PD) motor neurons found in the stomatogastric ganglion (STG) (Meyrand & Moulins, J Comp Physiol A,158:489-503, 1986). Previous work showed that bath-application of dopamine can transform the cpv muscle from a non-oscillatory state to an oscillatory state. We now find that a FMRFamide-like peptide is present in the motor nerves innervating the cpv muscle, and that FMRFamide and related peptides can evoke rhythmic movements of the cpv muscle in the absence of excitatory synaptic input.

Cpv muscles were isolated with the nerve attached, but all ganglia removed. Movement was monitored with a force-displacement transducer, membrane potential monitored intracellularly, and peptides were applied through a continuously flowing superfusion system. FMRFamide (10^{-6}M) and Helix peptide (pGluAspProPheLeuArgPheamide) (10^{-7}M) elicited strong rhythmic (0.75-1 Hz) contractions of the cpv muscle. This frequency is similar to those of the pyloric rhythm generated by the stomatogastric ganglion. Peptide-evoked contractions were as much as 7-fold larger than those produced by stimulation of the nerve in the absence of the peptide. The rhythmic contractions elicited by peptide could be entrained by synaptic stimulation.

The presence of a FMRFamide-like peptide in the shrimp stomatogastric nervous system was demonstrated by whole mount immunocytochemistry. As in lobsters and crabs, (Marder, Calabrese, Nusbaum, & Trimmer, J Comp Neurol, 259: 150-163, 1987), FMRFamide-like staining was seen in fibers in the stomatogastric nerve (STN), and in neuropilar ramifications in the STG. Unlike lobsters and crabs, two stained somata were seen in the STG. Stained fibers were seen in the motor nerves of the stomatogastric nervous system, including those eventually terminating on the cpv muscles.

These data suggest that a FMRFamide-like peptide may be neurally released onto or in the vicinity of the cpv muscles. This peptide may function to switch the muscle from a "follower" mode to one in which endogenously produced rhythmic contractions are entrained by neural inputs, as seen in the leech heartbeat system (Kuhlman, Li, & Calabrese, J Neurosci, 5:2310-2317, 1986).

Supported by NS 17813 and a fellowship from the Fondation pour la Recherche Medicale (PM).

349.9 PEPTIDE F_1: A MYOACTIVE LOBSTER PEPTIDE RELATED TO FMRF-AMIDE. *E.A. Kravitz, L. Kobierski*, B.A. Trimmer*, and M.F. Goy**. Neurobiology Dept., Harvard Med. Sch., Boston, MA 02115.

The tetrapeptide FMRFamide, originally isolated in 1977 by Price and Greenberg as a molluscan cardioexcitatory peptide, is the first isolated member of a large family of related peptides found in both invertebrate and vertebrate nervous systems. Considerable interest has focused on these peptides and their structural relationship to the vertebrate opioid peptides, a relationship strengthened recently by genetic analysis, which shows considerable sequence homology between the gene coding for FMRFamide peptides in Aplysia and the genes coding for several members of the vertebrate opioid family of peptides (Taussig and Scheller, 1986).

A large family of FMRFamide-like peptides also has been found in the lobster, Homarus americanus. Two members of this family have been purified and sequenced (Peptides F_1 and F_2, Trimmer et al., in press) and one has been synthesized (peptide F_1: Thr-Asn-Arg-Asn-Phe-Leu-Arg-Phe-NH_2). FMRFamide-like peptides have been localized in about 350 neurons in the lobster nervous system. The morphological localization has suggested possible roles of these peptides in integration of visual and olfactory information, in regulation of the anterior and posterior gut, and in the control of exoskeletal muscles (Kobierski et al., in press). In addition, a dense nerve terminal plexus containing these peptides covers the connective tissue sheath surrounding much of the ventral nerve cord, suggesting an important neurosecretory role for these substances.

The functional roles have been detailed further by examining the actions of synthetic peptide F_1 on several different types of lobster muscle and comparing these actions to the effects of FMRFamide, proctolin and the amines serotonin and octopamine. Peptide F_1 has significant long duration potentiating actions on all preparations that we have tested. These include the heart, the opener muscle of the dactyl of the walking leg and the oesophagus. The thresholds for F_1 actions on these tissues is in the 10^{-10}-10^{-9}M range, about 3-4 orders of magnitude lower than the thresholds for FMRFamide on the same preparations. F_1 increases the rate and strength of the heart beat, increases transmitter release and induces a contracture in exoskeletal muscles, and generates rhythmic contractions of the gut. These changes are seen with little or no change in cAMP levels in these tissues. Qualitative and quantitative differences exist between the actions of F_1 and the other modulator substances. Peptide F_1 therefore seems to be a potent myoactive agent in lobsters: its mechanism of action is under active investigation. (Supported by NIH).

349.10 PURIFICATION AND PROPERTIES OF PEPTIDE G_1, A PUTATIVE HORMONE THAT ALTERS CYCLIC GMP METABOLISM IN LOBSTER TISSUES. *Michael F. Goy*, Mark H-F. Kuo*, Michael Pavloff*, and Edward A. Kravitz.* (SPON: K. Dunlap). Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Levels of cyclic GMP, of cyclic GMP-dependent protein kinase, and of phosphoprotein substrates for the kinase are unusually high in invertebrates, like the American lobster. In an effort to understand the physiological role of this cyclic nucleotide, we have tried to identify hormones that affect its metabolism in lobster tissues. As part of this search, we have found that extracts of the sinus gland, a well-known crustacean neurohemal organ, potently stimulate cyclic GMP levels in lobster skeletal muscle, heart, gut, ventral nerve cord, and other tissues.

Fractionation of the sinus gland extract reveals three independent peaks of cyclic GMP-promoting activity. Two of these are relatively minor components, and have not yet been characterized. The main peak, which comprises about 80% of the total, is a 7-8,000 dalton peptide. We have purified it more than 10^6-fold by sequential ion exchange and reverse phase HPLC. Preliminary amino acid analysis, coupled with information about its chromatographic properties and relative abundance (about 1 pmol per sinus gland), suggests that this is a novel peptide. We have named it peptide G_1, because it is the first lobster peptide to be purified solely on the basis of its ability to affect cyclic GMP metabolism.

We have produced highly enriched fractions of peptide G_1 by gel filtration and ion exchange chromatography, and tested these fractions for physiological effects at the lobster neuromuscular junction. Lobster muscle is an important target for this peptide, showing up to 100-fold increases in cyclic GMP content after treatment with the peptide. Along with these biochemical changes, the enriched fractions cause a slow, reversible suppression of muscle contractility. The time course is particularly striking, with onset occuring over 30-60 min and washout requiring many hours. Contractile responses to nerve stimulation and potassium depolarization are both reduced, approximately equally. In contrast, the amplitudes of synaptic potentials during stimulation of the excitatory motor axon are slightly increased. This suggests a possible disruption of excitation-contraction coupling in the muscle fiber. Current efforts are focused on large-scale purification, in order to verify these observations with peptide that has been purified to homogeneity. (Supported by NIH grant NS21290).

349.11 **PRESENCE AND RELEASE OF A CCK/GASTRIN-LIKE MOLECULE IN THE LOBSTER STOMATOGASTRIC GANGLION.** G. Turrigiano* and A.I. Selverston. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

The stomatogastric ganglion (STG) of the lobster contains two central pattern generators (CPGs), the pyloric and the gastric mill CPGs. Each produces a characteristic pattern in the absence of sensory input, but recent work from several labs suggests that modulatory inputs can alter properties of CPG neurons to select among different stable patterns. Bath application of monoamines and of neuropeptides (FMRFamide and proctolin) can modulate the output of the STG, and immunohistochemistry has shown that these substances are present in the neuropil of the STG, and in soma in the commisural ganglia (CGs), which are connected to the STG by the stomatogastric nerve (STN). Recently cck/gastrin-like immunoreactivity has been reported in tissues of several invertebrates, including arthropods (B. Larson and S. Vigna, *Gen. Comp. Endocrin.* 50:469-475,1983), and a related peptide, leucosulfakinin, has been isolated and sequenced from cockroach heads (R. Nachman et al., *Science* 234:71-73,1976). This abstract reports the identification of cck/gastrin-like immunoreactivity in the STG nervous system of the lobster *Panulirus interruptus*, and suggests that a cck/gastrin-like molecule may be released into, and modulate the output of the STG.

Immunohistochemical localization of neurons and fibers was accomplished using a polyclonal antibody raised against the terminal sequence of cck (Immuno Nuclear Corp.). At least four cell bodies in the CGs show cck-like immunoreactivity, and fibers which appear to originate in the brain have neuropil in the CGs. Positively staining fibers were seen in the STN, which branched out into densely staining neuropil throughout the STG. None of the STG neurons themselves stained, and no fibers were seen leaving the ganglion. We tested the crossreactivity of this antibody using a sensitive immunoblot assay, and found that it crossreacted with peptides with the same terminal sequence as cck, but not with other small peptides such as proctolin and FMRFamide. The pattern of staining was very similar in *Panulirus* and *Procambarus clarkii*.

CCK and the structurally related caerulein peptide could modulate the output of the STG. When bath was applied at high concentrations (10^{-4} M) these peptides reliably turned on a pyloric rhythm in quiescent preparations, and in some preparations started up a gastric rhythm as well. These effects were reversible and took up to two hours to wash out.

In addition, we used our immunoblot assay to demonstrate that crude extracts of lobster stomachs and nervous systems contained cck/gastrin-like immunoreactivity, and that stimulation of the STN produced release of a cck/gastrin-like molecule into the STG. A small vaseline well was built around the STG, and the desheathed ganglion was bathed in 5 µl of saline with the protease inhibitor pmsf. The STN was electrically stimulated for ten minutes, and the saline collected and assayed for cck/gastrin-like immunoreactivity. The stimulated condition showed a many-fold stronger reaction than unstimulated controls. We are currently attempting to quantify this release using an ELISA assay.

Taken together, these results suggest that a cck-like molecule has a functional role in the STG. The high concentrations needed to produce a modulatory effect suggests that the endogenous substance is related to, but distinct from, mammalian cck. We are currently attempting to isolate and characterize the endogenous substance. (Supported by NIH NS09322 and NSF BNS81-18756 to A.I.S.)

349.12 A NEWLY IDENTIFIED MODULATORY PROCTOLIN-CONTAINING NEURON (MP NEURON) IN THE STOMATOGASTRIC NERVOUS SYSTEM OF THE CRAB, CANCER BOREALIS. Michael P. Nusbaum and Eve Marder. Dept. of Biology, Brandeis Univ., Waltham, MA 02254.

The pyloric rhythm of decapod crustaceans is generated by a well-defined neural network located in the stomatogastric ganglion (STG), one of the ganglia of the stomatogastric nervous system (The Crustacean Stomatogastric System, eds. Selverston & Moulins, 1987, Springer-Verlag). The neuropeptide proctolin is found in neuropilar processes in the STG, fibers projecting into the STG from more central ganglia and subsets of neurons in the oesophageal ganglion (OG) and the commissural ganglia (CGs) (Hooper & Marder, Brain Res., 305:186-191,1984; Marder et al., J. Comp. Neurol., 243:454-467,1986). Bath application of synthetic proctolin to the isolated STG causes an excitatory modulation of the pyloric rhythm (Hooper & Marder, 1984; Marder et al., 1986).

In the crab Cancer borealis we have identified a modulatory proctolin neuron (MPN). The MPN has a 15 micron soma and is found in the region of the OG. Intracellular Lucifer-yellow (LY) fills indicate that the MPN extends processes towards both CGs and towards the STG. The proctolin content of MPN is revealed by double labeling the neuron using intracellular LY dye filling and subsequent processing for proctolin immunoreactivity (anti-proctolin antibody courtesy of M. O'Shea & C. Bishop), visualized with a rhodamine conjugated secondary antibody.

Intracellular stimulation of MPN increases the pyloric frequency of slowly cycling preparations. The effect on pyloric rhythm frequency was proportional to the frequency of MPN firing. MPN stimulation also produces an increase in the amplitude of the slow wave oscillations and the number of impulses per burst in some of the pyloric circuit neurons, including the VD and LP neurons. For example, the number of impulses per burst in the LP neuron increases up to 70%. During prolonged MPN stimulation the effects increase during the first 3-5 seconds, then attain a peak action which persists for the duration of the MPN activity. The effects decline slowly during the 5-10 seconds after the cessation of MPN activity. No discrete postsynaptic potentials time-locked with MPN impulses have been seen in any pyloric network neuron. These data suggest a modulatory type of synaptic action for the MPN. The effects of MPN stimulation on pyloric cycle frequency and the number of LP neuron impulses per burst are statistically indistinguishable from those of bath application of synthetic proctolin (10^{-6}M).

350.1 TRANSNEURONAL CHANGES IN COCHLEAR RADIAL AFFERENT FIBERS FOLLOWING DESTRUCTION OF LATERAL OLIVOCOCHLEAR NEURONS. K.M. Spangler and W.B. Warr. Dept. of Anatomy, Creighton University School of Medicine, and Center for Hearing Research, Boys Town National Institute, Omaha, NE 68178.

Lateral olivocochlear (OC) neurons, which are found in or near the lateral superior olivary nucleus (LSO) are the major, if not exclusive, source of the efferent synapses found on the peripheral processes (radial afferent fibers) of the Type I spiral ganglion cells. One of the few observations relating to the possible functional role of the lateral OC neurons comes from a study on patas monkeys by Bodian and Gucer (*J. Comp. Neurol. 192*:785-796, 1980), in which they severed the entire OC bundle within the vestibular nerve and examined the ultrastructure of the organ of Corti. They found a dramatic trans-synaptic effect on the radial afferent fibers consisting of an increase in volume and engorgement with microtubules, neurofilaments, vesicles, and other organelles. This phenomenon was re-examined during the course of an EM degeneration study of the inner spiral bundle. The rat was chosen as a model because all lateral OC neurons projecting to one cochlea are located within the ipsilateral LSO and can be lesioned selectively. Six days after unilateral electrolytic lesions of the LSO, animals were perfused with aldehyde fixatives. Serial frozen sections (40 μm) of the auditory brainstem were mounted on glass slides. Alternate sections were stained for Nissl or acetylcholinesterase for evaluation of the extent of the lesion and possible interruption of the OC bundle. Additional fixative was perfused through the cochlea via the round and oval windows and the cochleas were prepared for EM. In two cases with nearly total ablation of the LSO, the inner spiral bundles from part of the middle turn of the cochleas were examined in detail. The two main preliminary findings were 1) that there was a substantial, but subtotal, reduction in the number of thin fibers (presumably efferents) in the inner spiral bundle, and 2) that morphological changes, like those described by Bodian and Gucer, were evident in a number of radial afferent fibers. These findings confirm the observations in the monkey, but additionally demonstrate that a lesion of the lateral OC neurons is a sufficient condition for the effect. Further investigations are in progress to explore the time course of this trans-synaptic phenomenon and its possible effects on the physiology of cochlear nerve fibers. Supported by the Deafness Research Foundation and NIH Grant # 1 R01 NS24060.

350.2 THE CENTRAL PROJECTIONS OF TYPE-II SPIRAL GANGLION CELLS IN RODENTS. M.C. Brown, A.M. Berglund and D.K. Ryugo. Departments of Otolaryngology, Physiology, and Anatomy and Cellular Biology, Harvard Medical School; and Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA. 02114.

The mammalian spiral ganglion contains two populations of neurons: type-I cells contacting inner hair cells and type-II cells contacting outer hair cells. Although the central projections of the more numerous type-I cells have been extensively studied, the central projections of type-II cells have not. We have labeled the central axons of both types of cells using focal extracellular injections of horseradish peroxidase (HRP) into the peripheral edge of the spiral ganglion. The tissue was processed using diaminobenzidine. Typically, these injections label fewer than 100 ganglion cells from a discrete region in the cochlear basal turn. Using light microscopy, we traced the central axons through serial sections to their terminations in the ipsilateral cochlear nucleus. It has been difficult to mark the entire extent of these neurons in cats and guinea pigs so smaller mammals (gerbils and mice) were used in order to minimize the distance from injection site to termination.

In agreement with previous labeling studies in cats (Kiang, N.Y.S. et al., *Science* 217:175-177, 1982) and guinea pigs (Brown, M.C., *Soc. Neurosci. Abstr.* 12:1264, 1986), type-II cells in gerbils can be separated from type-I cells since they usually have smaller cell bodies and project centrally with thinner (less than 1 μm diam.) axons. In contrast to type-I axons, the thinner type-II axons lack obvious constrictions and areas of darker labeling associated with nodes of Ranvier; thus our observations are consistent with the hypothesis that the type-II central axons are unmyelinated.

In gerbils, HRP-labeled thin axons from three type-II somata were reconstructed from the spiral ganglion to their terminals in the cochlear nucleus with no apparent fading of any branches. In 5 other instances, the somata were obscured, but the thin axons were fully reconstructed within the cochlear nerve and nucleus. Other thin fibers, some traced from type-II somata, were partially reconstructed. Most of these thin fibers, however, were consistent with the following description: they coursed with the thicker type-I axons in the nerve and bifurcated in a similar region of the interstitial portion of the cochlear nucleus, formed ascending and descending branches, and emitted terminals in the anterior (AVCN), posterior (PVCN) and the dorsal (DCN) subdivisions of the cochlear nucleus. Although the type-II axons gave off fewer branches than type-I axons, the axon varicosities and terminal swellings of type-II fibers were as widely distributed throughout the cochlear nucleus as the type-I endings labeled in the same focal injections. However, in two specific areas, type-II terminations were found where type-I terminations were usually absent: 1) the superficial granule cell region of the AVCN dorso-medial to the type-I endings, and 2) layer II (the granule or pyramidal cell layer) of the DCN, superficial to the type-I endings. Preliminary results in mice are consistent with the gerbil results.

These results suggest that afferent information from outer hair cells, carried by thin type-II central axons, reaches all three major subdivisions of the cochlear nucleus. Type-I and type-II cells adjacent in the spiral ganglion have a topographical overlap for a portion of their cochlear nucleus endings, and a striking spatial segregation of the furthest central portion of the their arborizations, where the type-II endings are in areas having a high density of granule cells. Since branches from medial olivocochlear efferents also terminate in the superficial granule cell region of AVCN (Liberman, M.C., and Brown, M.C., *Hearing Res.* 24:17-36, 1986), efferent and type-II fibers associated peripherally with outer hair cells may converge centrally in a heretofore undescribed neural system. 350.3 AXONS OF PRESUMPTIVE TYPE-II SPIRAL GANGLION NEURONS SYNAPSE WITH GRANULE CELLS OF THE CAT COCHLEAR NUCLEUS. T.E. Benson and D.K. Ryugo. Department of Anatomy and Cellular Biology, Harvard Medical School, Boston, MA 02115 and Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA 02114.

Type-II spiral ganglion neurons contact outer hair cells (OHCs) whereas type-I neurons contact inner hair cells (Kiang et al., Science, 217:175-177, 1982). Thus there is segregation of the afferent pathways for the two hair cell systems. Although much is known about the central projections of the type-I neurons, information concerning the type-II terminations is just emerging (Brown et al., preceding abstract; Ryugo et al., Soc. Neurosci. Abstr., 12:779, 1986). In the present study, we have analyzed central terminals of presumed type-II axons in the cochlear nucleus of the cat.

Data were derived from 2 cats where extracellular injections of horseradish peroxidase (HRP) were made into the auditory nerves and the tissue processed using diaminobenzidine. Thin fibers (0.5 µm diameter) were anterogradely labeled, and were identified as type-II axons using light microscopic criteria (ibid.). Serial section electron microscopy was then used to analyze 3 such fibers in the interstitial region of the cochlear nucleus, concentrating on varicosities, terminal swellings and postsynaptic targets. Throughout the lengths examined, these thin fibers were unmyelinated. Some varicosities and short collaterals contained mitochondria and vesicles but had no associated synapses.

Synapses originated from en passant and terminal swellings. All were of the asymmetric variety as judged by their postsynaptic density and contained vesicles having the same degree of roundness as those of HRP-labeled type-I terminals. Terminals of type-II axons, however, had vesicles of smaller diameter (46.3 $\pm$ 0.4 nm) compared to those of type-I axons (54.6 $\pm$ 0.4 nm) and a characteristically large proportion (41-77%) of their apposition with target structures was synaptic.

Dendritic shafts and spine-like profiles were the postsynaptic targets of type-II axons. One postsynaptic dendrite was observed to originate from a granule cell. In fact, the ultrastructure of all targets thus far examined is consistent with their origin from granule cells of the cochlear nucleus (Mugnaini et al., J. Neurocytol., 9:537-570, 1980). Granule cells may therefore represent a central locus for the convergence of type-II afferents and collaterals from the medial olivocochlear efferents. Such efferents contact OHCs (Liberman and Brown, Hearing Res., 24:17-36, 1986). A previously undescribed system for processing acoustic information involving OHCs and granule cells may be unfurling. [Supported by NIH grants NS13126, NS20156 and NSF grant BNS-20833]

350.4 MODULATION TRANSFER CHARACTERISTICS OF NEURONS IN THE DORSAL COCHLEAR NUCLEUS OF THE CAT. C.E. Schreiner* and R.L. Snyder* (SPON: J. Mendelson). Coleman Laboratory, 971 HSE, University of California at San Francisco, San Francisco CA 94143-0526.

In the face of growing evidence that neurons in the dorsal cochlear nucleus (DCN) might specifically encode behaviorally relevant aspects of temporally varying signals, amplitude modulated tones and noises were used to characterize temporal response properties of neurons within the DCN of chloralose-anesthetized cats. Single units were classified following the scheme of Young and Brownell (*J. Neurophysiol.* 39:282-300, 1976). After a basic characterization of148 single units, discharge rate and synchronization (vector strength = VS) modulation transfer functions (MTFs) were constructed. Best-frequency tonal stimuli and white or bandpass-filtered noises were used as carrier signals.

For signal levels 30 dB or more above the response threshold, synchronization MTFs had a low-pass, band-pass or double-peaked form. Double-peaked (W-MTF) curves consisted of a low-pass portion separated from a band-pass portion by at least a 30% deep notch in vector strength (VS). Two additional types of MTFs were frequently seen for rate MTFs: high-pass MTFs and all-pass MTFs. The majority of type II units (approximately 55%) exhibited low-pass synchronization MTFs. By contrast, relatively few type III and type IV units exhibited low-pass characteristics (26% and 11%, respectively). Band-pass synchronization MTFs constituted the largest group for type IV (67%) and type III units (62%), compared to 27% of type II units. The striking W-MTFs for synchronization were seen in approximately 22% of type IV units, 18% of type III units and 12% of type II units. Insufficient numbers of type I units were found to allow for any significant assessment of their MTF response characteristics.

For the populations of units with band-pass synchronization MTFs, a range of "best modulation frequencies" (BMF = the modulation frequency that produced the highest VS) was recorded. For units with CFs between 4 and 8 kHz, the encountered BMFs ranged from about 90 Hz to 630 Hz, with a mean of 290 Hz. The upper boundary of the BMF range appeared to be a function of CF. BMF ranges for different unit types largely overlapped ; no clear distinction of their BMF ranges was apparent.

The phase function of band-pass synchronization MTFs showed a smooth progression as a function of modulation frequency, compatible with a constant-delay hypothesis. In contrast, phase function of W-MTFs often showed a discontinuity at modulation frequencies corresponding to the notch in the VS curve; the MTF portion below and above the notch frequency had different phase characteristics. These results indicate that the two different portions of W-MTFs probably reflect different sources of input and/or modes of operation.

Additional evidence for the interaction of various inputs in the definition of temporal response characteristics of single unit was obtained by the use of amplitude modulated noises. Using noise of various bandwidth, the synchronization MTF type could commonly be converted, for example, from a low-pass MTF for a carrier tone, to a band-pass MTF for a narrow-band noise, to a W-MTF for a broad band noise.

The possible significance of these phenomena for periodicity coding is complicated by observed population differences, and by the apparent mutability of MTF response characteristics as a function of signal complexity.

350.5 SYNAPTIC DEVELOPMENT IN THE MONGOLIAN GERBIL DORSAL COCHLEAR NUCLEUS G. DiCarlantonio* & I.R. Schwartz, Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024

As the first step in an ongoing investigation of synaptogenesis in the gerbil cochlear nucleus, synaptic connections within the neuropil of the DCN were assessed. As the major synaptic element of the DCN molecular layer (ML), the development of the parallel fiber (PF) synapse is emphasized. Animals at 6,7,10,12,14,16,18, 20,22,28,76,88 & 120 days after birth (DAB) were perfused with mixed aldehyde fixatives and prepared for electron microscopy.

At 7 DAB, granule cell PFs are of small caliber with a few neurotubules and mitochondria and frequently contain vesicles. Although vesicle-containing terminals are rare, they increase in number at successively deeper levels of the ML. Most terminals are only slightly enlarged with a few round synaptic vesicles loosely associated with the presynaptic density. In the deeper DCN, PFs are sparse and large unmyelinated axons are present. Most dendrites are smooth-contoured with infrequent spines; these rarely receive synapses.

Three striking changes are present at 14 DAB. 1) There is a great proliferation of dendritic profiles; most have a swollen appearance, sparse matrix, and a few spines. 2) There is a great increase in number of PF boutons which tend to be more mature at deeper levels. The more developed terminals are expanded in volume with a greater density of synaptic vesicles, many of which are associated with the presynaptic density. The postsynaptic density is markedly thickened. Boutons which contact dendritic spines are frequently invaginated by the spine. 3) Number of synapses per unit area has increased. The majority of synapses are formed by PF boutons, but both the number of classes and density of terminals increase at successively deeper levels. Several types of boutons with a denser matrix occur. The most frequently encountered is large, irregular, contains 3-6 mitochondria, numerous large, round synaptic vesicles and forms moderately long, postsynaptically thickened synapses on large caliber dendrites.

By 21 DAB most PF terminals contact dendritic spines and are invaginated by the spines to form cup-shaped profiles. There is further proliferation of dendritic profiles; most are the profusely branching trunks studded distally with spines typical of fusiform and cartwheel neuron dendrites. Although present at 14 DAB, large caliber myelinated axons become more prominent in the deeper areas at this time.

Older animals showed few additional changes in synaptic structure, indicating that synaptic maturation, as manifested by morphologic features and density of synaptic connections, is virtually complete as early as 21 DAB.

Supported by NIH grants NS09823, NS14503 & NS14945.

350.6 LOSS OF CARTWHEEL NEURONS IN THE DORSAL COCHLEAR NUCLEUS OF THE MOUSE MUTANTS LURCHER, PURKINJE CELL DEGENERATION AND STAGGERER. A.S. Berrebi, J.I. Morgan, and E. Mugnaini, Laboratory of Neuromorphology, Biobehavioral Sciences Graduate Degree Program, Univ. of Connecticut, Storrs, CT 06268 and Dept. of Neuroscience, Roche Institute of Molecular Biology, Nutley, NJ 07110.

Several lines of research have suggested that within the mammalian dorsal cochlear nucleus (DCoN) there exists a cerebellar-like network of neurons. Like the cerebellar cortex, the DCoN contains mossy fibers, granule and Golgi cells, and parallel fibers. In the superficial layers of DCoN, two distinctive neuron families, the spiny cartwheel cells and the nearly aspiny stellate cells, bear some striking similarities to cerebellar Purkinje and stellate cells. In particular, cartwheel cells and Purkinje cells share numerous cytological and synaptic features and are glutamate decarboxylase and cerebellin-positive.

We have previously shown in "nervous" mice, a mutation which produces a characteristic mitochondrial alteration in Purkinje cells, that cartwheel cells are the only neurons in the cochlear nuclear complex that express the same anomaly as Purkinje cells. Moreover, the respective mitochondrial alterations appear within a comparable time frame (Berrebi and Mugnaini, Anat. Rec., 1987). We report here a cartwheel cell loss in lurcher, pcd, and staggerer, all murine mutants that suffer Purkinje cell death. On the contrary, in the weaver mutation cerebellar Purkinje cells and, likewise, DCoN cartwheel neurons are spared. The data are derived mainly from immunocytochemical analysis of serial brain sections treated with the PAP procedure of Sternberger after incubation with a rabbit primary serum raised against the recently discovered peptide, PEP-19 (Ziai et al., P.N.A.S., 1987). This neuropeptide, which contains a calcium-binding sequence, is an excellent marker for both Purkinje and cartwheel cells and the immunoreaction reveals not only their cell bodies, but also their dendritic and axonal processes (Mugnaini et al., Arch. Ital. Biol., 1987, in press). These findings support the hypothesis that cartwheel cells in the cochlear nuclei are homologous to Purkinje cells in the cerebellar cortex. These neuronal populations may arise from the same embryonic precursors, although their mature phenotypes are not identical (Wouterlood and Mugnaini, JCN, 1984). Studies of additional murine mutations affecting the cerebellum are in progress.

Supported by PHS-NS grant 09904 (E.M.) and NINCDS-NRSA Postdoctoral Fellowship 1F32 NS08175 (A.S.B.).

350.7 IMMUNOSTAINING OF GABA-ERGIC AND GLYCINERGIC INPUTS TO THE ANTEROVENTRAL COCHLEAR NUCLEUS. J. C. Adams, and R. J. Wenthold. Department of Otolaryngology and Communicative Sciences, Medical University of South Carolina, Charleston, SC 29425 and Lab of Neuro-otolaryngology, NIH, Bethesda, MD 20205.

There are a variety of inputs to the rostral pole of the cochlear nucleus but few details concerning the nature of these inputs are known. In this study HRP was injected into the anteroventral cochlear nucleus of cats to identify individual inputs. Sections were incubated to visualize the transported HRP and then incubated to immunostain either GABA or glycine. In the deep portions of the dorsal cochlear nucleus (DCN) there are many medium sized pleomorphic neurons that project to the rostral portion of the ventral nucleus. Large numbers of similar appearing cells in the deep DCN immunostain for glycine. A much smaller number of similar appearing cells in the deep DCN immunostain for GABA. HRP-labeled cells in the deep DCN were found to be immunoreactive for glycine and others for GABA. The possibility that both antigens are in the same neurons was not tested. In the lateral nucleus of the trapezoid body, HRP-labeled cells were also found to be immunostained for glycine and others for GABA. In the ventral nucleus of the trapezoid body, there are large numbers of GABA-ergic cells and few, if any, glycinergic cells. Accordingly, in this region HRP-labeled cells were found that immunostained for GABA, but none for glycine. These results suggest that a large proportion of the inputs to the anteroventral cochlear nucleus from the olivary complex and perhaps all intrinsic inputs from the DCN are inhibitory. The bulk of the DCN inputs appear to be glycinergic; all the inputs from the ventral nucleus of the trapezoid body appear to be GABA-ergic; and numbers of inputs from lateral portions of the olive appear to be equally glycinergic and GABA-ergic.

There is considerable heterogeneity between the various inputs to the anteroventral nucleus with regard to immunostaining with antisera to peptides. The glycinergic cells in the deep DCN appear to also immunostain for enkephalin and for neuropeptide Y. The GABA-ergic cells in the ventral nucleus of the trapezoid body immunostain for enkephalin and a subpopulation of these that project to low frequency portions of other nuclei immunostain for neurotensin. The heterogeneity of staining of these various inputs may be helpful in indentifying specific terminals within the anteroventral cochlear nucleus. Elucidation of these inputs should promote understanding of the organization of the nucleus.

Supported by NIH grant NS-21307.

350.8 CHANGES WITH ADVANCED AGE IN THE MORPHOLOGY OF THE RAT AUDITORY NERVE. V. Hoeffding* and M.L. Feldman. Dept. of Anatomy, Boston Univ. School of Medicine, Boston, MA 02118.

While cell loss in the spiral ganglion and degeneration of terminals in the cochlear nucleus have both been observed in aging rats (J. Comp. Neurol., 188, 429, 1979; Neurosci., 7, S67, 1982; Gerontologist, 22, 213, 1982), the effect of advancing age on the auditory nerve has not been investigated in this species. The present study is investigating auditory nerve structure in a series of 24 rats ranging from young adulthood (2 mo) to extreme advanced age (36 mo). The animals were perfused via the aorta with mixed aldehydes; blocks including the auditory nerve and part of the ventral cochlear nucleus were removed, embedded in Araldite, and sectioned in a plane transverse to the axis of the nerve. The analysis of the material includes counts of normal and degenerating auditory nerve fibers and of glial cells, mapping of fiber packing densities, and measurements of vascularity and of the cross-sectional areas of the nerves.

Results obtained thus far suggest that the number of normal auditory nerve fibers declines from a mean of about 21,500 in young adult rats to a mean of about 17,000 in the oldest animals studied. While there is substantial variability around these numbers, this represents an approximate fiber loss of 21% at 36 mo. Despite this loss of fibers, there is an age-related increase of about 50% in the cross-sectional area of the nerve. This increase in area accompanies a decrease in the packing densities of auditory nerve fibers and an increase in the thickness of myelin sheaths in older animals. Glial lipofuscin and cytoplasmic debris are occasionally encountered in young adult animals, but these deposits clearly increase in frequency and size with advancing age.

350.9 SPIRAL GANGLION CELL DENSITY IN YOUNG AND OLD GERBILS. E.M. Keithley, A.F. Ryan and N.K. Woolf. Division of Otolaryngology, Dept. of Surgery, UCSD Medical School and Veterans Administration Medical Center, La Jolla, CA 92161.

Recently it was shown that the cochlear nucleus (CN) of adult gerbils (Meriones unguiculatus) contains a microcystic neuropathy (Ostapoff et al., ARO, 10:209, 1987). In order to determine if there is an associated loss of spiral ganglion cells (SGC) which project to the CN, the number of SGC was counted in 2 month old and 29 month old animals. The maximum reported lifespan of gerbils in 48 months (average = 36 month old).

Subjects chosen for this study had normal external and middle ears and physiological data was gathered prior to perfusion. (see Neuroscience Abs. Woolf et al, 1987). Animals were perfused with mixed aldehydes. Cochleas were dissected and embedded in araldite. 2 um sections were stained with azure II. Nuclei of SGC were marked on paper with the aid of a drawing tube attachment on the microscope (500x) and counted. The density of SGC within each profile of the ganglion (#/mm^3) was computed by dividing the number of cells in a given profile by the volume of that profile. The profile volume was determined by measuring the area of Rosenthal's canal (mm^2) with a computer planimetry program and multiplying by the section thickness (mm) plus a factor to correct for the fact that the sections are much thinner than the cell nucleus.

The average cell density of the gerbil SGC is 1 x 10^5 cells/mm^3 and is relatively constant throughout the ganglion and the older animals had similar cell densities. The SGC appeared normal in size and did not contain lipofuscin granules in the older animals.

Young adult gerbils have a similar cell density to that seen in the rat and the cat. The lack of cell loss and lipofuscin accumulation in the older animals suggests that these animals may be just below the onset time for degenerative changes seen in the aged animals (60% of maximum life span). Cell loss and lipofuscin were reported for the rat to occur at 70% of the maximum life span. (Keithley and Feldman, J.C.N. 188:4292, 1979). It seems then that the microcystic inclusions in the CN are not the result of SGC degeneration.

350.10 PHYSIOLOGY AND ANATOMY IN THE AGING MONGOLIAN GERBIL AUDITORY SYSTEM. N. K. Woolf[1], A.F. Ryan[1], E.J. Silva*[1], E.M. Keithley[1] and I.R. Schwartz.[2] [1]Division of Otolaryngology, Department of Surgery, UCSD Medical School and Veterans Administration Medical Center, La Jolla, CA 92161 and [2]Division of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

Cochlear microphonic (CM), auditory nerve N1 compound action potential (AP) and auditory brainstem evoked potentials (ABR) were recorded from mongolian gerbils at either 30 DAB (days after birth) [N=7], 90 DAB [N=10] or 2-3 years of age (Mean=2.4 years; S.D=0.275) [N=9]. The average life span of the gerbil is 3.03 (±0.64) years.

Only cochleas for which external canals and middle ears were normal were included. All of the 30 DAB and 90 DAB candidates met these criteria. In contrast, 2/3's of the 25 older candidates presented impacted ears: 8 had two normal ears and 9 had only one.

Relative to 90 DAB subjects, the mean CM audiogram for the older gerbils exhibited a flat loss of approximately 10 dB for frequencies at or below 16 kHz, with a more pronounced loss of 22 dB at 32 kHz ($p < .02$, ANOVA). AP and ABR thresholds for the older gerbils were also increased approximately 20 dB above the 90 DAB values ($p < .02$, t-test). At 20, 40 and 60 dB SL, ABR morphology, peak latencies and inter-peak latencies for the three groups were similar.

Light microscopic examination of the cochleas of the older gerbils revealed good preservation of the organ of Corti, spiral ganglion cells, and stria vascularis.

The spongiform encephalopathy first noted by Ostapoff et al. (ARO 10:209,1987) was observed in all of the older gerbils. However, the older gerbils with clean external and middle ears used in the present study showed less pathology than a group of unselected animals 4-6 months old (which showed similar pathology to that reported by Ostapoff). Preliminary examination of the PVCN and other affected regions of the older subjects indicate no marked decrease in cell size or number, or loss of specific nuronal populations, associated with the pathology.

The physiologic and anatomic data suggest that the hearing loss in the older animals is of peripheral origin. They further indicate that when the condition of the external and middle ears is normal, brainstem cytopathology, though present, is not extensive. The data also suggests that the encephalopathy may not be strictly progessive with age.

Supported by Grant NS14945 from the NIH/NINCDS and the Research Service of the Veterans Administration.

350.11 ENDOCOCHLEAR POTENTIALS DECREASE WITH AGE IN GERBILS. R.A. Schmiedt, J.H. Mills*, and J.C. Adams. Department of Otolaryngology and Communicative Sciences, Medical Univ. of S.C., Charleston, SC 29425.

Endocochlear potentials (EPs) were recorded at four places along the cochlear duct in young and old gerbils. Measurements were obtained with micropipettes in scala media at 0.5, 4.0, 8.0 and 11.0 mm from the oval window. These distances correspond respectively to best frequencies of about 30, 8, 2 and 0.5 kHz. EP values measured in eight controls with ages less than 12 months showed little scatter between animals and followed known trends. EP values measured in similar fashion in 10 gerbils with ages between 29 and 31 months were significantly less than that of the controls in the very basal and apical regions of the cochlea. The table below compares the average values of the EP and the standard error of the mean (SEM) at each cochlear location for young and aged gerbils.

Location (mm):	0.5	4.0	8.0	11.0
Frequency (kHz):	30.0	8.0	2.0	0.5
Young EP (mV):	91.2	78.8	72.3	72.7
Young (± SEM):	1.9	2.9	4.0	3.7
Aged EP (mV):	76.7	74.2	73.1	45.9
Aged (± SEM):	2.7	4.3	4.7	9.8

Whole nerve action potentials (APs) recorded at the round window to tone pips showed that the older gerbils had threshold shifts relative to the controls of about 12 dB at 20 kHz, 13 dB at 8 kHz, 10 dB at 2 kHz, and 14 dB at 0.5 kHz. These shifts were not expected given the previously reported dependence of neural thresholds on acute changes of the EP brought about with furosemide (Sewell, W.F., J. Physiol., 347:685, 1984). In particular, the 30 mV decrease in the EP of the apical turn would be expected to be associated with a greater threshold shift than 14 dB. On the other hand, the AP shifts associated with the middle turns are not correlated with any EP shift. However, AP amplitudes were greatly reduced at suprathreshold levels at all frequencies in the old gerbils. Thus, the relation between EP and neural characteristics in aging animals is complex. Further, there is evidence that the decreased EP in at least the apical turn is due to changes in the functional anatomy of the lateral wall of the cochlea.

350.12 ULTRASTRUCTURE OF THE END BULB OF HELD IN CONGENITALLY DEAF CATS. S.A.Larsen and T.M.Kirchhoff*. Depts. of Anat. and Otolaryn., Univ. of Louisville Med. Sch., Louisville, Ky. 40292.

The cochlear nuclear complex is the first synaptic relay in the central auditory pathway. Within this complex, all information conveyed from the hair cells of the cochlea through the auditory nerve is received and recoded to be conveyed to higher levels in the pathway. Bock et al (Brain Res, 239:608, 1982) concluded that at least some central connections remain functional in the central auditory pathway in the absence of peripheral stimulation and that function may be restored by direct nerve stimulation. On the other hand, Gulley et al (Brain Res, 158:279, 1978) suggested that peripheral stimulation is important for maintaining synapses.

Using computer-assisted morphometric analysis of electron micrographs, we have studied the end bulb of Held (EB) synaptic termination of the auditory nerve on the soma of large spherical cells in the rostral anteroventral cochlear nucleus of normal-hearing (NH) and white-deaf adult cats (WD). WD cats are profoundly deaf from birth as a result of genetically determined cochlear degeneration and were selected from the investigator's breeding colony. Auditory brainstem responses were used to determine if cats were unilaterally or bilaterally deaf. Scanning electron microscopy revealed massive degeneration of the hair cells in the cochleas of the WD cats compared to that of the NH cats. There was considerable variability to the degree of auditory nerve fiber degeneration found in the WD cats but they all had extensive degeneration of the neurons in the anteroventral cochlear nucleus. In WD cats, large spherical cells and synaptic terminations of the EB were smaller compared to that found in NH cats. In addition, the EB had fewer membrane specializations associated with active zones and intact active zones were characterized by extremely dense presynaptic specialization and few synaptic vesicles.

Electrical stimulation of remaining auditory nerve fibers of profoundly deaf patients assumes that transneuronal effects of hair cell loss does not impair the function of remaining neurons or that the function can be reversed by electrical stimulation. We have reported degenerative changes in both the termination of the first-order fiber and the second-order neuron of the central auditory pathway. Further work to determine the reversibility of these changes with electrical stimulation is in progress.

Supported in part by a grant from the Deafness Research Foundation and University of Louisville Graduate Research Grant.

350.13 AGE-RELATED CHANGES IN THE VESTIBULAR GANGLION OF C57BL/6 MICE. J. C. PARK and V. A. FEDOR*. Dept. of Biological Sciences, Florida Institute of Technology, Melbourne, FL 32901.

We have been examining age-related changes in the mouse vestibular system in order to understand normal vestibular aging. This preliminary report concerns the vestibular (Scarpa's) ganglion of C57BL/6NNia mice. Ganglia from six young (5-9 wk) and six old (26-29 mo) mice were dissected and immersed in buffered glutaraldehyde. The superior and inferior divisions were separated and embedded in epoxy after routine osmium post-fixation and dehydration in acetone. The right ganglion from each mouse was serially sectioned into 5 um thick sections for cell counts. Nucleoli in every eighth section were counted, multiplied by the intervening sections and the total corrected for split nucleoli. The left ganglia were sectioned for TEM examination.

The most prominent ultrastructural change in the old neurons was an accumulation of membrane bound pigment, lipid droplets and foamy appearing inclusions, especially at the axon hillock. In older neurons, the myelin sheath appeared less well organized and contained myelin whorls.

Contrary to the spiral ganglion serving the cochlea, old mice maintained a constant number of vestibular neurons well past the mean of their expected life span. Young mice had approximately 2231±171 neurons and old mice had 2198±403. About 65% of the cells comprised the superior division supplying the horizontal and anterior ampullae and the utricle. The remainder were in the inferior division supplying the posterior ampulla and the saccule. The majority (94-97%) of neurons in both young and old ganglia were large, oval to round cells with a mean size of 31X24 um. These large cells were sheathed by many layers of compact myelin. The remainder were unmyelinated, smaller cells with an average size of 18X15 um.

Compared to the spiral ganglion of this mouse strain, where cell degeneration and loss is severe by 26 mo (G. M. Cohen and J. S. Grasso, Assoc. Res. Otolaryngol. Abstr., p. 120, 1987), aging changes in Scarpa's ganglion develop more slowly.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM III

351.1 AN ANALYSIS OF THE RECURRENT COLLATERALS OF PURKINJE CELLS IN ZONE X OF THE CAT'S CEREBELLUM. Georgia A. Bishop Department of Anatomy and Neuroscience Program. The Ohio State University, Columbus, Ohio 43210

In the present study, the axonal collaterals of 17 Purkinje cells in zone x have been analyzed subsequent to intracellular recording and staining of these cells with horseradish peroxidase. Nine cells responded to activation of the upper limb and 5 to stimulation of both the upper and lower limbs. The axonal collaterals of zone x Purkinje cells extend an average of 294.2 μm in the transverse plane and 520.8 μm in the sagittal plane. The collaterals of 10 of the 17 Purkinje cells remain confined to zone x. Five Purkinje cells have collaterals that extend into zone a and two project to zone b. Fifty-three percent of the varicosities derived from the recurrent collaterals (average number of varicosities/plexus = 98) are located within the Purkinje cell layer, 27% extend into the molecular layer, some near the pial surface, and 20% distribute to the granule cell layer. A comparison of collaterals derived from zone x Purkinje cells with those from zones a, b, and c (Bishop et al., New Concepts in Cerebellar Neurobiology, 1987) indicate that the primary lamina of distribution for the varicosities in all four zones is the Purkinje cell layer. However, two features distinguish the collaterals of zones x Purkinje cells. First, the average transverse extent of zone x collaterals is greater than that seen in other zones. Second the presence of beaded branches that extend to superficial aspects of the molecular layer are not present in other zones. This distribution pattern suggests that the sphere of influence of zone x Purkinje cell collaterals is greater in the transverse plane. In addition, the postsynaptic targets of zone x collaterals may be more varied than the collaterals derived from Purkinje cells in zones a, b, and c; potential targets in the molecular layer include stellate cells, the dendrites of Purkinje, basket and/or Golgi cells. However, the primary synaptic interactions are likely comparable to those described for zones b and c; these include the proximal dendrites of Purkinje cells and basket cells. The data obtained in the present study, combined with those derived from previous studies, indicate that there are features of the pattern of distribution of the recurrent collaterals that are uniform for Purkinje cells in zones, a, x, b, and c. However, the data also indicate that there are aspects of the collateral distribution, with respect to lamina and extent, that are specific to each zone. Therefore, afferent information may not be integrated via these local circuits in the same manner in each zone. (Supported by NSF BNS 8505971)

351.2 THE SYNAPTIC RELATIONSHIP BETWEEN PURKINJE CELL AXON COLLATERALS AND BASKET CELLS IN THE LATERAL VERMIS OF THE CAT. D.L. O'Donoghue, G.A. Bishop and J.S. King. Dept. of Anatomy and Neuroscience Program, Ohio State University, Columbus, OH 43210.

Intracellular recordings were obtained from basket cells (identified by intracellular injections of horseradish peroxidase, HRP) located in lobule V. Stimulation of the inferior cerebellar peduncle or peripheral nerves elicited a slow-rising, low amplitude, excitatory post synaptic potential that was interrupted by a fast-rising, large amplitude, inhibitory post synaptic potential (IPSP). Hyperpolarizing currents of low intensities, passed through the recording electrode, reversed the IPSP. The amplitude of the evoked IPSP was not graded with changes in stimulation intensity. At threshold intensities, the response was "all or none" in nature. These findings indicated this inhibitory input was derived from a single neuron. The IPSP's fast rise-time, and its reversal with low levels of hyperpolarizing currents, indicated that the inhibitory synapses derived from the single presynaptic cell were located on or close to the soma.

In order to determine the anatomical substrate for the unitary IPSP, the perimeters of two basket cells were examined in serial thin sections. The majority of synaptic profiles on the cells were small (<1 μm) and contained round vesicles. Two and four large boutons (1.5-2.5 μm) synapsed on each cell, respectively; they contained pleomorphic vesicles, numerous mitochondria, and a darkened cytoplasmic matrix. Two of the boutons originated from myelinated fibers of the ganglionic plexus. The cytological characteristics of the large boutons were comparable to the terminals of Purkinje cell collateral described previously by Mugnaini (in: The Comparative Anatomy and Histology of the Cerebellum, '72). However, this serial section analysis could not address the unitary nature of the relationship between Purkinje cells and basket cells. To determine this, Purkinje cells and their recurrent collaterals were stained intracellularly with HRP. Serial thin sections were cut through a portion of one collateral plexus. One to three HRP labeled varicosities from this plexus synapsed on at least three different basket cells. These labeled varicosities were 1.5-2.0 μm in diameter, contained pleomorphic vesicles, and numerous mitochondria. Although over 1/2 and 3/4 of the surfaces of two basket cells were examined, no unlabeled boutons were found with cytological features indicative of a recurrent collateral.

These physiological and anatomical data indicate that individual basket cells receive axosomatic terminals of recurrent collaterals derived from a single Purkinje cell. In addition, a single Purkinje cell may modify the activity of more than one basket cell. (Supported by NSF 8505971 and NIH 07814)

351.3 THE DEVELOPMENT OF ENKEPHALIN IMMUNOREACTIVE ELEMENTS IN THE OPOSSUM'S CEREBELLUM. J.J. Walker, R.H. Ho, and J.S. King. Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

Enkephalin (ENK) immunoreactive climbing fibers, mossy fibers and a beaded plexus of axons have been described in the adult opossum's cerebellar cortex (King et al., New Concepts in Cerebellar Neurobiology, 1987). In the present study we have used this peptide as a marker to study the ontogeny of these three forms of axon terminals. The indirect antibody peroxidase anti-peroxidase technique was used to localize ENK immunoreactivity in the cerebellum of pouch young opossums from postnatal day (PD) 1 to PD 83. By PD 5 ENK fibers with growth cone-like terminal expansions are present in the intermediate layer of the cerebellar anlage. Subsequently, the number of ENK fibers increase in the intermediate, and ventricular layers and by PD 18 discrete regions of dense punctate immunoreactivity are present within the nascent Purkinje cell layer and the undifferentiated cellular area deep to this layer. These immunoreactive elements are likely composed of immature mossy fibers as well as climbing fibers. Pericellular nests (nids) around Purkinje cell somata can be visualized by PD 35 and follow a sequence of development through PD 83 paralleling that described in Golgi preparations of human climbing fibers (Marin-Padilla, M., J. Comp. Neurol., 235:82-96, 1985). Immature mossy fiber rosettes can be identified in the internal granule cell layer on PD 40 and subsequently follow a sequence of maturation comparable to that described in Golgi impregnations of the opossum's cerebellum (O'Donoghue et al., Anat. Embryol., 175:341-354, 1987). Beaded ENK axons can be identified on PD 68 where they form a diffuse system of fibers primarily along the granule cell-Purkinje cell border. Between PD 40 and PD 68 there is generally an overlap in the distribution of developing ENK climbing and mossy fibers in discrete regions of vermal lobules II-VIII and X, whereas in the hemispheres climbing fibers predominate. However, in the adult ENK positive climbing fibers are no longer seen in the lateral folia (King et al., New Concepts in Cerebellar Neurobiology, 1987). The present results indicate that the terminal expansions of early arriving ENK axons are not present in cellular layers undergoing mitotic division. In addition, the transient appearance of ENK in discrete populations of developing climbing fibers in the lateral hemispheres suggests that: 1) cell death in the inferior olive, 2) the retraction of collaterals, or 3) a transient expression of this peptide, may be developmental events characteristic of this chemically defined system of axons. (We thank Dr. R. Elde for ENK antiserum 156C. Supported by NS-08798)

351.4 CORTICOTROPIN RELEASING FACTOR DISTRIBUTION IN THE CEREBELLUM AND PRECEREBELLAR NUCLEI OF THE CAT. Sharon Cummings, Georgia A. Bishop and James S. King. Dept. of Anatomy and Neuroscience Program, Ohio State University, Columbus, Ohio 43210

Corticotropin releasing factor (CRF) has been reported in some cerebellar afferent systems (Cummings et al., J. Neurosci., in press). As part of a continuing analysis of CRF in cerebellar circuitry, we have employed the indirect peroxidase, anti-peroxidase technique to map the distribution of CRF-immunoreactive (CRF-IR) fibers within the cerebellum and the precerebellar nuclei of the cat. Serial 60um transverse and sagittal sections of brains from adult cats perfused transcardially with picric-acid/phosphate (0.1M) buffered 2% paraformaldehyde were incubated with a primary antiserum to the rat CRF sequence.

CRF-IR climbing fibers were present throughout all cerebellar lobules, though the density of the fibers and the intensity of immunostaining was not uniform. CRF-IR mossy fibers were also widely distributed in the cerebellar cortex, but also were not uniform in density or in staining intensity. A plexus of CRF-IR fibers was present in the Purkinje cell layer; collaterals of CRF-IR climbing and mossy fibers may contribute to this plexus. Within the overall distribution of CRF-containing cerebellar fibers, several prominent patterns were apparent. The vermis contained five bands of intensely immunoreactive mossy fibers; these were most easily defined at the base of the lobules and in the anterior lobe. Climbing fibers were continuous across the width of the vermis in lobules I-X, though more darkly stained median and parasagittal bands of climbing fibers accompanied the mossy fiber bands of the anterior lobe. A wide band of darkly stained climbing fibers also extended rostro-caudally through the intermediate cortex of the anterior lobe; caudally this band merged with a climbing fiber band in the lateral aspect of vermal lobules VI and VII. The paramedian lobule contained a prominent median band of immunostained climbing fibers; few mossy fibers were apparent in this lobule. CRF-IR climbing fibers were present throughout lobus simplex and crus I; mossy fibers within crus I were more evident rostrally than caudally. A dense band of climbing fibers extended through the midline of crus II; mossy fibers were few in number, but increased rostrally at the base of the lobule. CRF-IR climbing and mossy fiber distribution in the flocculus and paraflocculus was irregular and patchy in appearance, and confirmed observations of earlier studies. Both fiber types were more heavily represented in the flocculus than in the paraflocculus. Finely beaded CRF-IR fibers, present in all deep cerebellar nuclei, were more abundant laterally than medially.

In colchicine pretreated brains, CRF-IR cell bodies were localized in several brainstem nuclei known to project to the cerebellum. In addition to CRF-containing somata in the inferior olivary complex, previously reported to be a source of CRF-containing climbing fibers (Cummings et al., J. Neurosci., in press), immunostained perikarya were present in the lateral, subtrigeminal, magnocellular and paramedian reticular nuclei; medial and inferior vestibular nuclei; the perihypoglossal complex, locus ceruleus, parabrachial nucleus and several raphe nuclei.

The existence of CRF in regions of the brainstem known to project to the cerebellum, and the wide distribution of CRF-containing climbing fibers and mossy fibers in the cerebellum, suggest a major functional role for this neuropeptide in cerebellar circuitry. We thank Dr. Burt Sharp for the CRF antiserum. (NS 08798).

351.5 DORSAL COLUMN NUCLEI PROJECTIONS TO THE INFERIOR OLIVE IN THE CAT. M.C. Perreault*, J. Courville. Département d'anatomie, Université de Montréal, Montréal (Québec) CANADA H3C 3J7.

Injections of high specific activity ^{3}H-leucine in the dorsal column nuclei and in all adjacent structures were used to demonstrate the projections to the olive. Two major areas of distribution are demonstrated. Within the rostral half of the olive, a predominantly contralateral distribution to most regions of the dorsal accessory olive originates from the cuneate nucleus. Nucleus gracilis only provides bilateral projections to the lateral regions of dorsal accessory olive. Rostral parts of the nucleus gracilis were not investigated. In addition, the cuneate nucleus sends extensive and dense projections to the medial accessory olive in the caudal half of the olive. Those are mostly ipsilateral. The main source of the projections to the olive appears to arise from ventral cells of the caudal two thirds of the cuneate nucleus. However, cells of all regions of the cuneate nucleus participate to the projection without any clear topographical arrangement. Several control injections in surrounding nuclei have been used to assess the contribution of the spinal trigeminal nucleus, dorsal reticular formation, nucleus of the solitary tract and the vestibular nuclei. There are overlaps between the territories of distribution of the dorsal column nuclei, and between those of the cuneate nucleus and the spinal trigeminal nucleus.

Supported by grant MT-6722 from Medical Research Council of Canada.

351.6 CORTICOTROPIN-RELEASING FACTOR-LIKE IMMUNOREACTIVITY (CRFLI) IN INFERIOR OLIVE PERIKARYA AND IN CLIMBING FIBER-LIKE PROFILES IN CEREBELLAR CORTEX OF MONKEY. C. I. Cha* and S. L. Foote (SPON: J. H. Carlson). Dept. Psychiatry, Univ. Calif., San Diego, CA, 92093.

Immunohistochemical methods were utilized to characterize the distribution of CRFLI in brain and spinal cord of two monkey species (Saimiri sciureus, Macaca fascicularis). As previously reported for both rodent and primate, many neurons in the parvocellular component of the paraventricular nucleus were labeled, and dense fibers were evident, streaming toward the median eminence from this nucleus. In other brain areas, substantial differences were evident between the distributions of labeled elements in monkey and those previously reported for rat. For example, although colchicine pretreatment was not used, densely labeled cells were evident in the monkey inferior olive. The vast majority of olivary neurons were immunoreactive, and perikarya in the medial accessory olive (MAO) were especially densely stained. In the cerebellar cortex, intensely reactive fibers were present in the molecular and Purkinje cell layers. These fibers exhibited many of the morphological characteristics of climbing fibers. For example, in sagittal sections, highly divergent axonal arbors, originating from individual axons at the base of the molecular layer, were evident. In coronal sections, only thin, paired profiles were present. Labeled fibers were most dense in the uvula, dorsal paraflocculus, and pyramis, areas which receive their climbing fiber input mainly from the MAO. In the vermis and intermediate zone, labeled axons were often organized into parasagittal "stripes" similar to those formed by subpopulations of climbing fibers. Labeled fibers were less dense in the lateral hemispheres, where stripes were not often apparent. Labeled axons exhibited other characteristics of climbing fibers: they formed efflorescences in the cortical granular layer and were evident in cerebellar nuclei. The present observation of CRFLI in the monkey olivo-cerebellar pathway is compatible with the previous observation of CRF mRNA within olivary neurons of rat, baboon, and human (Young et al., Molec. Brain Res. 1: 189-192, '86) and previous immunohistochemical findings in cat (Cummings et al., Neurosci. Abstr. 11: 683, '85) and human (Powers et al., Neurosci. Abstr. 12: 568, '86). The present observations thus reinforce the suggestion that CRF is contained within the primate olivo-cerebellar pathway. Furthermore, they indicate that MAO neurons and their climbing fiber projections may contain higher levels of CRF than other olivary subdivisions. Antisera generously provided by W. Vale and J. Rivier, Salk Institute.

351.7 EVIDENCE FOR THE EXISTENCE OF GLUTAMINERGIC PONTINE AFFERENT SYSTEMS IN THE RAT. B.G. Border and G.A. Mihailoff, Dept. of Cell Biology and Anatomy, Univ. of Texas Health Science Center, Dallas TX 75235.

The amount of biochemical evidence suggesting that glutamate (GLU) is an excitatory neurotransmitter in the central nervous system (CNS) has increased tremendously in the past decade. Recently, immunocytochemical (ICC) investigations have demonstrated large populations of neurons in many regions of CNS to be glutaminergic, including cells of the basilar pontine nuclei (BPN). In the case of the pontine nuclei, the glutaminergic neurons have been demonstrated to be components of the pontocerebellar system; these neurons are known to form mossy fiber terminals in the cerebellar cortex and synapse with glutaminergic granule cell dendrites. Little attention has been given, however, to the presence of glutaminergic axon terminals in the pontine neuropil, although several of the regions demonstrated to contain glutaminergic neurons are sources of afferent fibers to the pontine gray. Therefore, through the combination of retrogradely transported WGA/HRP and GLU immunocytochemistry, we have demonstrated several pontine afferent systems to be glutaminergic.

Following a ventral injection of WGA/HRP into the BPN, adult Long-Evans rats were perfused intracardially, the brains sectioned and reacted with TMB to visualize the WGA/HRP reaction product, and the tissue sections incubated with either a mouse monoclonal antibody (provided by Dr. A. Beitz) or a rabbit polyclonal antibody (provided by Dr. P. Petrusz), both directed against glutamate. Immunoperoxidase methods (either biotin-avidin or PAP) were used to visualize GLU-containing elements in the BPN. Our principal findings in these studies are the following. (1) As reported previously (Beitz et al., Neurosci 17(3):741-753, 1986), neurons in many subdivisions of the basilar pons appear to be immunoreactive for glutamate. (2) GLU-immunoreactive axons and axon terminals are present throughout the rostro-caudal extent of the BPN. (3) Double-labeling studies reveal neurons in the cerebral cortex, the dorsal column nuclei, the deep cerebellar nuclei, and the zona incerta that are labeled with both the black reaction product of retrogradely transported WGA/HRP and the reddish-brown product of ICC. Therefore, it can be assumed that these systems provide glutaminergic axons that terminate within the BPN. (4) Preliminary EM studies demonstrate GLU-positive synaptic terminals, neuronal somata, and dendrites within the BPN. Immunoreactive boutons contain round vesicles and exhibit asymmetric membrane specializations. Postsynaptic loci include both GLU-immunoreactive and nonreactive dendrites. Immunoreactive neurons exhibit large multipolar somata with infolded nuclei.

The present observations suggest that the origin of some of the GLU-positive axon terminals in the BPN arise from extrinsic sources. This finding provides evidence for the presence of multi-synaptic glutaminergic pathways within the CNS that involve basilar pontine afferent systems, neurons of the BPN and their respective pontocerebellar axons, and the granule cells of the cerebellar cortex. Supported by USPHS grant NS-12644.

351.8 POLYCLONAL HUMAN AUTOANTIBODIES REACTIVE WITH CYTOPLASMIC ANTIGENS OF CEREBELLAR PURKINJE CELLS ARE NON-SPECIES SPECIFIC AND OF MULTIPLE IMMUNOGLOBULIN CLASSES. J. C. Finley*, J. L. Smith* and V. A. Lennon. (SPON: E. Benarroch). Neuroimmunology Laboratory, Depts. of Immunol. and Neurol., Mayo Clinic, Rochester, MN 55905.

Purkinje cell autoantibodies are found characteristically in sera of patients with paraneoplastic cerebellar degeneration (PCD). At the ultrastructural level they bind principally to the endoplasmic reticulum and trans face of the Golgi (Rodriguez et al, J Neuropathol Exp Neurol 45:322, 1986). Apart from their serological usefulness in aiding the diagnosis of an autoimmune form of cerebellar degeneration, these antibodies offer potential tools for neuroscientists investigating cerebellar cells.

In this study we have investigated 6 positive PCD sera for immunoglobulin isotype and species specificity. Three of the patients had gynecological cancer, one breast cancer, one lymphoma and one suspected, but not yet proven, lung carcinoma. Control human sera (n = 145) included neurologically normal cancer patients, cancer patients with paraneoplastic syndromes not involving the cerebellum, and patients with non-neoplastic neurological disorders. These were negative for Purkinje cell antibodies of all isotypes.

The 6 PCD sera had high titers of IgG anti-Purkinje cell antibodies (1/1,000 to 1/128,000), two additionally had IgM (1/100 and 1/500), and another had IgA anti-Purkinje cell antibodies (1/1,000). Antibodies of IgE class were not found. Antibodies of IgG, IgM and IgA classes reacted as well with rat and mouse cerebellar tissue as with human, and antibodies of each class bound to the peripheral cytoplasm of discrete molecular layer cells in addition to Purkinje cells in the cerebellum of all species.

Because of its ready availability and superior viability, rodent cerebellar tissue should be a useful substitute for human tissue in clinical serological testing for Purkinje cell antibodies. Its use also should facilitate biochemical characterization of the autoantigen(s) of PCD. The antibodies themselves presumably will recognize cerebellar components of additional species, and may prove to be valuable probes for studying cerebellar anatomy and development. **Supported by grant CA 37343 from the National Cancer Institute.**

351.9 SPECIES DIFFERENCES IN CEREBELLAR CORTICAL MUSCARINIC RECEPTOR DISTRIBUTION: AN AUTORADIOGRAPHIC STUDY. A. Neustadt, A. Frostholm and A. Rotter. Department of Pharmacology, University of California, Irvine, CA 92717.

[^{3}H]Quinuclidinyl benzilate (QNB) was used to study the muscarinic acetylcholine receptor distribution in cerebella of mice, rats, guinea pigs and rabbits. Slide-mounted tissue sections of cerebellum were incubated for 90 minutes at 25^{o}C in 0.01M phosphate buffered saline pH 7.4, containing 1nM [^{3}H]QNB, and prepared for autoradiography. Control slides were incubated under the same conditions in the presence of 10μM atropine to determine the degree of non-specific binding. In mice, [^{3}H]QNB labeling was highest over the granule and Purkinje cell layers; relatively low labeling was present over the molecular layer and negligible binding was evident over the white matter. This distribution was seen in all lobules of the cerebellar cortex. In the rat, a similar laminar distribution of binding sites was observed. In addition, a considerable increase in autoradiographic grain density was seen over the molecular and granule cell layers of lobules 9 and 10 (uvula and nodulus) when compared to the remainder of the cortex, a distinction not observed in mice. A further characteristic feature of rat cerebellum was discrete columns of very high grain density traversing the molecular layer of lobule 10. Again, this pattern was not observed in mice. In the guinea pig, the molecular layer of the neocerebellum was of almost equal grain density to that of the granule cell layer. In the nodulus, ventral uvula, flocculus, ventral paraflocculus and lingula (lobule 1), the relative grain density between the two layers was reversed when compared to the same regions in rat and mouse, the molecular layer being of considerably higher grain density than the granule cell layer. In the vermis of lobules 6 and 7, a columnar pattern of high grain density was observed, similar to that over lobule 10 of the rat cerebellum. In the rabbit neocerebellum, the grain density was high, with barely discernible differences between the molecular and granule cell layers. In the paleo- and archicerebellum, a discrete band of very high grain density was observed over the Purkinje cell layer; moderate and low grain densities were present over the granule and molecular layers, respectively. Columns of high grain density were again observable over the molecular layer of several vermal regions, including lobules 1, 6, 7 and 10. The observed species differences in muscarinic receptor distribution reflect variations in the evolutionary development of phylogenetically older regions of the cerebellum and may indicate important functional distinctions between these animals.

351.10 THE RELATIONSHIP BETWEEN SYNAPTOGENESIS AND CYTOCHROME OXIDASE ACTIVITY IN PURKINJE CELLS OF THE DEVELOPING RAT CEREBELLUM. A.E. Mjaatvedt* and M.T.T. Wong-Riley (SPON: E. Godfrey). Dept. of Anat. & Cellular Biology, Med. Coll. of Wis., Milwaukee, WI 53226.

In the adult CNS, the level of oxidative metabolism, as indicated by cytochrome oxidase (C.O.) cytochemistry, can be correlated with the level of neuronal activity (Br.Res. 171:11,'79, Neurosci. 7:2337,'82). Specifically, heightened C.O. activity in postsynaptic neurons can often be correlated with a greater proportion of excitatory input, whereas the predominance of inhibitory inputs often results in a low level of C.O. activity postsynaptically. This relationship has not be explored in developing neurons. Purkinje cells (PC) of the neonatal rat cerebellum serve as a useful model since their somata go through a postnatal transition from receiving a predominantly excitatory input to that of an inhibitory one. We proposed that this transition of synaptic input would be paralleled by a change in C.O. activity within PC, peaking at the height of climbing fiber synaptogenesis onto the somata and decreasing to a low level in the adult when the PC receive mainly inhibitory basket cell input. Rat pups from birth to adult were anesthetized, perfused and the cerebella processed for light and EM C.O. cytochemistry. Counts of both asymmetrical (climbing fibers) and symmetrical (basket fibers) synapses on the somata indicated that excitatory synapses were first seen at P3, peaked at P10, and were absent in the adult. Mitochondria (mito.) of the PC somata were classified as dark (D), moderate (M) and lightly (L) reactive and the area of the mito. and PC cytoplasm were measured. At birth, D and M mito. occupied 1.7% of cytoplasmic (cyto.) area; L mito., 3.2%. This ratio reversed between P3 and P10, with D and M mito. occupying 5.8-7.2% of the cyto. area and L 2-3%. In the adult, D and M mito. decreased to 2.4%, and L mito. rose to 3.5%. The overall packing density of mito. increased from 6% of cyto. area at P3 to a peak of 14% at P10, then decreased to 6% in the adult. The cyto. area increased 10 fold during this time. Analysis of dendrites indicated a high degree of C.O. activity, particularly in the secondary branches, which receive predominantly excitatory inputs. This pattern persisted into the adult, in which somata were only lightly reactive. At all ages, we found a relationship between mito. size and C.O. activity. D mito. were larger than M which were larger than L. This suggests that mito. size may be an indicator of C.O. activity. Our data also indicate that the change in C.O. activity from high levels at P3-10 to low levels in the adult can be predicted from the change in synaptic input from a predominantly excitatory to an inhibitory one on the PC somata during maturation. This is supported by the observation that dendrites, which receive mainly excitatory input, consistently maintain a high level of C.O. activity throughout development to adulthood. (Supported by NIH NS18122).

351.11 THE CEREBELLUM AND INFERIOR OLIVARY COMPLEX OF A MONOTREME, TACHYGLOSSUS ACULEATUS. M-C. Holst* (SPON: D.T. Tracey) Sch. Anatomy, Univ.New South Wales, Kensington,N.S.W.,Australia 2033

The primitive mammals of Australasia, the platypus and spiny anteater or echidna, have an alleged mosaic of reptilian and mammalian characters. However, the monotreme cerebellum has previously been described as consisting basically of vermis and paraflocculus and hence being "avian" rather than "mammalian" or "reptilian" (Larsell, O., The Cerebellum from Monotremes through Apes, Univ. Minnesota Press, 1970); the inferior olivary complex (IOC) was also said to resemble that of birds (Kooy, 1917).

The morphology of the cerebellum of the echidna, Tachyglossus aculeatus was re-evaluated in intact and sectioned specimens. The pattern of fissures and medullary rays is mammalian. The vermis, anterior lobe hemisphere and paramedian lobule are relatively large, but the ansiform lobule is relatively small. The paramedian lobule comprises the prominent posterolateral area. Lobules 4 and 8 form large parts of the anterior and posterior lobe vermis, and the pyramis forms the posterior pole. The flocculonodular lobe is very small. The paraflocculus is made up of a series of small folia and does not form an obvious protrusion.

The cytoarchitecture of the echidna's IOC was ascertained from Nissl sections. The caudal IOC is directly comparable with that of other mammals, with homologues of subnuclei a, b and c of the medial olive (MO), nucleus beta and the dorsal cap of Kooy apparent. The rostral IOC is at first sight unlike that of other mammals. The homologues of the MO and dorsal olive form an arch around the homologue of the principal olive; the latter is relatively undifferentiated. The homologue of the rostral MO has both medial and lateral components. The dorsomedial cell column (dmc) is ventral to the medial cell group of the MO. The conformation of the rostral MO in Tachyglossus is in a more derived state than that found in the marsupial IOC; in the latter, the rostral MO is entirely lateral in position.

Olivary afferents to the vermis and hemispheres of lobules 5-8 were studied using the retrograde transport of HRP, bisbenzimide, or propidium iodide. The IOC projects to the contralateral cerebellum in a topographically organized pattern with caudal areas plus dmc supplying the vermis, and the rostral IOC projecting to the hemispheres. A longitudinal zonal organization is apparent. The projection is comparable to that in other mammals and validates the present subdivision of the echidna cerebellum.

In Tachyglossus, the total numbers of olivary and Purkinje cells, and the extent of climbing fiber divergence provide further evidence of "mammalian" character.

351.12 CERTAIN CEREBELLOPONTINE FIBERS PROJECT IN COLLATERAL FASHION TO THE THALAMUS, SUPERIOR COLLICULUS, OR INFERIOR OLIVE OF THE RAT. H.S.Lee, R.J.Kosinski, and G.A.Mihailoff. Dept. of Cell Biology, Univ. of Texas Health Science Center, Dallas, TX 75235.

Based on HRP and EM observations, Mihailoff et al. (J.C.N.195:221) provided indirect evidence that cerebellopontine fibers arise as collaterals of ascending and descending projections of the cerebellar efferent system. The objective of the present study was to directly visualize the collateralization of cerebellopontine fibers to the thalamus(Th), superior colliculus(SC), or inferior olive(IO), using a double fluorescence technique or a combined fluorescence-HRP method.

First, True Blue (TB) was injected into the ventrolateral nucleus of the thalamus and after three days, Nuclear Yellow (NY) deposited within the basilar pontine nuclei (BPN) of the rat, using a retropharyngeal(ventral) approach. With this combination, double-labelled (DL) cells were located in the interpositus (anterior and posterior) nuclei and the rostral part of the lateral cerebellar nucleus. The majority of DL neurons are medium to large in size and multipolar-shaped. In a second combination, TB was injected into the SC and after three days, NY was again deposited within the BPN. A much smaller number of DL cells relative to the first injection combination were present throughout the rostro-caudal extent of the lateral cerebellar nucleus and an even smaller number were located in the interpositus (anterior and posterior) nuclei. These cells are intermediate to large-sized and either bipolar or multipolar in shape. Finally in a third combination, NY was injected into the BPN and WGA-HRP deposited within the IO, again using a ventral surgical approach. In these cases, the majority of DL cells were located in the interpositus (anterior and posterior) nuclei and the medial portion of the lateral nucleus. The number of DL cells was similar to the BPN/SC combination and far less than that seen in the BPN/Th combination. These cells are relatively small in size and most are spindle-shaped. In each injection combination, single-labelled (SL) neurons of various sizes were also observed in the cerebellar nuclei. From all injection sites, SL but not DL cells were seen in the medial (fastigial) nucleus.

The morphology of DL cells in this study included a range from small to large multipolar somata as well as small bipolar or spindle-shaped neurons. Since the cerebellar input to BPN and IO is at least in part GABA-ergic, some DL cells in the BPN/IO cases might be GABA-ergic and probably inhibitory. Based on the relative number of DL cells observed in the interpositus and lateral cerebellar nuclei in these three injection combinations, a large proportion of cerebellopontine fibers originate as collaterals of axons projecting rostrally to the thalamus, while only a relatively small fraction arise as collaterals of cerebellar efferents to the SC or IO. Interestingly, ongoing studies of dorsal column nuclear efferents similarly reveal that while many of the cells projecting to the BPN also project in collateral fashion to the VPL thalamus, relatively few provide collaterals to the BPN and SC.

CLINICAL CNS NEUROPHYSIOLOGY I

352.1 ATROPINE EFFECTS SPONTANEOUS ELECTROENCEPHALOGRAM (EEG), PERFORMANCE AND INSTRUMENTAL ESTIMATES OF VIGILANCE IN HUMANS. W.B. Pickworth, R.I. Herning*, S.T. Higgins*, J. deBorja* and B. White* NIDA, Addiction Research Center, Baltimore, MD 21224.

The use of atropine in clinical medicine is widespread and recent reports of illicit use have appeared (Bower, Am J Psychiat 144, 383, 1987). Atropine increases scores on scales which measure drug-induced sedation and some subjects report euphoria and drug liking (Penetar and Henningfield, Pharmacol Biochem Behav 29:1111, 1986). Atropine disrupts performance on complex tasks (Dellinger et al, Aviat Space Environ Med 57:1185, 1986) and impairs memory. The purpose of these experiments was to compare changes in the spontaneous EEG, behavior, performance and instrumental estimates of vigilance, that follow atropine administration.

Seven male volunteers with a mean aged of 25.8 yrs and a mean weight of 73.5 kg were given a dose of atropine (1.5, 3 and 6 mg/70 kg) or a placebo (saline) on two occasions in a randomly assigned order of a crossover double-blind experiment. Subjects performed the auditory oddball task and the continuous performace task (CPT); two-minute samples of EEG were obtained while the subjects relaxed with eyes closed (EC) and eyes open (EO). Data were collected prior to the IM administration of drug, and at 2 hrs and 8 hrs after the drug. The power and peak frequency were analyzed by analysis of variance techniques in: delta (0.25-3.75 Hz), theta (4.00-7.00 Hz), alpha (7.25-14.00 Hz) and beta (14.25-25 Hz) bands. Instrumental estimates of vigilance were derived from power spectra criteria, theta/alpha power and beta/alpha power, proposed by Matousek and Petersen (EEG Clin Neurophysiol 55: 108, 1983).

Atropine caused several significant changes in the frequency and power of the spontaneous EEG. There were significant increases in delta power (EC, EO); whereas, alpha power (EC) and theta power (EC) were reduced by dose. Beta power (EC) was increased by the small doses but not larger ones. Delta, theta and beta frequency decreased over dose and time while alpha frequency (EO) increased over dose and time. The EEG slowing in all frequencies and enhanced power in the lower frequency bands coincided with subject reports of drowsiness. Atropine caused dose-related increases in errors on the oddball task and the CPT task. The P300 amplitude in the oddball task was systematically reduced across the dosage range. The effects of the 3 and 6 mg doses on most EEG measures were evident at the 8 hr recording. Situational tolerance was not apparent because dose repetitions did not cause significant decrements of EEG effects.

352.2 **UNFOLDING THE HUMAN CEREBRAL CORTEX INTO TWO DIMESIONAL FLAT MAPS**

Marc L. Jouandet, Michael S. Gazzaniga, Josh Bazell and William Loftus.
Division of Cognitive Neuroscience, Department of Neurology,
Cornell University Medical College, 1300 York Avenue, New York, N.Y. 10021

Correlations between neocortical areas and cognitive function in humans have been difficult to draw in fine detail for many reasons that have included: 1) Theoretical problems inherent in relating lesions to dysfunction; 2) The need to develop over the years sufficiently sensitive methods capable of qualitatively and quantitatively measuring human cognitive or emotional dysfunction following organic brain trauma; 3) The inability to precisely describe, until the recent development of Magnetic Resonance Imaging (MRI), the anatomical location and extent of cortical lesions in the brain of living humans independently of signs and symptoms; 4) A total lack of statistical information on the variations in human gyral and sulcal pattern which may constitute individual cortical "fingerprints"; 5) An absence of methodology capable of systematically relating, despite individual variations, the finer details of cortical gyral patterns to functional areas in the cortex.

Although the recent advent of MRI has made possible the visualization of white and grey matter and the precise localization of lesions in the brains of living humans, it is still difficult to appreciate the dimensions of cortical lesions and their relations to surrounding cortical areas and landmarks when they are spread over several individual brain slice images. It is also difficult to appreciate how a lesion in one individual may be comparable to a roughly similar lesion in another individual.

Computer reconstruction techniques designed to open the cortical sucli and flatten the convoluted cerebral cortex into the shape of two dimensional maps, developed only in the last several years in the study of animal cortical anatomy, may now be profitably applied to re-examine in greater detail localization of function in the human cerebral cortex. The classical approach to localization of fuction has involved first describing sensory, motor, cognitive and behavioral changes and then patiently waiting sometimes years for the final pathology reports describing the location and extent of the lesion. MRI has made the cortex and the lesion immediately accessible; the two dimensinal reconstruction progams simplify neocortical geometry. These maps will permit more precise quantitiative relations between lesion distribution and extent to higher cognitive dysfunction than has been hitherto possible by classic neurological methods.

Single human hemispheres have been flattened in 2 dimensions with the aid of new programs designed and written in our laboratory for the Macintosh Plus computer. For purposes of standardization and replicability, the first two brains processed were those taken from An Atlas of the Human Brain for Computerized Tomography (Matsui and Hirano, 1978). A two dimensional cortical map was reconstructed from a coronally sectioned brain, and another from a horizontally sectioned brain. The programs process line drawings of brain slices on which sulcal and gyral landmarks are registered. The individual sections are then aligned with one another. Further studies utilizing 2 dimensional maps are now in progress in our laboratory on MRI slices of living patients.

352.3 DERIVATIZED Tc-99m DIAMINE DITHIOL COMPLEXES FOR IMAGING OF REGIONAL CEREBRAL BLOOD FLOW. R.C. Walovitch, R.A. Morgan*, A.D. Watson*, E.A. Cheesman*, S.T. Garrity*, S.J. Williams*, Diagnostic Imaging Research, E.I. DU PONT DE NEMOURS AND CO., INC., N. Billerica, MA 01862.

A technetium based radiopharmaceutical which localizes in the brain according to regional cerebral blood flow will allow the non-invasive assessment of rCBF alterations under a variety of pathological states. Greater than 60 derivatized of neutral, lipophilic Tc-99m diamine dithiol complexes have been synthesized and evaluated in rats for potential clinical utility. An appended amine functionality has been determined to be the primary factor in increasing retention of the complexes. Two of these complexes RP-37 (N-Ethylpiperidine diamine dithiol) and RP-120 (N-Ethylpyrrolidine diamine dithiol) have adequate pharmacokinetic characteristics for further evaluation. Both compounds are extracted efficiently by the rat brain (brain uptake index values above 100). Dynamic planar imaging in monkeys also indicates that both compounds are well extracted (RP-37 = 5.3 and RP-120 = 4.5 %ID in the brain). Time activity curves from the monkey planar imaging studies were used to calculate whole brain biological half-life of the complexes which for RP-37 and RP-120 were 33 and 56 min respectively. Dual-labeled autoradiography in rat brain using [^{14}C]-iodoantipyrine and ^{99m}Tc show both complexes to be distributed according to rCBF. By 30min post administration both compounds show selectively hippocampal localization. Dynamic tomographic imaging in monkeys (CLEON 710 dedicated head system) corroborate the initial rat autoradiographic studies. However, by approximately 30min post compound administration the concentration of activity in various cortical brain regions appear to change at rates not related to blood flow. Clinical results with RP-37 are in accordance with these monkey imaging studies and this agent appears to be useful as an indicator of rCBF at early times post-injection.

352.4 A COMPARISON OF ELECTRICAL AND MAGNETIC COIL STIMULATION OF PERIPHERAL NERVES IN MAN. P.J.Maccabee*, R.Q. Cracco and V.E. Amassian. Depts. of Neurology and Physiology, SUNY Health Sci. Ctr. at Brooklyn, New York 11203.

Magnetic coil stimulation was recently introduced by Barker et al (1987, Neurosurgery, 20:100-109) as a convenient method of stimulating peripheral nerves and the cerebrum. Conventionally, the plane of the coil has been applied tangentially, which ensures that a high fraction of the magnetic flux enters the tissue, but introduces uncertainty as to the exact site of stimulation. Using ourselves as subjects, we compared focal cathodal electrical stimulation of arm nerves with various orientations of the magnetic coil. The latency-amplitude relations of the hypothenar EMG was first measured to electrical stimulation of the ulnar nerve, the focal cathode being located just above the medial epicondyle. Selective ulnar nerve stimulation was obtained when the plane of the circular magnetic coil (9 cm diameter) paralleled the long axis of the extended arm and was orthogonal to the arm. With this orientation, the effective site of stimulation was displaced proximally from the distal edge of the coil by up to ½ of the coil diameter. Maximal amplitude of the hypothenar EMG was obtainable by appropriately tilting the coil. Transverse orthogonal orientation was less effective. Laying the coil flat on the arm (i.e., tangentially) activated additional structures locally.

The lateral extent of stimulation was determined by longitudinal, orthogonal stimulation of the median nerve at the wrist, with recording of the thenar EMG. Moving in 5 mm increments in the ulnar-radial axis, a maximum was found over the tendon of palmaris longus, i.e., over the median nerve; the EMG was markedly attenuated at 10-15 mm on either side of this point. Again, transverse orientation of the coil stimulated less effectively. (Tangentially applied at the wrist, magnetic coil stimulation was surprisingly uncomfortable).

Orthogonal stimulation at an angle to the long axis of the humerus permitted the radial nerve to be identified laterally in the upper arm, the EMG recording being taken from the forearm extensors.

Summarizing, our findings suggest the utility of magnetic coil stimulation in clinical peripheral nerve studies, provided that its orientation is appropriate for focal stimulation.

352.5 ELECTROPHYSIOLOGICAL CORRELATES OF DYSLEXIA IN ADULTS: A 20 YEAR FOLLOW-UP. C. Naylor, R. Harter, F. Wood*, and R. Felton*. Sect. of Neuropsychology, Bowman Gray Sch. of Med., Winston-Salem, NC 27103 and UNC-G, Greensboro, NC 27412.

The purpose of this study was to a) assess the comparability of childhood and adult ERP indicants of reading disability (RD), and b) use these indicants to understand improvement in reading in a physiological context. The subjects were 38 males, 32 of whom had been tested in childhood. Of those 32, 24 met the criteria of specific RD in childhood (achievement scores on the Gray Oral and/or WRAT-R reading tests two or more years below grade level). All childhood and adult IQ scores were within normal limits.

Many subjects with RD in childhood had improved their reading skills by adulthood, although as a group they remained impaired relative to normal readers. Oral reading speed and spelling skills proved to be most resistent to remediation.

Event-related potentials were recorded over O1, O2, C3, C4, F3 and F4 to letter and color stimuli using a single stimulus presentation paradigm. Subjects with RD showed a general reduction in positivity starting at 150 msec and extending beyond the latency of the behavioral response. Adult subjects with RD, compared to the children with RD in the Harter et al. study, showed more diffuse reductions in electrophysiological response to both color and letter stimuli. Unlike children who showed greater left hemisphere deficits in central regions when compared to normal readers, the deficit in adults with RD was more widely distributed and bilateral in nature. As for children, the effect of RD was more prominent over central regions.

Reduced positivity at 240 msec over central regions replicated the findings of Harter et al. with children. The amplitude of central P240 was significantly correlated with both childhood and adult reading deficits. Central P240 was found to be a promising marker of dyslexia. The amplitude of central P240 may serve as a predictor of potential for reading improvement as well as an indicant of the degree of deficit in childhood and adulthood.

352.6 A TECHNIQUE FOR VISUALIZING THE NEURAL SYSTEMS INVOLVED IN ACTIVITY RELATED BRAIN DAMAGE. G.O. Ivy and N.W. Milgram. Div. of Life Sciences, Univ. of Toronto, Scarborough, Ontario, M1C 1A4

Hypertrophy of astrocytes in the CNS is a well known marker of neural trauma. We demonstrate here that patterns of astrocyte hypertrophy (AH) can be used to trace neural systems that are involved in abnormally heightened levels of electrical activity. Using additional histological and immunocytochemical methods, the degree of specific neural damage or death in various parts of the system can then be determined.

Rats were given one of several treatments: systemic injection of kainic acid (KA), repetitive electrical brain stimuation, or localized electrolytic lesions or stab wounds to various brain regions. After various survival times, the rats were perfused and the brains processed to demonstrate AH (using antibodies to GFAP) or necrosis (using PAS or nissl stains).

Both localized electrolytic lesions and stab wounds produced discrete patterns of AH which reflected known anatomical connectivity. In contrast, both KA and electrical brain stimulation produced recurrent seizure activity and induced patterns of AH that labeled specific neural systems. Three weeks following seizure activity AH was focused in the ventrolateral forebrain, the medial thalamus and hippocampus. Within these regions specific structures were affected. In the forebrain, AH was consistently seen in olfactory cortex, external capsule, endopyriform nucleus, the deep layers of insular cortex, and lamina Va of lateral neocortex; within thalamus AH was pronounced in the intralaminar nuclei, the rhomboid nucleus and nucleus reuniens; within hippocampus AH was particularly notable in the hilus of dentate gyrus. The PAS stain revealed that these areas contained cells in various stages of necrosis, a result that could also be detected in nissl stains. The numbers of regions affected and the extent of cell damage in those regions varied with extent of seizure activity. While cell death was typically seen in the hilar region of hippocampus, it was not typical in dorsal areas CA1 and CA3. In contrast, the endopiriform nucleus, external capsule and lamina Va of temporal and parietal neocortex exhibited marked necrosis, possibly indicating much lower thresholds for damage.

Our results indicate that a variety of different treatments, all of which produce generalized seizure activity cause a common pattern of degenerative changes in the brain that is clearly reflected in patterns of AH. Futher, while fields CA1 and CA3 of hippocampus are most commonly emphasized as being vulnerable to the excitotoxic effects of seizure activity, we show that structures such as the endopiriform nucleus, specific nuclei of the medial thalamus and the hilus of fascia dentata have a far greater vulnerability. It seems likely that similar patterns of degenerative changes occur in individuals afflicted with recurrent seizure disorders.

352.7 **ELECTROENCEPHALOGRAPHIC SPIKING ELICITED DURING SLEEP FOLLOWING MELATONIN ADMINISTRATION IN CATS.** R.K. Harper*, R.M. Harper and H.L. Lesse (SPON: S. Eiduson). Depts. of Psychiatry and Anatomy, and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

Melatonin has been shown to reduce sensory-related paroxysmal EEG activity and has been suggested to have anticonvulsant properties (Anton-Tay et al., Life Sci. 10:841, 1971; Fariello and Bubenik, Neurosci. Lett. 3:151, 1976; Brailowsky, EEG Clin. Neurophysiol. 41:314, 1976). Melatonin secretion rises nocturnally and may be associated with specific sleep stages. Certain sleep states activate some types of seizure discharge, and melatonin may interact with these states to modulate the incidence of abnormal EEG activity. We examined the incidence of abnormal EEG discharge during different sleep states following melatonin administration in cats kindled to produce amygdaloid seizure discharge.

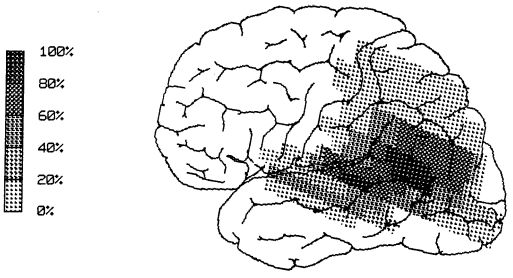
Five adult cats (4 female, 1 male) were surgically prepared with arrays of bipolar needle and concentric electrodes implanted bilaterally in the dorsal hippocampus and basolateral amygdala under stereotaxic guidance. Screw electrodes placed over the orbital plate and occipital bone provided indications of eye movement and cortical EEG respectively. The cats were kindled by daily stimulation of 3-Hz, 1/2-sec current delivered to the amygdala. Following kindling, daytime (0830-1630) control and test recordings of waking and sleeping EEG activity were obtained in a sound-attenuated chamber. Melatonin (40-45 mg/kg) was administered orally 24 hrs after onset of the control recording. Sixty-second samples of polygraphic activity were obtained during quiet and active (rapid eye movement) sleep periods, and instances of rapid-rise-time "spike" activity were tabulated. The occurrence of spike discharge in the cortex and amygdala was dramatically (as much as a factor of 17) increased during quiet sleep epochs following melatonin administration over control periods in all cats. Hippocampal spiking was increased to a lesser extent in two cats. EEG spiking during active sleep showed a smaller, but significant increase following melatonin.

The origin of this enhanced spike discharge following melatonin administration is unclear. Interictal spike discharge in kindled epilepsy has been associated with decreased probability of generalized seizure discharge, and a similar phenomenon may be operating here.

352.8 DEFINING FUNCTIONAL CORTICAL AREAS WITH "AVERAGED" CT SCANS R. T. Frey*, D. L. Woods, R. T. Knight, D. Scabini*, and C. C. Clayworth* Clinical Electrophysiology Laboratory, Dept. of Neurology, U.C. Davis, VA Medical Center, Martinez, CA, 94553 (SPON. I. Kwee).

Lesions of particular cortical areas may vary considerably in extent. We have developed computer software that permits the "signal averaging" of CT scans from patients with particular sensory, motor or cognitive symptoms. Lesions from individual patients are outlined on computer templates of CT sections. The computerized representations of the horizontal sections can then be added across subjects and averaged. In addition to lesion averaging, the lesions can be projected in lateral perspective and estimates are provided of (1) the variability in reconstructions from independent reviewers, (2) lesion volume, (3) the Brodmann areas and subcortical structures that have been damaged.

Averaging CT sections from selected patient groups reveals structure-function correlates more clearly than data from a single patient. Consider cortical lesions that produce left homonymous hemianopia: These may include parietal and temporal lobe structures, but an "averaged CT" from several cases would reveal the critical role of the right occipital cortex. The averaging of lesions can also clarify cortical areas implicated in less well understood functions. For example, shown below is a lateral perspective of left hemisphere lesions in 5 aphasic patients with bilateral reductions of the N_{100} component of the auditory evoked potential. This suggest that cortical areas near the parietal/temporal junction are critical for receptive speech perception and for the generation of the N_{100}.



352.9 **ENHANCEMENT OF CYCLIC AMP-STIMULATED Na^+ CURRENT BY THE CONVULSANT DRUG PENTYLENETETRAZOL IN IDENTIFIED NEURONES OF *Lymnaea stagnalis*.** Catherine R. McCrohan* and Rhanor Gillette (SPON Rebecca Prosser). Department of Physiological Sciences, Univ. of Manchester, Manchester M13 9PT, U. K. and Department of Physiology & Biophysics, University of Illinois, Urbana, IL 61801.

The convulsant drug pentylenetetrazol (PTZ) induces characteristic paroxysmal depolarizing shifts (PDS) in molluscan neurones resembling those recorded from mammalian neurones during epileptogenesis. Onozuka et al. (Brain Res. 269, 277) showed that PTZ elevates intracellular cAMP, while Argemi et al. (Bull. Math. Biol. 46, 903) suggested PDS generation required a persistent inward Na^+ current (I_{Na}). We have examined effects of PTZ on a cAMP-stimulated I_{Na} in neurones of the pond snail *Lymnaea*.

For injection of cAMP under voltage clamp, buccal neurones 1 and 2 were impaled with a voltage electrode and a 2-barreled current electrode, one barrel of which was used for iontophoretic injection of cAMP. PTZ was applied in saline at concentrations of 10-30 mM.

Injection of cAMP elicited a slow inward current in buccal neurones, which was voltage-independent, and which was abolished in 0-Na^+ saline. PTZ caused depolarization and intense bursting, sometimes leading to inactivation of the spike-generating mechanism. In the presence of PTZ, at a holding potential of -60 mV, both amplitude and duration of the cAMP-stimulated I_{Na} were significantly increased. Amplitude increased from 1.63 (0.6 s.e.m.) nA to 2.05 (0.64) nA ($P<0.001$) and duration from 27.79 (2.27) s to 36.71 (2.43) s ($p<0.001$; paired t-test, N=14). This effect was reversed by washing with normal saline. Similar enhancement occurred in the presence of the phosphodiesterase inhibitor IBMX (0.1 mM). PTZ inhibition of phosphodiesterase may contribute to PDS by augmenting endogenous cAMP, and thereby I_{Na}.

The cAMP-stimulated I_{Na} recorded at -70 mV was reduced following a 30 second depolarizing command step to 0 mV. This suggests that during PDS cAMP-stimulated I_{Na} may partially inactivate, thus contributing towards repolarization of the PDS. Supported by The Royal Society, The Nuffield Foundation and NSF BNS 8603816.

352.10 DIMINISHED P3 AMPLITUDE IN SCHIZOPHRENICS DURING CPT PERFORMANCE. R.J. Strandburg, J.T. Marsh, W.S. Brown, R.F. Asarnow,*D. Guthrie.* Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.

We previously observed that schizophrenic children produce significantly lower P3 amplitudes (compared with normals) during performance of the span of apprehension task. This task which is sensitive to schizophrenic psychopathology requires detection of a target letter within a briefly presented (50 msec) 12 letter array. Here we present a similar P3 reduction in schizophrenic children during a vigilance task, the Continuous Performance Task (CPT). Like the span, the CPT is sensitive to schizophrenia, however, it differs in its information processing requirements.

Single digits were presented at a fixation point every 1.25 sec. for 50 msec and were surrounded by up to nine distractor digits. Subjects were required to respond to the repetition of the same digit on successive trials (f=18%). Twelve schizophrenic and 13 mean age-matched normal children (S=11.5±1.2 yrs., N=11.2±1.2 yrs)each received 400 trials of the CPT. Informed consents were obtained for each subject.

ERPs were recorded from 19 International 10-20 System loci referenced to linked earlobes. A 2.5 sec. epoch including both the target and preceding stimulus was averaged offline. Only correct response trials (hits) were included in the averages. Baseline-to-peak and latency measurements were made for the P3 component elicited by both the target (T) and the preceding nontarget (NT) stimuli at the peak of the observed P3 field (PZ and CZ).

As expected, the hit rate for schizophrenics was significantly lower than for normals (69±14% vs 89±8%). The two groups did not differ in response latency or within and across subject response latency variability.

Schizophrenics produced significantly ($p<.05$) smaller P3 amplitudes at both leads for both the T (12.5 vs 16.8 μv) and NT (4.1 vs 8.7 μv) stimuli. There was no group by stimulus interaction suggesting that the two groups showed comparable increments in P3 to the rare, target stimulus. They also did not differ significantly in P3 latency (S=520±55 ms vs N=493±44 ms).

That P3 amplitude is diminished in schizophrenics across a wide variety of information processing tasks suggests that this component is measuring some aspect of performance evaluation such as confidence. The comparability and stability across groups of latency measures for both the P3 and the behavioral response suggests that this amplitude difference is not the result of latency jitter. These results are consistent with the ERP data from adult schizophrenics.

352.11 AUDITORY BRAIN STEM RESPONSES IN CHRONIC SCHIZOPHRENIC PATIENTS.

M. Igata*, M. Ota*, Y. Hayashida*, K. Abe*. (SPON:N. Yanagihara) Department of Psychiatry, University of Occupational and Environmental Health, School of Medicne. Iseigaoka 1-1, Yahatanishiku, Kitakyushu 807 Japan.

Many studies have been made recently on evoked potentials in schizophrenic patients to assess their perceptual abnormalities. We studied auditory brain stem responses (ABSRs) in chronic schizophrenics and compared with those of controls. We also examined a relationship btween ABSRs and psychiatric symptoms in chronic schizophrenics.

[Methods]

Subjects were 17 chronic schizophrenics and 17 controls. ABSRs were elicited by click stimuli (2 kHZ, 80 dBHL, 5/sec), and were recorded between the vertex (CZ) and mastoids. The amplitudes and the latencies of ABSRs (Wave I - V) were analyzed. Brief Psychiatric Rating Scale was used to assess the psychiatric symptoms in each patient.

[Results]

(1) No differences in latencies of the ABSRs were observed between chronic schizophrenics and normal controls. (2) The amplitude of wave V in chronic schizophrenics was significantly lower than that in normal subjects. (3) There were significant positive correlations between the amplitude of wave V and florid symptoms such as hallucinatory behavior, excitement and suspiciousness in the chronic schizophrenics.

[Comments]

ABSRs are considered to arise from structures in the auditory pathways. Wave V is thought to originate from generators in the region of the inferior colliculus (midbrain).
These results suggest; (1) chronic schizophrenics have neuronal low activities or synchronous disturbances of neuronal events with click stimuli in the midbrain area. (2) As concerned with chronic schizophrenics with florid symptoms, the neuronal activites of midbrain area are not so much decreased from those in normal subjects.

352.12 "CAT P300" RECORDED FROM MEDIAL SEPTAL AREA. J. Harrison and J. Buchwald. Brain Res. Inst., Ment. Res. Ctr., Dept. Physiol., UCLA Med. Ctr., Los Angeles, CA 90024.

The human P300 potential is a scalp-recorded positivity of approximately 300 msec latency which appears to be a neural correlate of cognitive functions such as sequential information processing and short-term memory. We have been studying an animal model of the P300 in an attempt to elucidate the generator substrate. The "cat P300" is a positivity in the 200-500 msec range which is significantly larger for rare than for frequent stimuli. We previously showed that complete bilateral ablation of the primary auditory cortex did not affect the auditory "cat P300", nor did bilateral ablation of polysensory association cortex. In contrast, bilateral ablation of the medial septal area resulted in disappearance of the "cat P300" several days after the lesion, which suggested that the septum is involved in modulation but not actual generation of the response.

In the present study we mapped the medial septal area with depth recordings using a P300 stimulus protocol. Blocks of 250 click stimuli with a 1.5 sec interstimulus interval were presented with loud clicks occurring 80% of the time and soft clicks occurring 15% of the time in a random order. These probabilities were reversed in some blocks. A tone pulse, followed by eyelid shock, occurred 5% of the time and elicited a conditioned response which focussed the cat's attention on auditory stimuli. Field potentials were recorded from a stainless steel depth electrode, and EEG was recorded simultaneously from a stainless steel skull screw at the vertex. We recorded from five adult cats, awake and restrained. In each 250-stimulus block the EEG and depth potential were averaged separately for the loud and soft clicks and tone. Recordings were made bilaterally in tracks which passed through the medial septal area, lateral septum and vertical limb of the diagonal band of Broca. Responses to the rare loud click were recorded at 1 mm intervals, and if a positivity relative to baseline occurred in the 200-500 msec range, responses to frequent loud clicks were recorded at the same site.

In all five cats P300-like potentials, i.e., a positivity in the 200-500 msec range, larger to the rare than to the frequent stimuli, were recorded in the dorsal part of the medial septal region. These responses were localized to an active site and generally disappeared abruptly at sites 1 mm lateral or ventral. Polarity inversions, i.e., reversal of the positivity referenced to a prestimulus baseline, were recorded along a number of tracks, usually ventral to a nearby positivity. A P300 was not always present at the vertex when a P300-like potential was recorded in the depth. These results support and extend our prior conclusion from the septal lesion studies, that the septal area is involved in P300 generation. (Supported by USPHS grants AG04088 and HD04612).

352.13 P300 RESPONSES TO LINGUISTIC AND PROSODIC STIMULI. R. Erwin, J.S. Buchwald, D. Van Lancker, J. Schwafel and D. Guthrie. Departments of Physiology and Psychiatry, Brain Res. Inst. and Mental Retardation Res. Ctr., UCLA, Los Angeles, Ca 90024.

Prosody is the intonational component of language which conveys emotional content (e.g., anger, happiness)) as well as linguistic information (e.g., the rising terminal inflection of a question). Whereas linguistic comprehension and production become abnormal or absent in cases of left (dominant) hemisphere damage, the comprehension and production of emotional prosody become abnormal after right hemisphere damage. Such data suggest that linguistic and prosodic components of language may be processed by relatively independent brain subsystems. In order to investigate this problem further, and to develop a normative data base as a forerunner to projected clinical studies, we have recently completed a sequence of electrophysiological experiments.

Subjects were a group of 14 normal adults (7 males, 7 females, 20-30 years of age). Recordings of the P300 event related potential were carried out from electrodes placed centrally (Cz) and laterally at left and right parietal (P3,P4) and temporal (T5,T6) locations. In an "oddball" P300 protocol, the rare stimulus (p=.2), to which the subject responded with a button press, was randomly interspersed with the frequent stimulus (p=.8). Stimuli were presented at 1.5 sec intervals in 300-trial blocks. All blocks were counterbalanced so as to reverse the probability of the rare and frequent stimuli. Four stimulus pairs were utilized: 1) phoneme pairs: ba/pa, 2) word pairs: rip/lip, 3) prosodic (linguistic) pairs: Bob (statement)/Bob (question), and 4) prosodic (emotional) pairs: Bob (angry)/Bob (happy). The stimuli were digitized from tape recordings and were equalized with regard to duration (440 msec $\pm$ 20 msec) and peak intensity (60 dB SPL $\pm$ 5 dB). Amplitude and latency measurements were made for evoked potential components N1,P2,N2,P3 and principal components analysis were also carried out. All data were subjected to ANOVA statistics.

In all cases the rare target stimulus produced a significant P300 response while none of the shorter latency components was consistently affected by stimulus probability. An electrode by condition interaction consistently occurred which reflected a larger P300 at parietal than at the temporal sites. Response latency varied as a function of stimulus: longest latencies were produced by word pairs and prosodic (linguistic) pairs while the shortest latencies resulted from phoneme and prosodic (emotional) pairs.

These data suggest that the neural substrate of the P300 reflects auditory discrimination involving a processing continuum, with fewer stages engaged by phonemes and emotional prosodic contrasts than by linguistic prosodic contrasts and words. (Supported by USPHS grant HD 05958).

352.14 EFFECTS OF ASSOCIATION CORTEX ABLATION ON CAT MIDLATENCY AUDITORY EVOKED POTENTIALS. L. Dickerson and J. Buchwald, Brain Res. Inst., Ment. Ret. Res. Ctr., Dept. of Physiol., UCLA Med. Ctr., Los Angeles, CA 90024.

A sequence of auditory evoked potentialS can be recorded from the vertex of the awake cat in response to repeated click stimuli. The auditory brainstem responses, originating from the brainstem auditory relay nuclei, occur within the first 10 msec. Subsequent to these short-latency components is the response generated by primary auditory cortex (wave 7, 10-15 msec latency), followed by a positive potential at 20-25 msec (wave A), attributed to post-synaptic projections of the ascending reticular activating system to the intralaminar thalamus. Subsequent to wave A is a pronounced negativity at 30-35 msec, wave N_A, and a large amplitude positivity, wave C, at 50-75 msec.

In a continuation of efforts to determine the generator origins of scalp recorded auditory responses, the objective of this study was to investigate the source or sources of waves N_A and C. Previous lesion studies indicate that wave C is abolished by complete bilateral hemispherectomy but is unaffected, as is wave N_A, by ablation of primary auditory cortex bilaterally, or by frontal lobectomy anterior to the pericruciate cortex. Unit studies of auditory association cortex, (especially the pericruciate area, PCA, anterior lateral gyrus, ALA, and medial suprasylvian gyrus, MSA) indicate that response latencies fall in the 16-50 msec range (Irvine and Huebner, J. Neurophysiol., 42: 107, 1979). Because of these and other data and because waves N_A and C follow wave A, we hypothesized that they might evolve from projections from intralaminar thalamus (probable source of wave A) to the various cortical association areas. Also, the prolonged duration of wave C suggested dual or multiple generators.

In a series of 6 cats, 10-12 recording sessions were carried out before and after surgery. Histological confirmation was made of all lesions. Three cats were subjected to bilateral ablation of auditory association cortex, areas PCA, ALA, and MSA. Wave C amplitude was reduced by 50% or more for 2-3 weeks; in some cases it began to approximate normal amplitude and configuration by 3-6 weeks post-operatively. The most striking and persistent alteration, however, was the persistent reduction and near-elimination of wave N_A. Three other cats were subjected to bilateral ablation of association areas ALA and MSA (but not PCA). Again, the most striking change was the great reduction of the negative wave N_A, while wave C was reduced in amplitude to varying degrees across subjects. These data suggest that association cortex (areas PCA, ALA and MSA) is essential for the 30-35 msec negative wave, N_A, and, although not essential, importantly contributes to the subsequent 50-75 ms positivity, wave C. (Supported by USPHS grant HD 05958).

353.1 OPERANTLY CONDITIONING MEDIAN NERVE SEP COMPONENT P100 IN HUMANS: SPECIFICITY AND EFFECTS ON SOMATOSENSATION.
R. DOWMAN, Dept. Surgery, University of Alberta, Edmonton, AB., Canada, T6G 2B7

Earlier work (Dowman and Rosenfeld, Brain Res. 333(1985)201) demonstrated rats could increase and decrease cortical SEP amplitude when reward was made contingent upon change, and that these changes were associated with alterations in nociceptive sensitivity. The present work is an attempt to demonstrate this phenomenon in humans.

SEPs, elicited by electrical stimulation of the median nerve at the wrist, were recorded from the scalp overlying the contralateral somatosensory cortex and frontal cortex, each referenced to the contralateral ear lobe, in 4 human subjects. Each SEP operant conditioning session consisted of 500 evoking stimuli given with a randon interstimulus interval (4.1 - 5.1 s). The SEP conditioning procedure consisted of 3 phases: Baseline, Uptraining (UTR) and Downtraining (DTR). During the UTR and DTR phases reward (money) was given for making P100 amplitude greater than (UTR) or smaller than (DTR) its Baseline mean. Correct responses were indicated by a 2000 Hz tone given 300ms following the evoking stimulus. Detection thresholds (DT), pain thresholds (PT), and pain tolerance levels (Ptol), determined by electrical stimulation of the index and middle fingers of the ipsilateral hand, were obtained immediately following each conditioning session. Subjects were given 10-30 sessions (1 session/day) in each phase.

Two subjects failed to demonstrate change in P100 amplitude. There were no changes in any SEP component amplitudes, DT, PT, or Ptol levels between UTR and DTR in these subjects. The other 2 subjects demonstrated significant change (40-60%) in P100 amplitude associated with conditioning. Both also showed comparable change in N60 amplitude. One of these subjects exhibited a smaller (15-20%) change in postcentral P25 and P40 component amplitudes in the direction of training, but no change in the precentral P22 and N30 component amplitudes. This subject demonstrated a 34% change (UTR> DTR) in DT, but no change in PT or Ptol. The other successful conditioner exhibited a 33% change in P40 amplitude that was inversely related to the change in P100 amplitude. This subject demonstrated change (UTR> DTR) in PT and Ptol, but not DT.

These results indicate that human subjects can operantly condition P100 amplitude, and that these changes may be associated with change in somatosensation. The different specificity of change in SEP amplitude exhibited by the successful conditioners may represent different strategies used to change P100 amplitude. These different strategies may be responsible for the different effects on somatosensation.

353.2 VISUAL EVOKED POTENTIALS (VEP) IN HYDROCEPHALIC CHILDREN.
G. Adler*, D. Neuenfeldt* and A.C.Nacimiento (SPON: J. Milde). Neurosurgical Research Laboratory and Department of Neurosurgery, Saarland University Medical School, D-6650 Homburg/Saar, F.R.G.

Visual evoked potentials are severely altered in children with hydrocephalus. During acutely increased intracranial pressure (ICP) an increase of latencies and amplitudes as well as disappearance of wave components can be observed. Although localization of the structures which may be encroached upon by the increased ICP is uncertain, involvement of the posterior thalamic radiation may be postulated, on account of its close spatial relationship to the lateral ventricle. We recorded VEP to diffuse light stimulation in a group of hydrocephalic, 2 to 11 year-old children treated with a shunt operation. Most of them were studied during periods of normal, stabilized ICP. In some cases, however, recordings were made before, during and after episodes of acute ICP increase, during which the following VEP changes could be frequently observed: a) increase of N70 latency, b) increase of P100 latency and amplitude, c) disappearance of N120 and P170 components, d) decrease of P100 and N200 amplitudes at increasing stimulation frequencies. These changes showed variable degrees of reversibility following normalization of ICP brought about by neurosurgical treatment. In hydrocephalic children with normal ICP similar VEP abnormalities could be observed, in spite of absence of evident neurological impairment, as well as of ventricular enlargement. These pathological VEP changes were often accompanied by deficits in cognitive visual performance. These results suggest that VEP analysis in hydrocephalic children a) may be used to monitor acute ICP increases; and b) may help detect, and allow correlation with chronic changes in visual information processing.

353.3 IMAGING OF EEG AND MEG (MAGNETOENCEPHALOGRAPHY) FOR THE ESTIMATE OF SOURCES IN THE HUMAN BRAIN RESPONSIVE TO ANTIDEPRESSANT DRUGS.
U.Ribary++, H.Weinberg+*, P.Brickett+*, R.J.Ancill++*, S.Holiday++*, J.S.Kennedy++* and B.Johnson+* (SPON: S.L.Dalterio). +Brain Behavior Laboratory, Simon Fraser University, Burnaby, Vancouver, B.C., V5A 1S6, Canada. ++Valleyview Hospital, Port Coquitlam, B.C., V3C 4J2, Canada.

The relative new MEG (magnetoencephalography) technology gives the possibility to further investigate drug effects in human brain. In our experiment, EEG (electroencephalography) and MEG midlatency responses to 40Hz auditory stimulation were combined to make estimates of sources responsive to drug treatments in depressed patients.

In the 40Hz response, EEG and MEG data were analysed in female patients (35-50 years old), suffering from major depression (diagnosed by standardized psychological tests), before, during and after drug treatment (imipramine or desipramine). EEG and MEG recordings were compared to those of control subjects matched for age and sex with respect to distribution, amplitudes, latencies and localization. The stady-state auditory midlatency response in humans is known to be maximal in amplitude and sinusoidal in form (in EEG and MEG) in response to 40Hz rates of stimulation. The MEG data reported suggest sources in the temporal lobe, which could be a part of a thalamo-cortical loop, becoming resonant at 40Hz. A number of different central brain systems, whose activities are changed during depression and following drug treatment, could be expected to influence thalamo-cortical systems.

Initial data suggests that MEG and EEG may be combined to estimate sources of the 40Hz response, and that these dipole estimates may be responsive to drug treatments. Preliminary EEG results in control subjects indicated that an equivalent dipole can be located in each hemisphere, which systematically changes in orientation through aproximately 360 degrees corresponding to different phases of the sinusoidal 40Hz response with respect to stimulus onset.

The data will be discussed in relation to a) the usefullness of the combination of EEG and MEG in dipole estimates, b) the use of source estimates of midlatency responses as indices of the locus and degree of drug action and c) the hypothesis that thalamo-cortical systems are responsible for the 40Hz response.

353.4 REDUCTION OF MORBIDITY, MORTALITY, AND LESION SIZE IN A RAT MODEL OF CEREBRAL INFARCTION WITH AMPHETAMINE.
A.A. Salo* and D.M. Feeney. (SPON: S. Sands). Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM 87131.

A homologous embolic model of cerebral infarction was developed in rat to study long-term behavioral deficits after stroke. The procedure required neither craniotomy nor anesthesia at the time of infarct, factors which can confound stroke studies and detract from the clinical relevance of an animal model. The technique involved insertion of an indwelling cannula into the right common carotid artery while the animal was fully anesthetized. After recovery from surgery and anesthesia at 48 h, a fragmented clot suspension was injected into the cannula. All of the animals subjected to this procedure demonstrated symptoms of stroke within seconds of clot injection. These included obtundation, circling behavior, piloerection, tonic deviation of the head, splaying of the contralateral limbs, and/or contralateral hemiparesis. Following stroke, the rats were evaluated for 30 days on a locomotor agility task. Continuous infusion of amphetamine (1 mg/kg/d x 7 days) or saline was begun 24 h postinfarct. Amphetamine-treated stroke animals showed significant, enduring improvements in locomotor function and level of morbidity which persisted beyond the period of drug infusion to the end of the experiment at 30 days poststroke. The survival rate for the amphetamine stroke group was significantly higher than that of the saline-treated stroke animals. In addition, lesion size in cortex was significantly less in the amphetamine animals than in the saline group. Supported in part by Sigma Xi Grants-in-Aid of Research and funds from DHHS Grant# 1 RO1 NS20220.

353.5 RELATIONSHIP AMONG CURRENT SOURCE DENSITY, INTRANEURONAL CURRENT AND MAGNETIC EVOKED FIELD IN TURTLE CEREBELLUM. Y.C. Okada and C. Nicholson. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

We have recently shown (Soc. Nsci. Abst. 12: 1132, 1986; Brain Res., 1987 in press) that a magnetic evoked field (MEF) can be measured at 2-5 cm from the turtle cerebellum in vitro during neural activity evoked by electrical stimulations of the dorsal midline. Here a study was made to determine whether the MEF in the same preparation is directly related to the internal longitudinal current (I_i) in active neurons. The cerebellum was removed from the brain and placed in 800 ml Ringer solution (100 mM NaCl; 5 mM KCl; 40 mM $NaHCO_3$; 3.5 mM Cal_2; 3.5 mM $MgCl_2$; and 20 mM glucose) gassed with 95% O_2 and 5% CO_2. It was suspended vertically with nylon netting, so that Purkinje cells were oriented horizontally and parallel fibers vertically. The peduncle was then stimulated with a 50 µs electrical pulse every 2 s. To test whether the I_i is directly related to the MEF, we first estimated I_i from the current source density (I_m). The I_m was determined from the laminar profile of the extracellular potential (V_e) measured in 50 µm steps. It showed strong current sources and sinks near the soma and dendrites of Purkinje cells. I_m was integrated along the depth of the cerebellum to estimate I_i/mm^2 of active tissue as a function of depth. Then, I_i was integrated once again along the depth to estimate the current dipole moment (Q) per mm^2 of active tissue. This second integration in effect ignores the higher order terms of a generalized description of the current generator, but is justified since we have determined the MEF to be dipolar. The Q over the entire active tissue was then estimated by multiplying Q/mm^2 by the surface area of the active tissue (6 mm^2) determined from a 2-D profile of the V_e over the entire cerebellum measured in 500 µm steps at a fixed depth of 350 µm from the ventral surface. The profile showed that the peduncular stimulation produced a rather simple pattern of activation confined in the ipsilateral half of the cerebellum. Although there were certain latency shifts in V_e at different positions, the waveforms were sufficiently uniform to justify the simple multiplication of Q/mm^2 by the active surface area. Based on Biot-Savart law, Q was used to calculate the normal component of the MEF at a field extremum at a distance of 16 mm from the cerebellar midline. The predicted MEF was similar in temporal waveform and magnitude to the MEF measured simultaneously with the V_e during the determination of the laminar profile. [Supported by NINCDS grant NS21149]

353.6 NOVEL FLASH EVOKED POTENTIAL (FEP) CHANGE PRODUCED BY DIAZEPAM IN RATS. R.S. Dyer G.C. Rigdon and L.M. Mayo*. Neurophysiology Branch, U.S. E. P.A. Research Triangle Park, NC 27711.

Benzodiazepines might affect the visual process, since benzodiazepine binding sites are found in the retina and cortex. The FEP is a measure of visual function which has been used successfully in identification of toxicological effects of compounds, partly because it reflects not only the integrity of the retinogeniculostriate system, but also because it reflects the general state of the subject. For example, the late negative peak of the FEP, peak N3, is generally maximal in amplitude when the subject is relaxed and awake; either increased or decreased arousal from this state should decrease the amplitude. In the present study we investigated the effects of i.p. diazepam on FEPs. We presumed that FEP peak N3 would be decreased by diazepam. Since some effects of drugs on FEPs are dependent upon background illumination, we investigated the effects of diazepam under both light (115 lux) and dark (<10 lux) background illumination conditions. Rats with chronic skull screw electrodes overlying visual cortex were administered either 0 (vehicle), 1.25, 2.50 or 5.0 mg/kg diazepam i.p., and tested either 10 or 40 min later. Amplitude and latency of the characteristic 3 positive and 3 negative peaks occurring within the first 200 msec after the flash were determined. As expected, diazepam decreased peak N3 amplitude. However this effect was only manifest when testing occurred with a light background, perhaps reflecting the generally larger peak N3 amplitudes recorded under these conditions. Diazepam produced two other background-dependent changes in the FEP waveform. Peak P1 amplitude was increased and peak N1 amplitude was decreased, but both effects occurred only when testing was done with a light background. The most novel effect of diazepam treatment, however, was a curious diazepam-dependent change in shape of the early negative peak. Whereas the typical FEP recorded from unanesthetized rats is initiated with a positive wave which peaks at about 22 msec (P1), followed by a negative wave which peaks at about 30 msec (N1), rats treated with diazepam demonstrated a novel negative peak (at about 22 msec) prior to P1 (which shifted to about 24 msec). The appearance of this peak was not dependent upon level of background illumination. Recordings obtained from the optic tract following diazepam treatment did not indicate that this activity reflected an augmentation of an early output from the retina. These findings have implications for the normal interpretation of FEPs, which holds that peak P1 reflects the earliest arriving input to the cortex from the lateral geniculate. It remains to be determined whether recordings obtained from the lateral geniculate nucleus are altered by diazepam, or if this effect reflects a heightened response to the click which accompanies the strobe flash.

353.7 MK801 PRODUCES CHANGES IN RAT FLASH-EVOKED POTENTIALS WHICH ARE MORE PCP-LIKE THAN KETAMINE-LIKE. L.M. Mayo*, G.C. Rigdon and R.S. Dyer. (SPON: M.I. Gage) Neurophysiology Branch, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

MK801, Ketamine and PCP all appear to block ion channels controlled by the NMDA receptor, as well as serving as agonists for the sigma opioid receptor. In rats, both ketamine and PCP change flash-evoked potentials (FEPs) by increasing amplitude of peak P1 and decreasing amplitude of peak N3. Ketamine also decreases peak N1 amplitude, but the effects of PCP on N1 amplitude are uncertain. A fundamental difference between PCP and ketamine appears to be with respect to peak P2. PCP decreases P2 amplitude, while ketamine has no consistent effect at dosages as high as 150 mg/kg (Mayo et al., Fed Proc '87,46:709; Dyer and Rigdon, Toxicologist '87,7:98). In this report we describe the effects of MK801 on FEPs recorded from unanesthetized unrestrained rats, and compare them to effects obtained using either ketamine or PCP. Three studies on Long-Evans hooded rats with chronic skull screw electrodes over visual cortex are reported here. In the first study, rats were tested immediately before receiving either saline (n=12) or 10 mg/kg PCP (n=12) i.p., and were retested 15, 30 and 60 min later. In the second study, rats were tested immediately before receiving i.p. injections of either saline (n=14), ketamine, 150 mg/kg (n=14), or MK801, 2 mg/kg (n=14), and were retested 15, 60 and 120 min later. In the third study, all rats (n=30) received saline, 0.1, 1.0, and 10 mg/kg MK801 immediately following a pretreatment recording session and were retested 30 min later. The intertreatment interval was at least 2 days, and order of treatments was randomized. In these studies, ketamine produced a profound decrease in amplitude of peaks N1 and N3, while increasing amplitude of peak P1. PCP also decreased amplitude of peak N1 and N3, while increasing amplitude of peak P1. PCP reduced P2 amplitude, but ketamine did not. MK801 increased P1 amplitude, and decreased N1, P2 and N3 amplitude. MK801, ketamine and PCP therefore have consistent effects upon peaks P1, N1 and N3. However PCP and MK801 also reduce the amplitude of P2, while ketamine does not do so at dosages up to 150 mg/kg. The data indicate that MK801 and PCP produce similar changes in FEPs recorded from unanesthetized rats, although MK801 appears to be more potent. The decreased P2 amplitude found following PCP and MK801 also occurs following administration of physostigmine, a cholinesterase inhibitor. Ketamine and PCP have been shown to block cholinergic receptors. It is curious that physostigmine, which should increase availability of ACh, and Ketamine and PCP, which should block the effects reduce availability of ACh, should have similar actions on P2 amplitude. This paradox, as well as the basis for the difference between MK801 and PCP on the one hand, and ketamine on the other, remains to be resolved.

353.8 A FURTHER ANALYSIS OF CORRELATION BETWEEN CNV AND REACTION TIME D.M.Jiang*, W.H.Yang*, B.Y.Wang* (SPON: B.Y.Yang). Division of Physiology, Dept. of Biology, Fudan Univ. Shanghai, China.

Relationships between contingent negative variation (CNV) and reaction time (RT) have been investigated in numerous literatures for years. However, the results were equivocal showing that different ways of analyzing CNV and RT suggested opposite conclusions (Rebert, C.S.: Electroenceph. Clin. Neurophysiol., suppl. 1973, 33: 172-178.).

In this experiment, a typical S1-S2 respond CNV paradigm and a selective average technique were employed to study the correlation between CNV and RT. 15 subjects were presented with foreperiod reaction-time trials: a warning flash was followed 1890ms later by a 1 kc tone and subject was instructed to respond to turn off the tone by pressing a button-switch as quickly as possible. This reaction at once stopped a digital meter which provided a measure of RT. The intervals of successive S1-S2 pairs ranged randomly from 30-60 sec. Each subject received a session of 30 S1-S2 pairing trials test. EEG was recorded from Cz and left mastoid using matched biopotential (Ag/AgCl) electrodes. An earth electrode was placed on left forearm. The slow potential shifts were amplified by a preamplifier with a time constant of 8 sec. Data involving EEG, eye movement and trigger pulse were stored on a FM tape recorder. The selective EEG average over a 5 sec epoch and area measurement of CNV were off-line worked out by an IBM-pc.

The results showed that there were no significant differences between the averaged CNV total area and RT ($P>0.05$). But significant differences were found by comparing the 5 fastest with the 5 slowest RTs in 30 trials session, the 5 CNV total areas with the fastest RTs were significantly larger than the 5 CNV total areas with the slowest RTs ($P<0.01$). However, further examining showed that the significant differences were only in the CNV late half area ($P<0.01$) not in the CNV early half area ($P>0.05$).

Our finding implies that the late component of CNV may be related to motor facilitation and reflect the cortical 'priming' process. (Supported by the Science Fund of the Chinese Academy of Sciences)

353.9 SCALP-RECORDED EVENT RELATED POTENTIALS FOR MOTOR SPEECH EVENTS AND LIP ELECTROMYOGRAPHY. M.E.Pratarelli*.(SPON:D. Strelioff), Salk Institute for Biol. Stud., Lab for Neuropsychol. P.O. BOX 85800, San Diego, CA., 92138.

Cortical evoked potentials that may reflect the planning of motor speech events were studied in an effort to assess the degree to which simple/basic differences in monosyllabic speech samples may be observable. Twelve scalp electrodes were positioned over visual and language centers and motor cortex to record the event related potentials. In addition to vertical and horizontal Electroocculograms, a single labial surface electrode was patched into two channels (one bipolar and the other monopolar in configuration;monopolar EMG and scalp electrodes and EOG were linked to both mastoids) to study the contractile latencies. The stimulus paradigm to elicit the speech samples consisted of 4 possible visually presented samples of the phonetic sounds /pa/, /pi/, /po/ and /pu/, presented 75 times each in random order for a total of 300 stimuli/utterances to which the subject was asked to utter the sounds as quickly as possible. In addition, 30 presentations of the word 'wait' were presented in a typical 'oddball' paradigm to which the subject was to refrain from speaking. 'Oddball' paradigms consist of presentations that are expected and a percentage (variable) that are not. 10 percent of the stimuli were thus oddballs. Stimulus ISI was 3500 milleseconds (msec) with 400 msec durations. Bandpass was set at .01 to 100 Hertz except for the EMG channels which were set at 10 to 100 Hertz. These variations were implemented to a) assess the optimum resolution of the muscle potentials for the purpose of subtracting muscle artifact from the EEG, and b) to isolate the mean latencies for the motor events.

A P300 component which is typically elicited in 'oddball' paradigms was observed with a latency of approximately 600 msec after the presentation of the word 'wait'. The subject, supported by the EEG records and the averages reported initiating an utterance they expected to be one of the four possible /p?/s but stopped short of vocalizing or releasing the burst seen in /p/ sounds. Assymetries over left/right hemispheres observed by other researchers were seen in certain conditions as was the enhancement of the N1 component (150 msec latency) over the left occipital region. The motor speech event may be reflected in a slight positivity following N1 and which differs from the averages of the identical stimulus set presented with instructions to read the verbal stimuli and not utter them.

Comparisons of read stimulus sets and read/uttered stimulus sets are presented as are comparisons of the reaction times extracted from the averages and by the technique of 'back-averaging'.

353.10 ELECTROPHYSIOLOGICAL INDICES OF NEURAL DEVELOPMENT IN HUMANS. J.H. Daruna and A. E. Rau. Department of Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, LA 70112

The brain's spontaneous electrical activity (EEG) as well as its event-related activity (ERPs) undergo significant change from infancy to adulthood (Courchesne, E., Electroenceph. Clin. Neurophysiol., 45:468, 1978; John, E.R. et al., Science, 210:1255, 1980). The extent to which the various electrophysiological changes reflect independent aspects of neural development has not been sufficiently investigated. The present study addressed this issue by examining the developmental course of several electrophysiological measures as well as their intercorrelations within narrow age groups.

The subjects were healthy individuals (N=24) of above average intelligence selected from the following age groups: 4,5,6,7,12 and 26 years. Brain activity was recorded from F3, F4, P3, and P4 scalp locations referred to the linked mastoids, while the subjects either passively viewed a static colorful display of animals or performed an auditory vigilance task. The electrophysiological measures were: 1) the absolute power within the delta, theta, alpha and beta bands derived from the spontaneous EEG recorded during the passive viewing task; and 2) the amplitude and latency of the N100, N200, and P300 components from ERPs to target events recorded during the vigilance task.

Several of the measures were found to have non-parallel courses of development. Delta power progressively decreased with age, whereas theta, alpha, and beta power initially increased, peaking at 5 to 6 years of age, and then gradually declined into adulthood. The latencies of N100 and N200 remained relatively stable with increasing age. In contrast, the P300 latency decreased rapidly during middle childhood and reached adult values by the age of 12 years. Changes in the amplitude of N100 and N200 paralleled each other until the age of 7, subsequently N100 increased and reached adult values by the age of 12, whereas N200 began declining and continued this trend into adulthood. P300 amplitude remained relatively stable with increasing age. Intercorrelations between the various measures within age groups were not significant. It is concluded, therefore, that these EEG and ERP measures are sensitive to relatively independent aspects of neural development.

353.11 VARIATIONS IN ABERRANT PURSUIT EYE TRACKING AS A FUNCTION OF CLINICAL STATE: IMPLICATIONS FOR STATE-TRAIT CONSIDERATIONS. R.T. Pivik, P.M. Cooper*, F.W. Bylsma*. Lab. of Psychophysiology, Univ. of Ottawa and Ottawa General Hospital, Ottawa, Ontario K1H 8L6.

Pursuit tracking dysfunction in psychotic patients has been repeatedly verified, but conflicting evidence exists regarding whether the incidence of these tracking interruptions varies with changes in clinical symptomatology. None of these investigations, however, has examined tracking performance in the same patients when actively ill and again when in remission. The present study provides such data.

Pursuit eye tracking performance was assessed in 10 psychiatric patients (9 schizophrenics; 1 manic depressive) and 10 age matched non-patient controls. Diagnoses were made independently by two psychiatrists (DSM-III criteria). All subjects were recorded twice: patients once when displaying active psychotic symptomatology and again when in remission ($\bar{X}$ interval = 9 months); control subjects were rerecorded after an average interval of 5.2 months. Horizontal and vertical eye movements were assessed electrooculographically (EOG: DC-300 Hz) while subjects tracked an oscillating target light (2.2 Hz) subtending a 20^{o} visual angle ($\pm 10^{o}$ from midline) under both light and darkened conditions ($\geq$10 min in each condition prior to testing). Data were tape recorded for off-line electronic processing and computer analyses. Artifact-free HEOG data were processed for incidence of velocity arrests (VAs: eye velocity $\leq 2^{o}$/sec) and root mean square error deviations (RMS: global target-eye movement discrepancy) according to standard criteria [Pivik, Biol. Psychiat.,14:859-879, 1979]. Data were statistically analyzed using repeated measures ANOVA procedures with post hoc tests when appropriate.

Control-patient tracking performance (VA & RMS) differed significantly only in the lighted condition when patients were actively ill ($p<.01$). Clinical improvement was associated with a significant decrease in VA scores for patients ($p<.01$) and the elimination of significant differences between groups. Dark adaptation reduced patient tracking errors to control levels regardless of clinical status. RMS scores were reduced by dark adaptation, but not as dramatically as VA scores.

The results, which for the first time provide eye tracking data from the same subjects while actively ill and again in remission, support a state-based interpretation of eye tracking dysfunction. Marked decreases in aberrant eye tracking during dark adaptation corroborate previous reports of this phenomenon [Pivik et al., Soc. Neurosci. Abst., 12:1092, 1986; Pivik et al., Prog. NeuroPsychopharmacol. Biol. Psychiat., in press] which have attributed this effect to subclinical cerebellar dysfunction in these patients.

354.1 INTERACTION OF THE INHIBITORY NEUROPEPTIDE GALANIN WITH EXCITATORY AMINERGIC AND PEPTIDERGIC MESSENGER SUBSTANCES IN MYENTERIC NEURONS OF GUINEA-PIG SMALL INTESTINE. C. Winkelmann, J.M. Palmer*, K. Tamura* and J.D. Wood. Dept. of Physiol., Coll. of Med., Ohio State Univ., Columbus, OH 43210.

Colocalization of peptides and amines in neurons of the enteric nervous system suggests that their opposing or orchestrated neuromodulatory actions on electrical behavior of nerve cells is important for appropriate signal transmission and control of gastrointestinal effector systems. Our aim was to investigate the interaction of the inhibitory neuropeptide galanin with other putative messenger substances on the electrical behavior of enteric ganglion cells and to elucidate its action on signal transduction in these cells. Conventional intracellular methods with 3 M KCl-filled microelectrodes were used to inject current and record electrical activity in AH/Type 2 myenteric neurons of guinea-pig small intestine in vitro. Application of galanin (0.1 nM to 1uM) to AH/Type 2 myenteric neurons mimics slow synaptic inhibition (slow IPSP). The inhibitory action of galanin consists of membrane hyperpolarization, decreased input resistance and decreased membrane excitability marked by suppression of action potential discharge. Membrane hyperpolarization by galanin was reversible near the estimated K^+ equilibrium potential suggesting that opening of K^+ channels was the ionic basis of its inhibitory action. Galanin, histamine, 5-hydroxytryptamine (5-HT), substance P, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP) and forskolin were applied to neurons by addition to the superfusing Krebs solution or by ejection from fine-tipped pipettes with nitrogen pulses of controlled pressure and duration. Prior application of galanin (1 nM to 0.1 uM) abolished or strongly suppressed the excitatory actions of histamine, VIP, the slow depolarizing response to 5-HT, substance P and forskolin. The excitatory response to CGRP was weakly suppressed after much longer exposure to galanin. Galanin exerted its antagonism of the other messenger substances in the presence of tetrodotoxin (0.5 uM) indicating that the responses were due to a direct action upon the impaled neurons. Inhibition of excitatory responses to these substances by galanin differed from that of adenosine. Adenosine inhibits receptor-coupled increase of cyclic AMP and does not offset the excitatory responses to substance P and CGRP. Our results suggest that galanin is a potent inhibitory peptide in the enteric nervous system and modulates excitatory responses to other putative messenger substances possibly by multiple receptor interactions through a common or convergent signal transduction pathway in the same neuron. Galanin may not only suppress receptor-coupled cyclic AMP generation but also may modulate intracellular Ca^{2+} homeostasis. (Supported by NIH grants DK07308 to J.M.P. and DK26742 to J.D.W., and Tokai Univ. Overseas Res. Grant to K.T.)

354.2 EFFECT OF GALANIN ON ELECTRICAL AND SYNAPTIC PROPERTIES OF MYENTERIC NEURONS OF GUINEA-PIG SMALL INTESTINE. K. Tamura*, J.M. Palmer*, C. Winkelmann and J.D. Wood (SPON: A. Humbertson). Dept. of Physiol., Coll. of Med., Ohio State Univ., Columbus, OH 43210.

Galanin, a 29 amino acid peptide localized in neurons and neural fiber tracts of the central and enteric nervous systems, is a putative brain-gut messenger. In myenteric neurons of the guinea-pig small intestine, galanin mimics slow inhibitory postsynaptic potentials (slow IPSPs). This action of galanin consists of membrane hyperpolarization, decreased input resistance and decreased membrane excitability marked by suppression of spontaneous and stimulus-evoked action potential discharge. Our aim was to elucidate the mechanism of galanin's inhibitory actions on neuronal electrical membrane properties and on synaptic transmission between myenteric ganglion cells. Conventional intracellular methods with 3 M KCl-filled microelectrodes were used to record electrical and synaptic behavior of myenteric neurons in vitro. Somal action potentials were evoked in AH/Type 2 neurons either by intracellular injection of depolarizing current pulses or by antidromic invasion of action potentials generated by focal extracellular shocks applied to neurites in interganglionic connective fibers. Single or repetitive electrical focal stimuli applied to interganglionic fibers also evoked fast or slow excitatory postsynaptic potentials (EPSPs). Galanin was applied by addition to the Krebs superfusion solution (0.1 nM to 10 uM) or it was microejected from fine-tipped pipettes (20 uM) with pulses of nitrogen at a controlled pressure and duration. Galanin suppressed somal membrane excitability marked by reduced frequency of spike discharge, increased threshold for spike discharge by depolarizing current, and blockade of evoked antidromic invasion of initial segment spikes. Galanin significantly reduced the Ca^{2+} component of tetraethylammonium (5 mM) enhanced somal action potentials, decreased the amplitude and duration of post-spike hyperpolarizing potentials (AH), and hyperpolarized the cell membrane (range 5-25 mV) which was reversible near the estimated K^+ equilibrium potential. The amplitudes of evoked fast EPSPs were reversibly reduced in the presence of galanin (ED_{50} = 20 nM), and slow EPSPs were aborted or blocked by microejected galanin. The fast nicotinic excitatory response to microejected acetylcholine was also suppressed in the presence of galanin suggesting a postsynaptic inhibitory action at cholinergic synapses in the myenteric plexus. Our results suggest that galanin exerts its potent inhibitory action on myenteric neurons through multiple mechanisms. The mechanism of suppression of synaptic behavior by galanin remains unclear; however, its inhibitory mechanism on somal membrane excitability appears to involve opening of K^+ channels and a reduction of Ca^{2+} current. (Supported by Tokai Univ. Overseas Research Grant to K.T., and NIH grants DK07308 to J.M.P. and DK26742 to J.D.W.)

354.3 THE CO-LOCALIZATION OF SUBSTANCE P AND PRODYNORPHIN IMMUNOREACTIVITY IN THE MEDIAL PREOPTIC AREA, BED NUCLEUS OF THE STRIA TERMINALIS AND MEDIAL NUCLEUS OF THE AMYGDALA OF THE GOLDEN HAMSTER (Mesocricetus auratus). S.W.Newman, C. Neal, Jr.* and J.Swann (SPON P.Coyle). Department of Anatomy & Cell Biology, University of Michigan, Ann Arbor, MI 48109.

Substance P and opiate neurons have been found in similar locations throughout the central nervous system in various species. The co-localization in the same neuron of substance P-like immunoreactivity with dynorphin-like immunoreactivity has been reported in the basal ganglia of birds, reptiles and mammals, and a comparison of substance P and enkephalin distribution in the rat brain has also been described. Although substance P and opiate immunoreactivity has been demonstrated in similar locations, with areas of co-occurrance, to date the co-localization of substance P and prodynorphin (the precursor for dynorphin A (1-8 & 1-17) and dynorphin B (1-13)) has not been demonstrated specifically for individual neurons in the medial preoptic area (MPOA), bed nucleus of the stria terminalis (BNST) and medial nucleus of the amygdala (AMe). These three areas in the Golden hamster have been demonstrated to be critical for male sexual behavior and show similar patterns of immunocytochemical staining for substance P and prodynorphin marker antibodies.

We have incubated colchicine-treated hamster brain tissue with primary antisera to substance P generated in rat and to the prodynorphin molecule generated in rabbit, in conjunction with FITC-labelled anti-rabbit and TRITC-labelled anti-rat secondary antibody. Using this technique we have demonstrated the co-localization of substance P and prodynorphin immunoreactivity in MPOA, BNST and AMe. Immunoreactivity for both peptides is strongest in mid to caudal MPOA with the most double labelling in the lateral part of caudal MPOA and almost no co-localization found in the medial part of caudal MPOA. Strongest immunocytochemical staining for both peptides in BNST is found in the medial BNST at its more dorsal-caudal extent, with extensive co-localization observed at this level. Co-localization in medial BNST is also observed as the nucleus extends ventrally at this caudal level. Though prodynorphin and substance P immunoreactivity is found in scattered locations from mid to mid-caudal AMe the strongest labelling for both peptides is found in the most caudal extent where extensive co-localization is observed. Since connections between BNST, MPOA and AMe are essential for normal mating behavior in the hamster, and both opiates and substance P have been shown to modulate this behavior in rodents, our findings suggest that these peptides may interact in the regulation of sexual behavior. 354.4 STUDIES ON INTERACTIONS BETWEEN NEUROPEPTIDE Y (NPY) AND NORADRENALINE IN RAT CEREBRAL CORTEX. C. Wahlestedt*, R. Ekman and R. Håkanson*. Departments of Pharmacology, and Psychiatry and Neurochemistry, University of Lund, Lund, Sweden.

Neuropeptide Y (NPY) is a 36 amino acid peptide with a C-terminal α-amide group. NPY occurs throughout the mammalian cerebral cortex, mostly in local circuit neurones but also in nerve fibres deriving from (noradrenergic) brain stem neurones (de Quidt, M.E. and Emson, P.C., Neuroscience, 18:545, 1986). In various other locations NPY interacts with noradrenergic transmission (Wahlestedt C. et al., Regul. Pept., 13:307, 1986).

This study examined synaptosomal preparations from the rat cortex with regard to the effect of NPY on the following parameters: i) Binding of α-1- (3H-prazosin), α-2- (3H-rauwolscine), and β-adrenoceptor (3H-CGP-12177) ligands, ii) uptake of 3H-NA, and iii) potassium-induced release of 3H-NA. Also, the effect of NA on the binding of 3H-NPY was studied.

NPY (0.1 μM) approximately doubled the number of α-1-binding sites (Bmax) without affecting the affinity (Kd). The NPY-induced up-regulation of α-1-sites was attenuated by GTP. Peptide YY (PYY) 13-36, which is believed to have certain properties in common with NPY, did not increase the Bmax for prazosin. NPY (0.1 μM) did not affect the binding of the α-2- or the β-adrenergic ligands.

Conversely, NA up-regulated NPY-binding sites. This effect is probably mediated by β-adrenoceptors, since isoprenaline mimicked the effect of NA.

Finally, the present study failed to detect any effects of NPY on the NA uptake by and release from the cortical synaptosomes.

354.5 **NEURONAL AND VASCULAR ASSOCIATIONS OF NEUROPEPTIDE Y IN RAT STRIATUM: SYNAPTIC INTERACTIONS AND CO-LOCALIZATION WITH GABAERGIC NEURONS, BUT NOT CATECHOLAMINERGIC TERMINALS.** *C. Aoki and V.M. Pickel,* Div. of Neurobiology, Cornell Univ. Med. Coll., NY, NY, 10021

Neuropeptide Y (NPY) co-exists with catecholamines (CA) in certain central and peripheral neurons and, like norepinephrine, exerts potent vasoconstriction of peripheral vessels. We examined the ultrastructural localization and neuronal and vascular associations of NPY in the rat dorsal striatum, a region enriched with CA (principally dopamine) terminals and GABAergic neurons. Antisera against NPY, the CA-synthesizing enzyme, tyrosine hydroxylase (TH), and GABA were supplied by the laboratories of Drs. T.L. O'Donohue, T.H. Joh and A.C. Towle, respectively. These were produced in goats, rabbits and rats and were simultaneously visualized in pairs by peroxidase-antiperoxidase and immunoautoradiographic labeling methods. NPY-like immunoreactivity (-LI) was detected in a few perikarya and proximal dendrites of neurons having indented nuclei and other characteristics of aspiny neurons. The dendrites received sparse (1 per 4 µm dendritic shaft) synaptic inputs from terminals forming either asymmetric or symmetric junctions. In dual labeling studies, 7% (1 per 13) of the terminals forming symmetric junctions exhibited GABA-LI; whereas none of the afferents were labeled for TH. Axon terminals were the most frequently encountered profiles exhibiting NPY-LI (168 terminals vs. 21 NPY dendrites/8500 μm^2). Only 83 out of the 163 terminals which exhibited NPY-LI formed recognizable junctions. The remaining processes were in contact either with other neurons, glia or the basement membranes of blood vessels. The obvious junctions were exclusively symmetric and included unlabeled (33 of 36) and GABA-labeled (3 of 36) dendrites and dendritic spines. The NPY terminals also frequently were seen in apposition with other unlabeled (13) or GABA-IR (1) terminals, but not to terminals immunolabeled for TH (n=135). However, in 3 cases so far examined, convergent inputs of NPY and TH terminals onto common unlabeled dendrites were identified. Co-localization of TH and NPY also was never detected, although a few cells exhibited both NPY and GABA-LI. We conclude that in the dorsal striatum of rat, 1) NPY is localized to aspiny interneurons which receive GABAergic afferents and terminate on GABAergic neurons and may have additional intracellular interactions with GABA; 2) NPY and CA may jointly modulate the output of common target neurons, but are not detected in direct synaptic contact or within the same terminal; 3) NPY - exclusive of NE - may modulate vascular diameter or themselves depend on circulating factors. (This work was supported by NSF grant BNS 8320120 to VMP and NIH grant NS07782-01 to CA.)

354.6 NEUROPEPTIDE Y/SEROTONIN INTERACTIONS IN THE RAT HYPOTHALAMUS. J. Guy*,[1], O. Bosler*,[2], G. Pelletier[1], (SPON: A. Dupont), [1]MRC Group in Molecular Endocrinology, Le Centre Hospitalier de l'Université Laval, Quebec G1V 4G2, Canada.[2] Laboratoire de Neurobiologie, CNRS, 13402 Marseille-Cedex, France.

Numerous studies have shown that neuropeptide Y (NPY) is largely distributed in the mammalian brain. In the hypothalamus, dense plexus of NPY immunoreactive fibers are present in the ventral part of the suprachiasmatic nucleus. In the arcuate nucleus, NPY staining is found in both cell bodies and fibers. These two hypothalamic nuclei are also known to receive a dense serotoninergic (5-HT) innervation from the mesencephalic raphe nucleus. Using a combined radioautographic and immunocytochemical technique in rats subjected to intraventricular injection of [^{3}H]-5-HT, we observed a striking overlap between the distribution of NPY immunoreactive fibers and [^{3}H]-5-HT uptake sites in these nuclei. By contrast, in the dorsal raphe nucleus of colchicine pretreated rats, NPY immunoreactive perikarya did not show any selective radiolabelling. Intraventricular injection of 5-7-DHT was used in order to destroy the serotoninergic afferents. Two weeks after this treatment, the NPY immunoreactivity was not affected while [^{3}H]-5-HT uptake sites were not detectable. These results suggest that NPY and 5-HT are present in two different neuronal systems. Accordingly, electron microscope observations confirmed that NPY immunoreactive and [^{3}H]5-HT labelled profiles belonged to separate neuronal systems with distinct morphological features. In the suprachiasmatic nucleus, direct axo-axonic appositions between the two types of differentially labeled terminals were ocasionally seen. More commonly, a radiolabeled and an immunoreactive afferent contacted the same perikaryon or dendrite. In the arcuate nucleus, direct appositions between ^{3}H-5-HT labeled terminals and immunoreactive cell bodies or dendrite could be observed. These direct appositions in both the suprachiasmatic and arcuate nucleus were seen without synaptic membrane differentiation. These data should be helpful in determining the possible importance of NPY/5-HT interactions in some physiological processes such as circadian rythmicity and pituitary hormone secretion.

354.7 INTERACTIONS AMONG SEROTONIN, SUBSTANCE P AND THYROTROPIN RELEASING HORMONE IN RAT SPINAL CORD VENTRAL HORN. S.R. White and G. Crane*. Dept. Vet. Compt. Anat., Pharmacol. and Physiol., Washington State Univ., Pullman, WA 99164-6520

The neuropeptides, substance P (SP) and thyrotropin-releasing hormone (TRH), appear to be primarily, if not exclusively, colocalized in terminals with serotonin (5HT) in the rat spinal cord ventral horn (Gilbert et al., Neuroscience, 7, 1982, 69; Wessendorf and Elde, J. Histochem. Cytochem. 33, 1985, 984). Microiontophoretic application of each of these three substances enhances rat spinal motoneuron excitability in situ (White, Brain Res. 335, 1985, 63). However, it is not known how these substances, which may be co-released from terminals in the ventral horn, interact to affect motoneurons.

Seven barrel micropipettes were used to apply TRH, 5HT, SP, glutamate (GLU) and control solutions while recording from antidromically identified lumbar motoneurons in urethane-anesthetized rats. 5HT (10-30 nA, 30-60 sec) and SP (10-40 nA, 1-3 min) each facilitated GLU-evoked activity of motoneurons and the facilitation was additive when these substances were applied simultaneously. Although the initial application of TRH (40-100 nA, 1-3 min) also enhanced GLU-evoked activity of motoneurons, rapid desensitization developed to repeated TRH administration. TRH applied simultaneously with 5HT decreased the facilitatory effect of 5HT applied alone. Consequently, peptides colocalized with 5HT in the spinal cord ventral horn appear to be capable of enhancing or diminishing the facilitatory effect of 5HT on spinal motoneuron excitability. (Supported by NIH, NS24388).

354.8 5-HYDROXYTRYPTAMINE DEPRESSES RETICULOSPINAL EXCITATORY POSTSYNAPTIC POTENTIALS IN MOTONEURONS OF THE LAMPREY. J.T. Buchanan* and S. Grillner. The Nobel Institute for Neurophysiology, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden.

The spinal cord of the lamprey, a lower vertebrate, is richly innervated by 5-hydroxytryptamine (5-HT) fibers, most of which originate from an intrinsic spinal system of cells that forms a dense ventromedial fiber plexus. The dendrites of motoneurons and interneurons extend into this plexus (Van Dongen, P.A.M. et al., J. Comp. Neurol. 234:523-535, 1985) where they make synaptic contact with the large axons of reticulospinal Müller cells. The histological association of 5-HT fibers with Müller axons and neuronal dendrites suggested that 5-HT might be modulating the excitatory postsynaptic potentials (EPSPs) from Müller axons to spinal neurons. We have tested that possibility, using paired intracellular recordings of motoneurons and single Müller axons in the in vitro preparation.

We found that 5-HT always reversibly depressed the chemical component of the Müller EPSPs in motoneurons (50 to 80% reduction). The effect was observed with either local application of a small volume of 10 mM 5-HT to the surface of the spinal cord or by bath-application of 1 µM 5-HT. In addition, 5-HT always slightly hyperpolarized the cells and either left unchanged or increased the amplitude of the electrotonic component of these dual-component EPSPs (<10% increase) indicating an increase in input resistance.

To investigate 5-HT's site of action, the sensitivity of the motoneurons to L- or D-glutamate was tested in tetrodotoxin, before and after 5-HT application. No significant change was observed. Glutamate activates the same postsynaptic receptors as the endogenous Müller axon transmitter (Buchanan, J.T. et al., Brain Res. 408: 321-325, 1987). In contrast to the findings in normal physiological solution, 5-HT application in tetrodotoxin only rarely hyperpolarized the motoneurons and produced no change in their input resistance.

The intracellularly recorded resting potential and action potential of the presynaptic Müller axons were not affected by 5-HT. A small calcium component of the action potential was revealed by application of tetraethylammonium, but 5-HT had no effect upon it.

We conclude that 5-HT depresses the EPSPs in motoneurons from Müller axons by a mechanism that is most likely to be presynaptic. The effect is not due to a decrease in postsynaptic receptor sensitivity, nor to a shunting effect in the motoneuronal dendrites. The functional significance of 5-HT's depression of Müller EPSPs may be that it is a mechanism for segmentally modulating the amplitude of descending brainstem input without altering the responsiveness of the segmental neurons to other inputs.

Supported by the Swedish Medical Research Council (Project number 3026) and NIH Fellowship 5 F32 NS07314-03.

354.9 BLOCKADE OF DOPAMINERGIC OR SEROTONERGIC RECEPTORS DOES NOT PREVENT THE METHAMPHETAMINE- OR 3,4-METHYLENDIOXYMETHAMPHETAMINE-INDUCED DECREASE OF TRYPTOPHAN HYDROXYLASE ACTIVITY. G.R. Hanson, D.M. Stone*, L.A. Matsuda*, J.W. Gibb and M. Johnson*. (SPON: J.W. Woodbury). Dept. Pharmacol. and Toxicol., University of Utah, Salt Lake City, UT 84112

A single administration of methamphetamine (METH) or 3,4-methylenedioxymethamphetamine (MDMA) decreases brain tryptophan hydroxylase (TPH) activity in several brain areas. METH differs from MDMA in its greater ability to release DA, while MDMA is a better releaser of 5-HT. The decrease of neostriatal TPH activity induced by METH can be prevented by depleting DA with α-methyl-p-tyrosine (Schmidt et al., 1985) or by 6-hydroxydopamine lesions of the substantia nigra (Johnson et al., 1987). This study attempts to determine 1) if METH- or MDMA-released DA affects TPH activity by interacting with its receptors, or 2) if 5-HT released by either of the amphetamine-like drugs, or induced by released DA, affects TPH activity by interacting with its receptor or auto-receptor. Sprague-Dawley rats were injected i.p. with haloperidol (3mg/kg), methiothepin (20 mg/kg) or ritanserin (1 mg/kg) 15 min prior to treatment with either METH (10 mg/kg, s.c.) or MDMA (5 mg/kg, s.c.). Concentrations of DA, DOPAC, HVA, 5-HT and 5-HIAA were measured with HPLC-EC. TPH activity was determined according to Ichiyama et al. (1970) and Sitaram and Lees (1978). Neostriatal TPH activity was decreased to 65% of control 1 h after the administration of METH; enzyme activity reached 45% of control 3 and 6 h after injection. Haloperidol did not attenuate the effect of METH observed 1 h and 3 h after the administration. This treatment with haloperidol increased DA release as suggested by increased concentrations of neostriatal DOPAC and HVA 75 min later. Coadministration with METH further increased the concentration of these metabolites. Methiothepin had a similar effect to haloperidol on the neostriatal dopaminergic parameters but increased concentrations of 5-HIAA in the frontal cortex and hippocampus, indicating that methiothepin interacted with 5-HT autoreceptors. This treatment with methiothepin had no effect on the decrease of neostriatal TPH activity induced by METH as well as the pretreatment with the 5-HT_2 receptor antagonist, ritanserin. MDMA decreased neostriatal TPH activity to 70% of control after 1 and 6 h, while the enzymatic activity reached 50% of control 3 h after treatment. Haloperidol did not prevent this decrease at 3 h after the MDMA injection, nor did methiothepin at any of the 3 observation times. These results do not support the involvement of DA receptors, 5-HT receptors nor autoreceptors in the decrease of central TPH activity induced by a single dose of METH or MDMA. 354.10 EFFECTS OF COCAINE ON NEUROTENSIN SYSTEMS OF THE RAT BRAIN. P.L. Smiley*, J.W. Gibb, and G.R. Hanson (Spon: L.M. Partlow). Dept. of Pharmacology and Toxicology, University of Utah, Salt Lake City, Utah 84112

Many of the stimulant effects of cocaine are similar to those produced by methamphetamine (METH). Our laboratory has previously demonstrated that single and multiple high doses of METH increase concentrations of neurotensin-like immunoreactivity (NTLI) in the striatum and substantia nigra of the basal ganglia as well as in the nucleus accumbens of the mesolimbic complex of the rat brain. In order to make comparisons with METH, we have evaluated the response to cocaine of neurotensin systems in these brain regions by measuring tissue concentrations of this peptide. We used for our radioimmunoassay a highly selective antiserum which could detect 2 pg of NTLI per sample. Six hours after single injections of cocaine (20 mg/Kg or 40 mg/Kg; i.p.), we observed significant increases of NTLI in the substantia nigra but found no apparent effect on neurotensin concentrations in the neostriatum, nucleus accumbens, and hippocampus. One hour following multiple doses of cocaine (30 mg/Kg, i.p.; q6h/5 doses), neurotensin levels in the neostriatum and substantia nigra were significantly elevated, but no effects were seen in the nucleus accumbens and hippocampus. The neurotensin concentration remained significantly elevated three hours after multiple dosing, but had substantially recovered in the neostriatum. These data indicate there are similarities in the response of striatal and nigral neurotensin systems to cocaine and METH. In contrast, the effects of cocaine on mesolimbic neurotensin systems are markedly different than those of METH. Possible mechanisms of action of cocaine on neurotensin systems will be addressed. (Supported by USPHS Grants DA 00869 and DA 04222)

354.11 EFFECTS OF METHAMPHETAMINE ON MESOLIMBIC NEUROTENSIN SYSTEMS OF THE RAT BRAIN. K.M. Merchant*, A.A. Letter*, J.W. Gibb and G.R. Hanson. Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112

We have previously reported that high doses of methamphetamine (METH) selectively alter the concentrations of neurotensin-like-immunoreactivity (NTLI) in the striatal-nigral regions of the rat brain. We hypothesize that these METH-induced changes are a result of the activation of the nigral-striatal dopamine pathway by this stimulant. Another dopamine system which is responsive to METH treatment projects from the ventral tegmental area to other CNS regions such as the nucleus accumbens and frontal cortex. For comparison with our previous findings, we have now examined the effects of METH administration on neurotensin systems associated with these mesolimbic structures. Eighteen hours following multiple doses of METH (15mg/kg, s.c.; q6h/total 5 doses), the concentration of NTLI increased by 100% to 150% in the nucleus accumbens and declined by 30% to 35% in the frontal cortex but was unchanged in the ventral tegmental area. A single dose of METH caused a similar change only in the nucleus accumbens suggesting that this structure is more sensitive than the frontal cortex to this drug treatment. Blockade of dopamine D_2 receptors with haloperidol (2 mg/kg, i.p.) or sulpiride (80 mg/kg, i.p.) altered the NTLI levels in both the nucleus accumbens and the frontal cortex in a manner similar to that of METH. This effect was additive to the alterations caused by METH when the drugs were administered concurrently. In contrast, D_1 receptor blockade by SCH 23390 (0.5 mg/kg, i.p.) had no effect alone, but attenuated the METH effect in both structures. These data suggest that the mesolimbic neurotensin pathways are closely associated with the dopaminergic systems and are differentially regulated by D_1 and D_2 receptors in much the same manner as the striatum. (Supported by USPHS Grants DA 00869 and DA 04222)

354.12 OPPOSING EFFECTS OF ROSTRAL AND CAUDAL ACCUMBENS CCK MICROINJECTIONS ON AMPHETAMINE-INDUCED LOCOMOTION F. J. Vaccarino and J. Rankin, Departments of Psychology and Psychiatry, University of Toronto, Ontario. M5S 1A1.

Current evidence indicates that the mesolimbic dopamine (DA) system is important for the expression of amphetamine (AMP)-induced behavioral activation. Studies indicating that a subset of mesolimbic neurons contain both DA and cholecystokinin (CCK) and that CCK terminals are present in the nucleus accumbens (N.Acc) raise the possibility that CCK may play a modulatory role in the expression of AMP-induced behavioral activation. Studies investigating the effects of intra-N.Acc CCK microinjections have found that CCK either potentiates (Crawley et al. J.Neurosci., 5: 1972, 1985) or attenuates (Van Ree et al. Eur. J.Pharmacol., 93:63, 1983; Weiss et al. Neurosci. Abs 12:1491, 1986) stimulant-induced behavioral activation derived from the N.Acc. The present study addresses the possibility that the effects of intra-N.Acc CCK microinjections on behavioral activation produced by systemic AMP are dependent on the rostral-caudal location of N.Acc CCK microinjections. To this end, rats were tested for the locomotor activating effects of systemic AMP following CCK microinjections into either the rostral or caudal N.Acc.

Male Wistar rats with cannulae implants aimed at either the rostral or caudal N.Acc were habituated to locomotor test cages. Following habituation, rats were tested for their locomotor response to intra-N.Acc microinjections of CCK in combination with systemic AMP (0.5 mg/kg S.C.) CCK was administered in the following doses: 0.0 (vehicle), 0.5 ng, 1.0 ng and 2.0 ng. Drugs were dissolved in saline. CCK was administered bilaterally in a 0.25 ul volume over 1 minute. CCK doses were administered in random order with a minimum of 2 no-pretreatment days separating drug tests.

The results demonstrate that rostral and caudal N.Acc CCK microinjections produce opposite effects on AMP-induced locomotion. Rostral N.Acc CCK microinjections dose-dependently attenuated, while caudal N.Acc CCK microinjections dose-dependently potentiated AMP-induced locomotion. CCK microinjections in the central N.Acc had no consistent effect. The present findings indicate that the effects of intra-N.Acc CCK on AMP locomotion depend on the rostral/caudal location of CCK suggesting that the N.Acc is functionally heterogenous with regard to CCK/AMP interactions. This research was supported by NSERC grant U0443 to FJV. CCK was generously donated by Mr. S. J. Lucania of E. R. Squibbs and Sons, Inc.

354.13 FAILURE OF CHOLECYSTOKININ TO ANTAGONIZE THE EFFECTS OF MORPHINE SULFATE WITHIN A CONDITIONED TASTE AVERSION PARADIGM. A.L. Riley, J.P. Mastropaolo, S. Pournaghash* and K. Moskowitz*. Psychopharmacology Lab, The American University, Washington, D.C. 20016.

Although conditioned taste aversions were initially examined in relation to their importance for traditional learning theory, they have recently been utilized as a pharmacological tool. One specific application of the taste aversion design is its use in assessing drug antagonism. For example, naloxone can block the induction of taste aversions by morphine in morphine-naive rats, as well as induce aversions in morhine-maintained subjects, presumably because of precipitated withdrawal.

The present experiments utilized the taste aversion design to assess the putative antagonistic interaction of cholecystokinin (CCK) and morphine. In Experiment 1, rats were given 20-min access to saccharin followed by an intraperitoneal injection of morphine sulfate (6 mg/kg). Subjects in Groups C10 and C30 also received an injection of CCK at 10 and 30 u/kg, respectively, while subjects in Groups N and W were given an injection of naloxone hydrochloride (10 mg/kg) or distilled water. This conditioning procedure was repeated every fourth day until three conditioning trials had been given. Although naloxone clearly attenuated the aversions induced by morphine sulfate, there was no attenuation of aversions in subjects receiving the combination of morphine and CCK, independent of the dose of CCK administered.

In Experiment 2, rats were injected for 21 consecutive days with either morphine sulfate (80 mg/kg) or distilled water. On Day 22, subjects in each of these two conditions were given saccharin followed by an injection of either CCK (10, 20 or 40 u/kg), naloxone hydrochloride (10 mg/kg) or distilled water. This conditioning procedure was repeated every fourth day until three conditioning trials had been given. Although morphine-maintained subjects acquired a robust aversion to the naloxone-associated taste (and displayed dramatic decreases in body weight following naloxone administration), CCK did not condition an aversion or affect body weight at any dose administered.

Although CCK has been reported to antagonize the effects of morphine within a range of behavioral paradigms, it was without effect within the taste aversion procedure, either as an antagonist in blocking taste aversions to morphine or as a precipitator of aversions in morphine-dependent animals. The basis for these differences are unclear although it is possible that the reported antagonism necessitates a procedure in which morphine and CCK produce opposite effects when given alone.

354.14 MODULATION OF HIPPOCAMPAL AND HYPOTHALAMIC [^{3}H]OXOTREMORINE-M DENSITY BY OPIATE AGONISTS AND ANTAGONISTS. Allan E. Johnson, Hector Coirini* and Bruce S. McEwen. Laboratory of Neuroendocrinology, Rockefeller University, N.Y., N.Y. 10021

Muscarinic cholinergic transmission mediates certain types of opioid stress analgesia (Terman et al., Brain Res.,372 (1986) 167). The administration of centrally active muscarinic anatagonists or lesions of the septohippocampal tract reduce this form of analgesia (Kelsey and Baker, Behav.Neurosci.,97 (1983) 945). To begin to specify the brain regions involved in the interaction of central muscarinic cholinergic and opioid transmission in the regulation of opioid stress analgesia, manipulations of opioid transmission on muscarinic receptor binding were studied with quantitative receptor autoradiographic techniques.

Female rats (200-250 grams) were ovariectomized and one week later implanted with Alzet minipumps containing either morphine sulfate (70mg/ml saline), naltrexone (70mg/ml saline) or saline. Forty-eight hours later, animals were decapitated, brains were removed, rapidly frozen in 2-methylbutane (-30°C) and stored at -70°C. Brains were sliced (14µm) with a cryostat at -12°C, thaw-mounted onto subbed slides, vacuum desiccated (2hrs, -5°C) and stored at -70°C. Muscarinic receptors were labeled with [^{3}H]Oxotremorine-M (OXO, 1.0nM; Spencer et al., Brain Res.,380 (1986) 59) with 1µM atropine sulfate used to define nonspecific binding. Labeled slices and plastic tritium standards (Amersham ^{3}H-microscales) were exposed to tritium-sensitive film (Amersham Hyperfilm-^{3}H) for 4 weeks. Binding was analyzed with a computer assisted densitometer that converted gray levels to femtomoles/mg tissue wet weight using the standard curve derived from tritium standards.

Autoradiographic analysis revealed that morphine treatment enhanced OXO binding in some hippocampal regions that contain high densities of µ-opioid receptors (Tempel et al., in press) such as the pyramidal cell layer of CA3, CA4, CA2 region of the radiatum, the molecular lacunosum layer and in the lateral habenula. Naltrexone treatment decreased OXO binding in areas containing high levels of κ-receptors such as the CA2 region of oriens layer and in the dorsomedial and ventromedial hypothalamic nuclei. Differences were not detected in other brain regions. Scatchard analysis of OXO binding in hippocampal and hypothalamic homogenates of morphine sulfate (100mg/ml) or naltrexone (100mg/ml) treated animals showed that differences in binding were due to differences in receptor density rather than affinity. These results support previous studies that implicate the muscarinic cholinergic system in the mediation of opioid stress analgesia. Supported by grant numbers NS07911 (AJ), TW03617 (HC) and MH41256 (BMc).

354.15 NALOXONE AND MORTALITY IN THE GERBIL STROKE MODEL, E.C. Benzel, C. Musgrove*. Division of Neurosurgery, Louisiana State University Medical Center, 1501 Kings Highway, Shreveport LA. 71130.

Endorphins and narcotics have been implicated in the exacerbation of neurologic deficits following stroke. In order to test the theory that narcotic antagonists might offer an improvement in neurologic sequellae following stroke, a gerbil stroke model was used to test varying doses of naloxone administered intraperitoneally, 45 minutes following carotid artery transsection, in 50 adult gerbils.

Lower dose naloxone (1.0-2.5 mg/kg) was more effective in preventing mortality than either control (sterile saline) or high dose (10 mg/kg) naloxone (1.0 and 2.5 mg/kg doses combined, offered a significant improvement in mortality over both the control and the high dose groups P=0.026).

The failure of high dose naloxone (10 mg/kg) in the face of low dose (1.0-2.5 mg/kg) efficacy illustrates a unique dose-response relationship. The etiology of this phenomena is uncertain. It could be that the narcotic agonist activity of naloxone dominates at a higher dose.

Other factors, perhaps, skewed the results presented here. This, however, is unlikely. A confounding effect of the anesthetic agent is unlikely since sodium pentobarbital was used in both the control and the naloxone treated animals. A systemic effect of naloxone may even play a role.

It is interesting that 10 mg/kg of naloxone is no more effective than the administration of saline. In this study, the dosage of naloxone demonstrated a clear correlation with survival and neurologic injury. It is apparent that a 1 to 2.5 mg/kg dosage of naloxone and the administration of the drug within 45 minutes of injury results in a substantial improvement in survival.

It appears that an appropriate dose of naloxone, administered early enough to alter outcome, may offer an improved survival in the gerbil stroke model. This obviously has significant implications with regard to the use of narcotic antagonists in humans with stroke.

355.1 ROLES OF THE DOPAMINERGIC SYSTEM ON THE REGULATION OF THE METABOLISM OF OPIOID PEPTIDES AND TACHYKININ IN THE STRIATONIGRAL PATHWAY. S. Li, P.M. Hudson, K. Nanry, M. Stachowiak, H.A. Tilson, and J.-S. Hong (spon: E. McNeill). LBNT, NIEHS, NIH, P.O. Box 12233, RTP, NC 27709.

It has been reported that the dopaminergic (DA) system exerts potent influence on the metabolism of [Met^5]-enkephalin (ME) and Substance P (SP) in the basal ganglia. Recent reports indicate that dynorphin-like immunoreactivity (DN-LI) is present in the striatonigral pathway and is found in high concentration in substantia nigra. However, the regulation of dynorphin (DN) in this pathway is not known. We have recently reported that repeated injections of a DA agonist, apomorphine (APO), caused dose-(0.5-5.0 mg/kg, s.c., twice daily) and time-related (1-7 days) increases in striatonigral DN-LI and SP-like immunoreactivity (SP-LI) but not ME-like immunoreactivity (ME-LI). These results, plus our previous finding that repeated injections of haloperidol increase the striatal level of ME-LI, but decrease the nigral level of SP-LI and do not alter the striatonigral levels of DN-LI, suggest differential regulation of these peptides by the DA system. The purpose of this study was to determine if APO-induced increase in the striatonigral levels of DN-LI and SP-LI is due to an increase in the biosynthesis by measuring the abundance of messenger RNA (mRNA) coding for these two peptides. Northern blot analysis, using cDNA or cRNA probes coding for precursor of dynorphin and tachykinin derived from rat brain, was used to quantitate the amount of mRNA. Seven daily injections of APO (5 mg/kg, s.c., twice daily) produced a 30-40% increase in mRNA coding for preprotachykinin and a 80-100% increase in preprodynorphin in the striatum. These increases in the abundance of mRNA were proportional to the increases in striatal levels of DN-LI and SP-LI, suggesting that APO treatment accelerates the rate of biosynthesis for these two peptides. To ascertain that the effects of APO are mediated through the nigrostriatal DA system, APO (5 mg/kg, s.c., twice daily for 7 days) and amphetamine (AMP, 5 mg/kg, s.c., twice daily for 7 days) were repeatedly injected to rats which had received prior unilateral nigral injection of 6-hydroxydopamine (6-OHDA, 10 ug in 0.5 ul). 6-OHDA did not alter the levels of DN-LI and SP-LI in striatum 3 weeks after lesion. APO caused significant increases in striatal DN-LI and SP-LI in both the nonlesioned and 6-OHDA lesioned sides. The increases of DN-LI and SP-LI in the 6-OHDA lesioned side were much greater than those in the nonlesioned side,presumably due to a hypersensitivity of DA receptors resulting from DA denervation. Seven daily injections of AMP increased striatal DN-LI and SP-LI in the nonlesioned side, but not in the 6-OHDA lesioned side. The striatal level of ME-LI was increased by 6-OHDA and this increase was attenuated by APO treatment. These results strongly suggest that the effects of APO and AMP on these neuropeptides are mediated through the nigrostriatal DA system.

355.2 SUBCELLULAR DISTRIBUTION OF MAMMALIAN TACHYKININS IN RAT BASAL GANGLIA. P.C.Emson, F.J.Diez-Guerra* and P.J.Richardson*. MRC Group, Dept. of Neuroendocrinology, Institute of Animal Physiology & Genetics Research, Babraham, Cambridge, CB2 4AT, UK.

A combined differential and density gradient centrifugation procedure was used to study the subcellular localization of the mammalian tachykinins in rat caudate-putamen and substantia nigra. Substance P, Neurokinin A, Neuropeptide K and Neurokinin B were found to be concentrated in the synaptosomal fractions, and in fractions containing heavy synaptic vesicles in both regions studied. Neuropeptide K showed a gradient distribution indicating its localization in a lighter vesicle population, compatible with its proposed role as Neurokinin A precursor. In contrast, the catecholamines dopamine and noradrenaline had a more wide spread distribution throughout the gradient. HPLC analysis of the immunoreactivity recovered showed that the tachykinin immunoreactivity coeluted with the relevant synthetic tachykinins, except in the soluble gradient fraction where neurokinin A immunoreactivity eluted in position consistent with neurokinin A3-10. These results show that, in the basal ganglia, the mammalian tachykinins are localized in fractions containing large dense cored synaptic vesicles. This vesicular localization would be consistent with the proposed role of the tachykinins as neurotransmitters and neuromodulators. The differences observed in the gradient distribution of neurokinin A and neuropeptide K in caudate-putamen and substantia nigra are consistent with peptide processing occurring during the migration of the tachykinin containing vesicles from the former region to the latter.

355.3 OPTIMIZATION OF HPLC-RIA ANALYTICAL PROTOCOLS FOR THE DETERMINATION OF SUBSTANCE P AND ITS FRAGMENTS IN THE SPINAL CORD. O.J. Igwe*, L.J. Felice*, V.S. Seybold and A.A. Larson. Depts. of Veterinary Biology, Veterinary Diagnostic Investigations and Cell Biology and Neuroanatomy, University of Minnesota, St. Paul, MN 55108.

A simple and sensitive reversed phase high pressure liquid chromatographic procedure combined with radioimmuno- assay (HPLC-RIA) was developed and optimized to quantify substance P_{1-11}(SP) and its amino and carboxy terminal fragments, SP_{1-4}, SP_{1-7}, SP_{1-9}, SP_{2-11}, and SP_{5-11}, some of which are natural metabolites in the spinal cords of mice. An extremely selective and efficient solid-phase extraction protocol was used for the preparative purification of tissue homogenates prior to subsequent analyses. The actual concentrations in spinal tissues were quantified from the calibration curves of the ratios of the peak areas of sample peptides and the internal standard versus the concentration of SP and its fragments. The sensitivity of the HPLC assay was 0.25 ug/ml for SP and all peptide fragments analyzed. The recovery from spiked acidified aqueous standards carried through the analytical protocol ranged from 60 to 92%. The precision, expressed as the coefficient of variation, ranged from 4.3% at the upper concentration limit to 25.8% at the lowest concentration limit. The sensitivity for the RIA was approximately 4 pg/ml for SP. The percentage cross reactivity of the SP antiserum to its amino terminal fragments was essentially zero in all cases while the cross reacticity with the carboxy terminal fragment (SP_{2-11}) was 50% with a sensitivity of approximately 16 pg/ml. This work was supported by USPHS grants #DA04190 and DA04090.

355.4 **ELEVATIONS IN UNAMIDATED SUBSTANCE P LEVELS FOLLOWING DISULFIRAM ADMINISTRATION TO RATS.** R. M. Kream*, M. S. A. Kumar*, W. El-Bermani*, M. L. Thompson*. (Sponsor: L. Shuster) Depts. of Anesthesiology, Anatomy and Pharmacology, Tufts University Schools of Medicine, Boston, MA. 02111.

Recent work has demonstrated that the relatively selective copper chelator N,N-diethyldithiocarbamate and its disulfide dimer, disulfiram (Antabuse) are effective inhibitors of peptide amidation in the pituitary. We have developed a highly sensitive and highly selective radioimmunoassay (RIA) for detection of the unamidated form of substance P (SP), SP-glycine (SP-G). We are thus able to quantify levels of SP-G without prior HPLC fractionation of tissue samples. In the present study, 10 rats were distributed into two groups, one receiving vehicle, the other 40 mg/kg bw disulfiram (suspended in 0.5% Tween-80 normal saline) subcutaneously daily for 10 days. At the end of the treatment period, the animals were sacrificed by decapitation and the following brain areas were rapidly dissected out: olfactory bulbs (OB), forebrain (FB), preoptic area (POA), medial basal hypothalamus (MBH), pons (P), medulla oblongata (MO). In addition, lungs and dorsal and ventral aspects of the spinal cord were also dissected out. Tissues were extracted in 2N acetic acid, freeze-dried and reconstituted for RIA and assayed for levels of SP and SP-G. Levels of SP-G were found to be increased over 200-fold (0.1-20 pg/mg tissue in brain and spinal areas receiving sensory afferents (medulla and dorsal spinal cord). In addition, similar increases in SP-G immunoreactivity were found in diencephalic areas. In contrast, SP levels were found to decline only 15% in the above areas, suggesting relatively slow turnover of the peptide in central nervous tissues. The most dramatic changes in SP/SP-G levels were found in the lung extracts where SP-G increased 300-fold with a corresponding decrease in SP levels of 25-30%. We are presently examining whether these changes in SP processing are physiologically relevant to pain responsiveness, as well as inflammatory processes in the respiratory system. (Supported by NIDA DA04128, RMK, and DA03797, MLT)

355.5 ONTOGENY OF SUBSTANCE P WITHIN MICRODISSECTED RABBIT BRAINSTEM NUCLEI. J.L. Gingras*. (SPON: MC McNamara). Dept. of Peds, Duke Univ. Med. Ctr., Durham, NC 27710.

Substance P has been demonstrated by immunohistochemical techniques within many discrete locations throughout the central nervous system (CNS), in some cases coexisting with other neuropeptides and/or classical transmitters (Ljungdahl,A., Hokfelt,T., Nilsson,G., Neurosci, 3:861, 1978; Chan-Palay,V., Jonsson,G., Palay,S., Proc. Natl. Acad. Sci., 75:1582, 1978). More specifically, substance P is found in brainstem areas known to integrate cardiorespiratory function and acts as a neurotransmitter and/or modulator. Additionally, when injected intraventricularly, substance P stimulates breathing (Yamamoto,Y., Lagercranz,H., vonEuler,C., Acta Physiol Scand., 113:541, 1981). This study reports preliminary data on five brainstem nuclei and describes the developmental characteristics of substances P within these specific microdissected brainstem nuclei (Locus Coeruleus, LC; dorsal raphe, dr; N. Parabrachialismedialis, NPBM; N.Reticulogigantocellularis, RGI; N. Tractus Solitarius, NTS). Rabbits of known age (postnatal days 3, 7, 14, 21, 2 months, adult) were sacrificed, brains were immediately removed, sectioned and frozen at -70 degree C. Central nuclear groups were removed by micropunch technique and pooled. Substance P was measured by RIA in duplicate samples and protein was measured by Lowry. Data are reported as ng substance P/mg protein. + denotes significance within groups by ANOVA $p<.05$.

	Day 3	7	14	21	2 mo	Adult
LC+	3.19±.77	3.15±.47	2.86±.65	1.45±.22	1.44±.46	1.26±.31
dr+	1.14±.11	1.94±.25	2.25±.54	1.81±.26	.89±.15	.99±.20
NPBM	1.78±.21	1.97±.16	1.91±.11	1.97±.19	1.63±.27	1.30±.18
RGI+	1.64±.02	2.38±.18	1.48±.09	1.46±.17	1.06±.21	.83±.10
NTS	5.01±.47	8.15±.55	6.70±.66	6.18±48	7.32±1.9	6.92±1.4

These data show that a) substance P levels are highest in the NTS at all ages, b) the developmental profiles for substance P are nuclei-specific and c) overall developmental patterns emerge. In the RGI and LC, substance P levels are relatively high at birth and decrease to adult values after the first few weeks of life. In contrast, substance P is low at birth in the dr, peaks at 14 days thereafter decreases to adult range. In the NTS and NPBM, substance P levels do not significantly change after birth. These data support the concept that neurotransmitter development is not synchronous throughout the CNS nor within specific regions of the CNS and suggests that the physiologic influences of substance P may also reflect these maturational changes.

355.6 TACHYKININ PEPTIDES AND mRNAS IN CULTURED MOUSE MESENCEPHALIC NEURONS. M.J Bannon and G. Kapatos. Center for Cell Biology, Sinai Reasearch Institute,Detroit,MI 48235.

Two to 3 week old cultures derived from dissociated embryonic day 13 mouse mesencephalon and plated at 1.5 million cells/35 mm dish were found after colchicine treatment to contain substance P (SP)-immunoreactivity localized primarily to small fusiform neurons. Acid-extracted cultures contained ~25-100 fm SP/dish was in the reduced form in situ, since 2-mercaptoethanol treatment did not alter immunoreactivity. Analysis by high performance liquid chromatography coupled to radioimmunoassays using both C- and N- terminally directed antisera demonstrated approximately equimolar amounts of SP and substance K (SK,neurokinin A), a related peptide derived from the same preprotachykinin (PPT) gene, in the cultures. The same cultures also contained the structurally related peptide neuromedin K(NMK,neurokinin B) which is derived from a seperate gene. Since SP immunohistochemistry had revealed both intensely stained and lightly stained neurons, it is conceivable that these represent authentic SP-containing and NMK-containing cells,respectively. Northern blot analysis using PPT gene and NMK gene derived clones confirmed the presence of mRNAs encoding SP,SK and NMK in culture. The interaction between these tachykinin neurons and the dopamine neurons with which they are cocultured (SN abstr 12:167.4,1986) is presently being investigated.

355.7 SUBSTANCE P REGULATION BY SECOND MESSENGERS IN DISSOCIATED CULTURES OF NEONATAL RAT VAGAL SENSORY NEURONS. D.B. MacLean and F.B. Wheeler*, Department of Medicine, Section on Endocrinology, Bowman Gray Sch Med of Wake Forest Univ, Winston-Salem, NC 27103.

The factors regulating substance P (SP) synthesis in and release from an unmyelinated subpopulation of vagal sensory neurons are largely unknown. To study this, we have developed dissociated cultures of neonatal rat nodose ganglion neurons. Neurons are dissociated in neutral protease and layered over previously dissociated rat atriacytes. In previous studies, we have demonstrated that substance P within these cultures is present in approximately 20% of neurons and accumulates in amounts of 10-20pg per plated ganglion/equivalent per day. The addition of NGF, 100ng/ml, doubles SP content. Basal release of SP is 0.036%/min of cell content during 20-40min epochs and in response to 50mM K+ rises to 0.15%/min. The sensory neurotoxin, capsaicin (CAP), stimulates SP release in amounts similar to K+.

To study possible second messenger regulation of SP, cultures were maintained for 5-7 days in the presence of phorbol myristate acetate (PMA, 200nM), the phosphodiesterase inhibitor IBMX (.1uM) or DbcAMP (100uM). In the presence of NGF, none of the treatments altered SP content. DbcAMP ± IMBX in NGF-deprived cultures restored SP levels to NGF-positive sister cultures. Prior exposure to PMA raised basal SP release during 20min release epochs (PMA 2.6±0.5 vs control 1.4±0.7% $p<.01$), did not alter K+ stimulated release but significantly reduced net stimulated K+ release (PMA 3.2±1.4 vs control 5.4±0.8%, $p<.02$). Both basal and stimulated release were enhanced by prior IMBX exposure in NGF+ cultures, e.g., 20 min K+ stimulated release, control 15±2 pg/well, IBMX 30±14 pg/well $p<.04$). Prior 6 day or acute exposure to forskolin stimulated SP release in amounts similar to CAP (2 hour release, basal controls 6.6±2.7%, prior forskolin 10.7±2.3%, acute forskolin 10.0±2.0% and CAP 11.9±1.9%).

These studies demonstrate that PMA (or protein kinase C) may modulate SP release mechanisms. The effect of NGF on SP content/synthesis is probably mediated by an adenylate cyclase-dependent mechanism. In addition, cAMP may have effects independent of NGF on SP release and, inferentially, on turnover.

355.8 EXPRESSION OF SUBSTANCE P IN THE CELL CYCLE OF THE TUMOR CELL LINE COLO 320. S.C. Feldman, S. Barnett*, S. Ramachandran*, S. Kolla* and G.P. Studzinski*. Depts. of Anatomy and Pathology, UMDNJ-New Jersey Medical School, Newark, N.J. 07103.

The occurrence of neuropeptides and other putative neurotransmitters in cells outside of the nervous system has been well-documented. We are interested in the role(s) of these molecules in cell growth, differentiation and in disease states including neoplasia. In this study we report the occurrence of the neuropeptide Substance P (SP) in cultures of Colo 320 cells, a cell line derived from a tumor of the endocrine cells of the gut.

Colo 320 cells were maintained in continuous cultures. Smears of cells were made on glass slides, fixed in buffered-formalin acetate and SP localized by immunocytochemistry. Antiserum to SP was purchased from ImmunoNuclear Corp.; intracellular staining was judged specific by the lack of immunoreactivity in cells in which the antiserum was preadsorbed with synthetic peptide. To determine the relationship of appearance of SP to stages of the cell cycle, immunocytochemistry was combined with autoradiography. Cultures were pulsed (1h) with ^{3}H-thymidine, processed for immunocytochemistry then dipped in emulsion, exposed for 2 days, developed and fixed. Cells were scored for the presence or absence of SP and/or silver grains in the nucleus.

SP was found in 30-50% of the cells in normally growing cultures. Combined autoradiography and immunocytochemistry indicated that although 25-60% of the cells were synthesizing DNA, only 10% of these contained the peptide. To further investigate the relationship between the appearance of SP in the cell and DNA synthesis cultures were treated with the polymerase inhibitor aphidicolin (10 or 20ug /ml, 1-6h). Inhibition of DNA synthesis for as little as 1 hour resulted in a marked increase in the number of cells expressing SP (90%). To determine if this was the result of new protein synthesis, cultures were treated with cycloheximide (70ug/ml). SP immunoreactivity was reduced 1h after exposure to the drug; by 6 hours less then 1% of the cells were immunoreactive. After removal of the drug, the proportion of cells exhibiting SP returned to control levels, demonstrating that loss of immunoreactivity was not due to damage of the cells.

These results are consistent with the hypothesis that expression of SP is cell-cycle related. Colo 320 cells may provide a good model for studies of the relationship of neuropeptides to cellular growth processes.

355.9 MOLECULAR CLONING OF MONKEY PROOPIOMELANOCORTIN (POMC) AND PHYLOGENETIC COMPARISON. P. D. Patel, T. G. Sherman, and S. J. Watson. Depts. of Neuroscience and Psychiatry, University of Michigan, Ann Arbor, Michigan 48109.

Proopiomelanocortin has received widespread attention due to its role as a neuroendocrine prohormone subserving numerous physiological systems. Some of the peptides cleaved from this prohormone have been intensively studied and fairly well characterized with respect to biological activity (i.e., adrenocorticotrophic hormone (ACTH), B-endorphin (BE), a-melanocyte stimulating hormone (MSH) in lower animals). Other sequences are equally well conserved across species, both at the nucleotide and at the peptide level, but as yet have not been physiologically characterized (e.g. N-terminal peptide, corticotropin-like intermediate lobe peptide (CLIP)). As part of a larger investigation into the processing and function(s) of POMC peptides, we have cloned and sequenced a cDNA for POMC from the pituitary of the old world monkey, Macaca nemestrina. We present here the complete nucleotide sequence, deduced amino acid sequence, and comparison at both levels with previously published POMC sequences.

In general, the monkey POMC clone is highly homologous to the human sequence. Certain peptide domains, e.g., signal peptide, b-MSH, ACTH, and the amino terminal portion of the N-terminal peptide through g-MSH are identical in these two species, and highly conserved in all species, lending support to the contention that all of these peptides serve the system in a vital capacity. The region between g-MSH and a-MSH, and the sequences spanning B-lipotropin show the greatest diversity in all species studied. These dissimilarities include single base frameshifts as well as larger deletions and/or insertions. Perhaps a more interesting observation, especially from the phylogenetic viewpoint, is that the monkey BE peptide contains residue changes intermediate between that of lower mammals (bovine, murine, rat) and that of the higher mammal (human). Other features include the expected pattern of dibasic cleavage sites and, in particular, the Arg-Arg cleavage site at the end of γ_1-MSH (in contrast to the corresponding Pro-Arg non-cleavage site found in rat and mouse POMC).

The 1.6 kilobase clone presented here has an unusually large 5' untranslated region, consistent with previous northern analysis of monkey mRNA and confirmed by S_1 nuclease analysis. The significance of this feature is not yet known, but studies are under way to analyze what may be two different sizes of message. RNase mapping will be utilyzed to compare this clone to Macaca rhesus POMC, for which a larger message is also observed.

355.10 HALOPERIDOL-MEDIATED CHANGES OF GAMMA-MELANOTROPIN AND β-ENDORPHIN PROCESSING IN THE RAT PITUITARY. L.P. Taylor*, J.H. Meador-Woodruff*, L. Corkins*, N. Ling and H. Akil (Spon: S. Watson). Mental Health Research Institute and Department of Psychiatry, University of Michigan Medical Center, Ann Arbor, MI, 48109-0720.

Gamma-melanotropin (γ_3MSH) is in the N-terminal domain of the β-endorphin (BE)/ACTH precursor, proopiomelanocortin (POMC), and is an important component of the pituitary-adrenal axis, potentiating ACTH-induced adrenocortical steroidogenesis. Gamma-MSH-IR exists in rat pituitary primarily as 5K and 11K forms (representing fully processed and glycosylated γ_3MSH, and γ_3MSH extended by the extreme N-terminal fragment of POMC, respectively), although a small percentage exists as precursor-sized material. Although mechanisms controlling processing and release of BE from the pituitary have begun to be elucidated, little attention has been focused on the control of processing of the N-terminal region of POMC; for example, BE in the intermediate lobe of the rat pituitary is felt to be under partial dopaminergic control. To further address this issue, the effect of chronic haloperidol on the processing of both BE and γ_3MSH in the anterior (AL) and intermediate (IL) lobes of rat pituitary was explored. Male Sprague-Dawley rats received daily IP injections of haloperidol (dose range 0 to 2 mg/kg) for 14 days; 24 hrs following the last injections, the rats were sacrificed by decapitation, the pituitaries immediately dissected into AL and IL, and quickly frozen on dry ice. Tissue was extracted in acetone/HCl, lyophilized, and resuspended in 1% formic acid. Aliquots were assayed for γ_3MSH-IR and BE-IR by specific RIAs that we have developed. Additional aliquots were subjected to gel filtration and HPLC, and fractions assayed for both peptides. In IL, chronic haloperidol induced a near-doubling of both total BE-IR and γ_3MSH-IR. This increase was attributable to a dose-dependent induction of fully-processed BE-sized and γ_3MSH-sized (5K) material. In AL, total content of both BE-IR and γ_3MSH-IR was unchanged. Chromatography revealed, however, that high doses of haloperidol caused a selective increase of 22K γ_3MSH-IR, with a corresponding reduction of more processed forms of γ_3MSH in AL. Higher doses of haloperidol promoted a selective increase of 31K BE-IR (POMC), with a corresponding reduction of β-lipotropin and BE. These results suggest that haloperidol alters the processing of POMC in rat pituitary at multiple sites. Chronic haloperidol induces the IL to store increased amounts of fully-processed peptides (BE and γ_3MSH). In AL, however, it appears that chronic haloperidol causes a relative inhibition of the conversion of POMC to 22K-ACTH and β-lipotropin, and of 22K-ACTH to the 16K N-terminal fragment and ACTH, resulting in the accumulation of these larger molecules.

355.11 IMMUNOCYTOCHEMICAL STUDIES OF PEPTIDYLGLYCINE α-AMIDATING MONOOXYGENASE (PAM). V. May, K. M. Braas, and B. A. Eipper. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD, 21205

The presence of a carboxyl terminal α-amide moiety confers biological activity to a number of neuroendocrine peptides. An α-amidating activity capable of producing α-amidated peptides from glycine-extended precursors has been described in plasma, CSF and several neuronal and endocrine tissues. The enzyme, peptidylglycine α-amidating monooxygenase (PAM), has been purified from bovine neurointermediate pituitary and occurs in multiple forms differing in apparent molecular weight and charge. To begin studies on PAM localization and regulation, and to enable screening of cDNA expression libraries for clones producing PAM, two rabbits were injected with purified enzyme; purified PAM preparations were labeled with ^{125}I to test for antibody production. To verify that the major labeled protein was the enzyme, the ability of the antisera to interact with ^{125}I-protein and active enzyme was compared. Incubation of bovine pituitary extracts to which ^{125}I-labeled purified PAM has been added with increasing amounts of antiserum covalently conjugated to Protein A Sepharose resulted in a dose-dependent parallel depletion of PAM activity and ^{125}I-protein from the supernatant. Bovine pituitary tissue extracts were subjected to SDS-PAGE and the resolved proteins transferred to nitrocellulose for Western analysis. When the blots were incubated with PAM antiserum and processed using either the avidin-biotin-peroxidase complex (ABC) or ^{125}I-Protein A technique, two major bands corresponding to PAM-A and PAM-B were observed. Although the anterior pituitary contains high levels of PAM activity, few amidated peptides are known to be synthesized there in sizeable amounts. Immunocytochemical studies with both antisera were performed to identify PAM producing cells in the pituitary. Bovine pituitaries were immersion fixed and embedded in paraffin. Tissue sections (8 μm) were incubated with PAM antisera diluted 1:2000-1:4000 in 0.1% gelatin and processed using a modification of the ABC immunocytochemical technique. Fixation with 4% paraformaldehyde preserved PAM antigenicity optimally without compromising tissue morphology. PAM immunoreactivity was localized to the cytoplasm of a distinct population of anterior pituitary cells and in specific regions of the neurointermediate pituitary lobe. Staining was absent when diluted antisera were preincubated with 1 μg/ml purified PAM. No staining was observed in rat or guinea pig pituitary suggesting that the antisera are species specific. Current studies utilizing serial sections and double labeling techniques are aimed at determining the identity of the PAM immunoreactive cells in the anterior pituitary.

355.12 IN SITU HYBRIDIZATION ANALYSIS OF INCREASED PREPROENKEPHALIN mRNA FOLLOWING LIMBIC SEIZURES. C.M. Gall[1], J.C. Lauterborn*[1], and J.D. White[2], [1]Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717 and [2]Division of Endocrinology, S.U.N.Y., Stony Brook, NY 11794.

Previous work by ourselves and others has demonstrated that recurrent limbic seizures induce an increase in enkephalin synthesis within hippocampus and entorhinal cortex as measured by increases in enkephalin content, preproenkephalin mRNA, and incorporation of ^{35}S methionine into chromatographically identified enkephalin (White et al., J. Neurosci. 7: 753-759). In the present study, in situ hybridization techniques were used to identify the cellular localization of elevated preproenkephalin mRNA in limbic structures following an episode of recurrent seizures.

A small electrolytic lesion was placed in the dentate gyrus hilus of adult male Sprague-Dawley rats under ketamine/xylazine anesthesia. This treatment has been demonstrated to induce recurrent limbic and behavioral seizures which begin 1-2 hrs postlesion and continue for 6-8 hrs thereafter. Hilus-lesioned rats included in this study exhibited a minimum of two stage 4 behavioral seizures. At 24 hrs postlesion, experimental and paired control rats were sacrificed by perfusion with 4% paraformaldehyde. Free-floating vibratome sections through hippocampus, entorhinal cortex, and amygdala contralateral to the lesion were processed for the localization of preproenkephalin mRNA using an ^{35}S-labeled cRNA probe and both film and emulsion autoradiographic techniques.

In control animals, hybridization was low in the limbic structures evaluated. A few cells were lightly labeled in the posterior cortical amygdala, layers II and III of entorhinal cortex, and layer II of piriform cortex. Within hippocampus, lightly labeled cells were occasionally observed within the pyramidal dendritic fields, and only very rarely within the dentate gyrus granule cell layer. In contrast, labeling was uniformly dense over the granule cell layer of experimental animals. Autoradiographic grain density was also very high over cells in layers II and III of ventral lateral entorhinal cortex, layer II of piriform cortex, the amygdalohippocampal area, and the posterior cortical amygdala. Moderate grain densities were observed over cells in the more dorsal medial and lateral entorhinal cortices and the lateral amygdala.

These data demonstrate that seizure activity can induce increased enkephalin synthesis in a number of brain areas and cell types and thereby support the conclusion that physiological activity has a large influence over the regulation of enkephalin synthesis in C.N.S. neurons. Moreover, these results indicate that the full population of neurons capable of enkephalin synthesis is not evident in the resting state. (Supported by BNS 8417098 and RCDA NS 00915 to C.M.G., and RR05736 and MH42074 to J.D.W.).

355.13 PLASMA OPIOID PEPTIDES: CHARACTERIZATION OF MET-ENKEPHALIN-IMMUNOREACTIVE PEPTIDES GENERATED BY PEPTIC DIGESTION. F. S. Shen* and I. Lindberg (SPON: K. Kratz), Department of Biochemistry and Molecular Biology, L.S.U. Medical Center, New Orleans, LA 70112

Singer et al have shown that plasma from various species can yield micromolar concentrations of met-enkephalin-immunoreactive peptides (MEIP) after digestion with pepsin (Endocrinol. 119, 1527, 1986). In an effort to understand the biochemical basis for this observation, we have attempted to characterize MEIP generated from plasma.

Rat plasma was digested with pepsin and analysed by radioimmunoassay, gel filtration, isoelectric focusing (IEF), and HPLC. Results obtained using gel filtration on Bio-Gel P-2 were similar to those obtained by Singer et al. Two peaks of MEIP were observed. The first peak of MEIP, which accounted for 84% of the total, eluted several fractions after the void volume, while the second peak eluted several fractions before the salt volume. When the first peak of MEIP was further analyzed by HPLC using a slow acetonitrile gradient, it was found to be heterogeneous in nature, with six immunoreactive peaks. In contrast to results obtained by Singer et al, none of these HPLC peaks exhibited a retention time similar to met-enkephalin or met-enkephalin sulfoxide.

Isoelectric focusing (pH 3-10 gradient) of MEIP generated by peptic digestion of plasma showed five peaks of immunoreactivity with isoelectric points of 3.6, 5.9, 7.3, 8.1, and 9.6. The peak at pI 9.6 contained 40% of the immunoreactive peptides. In view of the results of Singer et al as to the molecular weight of the precursor protein which gives rise to MEIP (65,000), we digested rat serum albumin (RSA) with pepsin in order to examine the possibility that RSA might be the precusor of plasma MEIP. Gel filtration of digestion products of RSA yielded a peak of MEIP with the same elution volume as that of the second peak of digested whole plasma. This result suggests that MEIP present in this second peak (which represents only 15% of total plasma MEIP) may be due to plasma RSA. Analysis by IEF of digestion products of RSA showed a completely different profile of MEIP; the main peak exhibited a pI of 3.4 (75% of the total) and smaller peaks were apparent at pIs 4.3, and 4.9

From these results, it appears that at least two proteins (RSA and an as yet unidentified protein) can give rise to MEIP upon peptic digestion. In addition, MEIP produced by peptic digestion of whole plasma appear to be heterogenous in nature. (Supported by DK35159).

355.14 MONOCLONAL ANTIBODIES TO AN ENDOGENOUS NEUROPEPTIDE WITH PUTATIVE MORPHINE-MODULATING ACTIVITY C.-H. Lee*, R. Brown*, E.A. Majane* and H.-Y. T. Yang Naval Medical Research Institute, Bethesda, MD 20814 and National Institute of Mental Health, St. Elizabeth's Hospital, Washington, D.C. 20032.

Two neuropeptides, FLFQPQRF-NH_2 (F-8-F-NH_2) and AGEGLSSPFTSLAAPQRF-NH_2 (A-18-F-NH_2), originally detected by antiserum raised against Phe-Met-Arg-Phe-NH_2 (FMRF-NH_2), were recently isolated from bovine brain and found to modulate morphine analgesia. (Yang et al., Proc. Natl. Acad. Sci. USA 82:7757, 1985) Using the antisera raised in rabbits to these two peptides, they were found to distribute unevenly in bovine brain and spinal cord. In addition to F-8-F-NH_2 and A-18-F-NH_2, there are still other FMRF-NH_2-like immunoreactive materials in mammalian brains. Some immunohistochemical studies indicated that the FMRF-NH_2 and neuropeptide Y (NPY) immunoreactivities are both stored in the same neurons. However, it is not clear whether it is possible to differentiate NPY from FMRF-NH_2-like peptides by immunohistochemical means using polyclonal antisera. Therefore, in this study, monoclonal antibodies were generated in an attempt to select an antibody capable of differentiating NPY-like from FMRF-NH_2-like peptides. Three murine monoclonal antibodies of IgG isotype to F-8-F-NH_2 were obtained through cell fusion and cloning. In an RIA using ^{125}I-YLFQPQRF-NH_2 as a tracer, these antibodies cross-reacted with other structurally related peptides. The relative immunoreactivities of these peptides expressed in $(B/B_0)_{50}$ (pmol/tube) are: F-8-F-NH_2, 0.9; A-18-F-NH_2, 7; PQRF-NH_2, 60; FMRF-NH_2, 200; γ_1MSH, 500; and RF-NH_2, 1,000. NPY, PYY or Met^5-enk-R^6-F^7 showed no cross-reaction even at 10,000 pmol/tube. This result suggests that these monoclonal antibodies recognize the C-terminal portion of F-8-F-NH_2 and that RF-NH_2 is required for the immunoreactivity. It also indicates that these monoclonal antibodies are capable of differentiating -RF-NH_2, the C-terminal dipeptide amide of FMRF-NH_2-like peptides, from -RY-NH_2, the C-terminal dipeptide amide of NPY. An extract from bovine spinal cord was analyzed by HPLC coupled with RIA using the monoclonal antibodies. The major immunoreactivity was identified as F-8-F-NH_2 and the minor one as A-18-F-NH_2, although there are some very small amounts of unidentified immunoreactive species. The specificity of these monoclonal antibodies is thus further confirmed and will be useful in differentiating the distribution of F-8-F-NH_2 or mammalian FMRF-NH_2-like peptides from that of NPY. (Supported in part by NMRDC 62758/MM58.527.01.0003).

PEPTIDES: PHYSIOLOGICAL EFFECTS I

356.1 RELEASE OF ATRIAL NATRIURETIC FACTOR (ANF) FROM PERFUSED RAT HYPOTHALAMIC EXPLANTS. R. Nissen*, J. Gutkowska* and L.P. Renaud (SPON: E. Cooper), Neurosciences Unit, Montreal General Hospital and McGill Univ. Montreal, Quebec, Canada H3G 1A4.

Several observations indicate that ANF, a circulating hormone released from cardiac myocytes, may function as a neuropeptide. Selective ANF binding sites and ANF-like immunoreactive neurons and fibers are described in basal forebrain and diencephalic structures known to regulate fluid balance and blood pressure. ANF is released from blocks of rat hypothalamus by calcium-dependent potassium depolarization. The recent detection of an ANF-like peptide in the rat neurohypophysis (Gutkowska et al., Peptides, 1987) and report of a possible co-existence of ANF within hypothalamic magnocellular oxytocin-secreting neurosecretory neurons (Jirikowski et al., Neuropeptides 8: 243, 1986) prompted us to examine for in vitro release of ANF-like peptides from the neurohypophysis.

Experiments utilized intra-arterial perfusion of oxygenated, warmed artificial cerebrospinal fluid to maintain acutely prepared explants of rat hypothalamus and basal forebrain (Randle et al., Neurosci. Lett. 65: 219, 1986). Following removal of the anterior lobe of the pituitary, a suction pipette was positioned over the neurointermediate lobe to collect samples of superfusate. Under basal conditions, samples assayed for ANF by radioimmunoassay revealed baseline values of 5-20 pg/ml. ANF levels were increased 6-10 fold when the perfusion media contained 60 μM norepinephrine or elevated sodium chloride (from 124 mM to 144 mM). ANF appears to be released from both a median eminence and a neurohypophysial site, possibly by different stimuli at each site. Supported by MRC.

356.2 EFFECTS OF VAGOTOMY AND HEMORRHAGE ON ATRIAL NATRIURETIC PEPTIDE. M.I. Phillips, B. Kimura* and W.E. Hoffman. Department of Physiology, University of Florida, Gainesville, FL 32610 and Department of Anesthesiology, Michael Reese Hospital, Chicago, Il 60616.

Atrial natriuretic polypeptides (ANP) have potent natriuretic, diuretic and vasorelaxant activities. ANP is released from atria during volume loading and sodium intake. ANP has also been found in the brain. To study the effects of hemorrhage on the brain and plasma ANP levels, we used normotensive rats subjected to 33% hemorrhage.

Sprague Dawley rats were anesthetized with chloral hydrate and catheterized in the femoral artery. One group was hemorrhaged, the other was control. A 2 ml sample was collected 30 mins. later. Atria and hypothalamus blocks were boiled, purified and ANP extracted. ANP from all sources was characterized by HPLC. Levels of ANP were measured by radioimmunoassay after Sep-Pak C-18 extraction. The antisera was anti-Rat 28 amino acid ANP. Hemorrhage significantly decreased plasma ANP (244 ± 81 vs. 41 ± 7 pg/ml, $P < 0.05$), elevated ANP levels in the atria (126 ± 12 vs. 169 ± 24 μg/g tissue, N.S.) and significantly increased levels in hypothalamus (19.7 ± 1.0 vs. 25.5 ± 0.6 ng/g tissue, $P < 0.001$).

The fall in plasma ANP could be due to a volume change acting on the atrial stretch receptors or to neural afferent input to the brain. To attempt to separate these possibilities, bilateral vagotomy was performed. Twelve rats were anesthetized with chloral hydrate as above. In 6 rats, bilateral vagotomy at the level of the carotids was performed. Two ml samples of blood were withdrawn. Both the control group and vagotomized group were hemorrhaged 33% and 2 ml blood taken 30 mins. later. The results showed that the effect of vagotomy was a huge rise in plasma ANP in 5 out of 7 rats (means: control, 244; vagotomy, 731 pg/ml). However, hemorrhage produced a significant decrease in plasma ANP in both groups. Considering the high baseline levels of the vagotomized rats, the fall was greater than in controls.

It is concluded that the vagus is important in controlling ANP levels and acts to inhibit release. During hemorrhage less ANP is released from the atria and this may be partly controlled by the vagus nerve in addition to less stretch on the stretch receptors. Opposite effects of hemorrhage on plasma ANP and hypothalamic ANP levels indicate brain involvement in the regulation of hemorrhaged-induced hypovolemia. The results point to a reflex brain ANP response to hemorrhage. (Supported by NIH grant 1-R01-HL27334 to MIP.)

356.3 HYPOTHALAMIC ACTION OF ATRIAL NATRIURETIC FACTOR TO INHIBIT PROLACTIN SECRETION. W.K. Samson*, E. Ramos* and R. Bianchi* (SPON: R.L. Moss). Dept. of Physiology, UTHSCD, Dallas, TX 75235-9040.

Atrial natriuretic factor (ANF) is produced in cardiac myocytes and in brain neurons. High levels of the peptides have been detected in the hypothalamus (Brain Res 365:105), the ANF gene is transcribed there (PNAS 83:6697), and ANF receptors have been identified in the diencephalon (PNAS 83:174). Its presence in a variety of hypothalamic nuclei and in the median eminence (Histochem 83:1) suggests a hypothalamic action of ANF. Indeed the peptide alters neuronal firing rate in the hypothalamus (Neuroendo 44:49) and we have demonstrated that it inhibits the release of AVP and LHRH in vivo and in vitro. Recently, the interaction of ANF with brain dopaminergic systems has been demonstrated (EJP 131:171). We examined, therefore, the possibility that ANF plays a role in the hypothalamic control of prolactin (PRL) secretion in the rat. ANF (atriopeptin III and ANF-28) in log doses ranging from one pico- to one micromolar had no significant effect on PRL release from dispersed, cultured anterior pituitary cells under either basal or stimulated conditions. Intravenous bolus injection (0.1, 1.0 or 10 micrograms) or constant infusion for 30 min (0.01 or 0.1 microgram/kg/min) of ANF also failed to significantly alter plasma PRL levels in conscious, castrated male rats. Third cerebroventricular injection of ANF (in 2 microliters saline) resulted, however, in a dose-related inhibiton of PRL secretion.

ng PRL/ml plasma (X±SEM)

	0'	15	30	60	90	120 min
Control (23)	30±4	29±3	23±4	26±3	30±4	32±4
0.1 nmole ANF (10)	30±6	22±3	23±5	19±4	23±3	26±4
1.0 nmole ANF (10)	27±7	14±3**	17±5	17±3*	13±3*	26±5
2.0 nmole	26±10	12±3**	7±2**	11±3*	13±3*	17±5

*p<.025,**p<.005 analysis of variance, multiple comparisons.

These results suggest the possibility that centrally produced ANF plays some role in the hypothalamic control of PRL secretion. Whether this possible action is exerted via dopaminergic mechanism, perhaps by inhibiting dopamine-beta-hydroxylase activity, as has been demonstrated in pheaochromocytoma cells in culture (NEJM 314:321), remains to be established. Alternatively, the possibility exists that ANF alters the release of some other PRF/PIF thus resulting in a reduced hypothalamic drive for PRL secretion. (Supported by NIH Grant HD09988, Project II to WKS.)

356.4 THE EFFECT OF OXYTOCIN AND PSYCHOLOGICAL STRESS ON NOREPINEPHRINE, DOPAMINE AND SEROTONIN IN DISTINCT BRAIN REGIONS. J.L. Muir* and H.P. Pfister*. (SPON: ENA)
Dept of Psychology, Univ. of Newcastle, NSW 2308, Australia.

Oxytocin (OXT) acts on catecholaminergic and serotonergic activity in the brain and appears to be a member of the class of neuromodulators, i.e. modulates the activity of the putative neurotransmitters in the brain. The effects of OXT have been examined to some extent, the main findings indicating that this peptide induces impairment of memory consolidation and retrieval processes (Bohus, B., Kovacs, G.L. & De Wied, D., Br. Res., 157:414, 1978). OXT also appears to be involved in the stress response, potentiating corticotropin-releasing factor (CRF)-induced release of adrenocorticotropic hormone (ACTH) (Gibbs, D.M., Vale, W., Rivier, J. & Yen, S.S.C., Life Sci., 34:2245, 1984). Exposure to a stressor also produces a number of changes in catecholaminergic and serotonergic systems in the central nervous system. These changes are reflected as decreased concentration of transmitter and/or increased concentration of metabolites. The purpose of this study was therefore to investigate the effect of OXT on brain catecholaminergic and serotonergic activity following predictable and unpredictable novelty stress.

Female rats were allocated to four groups: a group which received no injections, a group which received 1 ml/kg injections of the vehicle solution, a group which received injections of 5.8 IU OXT/kg and a group which received 11.6 IU OXT/kg. All injections were given via the i.p. route. Each of these four groups were further subdivided into three stress treatment groups: a control group, a predictable stress group (animals were subjected daily for 5 successive days to a single 30 min. exposure to a novel apparatus) and an unpredictable stress group (animals received one 30 min. exposure to the novel apparatus on each of 5 days at a randomly selected time within each 24 hr period). Following OXT and stress treatment, the brain of each animal was dissected into five brain regions: hypothalamus, hippocampus, striatum, midbrain and brainstem.

The results will be discussed in terms of the effects of oxytocin and stress treatment on the steady state level and "turnover" of norepinephrine, dopamine and serotonin in the five brain regions indicated.

356.5 OXYTOCIN INFUSIONS IN CAUDAL VENTROLATERAL MEDULLA ACTIVATES SUPRAOPTIC VASOPRESSIN-SECRETING NEURONS IN THE RAT. L.P. Renaud, J.H. Jhamandas, R.M. Buijs* and T.A. Day. (SPON: A.T. Tan) Neurosciences Unit, Montreal General Hospital and McGill Univ., Montreal, Quebec Canada, H3G 1A4

The magnocellular neurosecretory neurons (MNCs) of the hypothalamic supraoptic and paraventricular nuclei receive a prominent noradrenergic innervation from the A1 neurons of the caudal ventrolateral medulla (Sawchenko & Swanson, Science 214:685, 1981). Recent electrophysiological data indicate that this A1 innervation is excitatory and selective for vasopressin-secreting MNCs (Day et al., J. Physiol. 355: 237, 1984). The A1 region receives input from several CNS sites. Of particular note is a descending projection arising in the parvocellular paraventricular nucleus which may comprise oxytocin immunoreactive fibers (Buijs, Cell Tiss. Res. 192: 423, 1978). In order to evaluate a possible transmitter role for oxytocin at this site, we infused the hormone into the A1 area while recording the firing frequency of supraoptic neurosecretory neurons. Experiments utilized urethane or pentobarbital anesthetized male Sprague Dawley or Long-Evans rats. The hypothalamus and brainstem were exposed by a transpharyngeal approach. MNCs were identified by antidromic activation from the neurohypophysis and categorized as vasopressin- or oxytocin-secreting according to their firing pattern and sensitivity to baroreceptor input. Oxytocin infusions (100-250 pg) restricted to the A1 area were accompanied by a rise in the firing frequency of 16/19 vasopressin-secreting neurons. In contrast, 0/10 oxytocin-secreting neurons were similarly influenced. These data suggest that the peptidergic hormone oxytocin may participate in central neurotransmission within the caudal ventrolateral medulla to induce activation of supraoptic MNCs that secrete vasopressin into the systemic circulation.

356.6 PARALYTIC AND PRESSOR EFFECTS OF INTRATHECAL ARGININE-VASOPRESSIN IN THE RAT. A. Martinez-Arizala*, J.B. Long and J.W. Holaday. Neuropharmacology Branch, Department of Medical Neurosciences, Division of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20307.

Endogenous opioids have been implicated in the pathophysiology of spinal cord injury since opioid antagonists improve neurologic outcome following experimental spinal cord trauma. Among the endogenous opioids, Dynorphin A has been specifically implicated in injury mechanisms since it produces flaccid hindlimb paralysis after intrathecal (i.t.) administration in rats. Other peptides endogenous to the spinal cord also share this effect, specifically, we studied Arg^8-Vasopressin (AVP) at doses that cause hindlimb paralysis and an arterial pressor response after i.t. injection in rats. Male Sprague-Dawley rats (300-350 gm) under anesthesia (ketamine 50 mg/kg and xylazine 10 mg/kg) were implanted with catheters in the external jugular vein, the tail artery, and the lumbar subarachnoid enlargement. After allowing 24 hours for recovery, the cardiovascular and motor responses to i.t. and intravenous (i.v.) AVP were compared. Intravenous AVP (0.01 nmoles) did not alter motor function, but produced a moderate pressor response (mean maximum MAP change = 34 mm Hg) which was blocked by the i.v. injection of the V_1 receptor antagonist $d(CH_2)_5[Tyr(Me)^2]AVP$ (10 nmoles). Intrathecal injections of an identical dose of AVP produced a marked pressor response (mean maximum MAP change = 73 mm Hg) accompanied by hindlimb paralysis. Intrathecal (0.2 nmoles), but not intravenous (10 nmoles) injections of the V_1 receptor antagonist blocked both the paralytic and pressor effects of i.t. AVP (0.01 nmoles). Following recovery of motor function and normalization of blood pressure, repeat injections of i.v. AVP (0.01 nmoles) produced equivalent pressor responses whereas repeat injections of i.t. AVP (0.01 nmoles) revealed a marked refractoriness to both the paralytic and pressor responses. We conclude that 1) Dynorphin A is not unique among endogenous neuropeptides in producing spinal cord dysfunction in the rat, 2) responses to i.t. AVP exhibit a period of refractoriness, and 3) the pressor and paralytic effects of i.t. AVP are centrally mediated through the V_1 receptor.

356.7 INFLUENCE OF ACUTE AND CHRONIC CHANGES IN BLOOD VOLUME AND PLASMA OSMOLALITY ON ATRIAL NATRIURETIC FACTOR (ANF) AND ARGININE VASOPRESSIN (AVP) CONCENTRATIONS. P.A. Mason, K.M. Chu*, C.R. Freed, D. Bhaskaran, L.G. Ganousis*, A.S. Nies*, and J.A. Durr*. Depts. of Med. and Pharm., Univ. of Colo. Health Sciences Center, Denver, CO, 80262.

Atrial natriuretic factor (ANF) and arginine vasopressin (AVP) regulate extracellular fluid volume. Anatomically, the brain regions containing ANF and AVP are in proximity to one another along the AV3V region. We have investigated the effects of changes in blood volume (BV) and plasma osmolality (Posm) on the plasma concentrations of ANF and AVP. Male Sprague-Dawley rats (300-350 gm, n=22) had BV and Posm acutely altered with injections of 35% polyethylene glycol (8000 MW, 2 ml/100 gm body weight, i.p.) dissolved in 200, 600, or 1000 mOsm/kg of NaCl solution. Animals were killed 2 hr after the fluid challenges. Other animals (n=16) were water deprived for 0, 24, or 48 hr to study more chronic BV and Posm changes. All rats were decapitated and trunk blood was collected for determination of Posm, hematocrit, protein concentration, and plasma ANF and AVP concentrations. Normal hydrated rats showed a baseline plasma ANF value of 169 pg/ml and an AVP concentration of 6 pg/ml. In treated rats, the change in BV ranged from +12 to -24% and Posm ranged from 291 to 322 mOsm/kg. In the acutely-treated rats, a reduction in BV led to a fall in plasma ANF ($r=0.73$, $p<0.001$), while AVP increased ($r=-0.87$, $p<0.001$). When BV was held constant at -20% and osmolality was varied, plasma ANF fell as Posm increased ($r=-0.74$, $p<0.001$) while AVP increased ($r=0.53$, $p<0.05$). Similar results were seen in chronic water deprived rats. Decreased BV was associated with a fall in plasma ANF ($r=0.87$, $p<0.001$) and an increase in plasma AVP ($r=-0.67$, $p<0.005$). With increased osmolality, there was a reduction in ANF ($r=-0.45$, $p<0.05$) and an increase in AVP ($r=0.78$, $p<0.001$). Our results predict that a 24% decrease in BV would be required to suppress ANF completely. In conclusion, acute and chronic BV depletion results in a linear decrease in plasma ANF concentration, suggesting that ANF has a physiological role in normal BV control rather than being important only in volume expanded conditions. In acutely-treated rats, plasma ANF correlated inversely with Posm when both BV and plasma protein concentration were held constant at -20% and 4 g/dl, respectively. This result indicates that ANF varies with changes in Posm as well as BV. As expected, plasma AVP increased in response to reductions in BV and increases in Posm. Because ANF and AVP appear to be reciprocally related to alterations in BV and Posm, it is possible that the two neurohormones are mutual antagonists.

356.8 ELECTRICAL STIMULATION OF THE BED NUCLEUS OF THE STRIA TERMINALIS (BST) SUPPRESSES PGE_1 HYPERTHERMIA IN THE RAT BY RELEASING VASOPRESSIN IN THE VENTRAL SEPTUM. A.M. Naylor*[1], Q.J. Pittman[2] and W.L. Veale[2]. [1]MRC Reproductive Biology Unit, Edinburgh, Scotland EH3 9EW and [2]Dept. of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Perfusion of arginine vasopressin (AVP) through the ventral septal area (VSA) of the rat brain suppresses the fever evoked by the intracerebroventricular (icv) infusion of PGE. Evidence suggests that vasopressin may function in this area of the brain as an endogenous antipyretic via an action on a receptor resembling the peripheral V_1 subtype. One of the potential sources of AVP to the VSA is from a vasopressinergic pathway originating in the BST. These experiments were undertaken to determine what effect electrical stimulation of the BST would have on the fever evoked by icv PGE and how this effect could be modified by vasopressin antagonists injected into the VSA.

Male Sprague-Dawley rats were anesthetized (pentobarbital 70 mg/kg i.p.) and guide cannulae were implanted bilaterally above the VSA and unilaterally above a lateral cerebral ventricle. In addition, monopolar stimulating electrodes were implanted bilaterally in the BST. Following a 7 day recovery, body temperature was monitored continuously with transmitters (Minimitter Inc.) implanted in the peritoneal cavity. Infusion of PGE_1 (200 ng/10 µl) into a lateral ventricle evoked a rise in core temperature of 1.0°C. When this injection of PGE_1 was accompanied by electrical stimulation of the BST (monophasic, square wave pulses, 0.5 msec duration, 20 Hz) for 10 min prior to and 20 min following the icv infusion of PGE_1, the rise in core temperature was attenuated significantly ($n=6$). The suppression of PGE-hyperthermia was observed only when the electrodes were located in the BST. Stimulation of nearby areas such as the lateral septum did not alter the hyperthermic response. When electrical stimulation of the BST suppressed PGE_1 fever, similar stimulation in the absence of PGE_1 did not affect body temperature in the afebrile rat. When the vasopressin V_1 antagonist $d(CH_2)_5Tyr(Me)AVP$ (400 pmoles/side) was injected into the VSA electrical stimulation of the BST did not attenuate the PGE_1-hyperthermia when compared to controls with saline or V_2 antagonist $[d(CH_2)_5DValVAVP]$ ($n=6$).

These data indicate that electrical stimulation of a potential source of AVP to the VSA, the BST, suppresses PGE_1-fever. In addition, a vasopressin V_1 antagonist blocks the stimulation-induced suppression suggesting that endogenous AVP, released in the VSA in response to electrical stimulation of the BST, may be responsible.

Supported by MRC (Canada) and AHFMR. We thank Dr. M. Manning (Ohio) for the vasopressin antagonists.

356.9 DOES INTRATHECALLY ADMINISTERED VASOPRESSIN PRODUCE ITS PERIPHERAL CARDIOVASCULAR EFFECTS BY COMPROMISING SPINAL BLOOD FLOW? James P. Porter and Mark A. Schroer*. Dept. of Physiology, University of Louisville, Louisville, KY 40292.

Intrathecal administration of vasopressin (AVP) into the subarachnoid space of the spinal cord produces a marked increase in arterial pressure in rats. AVP-containing neurons are present in the spinal cord and it has been hypothesized that exogenously administered AVP mimicks a neurotransmitter-like effect of this peptide. However, AVP is a potent vasoconstrictor and the effects of intrathecal administration of the agent could be due to widespread neuronal hyperactivity resulting from compromised blood flow to the spinal cord rather than to a neurotransmitter effect on sympathetic preganglionic neurons. In the present investigation we tested the hypothesis that the effects of intrathecal vasopressin are due its vasoactive properties. Specifically, we compared the effects of intrathecal vasopressin to the effects produced by intrathecal administration of other vasoactive agents, namely angiotensin II (AII), norepinephrine (NE), and phenylephrine (PE). We reasoned that these agents should also produce an increase in arterial pressure when administered into the spinal cord if the effects of vasopressin can be explained by its vasoconstrictor action. Mean arterial pressure and heart rate were monitored in conscious, freely moving rats before and after administration of AVP (5 to 15 ng), AII (30 ng to 3000 ng), NE (200 ng to 1200 ng), or PE (200 ng to 1200 ng) into an indwelling intrathecal catheter. AVP produced the expected increase in arterial pressure that was accompanied by bradycardia. On the other hand, the other agents produced no effects at any of the doses used. In a second series of experiments, we sought to determine if prior intrathecal administration of vasodilating agents would attenuate the expected increase in arterial pressure with subsequent AVP injections. Bradykinin (1 µg), papaverine (1-30 µg), or vasoactive intestinal peptide (1-3.3 µg) were first given into the intrathecal catheter. Two minutes later 5 ng of vasopressin was also added to the spinal subarachnoid space. Papaverine and VIP had no effect on the increase in arterial pressure with subsequent administration of vasopressin. However, pretreatment with bradykinin significantly attenuated the AVP-response by 50%. It is unlikely that a vasodilator action of bradykinin contributed to this attenuation since the two other potent vasodilators had no affect. It is more likely that some neuroactive action of bradykinin was responsible. Taken together, these data do not support the hypothesis that AVP increases sympathetic outflow to the peripheral vasculature by constricting local spinal vessels and compromising blood flow to the spinal cord. The hypothesis that AVP acts directly on sympathetic preganglionic neurons is still tenable.

356.10 COLD EXPOSURE ALTERS ENDOGENOUS TRH AND NEUROTENSIN CONCENTRATIONS IN MOUSE BRAIN REGIONS. G. Bissette. Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710.

The study of thermoregulation has identified a large number of endogenous substances that can alter body termperature when injected into the CNS or periphery of a wide variety of experimental animals. These substances include classical neurotransmitters such as norepinephrine and serotonin, amino acids and neuropeptides. Few studies, however, have attempted to show neurochemical alterations in brain that are correlated with challenges to normal thermoregulation. Previous work has shown that centrally injected neurotensin (NT), an endogenous tridecapeptide can lower body temperature in a wide variety of animals and that a paradigm of cold-adaptation involving 4 days previous exposure to 4°C ambient temperatures can antagonize the hypothermic actions of subsequent CNS administration of NT. Thyrotropin-releasing hormone (TRH) has been shown to cause hyperthermia after CNS injection in several species and is also able to attenuate NT-induced hypothermia. Thus we examined regional brain concentrations of TRH and NT in male Swiss-Webster mice exposed to 4°C ambient temperatures for 3 hours daily for four consecutive days compared to naive controls. On the fifth day, one group of cold-adapted and one group of naive controls were exposed to one hour of 4°C cold before all mice were sacrificed and brains were removed and frozen. Eleven brain regions were subsequently dissected and extracted for peptide radioimmunoassay of TRH and NT. Protein estimation was performed using the Folin-phenol method and results were expressed as pg of peptide per mg protein. TRH and NT concentrations were similar to those reported previously in both regional distribution and absolute concentrations. TRH concentration was increased in the preoptic hypothalamus-diagonal band area and olfactory tubercles of animals exposed to the 4 day regimen compared to naive controls. Cold-adapted animals receiving one hour of cold stimulus on day 5 exhibited increased TRH concentrations in the frontal cortex and anterior caudate relative to cold-adapted animals without this stimulus. NT was unchanged in the preoptic hypothalamus-diagonal band of cold-adapted animals compared to controls and was increased in the substantia nigra-ventral tegmental area and anterior caudate in cold-adapted animals with one hour cold exposure on day 5 compared to animals without this final exposure. These data show that endogenous TRH and NT concentrations are altered by a regimen of cold-adaptation in brain regions known to subserve a major role in mammalian thermoregulation.

356.11 INTRACISTERNAL INJECTION OF TRH ANALOGUE, RX 77368, STIMULATED SEROTONIN RELEASE INTO THE GASTRIC LUMEN. R. L. Stephens*, Jr. and Y. Taché (SPON: H. Weiner). CURE, VA Wadsworth Medical Center, Dept. of Medicine, Brain Research Institute, UCLA, Los Angeles, CA 90073.

Serotonin (5HT) is present in mast cells of the gastric mucosa, and together with histamine is released into the gastric lumen after vagal stimulation. The release and functional role of serotonin in response to agents which act as vagal stimulants has not been studied. Central injection of TRH produces marked stimulation of gastric acid secretion, motility and lesion formation, and acts primarily by stimulating the vagus (Reg. Peptides 13: 21, 1985). In 2 hr pylorus-ligated rats, intracisternal (ic) injection of the stable TRH analogue, RX 77368, produced a marked, dose-dependent increase in the content of 5HT and its metabolite, 5HIAA, in the gastric juice as measured by HPLC with electrochemical detection.

RX 77368 (ng)	N	Acid output (μmol H^+/2h)	5HT (ng/2h)	5HIAA
1	5	187 ± 43	49 ± 12	113 ± 40
10	4	286 ± 77	64 ± 15	266 ± 109
100	7	406 ± 36	190 ± 58	381 ± 109

Atropine pretreatment (0.1 mg/kg; 20 min before ic injection) reduced RX 77368 (100ng) induced stimulation of gastric acid output by 95 % and 5HT and 5HIAA content by 79 % and 85 % respectively.

Treatment	N	Acid output (μmol H^+/2h)	5HT (ng/2h)	5HIAA
Saline + RX 77368	4	273 ± 79	208 ± 16	254 ± 102
Atropine + RX 77368	4	14 ± 9	45 ± 16	38 ± 19

However, para-chlorophenylalanine pretreatment (300 mg/kg; -72 and -48 h before ic injection) resulted in a 60 % reduction in RX 77368-stimulated 5HT release into the gastric juice, while gastric acid secretion was not significantly altered. It is concluded that 1) ic injection of RX 77368 produced a dose dependent stimulation in 5HT into the gastric lumen, 2) 5HT release is vagally mediated, as indicated by its atropine sensitivity, and 3) the stimulation of 5HT release can be dissociated from that of gastric acid output produced by central injection of RX 77368. 5HT release may mediate other changes in gastric functional parameters produced by central TRH, such as stimulation in gastric motility.

356.12 INHIBITION OF TRH STIMULATED GASTRIC SECRETION BY BOMBESIN MICROINJECTED INTO THE DORSAL VAGAL COMPLEX. T. Ishikawa* and Y. Taché. CURE, VA Wadsworth Medical Center, Department of Medicine and Brain Research Institute, UCLA, Los Angeles, CA 90073.

Bombesin injected into the cerebrospinal fluid inhibits gastric secretion stimulated by various secretagogues (Life Sci.,37:115,1985). Mapping of hypothalamic responsive sites demonstrated that bombesin suppressed gastric secretion only when injected into the paraventricular nucleus (Gunion & Taché, Brain Res., in press). The facts that midcollicular transection and ventricular plug did not prevent intracisternal bombesin induced inhibition of gastric secretion in pylorus ligated rats suggest that responsive sites must be located in the hindbrain (Gunion & Taché, Am. J. Physiol., in press).

Rats, fasted for 24 h, were anesthetized with urethane (1.5 g/kg, ip) and a double cannula was placed into the lumen of the non glandular part of the stomach. Saline or peptides were microinjected unilaterally into the dorsal vagal complex (DVC) using glass micropipet and pressure ejection of 100 nl. Microinjection of the stable TRH analog, RX 77368, (30 ng) into the DVC induced a long lasting stimulation of gastric secretion with a peak response occurring within 50 min. The gastric secretory response to TRH was dose dependently inhibited when bombesin (B) was concomitantly microinjected respectively at 1, 3 and 10 ng dose into the DVC.

Treatment	Dose ng/rat	N	Gastric Acid Output μg/60 min
Saline		8	10 ± 3
RX 77368	30	8	130 ±12
RX 77368 + B	1	6	85 ± 21
RX 77368 + B	3	8	51 ± 11
RX 77368 + B	10	7	23 ± 3

Peak secretory response to TRH (25 ± 3 μmol/10min) was inhibited by 84 % following bombesin (10 ng) microinjected into the DVC whereas that of pentagastrin infusion (10 ± 2 μmol/10min)) was inhibited only by 25 %. Bombesin injected intracisternally at 0.3, 1, 3 and 10 ng elicited a significant dose dependent suppression of pentagastrin response respectively by 11, 39, 56, and 74 %. These results demonstrated that bombesin acts in the dorsal motor nucleus to inhibit vagally-stimulated acid secretion whereas other brain stem or spinal site must also been involved in mediating the inhibition of pentagastrin-stimulated gastric secretion.

(Supported by the NIHDDK, grant AM 30110).

356.13 COMPARISON OF THE TRH ANALOG RGH 2202 WITH TRH: EFFECTS UPON THE RAT EMG. C.K. Haun, S.R. Beydoun, E.F. Hawkins, W.K. Engel and I. Tan* Departments of Anatomy & Cell Biology and of Neurology, USC School of Medicine, Los Angeles, CA 90033.

Thyrotropin-releasing hormone (TRH) has been used to enhance strength of patients with degenerative motor neuron diseases, e.g., ALS; however, high- or repeated-dosage can cause, instead, a temporary muscular weakening, termed "autorefractoriness" (AR) (Neurology 34, Suppl. 1, 147, 1984). We have studied this phenomenon in adult male Sprague Dawley (Holtzman) rats and compared the effects of a low-affinity TRH analog, RGH 2202 (RGH) (a gift from Gedeon Richter, Ltd., Budapest, Hungary.)

The rats' spinal cord was transected at T-8/9, and 3 weeks later, EMG recording electrodes were implanted in their left triceps surae muscles (both surgeries performed under methohexital). After 1 to several days the rats were suspended, awake, in a sling inside a shielded cage, and both direct and integrated EMG recordings were made. After a baseline recording period, s.c. injections of TRH or RGH (10 mg/kg) were given.

TRH produced an immediate increase in the spontaneous EMG activity, which reached a peak in 3-10 min., but declined rapidly, and by 90-120 min. post-injection the EMG activity averaged only 41% of the peak value. By comparison, RGH acted more slowly: the peak in enhanced EMG activity was attained at an average of 35 min., and by 90-120 min. the enhancement was still 75% of its peak. By 210-240 min. post-injection, the integrated EMG activity to TRH was down to 28% of its peak, whereas the response to RGH was still at 54% of its peak.

When a second 10 mg/kg dose of TRH was given 120 min. after the first, a second EMG peak response occurred, again at approximately 10 min. post-injection, but the second peak amplitude was only 61% of the first -- an apparent AR ("tachyphylactic") response. Contrastingly, the peak response to a second 10 mg/kg of RGH occurred with a somewhat greater latency than the first (ave. 45 min.) and the magnitude of this second peak, compared to the first, was undiminished (i.e., no AR). When the EMG was examined at 90-120 min. after the second injections, the integrated EMG activity for TRH was 46% of the value of the first peak. With RGH, however, the EMG activity was still 75% of that attained with the first injection.

We propose: 1) the refractoriness of peak responses with TRH, but not with RGH, may be further evidence for our postulated agonist-dependent TRH-receptor desensitization, which is lacking with low-affinity ligands (Biochem. Biophys. Res. Commun. 138, 1184, 1986), and 2) RGH, with its longer-lasting excitatory effects, should be tested further for use in treatment of motor neuron disorders. (Aided by a Biomedical Research Support Grant to the USC School of Medicine.)

356.14 THYROTROPIN-RELEASING HORMONE (TRH) AS AN EXCITATORY NEUROMODULATOR IN THE MAMMALIAN SPINAL CORD. I. PHYSIOLOGIC CHARACTERIZATION. Shripad B. Deshpande* and Jordan E. Warnick. Dept. of Pharmacol. & Exptl. Ther., University of Maryland School of Medicine, Baltimore, MD 21201.

TRH (1-pyroglutamyl-1-histidyl-1-prolinamide) is a putative neuromodulator/neurotransmitter which is found in greater amounts in the extrahypothalamic nervous system than in the hypothalamus itself. Significant receptor binding of TRH occurs in the spinal cord. Because of this and other evidence, TRH has been tried in the treatment of amyotrophic lateral sclerosis and has been implicated in the pathophysiology of the disease. Although TRH is known to potentiate the monosynaptic reflex (MSR) in amphibian and mammalian spinal cords, its action has been variable and the exact mechanism of this excitatory action (e.g., a direct effect on motoneurons or mediation via disinhibition) is not clear. Therefore, we have studied the actions of TRH on the MSR in spinal cord from neonatal rats, *in vitro*.

Since TRH was virtually ineffective in cords from female rats (Deshpande and Warnick, *Fed. Proc.* 46:1449, 1987), all experiments were done on cords from male rats. Spinal cords were removed from 7- to 10-day old rats, hemisected and placed in an experimental chamber. Suction electrodes were then attached to a pair of dorsal and ventral roots of the L_3-L_5 segments. Supramaximal stimulation of a dorsal root evoked a MSR from the corresponding ventral root. In some experiments a dorsal root reflex was simultaneously recorded from an adjacent dorsal root. Alternatively, conditioning stimuli applied to an adjacent dorsal root evoked both a strychnine- and picrotoxin-sensitive inhibition of the MSR.

TRH (1 nM-1 μM) produced a concentration-dependent potentiation of the MSR but did not influence the dorsal root reflex. At 1 nM, the effect of TRH was variable, half-maximal potentiation occurred at about 50 nM with maximal potentiation to 147% of control at 1 μM. The frequency-dependent depression of the MSR elicited at 0.1-1.0 Hz was reduced by TRH (30-100 nM). TRH did not depolarize the ventral root at concentrations up to 1 μM although raising the $[K^+]$ from 5 to 25 mM produced a concentration-dependent depolarization (0.25 mV/mM K^+). Raising or lowering the external $[Ca^{2+}]$ and raising the external $[Mg^{2+}]$ did not affect the potentiation induced by TRH. Neither strychnine-, picrotoxin-, nor bicuculline-sensitive inhibition were altered by facilitating concentrations of TRH. The effect of TRH seems to be specific for transmission between I_a afferents and α-motoneurons since multisynaptic pathways are not affected by the tripeptide. Both pre- and postsynaptic mechanisms appear to be involved in this effect. (Supported in part by USPHS grant NS21312.)

356.15 THYROTROPIN-RELEASING HORMONE (TRH) AS AN EXCITATORY NEUROMODULATOR IN MAMMALIAN SPINAL CORD. II. PHARMACOLOGIC CHARACTERIZATION. Jordan E. Warnick and Shripad B. Deshpande* (SPON: F.C. Kauffman). Dept. of Pharmacol. & Exptl. Ther., University of Maryland School of Medicine, Baltimore, MD 21201.

TRH is a tripeptide hormone which has received much attention for its role in the pathophysiology of amyotrophic lateral sclerosis and possible utility in treatment of the disease. We have shown that TRH potentiates the monosynaptic reflex (MSR) in cords from neonatal male but not female rats (Deshpande and Warnick, *Fed. Proc.* 46:1449, 1987). TRH did not potentiate the MSR in cords from castrated male rats but did in cords from ovariectomized female rats treated with testosterone (Warnick *et al., The Pharmacologist* 29: 1987). Thus, gender is a significant factor in the responsiveness to TRH. We now attempt to further define the pharmacology of TRH-induced potentiation of the MSR.

Spinal cords were isolated from 7- to 10-day old male rats, hemisected, placed in an experimental chamber and suction electrodes were attached to a pair of dorsal and ventral roots of the L_3-L_5 segments. Supramaximal stimulation of a dorsal root evoked a MSR from the corresponding ventral root.

The potentiation of the MSR produced by TRH (100 nM) was not prevented by atropine (1 μM), haloperidol (10 μM), methysergide (30 nM), cyproheptadine (1-30 μM) or ICS 205-930 [(3α-tropanyl)-1*H*-indole-3-carboxylic acid ester; 10 nM-3 μM], a potent and selective serotonin M-receptor antagonist (Richardson *et al., Nature* 316:126, 1985). On the other hand, diazepam (1-30 μM) depressed the potentiation produced by TRH without causing ventral root depolarization. TRH remained effective in spinal cords from rats treated previously on days 1-3 with 6-hydroxydopamine (i.p.). Methysergide completely blocked the MSR at 30 nM, an effect that was reversed by TRH. The MSR was restored to nearly 40, 60 and 90% of the control magnitude by the addition of 0.1, 0.3 and 1 μM TRH, respectively, in the presence of methysergide. On the other hand, 3,4-diaminopyridine (10 μM), in the presence of methysergide (30 nM), caused a nonspecific increase in both the MSR and polysynaptic activity. The potentiation induced by TRH does not appear to involve dopaminergic, muscarinic or serotonergic (type 2 and M) receptors or the blockade of rectifier K channels. Although TRH did not affect strychnine-, picrotoxin- or bicuculline-sensitive inhibition, high concentrations of diazepam antagonize TRH-induced potentiation. Thus, the effect of diazepam may be unrelated to the classical $GABA_A$/benzodiazepine receptors. The reversal of methysergide-induced blockade of the MSR by TRH indicates that the action of TRH may be specific for the monosynaptic pathway. (Supported in part by USPHS grant NS21312.)

356.16 LEUTEINIZING HORMONE-RELEASING HORMONE (LHRH) AND LEUMORPHIN (LEUM) HAVE DIFFERENT EFFECTS ON THE NEURONS OF MIDBRAIN CENTRAL GRAY IN FEMALE RATS. Y. Koyama*, Y. Oomura and H. Nishino*. (SPON: K. Yamaguchi) Natl. Inst. Physiol. Sci., Okazaki, 444 Japan

The midbrain central gray (MCG) participates in supraspinal control of the lordosis in female rats by receiving the descending input from the medial preoptic area (MPOA) and ventromedial hypothalamic nucleus (VMH) and by giving its own output to the gigant cellular nucleus of the medulla (GCN). Central applications of LHRH and LEUM have facilitatory effects on lordosis and these peptides are found in the hypothalamus and midbrain, areas known to be involved in lordosis. In this study, the effects of electrophoretic applications of LHRH and LEUM were examined in the MCG neurons identified by the response to electrical stimulation of the MPOA, VMH and GCN.

Forty-two ovariectomized, estrogen primed female rats were used under light urethane anesthesia. MPOA and VMH stimulation had mainly facilitatory effects on the MCG neurons; 31% (48/154) were excited and 16% (25/154) were inhibited by the MPOA stimulation, while 33% (51/153) were excited and 11% (16/153) were inhibited by VMH stimulation. Electrophoretic application of LHRH excited 25% (25/101) of MCG neurons and inhibited 13% (13/101) of them. Excitatory effects of LHRH could be obtained mainly in the MCG neurons which received excitatory input from the MPOA; 42% (12/31) of neurons which were excited by MPOA stimulation increased firing rate by LHRH, while in the neurons received excitatory input from the VMH, 28% (7/25) were excited by LHRH. LEUM caused excitation in 8% (7/93) of MCG neurons and inhibition in 25% (23/93) of them. Thirty-one percent (8/26) and 39% (11/28) of neurons which received neural input from the MPOA and VMH respectively, were sensitive to LEUM. MCG neurons identified antidromically by GCN stimulation were not sensitive to LHRH or LEUM. LHRH sensitive neurons and LEUM sensitive neurons seem to belong to discrete neural substrate in the MCG; LHRH neurons were found in the dorsal MCG, while LEUM neurons were in the ventro-caudal MCG, and of 41 neurons on which examined the effects of both LHRH and LEUM, only 7 % (3/41) were sensitive to both chemicals. These results indicate that the LHRH and LEUM have different roles in the control of lordosis by acting on the MCG neurons in a different manner.

356.17 [D-ALA^2,F5-PHE^4]-DYNORPHIN AMIDE, AN OPIOID ANALGESIC WITH LETHAL PROPERTIES. R.M. Kostrzewa, A.J. Kastin , D.H. Coy*, R. Brus*, H. Criswell and P.S. Keegan*. Quillen-Dishner College of Medicine, East Tennessee State Univ., Johnson City, TN 37614 and Veterans Administration Medical Center and Tulane University School of Medicine, New Orleans, LA 70146.

Analgesic non-lethal actions of the opioid peptide, dynorphin (1-13) have been characterized over the past several years. A novel analog, [D-Ala^2,F5-Phe^4]-dynorphin amide was prepared, and its pharmacological spectrum of activity has been investigated in the present study. In the hot plate analgesic test on albino and black mice, a 20 µg intraventricular (i.vtr.) dose of the analog produced an analgesic effect that was similar in potency and duration (ca. 3 hr) to that produced by a 20 µg i.vtr. dose of the parent dynorphin. This action of [D-Ala^2,F5-Phe^4]-dynorphin amide was effectively antagonized by naloxone (2 mg/kg i.p.), administered either before or after peptide treatment. In addition to the analgesic action, [D-Ala^2,F5-Phe^4]-dynorphin amide produced a Straub tail and a catatonic-like state in mice, that was also attenuated by naloxone. When studied in vitro on the electrically-stimulated mouse vas deferens preparation, [D-Ala^2,F5-Phe^4]-dynorphin amide inhibited contractile activity and had an IC_{50} of 108.2 ± 34.7 nM (S.E.), about 4-fold greater than that of dynorphin. This action was also attenuted by naloxone. An i.vtr. dose of 150 µg of [D-Ala^2,F5-Phe^4]-dynorphin in mice, and a cumulative series of i.vtr. doses up to 2600 µg in anesthetized rats, failed to produce a lethal effect. In the diallylbarbital (70 mg/kg i.p.) and urethane (200 mg/kg i.p.) anesthetized rats, [D-Ala^2,F5-Phe^4]-dynorphin amide did not modify blood pressure, heart rate and respiratory rate. However, when mice were treated with single intraperitoneal (i.p.) doses of [D-Ala^2,F5-Phe^4]-dynorphin amide, convulsive episodes were produced, and lethal effects were observed with a 30 mg/kg dose (LD_{50} = 60 mg/kg at 24 hr). No pathological changes were observed in mouse liver and kidney at 24 hr after a 50 mg/kg dose of the peptide analog. The analgesic and opioid-like behavioral effects (e.g. Straub tail and catatonic-like state) were probably produced by a direct action of [D-Ala^2,F5-Phe^4]-dynorphin amide at opioid receptors. The lethal action of [D-Ala^2,F5-Phe^4]-dynorphin amide may have been induced by a metabolite of the parent molecule, since i.p., but not i.vtr. doses produced that effect. The novel fluorinated dynorphin analog, [D-Ala^2,F5-Phe^4]-dynorphin amide, may be a useful chemical tool for studying opioid systems in the central nervous system.

356.18 Heterogeneous Effects of Opiate Drugs on Neurons Recorded from the Nucleus Accumbens Septi. R.L. Hakan*, and S.J. Henriksen.(SPON: N. Ling). Research Inst. of Scripps Clinic, La Jolla, CA, 92037

The nucleus accumbens septi (NAS) of the basal forebrain has been implicated through behavioral research to be critical for mediating the self-administration of opiate drugs in laboratory rats (Vaccarino, et. al., Pharm. Bioch. & Behav., 24, 61, 1986;). As part of an investigation to determine the actions of opiates at the cellular level within this structure, we have examined spontaneous neuronal activity as well as the cellular activity and field responses evoked by afferent pathway stimulation (ipsilateral fimbria). These events were recorded with single-barrel glass microelectrodes in halothane anesthetized rats. Cell firing rates were quantified using an on-line computer system for interstimulus and peristimulation histogram analysis. We then observed the effects of sytemically administered heroin and morphine (s.c.) on these electrophysiological parameters (one cell/subject; n=36). The most striking feature of single-cell activity in the NAS (n=100) was heterogeneity. That is, throughout the postero-medial, anterior and lateral regions of the NAS, both slow (<5Hz) and fast (>5Hz) spontaneously active cells were mixed with inactive cells which discharged only following stimulation. However, such regional analysis consistently found fast cells at the ventral NAS-olfatory tuberculum border. Synaptic "field" responses to ipsilateral fimbria stimulation consisted of an intial negative-going wave (≈7ms to peak) followed by a positive-going wave (≈19ms to peak). The amplitudes for either of these two field components rarely exceeded 2mv. The latencies for stimulation-evoked single cell discharges regularly coincided with both the negative and positive field components. Heroin and morphine most commonly depressed the discharge rates of spontaneously active cells in a naloxone reversible fashion (20/36 cells tested). Again heterogeneity was observed, in that other cells were excited (n=7/36) or were unaffected (n=9/36) by these drugs. "Field" responses and stimulation-evoked single cell activity were consistently unaltered by drug administration. Our results contrast with prior reports which have described homogeneous patterns of cellular activity within the NAS (Yang and Mogenson, Br. Res., 324, 69, 1984; White and Wang, J. Neurosci., 6, 274, 1986). Similarly, iontophoretically applied opioids have been previously reported to uniformly depress electrophoretically evoked cell activity in the NAS (McCarthy et. al., J. Physiol. Lond., 267, 40, 1977), while our work suggests a much more heterogeneous action. We observed that only spontaneously active cells were affected by opiate drugs while evoked cell activity was unaffected. This heterogeneity in discharge rate of NAS neurons and subsequent differential responsiveness to systemic opiate drugs is consistent with the known diversity of synaptic inputs into this region as well as the intrinsic "mosaic" of NAS cell islands (Chronister et. al., In: The Neurobio. of the Nuc. Acc., 173, 1981).

356.19 PEPTIDE FRAGMENTS DERIVED FROM THE β-CHAIN OF HEMOGLOBIN (HEMORPHINS) ARE CENTRALLY ACTIVE IN VIVO. T.P. Davis and F. Porreca. Department of Pharmacology, University of Arizona College of Medicine, Tucson, AZ 85724

Recently, Brantl et al., (Eur. J. Pharmacol. 125:309, 1986) reported that treating bovine blood with gastrointestinal enzymes leads to the formation of several opioid peptides. Two of these peptides (Tyr-Pro-Trp-Thr and Tyr-Pro-Trp-Thr-Gln), termed hemorphin-4 (H-4) and hemorphin-5 (H-5), respectively, correspond to the 34-37 and 34-38 fragments of the β-chain of bovine hemoglobin and the 35-38 and 35-39 fragments of human hemoglobin. Using the electrically stimulated myenteric plexus/longitudinal muscle preparation of the guinea pig ileum, they reported that the tetrapeptide, H-4, had an IC_{50} of 45.2μM and the C-terminally extended pentapeptide, H-5, had an IC_{50} of 46.1μM. Both of these effects were naloxone-reversible with the peptides showing unique enzymatic stability. Since hemorphins could be formed during physiological or pathological degration of hemoglobin, we were interested in determining if these peptide fragments exerted in vivo, central nervous system effects such as analgesia, inhibition of gastrointestinal transit or inhibition of the spontaneous micturition reflex as previously reported for the proenkephalin A fragments (Davis et al, Eur. J. Pharmacol., 111:177, 1985).

Solid-phase peptide synthesis of the two peptides was carried out using the Fmoc procedure. Purification was accomplished by semi-preparative HPLC with confirmation by amino acid analyses, low resolution fast atom bombardment mass spectrometry (FAB/MS) and FAB MS-MS which provided the peptide sequence. The effects in vivo of H-4 and H-5 were studied in two models of phasic and tonic pain, the mouse tail flick assay (TFA) (55^{o}C warm water, latency to rapid flick) and hindpaw formalin assay (PFA) (5% formalin, 5 μl volume, behavioral scoring), respectively. Additionally, two physiological endpoints, central modulation of bladder motility and central effects on intestinal propulsion of an oral radiolabelled marker were monitored in the mouse. Both H-4 and H-5 were given by the intracerebroventricular (i.c.v.) route in all tests. In the TFA, H-4 and H-5 (25-75 μg at +10 min) produced dose-related, naloxone-reversible analgesia with H-4 being about two times more potent. However, when H-4 and H-5 were tested in the PFA, they had no effect over the same dose range. H-5 produced an effect in the PFA only at a dose of 100 μg. Inhibition of gastrointestinal transit was not affected by either H-4 or H-5 (0.1 μg to 70 μg). H-4 or H-5 (5-20 μg) inhibited micturition contractions in a dose-related and naloxone-reversible fashion, and H-4 was once again about twice as potent as H-5. These data provide evidence that H-4 and H-5 can exert naloxone-reversible opioid actions in vivo and therefore may be physiologically important blood-borne peptides. (Supported by NIH DK36289 & NS 23710.)

356.20 ACTIVITY OF DIMERIC DERMORPHIN ANALOGS ON GASTRIC SECRETION IN THE RAT. A. Guglietta, L.H. Lazarus, B.J. Irons* and P. Melchiorri*. NIEHS, LBNT, Research Triangle Park, NC 27709, and Institute of Medical Pharmacology III, 00185 Rome, Italy.

Dermorphin (DM) (Tyr-D-Ala-Phe-Gly-Tyr-Pro-Ser-NH_2) is an opiate peptide isolated from the skin of South American frogs and has marked affinity for μ-type receptor. DM administered icv in rats produces analgesia, catalepsy, releases PRL, inhibits LH release and gastric secretion. Structure-activity relationship studies demonstrated the importance of D-Ala^2 for its action on gastric secretion and showed that none of the analogs tested was as potent as DM in reducing gastric secretion. In this study we investigated the action of several dimeric DM analogs on gastric secretion using the pylorus-ligated rat as a biological model. The use of dimeric peptides, in which two chains of the same peptide are linked directly through their carboxy terminal amide or through CH_2 group might give insight on a particular action of DM since dimeric peptides may have different receptor affinity and selectivity than the monomer. DM_1 dimeric-tetra-DM_2, dimeric-penta-DM_0, dimeric-penta-DM_2, [Sar^4]-dimeric-penta-DM_0 and [D-Arg^2, Sar^4]-dimeric-penta-DM_0 (the subscript represents the number of CH_2 groups) were injected icv in rats and 2 h later the animals were killed and the gastric volume, pH, [H^+] concentration and gastric acid output determined. All the peptides tested significantly ($p<0.05$) reduced the gastric volume and gastric acid output. DM dimeric-penta-DM_0, [Sar^4]-dimeric-penta-DM_0 and [D-Arg^2, Sar^4]-dimeric-penta-DM_0 also reduced the [H^+] concentration and increased the gastric pH, while dimeric-penta-DM_2 and dimeric-tetra-DM_2 were inactive in modifying these parameters. The percent of activity of the dimeric DM analogs compared to that of DM is summarized in the following table:

PEPTIDE	VOL	% pH	CONC	OUT
DM	100.0	100.0	100.0	100.0
Dimeric-tetra-DM_2	35.4	40.9	11.1	35.5
Dimeric-penta-DM_0	87.3	90.5	95.3	90.9
Dimeric-penta-DM_2	45.9	19.0	13.4	50.2
[Sar^4]-dimeric-penta-DM_0	106.2	126.8	117.5	106.7
[D-Arg^2, Sar^4]-dimeric-penta-DM_0	101.1	119.0	139.3	103.7

[Sar^4]-dimeric-DM_0 and [D-Arg^2, Sar^4]-dimeric-DM_0 were more potent than DM in suppressing gastric secretion in rats on all the parameters studied. These results extend the structure-activity studies on DM analogs and show for the first time that two analogs are more potent than DM in reducing gastric secretion in rats.

MESSENGER RNA REGULATION IV

357.1 LOCALIZATION OF NEURONS CONTAINING ESTRADIOL RECEPTOR mRNA IN THE RAT BRAIN AS STUDIED BY IN SITU HYBRIDIZATION. G. Pelletier, N. Liao* and M.G. Govindan*. MRC Group in Molecular Endocrinology, Le Centre Hospitalier de l'Université Laval, Quebec G1V 4G2, Canada.

The distribution of neurons which are capable of concentrating radioactive estradiol has already been reported in a few species. The purpose of the present study was to localize estradiol receptor mRNA within the rat brain using an in situ hybridization approach. Adult male rats were perfused with 4% paraformaldehyde in 0.1M phosphate buffer and frozen 10 μm section were cut with a cryostat. A synthetic oligonucleotide probe labeled with ^{35}S complementary to the mRNA coding for estradiol receptor was used. Sections were incubated in pre-hybridization buffer to reduce non-specific labeling. Following this, 100 μl of hybridization buffer containing 300,000 cpm were applied to each section at 37C for 2 days. After appropriate rinsing, the sections were exposed to X-Ray films for one day. Selected slides were subsequently coated with Kodak NTB2 liquid emulsion and exposed for 3 days. Observation of radioautograms (films or coated slides) revealed that strong labeling occurred in several brain areas including the cerebral cortex, hippocampus, amygdala, supraoptic nucleus, paraventricular nucleus, ventromedial nucleus, arcuate nucleus and olfactorius nucleus. In the positive regions, silver grains were detected over both nuclei and cytoplasm of neurons. Preincubation with RNAse completely prevented radioautographic labeling. In general, the results obtained with the in situ hybridization agree well with previous results obtained after injection of labeled estradiol. This approach should be very useful to study the effect of different factors on estradiol receptor gene expression in individual neurons.

357.2 **Regional Variations in the Concentration of Gonadotropin-Releasing Hormone (GnRH) mRNA in the Male Macaque.** L. Vician*, L.A. Adams*, L.J. Standish, D.K. Clifton* and R.A. Steiner. Depts of Ob/Gyn and Physiology and Biophysics, University of Washington, Seattle, WA 98195.

GnRH neurons are localized in specific brain regions, especially in the hypothalamus and other limbic areas. The regional distribution of GnRH cells could be an anatomical reflection of functional differences in the GnRH system. Indeed, besides its neuroendocrine function in controlling the secretion of LH and FSH, GnRH has been implicated as a neurotransmitter in the regulation of sexual behavior. This being the case, we might expect that the synthetic capacity of GnRH cells within a region would be related to the physiological role of those cells. For example, the neuroendocrine cells projecting to the median eminence might have a greater synthetic capacity and hence more GnRH mRNA than cells serving a more classical neurotransmitter function. To test the hypothesis that the synthetic capacity of GnRH cells varies as a function of neuroanatomical locus, we used in situ hybridization to determine the GnRH mRNA content of individual cells in the septum, diagonal band of Broca (DBB) medial preoptic area (MPOA) and ventral medial hypothalamus (VMH) of the male macaque, Macaca fascicularis (n=3). Paraformaldehyde-fixed coronal sections (20 μm) were prepared for in situ hybridization and incubated with a ^{35}S-labelled RNA probe complementary to the human GnRH mRNA sequence. Following the stringent wash, slides were processed for autoradiography and read by dark-field illumination. The number of photographic grains overlying each cell was counted by computerized image processing.

Region	Grains/Cell $\pm$ SEM
Septum	137 $\pm$ 23
DBB	116 $\pm$ 14
MPOA	127 $\pm$ 20
VMH	184 $\pm$ 50

These data indicate that there is a significant difference ($p<0.05$; 2-way ANOVA) in the GnRH mRNA content of cells in various regions of the forebrain and hypothalamus. This observation is consistent with the hypothesis that GnRH producing cells found in different brain regions serve different functions and that the expression of the GnRH gene in these cells is regulated accordingly.

357.3 CUSHING'S SYNDROME IN THE HORSE: PITUITARY HISTOLOGY AND EVALUATION OF POMC GENE EXPRESSION. D.R. Gehlert[+], N.O. Dybdal[o], W.R. Millington[+], B.M. Chronwall[+]. [+]Exper. Therap. Branch, NINCDS, NIH, Bethesda, MD 20892 and [o]Dept. Vet. Pathol., Univ. of California, Davis, CA 95616

A syndrome in old horses consisting of hirsuitism (long and curly hair) with an abnormal shedding pattern, hyperglycemia and general debilitation is associated with a pituitary intermediate lobe tumor. While a normal horse pituitary weighs between 1-3g the average tumor containing gland weighs 7 g. There is no focal lesion but rather a diffuse change from an old IL to a tumor. Histologically, the tumor tissue is adenomatous, hyperplastic and non-neoplastic. The tumor cells are indistinguishable from normal cells, however, an organization into rosettes is prominent within the tumor. Both normal tissue and tumor stain immunohistochemically for alpha-MSH. EM preparations of normal and tumor tissue show typical endocrine cells with high density of mitochondria, a well developed RER and filled with a great number of secretory vesicles. In order to examine the role of the POMC in this syndrome, we have evaluated POMC mRNA, β-endorphin immunoreactivity (iβ-END) and post-translational processing of β-END.

Equine Cushing's syndrome was associated with substantially elevated levels of circulating iβ-END. The iβ-END concentration of plasma from Cushing's horses was approximately 60-fold higher than that of controls. CSF iβ-END was also correspondingly elevated. However, the concentration of iβ-END in the tumor tissue itself was not significantly different than that of control intermediate lobe tissue . Separation of the individual molecular forms of β-END by cation exchange chromatography (N-acetylated and non-acetylated β-END-1-31, -1-27, -1-26) indicated that while the total iβ-END levels were unchanged, significant differences occurred in the pattern of β-END peptides in the tumor tissue. Specifically IL tumors contained significantly higher concentration of opioid-active, β-END-1-31, and lower levels of C-terminally shortened non-opioid forms (β-END-1-27 and -1-26) of the peptide than control IL.

POMC gene expression was examined using *in situ* hybridization and a dot-blot hybridization assay. A 35-mer oligonucleotide probe complementary to POMC mRNA was 3' end labeled with either ^{35}S-dCTP (*in situ* hybridization) or ^{32}P-dCTP (dot-blot hybridization). An intense hybridization signal was seen over both the IL from control horses and tumor tissue from the Cushing's horses. No significant differences in the relative levels of POMC mRNA were detected.

Theses results indicate that while equine Cushing's syndrome is characterized by markedly increased levels of circulating and CSF β-END, the synthetic capacity of the IL tumor appears to be similar to that of normal horse IL. It also appears that the extent to which β-END-1-31 is processed post-translationally is markedly reduced in equine Cushing's syndrome.

357.4 PROOPIOMELANOCORTIN mRNA EXPRESSION IN HUMAN PITUITARIES STUDIED BY QUANTITATIVE IN SITU HYBRIDIZATION. G. Mengod[1*], M.M. Vivanco[1*], A. Probst[2] and J.M. Palacios[1]. [1]Preclinical Research, SANDOZ LTD., Basle, Switzerland, CH-4002. [2]Dept. of Neuropathology, Inst. of Pathology, University of Basle, Basle, Switzerland, CH-4003.

In situ hybridization was used to localize and quantify the expression of mRNA coding for proopiomelanocortin (POMC) hormone in human pituitary glands obtained at autopsy. A 32-base synthetic oligonucleotide complementary to the 3' untranslated region of the human POMC mRNA, ^{32}P-labeled with terminal deoxynucleotidyltransferase was used as a probe. Brain paste standards containing known amounts of the "sense" 32-base oligonucleotide were used for quantification and standardization of the hybridization reaction and autoradiography. The specificity of the hybridization reaction was determined by competition experiments, RNAage treatment, hybridization with heterologous probes and by immunohistochemistry experiments. POMC mRNA was visualized autoradiographically only in the anterior lobe of the pituitary where it was distributed in a "patchy-like" organization. No hybridization was observed in the posterior lobe. Computer-assisted microdensitometric quantification of the POMC mRNA in 43 human pituitary glands revealed 1) no effect of postmortem delay (between 230 to 66 hours); 2) no influence of gender; 3) no influence of age between 42 and 103 years old. Because of the reported effects of dopaminergic drugs on POMC mRNA expression, we examined pituitary glands from several patients dying with schizophrenia (and treated with neuroleptics), Parkinson's disease (trated with L-DOPA). In addition, patients dying from Alzheimer's disease were also examined. When compared with healthy controls higher levels of POMC mRNA expression in schizophrenia pituitary glands and lower values in Parkinsonian's pituitaries were observed. Interestingly lower levels of POMC expression were also observed in Alzheimer's disease pituitaries. In contrast, the expression of β-acting mRNA was unaltered in these populations as compared to controls. These results show that in situ hybridization can be used to study POMC mRNA expression in human postmortem materials and that changes associated with disease and/or drug treatment can also be studied and correlated with changes in animal models of disease.

357.5 PHYSIOLOGICAL INDUCTION OF PROOPIOMELANOCORTIN mRNA IN THE FROG PITUITARY. R.M. Dores, R.G. Krause II, and M.E. Lewis. Department of Biological Sciences, University of Denver, Denver, CO and Medical Products Department, Experimental Station, E.I. DuPont Co., Wilmington, DE.

The release of alpha-MSH from the frog pituitary mediates the process of adaptation to a dark background by stimulating the dispersion of pigment in dermal melanophores. Since this adaptation depends upon continued release of this peptide, there should be increased demand for the precursor, proopiomelanocortin (POMC), which has been demonstrated using biochemical assays of in vitro biosynthesis. To determine whether these changes are due to increased amounts of POMC mRNA in the intermediate lobe of pituitary, frogs (Xenopus laevis) were dark adapted for 1-7 days prior to sacrifice. Plasma was collected for alpha-MSH radioimmunoassay, and the brain and pituitary were removed for in situ hybridization histochemistry using a radiolabelled synthetic oligonucleotide (30-mer) complementary to part of Xenopus laevis POMC mRNA. Exposure to a dark background resulted in rapid increases in plasma alpha-MSH levels and in dermal pigmentation, and over several days, a greater than ten-fold increase in pituitary intermediate lobe POMC mRNA hybridization signal. These results suggest that normal pituitary stores of alpha-MSH are sufficient for transient changes in coloration due to changes in environmental illumination, but that chronic changes induce a metabolic demand resulting in a marked increase in the mRNA encoding the precursor for this peptide. This research was supported by NIH grant DK 36587.

357.6 ANALYSIS OF RAT POMC HETEROGENEOUS NUCLEAR RNA FOLLOWING CRF TREATMENT IN VIVO. D. J. Autelitano*, M. Blum, M. Lopingco* and J.L.Roberts. Fishberg Center for Neurobiology, Mt. Sinai Med. Ctr., New York, NY 10029.

Previous studies from this laboratory have shown that chronic injection of corticotropin releasing factor (CRF) results in elevated levels of anterior pituitary (AP) mRNA, and lowered levels of neurointermediate lobe (NIL) mRNA in the rat. In the present study, we have used a highly sensitive S1 nuclease protection assay to analyze the levels of POMC heterogeneous nuclear RNA (hnRNA) as well as mRNA in AP and NIL following acute in vivo treatment with CRF to determine whether the long term changes in mRNA are proceeded by alterations in hnRNA.

Adult female Sprague Dawley rats were given a single subcutaneous injection of either synthetic rCRF (20ug), or vehicle, and were sacrificed at 0, 20 and 60 min., and at 4hrs. after treatment. AP and NIL were separated, pooled, (n=3), and RNA was isolated from both cytosolic and nuclear fractions. A cRNA probe spanning the entire region of exon 1 and a small portion of intron A of the POMC gene was used in a solution hybridization assay to detect POMC hnRNA and fully processed mRNA. Following hybridization and S1 nuclease digestion, samples were electrophoresed on 6% acrylamide gels, exposed to X-ray film,and the protected bands were excised, counted and quantitated by comparison to a standard curve of radiolabelled sense and antisense RNA generated from SP6 vectors containing the POMC exon1/intron A insert.

No changes in the relative amounts of cytoplasmic POMC mRNA were detected in AP or NIL following either 20 min. or 60 min. CRF treatment. CRF administration led to a 35%-40% increase in the detectable level of POMC hnRNA in the AP nucleus at 20 - 60 min. post CRF treatment; by 4hrs. after treatment, AP POMC hnRNA levels were 100% greater than their respective controls. Associated with the CRF induced increase in POMC hnRNA in the AP, levels of nuclear mRNA in AP were elevated 40%-50% above controls following 60 min. and 4hr. CRF treatment. In contrast to the AP, no alterations in the levels of nuclear POMC hnRNA or mRNA were observed in the NIL at any of the time points examined.

These data suggest that in the rat AP, CRF increases the relative abundance of POMC hnRNA, presumably by increasing the rate of gene transcription and/or by altering hnRNA processing. The lack of an effect on NIL POMC hnRNA may reflect differences in responsiveness to the given dose of CRF by corticotrophs and melanotrophs.

357.7 TRANSLOCATION OF A POSSIBLE DNA-BINDING PROTEIN IN ANTERIOR PITUITARY CORTICOTROPH TUMOR CELLS. J.F. Bishop, D. R. Gehlert and T.L. O'Donohue, Exper. Ther. Branch, NINCDS, NIH, Bethesda, MD 20892.

In order to identify intracellular protein messengers in eucaryotic cells, a method was developed to study the correlation between the phosphorylation state of a protein and biochemical events occuring in the cell. Thus, in AtT20-D16-16 cells, the phosphorylation states of both a 19 and a 14 kDa protein were significantly correlated with immunoreactive β-endorphin secretion (Bishop et al. Mol. Cell. Endocrinol., 1987 in press). Since the onset of POMC mRNA synthesis in response to second messengers follows a similar time course as seen for these phosphorylation events--increasing in approximately 15 to 30 minutes (Regina M Knight, personal communiation)--it is possible that these events are also involved in transmission of the signal to activate POMC gene transcription. Preliminary evidence (Bishop et al. Soc. Neurosci. Abst. 12:737, 1986) indicated that only the 14 kDA protein is present in both the nuclear and cytosolic fractions of AtT20 cells.

The present work was initiated to: 1) confirm the translocation of the 14 kDa phosphoprotein; 2) examine DNA-binding proteins in AtT20 cells and determine if the 14 kDa protein is itself a DNA-binding protein; and 3) develop methods to study correlation of phosphorylative changes in the nucleus and POMC gene activation. AtT-20 cells were prelabeled with ^{35}S-methionine and phorbol ester-stimulated changes in the distribution of the 14 kDa phosphoprotein were studied using a pulse-chase approach. Although ^{35}S-methionine-labeled 14 kDa protein was present in only very low concentrations, time dependent fluctuations in its distribution were seen, with a trend toward decreasing concentrations in the nuclear fraction over time. DNA-binding proteins were examined by binding ^{35}S-methionine-labeled nuclear proteins to dsDNA-cellulose followed by step elution with 500 mM and then 2 M NaCl. The majority of the bound proteins were eluted with 500 mM NaCl and most of these proteins were between 23 and 100 kDa. Two dimensional gel analysis revealed primarily basic proteins, including a high concentration of histones in the 2 M NaCl eluate. However, an approximately 14-16 kDa acidic protein with a pI very similar to the 14 kDa phosphoprotein was also seen.

To investigate the possible involvement of these DNA-binding proteins in POMC gene transcription, a correlative method was developed. Briefly, AtT20 cells were prelabeled with inorganic ^{32}P and the lysed cells were then fractionated via CsCl gradient centrifugation to separate proteins from RNA. Proteins were then TCA-precipitated repeatedly to remove salt and run on two dimensional gels. The RNA fraction was washed and run on formaldehyde gels comprised of 1% agarose. This procedure led to excellent recovery and resolution of ^{32}P-labeled proteins and, although the recovery of ^{32}P-labeled RNA was less reliable, several bands were seen between 3 and 10 kb. It is possible that one of these bands represents POMC heteronuclear mRNA (hnRNA). Densitometric scanning of alterations in protein phosphorylation and of alterations in the concentration of POMC hnRNA may provide a convenient method to select possible key phosphoproteins for investigation of their roles in the modulation of POMC gene transcription.

357.8 EXPRESSION OF OXYTOCIN AND VASOPRESSIN GENES IN THE LEYDIG CELLS AND THEIR REGULATION BY CYCLIC AMP. J.R. Dave*, R.V. Rebois*, S.G. Culp*, L. Liu*, B.Tabakoff and P.L. Hoffman*. (SPON: G.H. de Vries) Laboratory of Physiological and Pharmacological Studies, DICBR, NIAAA, Rockville, MD 20852 and DMNB, NINCDS, Bethesda, MD 20892.

Recent studies have demonstrated the presence of immunoreactive oxytocin (OT) and vasopressin (VP), OT and VP receptors and physiological functions for these hormones in the male reproductive tract of several species. The demonstration of very high (approximately 100-fold higher than circulating levels) concentrations of OT and VP in the testis have suggested that the testis represents a possible peripheral source of these hormones. The objectives of this study were to determine if (i) OT and VP genes are expressed in rat testis and (ii) human chorionic gonadotrophin (hCG), a known regulator of steroidogenesis in the testis which works by activation of adenylate cyclase, would modify the expression of these genes. Using oligodeoxyribonucleotide probes (courtesy of Drs. M. Brownstein and W. Scott Young, NIMH) for VP (complementary to the mRNA coding for the last 16 amino acids of the glycopeptide region, which has no analogous counterpart in the OT mRNA) and OT (complementary to the last 15 bases of the 5'-untranslated region and subsequent 33 bases), and Northern blot and slot blot techniques, OT and VP mRNAs were found to be present both in rat testis and in mouse-derived Leydig tumor cells (MLTC-1). The MLTC-1 cells were treated with either 50 pM or 2 nM hCG (a concentration of hCG which optimally stimulates cAMP secretion in these cells) or 1 mM dibutyrylcyclic AMP, respectively, for 24 hr, and VP and OT mRNA levels were quantitated. The hCG treatment of MLTC-1 cells produced a dose-related decrease in OT and VP mRNA levels. Dibutyrylcyclic AMP treatment also decreased OT and VP mRNA levels in these cells. Our data, thus, suggest that the testis could be a primary site of synthesis and processing of active OT and VP peptides in the male reproductive tract, and that cyclic AMP may be one of the regulators of these genes in the male reproductive system.

357.9 OSMOTIC REGULATION OF VASOPRESSIN mRNA IN THE SUPRAOPTIC NUCLEI DURING FETAL LIFE. S.M. Reppert and G.R. Uhl. (SPON: W.J. Schwartz). Children's and Neurology Services and Howard Hughes Medical Institute, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114

We recently used quantitative in situ hybridization techniques to examine the developmental appearance of hypothalamic vasopressin (prepropressophysin) mRNA in rats. We found that vasopressin mRNA levels in the supraoptic nuclei (SON) were reliably detected on day 16 of gestation, while mRNA in the suprachiasmatic nuclei (SCN) was detectable on day 21. Furthermore, we found regulated expression of the vasopressin gene in SCN on gestational day 21, as vasopressin mRNA levels exhibit a prominent day-night rhythm. In the present study, we examined the prenatal regulation of vasopressin mRNA levels in the SON by osmotically challenging pregnant rats.

Two groups of timed pregnant Sprague-Dawley rats were used. The control group was given food and tap water ad libitum throughout pregnancy. The dams of the experimental group were given food ad libitum and only 2% saline to drink starting on day 16 of gestation. On gestational day 21, dams and fetuses from both groups were weighed, decapitated, and the brains were immersion-fixed. Coronal sections (10 um) through the central portion of the SON were subjected to in situ hybridization using a 40-base ^{35}S-labeled oligonucleotide probe complementary to exon c of the vasopressin gene. Trunk blood from dams and fetuses was collected at sacrifice, and plasma osmolalities were measured by freezing point depression.

The 2% saline elicited a 9% increase in plasma osmolality in the dams (mean osmolality was 320 mOsm/kg vs 293 mOsm/kg for control dams). Similarly, serum osmolality was increased by 11% in the fetuses from the salt loaded group, compared to fetuses from control dams (means of 336 mOsm/kg vs. 304 mOsm/kg). Fetuses from salt loaded dams also weighed 28% less than fetuses from control dams. Regional analysis of the film autoradiograms showed that vasopressin mRNA levels in the SON of the osmotically stimulated fetuses were significantly higher than those in the SON of control fetuses ($p<0.005$; n=3 fetuses from each of 3 litters for each group). Similar differences were seen for SON vasopressin mRNA levels between the dams of the two groups.

These results suggest that osmotic stimuli can regulate vasopressin mRNA levels in the fetal hypothalamus well before the time that plasma vasopressin influences water balance in the developing rat. The findings also suggest that osmoreceptive tissues are responsive to stimuli while the central nervous system is at a relatively immature stage of development. Supported by PHS Grant DK-38116 and Howard Hughes Medical Institute.

357.10 DEVELOPMENT OF ARGININE VASOPRESSIN mRNA IN RAT HYPOTHALAMUS. Sandra G. McElligott and Frank Baldino, Jr. Medical Products Department, E. I. du Pont de Nemours and Co., Wilmington, DE 19898

Changes in the distribution and content of vasopressin (AVP) mRNA were compared with peptide expression during the perinatal development of the rat hypothalamus. Individual AVP mRNA-containing cells were resolved using in situ hybridization with a synthetic oligodeoxynucleotide probe complementary to the glycoprotein region of prepropressophysin mRNA.

Vasopressin mRNA was observed before birth (E16) in the magnocellular neurons of the supraoptic nucleus (SON), the paraventricular nucleus (PVN), and the nucleus circularis. In contrast, AVP mRNA was first detected at birth (PDO) in the parvocellular neurons of the suprachiasmatic nucleus (SCN). Since vasopressin neurons in the SON and PVN originate prior to the neurons of the SCN, these results demonstrate that each hypothalamic nucleus differentiates according to its own timetable regardless of its neuropeptide content. In general, the expression of AVP mRNA can be detected 1-2 days prior to peptide immunoreactivity. The time delay between the initial transcription of AVP mRNA and peptide expression may be due to low antigenicity or the immaturity of posttranslational processes. Although before birth these nuclei still lack adult architecture, the embryonic cells expressing AVP mRNA were confined to areas which express AVP in the adult brain and were not widely distributed throughout the brain.

Both autoradiographic grain counts of PVN cells and optical density measurements revealed increases in mRNA levels which correlated with the increase in postnatal peptide content. Therefore, changes in peptide content after birth may result from increased mRNA synthesis. The early differentiation of the prepressophysin products raises questions on the functional involvment of AVP in brain development. The expression of AVP mRNA is correlated with developmental trophic factors.

357.11 EXPRESSION OF NEUROPEPTIDE Y mRNA IN NEURONAL AND NON-NEURONAL TISSUE AND ITS RESPONSE TO RESERPINE TREATMENT AND STRESS - IN SITU HYBRIDIZATION AND IMMUNOHISTOCHEMISTRY. M. SCHALLING[1], A. ERICSSON*[3], H. PERSSON*[3], S.-Y. CHAI*[1], Å. DAGERLIND*[1], S. BRENE*[1], K. SEROOGY[1], J.M. LUNDBERG*[2], D. LARHAMMAR*[3], L. TERENIUS*[4], J. MASSOULIÉ*[5], M. GOLDSTEIN[6] and T. HÖKFELT*[1]. Departments of [1]Histology and [2]Pharmacology, Karolinska Institutet, P.O. Box 60400, S-104 01 Stockholm, Sweden, Departments of [3]Medical Genetics and [4]Pharmacology, Uppsala University, Uppsala, Sweden, [5]Laboratoire de Neurobiologie, Ecole Normale Supérieure, Paris, France, and [6]Department of Psychiatry, New York University, Medical Center, School of Medicine, New York, USA.

We have examined the content of neuropeptide Y mRNA and its product in cells in both neuronal and non-neuronal tissue in Sprague Dawley rat as well as in several different mouse strains. Northern blotting techniques have been used along with in situ hybridization and immunohistochemistry to define different NPY containing compartments in the adrenal gland and their response to drug treatment such as reserpine. Furthermore, the rat brain and especially the locus coeruleus have been analyzed biochemically and histochemically for their response to reserpine treatment. Computerized densitometry has been used to quantify data both from the in situ hybridizations and the Northern blotting experiments. In non-neuronal tissue, in situ hybridization has been used to identify megakaryocytes in spleen and bone marrow of the Sprague Dawley rat and several mouse strains as a site of NPY synthesis. These data have also been confirmed by immunohistochemistry and radioimmunoassay. In the adrenal gland, NPY synthesis and content was demonstrated both in chromaffin cells and in a population of ganglion cells, which were rich in acetylcholinesterase and thus probably are cholinergic. The enzyme tyrosine hydroxylase (TH) which coexists with NPY in both the rat adrenal medulla and the locus coeruleus, has been analyzed both with in situ hybridization and biochemically for its response to reserpine. A marked increase in TH and NPY mRNA was seen both in chromaffin cells and ganglion cells as early as 1 day after drug treatment. Some other peptides such as cholecystokinin (CCK) and vasoactive intestinal polypeptide (VIP) as well as the enzyme phenylethanolamine N-methyltransferase have also been analyzed along these lines.

357.12 **RAT NEUROPEPTIDE Y PRECURSOR MESSENGER RNA: CHARACTERIZATION, TISSUE DISTRIBUTION, AND REGULATION BY GLUCOCORTICOIDS, CYCLIC AMP, CALCIUM, AND NERVE GROWTH FACTOR.** H. Higuchi and S.L. Sabol. Lab. of Biochemical Genetics, NHLBI, NIH, 36/1C-06, Bethesda, MD 20892.

Neuropeptide Y (NPY) is an abundant and important transmitter-modulator in the central and peripheral nervous systems. To study regulation of the NPY precursor (prepro-NPY) gene in experimental systems, we isolated and sequenced rat brain prepro-NPY cDNA clones. The deduced structure of rat prepro-NPY (98 amino acids) consists of a 29-residue signal peptide followed by the 36-residue NPY sequence, a proteolysis/amidation site Gly-Lys-Arg, and finally a 30-residue COOH-terminal peptide. This structure is highly similar to that of human prepro-NPY (Minth et al. (1984) PNAS 81, 4577-4581), particularly with respect to the NPY and COOH-terminal peptides (100% and 93% amino acid identity, respectively). Such strong evolutionary conservation is consistent with important physiological activities of both NPY and COOH-terminal peptides.

Northern blot analysis of rat brain RNA revealed that prepro-NPY mRNA (~800 bases) is most abundant in the striatum and cortex, (7.7 and 7.2 pg/μg total RNA, respectively). The abundances in other regions, relative to that in striatum, were as follows: hippocampus 34%, hypothalamus 33%, medulla oblongata 18%, midbrain 9%, cerebellum 6%, and spinal cord 30%. These levels parallel the concentrations of immunoreactive NPY in these regions, except for the hypothalamus, which is richest in NPY. Abundant prepro-NPY mRNA was also found in the adrenal gland, spleen, heart, and lung (40%, 26%, 11%, and 7%, respectively, of the level in striatum); these tissues are known to be innervated by NPY-containing neurons.

We are studying the regulation of the prepro-NPY gene in clonal PC-12 rat pheochromocytoma cells and NG108-15 mouse neuroblastoma-rat glioma hybrid cells. Prepro-NPY mRNA abundances were measured by blot hybridization. In untreated PC-12 cells the level of prepro-NPY mRNA is low but positively correlated with cell density (0.03-0.2 pg/μg RNA). Treatment of cells for 25-48 hr with dexamethasone (Dex, 1 μM) or the adenylate cyclase activator forskolin (10 μM) increased prepro-NPY mRNA 2-5-fold, while treatment with both elicited 4-17-fold increases. The protein kinase C activator phorbol 12-myristate 13-acetate (PMA, 0.4 μM) and/or the calcium ionophore A23187 (0.4 μM) also elevated prepro-NPY mRNA levels several-fold in the presence but not in the absence of Dex or forskolin. Combined treatment with Dex, forskolin, PMA, and A23187 led to dramatic increases (40-50-fold). Treatment with nerve growth factor (NGF, 2.5 S, 50 ng/ml) for 48 hr elicited 2-4-fold elevations with or without Dex. In contrast to PC-12 cells, untreated NG108-15 cells have a high level of prepro-NPY mRNA (14 pg/μg RNA). Treatment with Dex for 48 hr elevated this level 2-fold, but treatment with forskolin, 8-bromo-cyclic AMP, or other differentiating agents (e.g. 2% dimethylsulfoxide) reduced the level to 20-30% of the control. These data reveal a complex portrait of regulation of the prepro-NPY gene by the independent but cooperative influences of cell type, differentiation state, glucocorticoids, cyclic AMP (apparently acting through different mechanisms in the two cell lines), calcium ions, and NGF.

357.13 **Effect of Hypophysectomy and Growth Hormone Administration on Pre-prosomatostatin mRNA in Three CNS Regions.** KV Rogers*, L Vician*, RA Steiner and DK Clifton*. Depts of OB/GYN, Physiology and Biophysics, and Psychology, University of Washington, Seattle, WA 98195.

Physiological evidence suggests that somatostatin (SS), released from the median eminence (ME), inhibits pituitary growth hormone (GH) release and that GH acts via short loop feedback to stimulate SS secretion. The mechanism of this feedback effect may involve changes in SS synthesis as well as release since hypophysectomy (HPX) reduces hypothalamic SS content in rats and the treatment of HPX rats with GH prevents this reduction. Lesion experiments indicate that the periventricular nucleus (PeN) of the hypothalamus and the medial basal amygdala (mAMG) are the major sources of ME SS. We hypothesized that HPX would reduce SS synthetic capacity in the PeN and mAMG, as reflected in a reduction in SS mRNA levels, and that the administration of bovine GH to HPX rats would prevent this reduction. We tested this hypothesis by using in situ hybridization and a computerized image analysis system to measure pre-proSS mRNA signal levels in individual cells of the PeN and mAMG of male rats in 4 different experiment groups: HPX, HPX + bGH, sham-HPX and sham-HPX + bGH. We also measured SS mRNA signal levels in the cortex, a CNS region that does not project to the ME. Results are shown below; grains/cell is an index of SS mRNA.

	Mean grains/cell		
Group	PeN	mAMG	cortex
HPX + vehicle	125 ± 10	120 ± 5	172 ± 15
HPX + bGH	177 ± 16	123 ± 6	178 ± 13
sham-HPX + vehicle	196 ± 31	135 ± 9	142 ± 10
sham-HPX + bGH	290 ± 29	155 ± 12	178 ± 11

In HPX rats, SS synthetic capacity was reduced in the PeN ($p<0.01$) and mAMG ($p<0.05$), but not in the cortex. GH treatment prevented this reduction in the PeN ($p<0.01$) but not in the mAMG. In addition, bGH treatment increased SS synthetic capacity in the PeN of sham-HPX rats ($P<0.01$) . We conclude that the level of circulating GH influences the expression of the SS gene in the PeN of the hypothalamus but that some other pituitary hormone, such as TSH, is necessary for the maintenance of mAMG SS biosynthesis. SS mRNA levels in the cortex are not influenced by circulating pituitary hormone levels. These data demonstrate differential regulation of SS gene expression as a function of neuroanatomical location. (Supported by NIH Grant HD-12629).

357.14 **STEROID REGULATION OF SOMATOSTATIN mRNA IN THE RAT HYPOTHALAMUS,** **H. Werner*, Y. Koch*, F. Baldino Jr. and I. Gozes.** (SPON: R. Simantov). Department of Hormone Research, The Weizmann Institute of Science, Rehovot 76100, Israel, and Biomedical Research Department, Neurobiology Group, E.I. du PONT de Nemours and Co., Wilmington, Delaware 19898, U.S.A.

The neuropeptide somatostatin (SS) plays a physiologic inhibitory role in the regulation of growth hormone secretion from the anterior pituitary gland through its secretion into the hypophyseal portal circulation. Since growth processes are sensitive to circulating steroid levels, we have investigated the involvement of gonadal steroids in the expression of the brain SS gene. The levels of SS specific mRNA in the adult rat hypothalamus/preoptic area and cerebral cortex were measured following gonadectomy and steroid replacement treatment, by using a quantitative densitometric hybridization assay.

Our results indicated that the levels of SS mRNA in the rat hypothalamus are significantly decreased following gonadectomy (72% and 64% from the intact female and male values, respectively). The levels of SS mRNA in the cerebral cortex are not significantly modified after castration. Daily injections of estradiol dibenzoate (20 μg/rat/day, s.c) to ovariectomized animals reversed the decrease in hypothalamic SS mRNA by 24 h after commencing the treatment. Testosterone administration (200 μg/rat/day) to orchidectomized rats resulted in resumption of precastration values following 7 days treatment, but not after 1 day.

The rapid increase in SS mRNA levels in response to estrogen treatment in the female rat may suggest that the steroid directly regulates the expression of the SS gene, probably at a transcriptional level. The modulation of the SS gene expression by estrogen may partly explain the estrogen inhibition of weight gain and linear growth by this hormone.

357.15 STUDIES ON AN NGF-INDUCIBLE GENE IN PC12. R.POSSENTI*°, A.LEVI*', U.DI PORZIO*", J.D. ELDRIDGE*", B.M.PATERSON*". °Dept. Experim. Medic. Univ. Tor Vergata, Rome Italy, 'Lab. Cell Biology CNR Rome Italy, "NIH, NCI Bethesda MD 20892. (SPON: G.F. Ayala)

The rat-derived PC12 cells have manteined the property of immature chromaffin cells to acquire a neuronal phenotype in response to nerve growth factor (NGF). To obtain probes to study the early regulation of gene expression by NGF in its target cells, we have screened, by a differential hybridization procedure, a cDNA library constructed from mRNA of PC12 cells exposed to NGF for 24 hours. Of the few cDNA clones defined by their property of corresponding to NGF-inducible mRNAs, the clone VGF8a was chosen for further characterization. The level of the mRNA mesaured by either S1 or Northern blot analysis, was induced up to 40-50 fold after 6 hours of NGF exposure, and remained high also in fully differentiated cells (14 days of treatment). Run-on experiments showed that the transcription of VGF8a was induced by NGF up to 5-6 fold.

Completed sequence of the protein (710 aa) has been deduced from nucleotide sequence of the cDNA. We could not find any homology with other proteins sequenced so far. The VGF8a protein shows a high per-cent of proline and cystine residues, that could provide a compact rigid structures, a highly hydrophobic NH_2 region and several target sites for trypsin-like proteases.

Furterly we subcloned two different regions of the cDNA in procariote expression vectors and immunized rabbits against the recombinant proteins. According to cellular fractionation criteria and immunofluorescence the VGF8a proteins is associated with intracellular membranes. Immunoprecipitation or Western blot analysis showed at least two distinct polipeptides of 80-85000 MW.

The final line of investigation involved the characterization of the regulatory sequence of the VGF8a gene. The genomic organization of the gene, as deduced from sequence analysis, is very simple with a single short intron in the 5' leader region of the mRNA. A tipical TATA box is situated 30 bp before the transcribed region and a CAAT box 40 bp upstream. Three distinct consensus sequences, tipical for the SP1 protein binding, are also present in the 300 bp long "promoter region". This region is sufficent to drive the transient expression of the CAT gene in PC12 cells but not in other cell lines.

This work was supported by grant PR.STR.AREA04 ST.PR.03 CNR.

357.16 DEVELOPMENTAL APPEARENCE OF SODIUM CHANNEL PROTEIN AND mRNA IN THE RAT BRAIN R. Scheinman[1], N. Edelstein*[1], A. Goldin*[2], R. Dunn*[3], V. Auld*[3], R. Moon*[1], N. Davidson*[2], and W. Catterall[1]. [1]Department of Pharmacology, University of Washington, Seattle, WA, 98195; [2]Division of Chemistry, California Institute of Technology, Pasadena, CA, 91125; and [3]Department of Medical Genetics, University of Toronto, Toronto, Canada, M5G 1L6.

The sodium channel (NaCh) from rat brain is a complex of α (260kD), β1 (36kD), and β2 (33kD) subunits. Functional NaCh may be quantitated by their ability to bind saxitoxin (STX). Previous measurements of binding of [3H]STX or [3H]tetrodotoxin show that STX receptors are detectable in the brain by day 1 after birth and increase progressively in number until the adult level is reached at day 21 to day 28. Here we compare this time course of appearance of STX receptors to the appearance of immunoreactive sodium channel protein and mRNA. NaCh α subunit protein was measured by immunoblotting or by immunoprecipitation with affinity purified antiserum. α subunits in immunoprecipitates were quantitated by phosphorylation with the cAMP dependent protein kinase. The timing of appearence of STX receptors and α subunit protein was similar. Low but detectable levels were observed on day 1 after birth and increased to the adult level by day 21 to day 28. cDNA clones encoding rat brain NaCh α subunits were isolated from a rat brain cDNA library constructed in the expression vector λgt11 by screening with affinity purified anti-α antibody. Appearance of α_x subunit mRNA was measured by Northern blot and by dot blot analysis using a ^{32}P labeled 2500bp cDNA probe cloned into the pGEM vector. The cDNA probe hybridizes to one size class of mRNA approximately 8.9 kb in length. This mRNA species is present at low but detectable levels as early as embryonic day 16. Maximum abundance is reached by day 7 and the level declines by day 14 to adult levels. The peak of mRNA coincides with the greatest rate of increase in sodium channel number. These data suggest that modulation of mRNA abundance is a primary mechanism of regulation of developmental appearance of α subunit protein and of functional sodium channels in the developing brain.

357.17 IDENTIFICATION OF TRANSCRIPTIONAL REGULATORY ELEMENTS OF THE MUSCLE NICOTINIC ACETYLCHOLINE RECEPTOR δ-SUBUNIT GENE. S.M. Evans*, P.D. Gardner, S. Heinemann and J. Patrick. Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138.

The mammalian muscle nicotinic acetylcholine receptor (AChR) mediates the synaptic interaction of nerve and muscle. The AChR is comprised of four subunits in the stoichiometry $\alpha_2\beta\gamma\delta$. Changes which occur in AChR expression during neuromuscular junction development are due in part to changes in transcript levels for each of the subunit genes. Denervation of muscle tissue results in a large increase in AChR subunit transcript levels, suggesting that AChR genes are regulated by the presence of the nerve.

As a start towards understanding the neural regulation of AChR subunit gene transcription, we have begun to isolate transcriptional control regions for each of the four subunit genes. We isolated two clones from a mouse genomic library (vector: λCh28) which hybridize under stringent conditions to a mouse AChR δ-subunit cDNA. One of these clones, λDG77, contains an insert of approximately 12kb and was subjected to detailed restriction enzyme and Southern blot analyses. A 1.8kb Xba I fragment of λDG77 hybridizes to the extreme 5' region of a δ-subunit cDNA. This genomic DNA fragment was subcloned upstream of the structural gene encoding chloramphenicol acetyltransferase (CAT) in the expression vector, pUC19.CAT. Transfection of BC_3H-1 mouse muscle cells with this CAT construct yielded readily detectable levels of CAT activity. However, when the 1.8kb fragment was subcloned in the opposite orientation into pUC19.CAT, no CAT activity was seen following transfection of BC_3H-1 cells. Thus, the transcriptional activity is orientation-dependent indicating the presence of a promoter element in this δ-subunit genomic DNA fragment.

We have used the fusing mouse muscle cell line, C2C12, to study the developmental regulation of this putative δ-subunit promoter. The expression of AChR subunit genes in C2C12 cells increases upon cell fusion. This increase is due, at least in part, to an increase in transcription of the AChR genes. Therefore, we determined if the transcriptional activity of the 1.8kb fragment is affected by the fusion process. As expected, little CAT activity was detected in extracts of unfused transfected cells while extracts of fused transfected cells contained easily measurable levels of CAT activity. Thus, in addition to being orientation-dependent, the transcriptional activity of the 1.8kb fragment of λDG77 appears to be developmentally regulated as would be predicted for transcriptional control elements of an AChR subunit gene.

357.18 DELETION ANALYSIS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR γ-SUBUNIT GENE PROMOTER. P.D. Gardner, S. Heinemann and J. Patrick. Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138.

We are interested in understanding the molecular mechanisms of nicotinic acetylcholine receptor (AChR) gene expression. It is well-documented that innervation has a profound influence on AChR gene expression in a developing muscle. It is likely that a nerve exerts this influence at the level of transcription of the AChR genes. To investigate this possibility further we have begun identifying transcriptional control elements of the AChR genes.

Recently, we identified a 1.1kb DNA fragment, located at the 5' end of the mouse muscle AChR γ-subunit gene, that confers cell type specific transcription of a reporter gene in transiently transfected mouse muscle cells. This transcriptional activity is developmentally regulated in the fusing mouse muscle cell line, C2C12. The 1.1kb fragment contains 750 base pairs of 5' flanking DNA, the first exon (5' untranslated and leader sequences), the first intron and a portion of the second exon (mature protein coding sequence) of the γ-subunit gene. To localize sequence elements necessary for transcriptional regulation of the γ-subunit gene, deletion analysis of the 1.1kb fragment was carried out. Deletion of 400 base pairs from the 3' end of the 1.1kb fragment leads to a loss of transcriptional activity in transfected muscle cells. The most notable feature of the deleted DNA is the first intron of the γ-subunit gene. Transfection of muscle cells with an expression clone in which the intron is used to promote transcription of a reporter gene yields no measurable transcriptional activity. Thus, the transcriptional activity of the 1.1kb fragment requires both 5' and 3' sequences.

Interestingly, sequence analysis indicates that the γ-subunit first intron contains two sequence elements that have striking homology with two well-documented transcriptional control elements. The first, located 33 nucleotides downstream of the exon/intron splice junction, is a 12 out of 13 base pair match with the core sequence of the SV40 enhancer. Fifty-eight base pairs downstream of this region, but still within the intron, is a 9 out of 10 base pair match with the Sp1 recognition site. Immediately adjacent to this potential Sp1 binding site is a potential stem and loop structure (13 base pair stem and 20 base loop). The role of these sequence elements in the regulation of transcription of the AChR genes is currently being investigated.

357.19 ELECTRICAL ACTIVITY REGULATES THE LEVEL OF mRNA ENCODING ALL FOUR SUBUNITS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR IN RAT SKELETAL MUSCLE. D. Goldman*, H. Brenner and S. Heinemann (SPON. S. Fisher). Mental Health Res. Inst. and Dept. of Bioch., Univ. of Mich., Ann Arbor, Mi., 48109; Dept. of Physiol., Univ. of Basel, Basel, Switzerland; and Salk Inst., Mol. Neurobiol. Lab., San Diego, Ca., 92138.

The nicotinic acetylcholine receptor (nAchR) is a pentameric integral membrane protein with a subunit composition $\alpha_2\beta\gamma\delta$. In adult vertebrate skeletal muscle the receptor is localized to the neuromuscular junction. However, prior to innervation or after denervation of adult muscle one finds receptors throughout the muscle fibers surface. The increase in extrajunctional receptors, following muscle denervation is a result of an increase in mRNA levels coding for the extrajunctional receptor. It is clear that activity induced in muscle by the nerve plays a role in regulating nAchR levels since electrical stimulation of denervated muscle can suppress the denervation induced increase in extrajunctional receptors.

In order to test the idea that electrical activity suppresses nAchR gene expression we measured the amount of receptor specific mRNA in denervated and denervated but chronically stimulated muscle. We find that in denervated muscle activity, elicited by extracellular electrodes, prevents an increase in extrajunctional nAchRs and their corresponding mRNAs. In addition, we find that activity will reduce the increased level of extrajunctional receptors and their mRNAs in 6 day denervated muscle that was subsequently stimulated with extracellular electrodes for an additional 5 to 7 days. These results are consistent with the idea that the motor neuron controls extrajunctional nAchR gene expression by the activity it induces in muscle.

357.20 ACETYLCHOLINE RECEPTOR REGULATION IN RAT PRIMARY MUSCLE IN RESPONSE TO BRAIN EXTRACT AND ASCORBATE. O. Horovitz* and M.M. Salpeter (SPON: O. Hamill). Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Fetal rat brain extract, when added to the growth medium of the rat-derived L5 muscle cell line, induces a 2-5 fold increase in surface acetylcholine receptor (AchR) site density (Neugebauer et al., Brain Res. 346:58, 1985). One active component in the rat brain was found to be ascorbate (Knaack & Podleski, PNAS USA 82:575, 1985), which causes a surface receptor increase (due to accelerated AchR insertion) similar to that produced by rat extract. Ascorbate also caused an increase in mRNA measured for the AchR α-subunit (Knaack et al., Neurosci. Abstr. 11:771, 1985). However, no similar significant increase in surface AchR site density has been observed in response to either brain extract or ascorbate in rat primary cells in culture, where the control levels of surface AchR density are initially more than 5-fold higher and equivalent to extrajunctional levels in denervated muscle (for review see Salpeter & Loring, Progress in Neurobiology 25:297, 1985). A question arises as to whether rat primary cells are unable to respond to these "receptor-stimulating" nerve factors or whether the lack of increase in surface receptors is controlled at a different level.

In the present study, we compared the response of rat primary muscle cells to that of L5 cells in order to evaluate the basis of their different responses to brain extract and ascorbate. Using AchR α-subunit specific RNA transcripts as a probe, we looked at the levels of m-RNA in both cell types by Northern analysis. We found that in rat primary cells, the control level of mRNA for the α-subunit of AchR (measured per unit total RNA) is about 8 times higher than in L5 cells. Yet, like L5 cells, rat primary cells respond to both rat brain extract and ascorbate by a significant (up to 4-fold) increase in the level of the mRNA transcript. Our results suggest therefore that the difference in response of L5 and rat primary cells to brain extract and ascorbate is probably regulated by post-transcriptional events.

Many studies using developing and adult innervated and denervated muscle have shown a co-regulation of receptor mRNA transcript levels and expression of surface AchR. Yet the correlation between these two variables differs widely in different cell types and under different experimental manipulations. The response of rat primary muscle cells to brain extract and ascorbate is one dramatic illustration of surface AchR levels not increasing in response to a stimulus which elevates some specific AchR mRNA transcripts. It therefore provides a good system in which regulation of surface AchR expression can be studied in a primary cell. (Supported by NIH grant GM 10422 to M.M. Salpeter)

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS III

358.1 **AMINO ACID CONCENTRATIONS IN RAT AUDITORY, OLFACTORY AND VISUAL STRUCTURES.** Judy A. Parli*, John E. Schemenaur*, Donald A. Godfrey and C. David Ross. (SPON: D. F. Peterson) Dept. of Physiology, Oral Roberts Univ., Tulsa, OK 74171.

To obtain an overall comparison of amino acid metabolism across prominent structures of 3 sensory systems, homogenates of cochlea, cochlear nucleus (CN), olfactory bulb (OB), and retina from 3-5 albino rats were analyzed for concentrations of amino acids and activities of some related enzymes. Homogenates of whole brain were also analyzed. Ortho-phthalaldehyde derivatives of amino acids were separated by reverse phase high performance liquid chromatography (HPLC) and quantified by fluorescence detection. Fluorometric enzymatic microassays were utilized to determine the activities of glutaminase, total and cytosolic aspartate aminotransferase (tAAT, cAAT), malate dehydrogenase (MDH), and lactate dehydrogenase (LDH).

	Cochlea	CN	OB	Retina	Brain
	Amino acid concentrations (mmol/kg protein)				
Asp	6.1	26.6	28.2	25.1	24.3
Glu	15.7	58.2	70.3	95.4	62.6
Asn	3.7	2.6	2.4	5.0	2.2
Ser	17.0	6.9	7.9	8.2	7.7
Gln	15.3	29.4	43.2	7.4	27.4
Gly	18.8	29.2	10.3	34.7	13.7
Thr	6.4	5.8	7.4	5.6	5.7
Arg	3.3	2.3	11.9	4.3	3.2
Tau	32.5	26.3	145.9	530.0	44.2
Ala	14.1	6.9	12.4	15.8	5.0
Tyr	1.4	0.6	1.3	3.4	1.1
GABA	1.3	11.9	82.8	39.5	33.8
Lys	7.5	5.2	6.8	13.0	3.7
	Enzyme activities (mol/kg protein per hr)				
Glutaminase	0.3	13.7	25.0	26.8	16.2
tAAT	12.6	117.7	123.1	167.9	104.4
cAAT	4.9	57.1	54.9	73.3	44.3
MDH	5.1	41.8	43.5	37.6	33.7
LDH	4.1	23.6	22.8	70.8	17.0

Other amino acids measured and found to be in very low concentrations were Met, Trp, Val, Phe, Ile, and Leu. Retina contains an extremely high concentration of Tau, as well as high concentrations of Gly and GABA. Tau and GABA levels are also high in olfactory bulb, whereas cochlear nucleus contains a high concentration of Gly. Cochlea has lower concentrations of most amino acids than the other tissues, with the notable exception of Ser. The glutaminase activities correlate well with the Glu concentrations of the tissues (correlation coefficient r = 0.96).

358.2 Ca2+–DEPENDENT RELEASE OF AMINO ACIDS IN HIPPOCAMPAL SUBFIELDS QUANTIFIED BY HPLC. P.A. Jarvie*, J.M. Wade* and J.T. Slevin. Depts. Neurology and Pharmacology, VA and Univ. Kentucky Med. Ctrs., Lexington, KY 40536-0084.

The hippocampal formation is ideally suited for studying the localization of neurotransmitter (NT) candidates in neurons. It contains three main excitatory neuronal projections: the afferent perforant path, mossy fiber system, and Shaffer/commissural path. These three consecutive pathways are well-characterized and are organized into distinct laminae. Superimposed on this excitatory system is an inhibitory one composed of a diffuse net of short-axon neurons, concentrated around both dentate granule and hippocampal pyramidal neurons. The most reliable and selective marker for amino acids as NTs is Ca2+-dependent, electrically or chemically-stimulated release. Work to date, including release of either preloaded 3H-amino acid or endogenous amino acid (micro-enzymatic method), suggests the NT of the perforant path is L-glutamate (glu); of the Shaffer/commissural system is either L-aspartate (asp) or glu; and of the mossy fiber system may be asp, glu, or neither.

We have measured K+-stimulated (55 mM), Ca2+-dependent (2.0 mM) amino acid release in tissue slabs roughly demarcating the regions of the dentate gyrus, mossy fiber axonal arbor (regio inferior), and Shaffer/commissural axonal arbor (regio superior); these were dissected from 500 μ coronal slices of hippocampus from 225g male Sprague Dawley rats. Ten μl aliquots of Krebs buffer, in which tissue slices were floated, were directly injected onto an HPLC where the sample was automatically derivitized with o-phthaldialdehyde. Amino acid derivatives were separated and detected fluorometricaly. Neither the putatiave inhibitory NT, taurine, or the glu precursor, glutamine, were released above baseline with K+ stimulation. Asp, glu and GABA were all released in all three areas in response to K+ stimulation; > than 80% was Ca2+-dependent. GABA release was uniform in all three regions in the range of 500 pmoles/mg protein/min. Calcium stimulated glu release was 20 to 30-fold higher than asp release. Glu release was highest in the dentate gyrus at 4 nmoles/mg protein/min. These data, determined using a very simple release method with direct HPLC measurement of the bathing medium, suggest that glu or perhaps a dipeptide containing glu, is the NT for all three major excitatory neuronal projections in the hippocampal formation. Furthermore, the homogeneous distribution of GABA release is similar to what has been described immunocytochemically using an antibody to GABA (Anderson, KJ. et al, Neurosci Letts. 69:7, 1986).

358.3 POSTEMBEDDING IMMUNOGOLD LABELLING PERMITS A SEMIQUANTITATIVE ASSESSMENT OF TAURINE CONTENTS IN DIFFERENT CELL TYPES AND PROCESSES IN RAT CEREBELLUM. O. P. Ottersen, Anatomical Institute, University of Oslo, N-0162 Oslo 1, Norway

We have used the method of Storm-Mathisen et al. (Nature, 301:517, 1983) to raise antisera against conjugated taurine (Madsen et al., Neurosci. Lett. 60:255, 1985; Ottersen et al., Exp. Brain Res. 59:457, 1985) in the belief that knowledge about the exact localization of this amino acid in normal and pathological brain tissue could provide important clues as to its functional roles. Ultrathin plastic-embedded sections of rat cerebella perfusion-fixed with a mixture of glutaraldehyde and paraformaldehyde were incubated with taurine antiserum no. 20 and subsequently treated with a secondary antibody coupled to colloidal gold particles. The densities of gold particles in different cellular profiles were determined with the assistance of a computer. In the cerebellar cortex the highest concentration of gold particles occurred in the somata, dendrites, and dendritic spines of the Purkinje cells, supporting previous light-microscopical observations. In a representative experiment (antiserum dilution 1:500) the following particle densities were found (density in Purkinje cell somata = 100%, values corrected for background): Golgi cell terminals 25%***, granule cell dendrites 23%, parallel fiber terminals 21%, granule cell somata 19%, stellate cell terminals 11%*, glial cytoplasm 8%, stellate cell somata 4%**, mossy fiber terminals 2% (asterisks represent values significantly different from preceding value; *p<0.025, **p<0.01, ***p<0.001, Student's t-test). In the cerebellar nuclei, taurine-like immunoreactivity was concentrated in boutons sharing the ultrastructural features of Purkinje cell terminals. These terminals showed a mean gold particle density that was about 60 % higher than that of the Purkinje cell somata.

Ultrathin sections containing a series of different amino acid-glutaraldehyde-brain protein conjugates were incubated in the same drops of sera as the tissue sections for simultaneous specificity control. The gold particle density over the taurine conjugate was at least two orders of magnitude higher than that over any of the other amino acid conjugates (which had densities near background level), indicating that the distribution of gold particles in the tissue was not confounded by crossreactivity with GABA, glutamate or other amino acids. The low taurine-like immunoreactivity in the stellate cell terminals does not support previous suggestions that these terminals mediate taurinergic inhibition. The present data suggest instead that taurine might play a role in the synaptic function of the Purkinje cell terminals. - Supported by NAVF.

358.4 EFFECTS OF COLCHICINE LESIONS AND KAINIC ACID ON OPIATE RECEPTOR SUBTYPES IN RAT HIPPOCAMPUS. D.C. Perry[1] and L.M. Grimes[2], [1]Department of Pharmacology, George Washington University, Washington, D.C., 20037 and [2]Curriculum in Toxicology, Univ. of North Carolina, Chapel Hill, NC 27154.

Enkephalin (ENK) and dynorphin (DYN) in hippocampal dentate granule cells and their mossy fiber projections may play a role in convulsant disorders. To determine which opiate receptor subtypes are involved, we employed quantitative in vitro receptor autoradiography to measure changes in binding to mu, lambda and benzomorphan (BNZ) sites after colchicine (COL) lesions (to selectively destroy granule cells) and/or kainic acid (KA) (which causes a depletion of ENK and DYN from mossy fibers, followed in 48 hrs by an increase in peptide levels). Anesthetized rats were given bilateral hilar injections of saline or COL (2.5 lg/0.5 ll). Two weeks later, surviving rats were given saline or KA (8 mg/kg sc); animals were sacrificed 48 hours later. Mu sites were labeled with 3H-dihydromorphine (10 lM naloxone (NAL) blank); BNZ sites were labeled with 3H-diprenorphine (DIP) in the presence of 10 lM morphiceptin and 200 nM [DAla^{2}DLeu^5]-enkephalin (2 lM DIP blank); lambda sites were labeled with 3H-NAL in the presence of 300 nM DIP (10 lM NAL blank) (Perry and Sadee, Eur. J. Pharm. 129: 147, 1986). Binding was quantitated using a Loats computerized densitometer.

Mu and BNZ binding was present over the pyramidal cell layer in CA1-3, and increased over a rostral-caudal gradient. With mu binding, COL caused a small (20%) decrease in CA1 and in caudal CA3; COL plus KA caused a further decrease (up to 40%). KA alone, however, caused a large increase (50-90%) in mu binding, especially in rostral CA3 regions. With BNZ binding, COL and COL plus KA caused decreases (30-35%) throughout, whereas KA alone increased binding (40%) in rostral sections, with no change in caudal sections. Lambda binding was located over granule cells and mossy fibers, with a rostral-caudal gradient opposite to mu and BNZ. COL decreased lambda binding 30-60%, while KA had little effect; however, the combination produced an even larger decrease (up to 80% loss in caudal sections). The anatomical distribution and response to lesions of mu receptors resemble that seen earlier for ENK while the pattern for BNZ receptor resembles that for DYN. The distribution of lambda sites is inversely proportional to the peptide densities; their response to physiological insult appears most similar to DYN. Lambda sites may represent autoreceptors on mossy fibers, or they may be located on dendrites of CA3 pyramidal cells and hilar neurons. Supported by DA04191 (DCP) and 5-T32-ES-07126 (IMG).

358.5 KAINIC ACID INJECTION INTO THE RAT SPINAL CORD DECREASES ADENOSINE A_1 AND A_2 RECEPTOR DENSITY. J. I. Choca, R. D. Green*, and H. K. Proudfit, Dept. of Pharmacology, University of Illinois at Chicago, College of Medicine, Chicago, IL 60612.

Studies in our laboratory and others have suggested separate roles for adenosine A_1 and A_2 receptors in the modulation of nociceptive stimuli at the spinal cord level. We have shown that rat spinal cord membranes contain both adenosine A_1 and A_2 receptors, which are coupled to the inhibition and stimulation of adenylate cyclase, respectively (Choca et al., 1987). In quantitative autoradiographic studies of spinal cord slices (20 um), the Bmax of [^{3}H]5'-N-ethylcarboxamide adenosine ([^{3}H]NECA) was nearly twice the Bmax of [^{3}H]N^6-(1-methyl-2-phenylethyl)adenosine ([^{3}H]R-PIA) in each of three spinal cord areas: 1)the substantia gelatinosa (SG), 2)the central canal (CC), 3)the ventral horn (VH). The binding sites characterized in spinal cord slices were identical to the sites characterized in membranes: 1)the K_d values determined in slices for [^{3}H]NECA and [^{3}H]R-PIA (Table 1) were the same as those reported for membranes, and 2)N^6-(cyclopentyl)adenosine (CPA) displaced [^{3}H]NECA from two binding sites (K_{i-1} = 0.36 ± 0.53 nM, K_{i-2} = 241 ± 277 nM) and [^{3}H]R-PIA from one site (K_i = 1.0 ± 0.4 nM; N=3). Thus, the binding characteristics of these ligands were identical in slices and in membranes. An estimate of A_2 receptor number was obtained by subtracting the [^{3}H]R-PIA Bmax (A_1 receptor number) from the [^{3}H]NECA Bmax (A_1 plus A_2 receptor number; Table 1).

Unilateral dorsal rhizotomy (DR, N=8, 4-6 roots cut), unilateral hemitransection (HT, N=9, Table 2) and complete spinal transection (not shown) failed to alter either [^{3}H]NECA or [^{3}H]R-PIA binding densities in the SG. On the other hand multiple unilateral kainic acid injections into the dorsal horn (0.2 ul 10mM solution in PBS) eliminated 37.2% [^{3}H]R-PIA and 41.7% [^{3}H]NECA binding densities (N=9, Table 2). In some spinal cord sections, kainic acid was capable of eliminating 100% of both [^{3}H]R-PIA and [^{3}H]NECA binding in the SG. These reults indicate that most, if not all, the adenosine A_1 and A_2 receptors in the SG are located on intrinsic neurons in the rat spinal cord. (Supported by PHS grant DA03980.)

358.6 ASSOCIATION OF ADENOSINE A1-RECEPTORS WITH PUTATIVE GLUTAMATERGIC NEURONS IN THE HIPPOCAMPUS OF THE RAT. J. Deckert and M.B. Jorgensen*. Unit on Neurochemistry, BPB, NIMH and SNB, NINCDS, Bethesda, MD 20892

Lesioning of cholinergic, adrenergic and serotoninergic hippocampal afferents and subsequent measurement of adenosine A1-receptors in a membrane binding assay suggested that adenosine A1-receptors were not associated with any of these hippocampal afferents (Murray T.F. and Cheney D.L., Neuropharm., 21:575-580, 1982). About 85% of the synaptic input to the outer two-thirds of the molecular layer of the ipsilateral dentate gyrus in rat brain is provided by entorhinal cortex neurons (Matthews D.A. et al., Brain Res. 115:1-21, 1976). These neurons are thought to utilize the excitatory amino acid glutamate as a neurotransmitter (Nadler J.V. et al., Nature, 260:538-540, 1976).

In a quantitative autoradiographic study with [^{3}H]cyclohexyladenosine as the ligand probe (Lewis M.E. et al., Eur. J. Pharm., 73:109-111, 1981) we investigated adenosine A1-receptors four days after unilateral surgical removal of the entorhinal cortex (Jorgensen M.B. et al., Acta Neuropath., in press). This selective lesion of the major single source of synaptic input to hippocampal granule cells resulted in a 40% loss of [^{3}H]cyclohexyladenosine binding in the molecular layer of the ipsilateral dentate gyrus as compared to the contralateral dentate gyrus and controls ($p < 0.01$, Scheffe-F-test):

	Molecular layer ipsilateral	contralateral
lesioned (n=5)	80±8 fmol/mg	133±8 fmol/mg
control (n=5)	130±11 fmol/mg	123±12 fmol/mg

(mean±SEM, [^{3}H]cyclohexyladenosine concentration 2.5 nM). No significant differences in [^{3}H]cyclohexyladenosine binding were observed between ipsilateral and contralateral or control stratum radiatum, stratum oriens and parietal cortex.

This strongly suggests that adenosine A1-receptors are either localized on these hippocampal afferents themselves or associated with their synapses with granule cells. This localization is consistent with the reported inhibition of [^{3}H]glutamate release from rat dentate gyrus slices by an adenosine analogue (Dolphin A.C. and Archer E.R., Neurosci. Lett., 43:49-54, 1983).

358.7 LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMISTRY FOR GLUTAMATE IN THE RAT SUPRAOPTIC NUCLEUS. R.B. Meeker, D.J. Swanson* and J.N. Hayward. Department of Neurology and Neurobiology Curriculum, University of North Carolina, Chapel Hill, N.C. 27514.

While glutamate (Glu) is thought to be a major excitatory neurotransmitter in the central nervous system (McLennan, 1983), its role in the release of vasopressin and/or oxytocin remains unclear. The development of a highly specific antiserum against Glu (Hepler et al.,1986), has allowed us to examine the distributions of Glu-like immunoreactivity (Glu-LI) in the rat supraoptic nucleus (SON). Rat brains were fixed by cardiac perfusion with 4% carbodiimide (or paraformaldehyde) + 15% saturated picric acid + 0.1 - 0.2% glutaraldehyde in 0.12 M phosphate buffer, pH 7.3. Coronal sections (50 μm) were cut on a Vibratome and immunocytochemically labeled for Glu using an antiserum dilution of 1:5000 and the ABC technique with diaminobenzidine as the chromagen. Under light miscrscopy (LM), a high level of Glu-LI was found in the SON. The perikarya of these magnocellular neuroendocrine cells stained with variable intensities ranging from intermediate to low levels. A major band of dense labeling was found in the region immediately ventral to the packed cell somata of the SON, in the ventral dendritic neuropil (VDN). Heavily labeled, punctate Glu-LI was observed throughout the VDN. Ultrastructural (EM) examination of the SON revealed low levels of reaction product within the cytoplasm of the magnocellular SON neurons, often associated with the rough endoplasmic reticulum (RER). In the VDN we found heavily labeled Glu-LI dendrites, axon-like processes and terminals. The darkly stained punctate structures observed in the VDN under LM, were identified in EM as cross-sections of large, heavily labeled dendrite-like processes. These processes occasionally contained neurosecretory granules (NSG) suggesting a magnocellular origin. In addition, Glu-LI terminals generally contained round, clear vesicles but occasionally contained both clear and dense-core vesicles. Most of the Glu-LI labeled terminals showed synaptic specializations contacting Glu-LI processes.

In summary, we find the rat SON heavily labeled with Glu-LI at LM and EM. The intermediate to low level of Glu-LI in the cell somata at LM appears to be localized in the RER at EM. The high level of Glu-LI in the VDN at LM is localized at EM in: 1) Dendrite like processes occasionally containing NSG; 2) Terminals containing round, clear vesicles; 3) Terminals containing mixed round, clear and dense-core vesicles. Each type of terminal formed specializations impinging on Glu-LI processes. These observations suggest that the SON receives significant glutaminergic innervation which may be an excitatory neurotransmitter for vasopressin and/or oxytocin release.

358.8 THE DISTRIBUTION AND MORPHOLOGICAL DIVERSITY OF GABA-CONTAINING NEURONS IN THE PREFRONTAL CORTEX OF HUMAN NEWBORN BABY Zheng Deshu, Gai Weiping*,Department of Anatomy, Hunan Medical College, Changsha, Hunan, People's Republic of China

GABA has been belived to be the principle neurotransmitter of the local neurons in the cerebral cortex.The distribution and morphological characteristics of the GABA-containing neurons are essential for understanding the function of the local neuron in the cerebral cortex.The prefrontal cortex of a human full term new born baby just after accident death was studied by means of immunocytochemistry technique with antibody directed against GABA(Immunonuclear corp.).GABA-containing neurons were found over all layers , all were nonpyramidal cells.The laminar distribution of GABA-containing neurons were not even between different layers,density in layer II was prominently higher than that in other layers.Density in layer III and layer IV was higher than that in layer V and layer VI.The tangential distribution over all layers was also uneven,but was not so obvious as that in laminar distribution.Diameters of positive neurons were between 5-16um(measured as a circle).There was a superficial to deep sequence of cell size,with the larger diameter being located in progressively deeper layers.The GABA positive neurons could be identified into three types;multipolar,bitufted and bipolar.Some of the GABA positive neurons were hard to identify,due to the poor staining of their processes.GABA positive endings were found surounding the somata and proximal dendrites of both the GABA positive and negative neurons,but not so numerous as found in the adult monkey prefrontal cortex.The result of the present study revealed that GABA-containing neurons in the prefrontal cortex of the human newborn baby have well developed,but whether laminar and tangential distribution pattern will change in a certain period after born, remains to be further studied.

358.9 REGIONAL DISTRIBUTION OF GABA-B AND GABA-A BINDING SITES IN RAT BRAIN: A COMPARATIVE, QUANTITATIVE AUTORADIOGRAPHIC STUDY. J.B. Penney, D.C.M. Chu and A.B. Young. Neuroscience Program and Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

Within the nervous system, the inhibitory effects of GABA appear to be mediated through two distinct receptor subtypes: GABA-A and GABA-B receptors. GABA-A receptors have been well characterized by various methods. The existence of GABA-B receptors in various CNS structures has been inferred from the biochemical and electrophysiologic actions of the GABA-B agonist, baclofen. Direct autoradiographic visualization of GABA-B receptors has been limited to the spinal cord and cerebellum. We have previously used [3H]GABA quantitative autoradiography to examine both GABA-B and GABA-A receptors in human postmortem tissue (Chu et al., Neurosci. Abstr. 11:725, 1985). In the present study, we used a similar assay to examine the kinetics, pharmacology and regional distribution of GABA-B receptors in rat brain. Comparison to the regional distribution of GABA-A receptors was also done.

[3H]GABA binding to GABA-B receptors at 4°C reaches equilibrium within 45 min. The association and dissociation rate constants for GABA-B binding to outer neocortical layers are $2.87 \pm 0.17 \times 10^{5}$ $min^{-1}M^{-1}$ and 0.0966 ± 0.0118 min^{-1}, respectively. A K_D value of 336 ± 40 nM is calculated for these results. Binding to GABA-B and GABA-A receptors is saturable. Analysis of Scatchard plots reveals that GABA-A receptors bind [3H]GABA with twice the affinity of GABA-B receptors. While the affinities of each type of GABA receptor are relatively uniform across regions, the B_{max} of both types of GABA receptor varies from region to region. There are roughly 2-3X as many GABA-A receptors as there are GABA-B receptors in regions where both occur. The distribution of GABA-B receptors in rat brain is different from that of GABA-A receptors in the olfactory bulb, cerebellum, thalamus, neocortex, medial habenula and interpeduncular nucleus. Other areas high in GABA-B binding include the medial and lateral geniculates, the superior colliculus and certain amygdaloid nuclei. Regions intermediate in GABA-B binding include outer cortex, striatum, thalamus and hippocampus. Low amounts of GABA-B binding occur in brainstem, basal forebrain, globus pallidus and subiculum. Binding to white matter tracts and ventricles is negligible. The distribution of GABA-B receptors is in agreement with previously postulated sites of action of baclofen.

Supported by USPHS grants NS19613 and 5 T32 GM07863.

358.10 MODULATION OF [35]S-TBPS BINDING BY THE GABA RECOGNITION SITE: AUTORADIOGRAPHIC EVIDENCE. C.A. Wilmot, A.M. Szczepanik* and D.B. Ellis*. Dept. Biochemistry, Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876.

TBPS, t-butylbicyclophosphorothionate, is a potent convulsant which blocks GABA-ergic neurotransmission by interacting with the convulsant site of the GABA/benzodiazepine/chloride ionophore receptor complex. [35]S-TBPS binding sites in cortical homogenate preparations are subject to allosteric modulation by benzodiazepines and GABA agonists. To visualize the anatomical location of these binding sites and to identify those areas modulated by the GABA recognition site, a method for [35]S-TBPS autoradiography was established. Autoradiograms were generated from rat brain sections (Wistar, male), freeze-dried, preincubated in buffer, incubated with [35]S-TBPS, 2 nM, 50-60 Ci/mmole, and exposed to Kodak X-OMAT AR film for 7 days, along with [35]S-brain mash standards, 230-382,500 dpm/mg protein. Specific binding, defined with 10 μM picrotoxin, was typically 95% of total binding. Adjacent sections incubated in the presence of 0.1 - 10 μM GABA showed a graded and complete inhibition of binding. The GABA antagonist, RU 5135, 10^{-9} to 10^{-7} M, totally reversed the effect of 10 μM GABA. In the presence of 10^{-7} M RU 5135 alone, binding was 60-70% of total specific, whereas in the combined presence of 10^{-7} M RU 5135 and 10 μM GABA, binding was increased up to 136% of total specific. Since RU 5135 itself has weak effects on [35]S-TBPS binding and potently reverses the inhibition produced by GABA, these results suggest that GABA affects [35]S-TBPS binding via an interaction at the GABA recognition site. Brain areas in which these effects were most prominent were the deep cortical layers of the motor and somatosensory areas of the frontoparietal cortex, globus pallidus, ventral pallidum, n. vertical limb of the diagonal band, anteromedial and ventrolateral areas of the thalamus, anterior pretectal areas, superior colliculus and the substantia nigra, pars reticulata. GABA-modulated [35]S-TBPS binding sites are thus site-specifically distributed in deep cortical layers, subcortical areas and mesencephalic areas.

358.11 RESOLVING GABA$_A$/BENZODIAZEPINE RECEPTORS: SUBCELLULAR LOCALIZATION IN THE CNS WITH MONOCLONAL ANTIBODIES. H. Möhler*and J.G. Richards (SPON: J.R. Martin), Pharma Res. Dept., F. Hoffmann-La Roche & Co., Ltd., CH-4002 Basle, Switzerland.

The ability of benzodiazepines to reduce the extent of anxiety, the degree of muscle tension, the likelihood of convulsions and the level of vigilance is triggered by their selective interaction with allosteric sites on GABA receptors in neuronal membranes of the CNS. A variety of morphological techniques are currently used to determine receptor expression, their numbers, affinity, cellular and subcellular localization and their regulation in microscopic regions of the CNS. For such investigations, high affinity radioligands, monoclonal antibodies and hybridization probes are essential tools. The resolution of receptor autoradiography, while providing invaluable quantitative data about benzodiazepine receptor ligands (Richards et al., this meeting), is unable to reveal the cellular and subcellular localization of receptors. Monoclonal antibodies raised against a purified GABA$_A$/benzodiazepine receptor complex that recognize either the α-subunit (50 kD) or the β-subunit (55 kD) have been used to visualize the subcellular distribution of the receptors in rat brain, spinal cord, retina and pituitary by immunocytochemistry (Richards et al., J. Neurosci., in press). The findings support a modulatory role of benzodiazepines in GABAergic synaptic inhibition in various regions of the brain (olfactory bulb, hippocampus, substantia nigra, cerebellum), spinal cord (dorsal horn), pituitary (anterior and neurointermediate lobes) and retina (internal plexiform layer). In the near future, it will be possible to study benzodiazepine receptor expression in the CNS by in situ hybridization, once the cDNA, encoding the subunit proteins, has been isolated.

358.12 LOCALIZATION OF PERIPHERAL BENZODIAZEPINE BINDING SITES TO ERYTHROCYTE MEMBRANES. J.M.M. Olson*, B.J. Ciliax, W.R. Mancini* and A.B. Young. Depts. of Pharmacology, Neurology and Neuroscience Program, University of Michigan, Ann Arbor, MI 48104.

Benzodiazepines (BDZ) bind to two pharmacologically distinct sites. The central BDZ receptor is located on CNS neurons. The sedative, hypnotic and anticonvulsant activities of benzodiazepines are mediated by these central receptors. The peripheral BDZ binding sites are located on adrenal, kidney, glia, and other non-neuronal tissues. The function and subcellular location of these binding sites are not yet known. Pharmacologically, PK 11195 and Ro 5-4864 bind to the peripheral site with nanomolar affinities while flunitrazepam, a benzodiazepine that binds to both central and peripheral binding sites, binds with mid-nanomolar affinity. Clonazepam binds specifically to central receptors.

Using subcellular fractionation of rat adrenal cells, Anholt and coworkers report that the peripheral benzodiazepine receptor is located on the outer mitochondrial membrane (J. Biol. Chem. 261: 576, 1986). Because mature human erythrocytes lack mitochondria, we performed binding studies on these cells to determine whether there are peripheral benzodiazepine binding sites which are not associated with mitochondria.

Erythrocytes were separated from leukocytes and platelets by centrifugation. Erythrocytes were then lysed in hypotonic sodium phosphate buffer, washed, and centrifuged to remove hemoglobin and other intracellular contaminants from the membranes. Binding assays were performed using 2.5 X 10^{-9} M [3H]PK 11195.

[3H]PK 11195 bound to both intact human erythrocytes and purified erythrocyte membranes in a specific, saturable manner. Nonspecific binding represented less than 17% of total binding. At 4°, maximum levels of binding (500 fmol/mg membrane protein) occurred by 90 minutes. IC-50 values for displacement of [3H]PK 11195 by unlabelled PK 11195, Ro 5-4864, flunitrazepam, and clonazepam were similar to those reported for other tissues containing the binding site. Unlabelled competitors followed the same rank order of displacement in intact rat erthyrocytes.

Our results suggest that non-mitochondrial binding sites, pharmacologically indistinguishable from the peripheral benzodiazepine binding sites demonstrated in adrenal cells and other peripheral tissues, are located on erythrocyte membranes.

358.13 CHARACTERIZATION AND DENSITY OF THE PERIPHERAL BENZODIAZEPINE BINDING SITES IN MITOCHONDRIA FROM DIFFERENT ORGANS. L. Antkiewicz-Michaluk, K.E. Krueger, A. Guidotti and E. Costa (SPON: W.M. Saidel). FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical Center, Washington, D.C. 20007.

Peripheral-type benzodiazepine recognition sites are found in many peripheral organs as well as the central nervous system and exhibit a different pharmacological specificity than that of the benzodiazepine recognition sites associated with GABA receptors. Peripheral-type benzodiazepine receptors are apparently localized on the outer mitochondrial membrane, yet considerable variation exists among different tissues in the density of these sites. To examine these differences more closely, we determined the relative density of specific binding sites for PK11195 on mitochondrial preparations from several organs of the rat. The following relative proportions of PK11195 specific binding sites versus protein content were observed: adrenal gland 1.00; lung, kidney, heart 0.10; liver, testis, skeletal muscle 0.04; brain 0.01. The specific activities of two mitochondrial enzymes, succinic dehydrogenase (SDH) and cytochrome c oxidase (CCO), also showed variation in each mitochondrial preparation, however, the ratio of SDH to CCO was nearly constant from all tissues. There was no correlation between the levels of PK11195 binding and the specific activities of these enzymes. This accounted for a ratio of PK11195 binding to SDH and CCO activities being 20-100 fold greater in adrenal gland mitochondria in comparison to the other organs. To further characterize the binding of benzodiazepine to mitochondrial populations from different tissues [^{3}H]PK14105, a photoaffinity ligand specific for peripheral type receptors (Doble et al., Mol. Pharmacol. (1987) 31: 42-49), was used. Specific binding of PK14105 was blocked by the addition of 1 uM PK11195. Following irradiation approximately 40% of the bound [^{3}H]PK14105 could not be displaced by PK11195, or dissociated from the membrane by warming to 20°C. The quantity of [^{3}H]PK14105 covalently incorporated into mitochondria from different organs paralleled that of specific PK11195 binding. SDS-polyacrylamide gel electrophoresis and autoradiography of mitochondrial membranes photolabeled with [^{3}H]PK14105 revealed a polypeptide band with an apparent M_r of 16,000 daltons. From all organs examined this component was not labeled when photolabeling was performed in the presence of 1 uM PK11195. These results demonstrate that the quantity of peripheral-type benzodiazepine receptors on mitochondria varies greatly from different tissue sources with adrenal gland mitochondria exhibiting the highest levels. The binding sites from different mitochondrial populations appear to be located in a common protein component evidenced by the photolabeling of a 16,000 dalton polypeptide.

358.14 ^{3}H-ALPIDEM: A HIGH AFFINITY LIGAND FOR IMIDAZOPYRIDINE RECOGNITION SITES IN THE PERIPHERY. S. Arbilla*, S. Tan*, B. Zivkovic, G. Perrault*, P. George*, J. Allen*, A. Wick* and S.Z. Langer. Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), 58, rue de la Glacière, 75013 Paris, France

Alpidem (ALP: 6-chloro(4chlorophenyl)2N,N di-n-propyl imidazo[1,2-a]pyridine-3-acetamide) displaces with high affinity (0.71 nM) ^{3}H-Ro 5-4864 binding to rat kidney. The radiolabelled compound (^{3}H-ALP 51.8 Ci/mmol, LERS Chemistry Department) binds to rat cerebral cortex membranes preincubated with Ro 5-4864 1 μM with a Kd of 1.50 ± 0.14 nM and a Bmax of 1438 ± 129 fmol/mg prot (n = 3). In the present study, ^{3}H-ALP was used to explore its binding characteristics in the rat kidney and platelets as well as human platelets. Crude membrane preparations (3 μg prot/ml) were incubated for 120 min at 25°C with ^{3}H-ALP (0.003 - 3 nM). Specific ^{3}H-ALP binding was defined in kidney in the presence of Ro 5-4864 1 μM and in platelets in the presence of PK 11195 2 μM.

Under these conditions, ^{3}H-ALP binding, in the three preparations was reversible and displaced by Ro 5-4864, PK 11195 and flunitrazepam but not by Ro 15-1788 or clonazepam.

Scatchard analysis of saturation data indicates that ^{3}H-ALP binds with high affinity to a single class of recongnition sites. The affinity constants (Kd) and maximal number of binding sites (Bmax) are shown in table 1.

Table 1 : Binding characteristics of ^{3}H-alpidem

	n	Kd (pM)	Bmax fmol/mg prot
Human platelets	3	289 ± 32	3754 ± 140
Rat platelets	3	44 ± 13	4500 ± 729
Rat kidney	5	57 ± 7	2493 ± 150

The Bmax for ^{3}H-ALP binding in the rat kidney was significantly reduced to 1228 ± 93 fmol/mg prot (n = 5, $p<0.001$) when measured 48 hr after the repeated administration of alpidem (100 mg/kg x 2 p.o., 10 days) (Table 1).

It is concluded that peripheral receptors in the kidney and platelets can be recognized not only by benzodiazepines or the isoquinolinecarboxamide PK 11195 but also by imidazopyridines like alpidem. As ^{3}H-ALP binding sites undergo down regulation, it is suggested that this recogntion site might be a functional receptor and that ALP behaves as an agonist. The high affinity of ALP for these sites indicates that ALP may prove useful in the understanding of the physiological or pharmacological functions associated with these receptors which are also present in the central nervous system.

358.15 USE OF THE SELECTIVE BENZODIAZEPINE-1 (BZ-1) LIGAND [^{3}H]-2-OXO-QUAZEPAM (SCH 15-725) TO LOCALIZE BZ-1 RECEPTORS IN THE RAT BRAIN. J.P. Yezuita*, R.T. McCabe, A. Barnett[1], L.C. Iorio*[1], and J.K. Wamsley (SPON: S.S. Stensaas). Depts. of Psychiatry and Pharmacology and Toxicology, Univ. of Utah, SLC, UT 84132, and [1]Biological Research Division, Schering-Plough Corp., Bloomfield, NJ 07003.

A metabolite of the benzodiazepine agonist quazepam, 2-oxo-quazepam (2OXOQ; 7-chloro-1-(2,2,2-trifluoroethyl)-1,3-dihydro-5-(2-fluorophenyl)-2H-1,4-benzodiazepin-2-one), has been studied to determine its binding characteristics for labeling the BZ receptor in sections of the rat brain. Autoradiographic measurements of brain regions known to bind BZ ligands indicate [^{3}H]-2OXOQ is selective for the BZ-1 receptor subtype.

Dissociation, association, and saturation experiments, as well as displacement studies, were performed to establish optimal binding conditions for use in generating autoradiograms. Specific binding was defined by incubating tissue sections taken from rat forebrain in 0.17 M Tris buffer (4°C; pH 7.4) containing 2 nM [^{3}H]-2OXOQ, while nonspecific binding was determined in the same manner except in the presence of 1 μM clonazepam.

The data obtained from these experiments indicate that the specific binding of [^{3}H]-2OXOQ is saturable and of high affinity, reaches equilibrium after 30 minutes of incubation, and has a dissociation time of approximately 10 minutes. Saturation curves reveal that the maximum specific binding reaches 40-45% at 4.5 nM [^{3}H]-2OXOQ. Scatchard analysis performed to estimate the number of receptors (B_{max}) and dissociation constant (K_d) gave results of 18.4 fmol/mg tissue and 1.6 nM, respectively. Additionally, displacement experiments demonstrate that [^{3}H]-2OXOQ is displaceable by both BZ and BZ-1 specific ligands.

Quantitation of grain densities on autoradiographic films showed differential binding in accordance with known distributions of BZ-1 and BZ-2 receptor sites. In particular, intermediate to high binding was observed in lamina IV of the cerebral cortex, substantia innominata, substantia nigra, zona incerta, and molecular layer of the cerebellum (BZ-1 sites), while low binding was measured in other layers of the cortex, as well as dentate gyrus and superior colliculus (BZ-2 sites). These results indicate that [^{3}H]-2OXOQ binds preferentially to the BZ-1 receptor subtype and has potential for use in delineating the actions of BZ-1 selective ligands. The tritiated form of this ligand, moreover, should provide a useful tool for further investigation of the density and distribution of BZ-1 sites in the CNS.

STRESS, HORMONES AND THE AUTONOMIC NERVOUS SYSTEM I

359.1 STRESS-INDUCED RENIN AND CORTICOSTERONE SECRETION IS BLOCKED BY DESTRUCTION OF CELL BODIES IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS. K.D. Richardson Morton*, M.S. Brownfield+, S.A. Lorens, and L.D. Van de Kar. Dept. of Pharmacology, Loyola University Medical Center, Maywood, IL 60153 and +University of Wisconsin School of Vet. Medicine, Madison, WI 53706.

We have previously reported that electrolytic lesions in the hypothalamic paraventricular nucleus (PVN) prevent the stress-induced increase in plasma renin activity (PRA) , plasma renin concentration (PRC) and plasma corticosterone levels following a ten minute conditioned emotional (fear) response (CER) paradigm (Richardson Morton et al., Neurosci. Abst. 12: 290.15, 1986). This experiment was designed to determine whether cell bodies in the PVN or fibers of passage through the PVN are involved in mediating the stress-induced increase in PRA, PRC and corticosterone levels. Bilateral stereotaxic microinjections of ibotenic acid (10 ug/ul; 0.3 ul per side) were performed 14 days prior to the stress procedure. Ibotenic acid is a neurotoxin that selectively destroys cell bodies while leaving fibers of passage intact. Histological evaluation of the tissue revealed cell death and lysis in the PVN where there was a concomitant suppression of corticosterone secretion. Ibotenic acid injection into the PVN prevented the effect of stress on PRA, PRC and corticosterone levels. Values for PRC (production of Angiotensin I under saturating levels of exogenous substrate) were slightly higher than those for PRA (production of Angiotensin I from endogenous substrate), but the stress-induced increase in PRA, PRC and corticosteorne levels were clearly blocked by ibotenic acid injection into the PVN. This suggests that the blockade of the effect of stress on PRA is not due to changes in renin substrate levels. The results with ibotenic acid suggest that neurons in the PVN play an important role in mediating stress-induced increases in renin and corticosterone secretion. (Supported by Sigma Xi and the Bane Charitable Trust).

359.2 REPEATED STRESS INCREASES ANGIOTENSIN II RECEPTOR NUMBER IN RAT PARAVENTRICULAR NUCLEUS AND SUBFORNICAL ORGAN. E. Castrén* and J.M Saavedra. LCS, NIMH, Bethesda MD 20892.

Angiotensin II (ANG) is a circulating neurohormone, which has a modulatory role in the regulation of sympathetic activity and pituitary hormone release. There are ANG receptors in the subfornical organ (SFO), in the hypothalamic paraventricular nucleus (PVN), and in the anterior pituitary.

PVN is a key site of the central regulation for the stress response. It regulates the sympathetic activity by direct connections to intermediolateral nucleus of the spinal cord. CRF-containing cells in the parvocellular PVN regulate the ACTH release from the anterior pituitary. PVN receives direct input from SFO, an organ which is partially outside the blood brain barrier and mediates information from circulating hormones to central nervous system.

Plasma renin activity, which reflects ANG plasma levels, is elevated during repeated stress suggesting that peripheral renin-angiotensin system is activated. We have studied the effect of repeated immobilization stress on ANG receptors in PVN, SFO and anterior pituitary by quantitative receptor autoradiography using ^{125}I-Sar^1-ANG as a ligand.

Immobilization (two hours per day for ten days) significantly increased the ANG receptor concentration in PVN and SFO without any significant effect on binding affinity. The B_{max} values (fmol/mg protein, mean±SEM) were 105±11 and 63±7 ($P<0.01$) in PVN ($n=7$), and 311±14 and 230±9 ($P<0.01$) in SFO ($n=6$) for stressed rats and controls, respectively. Repeated stress did not alter the ANG receptor number in the anterior pituitary.

The increase in ANG receptor concentration in SFO may represent an upregulation by elevated plasma ANG levels during the stress. This kind of upregulation has been described after chronic dehydration in SFO and zona glomerulosa of the adrenal gland. PVN, on the other hand, is inside the blood brain barrier and thus not affected by circulating ANG. The increased ANG receptor number in this nucleus suggests an important role for putative central renin-angiotensin system in the regulation of the stress response.

359.3 REGULATION OF TYPE I AND TYPE II GLUCOCORTICOID RECEPTORS IN RAT HIPPOCAMPUS BY STEROID AND PEPTIDE FACTORS. R.E. Brinton, L. MacIsaac* and B.S. McEwen. Laboratory of Neuroendocrinology, Rockefeller University, New York, NY 10021.

Because the hippocampus is implicated in cognitive and affective processes and is also a target for glucocorticoid action, we explored factors which regulate glucocorticoid receptors in the hippocampus (HC). Previous work demonstrated an influence of high levels of corticosterone (CORT) and of ACTH and vasopressin (AVP) on glucocorticoid receptor (GR) binding but did not distinguish between receptor subtypes (for review see McEwen, DeKloet and Rostene, Phyiol. Rev., 1986). In this study we utilized both adrenal steroids and AVP in an effort to observe the dynamic adaptive capability of both GR receptor types. To explore the specificity of regulatory factors, male Sprague Dawley rats were either adrenalectomized (ADX) or hypophysectomized (HX), or both. At the time of ADX or sham surgery, rats were treated with low to moderate levels of regulatory factors by subcutaneous Alzet minipumps for 3d. Cytosol GR were assayed in the presence of sodium molybdate with 3H-dexamethasone (DEX) as ligand and 2.5 uM CORT to define nonspecific binding. Type II receptors were distinguished from Type I by means of the specific type II receptor agonist, Ru 26988 (0.5 uM). Separation of bound from free 3H-DEX was accomplished by Sephadex LH-20 gel filtration. In ADX rats, a low dose of CORT (1 ug/h) produced in 6h a marked reduction in Type I GR receptors. This reduction was even greater when CORT (1ug/h) was delivered for 72h, but a significant recovery of binding occurred 6h after ceasing the CORT treatment. The depression and recovery of Type I binding at 6h indicates a rapid and sensitive regulation of Type I receptors in the HC which may reflect nuclear translocation or inactivation of binding. Type II receptors were down-regulated following 72h of 1 ug/h CORT. However, the Type II receptors did not show the rapid regulation observed for the Type I receptors at 6h. The regulation of glucocorticoid receptors by 1 ug/h CORT was unique for the HC and was not observed in the other brain regions examined. Administration of 1 ug/h aldosterone (ALDO) for 72h depressed binding to Type I but not Type II receptors in HX rats. HX elevated Type II receptors, whereas Type I binding increased only when the HX rats were ADX. The elevation of Type I receptors following 3d ADX was prevented by 1 ug/h ALDO. These data indicate that low levels of CORT and ALDO can have a pronounced and selective influence upon availability of GR binding sites in the HC. In vivo treatment with either 0.33-1 ug/h AVP reduced Type II receptor binding in the HC and reduced the apparent Kd of the Type I receptor. From these data AVP appears to have a regulatory influence upon both types of the GR in vivo.
(Supported by NIMH Grant MH41256).

359.4 SHORT-TERM CHANGES IN GLUCOCORTICOID RECEPTOR LEVELS IN THE RAT HIPPOCAMPUS. R.L. Spencer* and B.S. McEwen. (SPON: C. Fischette). Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY 10021.

Levels of the glucocorticoid receptor (GR) in the rat hippocampus (HC) vary under certain conditions such as adrenalectomy, corticosterone (CORT) treatment, stress, and aging. To study the response of the glucocorticoid system to stress and chronic alcohol consumption, we are further characterizing the binding properties and activation process of GR in the rat brain. Two distinct populations of glucocorticoid binding sites are found in HC cytosol. One, the Type I or corticosteroid receptor (CR), shows a relative binding affinity of CORT,aldosterone (ALDO) > dexamethasome (DEX), and the second site, the Type II or glucocorticoid receptor (GR), has a relative binding affinity of DEX>CORT>ALDO. Rats were adrenalectomized (ADX) prior to the binding assay in order to eliminate endogenous hormone. However, allowing only 16 hr of ADX to clear endogenous CORT may still result in some upregulation of receptor level. To examine this we compared the binding of ^{3}H-DEX (1-20 nM) to HC cytosol from 16 hr ADX or no ADX male Spraque-Dawley rats. Binding in the presence or absence of the pure GR agonist, RU26988 (.5 μM), was used to differentiate GR from CR binding, and CORT (2.5 μM) was used to assess non-specific binding. Using Scatchard analysis, the GR receptor for the 16 hr ADX rats had a Bmax of 329 fmoles/mg protein and a Kd of .73 nM; the CR receptor had a Bmax of 144 fmoles/ mg protein and a Kd of 2.0 nM. The cytosol from the non-ADX rats was divided into two equal portions. One portion was first passed through Sephadex LH-20 columns before incubation with ^{3}H-DEX in an effort to remove endogenous free CORT present in the cytosol. The Bmax for the GR receptor from the non-ADX rats was 50% of that measured in ADX cytosol. The two column step doubled apparent affinity of ^{3}H-DEX binding but did not change Bmax. There was no measurable CR binding in the non-ADX rats. To further assess if the different level of receptors present in ADX and non-ADX cytosol reflects a shuttling of receptor between cytosolic and nuclear compartments and/or a short-term upregulation of cytosolic receptor levels, we attempted to extract receptor from isolated nuclei and measure levels with our binding assay. Although we were able to measure the hippocampal nuclear uptake of an in vivo injection of ^{3}H-CORT, we were not able to measure with our in vitro binding assay specific ^{3}H-CORT or ^{3}H-DEX binding in protein extracts from HC cell isolated nuclei. Whether or not this indicates that the native receptor is unable to rebind steroid after entering into the nucleus or that the binding capability of the receptor is disrupted as a consequence of our isolation procedure is still under investigation. Supported by MH41256 and AA05256.

359.5 A METHODOLOGICAL IMPROVEMENT FOR STUDYING CHRONIC STRESS IN RATS. D.L. Pitman*, A.M. Schilling*, T. Pritzel*, C. Bashford*, J.E. Ottenweller* and B.H. Natelson. VA Med. Ctr. & Dept. of Neurosciences, New Jersey Medical School, E. Orange, NJ 07019.

We have developed a new method for studying chronic stress which avoids many earlier methodological problems. When animals can alter the intensity, duration, or frequency of shock in the chronic stress setting, the stress response is usually affected. Grid shock may be modified by postural changes or reduced by animals' excreta. Tail shock can be interrupted if the electrode slips. Additionally, rats instrumented with tail electrodes can gnaw at the apparatus; this is a coping mechanism which is known to further influence results. Additionally, investigators need to disturb animals in order to apply the electrodes. This in itself may act as a signal that stress sessions are to begin.

In our paradigm, animals live in the experimental apparatus and thus do not have to be disturbed for blood sampling or stressor administration. A leather belt (.5 in wide x 7" long) is fastened securely between the rat's hips and rib cage. The animal is placed on all fours in a wooden archway and secured to it by a loop sewed in the leather belt. The archway/belt with the animal is secured to a wire mesh tray and placed in an individually ventilated, light-tight, sound attenuated cubicle. For our on going work, each chamber has been provided with cue lights for Pavlovian conditioning.

Shock is delivered via subcutaneous flank electrodes which are implanted at the same time animals are initially placed into the apparatus. Blood is sampled via indwelling femoral artery catheters which are exteriorized out of each individual cubicle; this allows us to sample the animal without disturbing it in any way. Rats' activity is assessed by counting contact closures everytime the animal moves in the archway. With this set-up, rats can be given any pattern of unmodifiable signals/shock, can have blood samples taken, and activity monitored -- without disturbing the animal at all.

After placement in the apparatus, rats initially struggle but within 30 min become quiet. Body weight falls to approximately 90% of original weight and then stabilizes for the 2 week duration of our experiments. Both food and water intake show a similar pattern with reduced intake for the first two days and then a gradual increase over time. After one day of placement in the apparatus, plasma levels of corticosterone are elevated slightly (10-12 ug/dl) but fall by day 2 to levels comparable to a.m. levels found in free-ranging undisturbed rats (4-6 ug/dl).

359.6 STRESS-INDUCED CORTICOSTERONE SECRETION IN NEONATAL RATS:POSSIBLE NEURAL MEDIATORS. S. Clark*, S. Pachman*, Scott Lurie* S. Schanberg*, C. Kuhn. Duke University Medical Center, Durham, N.C. 27710

Although it has been suggested that the neonatal HPA axis is unresponsive to stress for up to 10 days, we have observed marked increases in corticosterone (CS) following exposure to either ether or maternal deprivation stress in rat pups as young as day 5 using a sensitive RIA for CS. To investigate possible neural mediators of these stress responses in rat pups, CS secretion evoked by several stimuli which increase CS in adult rats was compared in 10-day old and adult rats. Morphine (5 mg/kg), the cholinesterase inhibitor physostigmine (0.5 mg/kg), the alpha antagonists phenoxybenzamine (10 mg/kg) and yohimbine (1 mg/kg), and the dopamine-beta hydroxylase inhibitor diethyldithiocarbamate (400 mg/kg) were given to adult and neonatal rats and serum CS assayed by RIA. Each of these agents stimulated CS secretion in neonates from two- to four fold, although basal secretion in pups was markedly lower than that observed in adults, as previously reported. The degree to which each stimulus was suppressed by low dose (0.025 ug/kg) dexamethasone (DEX) also was similar in neonates and adults: the low dose of DEX suppressed responses to morphine and ether stress effectively, while stimulation produced by adrenergic blockade escaped from DEX suppression in both neonates and adults. A developmental difference in DEX suppression of physostigmine-induced CS secretion was observed at this dose of DEX, with suppression observed in pups, but escape in adults.

These findings suggest that many neural stimuli which alter CS secretion in the adult also are effective in neonates, despite the lower basal rate of secretion and the somewhat blunted responses. Tonic noradrenergic inhibition seems to play a dominant role in HPA regulation early in neonatal life. The inhibition of these responses by a low dose of DEX implicates the CRF neuron as the prime mediator of this response. This study also suggests that CS hypersecretion might prove to be a useful endocrine index for studying stress-induced behavioral disruption in developing animals, a possibility which has potential implications for investigation of endocrine correlates of childhood psychiatric disorders.

359.7 SENSITIZATION OF NEUROENDOCRINE RESPONSES TO REPEATED STRESS IN RATS. T.E. Orr*, B.N. Bunnell, E.H. Mougey* and J.L. Meyerhoff (SPON: L.J. Peacock). Dept. Psychology, Univ. of Georgia, Athens, GA 30602 and Dept. Med. Neurosciences, Walter Reed Army Inst. of Research, Washington, DC 20307.

Neuroendocrine responses to acute stress have been studied extensively while responses to chronic or repeated stressors have received less attention. Most reports from the latter studies suggest that responses are attenuated following a prolonged period of exposure to stressors. Studies from our laboratories have indicated that, in response to severe daily stressors, the neuroendocrine responses do not necessarily decrease in a linear fashion (Bunnell, B.N., et al., Neurosci. Abst., 10:95, 1984). Instead, there appears to be a period during which the responses are sensitized to some stressors. The present study sought to examine this sensitization in more detail by measuring the adrenal cortical responses to several stressors following 1, 2, 3, 4, and 5 days of exposure.

Two groups of 30 rats were placed in restraint cages and given daily 15 min exposure to intermittent 5 sec, .017 watt tailshock delivered on a 60 sec variable time schedule. One of these groups was not subjected to the two weeks of preexperimental handling that was given to all the other groups in the experiment. Another group of 30 rats was restrained in the cages, but not shocked, while a fourth group received 15 min of total immobilization each day. The last group of 30 served as home cage controls. Six rats from each group were killed each day for five days following exposure to the stressors. Trunk blood was collected in heparinized tubes and stored at -18°C until radioimmunoassay for corticosterone.

Plasma corticosterone was elevated in all four stress groups across all five days relative to home cage controls. Sensitization occurred on the second day in both the handled and nonhandled rats that received tailshock and persisted throughout the remainder of the experiment. A smaller rise in sensitivity occurred later in the restraint group, but no sensitization was observed with total immobilization.

Corticosterone ug/100ml (SEM)

Day:	1	2	3	4	5
Shock (unhandled)	27.5(2.4)	36.0(2.8)	34.9(1.7)	38.6(2.)	35.6(2.6)
Shock (handled)	21.6(2.0)	30.3(1.7)	29.2(0.5)	31.9(1.8)	31.9(2.1)
Restraint	20.3(1.6)	17.1(0.6)	25.1(2.5)	28.3(2.0)	28.7(3.0)
Immob.	24.3(2.1)	24.7(2.2)	24.6(3.7)	28.2(3.8)	25.9(3.8)
Home Cage	11.0(2.1)	8.4(2.3)	4.8(0.7)	8.1(2.0)	4.3(0.8)

359.8 HORMONAL AND BEHAVIORAL ALTERATIONS PRODUCED BY PRENATAL STRESS CONTROLLABILITY IN THE RAT. L.K. Takahashi,* C.M. Barksdale,* N.H. Kalin,* and J.A. Vanden Burgt* (SPON: M. Carnes). Dept. of Psychiatry, Univ. of Wisconsin-Madison, and Psychiatry Service, Wm. S. Middleton Veterans Hospital, Madison, WI 53705.

Female Sprague-Dawley rats were exposed to escapable shock (E), inescapable yoked shock (Y), or no-shock (C) treatments during the course of pregnancy to determine the effects of controllable and uncontrollable prenatal stress on stress-induced behavioral and hormonal responses in the offspring. Tail shocks (0.5 mA, 80 shocks per session) were given every three days throughout pregnancy in a wheel-turn box that allowed group E animals to terminate shock by spinning the wheel. Y animals received uncontrollable shocks using the same parameters as for E animals. C animals were simply restrained in the apparatus.

At 14 days of age, male-female littermates were examined under one of four conditions: separation (SP), separation control (SPC), shock (SH), and shock control (SHC). SP tests consisted of separating pups from their litter and placing them individually in a styrofoam cup for 10 min, after which they were decapitated and plasma was collected for ACTH determination. Pups in the SPC groups were decapitated immediately after removal from the litter. SH tests examined the effects of grid shock (five 1.0-s shocks, 0.5 mA, one shock per minute) on the development of analgesia using a tail-flick test. SHC conditions were identical except that shock was not delivered. Pups were decapitated for plasma collection immediately after analgesia assessment in SH and SHC tests.

The major findings were (i) SP produced a significant elevation in ACTH values (96.1 pg/ml) relative to SPC (44.2 pg/ml) treatment ($p < .001$); (ii) female pups had significantly higher ACTH values (179.2 pg/ml) than males (128.4 pg/ml) after SH treatment ($p < .01$); (iii) ACTH levels were significantly higher in pups from Y mothers (121.2 pg/ml) than in E (91.8 pg/ml) and C (98.0 pg/ml) pups ($p < .05$); and (iv) C pups exhibited significantly longer tail-flick latency scores (2.2 s) than E (1.5 s) and Y (1.2 s) pups after SH treatment ($p < .05$). These results indicate that stress-induced analgesic responsivity in offspring is diminished by both controllable and uncontrollable prenatal stress. That only pregnant rats lacking control over prenatal stress produce young with elevated ACTH levels suggests that maternal controllability ameliorates the effects of prenatal stressors on levels of stress-related hormones in the offspring.

359.9 THE NEUROPHARMACOLOGY OF SEPARATION-INDUCED DISTRESS IN NONHUMAN PRIMATES. N.H. Kalin,* S.E. Shelton,* and C.M. Barksdale* (SPON: B. Eichelman). Dept. of Psychiatry, Univ. of Wisconsin-Madison 53792, and Wm. S. Middleton Veterans Hospital, Madison, WI 53705.

Disruption of the primate mother-infant attachment bond is a naturally occurring stressor that results in marked behavioral, physiological, and endocrine activation. We studied the effects of alterations of benzodiazepine, opiate, and catecholamine systems on the behavioral and endocrine response of infant rhesus monkeys briefly separated from their mothers.

The benzodiazepine agonist diazepam (1.0 mg/kg) significantly decreased distress vocalizations and increased social behavior and activity in monkeys undergoing separation. This dose of diazepam also significantly reduced the separation-induced increase in pituitary-adrenal activity. The benzodiazepine antagonist Ro 15-1788 (10 mg/kg) significantly blocked diazepam's effect on activity and pituitary-adrenal hormones but did not affect diazepam's reduction of distress vocalizations.

The opiate agonist morphine (1.0 mg/kg) significantly reduced separation-induced distress vocalizations without affecting activity levels. When administered alone, the opiate antagonist naloxone (10 mg/kg) significantly increased distress vocalizations. A lower dose of naloxone, 0.1 mg/kg, had no intrinsic effects of its own but it blocked morphine's effect on reducing separation-induced vocalizations. When administered alone, this dose of naloxone significantly enhanced separation-induced increases in ACTH; with morphine, it blocked morphine's reduction of ACTH.

The α-2 agonist clonidine was administered in a wide dosage range (1, 10, 33, 67, and 100 µg/kg). The 1- and 10-µg/kg dosages had no effect on any of the separation-induced behaviors. Significant reductions in activity levels, locomotion, and distress vocalizations occurred with doses of 33, 67, and 100 µg/kg. That we could not find a dose that selectively reduced distress vocalizations without reducing activity levels suggests that the effects of clonidine on separation-induced vocalizations are secondary to sedation. We found that 0.1, 1.0, and 5.0 mg/kg of the β-adrenergic antagonist propanolol did not significantly affect any behavioral aspect of the separation response, but 20 mg/kg resulted in increased distress vocalizations associated with a significant decrease in activity.

Taken together, our results suggest that endogenous benzodiazepine and opiate systems play a role in modulating the separation response in infant primates.

359.10 DISSOCIATION OF TWO ASPECTS OF SEPERATION DISTRESS BY CHOLECYSTOKININ OCTAPEPTIDE. A. Weller* and E.M. Blass. Dept. of Psychology, Johns Hopkins Univ., Baltimore, MD 21218.

Acutely isolated rat pups emit ultrasonic distress vocalizations (DV) and display 'stress-induced analgesia' (SIA) as measured by a hot-plate paw-lift response. This study explored the influence of opioids and cholecystokinin (CCK) upon these responses to stress. Morphine (0.25 mg/kg i.p.) reduced DV and increased pain threshold. Exogenous sulfated CCK (1 & 2 ug/kg i.p.) selectively reduced the number of DVs, yet did not affect pain responsivity. This selectivity may imply seperate physiological pathways mediating behaviors during short-term seperation.

Opioid-CCK interactions were also examined. CCK did not antagonize the effects of morphine on either measure. On the contrary, subthreshold doses of morphine (0.125 mg/kg) and CCK (1 ug/kg as a second injection), while ineffective when injected with saline, were highly effective in reducing DV when injected in combination. CCK also strongly prevented the antagonistic effects of naltrexone on DV modified by endogenous opioids and morphine. Thus, opioid mechanisms seem to mediate both DV and SIA, while exogenous CCK selectively influences the vocalization component of the response to isolation stress.

359.11 THE RELATIONSHIP OF HORMONAL AND IMMUNOLOGICAL RESPONSES TO STRESS IN TYPE A BEHAVIOR. K.S. BLASDELL*, P. MILLS*, R.K. WALLACE, W.L. VAN ZANDT, R. SCHNEIDER*, K. WALTON, D. HILL*. Department of Physiological and Biological Sciences, Maharishi International University, Fairfield, IA, 52556.

The multidirectional communication between the nervous system, the neuroendocrine system and the immune sytem suggests that there may be differences in the hormonal and immunological responses to stress based on behavioral type. We recently reported that the proliferation response of lymphocytes to the mitogen phytohemagglutinen (PHA) showed highly variable individual response patterns during the experimental conditions of mental stress or rest. When these same subjects were divided into Type A and Type B groups, however, a significant pattern of response emerged. While Type A behavior has been associated with hyper-responsiveness of the cardiovascular system, the lymphocytes of Type A individuals appear to react and recover more slowly from stress than the lymphocytes of Type B individuals. Further, long-term practice of Transcendental Meditation technique appeared to modify the hormonal and immunological responses of Type A meditators in the direction of Type B subjects.

The present study is an extension of the previous work with the intention of exploring hormonal correlates which might influence these patterns. Serial blood samples were drawn from 23 right-handed males before and after two sessions of mental arithmetic separated by rest periods. The subjects were independently rated on the Structured Interview for Type A behavior. The immune parameters measured included PHA stimulation, total WBC and differential cell counts. Simultaneously, plasma levels of prolactin, norepinephrine, epinephrine and luteinizing hormone were measured.

ANOVA with repeated measures showed significant differences between Type A and Type B individuals across the experimental conditions on PHA response, WBC count, prolactin and epinephrine ($p = .01; .02; .0001; .01$, respectively). Further, Type A individuals showed a highly significant correlation ($p < .001$) between baseline PHA responses and the K_D for binding of [^{125}I] Iodocyanopindolol (ICYP) to the lymphocyte receptors. The PHA proliferation rate of Type As also displayed significant correlations with the levels of several hormones while Type Bs showed no consistent relationships on any of these measures.

These data indicate that behavioral type can affect the mitogenic responsiveness of lymphocytes. Furthermore, the relationship between mitogen response, neuroendocrine measures and acute stress is also dependent on behavioral type.

359.12 CHANGES IN HERPESVIRUS LATENCY IN A STRESSED POPULATION: IMPLICATIONS FOR PSYCHOLOGICAL MEDIATION OF IMMUNE RESPONSES. S. Kennedy*, J. Kiecolt-Glaser*, S. Malkoff*, L. Fisher*, C. Speicher* and R. Glaser*. (SPON: M. Torello). College of Medicine, The Ohio State University, Columbus, OH 43210.

It is becoming apparent that the immune system does not function in isolation, but instead is influenced by neural, endocrine and psychological factors, such as environmental stressors. Although the animal literature is replete with studies documenting the immunosuppressive effects of stress, there is relatively little empirical data to support these effects in humans.

The present study examined the effects of a psychological stressor, marital disruption, on cellular immune competence in 32 recently separated/divorced (S/D) males and 32 sociodemographically matched controls. Cellular immune competence was assessed by measuring plasma antibody levels (titers) to herpesviruses; typically, when the immune system is suppressed (during certain illnesses or in cases of immune disorders, for example), antibody titers are elevated, indicating virus reactivation.

Antibody titers to two herpesviruses, Epstein-Barr Virus (EBV) Viral Capsid Antigen (VCA) and Herpes Simplex Virus-Type 1 (HSV-1) were significantly elevated in the S/D group relative to controls, suggesting reactivation of latent virus as a result of a depressed cellular immune response. Serum albumin levels were comparable for both groups, ruling out the possibility that the observed differences in antibody titer were due to differences in diet or in nutritional status. In addition, self-report data indicated significantly greater depression, anxiety and loneliness (as measured by the Brief Symptom Inventory and the UCLA Loneliness Scale) in the S/D subjects.

These data suggest that psychological stressors may have negative consequences in terms of immune function, and are consistent with epidemiological data linking environmental stressors to changes in health status. Future studies will more clearly elucidate the role of neural and endocrine mechanisms involved in the immunosuppressive effects of stress.

359.13 SALIVARY CORTISOL LEVELS FOLLOWING APLLICATION OF CORTICOTROPIN RELEASING FACTOR (CRF) AND PSYCHOLOGICAL STIMULI IN HEALTHY MEN H. Lehnert, J. Beyer*, I. Gutberlet*, D.H. Hellhammer, S. Marrè*, P. Walger*, H. Vetter*. Dept. of Endocrinology, 2. Medizinische Klinik, 65 Mainz, Dept. of Physiological Psychology, University of Trier, 55 Trier and Medizinische Universitätspoliklinik, 44 Münster, FRG

The effects of CRF on salivary cortisol levels were studied in healthy young men with and without simultaneous administration of stressful stimuli. This study was performed in order to analyse the sequelae of different stressors and to study functional aspects of the hypothalamic-pituitary-adrenal feed-back system by comparison of basal, stress- and CRF-evoked cortisol concentrations.

12 healthy young male volunteers were exposed to four different situations on four consecutive days. In situation one they received a bolus of saline, in situation two 100 µg h-CRF (both single-blind). In situation three they had to perform mental arithmetics under noise distraction receiving an additional bolus of h-CRF at the end of the stress procedure (after 30 minutes). In situation four they underwent a stressful situation only and had to speak about their private and career goals in front of a sham-recording video camera (they were told that the recording was shown to speech analysts for evaluation). Blood pressure, heart rate and salivary cortisol samples were obtained every 15 minutes (and every 30 minutes during the last hour) over a course of 150 minutes. Mood and anxiety questionnaires were given before and following the CRF and stress application, respectively. Salivary cortisol was determined by a luminescence immunoassay.

Following CRF administration, salivary cortisol concentration reached a maximum after 30 minutes (from 26,2 to 44,8 nmol/l; $p < 0,015$). A similar increase was observed in situation three (by 72%), where CRF was administered following the stress. In no case had the stressful procedure any significant effect on salivary cortisol, we also did not observe an additive effect of stress and CRF. Surprisingly however, a marked and highly significant increase in salivary cortisol levels was found immediately before the beginning of the respective task, thus very likely reflecting anticipation of the task. These anticipatory increases ranged from 30 to 110% ($p < 0,005$). The integrity of the pituitary-adrenal feed-back system was demonstrated by a strong negative correlation between baseline and subsequent cortisol concentrations.

In summary, our data strongly support the salivary cortisol determination as a means for testing the pituitary-adrenal axis (e.g. by CRF application) and further demonstrate that increases in (salivary) cortisol might rather reflect anticipation of a stress than the stressful situation itself.

359.14 EFFECTS OF EXERCISE ON PLASMA ß-ENDORPHIN-LIKE IMMUNOREACTIVITY IN HUMAN. D.F. Richards* and C.A. Cahill. University of Maryland, Sch. of Nsg. Baltimore, MD. 21201.

The effects of physical stress on plasma ß-Endorphin-like immunoreactivity (ß-END-1-i) has been documented in animals and to a lesser extent in man. Presumably, stressors activate the hypothalamic/pituitary/adrenal axis to secrete ß-END-1-i into plasma. In the human, the study of this stress effect is handicapped by a number of factors. Ethical considerations limit the selection of the stressor to natural events which are thought to be stressful such medically necessary surgery. However, the degree to which these life events are stressful may vary between individuals. Therefore, the purpose of this study was to explore the effects of a standardized stressor on plasma ß-END-1-i . Twenty women were asked to walk or run on a treadmill at a rate sufficient to increase their heart rate to 75% of the calculated maximal level (75% of 220 minus age in years) and to maintain that rate for twenty minutes. Blood was collected by acute venipuncture before exercise began and at the end of twenty minutes.

Three distinct patterns of ß-END-like changes were observed. 1. In five cases, plasma levels pre-exercise were ten fold higher than those observed in the other subjects and did not change with exercise. In all of these cases more than one attempt to obtain the plasma sample was necessary. Repeated attempts to cannulate the vein may have caused ß-END-1-i to be released. Therefore, these findings were viewed as artifact and the data for these cases were not included in the statistical analysis. 2. In three cases no change in plasma levels were detected. This pattern suggests that for these individuals, the physical stressor was insufficient to activate the hypothalamic/pituitary/adrenal/axis. 3. In the majority of cases plasma levels of ß-END-1-i increase by 50% to 100% in pre and post-exercise samples. A paired t-test to compare pre and post exercise levels was carried out on the remaining 15 subjects and a statistically significant ($t=2.42$, $d.f.=28$, $p < .01$) difference in pre and post exercise levels was observed. Therefore, physical exercise sufficient to increase heart rate to 75% of the calculated capacity activates the hypothalamic/pituitary/adrenal axis and may be a useful tool in future studies of the effects of stress in the human.

359.15 COMPARISON OF TWO ANTISERA FOR MEASURING β-LPH IN HUMAN PLASMA. E.H. Mougey*, L.M. Lambe*, M.A. Oleshansky and J.L. Meyerhoff. (Spon: C.B.G. Campbell). Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307-5100.

Various psychological and physical stressors have been shown to elicit increases in plasma levels of hormones secreted from the the pituitary (prolactin, GH, ACTH, β-EP and β-LPH). We have previously reported increases in levels of β-EP and β-LPH in plasma samples from military volunteers during oral exams. These plasma samples were assayed by RIA using a commercial kit for β-EP (NEN Corp) following an extraction procedure which separates and concentrates these peptides from 1 ml of plasma. The antibody (Ab) in this kit cross-reacts completely with β-LPH.

To verify the validity and specificity of the β-LPH assay used above we also set up an RIA method using a β-LPH Ab obtained from C.H. Li. Human β-LPH obtained from Peninsula Labs was iodinated and purified on Sephadex G-50. The standards (10-200 pg β-LPH) and samples were added in a total volume of 200 ul. After addition of trace solution and first Ab the tubes were incubated for 3 days at 4°C. Second Ab (overnight at 4°C) was used to separate free from bound antigen. Blood samples were obtained from soldiers who were appearing before a "Soldier of the Month" board. These boards are rigorous, formal interviews conducted by a group of higher-ranking non-commissioned officers. Samples were collected at two early time periods on the day of the board (X,Y), at 20 min prior to entering the interview room (A), 5 min after beginning the interview (B), 20 min after beginning the interview (C) and at 5 min (D) and 20 min (E) after leaving the interview room. Plasmas were treated with aprotinin and stored at -70°C until assayed.

Plasma levels of β-LPH remained constant at the X,Y and A time points, showed a marked increase (50%) at B, remained elevated at C and returned to pre-interview levels at time points D and E. Comparison of β-LPH levels obtained after direct assay of 100 ul of plasma vs assay of extracts of 1 ml of plasma showed that the specificity and sensitivity of the β-LPH Ab is not sufficient to allow direct assay of human plasma samples. Furthermore, the Ab exhibited considerable cross-reaction with β-EP. However, the addition of 500 pg of β-EP to a plasma pool was not detectable in the β-LPH fraction following extraction. The plasmas from seven subjects were extracted and assayed with the β-LPH Ab and compared with values obtained with the β-EP Ab. All values were corrected for recovery. At time points X,Y,A,D and E the mean values for β-LPH by the two methods were comparable. At time points B and C values obtained with the β-EP Ab were slightly higher (7-14%) reflecting some contamination of the β-LPH fraction with β-EP. We concluded that the β-LPH Ab is satisfactory for the assay of human plasma provided that an extraction resulting in concentration of the β-LPH and separation from β-EP is performed. The β-EP Ab is also useful for measuring β-LPH in extracted samples except when high levels of β-EP are encountered.

359.16 STRESS-INDUCED ALTERATIONS OF GAMMA-MELANOTROPIN IN THE RAT PITUITARY. J.H. Meador-Woodruff*, E.A. Young*, N. Ling and H. Akil (Spon: R. Bradley). Mental Health Research Institute and Department of Psychiatry, University of Michigan Medical Center, Ann Arbor, MI, 48109-0720.

Gamma-melanotropin (γ_3MSH) is a 25 residue peptide in the N-terminal domain of the β-endorphin (BE)/ACTH precursor proopiomelanocortin (POMC), capable of potentiating the steroidogenic effect of ACTH on the adrenal cortex. It exists in rat pituitary as a 5K form (fully processed, glycosylated γ_3MSH) and an 11K form (γ_3MSH extended with the extreme N-terminal fragment of POMC). Gamma-MSH has been previously shown to be co-released with BE and ACTH following acute stress or treatment with secretagogues such as CRF. As this peptide evidently has a modulating role in the pituitary-adrenal axis, we examined the effect of chronic stress on pituitary and plasma forms of γ_3MSH in the rat. Male Sprague-Dawley rats were subjected to daily morning sessions of 30 minutes of swimming in 30°C water for 8 or 14 days. 24 hours following the last session, the rats were sacrificed by decapitation. Pituitaries were rapidly removed and dissected into anterior (AL) and intermediate (IL) lobes. Trunk blood was collected in EDTA-containing tubes and plasma was separated and collected. Both pituitaries and plasma were quickly frozen on dry ice and stored at -80°C. Plasma was processed using Sep-Pak C_{18} cartridges, and tissue by acetone/HCl extraction. Aliquots of these materials were subjected to Sephadex G-50 column chromatography, and aliquots of each fraction as well as from the crude extracts were assayed for γ_3MSH-IR by a specific RIA we have developed. After 8 or 14 days of chronic swim stress, the total content of γ_3MSH-IR in IL increased by 150-200%. Column chromatography revealed that unstressed animals had predominantly 5K γ_3MSH-IR in the IL, and stressed animals had elevations of both 5K and 11K forms; the induction seen in stressed animals was attributable primarily to an increase of the 11K fraction. For comparison, the BE content in IL shifted from N-acetyl BE 1-27 to N-acetyl BE 1-31 with this same stress. The γ_3MSH-IR in AL following chronic stress was minimally elevated; only 11K and larger forms were observed in both unstressed and stressed groups, and no processing shift was appreciated. The plasma levels of γ_3MSH-IR were identical between the two groups, existing as both 5K and 11K forms, with the 5K fraction predominating in both groups. Chronic swim stress thus appears to selectively induce γ_3MSH production in the IL, without a concomitant alteration in AL stores. Further, chronic swim stress followed by a 24 hour recovery period does not alter circulating levels or forms of γ_3MSH-IR. The possibility that an acute stress following this chronic stress paradigm has manifestations in plasma or the IL is currently under investigation.

359.17 STRESS INCREASES PLASMA CYCLIC AMP LEVELS IN GOLDEN HAMSTERS. K.M. Levy, B.N. Bunnell, E.H. Mougey*, M.A. Oleshansky and J.L. Meyerhoff. Dept. Psychology, U. Georgia, Athens, GA 30602 and Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307.

Cyclic AMP is a second messenger which mediates the cellular response to several neurohumors. Plasma levels of cyclic AMP have been reported to increase in response to stress in humans as well as in rats. As it may prove a useful indicator of physiological response to stress, we measured the plasma cyclic AMP response to stress in hamsters. Since catecholamines (which might stimulate plasma cyclic AMP increases) are increased many fold by decapitation, we took blood samples via chronically implanted jugular catheters.

Although the older literature indicates that cortisol is the primary glucocorticoid secreted by hamsters, more recent data show that their adrenal cortices secrete measurable amounts of both cortisol and corticosterone, and that acute restraint stress produces elevations in both steroids (Ottenweller, J.E., et al., Life Sciences, 37:1551, 1985). In order to compare the plasma cyclic AMP response with more established stress indicators, we also measured plasma cortisol and corticosterone responses to acute footshock stress.

Twelve adult male golden hamsters were implanted with jugular catheters under nembutal anesthesia. Following a 72 hour recovery period, 6 animals were subjected for 20 min to intermittent 4 sec, 1 mA footshock delivered on a 60 sec variable time schedule in sound attenuated shock chambers. The remaining animals served as home cage controls. Immediately following exposure to footshock, the hamsters were returned to their home cages and 3 ml of blood was drawn from each animal. All experimental procedures were completed during the first two hours of the light phase of the daily 12:12 LD cycle to minimize circadian variation. After centrifugation of heparinized blood, plasma for cyclic AMP assay was incubated for 10 min with NaAc buffer at 90°C to inactivate phosphodiesterase. Samples were stored at -18°C until assayed by RIA.

		Footshock	Control
cAMP	(pm/ml ± SEM)	68.1 ± 8.1	33.3 ± 9.9
Cortisol	(ug% ± SEM)	6.9 ± 0.6	1.4 ± 0.5
Corticosterone	(ug% ± SEM)	4.8 ± 0.7	1.8 ± 0.4

Footshock doubled plasma levels of cyclic AMP and increased plasma levels of both steroids as well. It will be important to identify the tissue source of the increase in plasma cyclic AMP. Numerous studies have shown that stress increases cyclic AMP in the anterior pituitary, but the increase in plasma cyclic AMP may reflect increases in other tissues, possibly mediated via enhanced sympathetic nervous system activity. Plasma cyclic AMP levels may prove a useful indicator of the physiological response to stress in hamsters.

359.18 PSYCHOLOGICAL STRESS INCREASES HEART RATE AND PLASMA LEVELS OF CYCLIC AMP IN MAN. J.L. Meyerhoff, M.A. Oleshansky, E.H. Mougey*, C.B. Wormley*, H.R. Smith*, L.K. Wittig*, T. Maxwell-Irving* and R.C. Perez*. Neurochemistry & Neuroendocrinology Branch, Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

We have previously reported that physical exertion produces increases in plasma levels of catecholamines and cyclic AMP. The present study was undertaken to determine whether cyclic AMP would also rise during the purely psychological challenge of a competitive oral examination. The oral exam is a rite of passage in several professions. As part of their training and preparation for promotion boards, soldiers are encouraged to appear before "Soldier of the Month" boards. These are contests held monthly to select and honor an outstanding soldier based on rigorous competitive interviews conducted by a panel composed of higher-ranking non-commissioned officers. The winner is selected on the basis of knowledge of job-related subject matter, personal appearance and quality of oral presentation. Twelve contestants volunteered to be studied during these competitions and gave written informed consent for heart rate monitoring and blood sampling during the 30 min interview. Heart rate was monitored using a PMS-8 portable physiological monitoring system (Vitalog Corp., Redwood City, CA). An i.v. needle was inserted in the median cubital vein and blood was collected through non-thrombogenic tubing attached to a Cormed pump (Medina, NY) which withdrew blood continuously at 0.1 ml/min between samples and at 5.0 ml/min at discrete sampling times. Blood samples (10 ml) were collected at 5 time points: after 20 minutes of sitting in a quiet waiting room prior to the interview (REST 20); 5 minutes after sitting in the exam room and beginning the interview (EXAM 5); 20 minutes after beginning the interview (EXAM 20); 5 minutes after returning to the waiting room and being seated (POST 5); and after sitting in the waiting room for 20 minutes (POST 20). Samples were centrifuged at 4°C and an aliquot of plasma was heated at 90 C for 10 min to inactivate phosphodiesterase. After centrifugation to remove the precipitate, the supernatant was frozen at -70°C until cyclic AMP levels were determined by RIA.

	REST 20	EXAM 5	EXAM 20	POST 5	POST 20
H.R.	86 ± 2.5	114 ± 5.4*	101 ± 4.0*	93 ± 3.4	89 ± 3.3
cAMP	32 ±3.6	51 ± 6.2*	39 ±4.0	35 ± 3.3	30 ± 3.6

Heart rate (HR) given in bpm, cyclic AMP in pm/ml, mean ± s.e.m.
Data analyzed by ANOVA, then by paired t-tests. N = 12, * = $p<0.001$.

Heart rate increased 33% in the first 5 min of the oral exam and remained significantly elevated throughout the exam. Plasma levels of cyclic AMP increased 59% in the first 5 min of the exam, but unlike heart rate, did not remain significantly elevated throughout the exam. We have recently reported increases in plasma catecholamines during oral exams, and the plasma cyclic AMP response may be related to sympathetic nervous system responses.

360.1 RETINAL ACTIVITY MODULATES EYE GROWTH: EVIDENCE FROM REARING IN STROBOSCOPIC ILLUMINATION. Michael D. Gottlieb and Josh Wallman. Biology Department, City College of CUNY, New York, NY 10031.

Various visual deprivations cause increased vitreous chamber growth resulting in myopia. Providing vision to the rapidly growing eye stops the excessive elongation. Does this effect of vision involve subtle neural processing of the visual information or does it result from the increased retinal activity that unimpaired vision brings? If the latter is the case, increasing the retinal activity in an animal deprived of form vision should reduce the growth toward myopia.

In chicks, visual field restriction produces eye enlargement and myopia only in the region of the retina that has been deprived of form vision. We infer that retinal activity in the deprived region is lower than normal since the retina views a homogeneous field rather than the heterogeneity of the real world. We here report on the effects of artificially increasing the activity level of a form-deprived region of the retina by rearing animals with stroboscopic illumination.

Chicks were raised for 1 week from hatching with an occluder over one eye that deprived the nasal retina of form vision. Ambient lighting was either a 10 Hz strobe, incandescent, or both, for 14 hours daily. All eyes were refracted at 30° temporal to the optic axis, i. e., in the deprived region of the retina.

Stroboscopic illumination greatly reduced the degree of experimental myopia in the region of the retina that had been deprived of form vision. The partially occluded eyes of chicks that had been subjected to stroboscopic plus incandescent light were hardly myopic in the region of the retina that had been deprived of form vision (median: -2.0 diopters, D, n=10); similar results were obtained after 2 weeks (-0.9 D, n=6) and with stroboscopic illumination alone after 3 weeks (-2.6 D, n=6). In contrast, the partially occluded eyes of chicks raised with incandescent light were myopic in the region of the retina that had been deprived of form vision (-13.5 D, n=11), as were those raised with a 100 Hz strobe plus incandescent light for 2 weeks. The unoccluded eyes, whether raised with incandescent light or incandescent plus stroboscopic light, were not myopic (+2.2 D and +2.9 D, respectively).

Two interpretations of these results are that some class of retinal neurons actively inhibits growth of the vitreous chamber, or that this growth depends on the overall activity of the retina. In either case, one can speculate that, during normal growth, the increased retinal activity elicited by a sharply focused image may stop the enlargement of the vitreous chamber when emmetropia is reached. (Supported by NIH EY 02727)

360.2 DENDRITIC DEVELOPMENT OF CHICK RETINAL GANGLION CELLS. S.M. Fraley. Dept. of Ophthalomology, New York Medical College, Valhalla, NY 10595

The development of ganglion cell dendrites in embryonic chick retina was studied in flatmounted retinae labeled retrogradely with horseradish peroxidase (HRP) and reacted with cobalt intensification of diaminobenzidine. Although the retrograde HRP transport method has the advantage of selectively labeling retinal ganglion cells, their dendritic trees often remain incompletely labeled when the enzyme is applied at some distance from the retina. In the present studies, an *in vitro* labeling procedure has been developed which permits HRP to be applied directly to the optic nerve immediately behind the eye. In addition to Golgi-like filling of the dendritic arbors, this procedure also affords control over the density of ganglion cell label. Thus ganglion cell classes were identified in retinal preparations labeled from HRP application to the whole optic nerve and the dendritic morphology of individual cells was analyzed in detail in preparations labeled relatively sparsely following HRP application to selective portions of the nerve.

Ganglion cells examined at the fourth day of incubation (E4) showed axons without discernible dendrites. Dendrites at E8-E9 were characterized by their thick-stemmed arbors, growth cones, and initial extension in the ganglion cell layer. Subsequent profuse growth was characterized by an increase in dendritic fields and extensions into the inner plexiform layer, and by E12-E13 ganglion cells showed distinctive dendritic morphologies. Preliminary analyses have identified at least four classes of ganglion cells: 1) a cell type located preferentially near central retina with primary dendrites extending from a unipolar soma, 2) a cell type with small round soma and dendritic field whose thin arbors extend radially from the soma, 3) a cell type with two or three thick primary dendrites extending bilaterally from an elliptical soma, and 4) displaced ganglion cells with large dendritic fields whose arbors extend radially from the soma.

360.3 CENTRIFUGAL FIBER PATTERNS IN LATE EMBRYONIC CHICK RETINA. V.M. Berthoud and S.M. Fraley. (SPON: F.E. Horvath) Dept. of Ophthalmology , New York Medical College, Valhalla, NY 10595.

Previous studies of centrifugal fibers in the avian retina have shown two types of terminal arborizations, described as divergent and convergent, that make synaptic contact primarily with amacrine cells. It is generally believed that terminal arborization in the inner nuclear layer emanates from a single parent axon. The present report describes the existence in chick of extensive intraretinal collateralization of the centrifugal fibers. It focuses on the patterns observed at hatching (E20-E21), a time when retinal morphology appears relatively mature.

It has been possible to fill the fine processes of centrifugal axons and the dendritic arbors of retinal ganglion cells using an *in vitro* technique to label the optic nerve with horseradish peroxidase (HRP). Analyses of labeled flatmounted retinae indicate that many centrifugal fibers arborize in a manner similar to that described by earlier workers. Thus single axons descending through the inner plexiform layer may form either compactly tufted arbors (convergent-type) or extensive, looping arbors (divergent-type) in the inner nuclear layer. In addition, many axons leaving the optic fiber layer issue collaterals which course obliquely for 1 cm or more through the inner plexiform layer. The collaterals in turn give off multiple short terminal processes which end in clusters of bouton-like swellings.

The function of extensive centrifugal fiber collaterals is as yet unknown although it may be speculated that they serve to enhance lateral interaction capabilities. Indeed, collateralization may provide an anatomical substrate for a physiologically defined peripheral effect similar to that described by McIlwain (J. Neurophysiol. 27: '64) in mammalian retina.

360.4 DEVELOPMENT OF SEROTONIN N-ACETYLTRANSFERASE ACTIVITY IN CHICKEN RETINA: LIGHT-DARK DIFFERENCE, CIRCADIAN RHYTHMICITY, AND EFFECT OF DIBUTYRYL CYCLIC AMP. P. Michael Iuvone, Dept. of Pharmacology Emory Univ. Sch. Med., Atlanta, GA 30322.

Serotonin N-acetyltransferase (NAT) is a key regulatory enzyme in the biosynthesis of melatonin in retina. In retina, as well as in pineal, NAT activity is regulated as a circadian rhythm, with peak activity at night. The nocturnal increase of NAT activity appears to occur by a cyclic AMP-dependent mechanism. To examine the development of regulation of NAT activity in chick retina, eggs were incubated under a 12 h light-dark cycle. NAT activity was low from embryonic (E) day 7-17. Daytime levels increased to a maximum at about day E20 and then declined slightly to post hatch (PH) day 3. No significant light-dark differences were observed until E20, when activity in the dark-period was 60% higher than that in the preceeding light period. The light-dark difference increased in magnitude markedly on the next day, the day of hatching, and continued to increase to a 6-fold difference by PH day 3. No further increase in magnitude was observed up to 4 weeks PH.

Circadian rhythmicity of NAT activity appears to develop at or prior to hatching. The mid-day vs mid-night difference in retinal NAT activity of chicks exposed to constant darkness was approximately 2-fold at PH day 2, PH day 6 and PH 4 weeks. Chicks exposed to constant darkness from hatching (exposed to light only *in ovo*) also displayed a 2-fold day-night difference on PH day 1.

To determine if the molecular mechanisms for increasing NAT activity develop prior to the development of light-dark differences, E14 retinas were incubated in vitro for 5 hours with or without dibutyryl cAMP and IBMX. Dibutyryl cAMP and IBMX elicited a significant (approx. 6-fold) increase in NAT activity.

These studies indicate that light-dark differences in NAT activity and entrainment of the circadian clock that regulates the NAT activity rhythm develop prior to hatching. Development of the cyclic AMP-dependent mechanism for increasing NAT activity appears to significantly preceed that of rhythmicity, suggesting that the onset of rhythmicity may be related to the onset of photoreception or development of the clock in the chick retina.

360.5 DEVELOPMENTAL CHANGES IN ULTRAVIOLET PHOTOSENSITIVITY IN RAINBOW TROUT. Craig W. Hawryshyn, Margaret G. Arnold*, Duane J. Chiasson*, and Patti C. Martin*. Department of Psychology, McMaster University, Hamilton, Ontario CANADA L8S 4K1.

A number of recent studies have reported the presence of ultraviolet (UV) photoreception (mediated by UV-sensitive cones) in vertebrates. Further work has shown that the ocular media in some of these species transmits UV radiation and that this transmission can greatly influence UV photosensitivity. The present study examines the changes in UV photosensitivity that occur during the growth of Rainbow trout.

We used the heart-rate conditioning technique (Hawryshyn and Beauchamp 1985) to measure spectral sensitivity in immobilized Rainbow trout (Salmo gairdneri). The Rainbow trout (Spring Valley Trout Farm, New Dundee, Ontario) utilized in the present study belonged to the same age cohort but varied slightly in size (40-90 grams body weight, 16.0-19.5 cm standard length). We attempted to "isolate" the sensitivity (340-540 nm range) of the UV-sensitive mechanism with a yellow (550 nm long pass) plus blue (460 nm 10 nm half max) colored background.

Two fish (44 and 60 g) exhibited a UV peak in the 380-400 nm region (λ max 390 nm visual pigment absorption curve vitamin A_2 correlates well), and a blue-sensitive mechanism shoulder in the 440-540 nm region (λ max 453 nm visual pigment absorption curve vitamin A_2 correlates well). On the other hand, two additional fish (both 90 g) showed blue-sensitive mechanism activity and lacked any evidence of a UV-sensitive mechanism peak. Spectral sensitivity of the two fish showing UV photosensitivity was remeasured (using same colored backgrounds as above) approximately one month later (average weight gain 25%). Both fish exhibited a loss of the UV peak and had a sensitivity that now conformed to the blue-sensitive visual pigment absorption curve.

There are several hypotheses which can account for this loss of UV photosensitivity in trout: (1) Increases in ocular media pigment density with size. (2) Selective photoreceptor damage with increasing vulnerability related to size or metabolic age. (3) Changes in the pattern of the retinal mosaic with development. Lyall (1957) and more recently, Bowmaker and Kunz-Ramsey (personal communication) have reported changes in the retinal mosaic of trout with age, especially with the accessory single cone which they believe contains the UV-sensitive visual pigment.

360.6 DOPAMINE INDUCES LIGHT-ADAPTIVE RETINOMOTOR MOVEMENTS IN BULLFROG CONES AND RPE VIA D2 AND D1 RECEPTORS. Allen Dearry, Sheldon Miller, and Beth Burnside. Department of Physiology-Anatomy and School of Optometry, University of California, Berkeley 94720.

We have been investigating the mechanisms of light and circadian regulation of retinomotor movements in lower vertebrates. We previously reported that dopamine induces light-adaptive retinomotor movements in green sunfish by acting on D2 receptors on photoreceptors and retinal pigment epithelial (RPE) cells in this species. Since dopamine is the predominant catecholamine in amphibian as well as in fish retinas, we have conducted similar experiments to examine the effect of dopamine on retinomotor movements in the bullfrog Rana catesbiena.

Bullfrogs were maintained on a 12 hr light/dark cycle, and experiments were begun 3 hr into the dark period. Retinas and eyecups with attached RPE were isolated from dark-adapted bullfrogs and cultured separately for 60 min in constant darkness. Following fixation, cone and RPE pigment retinomotor positions were determined.

In Ringer solution alone, cones contracted spontaneously to their light-adapted positions. We previously reported that such light-independent cone contraction also occurs in isolated fish retinas. This light-independent cone contraction could be prevented by adding IBMX or forskolin to the Ringer solution. In the presence of IBMX, dopamine ($\geq 10^{-6}$M) induced light-adaptive cone contraction. Dopamine-induced contraction was inhibited by sulpiride (a D2 antagonist) but not by SCH23390 (a D1 antagonist). In addition, LY171555 (a D2 agonist) induced cone contraction, whereas SKF38393 (a D1 agonist) was ineffective. These results suggest that dopamine induces light-adaptive cone contraction in bullfrog retinas by acting on D2 receptors.

RPE maintained its dark-adapted retinomotor position during culture in constant darkness. Dopamine and SKF38393, but not LY171555, induced light-adaptive pigment dispersion. Dopamine-induced dispersion was inhibited by SCH23390 but not by sulpiride. Furthermore, cAMP, IBMX, and forskolin also induced light-adaptive pigment dispersion. These results suggest that dopamine induces light-adaptive pigment dispersion in bullfrog RPE by acting on D1 receptors. Elevated levels of cAMP in bullfrog RPE are associated with light-adaptive retinomotor movement.

In summary, our results indicate that dopamine elicits light-adaptive retinomotor movements in fish and bullfrogs. In both species, dopamine induces cone contraction via D2 receptors. In both, dopamine has a direct effect on the RPE. However, dopamine induces pigment dispersion in bullfrog RPE through an interaction with D1 receptors, whereas dopamine interacts with D2 receptors on fish RPE. 360.7 EVIDENCE THAT LIGHT STIMULATES ENDOGENOUS DOPAMINE RELEASE AND METABOLISM IN RETINAS OF FROGS (XENOPUS LAEVIS). Jeffrey H. Boatright*, Martha J. Hoel*, and P. Michael Iuvone (SPON: F.A. King). Emory Univ. Sch. Med., Dept. of Pharmacology, Atlanta, Georgia 30322.

Recent pharmacological studies on the regulation of a melatonin synthesizing enzyme, serotonin N-acetyltransferase (NAT), in frog retina, suggest that the dopamine (DA) receptors that regulate NAT activity are occupied in light-exposed retinas but not in dark-adapted retinas (Iuvone et al., Brain Res., in press). To obtain a more direct measure of the effect of light exposure on DA activity in frog retina, we examined retinal tissue levels of DA and 3,4-dihydroxyphenylacetic acid (DOPAC), a principal DA metabolite, and the release of endogenous DA in light and dark. DA and DOPAC were measured by HPLC with electrochemical detection. Postmetamorphic Xenopus laevis were maintained on a 12 h light-dark cycle. In the first experiment, DA and DOPAC levels were determined in retinas of frogs dissected during the last 30 min of the light period or 2 hrs into the dark period. The concentrations of DA and DOPAC in light were 41% and 170%, respectively, higher than those in darkness. In the second experiment, eye cups were prepared during the last hour of the light period. Beginning at the time of light offset, eye cups were preincubated in darkness for 30-45 min. Following preincubation, they were transferred to fresh medium and incubated for 1 hr in light or dark. DA and DOPAC levels of retinas incubated in light were significantly higher (16% and 100%) than those in darkness. Analysis of DA in incubation medium following extraction and concentration indicated that endogenous DA overflow from eye cups was 3 fold higher in light than in dark. These studies suggest that DA release and metabolism in frog retina is stimulated by light exposure.

360.8 DO NEUROFILAMENT PROTEINS PLAY A ROLE IN CLOCKWISE GROWTH OF XENOPUS RETINAL NEURITES? P. Grant and Y. Tseng. Institute of Neuroscience, University of Oregon, Eugene, ORE 97403.

In an earlier in vitro study we found that Xenopus retinal fibers undergo developmental changes in growth behavior (Grant, P. and Tseng, Y., Abst. Soc. Neurosci. 12:119, 1986). While young embryonic neurites from explanted optic vesicles display no clockwise growth under any conditions tested, neurites from progressively older retinal explants show clockwise growth on laminin and fibronectin in serum-free medium. One hypothesis for this difference is that only mature neurites with cytoskeletons of helical neurofilament (NF) bundles are capable of clockwise growth. This implies that embryonic neurites, which show no clockwise growth, either lack all or some NF proteins, or are unable to assemble them if present. The former possibility seemed testable since synthesis of NF proteins in rat retina is developmentally regulated: the large 200K NF protein appears several days after the 140K and 68K (Shaw, G. and Weber, K., Nature, 298:277, 1982). Accordingly, Xenopus retinas of different stages (25 to 50) were cultured under conditions promoting clockwise growth. After the initial neurite outgrowth, explants were tested immunocytochemically with monoclonal antibodies against mammalian NF proteins. Antibodies to vimentin, GFAP, actin and tubulin were also tested. All but the 68K antibody reacted positively with retinal neurites at all stages. Contrary to the predictions of the hypothesis, the two large NF epitopes are present throughout development while the 68K epitope is undetectable suggesting that clockwise growth does not depend on a NF cytoskeleton. It is uncertain whether the antibodies are reacting with soluble NF antigens or proteins assembled into NF bundles. Alternatively, other non-NF antigens with similar epitopes may be present in Xenopus retinal neurites from the very beginning of ganglion cell differentiation. The data do not resolve these alternatives.

360.9 AN IN VITRO MODEL FOR QUANTITATIVE ANALYSIS OF RETINAL NEURON GROWTH IN THE CAT. P. Read Montague* and M.J. Friedlander
Neurobiology Research Center and Dept. of Physiology & Biophysics, University of Alabama at Birmingham.

The morphology of retinal ganglion cells (RGC) has been extensively studied in the intact retina. These cells form distinct morphological classes with regular arrangements of dendritic territories. The mechanisms by which these morphological types are established and the interactions that determine territorial boundaries of dendritic fields are not fully understood. We have developed an in vitro system to quantify and model RGC growth and development in a well controlled environment. Cat RGCs are particularly suitable for this type of study since a wealth of data on the distribution of projections of the various morphological types exist and the distribution of dendrites within the retina is essentially planar - thus a 2-dimensional cell culture environment does not necessarily force the RGC to assume aberrant morphological features. RGCs are obtained from cats between 3-14 months using a modified "peeling" procedure (Shiosaka et al., J. Neurosci. Meth. 10:229-235, 1984.) and/or enzymatic dispersion. RGC enriched fractions of cells are grown at low density on coverslips above a pre-established glial culture monolayer or directly on the monolayer on an inverted microscope stage. The development of individual cells is tracked for up to 2 weeks using time-lapse video phase microscopy. The continued growth of the glial monolayer and the growth of retinal glia is prevented by pulsed application of the mitotic inhibitor, cytosine-arabinofuranoside. Cultures are examined for immunoreactivity to neurofilament and glial fibrillary acidic protein (GFAP). All cells identified as neurons on morphological criteria were GFAP negative and neurofilament positive. The elaboration of neurites by these cells is being studied with respect to 1) pattern development of isolated individual cells' neurites in real time, 2) the effects of neighboring cells on an individual cell's neuritic development and 3) the degree of similarity of in vitro neuronal form to that observed in the intact retina. A predictive constrained diffusion model that includes aspects of the method of Mandelbrot ('fractal analysis') is used to characterize the cells' neurite coverage. This method assigns a numerical value to describe the plane filling nature of an individual cell's neuritic structure. Experiments are currently underway to pre-label the RGCs with fluorescent markers prior to the establishment of the cultures - this will allow definitive identification of the RGCs as distinct from the other retinal neurons in the culture.

360.10 RELATIONSHIP BETWEEN SMALL PUNCTATE LESIONS AND IMMEDIATE SHIFTS IN VISUAL ACUITY IN THE PRIMATE RETINA. D.O. Robbins, H. Zwick*, and R.C. Long*. Department of Psychology, Ohio Wesleyan University, Delaware, OH 43015 and Division of Biorheology, Letterman Army Institute of Research, San Francisco, CA 94129

Both long-term and transient shifts in visual acuity have been observed following exposure of the primate retina to CW and Q-switched lasers. Our previous results using Argon, HeNe, and Krypton CW lasers have shown that the duration of the initial deficit following foveal exposure was related to the energy of the 100 msec flash. Typically, immediate postexposure acuity was depressed by as much as 60% from its pre-exposure level and often this deficit lasted 45 minutes or longer for energies significantly below the ED50 level for distinct fundoscopic damage. Permanent shifts in acuity under a variety of viewing conditions have been shown to exist below the ED50 energy level and without evidence of fundoscopic changes.

More recently we have examined the consequences that small, but distinct, punctate foveal lesions have on acuity. Using minimal diameter, single, 15 nsec, Nd/YAG (514.5 nm) pulses only very slight and transient changes in acuity were noted although the animal's ability to maintain a consistent threshold acuity in the exposed eye was often affected. In the case of CW exposures, each individual flash was 100 msec in duration and while it was of lesser energy, the energy was presented for a much longer duration resulting in involuntary eye movements spreading the minimal diameter spot over a larger retinal region than that which occurred when using 15 nsec pulses. The increased variability in threshold acuity of animals exposed to single, Q-switched pulses could be explained in terms of a problem the animals might experience in localizing the target on an area of fovea outside that exposed by the laser pulse. We have also examined the effects that multiple pulses, producing larger areas of disruption, have on the ability of animals to maintain a stable, threshold acuity. As expected, as the total area of foveal involvement increases, the animal's threshold acuity decreases and becomes more reminiscent of those observed using CW flashes. A morphological verification of the area of involvement and its relationship to acuity will be presented.

We have also explored the extremely transient and immediate changes acuity during the first several seconds following both CW and Q-switched exposure as well as those more permanent changes which resulted from exposure to energies the ED50 level.

360.11 IMPAIRED LIGHT SENSITIVITY IN HYPOPIGMENTED ANIMALS. G.W. Balkema and U.C. Dräger. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

In previous work we have shown that pearl mutant mice, as well as albino mice and rats, have elevated visual thresholds in the dark-adapted state. Now we extend these findings to several other hypopigmentation mutants of the mouse, albino rats and rabbits. We compared incremental visual thresholds of normal black mice (C57BL/6J +/+) and the following mutants on the same background: beige bg/bg); pale ear (ep/ep); albino (c^{2J}/c^{2J}); in addition, we recorded thresholds from steel (Sl/Sl^{D}) and W-mice, two mutants with normal neural-tube derived pigmentation of the retinal pigment epithelium (RPE) but without any neural-crest derived pigment in the choroid or the rest of the body. Thresholds were measured, using tungsten-in-glass electrodes, from single units in the superior colliculus. The dark-adapted thresholds of the normally pigmented mice were similar to those reported in earlier studies. The albino mice were 25 times less sensitive than black mice; the pale ear mutants were 20 times less sensitive; beige mutants were 11 times less sensitive; and steel mutants were five times less sensitive than black mice. The mean threshold of dark-adapted black mice was 0.0092 cd/m^2. (SEM = 0.0062 < 0.0092 < 0.013); the mean threshold of albino mice was 0.23 cd/m^2 (SEM = 0.19 < 0.23 < 0.28), and the other mutants fell between black and albino. Cell counts from the outer nuclear layer in albino mice were not significantly different from those in black mice, and no outer-segment damage was found in albino retinas, thus excluding overt light damage as an explanation for the elevated thresholds. Incremental thresholds were also measured in hooded rats and compared to those in albino rats. The albino rats were 64 times less sensitive than the pigmented hooded rat in the dark-adapted state. The mean threshold for the hooded rat was 0.0012 cd/m^2 (SEM = 0.00082 < 0.0012 < 0.0016), and the mean threshold for the albino rat was 0.073 cd/m^2 (SEM = 0.049 < 0.073 < 0.11). Similarly, incremental thresholds were found to be elevated 40 times in albino rabbits (New Zealand-White) compared to pigmented (Dutch-Belted) controls; the mean dark-adapted threshold for the albino was 0.0008 cd/m^2 compared to 0.00002 cd/m^2 for the pigmented rabbit.

The light sensitivity deficit was roughly proportional to the reduction of melanin pigmentation both in the animals' RPE and choroid. This allows the following two tentative conclusions: first, the melanin pigment external to the photoreceptors influences retinal sensitivity; and secondly, this influence depends not only on the melanin content of the RPE, which is in close contact with the photoreceptors, but also on the melanin content of the choroid, which contains the blood vessels for nutrient supply to photoreceptor outer segments. Supported by EY01938 and EY05777.

360.12 **CYTOCHROME OXIDASE ACTIVITY IN THE DIABETIC RAT RETINA.** R.B. Caldwell, S.M. Slaprick*, and C. Uphoff*. Department of Anatomy and Neurobiology, The University of Tennessee, Memphis, TN 38163.

In the retina, a vascular barrier system analagous to the blood-brain barrier is present, and in diabetic patients alterations in this system contribute to a variety of visual problems. Permeability increases have been documented in both diabetic patient and animal retinas, but relatively little is known about the specific sites and cellular mechanisms of such alterations. Therefore, we have investigated the possibility that changes in active transport may contribute to increased permeability across the blood-brain barrier in diabetic retinas. Since activity of mitochondrial cytochrome oxidase has been demonstrated to be a reliable indicator of cellular metabolic activity and can therefore be correlated with energy requiring transport activity, we have used quantitative cytochemical techniques to localize this enzyme in retinas of spontaneously diabetic and control rats. In a previous study (ARVO, '87), we found that cytochrome oxidase activity is substantially increased within the retinal pigment epithelium (RPE) of diabetic rats. We have now compared the changes in mitochondrial cytochrome oxidase activity levels within the RPE with those in retinal photoreceptor inner segments.

Mitochondria were counted and assigned levels of cytochrome oxidase reactivity as dark, moderate, or light (Carroll and Wong-Riley, '84). In RPE cells of diabetic retinas, dark mitochondria totaled 52% compared with 34% in control retinas ($X^2 = 89.44$, $p < 0.001$). In photoreceptor inner segments of diabetic retinas, dark mitochondria totaled 17% compared with 14% in the controls ($X^2 = 2.30$, $p > 0.05$). This similarity of activity within the photoreceptor inner segments suggests that the increases in activity in the RPE are due to an alteration in blood-brain barrier function rather than a generalized increase in retinal metabolic activity.

A second study investigated the possible relationship between the increase in cellular metabolic activity and changes in RPE basal membrane surface area known to occur in diabetic rats (Grimes & Laties, '80; Grimes et al., '84). Stereological techniques were used to measure plasma membrane surface area at the basal aspect of the cells. This measure was then correlated with mitochondrial cytochrome oxidase activity within the same cell. RPE cells with significant increases or decreases in membrane surface areas were observed in the diabetic retina; however, the relationship between mitochondrial cytochrome oxidase activity and surface area was the same in the diabetic RPE ($r = 0.20$) as in the control ($r = 0.18$).

In summary, the demand for ATP appears to be increased in the diabetic RPE, suggesting that an increase may occur in energy requiring transport activity across this component of the blood-retinal barrier. This change does not appear to be due to alterations in membrane surface area which occur in diabetic RPE cells. (NIH EY-04618 and The Juvenile Diabetes Foundation).

360.13 ACETYLCHOLINE STIMULATES PHOSPHATIDYLINOSITOL TURNOVER IN RAT RETINA. S.M. Moroi*, M.H. Neff and N.H. Neff. Departments of Pharmacology and Pathology, The Ohio State University College of Medicine, Columbus, OH 43210.

Receptor activated phosphatidylinositol (PI) hydrolysis is a common mechanism for transmembrane signalling by various neurotransmitters and neuromodulators in brain. We report that acetylcholine (ACh) stimulates inositol 1-monophosphate (IP_1) accumulation two- to threefold above basal level in the rat retina. Retinas were isolated from male Sprague-Dawley rats and placed individually in Krebs buffer containing 10 mM lithium chloride and 1 uCi myo-[2-^{3}H]-inositol for one hour. Various cholinergic agonists were added for another hour and the stimulation was stopped with choloroform/methanol. Antagonists were present 20 minutes before the addition of agonists. IP_1 was separated by anion exchange chromatography and counted by liquid scintillation spectrometry. Carbachol causes a twofold maximal stimulation in a concentration- and time-dependent manner with an EC_{50} of about 15 uM. The stimulatory effect of carbachol was blocked by atropine. Pirenzepine, a selective muscarinic type 1 (M_1) receptor antagonist, also inhibited the carbachol-induced accumulation of IP_1. In contrast, the selective muscarinic type 2 (M_2) receptor antagonist, gallamine, did not block this effect. Other cholinergic agonists, oxotremorine, methacholine, arecoline, and McNeil A-343 stimulated IP_1 accumulation, but were significantly less efficacious than carbachol. The oxotremorine analogs, Oxo-2 and Oxo-4, also induced IP_1 formation. These results suggest that in the rat retina ACh stimulates PI metabolism by a M_1 cholinergic receptor.

360.14 VISUAL SENSITIVITY OF ADULT GOLDFISH AFTER 3 MO. CONSTANT LIGHT OR DARK. M.K. Powers, C.J. Bassi* and P.A. Raymond (SPON: J.S. McReynolds) Vanderbilt University, Nashville, TN 37240 and University of Michigan, Ann Arbor, MI 48109.

We have recently shown that the visual sensitivity of the rod system in goldfish (Carassius auratus) is related to (a) the planimetric density of rods in the retina and (b) the length of the rod outer segments (ROS). In previous experiments we found that adult fish housed in constant light (LL) or constant dark (DD) for 1 wk had elongated ROS and increased visual sensitivity. Thus, changes in visual sensitivity could be predicted from changes in ROS length (Bassi and Powers, Invest. Ophthalmol. Vis. Sci. 27 (Suppl), 236, 1986). In the present study we exposed adult fish to 3 mo. LL or DD, and recorded dark-adapted frequency-of-seeing functions by means of a classical conditioning paradigm (Powers and Easter, Vision Res. 18, 1137, 1978). Absolute thresholds were measured for 12 goldfish, 8-10 cm body length. Six were placed in constant light at 840 lux, and 6 were placed in constant dark. When threshold was re-measured 3 mo. later, it was decreased in all DD fish but highly variable in LL fish. On average, however, fish kept in LL were 0.2 log unit less sensitive than control (LD) fish, while fish kept in DD were 0.5 log unit more sensitive than controls. These changes were transient: thresholds returned to control levels within 1 day to 1 wk of the first post-exposure test. The results suggest that exposures of 1 wk to 3 mo. can influence visual sensitivity in goldfish, and that such effects are transient. More interestingly, they suggest the possibility that short and long exposures to LL may have different visual consequences, because thresholds after 1 wk were lower (Bassi and Powers, ibid) while thresholds after 3 mo. tended to be higher. In contrast, the effects observed at short and long exposures to DD were quite similar. The effects of long term exposure observed in this study could be explained either by known visual adaptation phenomena or by changes in ROS length. Histological analysis is currently underway to investigate the latter possibility. Supported by NIH grants EY03352, EY04318, K04-EY00246, and NSF grants BNS 8203268, BNS 8200981.

360.15 ELONGATION OF ROD OUTER SEGMENTS IN ALBINO RATS MAINTAINED IN CONSTANT LIGHT. D. J. Bare* and W. K. O'Steen. Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

The role of ambient lighting in the regulation of vertebrate rod outer segment length and therefore, in membrane addition and loss has been documented in both mammalian and non-mammalian species. Albino rat rod outer segments (ROS) respond to constant darkness (DD) by increasing their length and rhodopsin content (Battelle et al., 1978). Similarly, exposure of frogs and goldfish to continuous illumination (LL) results in ROS lengthening (Currie et al., 1978; Bassi et al., 1986) due to an inhibition of normal disc shedding and acceleration of disc assembly. However, changes in ROS dimensions due to LL in the rodent are unclear. A lack of any significant change in ROS dimensions in pigmented mice for both LL and DD contrasts with the DD lengthening of the albino rat (Besharse and Hollyfield, 1979).

Lengthening of rod outer segments by constant light exposure as seen in the frog and goldfish has now been demonstrated in the albino rat. Male, 8-week-old, albino rats were obtained from Harlan Sprague-Dawley labs and housed in polycarbonate cages with an ambient lighting intensity of 5 to 2 lux from the front to the back of the cage. An 8 a.m.:10 p.m. (14L:10D) lighting schedule was maintained for control animal adaptation to this low lighting environment. An experimental group was exposed to constant light of identical illuminance. Following a 7, 14 and 21 day adaptation period, a group of animals (n=5) was removed from each lighting regime and overanesthetized. The superior surface of each eye was marked with indelible ink, and the tissue was prepared for light microscopy. In a 7 μm thick section passing through the optic nerve, morphometric analyses were made of outer nuclear layer thickness and ROS lengths. Analyses for each group revealed no significant loss of photoreceptor nuclei in LL-maintained animals for the 3 week period examined. Similar analyses of ROS length for the 7 day group revealed no significant difference between cyclic and constant regimes. However, significantly longer outer segments existed across the circumference of the retina in the 14 day group ($p<0.001$) and the 21 day group ($p<0.01$) relative to cyclic controls. The greatest increase in ROS length occurred in the superior central retina. These results indicate that exposure of albino rats to constant light exerts a significant effect on membrane assembly-loss equilibrium which results in elongation of ROS. An exposure time between 7 and 14 days is apparently necessary for a shift in the equilibrium which is reflected in ROS length. Therefore, elongation of ROS in both LL and DD as demonstrated in amphibians appears to exist also in albino rats. Supported by NIH grant EY02359 (NEI).

360.16 DURATION OF RETINAL RESISTANCE TO DAMAGE FOLLOWING STIMULATION OF HEAT SHOCK PROTEIN SYNTHESIS. M. F. Barbe and M. Tytell, Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

Synthesis of heat shock proteins (HSPs) in response to potentially lethal stress is a highly conserved fundamental cellular response to injury. Many investigators have shown a temporal correlation between the induction of thermal resistance and synthesis of HSPs (Gerner et al., Cancer Res., 36: 1035, 1976; Subjeck et al., Brit. J. Radiol., 55: 579, 1982). Heat shock protein production correlates with protection of the retina against light damage (Barbe et al., Soc. Neurosci. Abstr., 12: 638, 1986; Barbe and Tytell, Invest. Ophthal. Vis. Sci., (in press) 1987.

In order to investigate the duration of that protection, we have examined the degree of retinal damage after different time periods between the heat shock and the light exposure. Pentobarbital-anesthetized adult male Sprague-Dawley rats had their body temperatures raised to 41°C for 15 minutes. They were then left at room temperature for 0, 2, 4, 8, 18, 24, or 50 hrs, after which they were exposed to 250 ft-c of light for 24 hrs in a box kept at 30°C. The rats were sacrificed 2 weeks post-light exposure. Light microscopic analyses of the photoreceptor layer (ONL) revealed that the protection from damage became significant at 4 hrs post-heat shock and lasted until 24 hrs post-heat shock, with the greatest protection being at the 8 hr interval. By 50 hr post-heat shock, the retinas were no longer protected from light damage. These results are consistent with the kinetics of synthesis of the heat shock proteins, which is greatest at 4 hr after hyperthermia. Our observations indicate that at the time when accumulation of the HSPs is the greatest in the retina, the photoreceptors are most resistant to light damage. Thus, there appears to be a temporal correlation between HSP synthesis and the protection of the retina from acute damage. Supported in part by NSF grant BNS 85-20838 to M.T.

360.17 TRANSPLANTATION OF RETINAL PHOTORECEPTORS TO LIGHT-DAMAGED RETINA: SURVIVAL AND INTEGRATION OF RECEPTORS FROM A RANGE OF POSTNATAL AGES. M. Silverman* and S. Hughes* (SPON: D. Eldredge). Central Institute for the Deaf and Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Because several forms of blindness are related to the loss of the retinal photoreceptors work was initiated in our laboratory to investigate the possibility of restoring some level of visual function through the transplantation of photoreceptors. In addition we wished to determine the effect of developmental age of the transplanted photoreceptors on their survival and ability to integrate with the host retina. Photoreceptors for transplantation were taken from neonatal rats ranging in age from 7 to 15 days. Within this period photoreceptor cells undergo a developmental sequence initiated by their segregation from other cells of the retina. They then form synapses within the outer plexiform layer, develop mature morphological characteristics such as inner and outer segments and finally become functional at 12 days. In order to maintain the organization of the photoreceptor layer, we devised a method for separating the intact photoreceptor matrix, the outer nuclear layer, from the donor retina. This method consists of vibratome sectioning of the flatmounted retina to isolate the outer nuclear layer. Hosts were adult albino rats blinded by two to four weeks of constant illumination, which destroyed the photoreceptors and left the remaining neural retina intact. Transplantation of the photoreceptor matrix to the host retina was accomplished using a transcorneal approach to the subretinal space, which minimized vascular trauma to the eye. We found that this approach does not appear to disrupt the integrity of the retina, which spontaneously reattaches to the back of the eye with the transplanted photoreceptors interposed between the retina and the underlying tissues. The photoreceptors at all ages studied survive transplantation, showing appropriate growth and development as well as apparent physical integration with the blinded host retina. These findings indicate that immature as well as fully developed retinal photoreceptor matrix can be successfully transplanted to form a new outer nuclear layer with mature blind retina. It is of interest that the degree of maturity at which retinal photoreceptors can be transplanted is in marked contrast to the immature developmental stage required by other CNS tissue for successful transplantation.

360.18 WHOLE CELL RECORDINGS OF ISOLATED RETINAL PIGMENT EPITHELIAL CELLS OF THE FROG. B.A. Hughes*, J. Immel*, and R.H. Steinberg (SPON: D.R. Copenhagen). University of California, Departments of Physiology and Ophthalmology, San Francisco, CA 94143.

We used the whole cell recording configuration of the patch-clamp technique to investigate voltage-dependent currents in single cells isolated from the retinal pigment epithelium (RPE) of the frog (Rana pipiens). The RPE-choroid was dissected from dark-adapted frog eyes and incubated in low calcium solution containing papain for 10 to 20 minutes to disperse cells. The morphology of the isolated RPE cells retained many characteristics of RPE cells in situ. Cells were columnar or cuboidal in shape and distinctly polarized. The apical end of the cell contained many melanin granules and long microvilli while the basal end was devoid of pigment and had a normal appearing surface. The standard extracellular solution consisted (in mM) of: 82.5 NaCl, 27.5 $NaHCO_3$, 2 KCl, 10 glucose, 1.0 $MgCl_2$ and 1.8 $CaCl_2$, and was saturated with 95% O_2 / 5% CO_2. In most experiments, the patch pipette contained (in mM): 75 $KMeSO_4$, 25 KCl, 17 $KHCO_3$, 5.5 EGTA-KOH, 2 $MgCl_2$, and 0.5 $CaCl_2$.

Seals in the range of 2 to 20 gigaOhms were made with patch pipettes on the basal membrane and the patch was ruptured by gentle suction. In 28 cells, the membrane potential ranged from -10 to -65 mV and averaged -25.6 +/- 13.7 mV (mean +/- SD). The input resistance and capacitance of these cells averaged 236.6 +/- 109.8 megaOhms and 37.3 +/- 18.9 pF, respectively. Extracellular Ba++ increased the Ohmic component of the input resistance by a factor of 1.84 +/- 0.44 (mean +/- SD, n=9). Voltage clamp of the membrane potential revealed a small active inward current. This current developed at potentials more hyperpolarized than -70 mV in approximately 30% of the cells and was not affected by extracellular Ba++. All cells exhibited an active outward current that appeared at potentials more depolarized than 30 mV. The outward current was carried largely by K+ since the magnitude of the current was sensitive to changes in extracellular [K+], and was blocked by the addition of extracellular Ba++ or the replacement of intracellular K+ with Cs+.

360.19 EFFECTS OF ADAPTATION ON TREE SHREW ERG SPECTRAL SENSITIVITY. H.M. Petry, B.R. Wooten*, J.P. Kelly*, and S. Agarwala*. Department of Psychology, S.U.N.Y. at Stony Brook, NY 11794 and Hunter Laboratory, Brown University, Providence, RI 02912.

The tree shrew retina is heavily cone-dominated, containing only about 3-4% rods (Immel, 1981). Psychophysical studies have shown this animal to possess dichromatic color vision of the deutan-type, presumably mediated by short-wave-sensitive (SWS) and long-wave-sensitive (LWS) cone mechanisms. This conclusion has been supported by microspectrophotometry (Petry & Harosi, 1985) and ERG flicker photometry (Jacobs & Neitz, 1986). To further study the retinal interactions underlying tree shrew color vision, we measured the spectral sensitivity of the b-wave component of the transient ERG waveform under differing conditions of adaptation. This component has been found to reflect activity of ON-bipolar neurons in other mammalian species (Knapp & Schiller, 1984).

Electroretinogram recordings were obtained from tree shrews (Tupaia belangeri) anesthetized with ketamine and xylazine. Signals were recorded using a gold foil corneal electrode referenced to a similar electrode on the other, unstimulated, eye. Monochromatic flashes of light (200 msec duration) were produced in one channel of a Maxwellian-view optical system using a 1000 W xenon source and a grating monochromator. Background illumination was produced by a second channel in which narrow-band interference filters were placed to produce the chromatic adaptation lights. Spectral sensitivity functions were obtained by varying the intensity of the monochromatic flashes to evoke a criterion b-wave response of 100 V. Data were obtained under dark-adapted conditions or on backgrounds of blue (451 nm), yellow (569 nm) or white light. Stimuli were presented at 20 nm intervals across the spectrum from 430 nm to 650 nm.

Under dark-adapted conditions, b-wave spectral sensitivity displayed a two-peaked function, with a broad major peak occurring at approximately 550 nm and a minor peak at 470 nm. A prominent notch was consistently located at 490-500 nm. Functions obtained under all conditions of light adaptation (i.e., blue, yellow and white light) were similar in shape and differed from the dark-adapted curves in that they failed to display the minor short-wave peak and the prominent notch. This suggests that the tree shrew's small population of rods make a substantial contribution to the ERG b-wave. The fact that differential chromatic adaptation failed to shift the long-wave peak or change the shape of the spectral sensitivity curve suggests that the SWS cones have weak or no input to the neurons that generate the b-wave, presumably the ON-bipolars. This is in contrast to the monkey retina where the SWS cones contribute primarily to the ON-bipolars (e.g., DeMonasterio, 1979).

360.20 REACTION TIME AND SENSITIVITY OF THE CAT TO BRIEF WHITE AND SPECTRAL INCREMENTS. M. S. Loop and G. Hortan*. Dept. of Physiological Optics, School of Optometry, Univ. Alabama at Birmingham, Birmingham, AL 35294.

Cats (4) were trained in a reaction time procedure to respond to luminance increments of various durations and spectral composition. Reaction time training required about 6 weeks and proved to be a very efficient psychophysical testing procedure characterized by 100% detection above threshold, 200-300 responses, and 20 threshold settings in a 30 min. testing session. Furthermore the animal's threshold variance was surprisingly uninfluenced by false positive rate and threshold settings were about three times more sensitive than results obtained in a Berkley Box two-choice apparatus.

Because the influence of stimulus duration is difficult to evaluate with other animal psychophysical techniques, and figures prominently in the physiological and psychophysical analysis of visual system function, we explored its influence on the cats' sensitivity, i.e. we took the targets-of-opportunity. All testing was conducted upon a photopic white background (30 cd/m^2) for a 10° increment. White increments of 25, 50, 100, 200 and 500 msec. indicated a critical duration of around 100 msec. Spectral sensitivity for 1000 and 50 msec. flashes both produced a two-peaked function with less sensitivity to the 50 msec. flashes. Reaction times at equivalent luminances from threshold were faster and less variable for a 50 msec. flash than for a 500 msec. flash, for both 455 nm and 561 nm spectral stimuli; the cats detected both wavelengths with equal speed.

These data indicate that the cat's psychophysical critical duration is compatible with electrophysiological estimates based upon retinal ganglion cell responses. The similar shape of the spectral sensitivity function for 50 and 1000 msec. flashes indicates that flash duration cannot account for the frequently reported absence of blue cone influence on cat ganglion cells. The reaction times to 50 msec. and 500 msec. flashes indicate that stimuli which produce relatively fast and brief ganglion cell discharge produce relatively fast and brief stimulus detectability. Supported by EY05576, EY03039, SO7RR0587, SO3RR03400.

361.1 PROENKEPHALIN-DERIVED PEPTIDES AND CATECHOLAMINES IN THE ADRENAL MEDULLA AND SUPERIOR CERVICAL GANGLION OF SPRAGUE-DAWLEY, SHR, AND WKY RATS. R. Rigual*[a], M.K. Stachowiak*[b], and O.H. Viveros[a] (SPON: R. Ferris), Department of Medicinal Biochemistry, The Wellcome Research Labs., RTP, NC 27709[a] and NIEHS, RTP, NC 27709[b].

The involvement of peripheral opioid peptides (OP) in blood pressure regulation is controversial. Parenteral administration of enkephalins have a biphasic action, producing hypotension by directly decreasing peripheral resistance and hypertension by reflex stimulation of J-receptors. A report by DiGuilio et al (Nature 278:646, 1979), indicated that levels of enkephalin immunoreactivity were decreased by 50% in the sympathoadrenal system of SHR as compared to WKY rats. We reexamined this strain difference in opioid activity using a radioreceptor assay, and investigated changes in enkephalin precursors and catecholamines (CA) at two stages of development. The dissected adrenal medulla of adult, age matched (6 months), male SHR, WKY and Sprague-Dawley (SD) rats had similar protein content. Native OP activity in SHR was not different from SD rats (2.90 ± 0.51 and 1.92 ± 0.69 pmol/mg protein respectively) but WKY had twice as much native OP (6.18 ± 1.75) Similary, WKY showed a marked increase in total medullary opioids (after trypsin and carboxypeptidase B digestion) as compared to SHR and SD rats (increases of 6.5 and 7.6-fold, respectively). SHR rats showed a moderate increase in CA as compared to WKY (dopamine (DA), norepinephrine (NE), epinephrine (E): 25%, 11% and 27% respectively); SD had NE and DA levels that were not different from WKY but E levels were increased by 57%. In the superior cervical ganglion (SCG) mean values for total and native OP were higher, but not significantly different in WKY as compared to SHR and SD rats. No differences were found in NE levels of SCG in any of the strains. In younger rats (7-8 weeks), the increase in total medullary OP levels in WKY was smaller than in adults (2.3-fold when compared to SHR) while native OP had twice the values of SHR. No strain differences in OP were found at this age in the SCG, but NE was higher in SHR. In conclusion, there appears to be no obvious correlation between the levels of blood pressure and the CA and opioid peptides content in the sympathoadrenal system of SD, WKY and SHR.

361.2 AGONISTS AT BOTH SIGMA RECEPTORS AND AT PHENCYCLIDINE RECEPTORS IN THE MOUSE VAS DEFERENS ACT VIA AUGMENTATION OF ELECTRICALLY EVOKED NOREPINEPHRINE RELEASE. B.G. Campbell[1]*, D.H. Bobker[1]*, F.M. Leslie[2], I.N. Mefford[3]* and E. Weber (SPON: W. Woodward). Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201, [2]Department of Pharmacology, University of California, Irvine, CA 92717 and [3]Section on Clinical Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

Sigma receptors and phencyclidine (PCP) receptors are two recently characterized sites in the mammalian central nervous system that have been proposed to mediate the psychotomimetic effects of benzomorphan opiates and of PCP, respectively. Studies attempting to determine the receptor that mediates the psychotomimetic and other effects of these drug classes have been hindered because PCP and many of the benzomorphans, including the prototypic sigma receptor ligand SKF 10,047, are not specific and interact with both sites. Furthermore, no in vitro model system containing sigma receptors has previously been described.

We report here that both the sigma receptor-selective ligand (+)-3-[3-hydroxyphenyl]-N-(1-propyl)piperidine [(+)3-PPP] and the PCP receptor-selective ligand 1-[1-(2-thienyl)cyclohexyl]piperidine (TCP) were active in the electrically stimulated in vitro mouse vas deferens. Both compounds produced an increase in the twitch amplitude, with a maximum increase of 251.0 ± 17.8 % (n=15) for (+)3-PPP and 338.2 ± 27.4 % (n=12) for TCP. The EC_{50} values were 57.2 ± 3.1 uM and 27.6 ± 3.2 uM, respectively. Other ligands with high affinity for either the sigma receptor or the PCP receptor also augmented the twitch amplitude.

Studies were carried out to determine the mechanism of this augmentation of the twitch amplitude. Systematic studies excluded the potential mediation of these effects through any previously characterized receptor (such as α_2) or through the mechanisms of inhibition of uptake or of norepinephrine(NE)-metabolizing enzymes.

Measurement of NE overflow in response to (+)3-PPP and to TCP revealed that the electrically evoked NE overflow was significantly increased at 200 uM for each compound ($p<.005$ and $p<.01$, respectively. Experiments in which isolated vasa were loaded with tritium-labelled NE confirmed that these compounds act via augmentation of NE release in the mouse vas deferens.

Data regarding competitive antagonists at the sigma receptor will be presented.

361.3 **ALTERATIONS IN MICTURITION REFLEXES AND SPASTICITY FOLLOWING CONTINUAL INTRATHECAL INFUSION OF MORPHINE IN HUMAN SUBJECTS WITH SPINAL CORD LESIONS.** R. M. Herman, D.W. Coombs*, R. Saunders*, M.C. Wainberg*. (SPON: H.L. Borison) Catholic Med. Ctr., Manchester, NH 03102 and Dartmouth/Hitchcock Med. Ctr., Hanover, NH 03756.

Morphine (MO), administered intraspinally by bolus injection, enhances bladder capacity in normal subjects, Ss (Rawal, N. et al., Anesth. Analg., 62:641, 1983) and Ss with chronic complete (CSCL) and incomplete (ISCL) cervico-thoracic spinal cord lesions. Further, in Ss with SCL, systemic and epidural MO, e.g. 200 µg/kg, and 3000 µg, respectively, depress nociceptive flexor reflexes and spasticity (Willer, J.C. and Bussel, B., Brain Res., 187:212, 1980; Struppler, A. et al., Life Sci., 33:607, 1983). These spinal actions of MO are reversed by i.v. naloxone. Such results convey a potential therapeutic advantage for chronic intraspinal delivery of MO. Subsequently, it was established that continual intrathecal infusion (c.i.t.i.) of MO, e.g. 500 µg/day, attenuates chronic spinal spasticity for periods greater than one year (Erickson, D.L. et al., Neurosurgery, 16:215, 1985). However, there is little evidence that this form of therapy modifies micturition reflexes. Our study examined the effect of bolus injections of i.t. MO (200 µg) and of c.i.t.i. MO (via an implanted Shiley INFUSAID^R constant rate pump; 500-900 µg/day for 4 mos. duration) on hyperactive vesical and somatic reflexes among 3 SCL Ss (2 CSCL, 1 ISCL). Micturition, or vesico-vesical and vesico-somatic, reflexes were assessed during slow and medium fill saline cystometry by measuring intravesical, intrarectal, and detrusor pressures, and EMG discharges from the external ano-urethral sphincters (EAUS) and various lower limb muscles; somato-somatic, e.g. flexor, reflexes were elicited by noxious and innocuous cutaneous stimulation of the foot. C.i.t.i. MO (and bolus i.t. MO) caused an increase in bladder capacity by altering the rate of detrusor reflex contraction, or the threshold and magnitude of the detrusor reflex response, and by intensifying vesico-sphincter activity; in effect, a 'low capacity' bladder (60-100 cc) was transformed to a 'moderate capacity' bladder (200-300 cc). Spontaneous EMG discharges, defined as flexor spasms or spasticity, were markedly suppressed in all 3 Ss despite the presence of strong motor reactions during cutaneous and vesical stimulation, and detrusor instability during vesical contraction. Tolerance and side-effects were not apparent. In contrast, bolus i.t. MO induced considerable inhibition of spontaneous discharges and all stimulus-evoked reflexes. Pruritus was the principal side-effect. These actions by bolus i.t. MO were antagonized by i.v. naloxone. Summarizing, c.i.t.i. MO at doses below 1000 µg/day may provide therapeutic benefit to Ss with SCL when a hyperreflexive, low capacity, micturition system and/or spasticity interfere with the S's quality of life and when these phenomena are refractory to routine oral medication. (Partial Support: Spinal Cord Soc.; Dartmouth/Hitchcock, Catholic Med. Ctrs.)

361.4 **THE EFFECT OF LOW DOSE INTRATHECAL MORPHINE ON BLADDER CAPACITY IN HUMAN SUBJECTS WITH SPINAL CORD LESIONS.** M.C. Wainberg*, R.M. Herman, M.K. Willscher*, P.F. delGiudice*. Catholic Med. Ctr., Manchester, NH 03102

The role of endogenous opioid peptides in the central control of micturition has recently received considerable attention (e.g. de Groat, W.C. and Kawatani, M., Neurourol. Urodyn., 4:285, 1985; Maggi, C.A. and Meli, A., J. Auton. Pharmacol., 6:133, 1986). In normal animals, (Bolam, J.M. et al., J. Auton. Nerv. Syst., 16:261, 1986) and man (Aoki, M. et al., Masui, 31:939, 1982; Rawal, N. et al., Anesth. Analg., 62:641, 1983), intraspinal administration of the exogenous opioid morphine (MO), a mu agonist, leads to naloxone sensitive increase in bladder capacity and retention of urine. Our single blinded study examined the outcome of randomly delivered bolus intrathecal (i.t.) injections of MO (50, 100, 200, 400 µg) upon bladder capacity among 6 subjects (Ss) with suprasacral spinal cord lesions (SCL) secondary to trauma (3) and multiple sclerosis (3). Micturition reflexes were investigated utilizing slow and medium fill saline cystometry accompanied by EMG recordings from the external ano-urethral sphincters (EAUS) and lower limb muscles. Within 10-15 mins. of the injection, bladder capacity (defined as the volume at the initial occurance of leakage per urethram, the urgent desire to void, or a capacity of 700 cc) increased markedly in all Ss (190-475%), modifying a 'low capacity' bladder (30-120 cc in 5 Ss) to a 'moderate capacity' bladder (200-525 cc). The mechanisms responsible for this behavior appeared to be lesion dependent. During bladder filling, Ss (3) with complete lesions exhibited a reduced rate of detrusor reflex contraction with little change in reflex threshold and magnitude of reflex contraction. In contrast, Ss (3) with incomplete lesions revealed a higher detrusor reflex threshold, and reduced strength of detrusor contraction. This discrepancy may be ascribed to MO's action on the afferent limb of two distinct micturition reflex pathways, spinal and supraspinal, respectively. Soon thereafter (1-2 hrs.), volume evoked enhancement of EAUS EMG discharge and of vesico-sphincter dyssynergia appeared without a change in the threshold of EMG firing. Detrusor instability and vesical induced limb motor discharges during filling and contraction, both prominent features of the hyperreflexive micturition reflex system in SCL, were abolished. Alterations in bladder capacity persisted for 12-22 hrs., while augmented vesico-sphincter and suppressed vesico-limb motor reflexes, and detrusor stability endured considerably longer. Among both groups of Ss, the described effects on micturition reflexes were dose insensitive but were antagonized by i.v. naloxone (20 µg/kg). These observations suggest that i.t. MO interferes with vesico-vesical reflexes and vesico-somatic integration by binding to mu receptors, located at sacral spinal cord sites involved in regulating micturition reflexes.

361.5 CARDIOVASCULAR, CATECHOLAMINE AND ENKEPHALIN RESPONSES TO RESTRAINT STRESS: EFFECTS OF ADRENAL DEMEDULLATION AND/OR GUANETHIDINE. B.A. Barron, K. Pierzchala* and G.R. Van Loon, Department of Medicine, University of Kentucky and VA Med Center, Lexington, KY 40511.

Adrenal and sympathetic nerve contributions to plasma levels of Met-enkephalin immunoreactivity (ME) and catecholamines (CA) were studied using adrenal demedullation (DMED) and chemical sympathectomy. Adult male Sprague-Dawley rats were divided into four groups: Sham-operated/saline, Sham-operated/ guanethidine (GUAN) 25 mg/kg/day, DMED/saline, and DMED/GUAN. After 4 weeks of GUAN treatment or demedullectomy, rats were restrained for 30 min while blood samples were taken for CA and ME and cardiovascular parameters monitored. DMED decreased basal plasma epinephrine (EPI) and eliminated the increase seen during restraint stress. GUAN lowered plasma norepinephrine (NE) and decreased the stress-induced elevation. DMED plus GUAN eliminated the stress-induced plasma NE increase. These results indicate that the stress-induced increase in plasma EPI is derived from the adrenal medulla, whereas the stress-induced increase in plasma NE is derived from both the adrenal and sympathetic nerves. GUAN and GUAN plus DMED resulted in elevated basal plasma ME. Restraint stress caused an increase in plasma ME which was potentiated by DMED and eliminated by GUAN treatment. From these results we conclude that the source of basal plasma ME was not simply the adrenal medulla or the sympathetic nerves. However, the plasma ME response to restraint stress appears to derive from sympathetic nerves. GUAN treatment decreased the tachycardia seen in response to restraint stress. DMED had no effect on the heart rate response; therefore only the sympathetic nerves are involved in the tachycardia seen during restraint stress. GUAN attenuated the initial response in mean arterial pressure (MAP) and eliminated the prolonged pressor response to restraint stress. DMED potentiated the pressor response, while DMED plus GUAN produced an initial hypotensive response and totally eliminated the pressor response. Sympathetic nerves appear to be primary in mediating the pressor and tachycardic responses to stress, whereas the adrenal medulla may buffer the pressor response through vasodilatation. Possible roles for ME in altering these cardiovascular responses to stress are postulated.

361.6 PLASMA MET-ENKEPHALIN RESPONSES TO STRESS: COMPARISON OF MILD RESTRAINT WITH IMMOBILIZATION. K. Pierzchala,* P. Zeman,* R. Kvetnansky and G.R. Van Loon. VA Medical Center and Dept. of Medicine, University of Kentucky, Lexington, KY 40511 and Institute of Experimental Endocrinology, Centre of Physiological Sciences, Slovak Academy of Sciences, Bratislava, Czechoslovakia.

Met-enkephalin and related peptides derived from proenkephalin A are colocalized with catecholamines in the chromaffin cells of the adrenal medulla, in sympathetic ganglia and in sympathetic nerve terminals. However, regulation of the in vivo secretion of Met-enkephalin and these related peptides is poorly understood. We have examined the stress-induced secretion into plasma of Met-enkephalin, present both in free native form and in association with larger peptides (cryptic) Met-enkephalin. Rats received an indwelling carotid cannula for blood sampling, and blood was collected in citrate, EDTA and aprotinin for measurement of plasma Met-enkephalin by radioimmunoassay. We have compared the plasma Met-enkephalin responses to a mild restraint stress in plastic cylinders with the more severe stress of immobilization. In Sprague-Dawley rats exposed to a mild restraint stress, plasma Met-enkephalin increased from a basal level of 7.8±0.6 pM to a peak of 30.8±0.9 pM at 0.5 min, and the peak was maintained for only 2 min before gradually decreasing to basal level by 10 min in spite of continued restraint. Plasma concentration of cryptic Met-enkephalin was about 500 fold higher at 3738±251 pM and increased ($p<0.01$) to 5410±548 after 0.5 min of restraint. Of considerable interest, thirty min of restraint produced a second peak of both free and cryptic Met-enkephalin just before the end of stress. In a separate study, using Wistar rats, animals were completely immobilized for 150 min. In contrast with the transient response to milder restraint, immobilization produced somewhat greater increases in plasma concentrations of both native and cryptic Met-enkephalin by 1 min and these increases were maintained throughout 150 min of stress. Thus, plasma levels of both free and cryptic Met-enkephalin increase in response to acute stressful stimuli, but show differences in the pattern of responses when exposed to different stressors.

361.7 ENDOGENOUS OPIOID PEPTIDE MEDIATION OF THE ANTINOCICEPTIVE RESPONSE IN RATS WITH STREPTOZOTOCIN-INDUCED DIABETES MELLITUS. M. Kolta,* K. Pierzchala,* and G.R. Van Loon (SPON: J.A. Roy). Dept of Medicine, Univ of Kentucky and VA Med Center, Lexington KY 40511.

Alteration of pain perception represents a complication of diabetes mellitus in man and laboratory animal models. The present study was designed to examine possible mechanisms mediating this disordered pain perception in rats with diabetes induced by streptozotocin (STZ, 50 mg/kg, iv). We examined the time course of development of the antinociceptive response, the effects of treatment with insulin, and whether diabetes alters CNS and peripheral Met-enkephalin (ME) levels. STZ-induced diabetes in adult male Sprague-Dawley rats resulted in the gradual development over 6-7 weeks of a significant increase in the pain threshold as tested by the hot plate and/or tail flick latency tests. Insulin replacement therapy initiated after development of the hypoalgesic response normalized not only glucose levels and body weight but also the increase in hot plate latency in diabetic rats. This hypoalgesic response appears to be mediated through opioid receptors since naltrexone at either 1.0 or 0.3 mg/kg ip reversed completely the increase in hot plate or tail flick latency. In addition, the concentration of native ME in spinal cord of STZ diabetic rats was 5-fold higher than that of nondiabetic controls. Native, cryptic (after digestion with trypsin and carboxypeptidase B) and total ME concentrations were decreased in neurointermediate lobe and anterior pituitary, whereas none of these forms of ME were altered quantitatively in nucleus accumbens, neostriatum or hypothalamus of diabetic rats when compared with nondiabetic controls. There is a 3-fold increase in native ME concentration in plasma of diabetic rats. The concentration and content of cryptic and total, but not the native ME, were significantly reduced in the adrenal medulla. Concentration of native ME in the pancreas was significantly reduced in the diabetic rats. This study provides evidence for opioid peptide mediation in diabetic rats of antinociception which can be prevented by insulin treatment. It also provides evidence for altered synthesis and/or release of ME in some CNS regions and peripheral tissues of STZ diabetic rats. However, it remains to be determined whether ME is the endogenous opioid mediating this antinociception and whether the effect is mediated in CNS or periphery.

361.8 ENDOGENOUS OPIOID MODULATION OF CARDIOVASCULAR RESPONSES TO STRESS. L. Marson and G. R. Van Loon. VA Medical Center and Department of Medicine, Univeristy of Kentucky, Lexington, KY, 40511.

Under nonstressful conditions, systemic or central administration of naloxone does not alter mean arterial blood pressure (MAP) or heart rate (HR). However, naloxone increases MAP during haemorrhagic or endotoxic shock. Injection of naloxone directly into the paraventricular nucleus of the hypothalamus of conscious restrained rats potentiates the epinephrine response to restraint stress without affecting MAP or HR responses to stress. To further investigate the role of endogenous brain opioids on the regulation of MAP and HR during restraint stress, we compared the effects of naloxone injected acutely (5 or 50 nmoles in 10ul) with naltrexone administered chronically (54 nmoles/hour for 10 days via Alzet® minipumps) into the lateral ventricle of conscious rats. Rats were implanted with cannulae into the lateral ventricle and carotid artery. Blood samples for measurement of plasma epinephrine (EPI) and norepinephrine (NE) were taken at intervals during the experiment, and systolic pressure (SYS), diastolic pressure (DIAS), MAP and HR were recorded continuously. Prior to restraint stress, injection of naloxone had no effect on SYS, DIAS, MAP, HR or plasma EPI or NE concentrations. Restraint stress increased SYS, DIAS, MAP, HR and plasma CA levels. Naloxone, 5 nmoles, potentiated the tachycardia response to restraint, but attenuated the restraint stress-induced increase in DIAS, SYS, and MAP. Naloxone, 50 nmoles, attenuated not only the increases in SYS, DIAS and MAP, but also the stress-induced tachycardia. In the chronically treated rats, naltrexone attenuated the stress-induced tachycardia and blocked the hypotensive response which occurs following the transient pressor response to restraint seen in the chronic saline-treated rats. Thus, both acute and chronic administration of an opioid antagonist reduces the arterial blood pressure and HR changes seen in response to restraint stress. These findings support the involvement of an endogenous opioid peptide in modulating the acute changes in arterial blood pressure and HR during stress. (Supported by the Veterans Administration and the University of Kentucky Tobacco and Health Research Institute.)

361.9 NALOXONE-REVERSIBLE DIURNAL INCREASES IN NOCICEPTIVE THRESHOLD IN THE EQUINE. S.G. Kamerling, C.A. Bagwell*, and J.G. Hamra*. Dept. of Vet. Physiol. Pharmacol. and Toxicol., Sch. of Vet. Med., Louisiana State Univ., Baton Rouge, LA 70803.

A diurnal variation in nociceptive threshold has been observed in rodents and other species (Frederickson et al., Science 198:756, 1977). Some studies have correlated this time-dependent elevation in pain threshold with increases in brain opioid levels (Wesche and Frederickson, Life Sci. 24:1861, 1979). Recent studies from this laboratory demonstrated a diurnal rhythm in pain sensitivity in performance horses (The Pharmacologist 28:169, 1986). Nociceptive thresholds were significantly elevated at 0900h, compared to thresholds obtained at 0600h, 1200h, 1800h and 2400h. Plasma beta-endorphin levels were also significantly higher at 0900h than at any other time of day. Diurnal variation of other physiologic parameters was also observed. Cardiac rate and pupil diameter were significantly greater, while respiratory rate was significantly lower at 0900h than at most other times of the day. These data led to the hypothesis that the diurnal rhythm in nociceptive sensitivity and autonomic responses in the equine are endorphin/opioid-receptor mediated. To test this hypothesis, naloxone (0.75mg/kg, i.v.) was administered to 8 horses at 0900h. Three baseline nociceptive thresholds were determined at 10 minute intervals, after which naloxone or saline was administered according to a single-blind crossover design. Three post-treatment observations were made at 10 minute intervals for 30 minutes. Nociceptive thresholds were quantified by measuring the latency to onset (sec) of the skin twitch and forelimb flexion reflexes following noxious thermal stimuli. Naloxone produced a slight but significant reduction in the forelimb withdrawal reflex latency ($p<0.05$), and a similar reduction in the skin twitch reflex latency which approached statistical significance ($P = 0.05$). These decreases were only significant at 10 minutes postinjection. However, marked sustained increases in respiratory and cardiac rates were observed for 30 minutes following naloxone administration. A marked increase in the frequency of defecation was also observed during this period. These data extend previous observations and support the hypothesis that nociceptive threshold and autonomic function are under 'opioidergic' control in the equine.

361.10 EXERCISE AND PHYSICAL CONDITIONING ALTER BETA-ENDORPHIN RELEASE AND NOCICEPTIVE THRESHOLDS IN PERFORMANCE HORSES. Jena G. Hamra*, Steven G. Kamerling, Cleo A. Bagwell* and John F. Freestone* (SPON: Steven A. Barker). Dept. of Veterinary Physiology, School of Veterinary Medicine, Louisiana State University, Baton Rouge, LA 70803.

Intense physical exercise produces a stress-induced increase in plasma beta-endorphin levels in man (S.R. Gambert et al, Proc. Soc. Exp. Biol. Med 168:1, 1981). Recent studies have not demonstrated a correlation between exercise intesnsity and endorphin release nor have they shown alterations in pain threshold following exericse. The present study endeavored to demonstrate a relationship between intense physical exercise, beta-endorphin release, and nociception in horses subjected to racing conditions. The effect of physical conditioning on the response to intense exercise was also evaluated. Ten Thoroughbred racehorses were subjected to a 2 furlong gallop at maximal speed. This procedure was repeated after a 10 day interval with subjects receiving naloxone (0.75 mg/kg) prior to the gallop. The 2 furlong gallop was repeated again after a nine week conditioning period which consisted of a regimen of galloping, swimming and walking. Exercise intensity was then increased to a 5 furlong gallop with a pretreatment of saline or naloxone (0.75 mg/kg) prior to exercise. Nociceptive thresholds were quantified by measuring the latency (sec) to onset of the skin twitch reflex following thermal cutaneous stimulation. Plasma beta-endorphin levels were determined using radioimmunoassay. Measurements were obtained before and over a thirty minute period following the 2 and 5 furlong gallops. Intense exercise produced a significant prolongation of the skin twitch reflex latency which was blocked by naloxone administration. Physical conditioning attenuated the increase in pain threshold following the 2 furlong gallop. However, following the 5 furlong gallop there was again a significant increase in pain threshold which was blocked by naloxone. Plasma beta-endorphin levels were significantly increased following the 2 furlong gallop and returned to baseline faster in the conditioned animal. Significantly higher levels were noted following the 5 furlong gallop. Naloxone administration significantly prolonged the increase in beta-endorphin following both the 2 furlong and 5 furlong gallops. These data suggest that intense physical exercise produces analgesia in the horse which may be mediated by beta-endorphin and/or opioid receptors and that this response to exercise is modified by physical conditioning. 361.11 TRANS-CRANIAL ELECTRO-STIMULATION INCREASES TAIL FLICK LATENCIES AFTER NOCICEPTIVE CHALLENGE. M. Skolnick, C.D. Collard#, R. Hamilton#, L. Hudson-Howard#, C. Hymel# and O. Wilson#. Neurophysiology Center, Univ. of Texas Health Sciences Center, Houston, TX 77030. I. Capel#. NE London Polytech. London, England.

The analgesia induced by Transcranial Electrostimulation treatment (TCET) in male 200 g Sprague-Dawley rats was measured in three experiments. Recent work suggests that this effect is mediated by endogenous opioid systems (Murray, J.B. et. al. this volume).

Electrical stimuli consisted of biphasic charge-balanced rectangular pulses with positive amplitudes of 10 microamperes and repetition rate of 10 hz. Stimulation was either continuous with a positive pulse width of .1 msec (Mode 1), or intermittent with a positive pulse width of 2 msec and an 8 sec pause between successive packets of 256 pulses (Mode 2).

The animals were placed in plastic restrainers and stimulated bilaterally through gold plated, stainless steel electrodes previously inserted into each pinna at the vertex of the antihelix. Analgesia was assessed using the modified tail flick test. Each animal's tail was immersed (1 inch) in water at a controlled temperature of 50°C. The time, averaged over three trials, from submergence to the first coordinated motor response was taken as the tail flick latency (TFL). The difference in TFL before and after TCET was taken as a measure of analgesia.

In Experiment One, rats stimulated with mode 1 or 2 were compared to a control group that did not receive TCET. Both modes 1 and 2 were found to produce statistically significant increases in TFL (45% and 25%, respectively) as compared to a control group that did not receive TCET ($n = 42$, $p < .001$). Mode 1 produced significantly greater increases in TFL than Mode 2 ($p < .05$).

The relationship between the duration of TCET and resultant analgesia was investigated in Experiment Two. On successive davs the animals were stimulated for 0, 10, 20, 30, 40, 50, or 60 min. with either Mode 1 or 2. Both Modes 1 and 2 produced analgesia which increased with stimulation time, reaching a maximum after 30 min. ($n = 24$, $p < .001$) and decreasing thereafter.

Experiment 3 measured the duration of analgesia following 30 min of TCET with either Mode 1 or 2. The degree of analgesia was assessed immediately, 40, 80, 120, 160, 200, and 240 min after stimulation. Mode 1 stimulation was found to produce a significantly longer lasting analgesia than mode 2 ($n = 31$, $p < .05$) with Mode 1 lasting 200 min and Mode 2 lasting 80 min. (Sponsored by NMR Centers, Inc.)

361.12 TRANSCRANIAL AURICULAR ELECTROSTIMULATION (TCET): NALOXONE-REVERSIBLE ATTENUATION OF PAIN SENSITIVITY AND OPIATE ABSTINENCE SYNDROME. J.B. MURRAY*, F.C. SCHWEITZER*, G.G. LOCKE*, L.A. SWEET*, S.G. CRON* AND D.H. MALIN. Univ. of Houston - Clear Lake, Houston TX 77058.

Certain parameters of electrostimulation delivered bilaterally to the ear have been reported to induce analgesia in the rat (Skolnick, M. et al, this volume). Experiment 1 attempted to confirm this effect and test whether it is naloxone-reversible and thus presumably endorphinergically mediated.

Under chloral hydrate anesthesia, 36 male 175g Sprague-Dawley rats were bilaterally implanted through the apex of the antihelix with gold plated stainless steel electrodes. Four days later, rats were placed in cylindrical plastic restrainers and connected through 200 k ohm to a computer-controlled stimulator. Rats received 30 min. of either zero stimulation ("sham treatment") or 10 Hz, 10 microamp, 2 msec rectangular pulses, grouped in packets of 256 pulses separated by 8 sec. pauses. Each pulse was constructed so that there was no net polarizing current. Fifteen min. before termination of stimulation, rats were injected s.c. with 3 mg/kg naloxone or with saline vehicle alone.

Each rat was tested on a "blind" basis for pain sensitivity (50°C wet tail flick) immediately before and after stimulation. Rats receiving TCET plus saline were the only group to show a significant pre/post increase in tail flick latency (0.93 secs ± 0.29 secs., $p<.01$). According to Dunnett's Test, the TCET + saline rats showed significantly greater increase than the TCET + naloxone, sham + saline or sham + naloxone groups, $p<.05$.

Since these results suggest an endorphinergic effect of TCET, it seemed possible that TCET might modulate opiate abstinence syndrome. In Experiment 2, 12 225g rats were rendered dependent by s.c. infusion for 7 days with 0.89 mg/kg/hr morphine sulfate via Alzet 2ML1 osmotic minipumps. A day after pump removal, animals received either TCET (as above, except with no pauses) or sham treatment. They were then placed in a clear plastic chamber and observed for 15 minutes under "blind" conditions for abstinence signs. The predominant signs were wet-dog shakes and genital licking/seminal ejaculation. TCET-treated rats showed 11.3 ± 2.6 overall signs as compared with 25.7 ± 2.7 signs for the sham-treated controls. This difference was highly significant, $p<.005$. TCET-treated rats also exhibited significantly fewer wet-dog shakes and genital licks. The anti-abstinence effect appears to be naloxone-reversible, since TCET failed to reduce abstinence signs when compared with sham treatment in rats injected with 3mg/kg naloxone s.c. The results suggest that TCET might possibly be of value in the management of opiate abstinence syndrome. (Supported by NMR Centers, Inc.)

361.13 THE ROLE OF SEROTONERGIC PATHWAYS IN ALFENTANIL-INDUCED MUSCLE RIGIDITY IN THE RAT. M.B.Weinger*, N.T.Smith*, T.L.Yaksh, and G.F.Koob.(SPON:D.A.Mac Neil).Dept.of Anesthesiology, Univ. of Calif., San Diego,Dept. of Neurosurg. Res.,Mayo Clinic, and Div.of Preclin. Neurosci., Scripps Clinic, La Jolla, CA 92037.

Muscle rigidity is a potentially life-threatening complication of high-dose opiate anesthesia. Recent work has implicated the brainstem raphe nuclei in the expression of opiate-induced rigidity. Direct injections of methylnaloxonium (MN), a quaterary opiate antagonist, in the area of the nucleus raphe pontis (RPn) significantly attenuated alfentanil (ALF) rigidity [Brain Res. 386:280,1986]. Like the other raphe nuclei, the RPn contains serotonergic cell bodies with both ascending and descending projections. Systemic pretreatment with ketanserin, a selective serotonin antagonist, prevents ALF-induced rigidity [Anesthesiol. 65:A344,1986]. The present studies were designed to further characterize the role of other brainstem sites in opiate rigidity as well as to assess the importance of descending serotonergic systems in ALF-induced rigidity.

Male Wistar rats were implanted with 23-gauge chronic guide cannulae aimed at discrete brainstem nuclei. Following intracerebral pretreatment with MN (0.125 μg) or saline, muscle rigidity was measured by electromyographic (EMG) recordings from the gastrocnemius muscle. After obtaining baseline measurements, ALF (0.5 mg/kg s.c.) was injected and data were collected for 60 min. In another study, rats were chronically implanted with intrathecal catheters. The effects of intrathecal injections of ketanserin (25-37.5 μg), methysergide (15-45 μg), or saline on ALF-induced changes in EMG activity were determined. Other animals were intrathecally pretreated with either 75μg of 5,6-dihydroxytryptamine or ascorbic acid vehicle and had EMG activity in response to ALF measured one week later.

MN injections in the region of the periaqueductal gray and deep layers of the superior colliculus as well as those in the region of the RPn and the nucleus reticularis tegmenti pontis significantly attenuated ALF rigidity. MN injections in the area of the raphe magnus, raphe pallidus, or the dorsal tegmentum had no effect. The intrathecal injection of the serotonin antagonists ketanserin and methysergide failed to attenuate ALF rigidity. In addition, a greater than 80% reduction in spinal serotonin levels after pretreatment with 5,6-dihydroxytryptamine did not blunt the rise in EMG activity due to ALF.

The results of these studies suggest that discrete hindbrain regions known to contain serotonergic and GABAergic pathways are involved in mediating ALF-induced muscle rigidity in the rat. Additionally, the site of serotonin's modulatory role appears to be supraspinal. Further studies will lead to an improved understanding of the central sites of opiate action.

361.14 ENKEPHALIN IN THE A10 REGION INCREASES DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS AS ASSESSED BY IN VIVO VOLTAMMETRY. D. Jackson, J.O. Schenk*, and P.W. Kalivas* (SPON: R. Kuczenski), Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, and Department of Chemistry, Washington State University, Pullman, WA.

A number of studies have shown that the injection of enkephalin analogues into the A10 dopamine (DA) region activates DA neurons projecting to the nucleus accumbens. Thus, intra-A10 injection of enkephalin analogues produces a motor stimulant action that is blocked by injection of DA receptor antagonists into the nucleus accumbens. Furthermore, this motor stimulant effect is associated with an increase in the postmortem levels of DA metabolites. In the present study, in vivo chronoamperometry was employed in the nucleus accumbens to evaluate a change in catecholamine release following injection of the mu opioid enkephalin analogue, DAGO, into the A10 region.

Male Sprague-Dawley rats were anesthetized with chloralose, mounted in a stereotaxic apparatus, and a carbon fiber (40 μm diameter) working electrode implanted into the nucleus accumbens. The reference and auxiliary electrodes were placed in contact with the dura, and a stainless steel injection cannula was implanted into the A10 region ipsilateral to the working electrode. An oxidation potential of 0.5 V was applied to the working electrode for 5 sec every 10 sec to oxidize catecholamines. After a stable baseline had been obtained (1-2 hr), a microinjection of DAGO (0.15 nmole in 0.5 μl) was made into the A10 region. Following a 90 to 120 sec lag, a large increase in the signal obtained from the nucleus accumbens was measured corresponding to 8 to 10 μM DA in the external calibration. After 30 to 90 sec the signal was reduced by 50%, and remained elevated at this level for 30 to 45 min. Although experiments are now underway to verify the content of the electrochemical signal measured in the nucleus accumbens, the large amount of DA in the accumbens and the previous postmortem data support the possibility that this signal is comprised predominately of DA or its metabolite DOPAC. Thus, these data corroborate the earlier postmortem studies demonstrating that intra-A10 injection of opioids activates DA transmission in the nucleus accumbens, and they illustrate a method whereby a detailed time course of this activation can be quantified.

361.15 INHIBITION OF EVOKED STRIATAL DOPAMINE RELEASE BY SELECTIVE KAPPA RECEPTOR AGONISTS. D.W. Clow* and K. Jhamandas. Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada.

Kappa opioid receptor subtypes have been found to exist in the striatum of several species, but their functional significance is largely unknown. It has been reported that exogenous and endogenous kappa agonists are capable of depressing both the spontaneous and potassium-evoked efflux of ^{3}H-dopamine (Mulder et al., Nature, 308: 278, 1984); however, little is known about kappa agonist action on endogenous dopamine (DA) release.

In the present study we have addressed this question using both a highly selective synthetic kappa agonist, "U-50,488H" as well as a putative endogenous kappa agonist, "dynorphin (1-13)". Brain slice superfusion, coupled with an alumina/perchloric acid extraction, was used to collect and isolate the DA. Separation and quantitation of the DA was carried out by HPLC coupled to electrochemical detection. U-50,488H produced a concentration-dependent inhibition of potassium-evoked DA release which was insensitive to naloxone. A putative kappa receptor antagonist, Win 44,441-3, produced a time-dependent reversal of the U-50,488H mediated inhibition. Neither Win 44,441-3 nor naloxone (1.0 μM) influenced the spontaneous or evoked release of DA when applied alone. Dynorphin (1-13), in the presence of bestatin (20 μM), produced a concentration-dependent inhibition of potassium-evoked outflow (to a maximum of 60% of control) while having no effect on the spontaneous release.

These findings suggest that the striatal release of endogenous dopamine is modulated by kappa opioid receptors.

361.16 OPIOID MU RECEPTOR AGONIST AND NMDA RECEPTOR ANTAGONIST PRODUCE SIMILAR DEPRESSION OF SYNAPTIC TRANSMISSION IN THE RAT SPINAL DORSAL HORN: AN IN VITRO STUDY. S. Jeftinija, Dept. Vet. Anatomy, Iowa State University, Ames, Iowa, 50011.

Much evidence has accumulated to suggest that excitatory amino acids (EAA) are produced by small sensory neurons and mediate excitatory neurotransmission in the mammalian spinal cord. Even more evidence has accumulated to suggest an inhibitory role of opioids in the superficial laminae of the dorsal horn. For both opioids and EAA a heterogeneity of receptors have been disclosed. In order to provide more direct information on the physiological role and mechanism of action of EAA and opioids in the dorsal horn we developed an in vitro preparation. The horizontal spinal cord slices (400-500um thick) and the functionally connected dorsal root with the dorsal root ganglion were obtained from 18-25 days old rats following lumbosacral laminectomy. Conventional intracellular recording from dorsal horn neurons and dorsal root ganglion neurons using 3M K-acetate-filled electrodes was employed. Dorsal roots were electrically isolated from the spinal cord slice and stimulated with pulses of different intensity and duration to evoke afferent volleys monitored intracellularly from dorsal root ganglion neurons. Low intensity stimulation (5-10V; 0.02ms) of the dorsal root activated only large myelinated fibers and evoked fast excitatory postsynaptic potentials (e.p.s.p.) in spinal dorsal horn neurons. Higher intensity stimulus (20V;0.2ms -35V;0.5ms), sufficient to excite small myelinated and unmyelinated afferent fibers and corresponding small dorsal root ganglion neurons resulted in a large and more complex e.p.s.p. Thus, the initial burst of action potentials was followed by a prolonged depolarization with or without subsequent firing of action potentials. Bath application of 2-amino-5-phosphonovaleric acid (2-APV; 1 to 2x10^{-4}M), which reversibly abolished N-methyl-D-aspartate (NMDA) responses, produced a pronounced depression of the e.p.s.p. Synaptic activation by volleys in low threshold fast conducting presumably Aß fibers was not affected by 2-APV. Depression of a portion of the e.p.s.p. induced by activation of small diameter primary afferent fibers was also produced with (D-Ala^{2}, N-Me-Phe^{4}, Gly^{5}-ol)-enkephalin (DAGO; 10^{-7}-5x10^{-6}M) in concentrations that did not have a measurable effect on resting membrane potential or conductance. However, concentrations of DAGO that hyperpolarized the neurons depressed the e.p.s.p. induced by activation of large myelinated primary afferent fibers. These findings are consonant with involvement of NMDA receptors in synaptic transmission from small diameter primary afferents. In addition, the data suggest that opioids modulate NMDA receptor mediated EAA excitatory synaptic action in the dorsal horn by acting at mu receptor sites. Supported by NIH Grant 2 S07 RR07034.

361.17 THE EFFECTS OF THE KAPPA OPIOID RECEPTOR AGONIST U 50488H ON KAINIC ACID NEUROTOXICITY. W. Lason*, J. N. Simpson* and J. F. McGinty. (SPON: W.R. Wooles) Department of Anatomy, School of Medicine, East Carolina University, Greenville, N.C. 27858.

The specific kappa opioid receptor agonist, U 50488H has recently been shown to possess anticonvulsive and antiischemic properties (Tortella, et al., J. Pharmacol. Exp. Ther. 237:49, 1986; Tang, A.H., Life Sci. 37:1475, 1985). We investigated the ability of this compound to prevent kainic acid induced neuronal loss in the rat hippocampus. All intracerebroventricular injections (i.c.v.) were performed through chronically implanted cannulae in conscious male Sprague Dawley rats. For histological analysis, rats were perfused transcardially with a 4% paraformaldehyde solution 72 hours after injection and microtome sections were stained with Richardson's Nissl stain. I.c.v. injection of 1 nmole of kainic acid evoked behavioral seizures and neuronal loss exclusively in CA3 and CA4 fields of the hippocampus. U 50488H (up to 200ug, i.c.v. or 10 and 20 mg/kg, i.p.) had no effect either on behavioral seizures or on neuronal loss resulting from i.c.v. kainic acid administration. In contrast to i.c.v. injection, systemic administration of kainic acid (10 mg/kg, i.p.) caused severe neuronal damage in several brain regions, notably in the CA1 fields of both hippocampi. Pretreatment of the rats with U 50488H (10 or 20 mg/kg, i.p.) delayed, in a dose dependent manner, the appearance of seizures, significantly decreased the number of wet dog shakes, and almost completely protected the CA1 hippocampal neurons from degeneration. In contrast, U 50488H did not protect these animals against status epilepticus, body weight loss, or against extensive neuronal degeneration in other brain regions, particularly entorhinal cortex. Our data indicate that U 50488H has a protective effect on the CA1 hippocampal neurons most vulnerable to anoxic-ischemic damage following systemic kainic acid. Supported by DA 03982.

361.18 **EXCITATORY AMINO ACID ANTAGONISTS INHIBIT THE EFFECTS OF INTRATHECAL DYNORPHIN (1-13).** **R.M. Caudle* and L. Isaac. Dept. of Pharmacology, Univ. of Ill. Col. of Med., Chicago, IL 60612.**

Previous work suggested that elevation of tail-flick latency in rats following an intrathecal injection of dynorphin (1-13) (DYN) resulted from neuronal death. An electrophysiological study of DYN's effect on spinal reflexes was undertaken to ascertain the specificity of this effect.

Male Sprague Dawley rats were anesthetized with pentobarbital. The spinal cords were exposed by laminectomy and severed at L1. Dorsal and ventral roots from spinal segment L5 were isolated. The dorsal root was placed over platinum stimulating electrodes while the ventral root was placed over platinum recording electrodes. DYN (80 nmols, N=3) applied *in situ* onto the spinal cord resulted in a potentiation of the C-fiber initiated reflex followed by a loss of the reflex. Reflexes initiated by afferents from groups I-III were not affected. In another group of rats DYN (80 nmols, N=5) or saline (20 microliters, N=10) was administered intrathecally 1-30 days prior to recording. A C-fiber initiated reflex could not be evoked in DYN treated animals that had lost the tail-flick. The group I-III initiated reflexes in these animals, however, were present. All reflexes were clearly evoked in the saline treated animals. These findings indicate that intrathecal DYN initiates an excitotoxic event resulting in loss of the C-fiber reflex which is expressed behaviorally as an irreversible elevation of the tail-flick latency.

To test the hypothesis that an excitatory amino acid mediates the toxicity observed after intrathecal DYN, varying doses of excitatory amino acid antagonists were co-injected with DYN (80 nmols). The N-Methyl-D-Aspartate (NMDA) receptor specific antagonist 2-amino-5-phosphonovalerate blocked the effects of DYN on the tail-flick at a dose an order of magnitude lower than the non-specific excitatory amino acid antagonist gamma-D-glutamylglycine.

These data demonstrate that dynorphin-induced neurotoxicity, in rat spinal cord, is mediated through the NMDA subclass of excitatory amino acid receptors.

361.19 PROTECTION AGAINST MORPHINE-INDUCED EXPLOSIVE MOTOR BEHAVIOR BY THE EXCITATORY AMINO ACID ANTAGONIST, 2-AMINO-7-PHOSPHONOHEPTANOIC ACID. Y. F. Jacquet. Behavioral Neuropharmacology Laboratory, Nathan Kline Institute, Orangeburg, NY 10962.

2-amino-7-phosphonoheptanoic acid (2-APH) is a potent antagonist of excitatory amino acid receptors, preferentially those activated by N-methyl D aspartic acid (NMDA). In the present study, an injection of (±)-2-APH (17.5 nmol/0.5 uL) bilaterally in the rat periaqueductal gray (PAG) 10 min prior to a bilateral (-)-morphine (53 nmol/0.5 uL) injected at this same site potently blocked the occurrence of the explosive motor behavior (EMB) that is normally seen after morphine (53 nmol) injected in this site.

We (Jacquet et al, Science 198:842,1977) previously reported that an injection of (+)- or (-)-morphine in the rat PAG resulted in an EMB (characterized by rapid and repeated high leaps and shrill distress vocalizations) that was not blocked by the potent opiate antagonist, naloxone. Recently, we (Squires et al, Neurosci.,12:660,1986) found that this nonstereospecific morphine action in the rat PAG could be mimicked by GABA antagonists (e.g., bicuculline methiodide, picrotoxin), and blocked by GABA or the GABA potentiator, diazepam; in receptor binding studies, morphine dose-dependently reversed the inhibition by GABA of the binding of ^{35}S-t-butylbicyclophosphorothionate (TBPS) to picrotoxin binding sites, similar to the action of othr GABA antagonists. Based on these findings, we concluded that morphine-induced EMB was due to GABA receptor antagonism. The present findings of 2-APH antagonism of morphine-induced EMB suggest that in addition to GABA receptor blockade in the PAG, an additional mechanism underlying EMB consists of the resulting unopposed excitatory actions of endogenously-occurring excitatory amino acids in the PAG.

An injection of N-methyl DL aspartic acid (NMDLA) (50 nmol/0.5 uL) in the rat PAG resulted in wild running, convulsions and occasional deaths (similar to the syndrome reported for intracerebroventricularly-injected mice by Croucher et al, Science 216: 899,1982). Since all behavioral components of EMB were not mimicked by NMDA injected at this site, we concluded that EMB is the result of the unopposed excitatory actions of other excitatory amino acid receptors in the PAG in addition to the NMDA receptor. Phencyclidine (PCP) given 10 min prior (10-25 nmol/0.5 uL) failed to antagonize, but potentiated, the actions of NMDLA (50 nmol/0.5 uL) at this site.

361.20 EARLY KAINATE-INDUCED CHANGES IN HIPPOCAMPAL GABA AND ENKEPHALIN METABOLISM. P. Hudson*, L. Grimes, P. Lee, S. Li* and J. Hong. (SPON: M. Bonner) Lab. of Behavioral and Neurological Toxicology, NIEHS/NIH, Research Triangle Park, NC 27709 and Toxicology Curr., UNC-CH, Chapel Hill, NC 27514

Systemic kainic acid (KA) causes a rapid increase in hippocampal metabolic and EEG activity (Lothman, E. W., Brain Res, 218: 299, 1981). Both KA and enkephalin (ENK) are thought to enhance hippocampal epileptiform activity by blocking release of GABA (Zieglgänsberger, W., Science, 205:415, 1979; Fisher, R. S., J. Neurosci., 4:1312, 1984), but the extent to which ENK mediates a KA-induced effect on GABA and the extent to which these interactions are involved in the initiation of behavioral seizures are unknown. It is clear, however, that lesions of the opioid-containing granule cells, which reduce hippocampal ENK by 50%, do not block KA-induced convulsions (Grimes, L., Neurosci. Abstra., 12:412, 1986), suggesting that ENK contained in another population of neurons may be responsible for putative actions on hippocampal excitability. The purpose of the present studies was to determine whether systemic KA affects hippocampal GABA or ENK metabolism prior to the onset of behavioral convulsions and whether such effects also occur following lesions of the opioid-containing dentate granule cells. Male Fischer-344 rats were used in these studies. Rats (30) were injected with KA (8 mg/kg, sc) or saline (SAL) and killed after exhibiting wet dog shakes (WDS) or seizures. Limbic brain regions were assayed for amino acids using high performance liquid chromotography (HPLC). Rats (30) were given unilateral injections of colchicine (COL) (1 ug/site) into dorsal and ventral hippocampus, treated with KA or SAL 2 weeks later, and killed prior to the occurrence of WDS or after seizure onset. Brain regions were taken for amino acid analyses or blot hybridization studies using a cDNA probe for proenkephalin mRNA. Brain regions from 32 rats, injected with a lower dose of KA (6 mg/kg) and killed 2.5 hr later, were dissected for radioimmunoassay of opioid peptides or blot hybridizations studies of proenkephalin mRNA. Increases in hippocampal GABA and proenkephalin mRNA were correlated with the number of WDS. These changes occurred from the onset of shaking behavior. Hippocampal ENK rose at the onset of shaking behavior and then gradually declined, indicating that the rate of precursor processing and peptide utilization were increased. These findings suggest that KA-induced interactions between hippocampal ENK and GABA are possible, but critical appraisal requires completion of lesion studies.

361.21 OPIOID MU AND DELTA RECEPTOR ANTAGONISTS REDUCE WET DOG SHAKING ELICITED BY PERFORANT PATH STIMULATION IN RATS. C.L. Mitchell, M.I. Barnes*, S. Rahmaan*, P.M. Hudson*, and J.S. Hong. Lab. Behav. Neurol. Toxicol., Nat'l. Inst. Environ. Health Sci., NIH, Research Triangle Park, NC 27709.

Wet dog shaking (WDS) elicited by perforant path stimulation (PPS) produces a decrease in hippocampal levels of methionine-enkephalin (Mitchell et al., Fed. Proc. 46: 6597, 1987). Moreover, *intrahippocampal injection of either μ or δ, but not K, opioid receptor agonists elicit* WDS (Obie et al., Fed. Proc. 46: 6598,1987). The present study was undertaken, therefore, to determine if either μ or δ receptor antagonists, or both, would reduce WDS elicited by PPS.

Three separate experiments were conducted. These compared effect of (1) β-FNA (μ antagonist) vs. vehicle; (2) ICI 174864 (δ antagonist) vs. vehicle; and (3) combination of β-FNA and ICI 174864 vs. vehicle. Each group of animals was used for only one experiment. Male Fischer-344 rats were implanted unilaterally with bipolar PPS electrodes. Forty-eight hours after surgery all animals were stimulated to determine the threshold for eliciting WDS. The animals were then paired according to this threshold. One of each pair was placed in the vehicle group and the other in the drug group. All injections were made intraventricularly in a volume of 5 μl. The vehicle was artificial cerebrospinal fluid. β-FNA was injected in a dose of 10 μg, 24 hrs. prior to testing. ICI 174864 was injected in a dose of 2 μg, 10 minutes prior to testing. Vehicle control animals were stimulated to the point of exhibiting approximately 75 WDS. Each animal in a drug group was stimulated the same number of times as the animal to which it was yoked in the control group.

The threshold for eliciting WDS was not altered by the antagonists. Both β-FNA and ICI 174864 significantly reduced WDS. For β-FNA the mean number of shakes was 49 vs. 76 for the vehicle group (VG). For ICI 174864 the mean was 53 vs. 79 for the VG. The combination also reduced WDS (mean of 53 vs. 78 for the VG) but was not more effective than either agent alone.

These results lend further support to the notion that endogenous opioid peptides play a role in regulation of hippocampal excitability. Moreover, they suggest that both μ and δ receptors may be involved in this type of WDS.

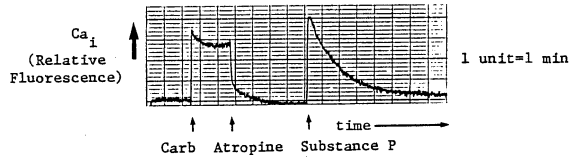
361.22 INTRAHIPPOCAMPAL INJECTION OF OPIATE PEPTIDES PRODUCE WET DOG SHAKES, CONVULSIONS AND CHANGES IN THE LEVELS OF AMINO ACIDS. P.H.K. Lee, J. Obie*, P. Hudson* and J.-S. Hong. Laboratory of Behavioral and Neurological Toxicology, NIEHS, NIH, Research Triangle Park, NC 27709.

Opiate peptides have been demonstrated to produce wet dog shakes (WDS) and epileptiform discharges in rats when administered intraventricularly. The purpose of this study is to obtain further information to support the hypothesis that opioid peptides in the hippocampus may play a role in mediating WDS and seizure activities. Injections of specific mu receptor agonist, [N-MePhe^3, D-Pro]$_2$morphicaptin (PLO17, 1-10 μg), and delta receptor agonist, [D-Ala^2, D-Leu^5]-enkephalin (DADLE, 1-10 μg), to the ventral hippocampus produced convulsive seizures and numerous WDS, suggesting that both receptors are involved in the mediation of these behaviors. However, injections of high dose of PLO17 (10 μg) to the dorsal hippocampus, frontal cortex and striatum produced neither WDS nor convulsions, therefore indicating that the ventral hippocampus is a sensitive site for these actions of opiate peptides. The levels of hippocampal glycine and gamma-aminobutyric acid (GABA) were increased but aspartate was reduced after PLO17 injection. Pretreatment with Beta-funaltrexamine hydrochloride (B-FNA), an irreversible mu receptor blocker, attenuated PLO17-induced WDS and convulsions. It also restored the PLO17-induced changes in the levels of hippocampal amino acids to that of control values. These results suggest that opiate-induced WDS and convulsive seizures are receptor mediated and may be acting through a disinhibition mechanism by attenuating the release of inhibitory amino acids in the hippocampus. Nevertheless, the degeneration of hippocampal granule cells by intrahippocampal injection of colchicine attenuated PLO17-induced WDS but potentiated the severity of convulsions, therefore suggesting that these two behaviors may be mediated by different pathways in the hippocampus. These data give further evidence to the idea that opioid peptides in the hippocampus may play an important role in regulating hippocampal excitability.

PEPTIDES: PHYSIOLOGICAL EFFECTS II

362.1 SPECIFIC-DESENSITIZATION OF SUBSTANCE P RESPONSES. B.R. Talamo, S. Soltoff, and M.K. McMillian. Depts. of Neurology and Physiology, Tufts Med. School, 136 Harrison Ave., Boston, MA 02111

Three types of receptors mediate increases in cytoplasmic calcium (Ca_i) in rat parotid acinar cells, but only the response to substance P rapidly desensitizes. Dissociated acinar cells loaded with Fura 2 show a sharp increase in Ca_i on addition of the muscarinic agonist carbachol, the α-adrenergic agonists phenylephrine and norepinephrine or substance P. Ca_i remains



elevated for many minutes in the presence of carbachol or norepinephrine, but drops off precipitiously after substance P addition, falling to 50% of the maximaum value within 2 min. The tachyphylaxis to substance P cannot be overcome by the subsequent addition of more substance P. Furthermore, it is specific to substance P; carbachol added subsequently can still stimulate an increase in Ca_i. Desensitization appears to occur more rapidly than depletion of the intracellular pool of calcium. In the presence of extracellular EGTA, carbachol can completely deplete this intracellular pool so that subsequent addition of substance P has no effect. However, when substance P is added first, Ca_i rises transiently and falls to resting levels, but subsequent addition of carbachol can still elevate Ca_i.

Other responses to substance P also show tachyphylaxis. The generation of ^{3}H inositol-phosphates by substance P in cells preloaded with ^{3}H inositol is similar to that generated by carb at early times (1 min or less), but reduced relative to that by carb at all times after 3 min. These results indicate that the specific desensitization to substance P is not due primarily to inactivation of the peptide and must be at an early step, possibly at the receptor or as a result of its interaction with Plipase C and mobilization of Ca^{++}. It appears that the substance P response shows important differences from that to muscarinic and α-adrenergic agonists in spite of the strong parallels in mechanisms of cellular activation. Further studies characterizing the calcium requirement for desensitization and the time dependence of desensitization and recovery are in progress.

362.2 BLOCKADE OF THE PRESSOR AND TACHYCARDIC RESPONSES TO SUBSTANCE P IN ANESTHETIZED RATS. J.C. Hancock and T.W. Smith*, Dept. Pharmacol., East TN State University, Quillen-Dishner College of Med., Johnson City, TN 37614.

At high doses, substance P (SP) evokes a pressor response in anesthetized rats (Hancock and Hoover, Pharmacologist, 1983). The present study was directed at determining the mechanism of that effect. Experiments were conducted in Sprague-Dawley rats anesthetized with 1.2 g urethane/kg. Arterial pressure was recorded from the left femoral artery. Drugs were injected into the rt. jugular sinus. Intravenous injection of 2.5 to 50.0 μg substance P/kg caused short duration, dose-dependent increases in peripheral arterial pressure and heart rate which were not blocked by the ganglion blocking agents, hexamethonium or chlorisondamine in doses that prevented the blood pressure and heart rate response to bilateral carotid occlusion. Following ganglion blockade, the threshold for initiating the pressor response was lowered from 4.3 ± 0.04 μg SP/kg (n=12) to 1.6 ± 0.15 μg/kg (n=10), ($p < 0.5$). The magnitude of pressor response to 10 μg SP/kg was increased from 27 ± 4.8 mmHg to 33 ± 2.4 (n=7 : $p < .01$). Pretreatment of rats, 24 hrs. prior to the experiment, with 1 mg reserpine/kg i.p. totally prevented the pressor and tachycardic responses to 10 g SP/kg (n=6).

Propranolol 0.5 to 1.0 μg/kg i.p. significantly reduced the tachycardic ($p < .05$ n=4) but not the pressor response to 10 g SP/kg. Higher doses (5-20 mg/kg) i.v. selectively reduced the tachycardic response in only 4 of 7 rats. Phentolamine, 1 to 7 mg/kg, significantly decreased the pressor ($p < .001$) but not the tachycardic response to 10 μg SP/kg. Phenoxybenzamine prevented both the pressor and tachycardic response to 10 μg SP/kg (n=5).

It is concluded that SP has an effect on autonomic ganglia to increase sympathetic nervous system activity. This effect is not evident with lower doses of SP (.005 to 1 μg/kg) because of the prominent action of SP in these doses to cause vasodilation. A central nervous system site of action is unlikely since nicotinic ganglion blockade in doses that prevented the pressor and tachycardic response to carotid occlusion did not prevent the pressor and tachycardic response to SP. The blockade of the pressor and tachycardic responses caused by SP by phenoxybenzamine is consistent with the observation that phenoxybenzamine blocks tachykinin receptors (Buck and Burcher, Neuropeptides, 1987, 9, 33-39). (This study was funded by a grant from the East Tennessee State University Research Development Committee).

362.3 NEUROTENSIN FACILITATES RELEASE OF SUBSTANCE P FROM PRIMARY AFFERENT NERVE TERMINALS IN THE GUINEA PIG INFERIOR MESENTERIC GANGLION. W.H. Stapelfeldt*, V.L.W. Go* and J.H. Szurszewski (SPON: E. Richelson). Department of Physiology and Biophysics and GI Unit, Mayo Medical School, Rochester, MN 55905.

We previously reported that neurotensin (NT) or a related transmitter of central preganglionic nerves facilitates peripheral sympathetic reflex activity through the guinea pig inferior mesenteric ganglion (IMG) by presynaptically releasing a non-cholinergic excitatory transmitter from peripheral afferent nerve terminals (Soc. Neurosci. Abst. 12: 1496, 1986; Gastroenterology 92: 1651, 1987). Since substance P is known to function as an excitatory afferent transmitter in the IMG, the present study was designed to determine the possibility of substance P mediating this response to NT. The IMG and attached lumbar colonic nerve trunks (LCN) were dissected from normal and capsaicin treated (100 mg/kg s.c.) guinea pigs, pinned down in an organ bath and superfused with oxygenated Krebs solution at 37°C. Intracellular recordings were obtained from ganglion cells using 3M KCl filled borosilicate glass micropipets (35-55 MΩ), LCN trunks were stimulated with bipolar platinum electrodes, and peptides were administered by addition to the superfusion medium. While 61% of neurons studied in ganglia from normal untreated guinea pigs exhibited a transient membrane depolarization (5.1 ± 1.2 mV) during superfusion of NT^{8-13} (5 μM), no such response was observed in ganglia from capsaicin-treated animals. Slow EPSPs in response to repetitive LCN stimulation were still evoked in most of the neurons tested indicating integrity of capsaicin-insensitive noncholinergic afferent pathways in these ganglia. Subsequent radioimmunological analysis of the neuropeptide content of these ganglia and also of the distal colon, celiac-superior mesenteric plexus, dorsal root ganglia (L1-L4), and lumbar spinal cord of the same animals revealed that material coeluting with synthetic porcine substance P on HPLC (10-60% acetonitrile, 0.1% morpholine) was depleted from the prevertebral and dorsal root ganglia, reduced by 50% in the spinal cord and by 30% in the colon of capsaicin treated animals, while the peptide content of other excitatory afferent transmitter candidates such as VIP, CCK, and bombesin was not different in these tissues compared to untreated normal animals. NT-induced transient membrane depolarizations and associated increases in conversion of evoked (LCN) subthreshold fast EPSPs to action potentials in normal ganglia were abolished or markedly attenuated after desensitization of ganglion cells to exogenously superfused substance P. In conclusion, these findings suggest that the facilitatory action of NT on peripheral afferent synaptic input to ganglion cells is mediated by release of substance P from nerve terminals of primary afferent neurons in the IMG. (Supported by DK 17632 and DFG Sta 252/1-1.)

362.4 INHIBITORY ACTIONS OF GALANIN AND SOMATOSTATIN 28 ON RAT SPINAL DORSAL HORN NEURONS. M. Randic, G. Gerber*, P. D. Ryu*, and I. Kangrga* (SPON: W. Steele). Dept. Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011.

Galanin, a 29 amino-acid peptide and somatostatin 28 (SS-28) are widely distributed in the rat central nervous system, including the spinal dorsal horn as demonstrated in immunohistochemical and radioimmunological studies. High density of galanin binding sites was shown in the superficial layers of the rat spinal dorsal horn. The effects of dorsal rhizotomy and capsaicin treatment suggested that galanin occurs in unmyelinated primary afferent fibers. SS-28 immunoreactivity is present in small dorsal root ganglion cells. Since actions of galanin and SS 28 on spinal dorsal horn neurons are still unknown, we examined the effects of these peptides on membrane properties and fast and slow excitatory synaptic transmission in the rat spinal dorsal horn.

Rats 16 to 22 days were used. Transverse or horizontal spinal cord slices, the latter with attached dorsal roots and ganglia were made. Cells were activated either directly with current injection via the bridge circuit, or synaptically by electrical stimulation of a lumbar dorsal root or dorsal root ganglion neurons. Peptides were applied by bath perfusion. Standard techniques were used for intracellular recording from dorsal horn neurons.

Both galanin (10^{-7} to 10^{-6}M for 1 to 7 min) and somatostatin 28 (10^{-7} to 10^{-6}M for 1 to 2 min) hyperpolarized dorsal horn neurons and caused reduction in frequency of presumptive spontaneous synaptic potentials. In 2 cells, however, a distinct depolarization was observed with galanin. While the hyperpolarization produced by galanin appears to be associated with an increase in neuronal input resistance, in the case of somatostatin 28 a fall in resistance was recorded. In the presence of TTX and TEA, galanin produced a reversible decrease in the duration of calcium spike. In the same cells apamin (5 x 10^{-8}M for 2 min), an 18 amino-acid polypeptide constituent of bee venom known to cause a block of $g_{K(Ca)}$ in a variety of tissues including spinal motoneurons, depolarized dorsal horn neurons and produced an increase in the duration of calcium spikes.

Galanin caused a marked, dose-dependent decrease in the amplitude and duration of fast and slow excitatory synaptic potentials. The depressant effect of galanin on the fast and slow excitatory synaptic transmission was reversible and the full recovery was observed within 10 to 20 min after removal of the peptide from the bath.

Our results are consistent with a neuromodulator role for galanin and somatostatin 28 in the rat spinal dorsal horn. The data obtained with apamin are consistent with the possibility that apamin increases the duration of the Ca spike by blocking $g_{K(Ca)}$ of dorsal horn neurons. Supported by NSF and USDA.

362.5 SOMATOSTATIN CAUSES HYPERPOLARIZATION OF CA1 PYRAMIDAL NEURONS BY ACTIVATION OF A MEMBRANE K^+ CONDUCTANCE. T.W.J. Watson and Q.J. Pittman. Neuroscience Research Group. University of Calgary, Calgary, Alberta, Canada T2N 4N1.

The cyclic tetradecapeptide somatostatin (SS_{14}) is a putative CNS neurotransmitter. We consistently observe a hyperpolarizing action of SS_{14} on rat CA1 pyramidal neurons and the purpose of these experiments was to examine the ionic mechanism underlying this hyperpolarization. 400 μm thick coronal rat hippocampal slices were placed in the well of a recording chamber and completely submerged and continuously perfused with oxygenated (95% O_2/5% CO_2) artificial CSF (conc. mM: NaCl 124, NaH_2CO_3 26, glucose 10, $MgSO_4$ 2, KCl 1.8, KH_2PO_4 1.25, $CaCl_2$ 1.5, pH 7.4) at a rate of 1.5-2.0 mls/min and maintained at 32-24°C. Intracellular voltage recordings from CA1 pyramidal neurons were obtained using high resistance (100-180 mΩ K^+-acetate) glass capillary microelectrodes and conventional recording techniques. Known concentrations of SS_{14} were added to the bath via an alternate perfusion line linked through a 4-way stop cock. 85% of CA1 pyramidal neurons exposed to 2μM SS_{14} exhibit a 3-8 mV hyperpolarization and suppression of spontaneous firing with response threshold being in the nanomolar range. This hyperpolarization is associated with an increase in membrane conductance and persists in 1 μM TTX and low Ca^{++} (0.5 mM) high Mg^{++} (3.5mM) where synaptic transmission is blocked. The response is blocked by membrane hyperpolarization but does not show a clear reversal potential. This SS_{14} induced hyperpolarization is not altered by recording with 2M KCl filled electrodes and thus is not Cl^- dependent. The action of SS_{14} persists in 10 mM extracellular tetraethylammonium (TEA) and following intracellular Cs loading using Cs acetate electrodes; under these conditions, in addition to hyperpolarization, SS_{14} also reduced the duration of the characteristically broadened action potentials. No change in the AHP was noted. In 5 out of 5 cells the hyperpolarizing response to SS_{14} was completely blocked by 1 mM tetrabutylammonium and was significantly reduced in 8 cells by 1 mM extracellular $BaCl_2$. We conclude that in rat CA1 pyramidal neurons, SS_{14} exerts a direct hyperpolarizing action mediated by activation of a membrane K^+ conductance that is relatively resistant to TEA and Cs.

362.6 SOMATOSTATIN REDUCES EXCITABILITY BY ENHANCING THE INWARD RECTIFICATION IN CULTURED LOCUS COERULEUS NEURONS. M. Inoue*, S. Nakajima and Y. Nakajima, Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907.

Somatostatin is a neurotransmitter which produces neuronal hyperpolarization through an increase in K^+ conductance (Katayama & North, J. Physiol., 303:315, 1980); however, it is not clear what type of K^+ channels are involved. Dissociated neurons from the locus coeruleus of newborn rats were cultured for about 3 weeks (Masuko et al., J. Neurosci., 6:3229, 1986). Whole cell clamp experiments revealed that application of 0.1 μM somatostatin by pressure ejection produced a slow outward current when $[K^+]_o$ was 2.5 mM and the holding potential was -70 mV. Somatostatin-sensitive currents at various potentials were computed by subtracting control currents from currents during somatostatin application. The relationship between the somatostatin-sensitive currents and potentials revealed an inward rectification, currents increasing in the hyperpolarizing direction and decreasing in the depolarizing direction. The somatostatin-sensitive current reversed its polarity near the K^+-equilibrium potential (-105 and -86 mV at $[K^+]_o$ = 2.5 and 5 mM, respectively). Cs^+ and Ba^{2+}, each at 0.1 mM suppressed the somatostatin-induced conductance in a voltage-dependent manner. Calcium-dependent K^+ conductance does not seem to be involved in the somatostatin-induced response because: (1) apamin at 20 nM had little effect on the response, while apamin abolished the slow after-hyperpolarization produced by repetitive action potentials; (2) TEA^+ (2 mM) had only a small effect on the somatostatin response, while the TEA^+ considerably inhibited the outward currents produced by depolarization to -20 mV. The somatostatin-induced response was almost completely blocked by treating the neurons with pertussis toxin (500 ng/ml) for at least 18 hours. When the patch pipette was filled with GTP-γ-S (500 μM), somatostatin application produced an almost irreversible outward current. We conclude that the somatostatin-induced hyperpolarization, which occurs over a high membrane potential range (say, more negative than -70 mV), is caused by an enhancement of the inwardly rectifying channels, and the response is mediated through a G-protein (possibly Gi or Go) that is sensitive to pertussis toxin. Supported by NIH grant AG06093.

362.7 **INTRATHECAL SOMATOSTATIN CAUSES HINDLIMB PARALYSIS AND REDUCES SPINAL CORD BLOOD FLOW IN RATS.** J.B. Long, A. Martinez-Arizala*, J.M. Kraimer[1,]* and J.W. Holaday. Neuropharmacol. Br, Dept. of Med. Neurosci., Div. of Neuropsych., and [1]Div. of Surg., Walter Reed Army Inst. of Res., Wash., D.C. 20307-5100.

Somatostatin (SOM) is distributed throughout the CNS and has been linked to diverse neuronal functions. When injected into the subarachnoid space of the rat lumbar spinal cord (SC), SOM causes loss of hindlimb (HL) motor and nociceptive function. Intrathecal (i.t.) dynorphin A (1-13) and arg[8]-vasopressin also produce flaccid HL paralysis in rats which is associated with striking reductions in lumbosacral SC blood flow (BF) (Long et al., NIDA Monograph 75: 524, 1986 and Fed. Proc. 46: 1125, 1987). In these experiments we determined whether paralytic i.t. doses of SOM also alter SC BF, and examined SOM effects on HL function and SC perfusion following pretreatment with the SOM receptor antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)].

HL motor function was examined following intervertebral injection of SOM through 30 ga needles into the L4-L5 subarachnoid space of halothane anesthetized 300-350 g SD rats. Neurological evaluations using a 0-3 grading scale were made at varied intervals following injections. SC BF was examined following SOM injection through PE 10 i.t. catheters (8.5 cm) into the lumbar subarachnoid space of rats anesthetized with ketamine and xylazine (50 and 10 mg/kg, i.m., respectively). Two sequential injections of radiolabeled microspheres (10 min preceding and 5, 10 or 60 min following i.t. SOM injections) provided pre- and post-treatment measurements of cardiac output (CO) and BFs to the brain and cervical, thoracic, and lumbosacral SC.

SOM (1-25 nmoles) produced a dose-related HL paralysis within 1-3 min of injection. With lower doses of SOM (1-6 nmoles), rats recovered some degree of HL motor function within 48 hrs of injection. Higher SOM doses (12-25 nmoles) produced persistent motor impairment. SOM (6.2 and 12.5 nmoles) also significantly reduced BF to lumbosacral SC (41 and 80%) without altering CO or reducing BFs to the brain or other SC regions. The SOM antagonist (5 min pretreatment with 0.3 nmoles) blocked the HL paralysis produced by 3.1 and 6.25 nmoles of SOM, and significantly improved neurological recovery 24 hrs following i.t. injection of 12.5 nmoles of SOM. At this dose, the SOM antagonist also blocked lumbosacral BF reductions produced by 6.25 moles of SOM, and did not by itself alter SC perfusion. However, higher doses of the antagonist (0.6-2.5 nmoles) produced HL paralysis, indicating that this compound is a potent partial agonist at the receptor sites underlying these neurological deficits. Thus, SOM produced HL paralysis and reduced SC BF through interactions with a recognition site which could be at least partially blocked by the SOM antagonist. These results indicate a need for concern over the clinical application of i.t. SOM for analgesia (Chrubasik et al., The Lancet 2: 1208, 1984), and also suggest a possible role of endogenous SOM in SC injury mechanisms.

362.8 PROLONGED EXERCISE ELEVATES NEUROTENSIN LEVELS IN BLOOD AND ADRENAL GLANDS IN FEMALE RATS. J. F. Axelson and C. F. Ferris. Psychology Department, Holy Cross College, Worcester, MA 01610, Physio. Dept., Univ. Mass. Med. Cent., Worcester, MA 01520.

To examine the effects of prolonged exercise on neurotensin levels in adrenal glands and in systemic circulation, samples from female rats forced to SWIM were compared to control animals subjected to different treatments for the same duration as SWIMMERS. These control groups consisted of animals: 1) forced to wade in water; 2) RESTRAINED in small plexiglass chambers; and 3) living in SEDENTARY conditions. Daily SWIMMING, WADING, and RESTRAINING manipulations were increased in 15 minute increments until animals reached a maximum of 2.5 hours and then continued for one month. At the completion of the last day of exercise or control manipulations, animals were decapitated to obtain adrenal glands and blood samples. SWIM and RESTRAINED groups had three and two-fold increases in corticosterone, respectively, when compared to both WADING and SEDENTARY animals, which did not differ. A six-fold increase in mean adrenal neurotensin-like immunoreactivity (NTLI) content was seen in SWIMMERS when compared to all other groups.

In a second experiment, animals forced to SWIM were compared to SEDENTARY animals. After four weeks these animals had reached 2.5 hours of daily swimming and all animals were anesthesized with ether, the adrenals were removed, and blood collected from the abdominal aorta. Pools of adrenal glands and plasma were extracted and processed for the chromatographic (HPLC) and immunochemical characterization of neurotensin for the respective tissue. SWIMMER's pooled adrenal glands showed a pronounced elevation of NT (655 fmol/gm) when compared to SEDENTARY animals (209 fmol/gm). Following HPLC, NT and its' N-terminal metabolites, were two-fold higher in abdominal aorta blood samples in SWIMMERS when compared to controls. Recently, we have found that although adrenal NT levels appear to be chronically elevated in animals exercising for prolonged periods of time, NT levels immediately following swimming are elevated from those seen prior to exercise manipulations. In summary, forced swimming appears to be a reliable method for inducing a pronounced increase in the level of NT in both the adrenal gland and systemic circulation.

362.9 THE NEUROTENSIN (NT) ANALOGUE XENOPSIN ALSO EXCITES NIGRAL DOPAMINE NEURONS AND INDUCES HYPOTHERMIA IN RATS. S. Bischoff*, M. Heinrich*, E. Küng*, M. Pozza*, M. Schaub*, K. Stöcklin* and A. Vassout* (SPON: G.E. Fagg). Pharma. Res. Dept., Ciba-Geigy Ltd., 4002 Basle, Switzerland.

The tridecapeptide NT exerts many peripheral and central biological activities in rats and other species. Several natural structurally-related analogues have been isolated, among them Xenopsin, discovered in the skin of the frog Xenopus Laevis. This octopeptide presents analogies with the C-terminal end of NT and possesses a Trp residue in the corresponding 11 position of NT.
In this study, we compared the effects of Xenopsin with NT, the fragments NT_{8-13}, NT_{1-8}, and the analogue D-Trp^{11} a) in NT radioligand binding assays, b) on nigral DA neuronal firing rate, and c) on body temperature, all tests being performed in rats.
Xenopsin competed with NT binding sites in brain with IC_{50}'s of 300 and 9.5 nM in ^{3}H- and ^{125}I-NT radioligand binding assays respectively. In comparison, the IC_{50}'s of the other peptides were the following for competition with both radioligands: NT: 15/2.2 nM; NT_{8-13}: 2/1.5 nM; D-Trp^{11}: 1000/1570 nM. NT_{1-8} was inactive.
In electrophysiological studies, Xenopsin excited DA neurons in the substantia nigra (SN) pars compacta. The recordings were made on 400 µm coronal sections of the SN at 0.1 µM. Increased DA neuron firing rate was also found with NT, NT_{8-13} and D-Trp^{11} at 0.1 µM whereas NT_{1-8} was inactive. Compared to NT, all active peptides were equally or even more potent than NT.
Finally, effects on thermoregulation were evaluated by icv injection in rats implanted with cannula into the left lateral ventricle. Xenopsin produced hypothermia comparable to NT in its amplitude (-3°C), duration of action (about 2 h) and estimated ED_{50} (10 µg). D-Trp^{11} was more and longer active (ED_{50}: 0.17 µg), NT_{8-13} much less (ED_{50}: 130 µg) and NT_{1-8} inactive.
Although the existence of Xenopsin in rat brain is still a matter of controversy, our data confirm an interaction with low and high affinity NT binding sites and demonstrate that this analogue of NT can mimic both in vitro and in vivo biological activities of NT. Whether Xenopsin acted via its own or via NT receptors remains to be clarified.

362.10 SPECIES DIFFERENCES IN THE EFFECTS OF BENZOTRIPT, A CHOLECYSTOKININ ANTAGONIST, IN THE HIPPOCAMPAL CA3 REGION. D.B. Jaffe*, P.G. Aitken, J.V. Nadler (SPON: M.M. Okazaki). Depts.of Physiology and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

The rat and guinea pig differ in the distribution of neuronal cholecystokinin-like immunoreactivity (CCK-IR) in the hippocampal CA3 region. In the rat, CCK-IR is found only in interneurons, whereas in the guinea pig CCK-IR is found in the mossy fibers as well as in interneurons. We undertook the present study to determine if these species differ in the effects of CCK and of benzotript (BZT - a CCK antagonist) on CA3 electrophysiology.

Transverse hippocampal slices were prepared from Sprague-Dawley rats or Hartley guinea pigs and maintained at 35.5°C in an interface chamber. An extracellular recording electrode was placed in stratum pyramidale of CA3b, and a monopolar stimulating electrode was positioned to activate the mossy fibers. Electrode positions were adjusted to maximize the mossy fiber (MF)-evoked response. Input/output (I/O) curves were generated by plotting the amplitude of the MF-evoked response versus stimulus current over a range of stimulus intensities. Drugs were applied by dissolving them in the perfusion medium. CCK octapeptide, sulphated, was applied at 100nM and BZT was applied at 200µM. These concentrations were chosen to achieve a maximal effect based on the reported affinities of these compounds for CCK receptors. I/O curves were generated before drug application, after 30 minutes of perfusion with drug-containing medium, and after 30 minutes of drug washout. During drug application, slices were monitored for the occurrence of spontaneous synchronized activity ("bursts"). To provide a single statistic indicative of any drug-induced changes in I/O curves, a control value was first determined as the average area under the pre-drug and post-drug I/O curves. The area under the experimental I/O curve was then determined and expressed as a percentage of the control value. Statistical significance was assessed by performing a 2-way ANOVA on the raw I/O data. CCK had no effect on spontaneous activity or I/O curves in either rat or guinea pig slices. In contrast, BZT caused spontaneous bursting in both rat (0.53 ± 0.14 Hz) and guinea pig (0.55 ± 0.31 Hz). In addition, BZT had opposite effects on I/O curves in these two species. In rat slices, BZT increased the area under the I/O curve by 47%, indicating enhanced synaptic transmission or pyramidal cell excitability. In guinea pig slices, BZT decreased the area under the I/O curve by 28%, indicating a net depressant effect. All effects of BZT reversed upon washout. These results imply that endogenous CCK has a primarily depressant action on area CA3 of the rat, but a primarily excitatory action in area CA3 of the guinea pig. This difference may be related to the different anatomical locations of CCK-IR in the two species.
(Supported by NIH grant 17771).

362.11 EFFECTS OF CCK-8 IN COMBINATION WITH OTHER GUT PEPTIDES ON FOOD INTAKE IN MICE. A.J. Silver,* J.F. Flood and J.E. Morley. GRECC, VA Medical Center, Sepulveda, CA 91343

A number of gastrointestinal peptides inhibit food intake. It has been suggested that a combination of these peptides may act physiologically to terminate a meal. This research tests the hypothesis that combinations of peptides have an additive effect on food intake. Further, it is postulated that somatostatin may attenuate bombesin's effect on food intake by reducing bombesin's ability to release CCK.

The effects of CCK-8, bombesin (BOM) and gastrin releasing peptide (GRP), inhibited food intake relative to saline treated mice in a dose response manner. Doses of CCK-8, BOM or GRP which inhibited feeding by about 20% were combined with doses of somatostatin (SOM, 80 ug/kg) or glucagon (GLU, 5 ug/kg) which also inhibited feeding about 20%. When BOM or GRP were combined with SOM the observed effect on feeding was less than one would predict assuming simple additivity. However, when GLU was combined with BOM or GRP the effect on food intake was only additive.

CCK-8, SOM and GLU were hypothesized to involve independent effects on food intake; we found that the effect of CCK-8, SOM and GLU given in combination was what would be expected based on additivity.

CCK-8 (1, 2, 3 ug/kg) and BOM (0.25, 0.50, 0.75 ug/kg) yielded 9% to 45% inhibition of food intake in a dose dependent manner. Combinations of CCK-8 and BOM at a fixed ratio of 4 to 1 (BOM to CCK-8) yielded less inhibition than would be expected based on additivity. Varying the ratio of BOM to CCK-8 from 4:1 to 6:1 yielded only slightly less than additive effects on food intake. The results confirm the hypothesis, in that, the observed amount eaten was less only in combinations involving BOM, GRP and SOM; BOM failed to add to CCK inhibition of feeding. This suggests that bombesin at low doses produces its main effect by releasing CCK. CCK, glucagon and somatostatin produced additive effects in keeping with the hypothesis that the release of a combination of GI hormones is responsible for the termination of a meal.

362.12 FURTHER STUDIES ON THE ALTERATION IN BLOOD PRESSURE FOLLOWING INTRATHECAL INJECTIONS OF NEUROPEPTIDE Y IN THE ANESTHETIZED RAT. X. Chen* and T.C. Westfall (SPON: M. Walz). Dept. of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Previous studies from our laboratory have shown that the intrathecal injection of neuropeptide Y (NPY) has a depressor effect in normotensive Sprague-Dawley and Wistar Kyoto rats as well as DOCA hypertensive rats, but not in the Spontaneously Hypertensive Rat (Soc. Neurosci. Abs. 12:221, 1986). It has also been observed that the depressor effect of NPY involves alpha$_2$ and beta adrenoceptors. The purpose of the present study was twofold: first, to examine the effect of the intrathecal administration of NPY at a different spinal level on arterial blood pressure and heart rate in the anesthetized rat and second, to further examine the mechanism of the depressor effect of NPY by examining the response in animals treated with reserpine to deplete catecholamines.

Male Sprague-Dawley rats weighing 200-300 gms were used. Rats were anesthetized with urethane (1.6 g/kg, i.p.). For intrathecal injection the atlantooccipital membrane was exposed by a middle incision through the trapezoidal and rhomboid muscles, keeping the head flex at 35^{o} one polyethylene catheter (PE10) was inserted 4 or 6 cm down the spinal subarachnoid space (about T4 and T10, respectively) through a puncture of the atlantooccipital membrane. NPY was dissolved in saline and slowly injected at a volume of 10 µl. For reserpinized rats, reserpine (1 mg/kg, i.p.) was given at 48 hr and 24 hr before experiments. Arterial blood pressure was measured by a catheter placed on the left carotid artery. Heart rate was measured by EKG. For norepinephrine analysis, tissues (heart and a 4 cm segment of spinal cord) obtained at the end of the experiment were homogenized in 0.1 N perchloric acid, concentrated by alumina column chromatography, and norepinephrine measured by high performance liquid chromatography coupled to electrochemical detection. It was observed that there was a significant reduction of blood pressure and heart rate in Sprague Dawley rats following the intrathecal injection of 0.1 nmol of NPY into the spinal cord at the level of T4. The maximum reduction in blood pressure and heart rate was 16.20±1.39% ($P<0.01$) and 9.8±2.4% ($P<0.05$), respectively. Pretreatment with reserpine depleted norepinephrine levels in the heart and spinal cord by 94% and 53%, respectively. In these animals, the depressor effect of intrathecal injection of 0.1 nmol of NPY (T10) was significantly attenuated ($P<0.05$).

These results suggest that NPY produced similar depressor effects when injected to different spinal levels (T4 or T10). In addition, this effect is closely associated with spinal cord catecholamines.

362.13 **NEUROPEPTIDE Y: PRESYNAPTIC INHIBITION IN RAT HIPPOCAMPAL AREA CA1 MAY INVOLVE CALCIUM CHANNEL MODULATION.** W. F. Colmers, K. D. Lukowiak and Q. J. Pittman. Dept. of Medical Physiology, University of Calgary, Calgary, AB, T2N 4N1 CANADA

Neuropeptide Y (NPY), the most abundant peptide yet isolated from mammalian nervous tissue, has recently been shown to presynaptically inhibit transmission at the stratum radiatum-CA1 pyramidal cell excitatory synapse in the rat hippocampal slice, in vitro. The mechanism of NPY's action is not clear; however, two likely possible mechanisms are that NPY either turns on a potassium conductance, or turns off a calcium conductance at the presynaptic terminal. We tested these possibilities by manipulating potassium and calcium influxes.

Transverse, 400 µm thick slices were prepared from hippocampus of 125-300g male Sprague-Dawley rats, and maintained at 32° C submerged under constant perfusion of carbogenated medium, in which test substances were dissolved just prior to use. Standard techniques were used to record intracellularly (100-200 MΩ, K-acetate electrodes) and to record field potentials in area CA1 extracellularly as described previously (J. Physiol. 383:285).

Application of the K^+ channel blocker 4-aminopyridine (4AP) at the relatively low concentrations of 10-50 µM enhanced synaptic transmission evoked by a single, brief shock to stratum radiatum. Somatic input resistance of the CA1 pyramidal neurons was not significantly affected by these concentrations. NPY (1 µM), in the presence of 4AP, was without its usual potent inhibitory action on the extracellularly-recorded population spike (PS) or intracellularly measured EPSP. Because the delay in membrane repolarization caused by K^+ channel blockade could enhance terminal calcium influx through other calcium channels, so as to overwhelm a potential NPY blockade of some of the calcium channels, the calcium concentration in the medium was lowered to compensate. Application of 1 µM NPY in the presence of 10 µM 4AP and 0.7 mM Ca^{++} caused a reversible reduction in both PS and EPSP (49.3±14.31% and 66.1±3.5% of control, respectively; $P< 0.001$). While NPY was without effect in 50 µM 4AP and 0.7 mM calcium, a further reduction of calcium to 0.5 mM restored NPY's inhibition of PS and EPSP (50.1±10.9% and 51.4±5.1%; $P <0.001$).

The results indicate that NPY's effects are not due to activation of a 4AP sensitive conductance, as reduction of calcium influx restores the peptide's action. Because 4AP increases terminal input resistance, NPY-mediated activation of a different K^+ channel would actually have a greater hyperpolarizing effect, thereby enhancing inhibition. The data are consistent with an NPY-mediated decrease in calcium influx at the presynaptic terminals in CA1. Supported by MRC of Canada. 362.14 NEUROPEPTIDE Y AFFECTS THE RELEASE OF LHRH FROM THE MEDIAN EMINENCE IN VITRO. F.D. Sabatino and J.K. McDonald. Dept. of Anat. & Cell Bio., Emory Univ. Sch. Med., Atlanta, GA 30322.

Intracerebroventricular administration of neuropeptide Y (NPY) in female rats decreases or increases plasma levels of luteinizing hormone (LH) depending on plasma levels of gonadal steroids (Kalra & Crowley, Life Sci. 35: 1173, 1984; McDonald et al., Neurosci. Abstr. 10: 1214, 1984; PNAS 82: 561, 1985). We have investigated the hypothesis that these effects are mediated by direct effects on the release of LH-releasing hormone (LHRH) from the median eminence (ME). Recent evidence has also shown that NPY can stimulate the release of LHRH from medial basal hypothalamic fragments in vitro (Crowley et al., Neurosci. Abstr. 12: 1414, 1986). In the first set of experiments, individual ME fragments from ovariectomized (OVX) rats treated with estradiol (E_2), E_2+progesterone (P) or oil vehicle were incubated in Locke's medium containing low $CaCl_2$ (0.8mM) for 15 min followed by two 30 min periods. KCl (56mM), NPY (10^{-6}, 10^{-7}, and 10^{-8} M), or control medium was applied at the start of the second 30 min. The ratio of LHRH released post/pre stimulation was examined within and between steroid treatment groups. KCl significantly stimulated LHRH release although NPY had no effect on LHRH release from ME fragments obtained from OVX and OVX-E_2+P treated rats. However, NPY (10^{-6}M) significantly stimulated the release of LHRH in the OVX-E_2 group compared to both the OVX and OVX-E_2+P groups. In a second set of experiments, ME fragments were incubated in Krebs-Ringer medium containing higher $CaCl_2$ (2.5mM), and additional doses of NPY (10^{-5}, $5x10^{-6}$ and $5x10^{-7}$M). The ME concentration and basal release of LHRH was significantly greater in the OVX-E_2+P group than in both the OVX and OVX-E_2 groups. KCl significantly stimulated the release of LHRH in all groups examined although NPY had no effect on LHRH release from ME fragments from the OVX and OVX-E_2+P groups. However, NPY(10^{-5}M) significantly stimulated LHRH release from ME fragments of OVX+E_2 rats. The lower dose of NPY ($5x10^{-6}$M) produced an intermediate stimulation while 10^{-7}M significantly inhibited LHRH release in this group. These results suggest that NPY can stimulate or inhibit LHRH release from the isolated ME depending on the plasma level of gonadal steroids. Supported by NIH HD19731, HD00727, and March of Dimes 5-524.

362.15 MEASUREMENT OF THYROIDAL VIP CONTENT BY RIA UNDER HYPER- AND HYPOTHYROID CONDITIONS. M. Michalkiewicz, L.J. Huffman, J.M. Connors, and G.A. Hedge, Physiology, West Virginia University Medical Center, Morgantown, West Virginia 26506.

Vasoactive intestinal peptide (VIP)-containing nerve fibers impinge upon both follicle cells and blood vessels in the thyroid gland. Since the administration of exogenous VIP results in increased thyroid blood flow, we investigated changes in thyroidal VIP content under a variety of conditions which are known to change circulating thyroid hormone levels or thyroid blood flow. We first validated the use of a radioimmunoassay (RIA) for VIP for the measurement of tissue VIP content. The VIP antiserum, generated in the rabbit, did not cross-react with known homologs, e.g. PHI, secretin, and GRF or 16 other neuropeptides. The within and between assay precisions were 4.6 and 11.5%, respectively. Recovery of VIP from 22 samples of .67M acetic acid extracts of bovine and rat thyroid tissue was 83.3% and serial dilution curves of these extracts were parallel to standard curves using porcine VIP in the RIA. Thyroid VIP concentrations (ng/g) were found to vary among species: bovine (145.1); porcine (6.43); dog (34.12); and rat (19.65 + 2.57). Relative to concentrations of VIP in other tissues in the rat, thyroid VIP levels were lower than VIP levels in the gut, brain, anterior pituitary, and adrenal. We next assessed rat thyroidal VIP content under the following conditions known to change thyroid function: cold exposure (4°C, 4 hrs); propylthiouracil (PTU: 1 mg/100g, ip, 6 days); and T_4 (5 µg/100g, ip, 6 days) treatment. As expected, plasma TSH (.68 + .09 µg/dl) and T_3 (102.1 + 4.4 ng/dl) levels were elevated in rats undergoing cold exposure above values for control rats (.47 + .05 µg/dl and 59.5 + 4.8 ng/dl, respectively). Following administration of the thyroid inhibitor, PTU, plasma T_3/T_4 levels were suppressed while plasma TSH was increased two-fold. We have also found that this treatment is associated with marked increases in thyroid blood flow. In T_4-treated rats, plasma TSH levels were undetectable. In spite of these documented changes in thyroid function, thyroidal VIP content remained unchanged in cold-exposed, PTU, and T_4-treated rats. There was, however, a tendency for VIP concentrations to be lower in PTU-treated rats presumably due to the 78% increase in thyroid weight (16.5 + .5 mg in control rats vs. 29.3 + 2.5 mg, $p < .05$). Thus, our findings provide no evidence that the extensive VIP-ergic innervation of the thyroid is involved in modulating circulating thyroid hormone levels or thyroid blood flow. 362.16 CYCLIC AMP MEDIATES THE EFFECTS OF VASOACTIVE INTESTINAL PEPTIDE ON CHROMAFFIN CELL ENKEPHALIN LEVELS. Steven P. Wilson. Department of Pharmacology, University of South Carolina School of Medicine, Columbia, SC 29208

Vasoactive intestinal peptide (VIP) increases the levels of enkephalins and larger proenkephalin fragments containing enkephalin sequences (ECPs) in primary cultures of bovine adrenal medullary chromaffin cells (Wilson, S.P., Life Sci. 40:623, 1987). A maximally effective concentration of 5 µM VIP increased enkephalins and ECPs by an average of 72%; the half-maximally effective concentration was 1 to 2 µM. Maximum effects were observed after 48 hr of continuous treatment; however, only 8 hr of exposure to VIP was necessary to maximally elevate enkephalin and ECP levels when measured 3 days later. Secretin (10 µM) was approximately one-half as effective as VIP in increasing ECPs, whereas glucagon, neurotensin, somatostatin, and neuropeptide Y did not alter chromaffin cell ECPs.

VIP (5 µM) elevated cyclic AMP levels in the cultures by 40 to 150% in 15 min. Elevated cyclic AMP levels were also observed up to 24 hr after addition of VIP but were lower than the 15 min values. The effects of VIP on cyclic AMP levels were potentiated by cyclic nucleotide phosphodiesterase inhibitors including theophylline and 3-isobutyl-1-methylxanthine, which also increased chromaffin cell cyclic AMP levels, and Ro20-1724, which alone produced little or no change in cellular cyclic AMP. There was a general correspondence between the concentrations of VIP which elevated cyclic AMP and those which elevated enkephalin and ECP levels.

VIP caused some loss of cellular catecholamines; however, this effect was not blocked by hexamethonium or d-tubocurarine, nor did these drugs alter the effects of VIP on enkephalins and ECPs. In short-term experiments (up to 2 hr), VIP did not induce secretion but potentiated that in response to nicotine. Secretagogues, including nicotine and histamine, and other compounds such as substance P, angiotensin II, insulin, reserpine, and tetrabenazine failed to alter chromaffin cell cyclic AMP levels.

Hence, VIP appears to evelate chromaffin cell enkephalin and ECP stores via a cyclic AMP-dependent mechanism. Because VIP is found in nerve terminals innervating the adrenal medulla, this neuropeptide may be a trans-synaptic modulator of chromaffin cell function via adenylate cyclase. (Supported by National Science Foundation grant BNS 86-04295.)

362.17 EVIDENCE THAT VASOACTIVE INTESTINAL PEPTIDE ADMINISTERED DIRECTLY TO THE SPINAL CORD PRODUCES ANALGESIA IN RATS. Barry R. Komisaruk, Cynthia Banas*, Stephen B. Heller*, Beverly H. Whipple, Guy F. Barbato* and Frank Jordan*. Institute of Animal Behavior and Department of Chemistry, Rutgers-The State University of New Jersey, Newark, N.J. 07040.

Vaginocervical stimulation increases firing rate in the pelvic nerve (Science,178:1295,1972), whose terminal distribution in the spinal cord corresponds to that of Vasoactive Intestinal Peptide (VIP) (Somatosens. Res., 1:69,1983; Nature, 305:143,1983). We hypothesized that the powerful analgesia produced by vaginocervical stimulation would be mimicked by administration of VIP directly to the spinal cord. VIP (5ug in 5ul saline) injected intrathecally (i.t.) at the lower lumbar level via a chronically-implanted PE10 catheter significantly increased tail-flick latency (TFL) to radiant heat more than 120% over control pre-injection baseline levels within 3 min post-injection. VIP (500ng and 250ng, but not 50ng), also significantly increased TFL. TFL elevation persisted for 10 min only with 5ug VIP (n=10/group). In a second experiment (n=11/group), naloxone HCl was administered i.p.,(10 mg/kg), 30 min before i.t. injection of VIP (5ug or 2.5ug). Control groups received only saline, naloxone, or VIP alone at these doses. TFL in the VIP-alone groups was significantly greater (60-62% above baseline) than in the saline or naloxone-only groups (1-6% above baseline). TFL in the VIP + naloxone groups (18-49% above baseline) did not differ significantly from the VIP-only groups. TFL in the VIP (5ug, but not 2.5ug) + naloxone group was significantly greater than TFL in the saline group. Using a different behavioral assay, vocalization threshold to tail shock was significantly elevated by administration of VIP (5 ug) at 3-10 min and 20 min post i.t. injection. At 5 and 10 min the VIP 5ug group was also significantly elevated over the VIP (5 ug + naloxone) group. These data indicate that VIP produces analgesia via both opiate and non-opiate-modulated pain pathways, since naloxone was more effective in antagonizing the analgesic effect of VIP on the vocalization threshold test than on the TFL test. 362.18 SALMON CALCITONIN ANALOGUE WITH IMPAIRED HELICAL STRUCTURE INTERACTS SELECTIVELY WITH BRAIN RECEPTORS FOR CALCITONIN IN RAT. M. J. Twery, P. K. Seitz[s], G. A. Nickols[s], C. W. Cooper[s], R. Orlowski[1s], and J. P. Gallagher. Dept. of Pharmacology and Toxicology, Univ. of Texas Medical Branch, Galveston, TX 77550 and [1]Armour Pharmaceutical Co., Kankakee, IL 60901.

An amphipathic helical conformation in a region of the calcitonin (CT) molecule contributes to the high potency of the hormone in lowering serum calcium. Since CT also has potent effects on behavior and neuronal activity, the present investigation was carried out to compare the conformation-activity relationship of salmon CT (SCT) and gly[8]-des-leu[16]-D-arg[24]-SCT (CTA), an analogue with reduced helix forming ability, in brain and in a peripheral tissue possessing sensitivity to CT. Determinations of adenylate cyclase (AC) activity, ^{125}I-SCT binding and ^{125}I-calcitonin gene-related peptide (CGRP) binding were made using forebrain tissue and kidney cortical membranes taken from male rats (250-350g) and prepared by homogenization and differential centrifugation through sucrose. The specific binding of ^{125}I-SCT was displaced by CTA (0.1-10 uM) in brain, but not in kidney, membranes. Neither CTA (1 uM) nor SCT (0.3 uM) displaced the binding of ^{125}I-CGRP to brain membranes. In brain membranes basal AC activity (174 pmol/mg/min) was inhibited 24-50% by CTA (0.1 nM-1 uM) and 10-20% by SCT (0.1 nM-1 uM). In contrast, the AC in renal membranes activity was stimulated. SCT (0.1 nM-1 uM) increased basal AC activity (5.8 pmol/mg/min) two to five fold. CTA increased basal AC activity by only two fold at the highest concentration tested (1 uM). In renal membranes the guanine nucleotide-stimulated AC activity was also increased by SCT (0.1 uM) but not by CTA (0.1 uM).

Electrophysiological studies were performed in vitro using a submerged brain slice preparation from male rats (120-180g) containing the septal nuclei. Intracellular single electrode recordings made from septal neurons during superfusion of CTA and SCT revealed that both peptides were capable of producing either membrane hyperpolarization (2-10 mV) or depolarization (2-5 mV) accompanied by changes in membrane conductance. These results indicate that CTA has pharmacological activity in brain similar to that of SCT and that CTA lacks the high potency of SCT at CT receptors in peripheral tissues. The findings are consistent with the low potency of CTA (2.5 IU/mg) compared to SCT (4500 IU/mg) in lowering serum calcium peripherally. While the amphipathic helical conformation of the CT molecule appears important for the high potency of the hormone peripherally, we conclude that this conformation is not essential for the actions of CT at sites in the central nervous system.

362.19 MULTIPLE ACTIONS OF CALCITONIN GENE-RELATED PEPTIDE ON RAT SPINAL DORSAL HORN NEURONS. P. D. Ryu* G. Gerber*, and M. Randic. Dept. of Vet. Physiol and Pharmacol, Iowa State University, Ames, IA 50011.

Calcitonin gene-related peptide (CGRP) is a 37 amino acid peptide encoded in nervous tissue by alternate processing of the primary transcript of the calcitonin gene. In the dorsal horn of the spinal cord, CGRP-like immunoreactivity (CGRP-LI) is likely to be of primary afferent origin and is found in highest density in laminae I, II and V. In the dorsal root ganglia CGRP-LI was observed in most of the small and some of intermediate size cells. At the ultrastructural level, axonal varicosities containing CGRP-LI were presynaptic to vesicle-containing profiles. Asymmetrical synapses are formed on spines, small and large caliber dendritic shafts, and occasionally somata of dorsal horn neurons. In addition, the release of CGRP from dorsal root and trigeminal ganglia has been demonstrated in vitro. These data suggest that CGRP may play a functional role in the transmission of sensory information in the dorsal horn. Our experiments were designed to examine the actions of CGRP on membrane properties and fast and slow excitatory synaptic transmission in the spinal dorsal horn.

Rats 14-20 days old were used. Transverse or horizontal spinal cord slices, the latter with attached dorsal roots and ganglia were made. Intracellular recording from dorsal horn neurons using 3M K acetate microelectrodes was employed. Fast and slow excitatory synaptic potentials were evoked by electrical stimulation of a lumbar dorsal root or dorsal root ganglion neurons. Tested compounds were applied by bath perfusion in known concentrations.

CGRP (10^{-7} to 10^{-6} M for 1 to 15 min) produced a dose-dependent, prolonged depolarization, which is frequently preceded by hyperpolarization. Both membrane effects were present in a TTX-containing solution, and even enhanced. The depolarization was associated with increased synaptic activity and in some cells enhanced probability of action potential discharge in response to indirect stimulation. Neuronal input resistance during CGRP-induced depolarization appeared to decrease in some cells but increased in other cells. CGRP augmented depolarizations to L-glutamate and NMDA in about 30% of cells. In TTX and TEA solution, CGRP modified duration of Ca spikes of dorsal horn neurons. The reversible increase in Ca spike duration was also observed in dorsal root ganglion cells. In the presence of TTX, CGRP infrequently elicited rhythmic oscillations of the membrane potential which were blocked by cobalt ions. Augmentation of composite fast low and high threshold e.p.s.p.s., and slow e.p.s.p.s. was observed in more than half of tested dorsal horn neurons in which CGRP produced no depolarization or changes in input resistance. Our results are consistent with a neurotransmitter or neuromodulator role for CGRP in the rat spinal dorsal horn. Supported by NSF and USDA.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: VESTIBULAR SYSTEM III

363.1 HEAD MOVEMENTS OF THE LIZARD DURING OPTOKINETIC AND VESTIBULAR STIMULATION. H. B. Wang* and J. H. Anderson (SPON: J. Fohlmeister). Dept. Otolaryngology and Physiology, Univ. Minn., Mpls., Minn. 55455.

The contribution of optokinetic and vestibular inputs to the control of eye movements has been extensively studied in normal and sensory conflict situations. The latter has served to define some of the adaptive capabilities of the vestibulo-ocular reflex (VOR) in mammals. Also, the vestibulo-collic reflex (VCR), which contributes to the control of gaze together with the VOR, has been studied in some species under normal conditions. However, the adaptive behavior of the VCR has not been well defined and to more completely study adaptation of gaze it is necessary to do so. The present work is aimed at this.

The lizard, varanus exanthematicus, was used. Each animal was restrained but its head was free to move. Head position was measured with the magnetic search coil technique. Sinusoidal rotations from 0.02 to 0.8 Hz were applied during three stimulus conditions: rotation of the animal in the dark (vestibular), rotation of the visual surround (visual), and rotation of the animal together with the visual surround (visual/vestibular conflict).

During pure vestibular stimulation, the gain (head velocity/stimulus velocity) varied from 0.05 to 0.25 over the frequency range. At a given frequency the VCR gain increased as the maximum stimulus velocity increased from 10 to 50 deg/s. For frequencies from 0.02 to 0.1 Hz the phase lead of the VCR decreased from about 80 to 10 deg. During optokinetic stimulation the gain decreased from 0.35 to 0.05 and the phase changed from a lead of 20 deg to a lag of 30 deg over the frequency range. In the conflict situation there was a reduction in the amplitude of the head movement so that the gain was less than 0.05 for frequencies below 0.1 Hz. To test for possible adaptation of the VCR, continuous rotation at 0.08 Hz was used. After four hours in the conflict situation the gain of the VCR decreased from 0.15 to 0.025. If the animals were deprived of vision at this time, the gain remained low for one to two hours.

These results provide a quantitative description of the visual and vestibular evoked head movement responses in the lizard. The gain of the VCR can be reduced by a visual/vestibular conflict situation and this reduction can be maintained. (Supported by NIH NS-16567.)

363.2 A COMPARISON OF NECK REFLEXES IN ALERT AND DECEREBRATE CATS. J.M. Banovetz*, S.A. Rude*, S.I. Perlmutter*, B.W. Peterson, and J.F. Baker, spon. by S. Vanden Noven, Dept. of Physiol., Northwestern Univ. Med. Ctr., Chicago, IL 60611)

The two sensory systems involved in neck reflex control are organized in fundamentally different ways. Vestibular inputs are in a 3 dimensional canal frame and neck stretch inputs in a 30 dimensional muscle frame. To generate a neck movement, however, both must be projected to the muscle frame. Kinematic properties of the reflexes may provide clues as to how these transformations take place, and how the reflexes interact in head stabilization.

We have studied vestibulo-collic (VCR) and cervico-collic (CCR) reflexes in four cats, two in the alert state and two in both alert and decerebrate states. The reflexes were elicited by rotating either the head and body together (VCR) or rotating the body while the head remained fixed (CCR). Rotations were done in three dimensions about 22 axes passing through the C1-C2 neck joint. The cats rested in the prone position on the rotator with their heads held pitched 28 degrees below the stereotaxic plane. In alert cats we were able to elicit a well modulated VCR, but the CCR was inconsistent. Some muscles showed brief periods of CCR modulation, but all muscles remained at a tonic firing rate throughout most of the rotations. After decerebration, however, the CCR became much stronger, showing consistant modulation. The VCR remained strong after decerebration. 5 muscles were studied in detail, and each was characterized by a maximal activation direction (MAD), the direction of rotation which produced the maximum response in the muscle.

Biventer cervicis, Splenius, Occipitoscapularis, and Rectus Major had MAD's close to pitch, with significant yaw and roll components. Complexus had a MAD closest to roll, with a significant pitch component and a small yaw component. The following is a table of the normalized decerebrate VCR components for the 5 muscles, and the difference, in degrees, between the alert and decerebrate VCR's and the decerebrate CCR and VCR.

muscle	yaw	pitch	roll	aVCR-dVCR	dCCR-dVCR
biventer	0.221	0.962	0.160	4.6	3.5
complexus	0.272	0.478	0.831	4.2	19.0
occipito	0.347	0.776	0.526	16.0	17.6
splenius	0.472	0.704	0.512	16.7	3.9
rectus M.	0.356	0.880	0.284	2.7	10.0

Decerebration had little effect on the MAD's of the VCR in 3 muscles, and produced moderate shifts in 2. The CCR MAD's were also generally similar to those from the VCR experiments. These data suggest that neck muscles have one primary direction of activation for both the CCR and VCR reflexes, and that the CCR is often suppressed in the alert cat.

Supported by NIH grants EY05289, EY06485, and NS22999.

363.3 HABITUATION OF THE EARLY VESTIBULO-OCULAR REFLEX (VOR) IN CAT. L.H. Snyder* and W.M. King. Dept. Physiology, Univ. Rochester, Rochester, NY 14642

Repeated steps of angular head velocity in cat cause habituation of vestibular nystagmus (VN). There appear to be two components of vestibular habituation: 1) a specific suppression of slow phase eye velocity (SPEV) during the first 4 s of nystagmus, and 2) a shortening of the duration of VN evoked by the velocity steps. Jeannerod, et al., (Biol. Cybern. 22: 39-48, 1976) assumed habituation to be an adaptive modification of the VOR, and modelled it as 2 parallel inhibitory mechanisms.

This report is concerned with the early suppression produced by habituation during the first 4 s of vertical VN. Further study of early habituation was prompted by evidence suggesting that the first seconds of the VOR are critical for gaze stabilization. To elicit the vertical VOR, cats were placed on their sides and rotated about their interaural axis. Eye velocity was recorded with high temporal resolution using a scleral search coil.

The following observations were made. 1) SPEV during the first beat of nystagmus was not altered by habituation. 2) SPEV was suppressed after the first nystagmic beat, but recovered within 4 s to the velocity attained in unhabituated VN. 3) SPEV appears to determine the frequency of fast phases (beat frequency) in unhabituated VN. However, when SPEV was suppressed by habituation, beat frequency was more appropriate to the unsuppressed SPEV of an unhabituated response. 4) Intense novel stimuli immediately extinguished early habituation.

Observation 2 suggests that although habituation strongly suppressed actual eye velocity, an internal representation of velocity was not effected. A velocity storage network has been posited to explain how VN outlasts peripheral nerve activity. If habituation reduced the charge received by the velocity storage network, SPEV could not have recovered to the level seen in unhabituated VN after the interval of early suppression. Therefore, velocity storage was uneffected by habituation. Observation 3 implies that beat frequency was dependent not on actual eye velocity but on an internal representation of eye velocity that also was unaffected by habituation.

Jeannerod, et al.'s model of habituation must be modified to account for these findings. First, the site of early habituation must be relocated to a site downstream of the velocity storage network. Second, the sparing of the first nystagmic beat must be incorporated into the model. Finally, evidence from this study and other data suggest that the early and late components of habituation may not be two aspects of a unitary process, but instead may originate from different neural networks possessing different connectivity and serving different functions.

Supported by NIH Grants GM07356 and EY04045.

363.4 SUPPRESSION OF POST-ROTATORY NYSTAGMUS DEPENDS ON AMPLITUDE NOT FINAL POSITION OF ACTIVE HEAD MOVEMENTS. L. Michaud*, P. DiZio, and J.R. Lackner (SPON E. Sullivan). Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

Repositioning the head following a sudden stop from constant velocity vertical z-axis rotation shortens the time constant (Tc) of slow phase decay of the vestibuloocular reflex (VOR) (Guedry, 1965; Benson & Bodin, 1966). Larger amplitude head movements lead to more suppression (Schrader, Koenig & Dichgans, 1985). Our study was conducted to determine whether sensorimotor signals associated with head movements per se or final head position relative to gravity mediate suppression.

Subjects (n=17) were rotated in the dark for 60 s at 60°/s about a vertical z-axis with their heads upright (0°), ventriflexed (-20° and -40°) or dorsiflexed (+20° and +40°). Following a sudden stop, Tc was measured to assess the effects of head position alone. In other trials, 1 s after a sudden stop subjects made active, mechanically constrained 20° or 40° pitch back head movements ending at 0°, +20°, or +40°. All subjects were exposed to all conditions in balanced order on four test days within a one month period. We compared trials with equal amplitudes but different final positions and trials with identical final positions but different amplitudes.

The Mean Tc's (in seconds) and their standard deviations are presented below.

Amplitude	Final Position				
	-40°	-20°	0°	+20°	+40°
0°	15.3(6.2)	16.0(6.3)	15.1(5.7)	16.8(6.8)	14.7(2.9)
20°			10.7(2.9)	11.4(3.0)	10.1(2.2)
40°			10.0(2.9)	8.4(2.6)	9.8(3.1)

An analysis of variance showed no effect of head position on Tc following sudden stops without head movements. Tc was significantly ($p<.005$) shorter with 40° than with 20° amplitude head movements, and there was no effect of final head position.

Thus, suppression of post-rotatory nystagmus seems to depend on the amplitude of active pitch back head movements but to be independent of final head position relative to gravity. This suggests that efferent and cervical afferent activity as well as otolith and vertical canal activity during post-rotatory head tilts trigger VOR suppression.

363.5 RETINAL IMAGE SLIP AND VESTIBULO-OCULAR REFLEX GAIN DURING LOCOMOTION AND VIGOROUS HEAD ROTATION. G.E. Grossman, D.J. Lanska*, W.P. Huebner*, S.M. Nazarian*, R.J. Leigh. Ocular Motility Lab, Cleveland VA Medical Center, Case Western Reserve University, Cleveland, Ohio 44106.

We measured retinal image stability in 5 subjects during walking, running, and vigorous active head rotations in yaw and pitch. While walking and running "in place" for 30 seconds, subjects attempted visual fixation of a target at a distance of approximately 100 meters. They also attempted visual fixation of a target (a cross) at a distance of 7.3 meters while rotating the head in yaw and then in pitch at a steady high frequency for 15 seconds. Gaze (eye position in space) and head rotations were measured using a magnetic search coil system. After filtering at 40 Hz, data were digitized at 100 Hz, differentiated and analyzed using an interactive program to yield values for velocity and power spectra. Result values below are medians (range).

All subjects experienced illusory movement of the visual target during large-amplitude vigorous head rotation; peak retinal error velocities (PREV) were 38°/sec (13-69) in yaw and 24°/sec (6.6-41) in pitch. PREV was greater during running than walking ($p<.05$). Running in place produced PREV in yaw of 2.0°/sec (1.4-4.1) and in pitch 7.3°/sec (5.6-10). During walking, PREV was 1.5°/sec (.8-1.7) in yaw and 1.2°/sec (.9-1.6) in pitch.

The gain of the vestibulo-ocular reflex (VOR), defined as peak eye-in-orbit velocity/peak head velocity, was less during vigorous head rotations, both in yaw and pitch, than during walking ($p<.05$). VOR gain during vigorous head rotation was .84 (.82-.93) in yaw and .91 (.83-.94) in pitch. VOR gain during walking was .93 (.92-.98) in yaw, and 1.0 (.91-1.1) in pitch. VOR gain of yaw rotations during jogging was .93 (.89-.98); this was not significantly different from active head rotations. However, pitch rotations during jogging had a higher VOR gain, 1.05 (.90-1.2) than voluntary pitch head rotations.

The lower VOR gain during voluntary head-shaking was not simply due to increased frequency. Pitch rotation frequencies during running, 5.6 Hz (2.4-7.6) were as high as or higher than those of active head rotations, 2.7 Hz (2.4-3.0), but VOR gain was lower during the latter. Similarly, we compared harmonic frequencies (pitch) during walking with fundamental frequencies of similar magnitude during active head rotation; VOR gain was lower for the latter. These data suggest that the higher retinal error velocities during vigorous active head rotation reflect (1) higher peak head velocities (2) a saturation of the VOR that may be velocity or acceleration dependent.

363.6 MEASURING VERTICAL CANAL FUNCTION THROUGH CALORIC INDUCED POSTURAL SWAY. R. N. Thakor*, T. C. Hain, R. Proctor* , Depts of Otolaryngology and Neurology, Johns Hopkins University, Baltimore, Maryland 21205.

Caloric testing does not detect unilateral lesions of the vertical semicircular canals primarily because their stimulation induces nystagmus that is vertical and torsional, which is not well measured using electro-oculography. However, vestibular stimuli that cause compensatory torsion of the eye, should induce lateral sway of the body. Lateral sway can be measured with a posture platform.

Accordingly, we performed calorics in 5 normal subjects, standing with the head pitched 30 deg down from upright, to make the lateral canals horizontal. Each ear was irrigated with water at 10° C for 40 seconds (flow rate 300 cc/min). Immediately thereafter, the position of the center of gravity was measured for 6 consecutive 20 second epochs on a servo-driven posture platform. In order to reduce proprioceptive cues, the lateral component of any change in position of center of gravity was fed back to the platform at 50% gain to partially null changes in the angle between the leg and the foot.

We found that caloric irrigation caused a shift of the center of gravity toward the side of irrigation. The mean maximum shift, occurred on average at 74 sec, (range 20-100) and was 0.53 ± .59° (mean ± sd, signs adjusted for side of irrigation). Peak-to-peak lateral sway, averaged over all 6 epochs, increased 0.43 ± 0.36° over the baseline. We also examined the effect of using other values of feedback gain. If no feedback was used, little shift of the center of gravity occurred. 100% feedback resulted in a fall in about half the trials.

Presumably, the ipsilateral shift in the center of gravity occurs to compensate for a sensation of roll to the opposite side. As the anterior vertical canal experiences a temperature differential during caloric irrigation (Dohlman, Acta Otol. Suppl. 5:1, 1925), our results could be due to its stimulation. While a direct thermally induced reduction in firing rate of the vestibular nerve is a second possible explanation, our results indicate that measurements of sway combined with caloric irrigation could be a powerful tool for evaluation of the function of the vertical semicircular canals.

363.7 THE EFFECTS OF AGING ON THE NYSTAGMIC RESPONSE TO IMPULSIVE CHANGES IN VESTIBULAR AND OPTOKINETIC STIMULI. P. DiZio and J. R. Lackner. Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

Falling-related injuries increase in frequency around age 65 (Fife, Barancik, & Chatterjee, Am. J. Pub. Hlth., 1984). This may be due in part to age-related structural changes in the vestibular system (Johnsson, Laryngoscope, 1971; Engstrom, Bergstrom, & Rosenhall, Arch. Otolaryng., 1974; Shuknecht, Igarashi, & Gacek, Acta Otolaryng., 1965). We have attempted to identify age-related changes in oculomotor responses attributable to specific vestibular changes.

We exposed 7 healthy elderly (mean age, 67.7) and young (mean age, 19.1) individuals to sudden stops after 60 s of 60°/s body rotation about a vertical axis in the dark. The step gain (Gvn) of nystagmic slow phase velocity was measured to assess the short time constant of the cupula-endolymph system and the integrity of the direct pathway of the vestibuloocular reflex (VOR); the time constant of slow phase velocity decay (Tvn) was determined to assess the long time constant and the combined activity of the direct and indirect pathways (Robinson, Exp. Br. Res., 1977; Cohen, Matsuo, & Raphan, J. Physiol., 1977).

There were no differences in Gvn across age groups, but Tvn was significantly ($p<.025$) longer in the elderly (20.1 s) than in the young (16.3 s). This pattern suggests that the long time constant and/or some aspect of the indirect VOR is more sluggish in elderly than in young individuals.

To test directly whether the velocity storage integrator of the indirect VOR (Raphan, Matsuo, & Cohen, Exp. Br. Res., 1979) was responsible for the longer time constant in the elderly we exposed 4 of the elderly and 4 of the young individuals to 60 s of 60°/s optokinetic stimulation and measured the decay constant of after-nystagmus (Tokan). We also measured the gain of the slow phase velocity of optokinetic nystagmus (Gokn).

In contrast to Tvn, Tokan was significantly shorter (3.60 s) in the elderly than in the young (8.97 s). For young subjects, Gokn was constant across the 60 s stimulation period, averaging 51.8°/s; however, for the elderly Gokn fell from 52.1°/s at 5-10 s to 35.9°/s at 55-60 s.

If the models of Robinson (1977) and Raphan et al. (1977) hold, the observed age-related increase in Tvn and decrease in Tokan may mean that there is an age-related increase in the cupula-endolymph long time constant and a decrease in the decay rate of velocity storage. These alterations in time constants and the unexpected decline in eye velocity during optokinetic stimulation in the elderly could diminish postural and visual stability during low frequency body movement.

It is well known that visual vestibular interaction is an essential component of normal vestibular function. In a recent animal study, the elimination of visual input from the eye ipsilateral to an induced peripheral vestibular lesion, significantly retards central vestibular compensation.

The present study investigated the effect of monocular and binocular visual fixation suppression of caloric induced nystagmus in man. Patients with peripheral and central vestibular dysfunction (n: 80) underwent caloric testing using 0°C irrigation. Resulting nystagmus was recorded using D.C.-EOG with eyes closed. Fixation suppression was obtained for ten seconds under three different conditions: both eyes open, right eye fixating and left eye fixating. Nystagmus was analyzed by evaluating the maximum slow phase velocity in each fixation period. Fixation suppression (nystagmus velocity EO/EC) above 50% was regarded as abnormal.

Results showed that the eye ipsilateral to the irrigated ear suppressed nystagmus greater than the contralateral eye (factor of 2). The degree of fixation suppression was similar with both eyes as with the ipsilateral eye. Furthermore, the contralateral eye was not able to suppress nystagmus below 50%. It is concluded that ipsilateral visual input is essential in suppressing induced vestibular nystagmus and therefore, modifying visual vestibular interaction. Anatomical, physiological and clinical implications discussed.

363.9 HYPO AND HYPERGRAVITY IN PARABOLIC FLIGHT AFFECT OCULAR TORSION: HOW DO THESE CHANGES RELATE TO OCULAR COUNTERROLLING IN 1G? S.G. Diamond, C.H. Markham, K.E. Money*, N.M. Kirienko*, D.G. Watt, W.H. Johnson*. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024, USA; DCIEM, Downsview, Canada; NRC Canada, Ottawa, Canada; St. Michael's Hospital, Toronto, Canada; McGill University, Montreal, Canada.

Ocular torsion is a reflex governed by gravity receptors in the otolith organs of the inner ear. Money et al. conducted a study during parabolic flight of a KC-135 aircraft to test the hypothesis that in 1G the eyes are normally held in the appropriate torsional position by central vestibular mechanisms that have adapted to otolith inputs which are not perfectly symmetric. Six healthy subjects were subjected to 0G and 1.8G alternately occurring in 6 to 10 parabolas. Two photographs of a single eye were taken in these hypo and hypergravity episodes, each of which lasted about 25 sec. Measurements of ocular torsion were later made using a twin projector system accurate to 0.1°.

Results showed that two subjects had a clear phasic response, with the eyes torting in one direction at 0G and in the other direction at 1.8G. The responses of these two persons were opposite in polarity, possibly reflecting their individual asymmetries. A third subject showed large phasic changes during the first 4 parabolas, with both the amplitude and phasic characteristics diminishing as that flight and a subsequent one progressed. Two other subjects showed moderate torsional changes without clear relation to gravitational changes. The sixth subject had consistent torsion in one direction with both hypo and hypergravity.

The wide range of responses suggested that an examination of ocular counterrolling (OCR) in the normal 1G environment might provide a baseline for better interpretation of the parabolic flight results. These studies are under way. Preflight examination of OCR consists of rolling the subject about the naso-occipital axis at 3°/sec constant velocity to 90° right ear down, reversed and rolled to 90° left ear down, and the procedure repeated without stopping. The same protocol is then followed in earth-horizontal long axis (BBQ) rotation. Postflight examination is a duplicate of preflight studies. Both eyes are photographed at each 10° of rotation. Well established norms of consistency, conjugateness, smoothness and symmetry permit evaluation of a given subject's OCR.

Inflight parabolic studies of subjects whose preflight and postflight OCR are known should enable a more definitive test of the otolith asymmetry hypothesis. Ideally, the preflight OCR will demonstrate the adapted response in the normal 1G environment, parabolic studies reveal inherent asymmetries, and sequential postflight studies show the return to the adapted state.

363.10 EVIDENCE FOR OTOLITH COUPLING TO VELOCITY STORAGE IN HUMAN OPTOKINETIC AFTERNYSTAGMUS. S.H. Lafortune, D.J. Ireland*, R.M. Jell. Depts of Physiology and Otolaryngology, University of Manitoba, Winnipeg, CANADA

A common velocity storage mechanism is thought to be involved in the generation of both post-rotatory nystagmus (PRN) and optokinetic afternystagmus (OKAN). Schrader et al. (1985) have shown that active head tilts suppressed PRN in humans. In monkeys, OKAN can also be suppressed by tilts (Raphan & Cohen 1981; Waespe et al. 1985). This tilt induced suppression was attributed to activity arising in the otolith organs which had coupled to the velocity storage mechanism thereby "dumping" its contents. To test the hypothesis that otolith organ mediated activity can couple to the horizontal velocity storage in humans, we have examined the effects of active head movements about the pitch, roll, or yaw axes on human horizontal OKAN. Subjects (N=6) were exposed to randomized optokinetic sessions performed at weekly intervals: one session per head movement examined, one control session with no head movement. Each session consisted of one OKN/OKAN head movement trial in one direction followed by a head movement trial in the opposite direction, each trial preceded and followed by a control trial without head movement. One trial consisted of 60 seconds optokinetic stimulation at 40 deg/sec, followed by a "lights out" period of 60 seconds. In each head movement trial, subjects were instructed to briskly execute one 90 deg. active head movement on cue (4 seconds after lights out) and to maintain their head in the new position until the end of the trial. Head movements examined were: pitch forward, pitch back, roll left, roll right, yaw left, yaw right. The degree of tilt-induced OKAN suppression was measured as the area computed under the decay curve relative to the control curves. Active head tilts about the pitch axis, either forward or backward, were found to produce significant OKAN suppression i.e. "dumping" of the velocity storage ($p<0.01$) relative to control trials. Pitch forward tilts exerted the strongest effect ($p<0.005$). Active roll right tilts also produced significant dumping ($p<0.005$). Although not significant at $p=0.05$, a similar effect was observed with roll left tilts. No dumping was observed following a yaw movement. Head movement trials did not alter subsequent control trials as measured by the consistent OKAN double exponential decay coefficients obtained in control trials. We conclude that otolith organ mediated activity arising from pitch or roll tilts can couple to the horizontal velocity storage in humans, thereby suppressing ongoing OKAN. 363.11 **Dynamic otolith stimulation improves the horizontal vestibulo-ocular reflex.** S. A. Rude* and J. F. Baker, Dept. of Physiology, Northwestern University Medical School, Chicago, Il. 60611

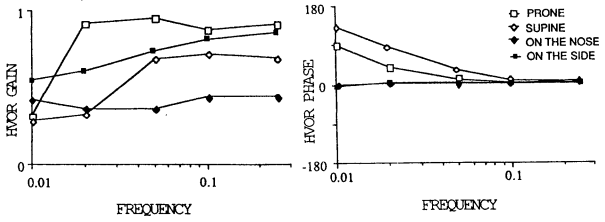
The horizontal vestibulo-ocular reflex (HVOR) is generally studied in an earth-horizontal plane during vertical-axis rotations. These rotations stimulate the semicircular canals to produce the HVOR without dynamically stimulating the otoliths. If the head and rotation axis together are tilted (e.g., ninety degrees from this vertical axis position to a horizontal axis position), the same rotation with respect to the head now presents the same stimulus to the semicircular canals but adds a dynamic stimulus to the otoliths. Does this added otolith stimulation contribute to the HVOR?

We compared the HVOR from horizontal canals to the HVOR from horizontal canals plus otoliths using electrooculographic measurements in 4 cats (13 experiments) during sinusoidal rotations in the dark at frequencies from 0.01 Hz to 2.5 Hz in 5 body orientations. For horizontal canal HVOR (vertical axis rotations) we placed the whole body in the normal (prone) position or on the back (supine). For horizontal canal plus otolith HVOR (horizontal axis rotations) we placed the whole body on the left side, right side, or with the nose down (as though descending a tree).

At 0.01 Hz, the horizontal canal plus otolith HVOR (filled symbols below) showed a higher gain and a more accurately compensatory phase than the HVOR produced by horizontal canal stimulation alone (open symbols). Canal plus otolith HVOR gain remained relatively constant across all frequencies, while the HVOR gain from canal only orientations fell dramatically during low frequency rotations. In addition, gain decreases and phase advances were seen in the supine position at frequencies higher than in the prone position. Supported by NIH grants EY05289, EY06485.



363.12 A BILATERAL MODEL FOR EYE VELOCITY STORAGE IN THREE DIMENSIONS. J. H. Anderson. Dept. of Otolaryngol. and Physiol., Univ. of Minn., Minneapolis, MN 55455.

Recently a three dimensional model for velocity storage has been proposed (Hain, Biol. Cybern., 54:337-350, 1986). It incorporates both spatial transformations and positive feedback loops for visual/vestibular interactions which give rise to the storage of an eye velocity signal. However, the dynamics of the storage network are first order and the model does not describe the reversal phases of optokinetic after-nystagmus (OKAN) and post-rotatory nystagmus (PRN). The present work proposes a generaliztion of a bilateral model for velocity storage in the horizontal plane (Anderson, Assoc. Res. Otolaryn., 1987). The dynamics are second order and the full time course of OKAN and PRN can be described.

The model has three bilateral networks for the canal planes, each of which has a coupling between the two vestibular nuclei (VN), a feedback pathway to each VN which includes a leaky integrator, and bilateral coupling of the optokinetic pathways. The model can be represented by a matrix equation:

$$\underline{o} = \underline{A}^{-1}(\underline{r} + \underline{H}^{-1}\underline{c})$$

$\underline{A}$ represents the bilateral coupling between the two leaky integrators for each canal plane and can be partitioned so that its diagonal elements are each 2x2 matrices, one for each canal pair ($\underline{A}_h^{-1}$, $\underline{A}_a^{-1}$, $\underline{A}_p^{-1}$). $\underline{H}^{-1}$ is diagonal and represents the leaky integrators. $\underline{c}$ and $\underline{r}$ are the vestibular and retinal slip vectors in canal coordinates. $\underline{o}$ is a vector representing the output of the storage network. Eye velocity is obtained with coordinate transformations of this vector.

Depending upon the relative strengths of the several gain elements, the system can be over- or underdamped. The latter can be the case if the coupling of the optokinetic pathways have gains which are non-linear functions of $\underline{r}$ and will give rise to the reversal phases of OKAN. If $\underline{A}_a = \underline{A}_p$, then the vertical component of OKAN can have a profile like that of the horizontal but the time constant of the eye velocity during the OKAN can have a value during upward stimulation which is different from that during downward stimulation.

The present model is a frequency domain representation of a network for the eye velocity storage mechanism. It can account for the reversal phases of OKAN and PRN and the asymmetry of the vertical component of OKAN. Also, deficits following unilateral vestibular dysfunction can be simulated.

LEARNING AND MEMORY: PHYSIOLOGY IV

364.1 PERSEVERATIVE RESPONDING IN MALE AND FEMALE WISTAR RATS: EFFECTS OF TESTOSTERONE. A. van Hest*, F. van Haaren and N.E. van de Poll*. Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, the Netherlands.

Behavioral differences between male and female rats in non-reproductive behavior have been observed in a number of different experimental procedures. When exposed to operant schedules of reinforcement, male-female differences have been shown to be determined both by the absence or presence of different gonadal hormones as well as by the specific requirements of the experimental procedures. It has been suggested that some of the differences between male and female rats may also be a function of the fact that males are less likely than females to adapt to changes in environmental conditions. Perseveration has been observed in autoshaping procedures in which male rats, but not female rats, continued to respond on a lever which was no longer correlated with the presentation of food (van Haaren, F., A. van Hest and N.E. van de Poll, Learn Motivat, in press). Perseverative responding in male rats has been attributed to high levels of circulating testosterone (Thompson, W.R. and J.S. Wright, Physiol Psychol, 7:291-294, 1979). The present experiment was designed to investigate the effects of gonadectomy and chronic testosterone suppletion on perseverative responding. Response perseveration was investigated in an experimental procedure which has previously been shown to be sensitive to pharmacologically-induced behavioral perseveration and stereotypy.

Different groups of intact, gonadectomized or gonadectomized plus chronically testosterone treated male and female Wistar rats were exposed to a procedure in which reinforcers were randomly assigned to one of two levers in the experimental chamber. One response on the lever to which the reinforcer was assigned was sufficient to produce a Bio-Serve 45 mg food pellet. Responding on the lever not selected for reinforcement had no programmed consequences. Sessions ended after 40 reinforcers had been presented.

Perseveration, defined as the percentage of trials on which more than one response on the lever not selected for food was made prior to switching to the selected lever was highest for testosterone treated subjects. Females made more responses on the lever which had been selected for food on the preceding trial, whereas males showed a preference for one of the two levers irrespective of its previous association with reinforcement. The results of the present experiment thus suggest that males might be less sensitive to the consequences of responding as compared to females. This behavioral difference between the sexes may at least be partly mediated by the male hormone testosterone.

364.2 EFFECT OF PHORBOL ESTERS ON INHIBITORY PROCESSES IN RAT HIPPOCAMPUS. J. Turnbull*, D. Muller*, M. Baudry, G. Lynch (SPON: D. Arst). Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717.

Activation of Protein Kinase C (PKC) has been suggested to be critically involved in the induction of long-term potentiation (LTP) in the hippocampus. This is based in part on the correlation of LTP with the phosphorylation of a PKC substrate (protein F1) and on the long-lasting increase in synaptic efficacy observed following treatment with phorbol esters which directly activate PKC. Moreover, it has been difficult to induce LTP after PKC activation with phorbol esters. However, the reported effects of these compounds are numerous, and include increased transmitter release, modification of receptors, and changes in the membrane resistance and channel characteristics of the post-synaptic cell. Thus it is not clear that the effects of the phorbol esters are specific and indicative of a selective role for PKC activation in LTP formation.

In the present study, we have investigated the effects of phorbol dibutyrate (PDBu) on inhibitory mechanisms in the rat hippocampus using a standard in-vitro slice preparation and a paired-pulse paradigm. Stimulating electrodes were placed in the stratum radiatum of hippocampal field CA1 and homosynaptic or heterosynaptic pulses were delivered, with a usual interpulse interval of 40 msec. Recording electrodes were positioned in the dendritic field and the cell body layer of field CA1. In the dendritic field, treatment with PDBu (2-10 μM) produced a marked enhancement of the first response as expected, while there was reduced facilitation of the second response to homosynaptic stimulation. In the cell body layer, the first response was markedly enhanced while the second response was profoundly inhibited in both the homosynaptic and heterosynaptic paired-pulse stimulation paradigm. This heightened inhibition was present over a wide range of stimulation intensities and was at least partially bicuculline sensitive. Moreover, significant LTP could still be obtained after PDBu treatment had produced a marked increase in the synaptic response.

These findings suggest that the known actions of the phorbol esters should be extended to include potentiation of inhibitory processes, and may explain in part the difficulty in producing LTP after phorbol ester administration. They do not provide any additional evidence supporting a central role of PKC in the formation of LTP.

364.3 HIPPOCAMPAL PLACE CELLS AT WORK AND AT REST: A 2-DEOXYGLUCOSE AUTORADIOGRAPHIC STUDY OF HIPPOCAMPAL CIRCUIT FUNCTIONS. L.T. Thompson and P.J. Best, Depts. of Neuroscience and of Psychology, Univ. of Virginia, Charlottesville, VA 22903-2477.

Past work in our laboratory has examined chronic electrophysiological correlates of hippocampal pyramidal unit activity recorded in freely-moving rats. The rate of unit activity has been examined during sleep and during a number of behaviors, including cognitive mapping task performances on radial arm mazes. These neurons fire at high rates during slow-wave sleep (SWS) and are inhibited from firing during paradoxical (REM) sleep. Many of these neurons exhibit *place field* activity; i.e. their firing rate varies significantly as they pass through one or more places within a given environment while performing win-shift (WSH) or win-stay (WST) tasks. Work in other labs has suggested that EEG theta activity in waking rats reflects inhibitory modulation of neural activity within the hippocampus. Although much is known about the relationship of single-unit activity in such behavioral states, comparisons of regional metabolic activity have not been correlated with data from unit recordings. The present study examines regional glucose utilization in the hippocampus under waking and sleeping conditions relative to known electrophysiological properties of pyramidal neurons.

Six groups of young male Long-Evans rats were pretrained for experimentation. Two groups were selectively deprived of REM or of all sleep for 60 hr, and tested during REM or SWS rebound. One group was tested while running rapidly in a wheel for water reinforcement, a condition in which theta activity predominates in the hippocampal EEG. Two other groups performed radial maze tasks, with the place rewarded either changing each trial (WSH) or staying constant for each trial (WST). One group served as immobile waking controls. 250 µCi of [^{3}H] 2-deoxyglucose was administered, and the rats were sacrificed 45 min later. Autoradiographs were prepared from thaw-mounted chloroform-extracted sections using LKB Ultrofilm. The optical density of individual hippocampal laminæ in CA1, CA3, and dentate gyrus as well as subicular subfields was measured via densitometry, and ratios of grey / white matter glucose utilization were obtained.

Hippocampal unit activity reliably predicted glucose utilization measured in several laminæ in the waking groups. Under conditions in which pyramidal cells display *place field* related increases in firing, glucose utilization increased within dendritic and pyramidal cell body layers. Theta activity was associated with decreased glucose utilization in the same layers. Increased pyramidal cell activity was also associated with increased glucose utilization in subicular subfields. In contrast, although glucose utilization increased during SWS, the greatest increases were observed during REM, when pyramidal neurons are the least active. Clearly, in some of our conditions glucose utilization is predicted by single-unit data. Discrepancies indicate that similar patterns of unit firing can be generated by divergent patterns of hippocampal activation.

364.4 SELECTIVE CONTRIBUTION OF THE BASOLATERAL AMYGDALA AND THE PYRIFORM CORTEX TO THE ACQUISITION OF CONDITIONED TASTE- AND CONDITIONED ODOR-AVERSION LEARNING. N. Beaulieu*, S.Schwartzberg* and M. Petrides. Department of Psychology, McGill University, Montreal, Quebec H3A 1B1.

Various studies have implicated the amygdala, and more specifically the basolateral amygdala (BLA), in the control of flavor-aversion learning. Previous work conducted in our laboratory has also demonstrated that lesions of the BLA, that include the pyriform cortex, disrupt the acquisition of an aversion to an odor that is successively paired with Lithium Chloride (LiCl) toxicosis.

The present studies investigated the effect of bilateral electrolytic lesions restricted either to the BLA or to the pyriform cortex of rats on the acquisition of a conditioned taste aversion (CTA) and a conditioned odor aversion (COA). In the CTA experiment, the animals were tested for their ability to acquire an aversion to a sucrose solution (CS) that was paired with LiCl toxicosis (US). The animals were maintained on a water-deprivation schedule and trained to drink water from a Richter tube for 20 minutes a day for 5 consecutive days. On the day of conditioning, the animals were exposed to a sucrose solution (1.5%) which was followed by an intraperitoneal injection of LiCl (20ml/kg) to induce sickness. The acquired aversion was defined as a suppression of drinking when the animals were re-exposed to the sucrose solution, three days following the CS-US pairing day.

In the COA experiment, the rats were tested for their capacity to acquire an aversion to an odor (isoamyl acetate) that was paired with LiCl toxicosis. The animals were water-deprived and subjected to three CS-US pairings on 3 different drinking sessions. Three recovery days were allowed between each drinking session. The acquired aversion to the odor was again defined as a suppression of water-drinking in the presence of the odor after one, two and three conditioning sessions.

Lesions restricted to the BLA resulted in a clear attenuation of both the CTA and the COA, whereas damage to the pyriform cortex caused an impairment only in the acquisition of the COA. These results demonstrate a dissociation between the roles of the BLA and of the pyriform cortex in the acquisition of conditioned aversions to gustatory and olfactory stimuli. In light of this finding, it may be suggested that the BLA, which receives information from all sensory systems, is involved in the acquisition of aversions in various modalities, whereas the pyriform cortex, which receives information primarily from the olfactory system, may be involved more specifically in olfactorily-cued learning contingencies. Supported by NSERC grant A7466.

364.5 EXPERIENCE-INDUCED SPECIFIC CHANGES IN THE FREQUENCY RESPONSE FUNCTION OF UNIT CLUSTERS IN THE MEDIAL GENICULATE NUCLEUS OF THE GUINEA PIG. R.C. Lennartz*, J.F. Bourg*, K.T. Fan*, and N.M. Weinberger. Center for the Neurobio. of Learning & Memory and Dept. of Psychobio., University of California, Irvine, CA 92717.

Learning-induced changes in the responses of sensory neurons in the central nervous system have been reported by a number of investigators. Previous research has demonstrated changes in the evoked responses of cells in the medial geniculate complex (MG) and the auditory cortex during classical conditioning. Such effects could be due to learning-induced changes in general arousal level. However, CS-specific alterations in the frequency response function (FRF) of auditory cortex neurons were observed as a result of classical conditioning (Diamond and Weinberger, Brain Res., 1986, 372, 357-360), demonstrating that learning causes specific modifications in the processing of significant stimuli. The present study sought to determine if FRF changes develop in the MG consequent to auditory experience. FRFs were obtained while the animals were anesthetized to further control for arousal effects.

Unit clusters were recorded from the medial geniculate of guinea pigs with chronically implanted microelectrodes. The basic experimental procedure involved three days of recording. Day 1: the FRF (1 - 30 kHz) was determined with the animal under general anesthesia (Rompun, 20 mg/kg and ketamine, 100 mg/kg). Day 2: The animal underwent 20 classical conditioning trials (CS = tone, 6 seconds; US = shock, .3 sec, at US offset; ITI = 1 to 2 minutes). The subject was then anesthetized and an FRF determined. Day 3: A third FRF was obtained under anesthesia. This three day procedure was followed in most animals by either a second three day run (several days later) using a different tone as the CS or by a two-tone discrimination procedure (30 trials each of the CS+ and CS-).

The post-conditioning FRFs revealed changes that were specific to the tones used as the CSs; such specificity could be observed 24 hours after training. Therefore, CS-specific modification of FRFs are not restricted to auditory cortex. It is noteworthy that these data demonstrate for the first time that the anesthetized brain can show evidence of neural storage of information acquired while the animal is in the waking state.

364.6 TIME-DEPENDENT MODIFICATION OF THE MEMORY TRACE EVIDENCED BY PRE-TEST CUING IN RATS: P. Gisquet-Verrier* and T. Alexinsky* (SPON: J. Hirsch). Dept de Psychophysiologie, LPN2, C.N.R.S., 91190 Gif-sur-Yvette, FRANCE.

Following a partial brightness discrimination avoidance training in a Y maze, various pretest cuing procedures can enhance the retention performance when delivered before the retention test. Presentation of the conditioned stimulus (CS) was the most effective treatment shortly after training while exposure to the experimental context was most effective at long term (Gisquet-Verrier and Alexinsky, 1987 and in Press). These results could be due to a spontaneous reorganization of the memory trace over time. They could also be due to effects of cuing on different aspects of the memory processes e.g. consolidation or retrieval. An effect on memory storage processes would be expected to be long-lasting while an effect on retrieval processes would be transient.

The 180 rats of the present experiment were trained to escape or to avoid a footshock in a Y maze with a brightness discrimination for 15 trials. Testing occurred either one hour or 21 days later. For the animals tested after one hour, presentation of the CS (5-2sec intermittent light flashes) occurred either 0, 5, 10 or 20 min prior to the retention test. For the animals tested after 21 days, presentation of the experimental context (exposure to the experimental room) occurred either 0, 5, 10, 20 min, 1 or 24 hr before the retention test. The results indicate that in both conditions, cuing significantly enhanced the retention performance when delivered 5 or 10 min before the retention test and had only slight effects when delivered 20 min prior to the retention test. Moreover, there was no effect from an exposure to the experimental context 1 or 24 hr before testing.

The transient effect of cuing obtained for both the retention intervals indicates that cuing does not induce an elaborative process that would maintain over time but rather induces a phasic effect that fits well with a retrieval interpretation. Our previous findings indicating that the nature of the initial information leading to the best retention performance changes as a function of time appears then to be due to a reorganization of the memory trace that occured spontaneously over time.

364.7 ELECTROPHYSIOLOGICAL INVESTIGATIONS OF HABITUATION AND PRE-PULSE INHIBITION USING A NOVEL TECHNIQUE TO RESTRAIN AWAKE RATS. J.Cassella and M.Davis, Dept Psychiatry, Yale Univ Sch Med, New Haven, CT 06508.

The need to relate single cell activity to behavior has necessitated the development of appropriate preparations. We have developed a technique that permits the study of single-unit activity using glass micropipettes and conventional microdrives in restrained, awake rats. A unique feature of this preparation is that rats are kept still during electrophysiological recording by infusing a small amount of local anesthetic through a catheter chronically implanted into the spinal epidural space, resulting in a temporary mid-body to hind-limb motor blockade. The animal is placed in a modified stereotaxic device by a bolt attached to its skull.

The acoustically-elicited pinna response, a component of startle, displays various forms of behavioral plasticity (Cassella & Davis, Beh. Neurosci., 100, 1986).The motor neurons innervating the pinna are located in the medial facial motor nucleus (MFMN). As an initial application of the above technique, single-unit activity was recorded from the MFMN in awake, restrained rats that received acoustic clicks under conditions known to produce behavioral habituation and pre-pulse inhibition. Each rat was infused epidurally with tetracaine HCl, placed in the modified stereotaxic, and given a brief adaptation period. While lowering the single barrel micropipette acoustic stimuli were presented every few seconds. When positioned near a cell that responded to these stimuli with a 5-10 ms latency the stimulation was terminated and 15 min elapsed before testing.

For habituation tests, an acoustic click was presented for 20 trials at a 2 sec interstimulus interval. For pre-pulse inhibition tests, the rats received 25 clicks presented alone or preceded 100 ms by a weak noise burst. During habituation testing cells in the MFMN fired less often and with increased first-spike latency as a result of repeated stimulus presentation. For pre-pulse testing, cells in the MFMN fired less often and/or at longer latency on the trials when the pre-pulse stimulus was presented. These data are consistent with behavioral observations found under similar conditions, supporting the validity of this technique for studying the cellular correlates of plasticity of the acoustically-elicited pinna response.

Previously we proposed that the pinna response pathway is composed of the ventral cochlear nucleus, paralemniscal zone of the ventral lateral lemniscus(PLZ), and MFMN (Cassella & Davis, Neurosci. Abs., 1986). We now find that cells in the PLZ respond to a click with a latency of approximately 3 ms. The pinna response pathway is currently under investigation using a variety of methods including orthodromic and antidromic stimulation. Once the structures in series with the MFMN are identified, the locus and nature of plasticity of the pinna response can be determined.

364.8 LOCALIZED ACETYLCHOLINE APPLICATION MODULATES SENSORY EVOKED RESPONSES AND PERFORANT PATH FIELD POTENTIALS IN BEHAVING RATS. T.C. Foster* and S.A. Deadwyler (SPON: J.H. Ryu) Dept. Phys. & Pharm, Bowman Gray Sch. of Med., Winston-Salem, NC 27103.

Past research from this lab indicates that two major pathways to the dentate gyrus are responsible for the two characteristic negative components of auditory evoked potential recorded in the outer molecular layer of the dentate gyrus (OM AEP). An early N1 component of the OM AEP reflects perforant path tone evoked synaptic activity in the dentate gyrus while the N2 component is modulated by septal input (Deadwyler et al., Science, 211:1181, 1981). The purpose of this study was to evaluate the effects of locally applied acetylcholine (ACh) on the two components of the OM AEP.

Saline and drug filled pipettes for recording and drug application were lowered by a microdrive assembly and localized in the OM via stimulation of the perforant path. Stable behavior was maintained in the animals by recording during criterion performance of a single tone discrimination task. Randomly on 1/2 of the trials in a 100 trial behavioral test session microdrops (70-100 picoL) of 500 uM ACh were pressure ejected 15 sec before tone onset. A single perforant path stimulus was also delivered 500 ms before tone onset. In other experiments pipettes lowered into the granule cell layer measured the effect of ACh on the amplitude of the perforant path evoked synaptic response (EPSP) as well as the population spike amplitude to determine the time course of the ACh effect. Results showed that ejection of ACh during performance of the tone discrimination task resulted in a significant decrease in the amplitude of the N1 component of the OM AEP ($p < 0.01$) and an increase in the amplitude of N2 which was marginally significant ($p < 0.05$). The amplitude of perforant path elicited field potentials recorded in the OM were also decreased slightly for ACh vs non ACh trials. ACh ejected in the granule cell layer resulted in a significant increase in the population spike amplitude ($p < 0.05$). The time course of peak population spike increase after ACh application was 15 sec. Control sessions utilizing saline ejection did not have a significant effect on any of the variables measured. Results suggest that cholinergic inputs to the dentate gyrus modify behaviorally sensitive sensory evoked potentials in the rat.

364.9 LEARNING CAN AFFECT THE FACE-SELECTIVE RESPONSES OF NEURONS IN THE SUPERIOR TEMPORAL SULCUS OF THE MONKEY. Gordon C. Baylis, Michael E. Hasselmo* and Edmund T. Rolls. University of Oxford, Department of Experimental Psychology, Oxford, OX1 3UD, England.

There are neurons in the cortex of the superior temporal suclus of the macaque with responses selective for faces (Baylis et. al. Brain Res. 91, 91-102., 1985). These responses also show selectivity for the particular face stimulus. It has been suggested that this selectivity is based both on the identity and expression of the stimulus face (Hasselmo et. al. Neurosci Lett. 26: S571, 1986). The present series of experiments examines the extent to which learning is necessary for the selectivity between faces exhibited by these neurons.

In a first experiment the responses to a familiar set of faces was determined, then a totally novel face was introduced into the set. 32 cells were tested with a total of 43 novel faces. First, it was found that the mean response to novel faces in the first two presentations was significantly different from the mean response for all presentations of the novel faces, suggesting that learning was required to establish the final mean firing rate. Second, it was found that in 5 out of 43 cases a change occured in the pattern of responses to the familiar faces (as shown by a significant interaction of face and pre vs. post novel in an ANOVA), and 9 out of 43 cells showed a change in mean response after the addition of the novel image (as shown by a significant effect of pre vs. post novel).

In a second experiment a large set of novel faces were presented to the monkey whilst recording the activity of a cell with face-selective responses. 15 cells were tested on 19 different sets of faces. First, the responses to images in the first presentation varied from the subsequent baseline significantly more than the responses in other presentations, supporting the above data. Furthermore, in a subset of these cells the pattern of responses to the set of face stimuli changed across the early presentations, as measured by an ANOVA. This suggests that these cells differentiate faces in a way which is modified by experience.

These experiments show that changes in response to a face can occur as the face becomes familiar. In addition, for some cells there is a change of pattern of response to familiar faces as a novel face is incorporated with the familiar set. This pattern of data would be expected from a number of models of distributed memory. In particular, a competitive learning network model predicts both the change in response to novel faces and the alteration of response to familiar faces with the incorporation of new faces.

364.10 EFFECTS OF PHORBOL ESTER ON THE RELEASE OF EXCITATORY AMINO ACID IN THE CA1 HIPPOCAMPAL REGION OF THE ANAESTHETIZED RAT. By Y. BEN-ARI , L. ANIKZTEJN* and M.P. ROISIN.* U.29 INSERM. Hôpital de Port-Royal. 123 Bd de Port-Royal. 75674 Paris. Cedex 14.

In the hippocampal slice. application of phorbol ester produces a long term potentiation (LTP) of synaptic transmission which is reminiscent of the LTP produced by a high frequency train of stimulation (Malenka et al. Nature 1986. 31 - 175). The aim of the present study was to examine whether the LTP induced by phorbol ester is associated with a persistent enhanced release of endogenous excitatory amino acids.

Adult male wistar rats were anaesthetized with urethane and a push-pull cannula (0.5 mm O.D.) introduced in the stratum radiatum of CA1 : an electrode-glued to the cannula enabled to record the commisural-schaffer collateral response. ACSF was perfused at a flow rate of 10 ul/min and the concentrations of amino acid measured by HPLC in 50 ul (i.e. 5 minutes samples).

Application of phorbol 12-13 diacetate (PDAC - 500 uM) for 5 min produced an enhancement of the epsp (40 % over the control). The potentiated epsp persisted with little variation for prolonged periods (2 hrs or more ; n = 8). HPLC analysis of the perfusates revealed a highly significant increase in the concentration of endogenous glutamate and aspartate. This increase was maximal 5-10 min after application of the drug (560 % + 169 in comparison to the control pre-drug values ; n = 8). However, starting from the 3rd sample (15 min after PDAC application). the level of glutamate and aspartate returned to the control (pre-drug) values. Thus, 20 to 90 minutes after PDAC, the levels of endogenous glutamate and aspartate were not significantly different from the control values even though the field epsp was still potentiated.

These observations suggest that the long lasting enhancement of the epsp produced in CA1 by PDAC is not due to a sustained enhanced release of excitatory amino acids.

364.11 STUDIES OF CONDITIONING OF NEURONS IN LOCUS COERULEUS OF THE RAT. M. Segal* and S.J. Sara (SPON: M. David). Dept. of Neuroscience, Weizman Inst. of Science, Rehovot, ISRAEL and Lab. Physiologie Nerveuse 2, C. N. R. S., Gif-sur Yvette, FRANCE.

The noradrenergic nucleus locus coeruleus (LC) might play a unique role in learning and memory by modulating attention and providing the necessary tonal influence on target areas involved in specific information processing. If these neurons do perform such a function, they should respond early in conditioning to stimuli paired with positive as well as negative reinforcement. The context of the CSs might also be expected to elicit CRs in these neurons.

Pavlovian conditioning paradigms were used to study LC neuronal activity in parallel with the acquisition of behavioral responses to stimuli associated with shock or water reinforcement. Before training the rats were implanted with a movable microelectrode aimed at the LC; electrode placements were confirmed histologically.

One experiment paired a tone of a specific frequency with water reinforcement, while another tone (CS-) was never followed by water. In most cases there was a significant increase in neuronal response to the CS+ as conditioning progressed, with a decrease or total absence of response to CS-. When the significance of the CSs was reversed there was a rapid increase in response to the former CS-, usually on the first few trials, with no immediate decrease in response to the former CS+.

In an aversive paradigm, the CS+ was followed by ear shock. The presentation of each CS+ or CS- was announced by a flashing light which terminated with CS offset. At a behavioral level there was good differential responding to the CSs and little response to the light. At a cellular level, on the other hand, the neurons responded to both CS+ and CS- throught the habituation trials and the 60 conditioning trials. There was, however, a small but significant increase in the response to the CS+ early in conditioning. The response to the warning light habituated rapidly, but the cells began responding again to this stimulus on the first conditioning trials.

These results indicate that LC neurons are involved in learning in appetitive as well as aversive situations; in aversive learning there appears to be more generalization of the response to include CRs to the context which contains the nominal CSs (flashing light). That LC cells respond rapidly to changes in significance of the stimuli is consistent with the hypothesis that the noradrenergic system plays a role in learning by modulating selective attention.

364.12 STIMULATION OF THE PERFORANT PATH AS A CONDITIONED STIMULUS : LONG-TERM POTENTIATION IN THE DENTATE GYRUS AND BEHAVIORAL CONDITIONING. S. Laroche, V. Doyère* and V. Bloch*. Département de Psychophysiologie, C.N.R.S., 91190 Gif-sur-Yvette, France.

Learning a tone-shock association in rats is followed by increased long-term potentiation (LTP) a perforant path synapses (Laroche, Bergis, Bloch, Neurosci. Abstr., 9:645, 1983) and increased release of radiolabelled glutamate in the dentate gyrus (Laroche, Errington, Lynch, Bliss, Behav. Brain Res., 1987, in press). In the present experiment, high-frequency stimulation of the perforant path was used as a conditioned stimulus (CS) to allow direct estimation of the strength of a population of synapses necessarily involved in the learning task. Rats (n=40) were chronically implanted with a recording electrode in the dentate gyrus and a stimulating electrode in the ipsilateral perforant path. Nine animals also received a stimulating electrode in the contralateral hilus to activate the commissural fibers. Conditioned suppression of lever pressing for food reward was the behavioral index of conditioning. Rats were first trained to press a lever for food pellets (60-sec Variable Interval). Classical conditioning (C) or pseudoconditioning (PC) sessions with 6 trials a session were then given. The CS (400Hz-20msec perforant path trains at 1Hz during 6 sec) terminated with a footshock (0.5 sec) as US. The CS intensity was set to a value which gave a population spike of approximately 1mV in groups 1C (n=11) and 2PC (n=7), and at an intensity below spike threshold in group 3C (n=4). For groups 4C (n=5) and 5PC (n=4), each perforant path train, above spike threshold, was preceded by a high frequency stimulation of the contralateral hilus (400Hz-12msec) with 8 msec interval onset to onset. Nine control animals (group 6) received only high-frequency stimulation of the perforant path.

Learning the brain stimulation-shock association, as assessed by suppression of lever pressing for food during the CS period, was significant from session 2 in group 1C in which the CS induced LTP of the population EPSP and of the population spike. Animals in group 3C in which no LTP was produced did not learn the association even after 6 conditioning sessions. Unexpectedly, LTP in the dentate gyrus was masked rather than blocked by the commissural trains in groups 4C and 5PC: no change in the slope of the population EPSP occurred during session 1 but a significant increase in slope was observed 24h later, before session 2. Learning was retarded in group 4C as compared to group 1C in which LTP was evident on session 1.

These data desmonstrate that perforant path trains can be used as a CS in a conditioned suppression paradigm provided that stimulation parameters allow LTP to develop at the activated synapses. The parallel postponement in LTP and behavioral conditioning when nearly concomitant commissural and perforant path trains are used, further suggests a correlation between increased synaptic strength and learning the CS-US association.

364.13 ELECTRICALLY EVOKED STARTLE: REFRACTORY PERIODS AND TEMPORAL SUMMATION IN BRAINSTEM PATHWAYS. J.S. Yeomans, M. Davis, J.B. Rosen and J. Barbeau*. Dept. Psychology, Univ. Toronto, Toronto, Canada M5S 1A1, and Dept. Psychiatry, Yale University.

The acoustic startle reflex is thought to be mediated by a brainstem and spinal cord circuit consisting of the ventral cochlear nucleus, an area just medial to the ventral nucleus of the lateral lemniscus, nucleus reticularis pontis caudalis and spinal motoneurons (Davis et al., 1982). Startle-like responses can be elicited by electrical stimulation with a single pulse in each of these sites in rats. The present study used single pulse pairs to evaluate the refractory periods and temporal summation properties within this circuit. A stronger response occurred if a second pulse was delivered 0.5 to 10 msec after the first pulse. The added effect of this second pulse was measured by the increased startle amplitude, or by the decreased current required to produce a constant startle amplitude. In cochlear nucleus sites, the effect of the second pulse increased as the interval between the two pulses increased from 0.4 to 2.0 msec, consistent with recovery from refractoriness. In caudal pontine or medullary reticular formation sites, the effect of the second pulse increased sharply at interpulse intervals from 0.3 to 0.5 msec, suggesting that very short refractory period axons mediate the startle response in these sites. At these caudal sites, the effect of the second pulse declined exponentially at interpulse intervals from 2.0 to 50 msec, with a time constant of 4 msec. This time constant is almost identical to EPSPs recorded previously in cat spinal motoneurons driven monosynaptically by reticular formation stimulation (Grillner and Lund, 1968; Peterson et al., 1979). The fast exponential decline suggests that reticulospinal axons mediating startle activate spinal motoneurons monosynaptically. Temporal summation declined more slowly in cochlear nucleus sites, suggesting that these sites do not connect monosynaptically to motoneurons.

In reticular formation sites near the facial nerve, a second peak in the two-pulse curve was observed at interpulse intervals near 10 msec. The second peak was blocked by local anesthesia of the ipsilateral face, but not the contralateral face, suggesting that a single twitch of facial muscles facilitates startle.

364.14 **BEHAVIORAL CORRELATES OF HIPPOCAMPAL PLACE CELLS.** C.A. Paul*, S.I. Wiener, and H. Eichenbaum. (SPON: A. Levey) Department of Biological Sciences, Wellesley College, Wellesley, MA 02181.

Several investigators have observed that the activity of hippocampal complex spike cells is determined by the animal's presence in specific locations in an open environment, called place-fields. In general, these experiments either ignored ongoing behavior, or arranged the task so that behavior was largely homogenous throughout the environment. In contrast, other investigators have observed that hippocampal units fire in relation to specific sensory or behavioral events in learning tasks. Often these relevant behaviors occur primarily when the animal is in a particular place, thus confounding the "behavioral" and "place" correlates.

We studied the behavioral correlates of hippocampal units in an open environment that is sensitive to place-related unit activity. Rats were trained to move to the center of a .4m-sq arena to initiate a 40sec trial, signalled by a pulsing tone. After trial initiation, the rat was given water-rewards on its first visit to each of four reward cups located near different corners of the arena. Return visits within a trial were not rewarded. Among complex spike cells, identified by average firing rates of about 1/sec and by localization within the CA1 pyramidal layer, over 80% had at least one clear place-field, consistent with other reports on place cells. However, the locations of place-fields were not uniformly distributed about the arena. Nearly every place-field included at least one of the reward-cups or the trial-initiation area. About half of the place cells fired selectively in more than one of these significant loci, with a preference for one place. Furthermore, unit firing was dependent on specific behavioral variables. The firing of place cells was usually time-locked to arrival at a reward cup. About half the place cells fired reliably according to the speed of the rat's movement through the field. Some units fired at higher rates the faster animal moved and other units fired maximally at a particular speed of movement. About half of the place cells varied firing rate reliably with the direction of movement. Most of these units preferred a single direction; a few had opposing bidirectional selectivity. Some cells fired selectively during particular goal-directed trajectories, e.g., during movement from one specific cup toward another. Other cells fired differentially on the initial versus return visits to a cup, or fired differentially depending on the order of cup visits.

Thus, consistent with anecdotal reports, we found that the activity of place units is modulated by ongoing behavior. Speed and directional tuning may be viewed as elaboration on the proposed spatial mapping functions of these cells. However, we interpret these findings as consistent with our other observations: that place-fields are found predominately at task goals and that most units fire during goal-directed movements. The combined results support the view that hippocampal units fire primarily during behavioral interactions with specific targets that are defined both by complex cues and by task-relevance, and their activity is not determined by place *per se*. Supported by PHS NS18744 and NSF BNS85-07677.

364.15 **HIPPOCAMPAL "DECISION" CELLS IN RATS IN A SIMULTANEOUS-CUE ODOR DISCRIMINATION TASK.** S.I. Wiener, H. Eichenbaum, C.A. Paul* and M. Kuperstein. Dept. of Biological Sciences, Wellesley College, Wellesley, MA 02181.

The purpose of this study was to determine the behavioral correlates of hippocampal unit firing during performance on an olfactory discrimination task. Previously, using a successive cue-odor discrimination paradigm, we[1] described: a) "goal-approach" cells that fire time-locked to movements toward task-relevant loci and b) "cue-sampling" cells that fire time-locked to the onset of odor sampling and during the discriminative response.

In order to better isolate the critical task events during odor sampling and response selection, and to examine spatial correlates of firing, we analyzed extracellular unit activity during performance on a simultaneous cue, go-left/go-right odor discrimination task. The rats initiated each trial by entering a small area where S+ and S- odors were presented from separate ports. To receive a reward, the rat was required to approach and poke its nose into the port emitting the S+ odor regardless of its location, which varied randomly across trials. In 200 to 300 trial sessions, rats were presented with two different odor-pair discriminations in random sequence.

Over 140 isolated units had firing increases time-locked with one or more specific task-related behaviors. Of these, 24 cells fired maximally as the rat paused before the odor ports, with a precipitous drop in firing at the onset of movement toward the odor port for the nose-poke response. These cells correspond to cue-sampling cells, however the firing occurred only during sampling prior to making a response. Since their firing correlates well with when the rat had to decide its response, they are termed "decision cells". Some decision cells fired maximally as the rat sampled a particular port, or sampled a particular pair of odors in a particular configuration. The activity of the decision cells did not seem to be determined by "place", since this firing increase did not occur as the rat passed through this same place while exiting the port. Other cells fired maximally at or just after the nose-poke (rather than prior to the nose-poke, as is the case for decision cells). Some of these cells also fired preferentially for a specific odor pair and/or spatial configuration.

In conclusion, a population of hippocampal neurons are selectively active during the decision-making phase of a discrimination task; a subgroup of these cells fired preferentially in relation to specific, relevant stimulus parameters. Each of these response patterns indicates that hippocampal units are sensitive to specific cognitive aspects of behavior.

364.16 SIMILAR DEFICITS CAUSED BY FRONTAL AND SEPTAL LESIONS IN PROBLEM SOLVING MAY REFLECT DISRUPTION OF DIFFERENT MEMORY MECHANISMS. B. Poucet* & T. Herrmann+. (SPON : C. Thinus-Blanc). Lab. of Fonct. Neurosc., CNRS, 13402 Marseille, France and Dpt. of Psychol., U. of Guelph, N1G 2W1 Ontario.

Previous studies have shown profound deficits in rats with damage to the septo-hippocampal complex or to the medial frontal cortex on the Maier three-table problem. In this task, animals are required to integrate information concerning the spatial relations existing among the three tables with information concerning the daily locus of food. However, it is still unclear whether the deficit shown by lesioned animals is caused by an unability to form or to use a cognitive representation of the problem space, or by a more specific working memory impairment. In addition, it may be the case that septal and frontal lesions disrupt discrete and different psychological mechanisms involved in the rat's ability to use space to solve problems. An attempt to contrast the effects of lesions of the medial frontal cortex and of the septum was made in two experiments using the same basic procedure, i.e. a preliminary exploratory experience of the three tables followed by a feeding phase on one table and finally a test trial during which the subject had to return to the table on which it had just been fed. In Exp.I, the food was located on the same table throughout the 18 days of testing (spatial learning task) and the start tables were randomly varied from day to day. In Exp.II, the start was kept constant but the food was randomly distributed on one or the other of the two remaining tables (spatial memory task). In both experiments, frontal and septal animals were impaired relative to normals which performed successfully even at the start of testing. However, while performance of frontals and septals remained at a random level in Exp.II, it gradually improved with testing in Exp.I (reaching the level of normals on the last block of trials). Additionally, there was a mild but nevertheless consistent tendency of all lesioned animals to improve their performance over the successive trials of each daily session. Analysis of exploratory behavior revealed a selective deficit of septals both in terms of habituation and of efficiency. This suggests that septal animals unlike normal or frontal animals are unable to form a cognitive spatial representation providing flexible access to information although they can acquire some spatial information of constant and important value. In contrast frontal animals would be unable to maintain specific information in their spatial representation as a result of a storage deficit. It is concluded that frontal and septal deficits would be best accounted for by considering their common participation to a declarative memory system, as opposed to a procedural memory system.

364.17 SPATIAL PROBLEM SOLVING BY RATS WITH HIPPOCAMPAL LESIONS. N. Chapuis+and T. Herrmann+. (SPON : B.E. WILL)
Lab. Neurosc. Fonction., CNRS, 13402 Marseille, France and Dpt of Psychol., Univ. of Guelph, N1G 2W1 Ontario, Canada.

The aim of this study was to investigate the effects of hippocampal lesions on exploratory behavior and subsequent performances in a complex spatial problem solving task. An elevated "wheel-maze", made up with eight arms radiating from a central platform and a peripheral linking alley, was used. After a 15' exploration phase, the subjects were allowed for 1 min to eat food which was placed at the end of one of the eight arms. This phase was immediately followed by three test trials during which the rat was placed at the central platform and had to go to the food. The sequence "exploration-feeding phase-test trials" was repeated three times during eight days using the eight possible locations for food, pseudo-randomly distributed.

The results showed that hippocampals explored more than normals during each 15' session although both groups displayed within-session habituation.

In addition, during the tests, the intact rats chose more accurately the direct path leading to the goal and their performances improved both within and between the sessions. In contrast, the choice accuracy of the lesioned rats did not increase over trials either, within or between the daily test session. Since the location of the goal was the same over the three daily trials, the lack of within session improvement suggests that hippocampal animals would not even be able to use non spatial strategies. A detailed analysis of the exploratory patterns is currently conducted in order to find out differences in the exploratory strategies since the hippocampal rats habituate in this complex maze, what contrasts with the lack of habituation usually observed in such subjects.

365.1 IMIPRAMINE POTENTIATES COCAINE-INDUCED FACILITATION OF BRAIN STIMULATION REWARD. R.A. Frank, T. Pommering* and D. Nitz*. Dept. of Psychology and Psychiatry, Univ. of Cincinnati, Cincinnati, OH 45221-0376.

The tricyclic antidepressant imipramine has recently been used to treat cocaine dependence. It has been suggested that this drug reduces cravings for cocaine during abstinence and may even block cocaine euphoria (Kleber & Gawin, NIDA Monograph 50, 1984). The latter hypothesis was tested by examining the influence of imipramine and cocaine administered separately and together on self-stimulation train-duration response functions. Male Sprague-Dawley rats had electrodes implanted in the ventral tegmental area under sodium pentobarbital anesthesia. Following a 10 day post-operative recovery period, the animals were screened for self-stimulation and 20 rats were selected for further study. In the next phase, self-stimulation train-duration response functions were generated for each rat following 5 days of saline injections. Subsequently, the animals received 10, 20 or 30 mg/kg cocaine HCl (IP) 15 min prior to testing. Once the responses to cocaine alone had been determined, the rats in each dosage group were divided into cocaine and cocaine plus imipramine groups. Either 10 mg/kg imipramine or saline was injected (IP) 15 min prior to cocaine administration (which was given 15 min prior to testing and at the original dose). The double injection procedure was run for six consecutive days followed by a three day, postdrug baseline. Cocaine lowered self-stimulation thresholds in a dose-dependent manner, and imipramine accentuated this effect, doubling it at 30 mg/kg. Imipramine's potentiation of cocaine's effect was not due to the simple addition of cocaine and imipramine's effects because imipramine produced not change in thresholds when administered alone. The results of the present experiment indicate that acute imipramine enhances rather than blocks cocaine euphoria. This finding may limit the usefullness of tricyclic antidepressant treatment for cocaine abuse.

365.2 LACK OF TOLERANCE TO THE THRESHOLD RAISING EFFECTS OF MORPHINE ON THE DETECTION OF NON-REWARDING BRAIN STIMULATION. J. Williams and C. Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Morphine sulfate (MS) lowers the threshold for rewarding brain stimulation to the medial forebrain bundle-lateral hypothalamic (MFB-LH) area and raises the threshold for escape from aversive brain stimulation to the mesencephalic reticular formation (MRF). Also, there is no tolerance to the threshold lowering effects of MS on rewarding brain stimulation, however, there is tolerance to the threshold raising effects of MS on aversive brain stimulation. Since the rewarding electrical stimulation is delivered to the MFB-LH and the aversive stimulation to the MRF, the possibility exists that the differences in the development of tolerance are a function of the site stimulated. In order to determine the role of the site of stimulation, detection thresholds for intracranial electrical stimulation to both MFB and MRF were measured after chronic administration of MS. The levels of stimulation used for determining detection thresholds are by themselves neither positively nor negatively reinforcing; however, these levels of stimulation can be used as discriminative stimuli in a simple instrumental task.

Bipolar stainless steel electrodes were stereotaxically implanted in male F-344 rats (Charles River Laboratories). Electrodes were located bilaterally into the MFB-LH and unilaterally into the MRF areas. Two groups of animals were trained to make an instrumental response to a 0.5 sec stimulation cue (S1) to the MFB or MRF, respectively. Responding to the cue was maintained by the delivery of a reinforcing stimulus (S2) to the MFB-LH area. Detection thresholds were determined by varying the current intensity of the brain stimulation cue (S1) according to a modification of the psychophysical method of constant stimuli. The reinforcing stimulus (S2) remained at a fixed highly rewarding intensity level. MS was infused for 7 days by means of an Alzet osmotic pump implanted subcutaneously between the scapulae of the animal. Chronic infusion of MS failed to cause tolerance to the threshold raising effects of a test dose of MS s.c. given on day 6 of the pump infusion period in either the MFB or MRF groups. MS infusion rates were sufficient to cause tolerance to the effect of the test dose of MS on the escape from aversive stimulation to the MRF or on the tail-flick analgesia procedure. These results suggest that the presence or absence of tolerance to MS effects on the threshold for rewarding, aversive, or detection of brain stimulation is not due to the specific brain site stimulated but is related to the functional nature of the task.
(Supported in part by NIDA grant DA 02326 and NIDA Research Scientist Award (CK) DA 00099).

365.3 EFFECTS OF CRF ON SEPARATION DISTRESS AND JUVENILE PLAY. J. Panksepp, L. Crepeau* & M. Clynes[1]. Dept. of Psychology, Bowling Green State University, Bowling Green, OH 43403 and [1]N.S.W. Conservatory of Music, Sydney, Australia.

Brain CRF systems are confluent with circuits which mediate distress vocalizations (DVs) resulting from social separation. Thus, in addition to mediating a generalized stress response, CRF neurons may have an executive function in elaborating distressful social emotions. To evaluate that possibility, we measured the effect of intracerebroventricular adminstration of rodent CRF on emission of separation induced DVs in young domestic chicks and rough-and-tumble play in juvenile rats.

Young domestic chicks (4 days of age; n=8-16 per group) were isolated from their flock and administered 0.04, 0.2, 1.0 or 5.0 µg CRF or 3 µl of acidified distilled water vehicle into the fourth ventricle region and frequency of DVs was automatically recorded for four 5 min blocks. Testing was conducted during the first and third test-periods in plain sound-attenuated isolation boxes (36 x 32 x 33 cm), and during the second and fourth periods in similar boxes in which the walls were coverd by mirrors. The average level of control DVs in the plain boxes was 280 per 5 min, and this was increased in dose dependent fashion, with the 5 µg dose producing a 41% increase. A more dramatic effect was observed in the mirrored condition (which reduced baseline vocalizations to 57 DVs/5 min). At CRF doses above 0.2 µg, the ability of mirrors to reduce vocalizations was essentially eliminated. This seemed to reflect a general inhibition of social comfort since animals continued to vocalize when returned to their flocks. The effect lasted up to six hours following the highest doses, and was present in birds which were tested up to 30 days of age. The ability of music to reduce DVs was also evaluated (Beethoven's Opus 106), and CRF also attenutated this inhibition.

If the increased DVs reflected emotional distress akin to that produced by social isolation, it was predicted that CRF would also diminish the vigor of social play. Play of juvenile Long-Evans rats (20-33 days of age; n=24) was measured by frequency of pinning, dorsal contacts, and overall rough and tumble activity on a motion detector platform. CRF, in doses of 0.5 and 1.0 µg administered to the 3rd ventricle region eliminated play 30 min following treatment (by all the indexes used). A 0.25 µg dose reduced play to about 50% of control levels, while a 0.125 µg was without reliable effect.

These results suggest that brain CRF systems may have a key role in the activation of emotional processes related to the perception of social isolation.

365.4 FUNCTIONAL MAPPING OF THE EFFECTS OF MIDBRAIN RETICULAR STIMULATION ON THE CEREBELLUM AND BRAINSTEM DEMONSTRATED WITH 2-DEOXYGLUCOSE. F. Gonzalez-Lima. Dept. of Anat., Coll. of Med., Texas A&M Univ., College Station, TX 77843.

Autoradiographic [^{14}C]2-deoxyglucose (2-DG) procedures were used to map the functional activity of the cerebellum and brainstem during electrical stimulation of the deep mesencephalic nucleus of the midbrain reticular formation (MRF) in behaving rats. Quantitative determinations of 2-DG uptake in 71 structures of MRF-stimulated rats were compared to those of control rats without stimulation. The major finding in the cerebellum was a large increase in 2-DG uptake observed in the flocculus of MRF-stimulated rats showing a "freezing" defensive response. The peak of labeling in the flocculus was greater than any other peak of labeling measured in the cerebellum of MRF-stimulated or control rats. Structures showing significant decreases in 2-DG uptake included the 3 deep cerebellar nuclei and the 3 vestibular nuclei. The most pronounced suppressive effects of MRF stimulation were on the medial and lateral vestibular nuclei. The structures activated in the midbrain, caudal to the stimulation site, are part of the reticular formation and the central gray. The changes in metabolic activity revealed by 2-DG provide a first anatomical demonstration of: (1) the activating effects of MRF stimulation on the flocculus, and (2) the suppressive effects of MRF stimulation on deep cerebellar and vestibular nuclei. The observed patterns of metabolic activation and suppression were correlated with the known electrophysiological properties of the structures affected by MRF stimulation. The findings are consistent with specific effects of MRF stimulation on floccular-vestibular-visual interactions that may be disruptive to learning functions such as adaptability of the vestibulo-ocular reflex. They also support the existence of arousal-dependent MRF mechanisms for the modulation of cerebellar function. In addition, structures activated during MRF-evoked bradycardia were located in the caudal medulla. The largest increase was observed in the caudal nucleus ambiguus. Significant increases were also found in the dorsal motor nucleus of vagus and in the nucleus of the solitary tract. It was concluded that bradycardia induced by MRF stimulation may be mediated by brainstem descending pathways between the activated regions of the midbrain and the medullary nuclei known to induce bradycardia upon electrical stimulation. The results suggest that the midbrain central gray and reticular formation may play a role as modulators of a functional cerebellar-medullary circuitry for emotional expression of somatomotor and autonomic responses to arousing stimuli.

365.5 LOCOMOTION AND ANALGESIA AFTER NICOTINE MICROINJECTIONS ALONG THE CHOLINERGIC PATHS ASCENDING FROM Ch5 AND Ch6 IN RATS. Edgar T. Iwamoto and Edwin C. Williamson*. Dept. of Pharmacology, University of Kentucky College of Medicine, Lexington, KY 40536.

The cholinergic projection arising from the pedunculopontine nucleus of the pontomesencephalic reticular formation (cell group Ch5, Mesulam et al. 1983) projects to the thalamus and the substantia nigra. The Ch6 neurons are within the laterodorsal tegmental nucleus in the periventricular gray. We now report the effects of microinjections of nicotine along these pathways in adult male Sprague-Dawley rats.

Nicotine base, 0.25 to 6 µg buffered in 0.5 µl of artificial CSF, was injected unilaterally into the pedunculopontine-nigral Ch5 path using a pressure injection method in freely-moving rats (Iwamoto et al. PBB 20:959, 1984). Animals were confined within a glass cylinder 20 cm in diameter and 20 cm high during the experiments. Nicotine induced dose-related, head-to-tail, turning movements immediately after injection which lasted less than 3 minutes. The direction of the whole-body turning was contralateral to the side of injection. A dose of 0.25 µg of nicotine induced 4 ± 1.2 (S.E.) complete turning movements within 3 min while the 6 µg dose induced 11 ± 0.9. Five µg of chlorisondamine injected into the Ch5 path 2 weeks before 6 or 12 µg of nicotine, and 10 µg of mecamylamine co-administered with 6 µg of nicotine, completely antagonized the nicotine-induced movements. Thirty min pretreatment with 30 µg/kg s.c. of spiperone completely blocked the turning induced by 12 µg of nicotine injected into the Ch5 path. Thirty min pretreatment with 0.1 but not 0.01 mg/kg s.c. of scopolamine blocked the turning induced by 6 µg of nicotine. Microinjections of 0.1 µg kainic acid at the same site caused a completely different syndrome: backward movements and convulsions. Injections of 0.5 to 6.0 µg of nicotine into the adjoining Ch6 sector in the periventricular gray induced (in addition to turning) antinociception for 15 min as assessed by the 50°C hotplate and tailflick methods; the analgesia was antagonized by coinjections of mecamylamine but not by 10 mg/kg s.c. of naloxone. The data suggest that the region of the pontomesencephalic reticular formation and periventricular gray is sensitive to low concentrations of nicotine. Our current hypothesis is that unilateral nicotine injections along the pedunculopontine-nigral Ch5 pathway in rats induces release of acetylcholine onto muscarinic receptors located on A9-A10 dopamine cell bodies causing the stimulation of ascending dopaminergic pathways which results in contralateral turning movements. In addition, the antinociceptive effects of nicotine injected into Ch6 may involve cholinergic mechanisms. (Supported by the KTRB).

365.6 EFFECTS OF INTRA-HIPPOCAMPAL ADMINISTRATION OF COLCHICINE ON INCENTIVE CONTRAST AND ON RADIAL MAZE PERFORMANCE. C.F. Flaherty, G.A. Rowan*, D.F. Emerich , T.J. Walsh. Psychology Department, Rutgers University, New Brunswick, NJ 08903

The consummatory behavior of rats shifted from a 32% to a 4% sucrose solution declines to a level substantially below that of unshifted animals that have experienced only the 4% solution (a negative contrast effect-NCE). This decrement in performance is attenuated by anxiolytics and by lesions of the amygdala (Becker & Flaherty, Psychopharm., 80:35, 1983; Becker, et al, Physiol. Behav., 22:903; 1979).

In three experiments we investigated the effects of intradentate administration of colchicine on successive negative contrast in consummatory behavior, anticipatory contrast and reversal, and radial-arm maze performance.

In Experiment 1 the colchicine treated rats were not different from CSF treated rats or untreated rats in the consumption of 32% and 4% sucrose solutions, nor in degree of negative contrast produced by a shift from 32% to 4% sucrose.

In Experiment 2 there was no difference in degree of anticipatory contrast nor in the reversal of anticipatory contrast in treated and untreated rats.

In Experiment 3 the colchicine treated rats were deficient in radial-arm maze performance--making fewer correct responses each day, and requiring more responses to attain eight correct arm entries. This decrement in maze performance is consistent with earlier reports of the effects of colchicine treatment (Walsh, et al, Brain Res., 398:23, 1986).

These data suggest hippocampal involvement in complex maze performance but not in consummatory behavior, and/or sensory memory.

365.7 SELECTIVE EFFECTS OF DIAZEPAM ON LATERAL HYPOTHALAMIC RESPONDING: EVIDENCE FOR SEPARATE NEURAL SUBSTRATES FOR REWARD AND ESCAPE. S. E. Carden and E. E. Coons*. Psychology Dept. New York Univ. New York, NY 10003

Lateral hypothalamic (LH) self-stimulation and escape responding was evaluated in 4 pure-reward and 4 reward-escape rats. Thresholds of response and barpressing rates across four stimulation levels were measured both for LH onset and offset.

With the administration of diazepam, self-stimulation thresholds decreased and barpressing rates for onset increased in a dose-dependent manner for both groups. Changes of this type are generally associated with the potentiation of reward.

Although Liebman (Neurosci. and Biobehav. Rev., 9:75-86, 1985) concluded that diazepam alters performance by diminishing an aversive component of LH stimulation, in the current study, escape thresholds and escape rates evidenced no drug-related modulation.

There is electrophysiological (Shizgal, P. & Matthews, G., Brain Res., 129:319-333, 1977) and pharmacological (Atrens, D., et.al., Psychophar., 71:97-99, 1980) evidence of separate neural substrates for reward and aversion in the LH. The results obtained here were consistent with the simultaneous stimulation of a diazepam-sensitive reward system and a diazepam-resistant aversion system, which is powerfully engaged in reward-escape animals only.

If this aversion is activated simultaneously with reward - but only in reward-escape animals - then there should be systematic differences between groups on self-stimulation trials. To test this possibility, in a second experiment, self-stimulation and escape rates for 6 pure-reward and 6 reward-escape rats were measured. Stimulation level and train length were manipulated, with and without diazepam. This allowed us to explore the summative effect of a longer train length in both groups.

All animals produced higher barpress rates for long trains than was predicted by short train performance, regardless of drug condition. However, the increase in reward value which accompanied longer stimuli was greater for pure-reward rats. The indication is that long trains are relatively more rewarding to pure-reward than to reward-escape rats. Therefore, even on self-stimulation trials, it is possible to distinguish pure-reward from reward-escape animals.

In addition, in the first experiment, self-stimulation thresholds were found to be higher and barpressing rates to be lower for reward-escape animals, across all conditions. This is consonant with a theory that sees in reward-escape rats a reward system which is being modulated by the simultaneous stimulation of an aversive substrate.

365.8 **THE NAPLES HIGH- AND LOW-EXCITABLE RATS: NEW GENETIC MODEL FOR WHAT?** **A.G. Sadile, A. Cerbone* and L.A. Cioffi*. Inst. Human Physiol. and Med. Phys., 1st Med. Sch., Univ. of Naples, I-80138, Naples, Italy.**

The Naples High- (NHE) and Low-Excitable (NLE) rat strains have been selectively bred for divergent locomotor reactivity in a modified Lat's box, from an outbred population of Sprague-Dawley rats by Sadile et al. ever since 1976 and now over 25 generations of continuous genetic pressure. Aim of this report is to outline their behavioral profile and to propose their usefulness in behavioral physiology. In order to verify whether the differences in exploratory activity were due to differences in "reactivity" or in "activity", NHE/NLE rats were tested in spatial novelty situations of increasing complexity, an open-field of the Animex type, an hole-board or a Lat's box for a 10min-exposure, or in an activity cage for 3 consecutive days. The circadian activity of NHE/NLE rats was strikingly similar in the activity cages, whereas their "reactivity" upon short exposures to "novelty" situations differed more as the level of complexity increased, i.e. by 20% in the Animex box, by 40% in the hole-board and by a factor of two in the Lat's maze. Moreover, this differential reactivity was not attibutable to different thresholds for nociceptive stimulation, since paw-lick latencies on hot-plate were also very similar.

Furthermore, indirect comparisons were made with other strains, which were based on two-way active avoidance in a shuttle-box, emotionality indices as defecation scores and corticosterone plasma level and arterial blood pressure. A) NHE/NLE rats are both learners in to-criterion acquisition of avoidance in a shuttle-box, in contrast with the Roman High- (RHA) and Low-Avoidance (RLA) or with the Syracuse strains (SHA/SLA). Upon retention tests on five consecutive days, their behavioral coping strategies shifted, since 50% of the NHE and NLE changed from avoidance to freezing responses. B) Corticosterone plasma level. Not different was the basal level, nor the level after exposure to an open-field (nor defecation scores), in contrast with Maudsley Reactive (MR) and non-reactive rats (MNR); C) Arterial blood pressure. NHE and NLE did not differ in arterial blood pressure, in acute anaesthesized preparations, in contrast with the Spontaneoulsy Hypertensive rats (SHR). Thus, the factors determining reactivity, avoidance learning and neurovegetative responses seem to be controlled by and located on different genes. For, the Naples lines offer the possibility to study reactivity to a spatial novelty independently from the others. In conclusion, since the NHE and NLE rats are hyper- and hypo-reactive in spatial novelty situations, with intact learning ability and neurovegetative responses, they could be used as animal model for the study of hippocampal function, since normal reactivity is thought to be dependent on its integrity, and of non associative behavioral processes.

365.9 INTRAVENOUS SELF-ADMINISTRATION OF THE INDIRECT DOPAMINE AGONIST AMFONELIC ACID. N.L. Goodman* and L.J. Porrino (Spon: C. Kennedy). Neuropsychopharmacology Laboratory, Addiction Research Center, NIDA, Baltimore, MD 21224.

The effects of the psychostimulant, amfonelic acid (AFA), are mediated through its actions on central dopaminergic neurons. Behaviorally, AFA produces hypermotility and stereotypy in rats. These behavioral actions are similar to those produced by amphetamine and cocaine, psychostimulants which are known to be self-administered. Intravenous self-administration (IVSA) is a frequently used animal model that can provide information about the reinforcing efficacy as well as the abuse potential of a drug. We have assessed the reinforcing properties of AFA using the self-administration paradigm.

Four male Lewis (250-350 g) rats were prepared with chronic venous catheters under pentobarbital anesthesia. Following recovery from surgery, rats were trained to self-administer cocaine at a dose of 1.0 mg/kg/infusion on an FR10 schedule in daily 4 hour sessions. After stable rates were obtained, rats were tested with AFA in doses of .0625, 0.125, and 0.25 mg/kg/infusion in either 4 or 8 hour sessions.

AFA was self-administered in all rats tested. Increases in the unit dose of AFA produced dose-dependent decreases in injection rates. Response rates were consistent within animals for each dose, but there was a high degree of variability between animals. Rates of self-administration of AFA were generally lower than those obtained for cocaine even at the lowest AFA dose tested. This difference in overall rates may be a reflection of the longer duration of action and greater potency of AFA as compared with cocaine.

These data demonstrate that AFA is reliably self-administered in rats, and provide further support for the similarity of the behavioral effects of AFA and other psychostimulants shown in other paradigms (Schechter, PBB, 26:413-416, 1987; Aceto et al, Eur. J. Pharm. 10:344-354, 1970; Shore, J. Pharm. Pharmacol. 28: 855-857, 1976). Furthermore, these results strongly suggest that AFA may have significant potential for abuse.

365.10 IDENTIFICATION OF CANDIDATE REWARD PATHWAYS BY MEANS OF PSYCHOPHYSICAL INFERENCE AND COMPOUND ACTION POTENTIAL RECORDING. I. Kiss* and P. Shizgal. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, QUE., Canada H3G 1M8.

An important step toward identifying neurons responsible for brain stimulation reward is to demonstrate concordance between psychophysical and electrophysiological measures of neural properties such as the refractory period and conduction velocity. Of the electrophysiologically identified cells driven by rewarding stimulation, only those with characteristics within the range of the psychophysically-derived values can be considered as plausible candidates.

The present study complements previous work comparing electrophysiological and psychophysical estimates of refractory periods. To trace the fibers rather than the somata of the candidate reward neurons, macroelectrode recordings of compound action potentials were used in lieu of microelectrode recordings of antidromic, single-unit spikes.

Several problems were encountered in recording compound action potentials elicited by lateral hypothalamic (LH) stimulation. Despite the use of conventional methods for reducing the shock artifact, it sometimes obscured portions of the neural response. Also, paired-pulse records were sometimes difficult to interpret due to the overlap in time between components of the two responses. To remove the shock artifact from single pulse records, we used a double subtraction technique. A pair of pulses was delivered with the intra-pair interval set to a value close to the estimated absolute refractory period of the most excitable MFB neurons. A record obtained by delivering a single pulse was then subtracted from this paired-pulse record. If local potentials have decayed before recovery from refractoriness begins, if artifact and response components sum linearly, and if the artifact does not vary with the C-T interval, the result should be a record consisting only of the artifact. Moreover, subtracting this "artifact-only" record from a single-pulse record would yield a "pure", artifact-free record. To separate the contributions of the responses produced by conditioning and test pulses, we used an analogous triple subtraction technique.

Recovery from refractoriness in pathways directly activated by rewarding LH stimulation was estimated with the aid of these techniques. Recording sites were found in the region of the ventral tegmentum, the substantia nigra, and the ventral portion of the central grey in which the electrophysiological measure of recovery from refractoriness substantially overlapped psychophysical estimates obtained with the same stimulation electrodes, currents and pulse durations. These findings suggest that fibers coursing caudal to the ventral tegmental nucleus of Tsai may compose part of the directly activated substrate for the rewarding effect of LH stimulation.

365.11 REVERSAL OF MORPHINE INDUCED FACILITATION ON REWARDING ELECTRICAL BRAIN-STIMULATION BY NALOXONE: EVIDENCE FOR DIRECT PHARMACOLOGICAL ACTIVATION OF OPIATE RECEPTORS. M. Moolten* and C. Kornetsky. (SPON: L. Volicer). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Although morphine will increase the sensitivity of animals to rewarding brain stimulation and increase the rate of response for such stimulation, it has been argued that the effects are due to non-pharmacological actions of morphine, and thus not to opiate receptor activation. It was reported that the rate increasing effects of morphine during intracranial self-stimulation (ICSS) are not reliably reversed by naloxone once the morphine effect has been initiated (Hand and Franklin, 1986), suggesting that associative, non-pharmacological factors may be involved in morphine's reinforcing properties. In an attempt to further elucidate the mechanisms involved in morphine's facilitation of ICSS, we administered naloxone at the time of maximum effect of morphine on the threshold for rewarding brain-stimulation.

Bipolar stainless steel electrodes were stereotaxically implanted in the medial forebrain bundle (MFB) of male F-344 rats (Charles River Laboratories). Animals were trained to turn a wheel manipulandum to obtain rewarding electrical stimulation to the MFB. Brain-stimulation reward thresholds were determined by using a modification of the psychophysical method of limits. In all animals morphine (2 or 4 mg/kg s.c.) caused significant lowering of threshold which persisted throughout the 100 min testing session. When naloxone was given 40-60 minutes following morphine administration, it caused a dose-dependent antagonism of the threshold lowering effect. Doses as low as 0.125 mg/kg i.p. completely reversed the morphine induced facilitation in all animals at all morphine doses tested.

These results clearly demonstrate that morphine's facilitation of the reinforcing properties of rewarding brain-stimulation is mediated by opiate receptor activation.

365.12 COCAINE EFFECTS ON REWARDING BRAIN STIMULATION AS ASSESSED BY THE QUANTITATIVE 2-DEOXYGLUCOSE METHOD. G.T. Bain*, L.J. Porrino† C. Caplan* and C. Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118 and †Addiction Research Center, NIDA, Baltimore, MD and ‡Laboratory of Cerebral Metabolism, NIMH, Bethesda, Md.

Systemically administered cocaine has been shown to increase the sensitivity of the rat for rewarding electrical stimulation to the medial forebrain bundle (MFB) (Esposito, et al., Pharmacol. Biochem. Behav. 8:437, 1978). The specific structures which may be directly involved in this phenomenon have yet to be determined. In the present study the quantitative 2-(^{14}C) deoxyglucose (2-DG) method was used (Sokoloff, et al., J. Neurochem. 2:897, 1977) to determine those areas which are functionally involved in this interaction of cocaine and rewarding brain stimulation.

Bipolar stainless steel electrodes were stereotaxically implanted into the MFB of male F-344 rats (Charles River Laboratories). The animals were trained to press a lever to receive rewarding brain stimulation. Each response resulted in the delivery of a single 500 msec 160 Hz stimulation at an intensity adjusted for each subject to produce an 80% of maximal response rate. Animals were given 10 mg/kg of cocaine i.p. or saline immediately prior to the administration of 2-DG. The standard protocol (Sokoloff, et al., 1977) for determination of local cerebral glucose utilization (LCGU) was then followed. LCGU was measured both ipsilateral and contralateral to the site of electrical stimulation in the MFB and in selected portions of the forebrain previously implicated in brain stimulation reward and/or cocaine self-administration. Preliminary analysis of the data indicate that there was, for the most part, no difference in the anatomical distribution of rates of LCGU between the cocaine and the saline treated animals. However, a marked bilateral increase in LCGU was seen in the olfactory tubercle, and to a lesser extent in the nucleus accumbens in the cocaine treated animals as compared to the saline treated animals.

These effects of cocaine on LCGU during rewarding brain stimulation observed in the present study are similar to those reported previously with d-amphetamine (Seegar, et al., Neurosci. Abst. 307, 1984).

365.13 EVIDENCE FOR DOPAMINERGIC AND NOT SEROTONERGIC MEDIATION OF THE THRESHOLD LOWERING EFFECTS OF MDMA ON REWARDING BRAIN STIMULATION. M.P. Bird*, †C.N. Svendsen*, C. Knapp*, †C.C. Hrbek*, †E.D. Bird and C. Kornetsky. (SPON: A. McCall) Laboratory of Behavioral Pharmacology, Boston Univ. School of Med., Boston, MA 02118 and McLean Hospital/Harvard Med. School, Belmont, MA 02178.†

We have previously shown that 3,4-Methylenedioxymethamphetamine (MDMA) lowers the threshold for rewarding brain stimulation, a model for drug induced euphoria. Recent reports have shown that MDMA produces long lasting depletion of brain serotonin (5-HT) with only transient changes in dopamine (DA) levels. Although there is evidence that both DA and 5-HT are involved in MDMA's behavioral effects the mechanism(s) underlying its reinforcing properties remain unknown. In order to determine the relative contribution of 5-HT and DA to MDMA's reinforcing actions, the effects on brain-stimulation reward of the 5-HT_2 antagonist Ly-53857 and the D_2 antagonist pimozide were determined alone and in combination with racemic MDMA.

Bipolar stainless steel electrodes were stereotaxically implanted in the medial forebrain bundle (MFB) of male F-344 rats (Charles River Laboratories). Animals were trained to turn a wheel manipulandum to obtain rewarding electrical brain stimulation to the MFB. Reward thresholds were determined using a modification of the psychophysical method of limits. MDMA (2.0 mg/kg s.c.) significantly lowered the reward threshold in each animal. By themselves pimozide (0.2 to 0.4 mg/kg i.p.) significantly increased the reward threshold while Ly-53857 (2.0 to 8.0 mg/kg i.p.) was without effect. In all but one subject pretreatment with 0.2 mg/kg of pimozide completely blocked the threshold lowering effect of 2.0 mg/kg of MDMA and raised the reward threshold of one animal, while a higher dose of pimozide (0.4 mg/kg) antagonized 2.0 mg/kg of MDMA in 2 animals and raised the reward threshold in 2 others. In contrast to pimozide, Ly-53857 had no effect on MDMA's threshold lowering action. To further assess the pharmacologic activity of MDMA brain monoamine concentrations were measured using HPLC with electrochemical detection (Clin. Chem. 30:1046, 1984). Preliminary data indicates that MDMA (2.0 mg/kg s.c.) significantly decreased 5-HT levels in striatal and hippocampal tissue but significantly increased concentrations of striatal dopamine 1 hour post injection. Taken together these results strongly suggest that the reinforcing effects of MDMA are mediated by D2 and not 5-HT_2 receptor stimulation.

365.14 HALOPERIDOL BLOCKS CONDITIONED PLACE PREFERENCES INDUCED BY REWARDING LATERAL HYPOTHALAMIC STIMULATION IN RATS. C.L.Duvauchelle* and A. Ettenberg (SPON:H.J.Carlisle).Dept of Psychology, University of California, Santa Barbara, CA 93106

While dopamine antagonist neuroleptic drugs have long been known to interfere with reinforced operant responding, identification of the precise mechanism by which these drugs exert their behavioral effects has proved difficult. A major problem in this regard has been that both reward-attenuation and motor-impairment hypotheses make similar predictions about the behavioral deficits observed in drugged animals. To overcome this problem, we have employed a test procedure (the "conditioned place preference") in which neuroleptic induced changes in brain-stimulation reward can be identified at a time when the direct pharmacological effects of the drug are no longer present.

Male rats implanted with lateral hypothalamic electrodes were shaped to lever-press for rewarding 0.5s trains of 60Hz sine-wave stimulation. Current intensities were identified for each rat that produced steady responding during daily 15 min sessions. Once operant rates had stabilized, a 3-day preference procedure was begun. The test apparatus was a rectangular enclosure consisting of two distintive sides (ea 42x42x38cm) varying in color, floor texture an odor. On Day 1, a Baseline was determined by recording the amount o time a rat spent on each side of the apparatus. On Day 2, every rat received a single IP injection of either haloperidol (0.15 or 0.3 mg/kg HAL) or its lactic acid vehicle solution (VEH) 45 min prior t the first of five 5min exposures to each of the two distinct test environments. Rats were administered rewarding brain stimulation during the times they were in the "less preferred" environment (as determined on Baseline day). The stimulation rate and parameters were based upon each rat's self-stimulation performance during the final three days of training. No stimulation was delivered while rats were in the "preferred" side of the apparatus. These subjects had been pretreated with 0.0, 0.15 or 0.3 mg/kg HAL (n=6/group). Additional HAL and VEH control groups experienced the same condition (either rewarding brain stimulation or no stimulation) in both test environments. On Day 3 (24hrs after drug/veh treatments), a second place preference test was conducted in the same manner as on Day 1.

Rewarding brain stimulation produced a dramatic shift in place preferences towards the stimulation-paired side. This effect was prevented by pretreatment with the high, but not the low, dose of haloperidol. None of the control groups demonstrated changes in place preference and haloperidol did not in and of itself produce shifts from baseline preferences on test day (24 hrs post-injection) These data are consistent with the view that the reward produced by lateral hypothalamic stimulation can be attenuated by administration of dopamine receptor antagonist neurolpetic drugs.

365.15 EFFECTS OF CHLORDIAZEPOXIDE AND MORPHINE ON CER-ATTENUATED JUVENILE RAT PLAY. L. Crepeau* & J. Panksepp (SPONSOR: F. DeEskinazi) Dept. of Psychology, Bowling Green State University, Bowling Green, OH 43403

Juvenile play was evaluated during the acquisition of a conditioned emotional response (CER) paradigm where a tone was presented predicting inescapable footshock, as well as during extinction of the tone-shock contingency. The ability of chlordiazepoxide (CDP) and morphine sulfate (MS) to maintain and resurrect play behavior in the context of such threat was also evaluated.

Juvenile Long-Evans rats (21 days of age; n=40 pairs of same-sex littermates) were divided into 4 treatment groups. For 7 CER acquisition test days, group 1 (n= 5 pairs) controls received injections of vehicle and no footshock. Group 2 (n=10 pairs) received CDP. Group 3 (n=10 pairs) received morphine. Group 4 (n=15 pairs) received vehicle injections (1 cc/kg). 20-30 minutes after i.p. injections, animals were tested during three 2-minute trials each day During the middle 2 minute period a 1 KHz tone was presented, followed by a 1.5 second, .5 mA footshock. The two surrounding trials acted as pre- and post-shock measurement periods. For the 5 CER extinction test days, half the animals in groups 2 and 3 continued to receive CDP or MS, and half received vehicle. Group 4 was divided into three sets of 5 pairs. These animals received either vehicle, CDP or MS. Play was scored by measurement of pins, dorsal contacts and overall platform activity.

During acquisition testing, rates of play did not demonstrate a CER specific to the tone, but play, especially during the last two days of acquisition, was reliably reduced during all 3 test trials, suggesting the development of fear to contextual cues of the play situation.

During the last 2 days of CER acquisition testing, the overall mean frequency of pins per session was 7.8 and 8.4 for non-shocked control animals, 3.4 and 3.8 (55% lower than controls) for CDP and MS treatments, and essentially zero for the vehicle-treated group. Similarly, dorsal-contact solicitations averaged 11 and 11 in control group animals, 4 and 4 (64% lower) in the CDP and MS groups, and 2 and 1 (86% lower) in group 4. Activity counts among control group animals were 132 and 137, 44 and 45 (67% lower) in the CDP and MS groups, and 11 and 10 (92% lower) in group 4 (all reductions were reliably lower than control ($p < .01$), as well as CDP and MS levels ($p < .05$)).

CER extinction was faster in the CDP and MS groups, whether or not the drugs were still given during CER extinction. Play levels were comparable to non-shocked controls by the second extinction day in CDP-treated animals, and on day 3 in MS group animals. Animals in the vehicle group took 5 days before play levels had returned to normal. Both CDP and MS maintained play and facilitated recovery of play behaviors during CER training and extinction. The neural mechanisms which elaborate this effect need to be investigated further, since opioids and BZs appear to act on distinct neural structures.

365.16 THE HEXADYAD PRIMARY EMOTIONS AS A NEUROSCIENCE WORKING HYPOTHESIS. B. E. Morton, Dept. of Biochemistry and Biophysics
University of Hawaii School of Medicine, Honolulu, HI 96822

Just as the infinity of perceived colors are produced from combinations of the three primary colors, so also the large variety of affects which can be experienced may be the summation product of a few primary emotions. Earlier lack of this concept would account for disagreement among authors about emotion classifications.

It is here proposed that in organisms with brains containing a limbic system, there are six independent, opposed pairs of primary emotions. Each primary emotion pair consists of a range between appetitive and aversive extremes. The output of a primary pair can reside only at one point within that range at a given time. The ongoing emotional experience of such an organism results from the continual summation of these six variable range points.

The proposed six primary emotion pairs (and their abbreviated biological significances) are:

1. CONFUSION-SURPRISE (ignorant) vs. CERTAINTY-EXPECTANCE (knows)
2. FEAR (less powerful than) vs. CONFIDENCE (more powerful)
3. DISGUST (rejects) vs. PLEASURE (accepts)
4. ANGER (harmed by other) vs. GRATITUDE (helped by other)
5. GRIEF (loss-failure) vs. ELATION (win-success)
6. DESIRE (deprived) vs. SATISFACTION (satiated)

Each primary emotion pair provides fundamental survival benefits to the organism and thus must have been selected and preserved by evolution. In humans if immediate emotional responses are prolonged for hours, they are moods; if relatively habitual, they become personality traits. The hexadyad primary emotions can be plotted in a circumpolar array which is useful in depicting such personality traits.

The output position within the range of an appetitive-aversive primary emotion pair appears to be controlled by the relative activity or balance of activities of specific brain elements which can also be manipulated by drugs. For example the Fear-Confidence primary emotion pair appears to be controlled by a norepinepherine output coming from the locus ceruleus. Thus, fear levels in humans can be manipulated by alpha2 and beta2-adrenergic ligands altering noradrenergic synaptic transmission. Such produce emotional manifestations ranging from foolhardiness to terror. Locus ceruleus activity itself can also be altered by benzodiazepine-GABA-chloride channel ligands to produce a like range of emotional responses.

Similarly, it appears that the Elation-Grief pair is produced by subelements of the dopaminergic-enkephalinergic systems separate from the locus ceruleus. The sites and pharmacologic identities of other primary emotion pairs can in principle also be determined. Thus, the hexadyad primary emotions hypothesis would seem to provide a useful framework within which to organize data and research on the production and significance of brain emotional output.

365.17 IBOTENIC ACID LESIONS AND LATERAL HYPOTHALAMIC SELF-STIMULATION
M. Waraczynski and J.R. Stellar, Dept. of Psych., Northeastern University, Boston, MA 02115.

Several recent studies (Velley, et al., Brain Res., 268: 79-86, 1983; Nassif, et al., Brain Res., 332: 247-257, 1985; Lestang, et al., Neurosci., 15: 379-388, 1985) support a role for endemic lateral hypothalamic neurons in self-stimulation in rats by using the excitotoxin ibotenic acid to destroy these neurons while leaving fibers of passage intact. Anatomical investigations (Schwarcz, et al., Brain Res., 37: 199-216, 1979; Hastings, et al., Brain Res., 360: 248-256, 1985) have confirmed this axon-sparing property by showing that forebrain monoamine concentrations are not significantly decreased following lateral hypothalamic ibotenic acid lesions. However, loss of myelin in intact axons following lesion could substantially alter stimulation's effectiveness in generation of action potentials.

We injected into the lateral hypothalamus of rats, over a 20 minute period, 1 ul of 3.5-4.0 ug/ul of ibotenic acid (Sigma) dissolved in phosphate buffer and titrated to a pH of 7.2-7.4 with 0.1 M NaOH, in accordance with the protocol used in studies cited above. After two weeks survival time, animals were sacrificed, brains were removed, and tissue was sectioned in the sagittal plane. Alternate sections were stained for Nissl substance (cresyl violet) and myelin (hematoxylin). Cresyl staining revealed the area of lesion as a region of cell loss and heavy glial proliferation. In the hematoxylin stained sections, the area of lesion appeared almost completely bleached, although fibers directly rostral and caudal were darkly stained. Behavioral testing showed that ibotenic acid lesions both rostral and caudal to the stimulating electrode can be effective in degrading reward effects, as measured by lateral shifts in rate-frequency functions relative to pre-lesion testing.

The histological results suggest that lateral hypothalamic injections of ibotenic acid may substantially demyelinate the local area. If so, then degradation of the effectiveness of stimulation in eliciting action potentials could account for the behavioral results of this and previous experiments. However, the fact that rostral ibotenic acid lesions can be more effective than similarly placed transections (Waraczynski, Neurosci. Abst., 11: 1173) argues for some role of endemic lateral hypothalamic neurons in stimulation reward effects. Resolution of this issue depends on histological studies of the demyelinating effects of ibotenic acid in and out of the lateral hypothalamus. This work is in progress.

365.18 REFRACTORY PERIODS FOR HYPOTHALAMIC SELF-STIMULATION ARE SHORTENED BY ALPHA-FLUPENTHIXOL INJECTIONS. P. Krevs*, J. Yeomans and K. Buckenham* (SPON: J. Nobrega). Dept. of Psychology, Univ. Toronto, Toronto, Canada M5S 1A1.

Refractory periods for medial forebrain bundle (MFB) axons mediating self-stimulation in rats are mainly in the 0.4 to 1.2 msec range when measured with standard frequency threshold methods (Yeomans, 1979). MFB axons of midbrain dopamine cells have absolute refractory periods from 1.2 to 2.5 msec (Yeomans, Maidment & Bunney, 1986), and so cannot be the primary substrate for MFB self-stimulation. When high currents, small electrode tips or long pulse durations are used, however, the range of refractory periods for self-stimulation widens to 0.4 to 5.0 msec (Yeomans, Mercouris & Ellard, 1985; Bielajew, Jurgens & Fouriezos, 1985). These stimulation conditions allow high-threshold axons, such as dopamine axons, to be directly excited (Yeomans, Maidment & Bunney, 1986). Are the long-refractory period, high-threshold axons added by high currents, small tips and long pulse durations dopamine axons?

We tested this idea that dopamine axons can be a second directly activated substrate for MFB self-stimulation by injecting the dopamine receptor blocker alpha-flupenthixol into self-stimulating rats. In a narrow dose range (0.1 to 0.4 mg/kg i.p.), the refractory period curves shifted to the left. These doses shifted the baseline frequency threshold only 10 to 30%. A dose of 0.05 mg/kg had no effect, while doses above 0.4 mg/kg prevented reliable threshold testing. Since small tip electrodes were used, the baseline refractory periods were 0.4 to 5.0 msec, but alpha-flupenthixol reduced the range to 0.4 to 1.5 or 2.0 msec. The biggest effects were at the intrapair intervals of 1.0 and 1.5 msec. The shift was similar to the leftward shift observed by using large electrode tips (Yeomans, Mercouris & Ellard, 1985). This suggests that dopamine axons can be a second directly activated substrate for MFB self-stimulation.

(Supported by NSERCC grant A7077 to J.S.Y.)

AGING AND DEMENTIA: MOLECULAR BIOLOGY II

366.1 REARRANGEMENTS OF CHROMOSOME 21 IN KARYOTYPICALLY NORMAL DOWN'S SYNDROME AND ALZHEIMER'S DISEASE. J.M. Delabar, N. Créau-Goldberg, D. Goldgaber, A. Nicole, I. Ceballos, Z. Rahmani, J.L. Blouin, Y. Lamour, M. Roudier, P. Davous, A. Gegonne, P. Amouyel, D. Stehelin, D.C. Gajduzek and P.M. Sinet, CNRS, Laboratoire Biochimie-Génétique, Hôpital Necker, 149 rue de Sèvres, 75743, Paris, France. (SPON: P. Dutar)

The copy numbers of the Cu-Zn superoxide dismutase(SOD1)gene, of the proto-oncogene ets2(ETS2), of the gene encoding the amyloid polypeptide of Alzheimer's disease(AD-AP gene), of the estrogen-inducible sequence expressed in breast cancer(BCEI) and of an anonymous DNA sequence(D21S11) were assessed in leukocyte DNA from karyotypically normal Down's syndrome patients and from sporadic cases of Alzheimer's disease.

Human cDNAs for the pro α 1(I) collagen gene localized on chromosome 17 and for the proα2(I) collagen gene localized on chromosome 7 were used as reference probes.

Karyotypically normal Down's syndrome patients have a duplication of SOD1, ETS2 and AD-AP. Alzheimer patients have a duplication of ETS2 and AD-AP. D21S11 and BCEI show a normal copy number. DNA analysis by pulse field gel electrophoresis of this rearranged "critical" region of chromosome 21 is presented.

Supported by CNRS, Necker, INSERM.

366.2 PYRAMIDAL NEURON RNA IN PICK'S VS ALZHEIMER'S DISEASE. J.A. Doebler, R.E. Rhoads*, A. Anthony* and W.R. Markesbery*. Dept. of Biochemistry and Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY 40536 and Dept. of Biology, Pennsylvania State University, University Park, PA 16802.

Although disturbances in nucleic acid metabolism/protein synthesis are characteristic of Alzheimer's disease (AD), other dementing disorders, such as Pick's disease (PD) remain unstudied. We conducted comparative analyses of RNA alterations in frontal (area 9) and occipital (areas 18,19) cortex of patients with autopsy proven PD and AD. Azure B-RNA staining and scanning-integrating microdensitometry were used to determine total RNA contents of pyramidal neurons in layers III and V. Significant (15-45%) RNA loss was evidenced in neurons of both cortical areas and layers in both PD and AD, relative to those of age-matched, non-demented controls (Table). This RNA loss was generally more marked in PD than in AD. In both PD and AD the severity of the RNA loss was not greatly enhanced in frontal cortex, which is more prone to morphological alterations than the relatively resistant occipital cortex. AD-associated neuronal RNA loss was substantially greater in layer V than in layer III in both cortical areas, but this was apparent only in the atrophic frontal area in PD. Overall, the data support the existence of a major disorder in neuronal RNA metabolism in PD as well as AD. However, this RNA loss does not appear to be related to the abundance of classical neuropathological alterations in either disease. Whether the augmented RNA loss in layer V signifies selective or primary damage to the lower cortical layers remains to be ascertained. (Supported by NIH grants 1PO1-AG05119 and 1P50-AG05144).

Table. Pyramidal Neuron RNA (Absorbency units ± SEM)

	Area 9		Areas 18, 19	
	Layer III	Layer V	Layer III	Layer V
Control (N=12)	105.9±5.1	107.3±4.6	85.8±3.9	82.2±1.8
PD (N=6)	71.2±6.2*	59.0±4.9*	60.4±4.9*	56.0±4.5*
AD (N=11)	89.7±4.9*	69.1±3.2*	69.7±3.0*	55.0±2.8*

*Significantly different from the control value, $P<0.05$, 2-sided t-test.

366.3 CLONING OF POLY(A)RNA DIFFERENTIALLY REGULATED IN ALZHEIMER'S DISEASE FROM A HIPPOCAMPAL cDNA LIBRARY. P.C. May, S.A. Johnson*, J.N. Masters, M. Lampert-Etchells* and C.E. Finch. Andrus Gerontology Center, USC, Los Angeles, CA 90089.

We examined the effects of Alzheimer's disease (AD) upon gene expression in the hippocampus. A hippocampal cDNA lambda gt10 library was prepared with poly(A)RNA extracted from normal and AD hippocampus. Total RNA was isolated from frozen brain tissue by the guanidinium isothiocyanate/cesium chloride procedure and poly(A)RNA enriched by two passes over oligo d(T) cellulose. In contrast to a recent report (Boyes et al., 1986, Soc. Neurosci. Abs. 12:944), comparable yields of total and poly(A)RNA were obtained from AD (382±24 ug RNA/g tissue, 1.1% poly(A); n=9) and control (334±32 ug RNA/g tissue, 1.1% poly(A); n=11) hippocampus. Poly(A)RNA from AD (n=4) and control (n=6) were separately pooled (ca. 2-3 ug/individual) and aliquots used as a template for cDNA synthesis. Similar sized cDNA was synthesized from AD and control poly(A)RNA and ranged from approximately 0.5 Kb to 5 Kb (average size 1.5 Kb). The cDNA library was prepared by pooling equal amounts of AD and control cDNA, cloning the combined cDNA into a lambda gt10 vector and packaged in vitro to give a library of 2 X 10^6 recombinant lambda gt10 phage. Of 50,000 recombinants screened using differential hybridization with cDNA probes made from AD or control poly(A)RNA, 61 gave differential signals in AD hippocampus (either increased or decreased in prevalence). Nine clones of 14 clones picked for further study have been confirmed by 3 independent slot blot hybridization experiments to be differentially regulated in AD. These clones range in size from 0.4 to 4.4 Kb and represent poly(A)RNA sequences in AD hippocampus that are increased in prevalence from 2 to 5 fold relative to their levels in normal hippocampus. Clones selected as non-changing controls expressed differential signals averaging 0.9 ± 0.1 (mean ± SEM, n=5). These AD-specific clones will be further characterized by hybridization to individual AD and control RNA blots to ascertain the range of prevalence changes between individual AD samples and analyzed by in situ hybridization techniques to identify the cell types containing the cloned sequences. These AD-specific changes in RNA prevalence may reflect genomic responses to neurodegeneration and deafferentation. For example, degeneration of the entorhinal cortex/hippocampal circuit represents an early and major lesion in AD which results in a functional deafferentation of the hippocampus. This study may also identify a subset of genes whose increased expression in AD hippocampus predisposes select neurons to neurodegenerative insults. Supported by ADRC Grant # AG05142 and the MacArthur Foundation Research Program On Successful Aging (CEF)and the Samuel A. Blank Research Grant from the ADRDA (SAJ).

366.4 GLIAL FIBRILLARY ACIDIC PROTEIN mRNA INCREASES DURING A WASTING AGONAL STATE IN OLD MICE. IMPLICATIONS FOR THE INCREASED GFAP mRNA IN ALZHEIMER'S DISEASE. J.R. Goss*, D.G. Morgan, and C.E. Finch. (SPON: M.N. Gordon). Andrus Gerontol. Ctr. & Dept. of Biol. Sci., Univ. of Southern Calif., Los Angeles, CA 90089-0191.

The examination of postmortem human brain tissue forces biological researchers to consider extraneous variables such as postmortem interval, medication history, and the agonal state of the tissue donor. In previous studies we found no major influence of postmortem interval on the quantity or quality of brain RNA up to 48 hours in young rats (Johnson, Morgan, and Finch, J.Neurosci. Res. 16:267, 1986). In an attempt to model the human agonal condition in Alzheimer's disease (AD) which often includes a prolonged wasting phase of cachexia, hypoxia, and acidosis, we examined the brains of a few mice which were slowly approaching death from natural causes during aging.

Wasting mice were identified by daily observation. They typically failed to ambulate when gently prodded, exhibited slight resting tremors, and felt slightly cold to the touch. Necropsies revealed a gross intestinal tumor in one animal, enlarged spleens in two mice, and empty stomachs in two mice. Wasting mice consisted of 3 female C57BL/6NNia (27mo.) and 1 male C57BL/6J (31mo.). Healthy mice (confirmed observationally and by necropsy) of the same cohort served as controls. Brains were removed and frozen at necropsy. RNA was prepared from frozen brains by the guanidinium thiocyanate/CsCl centrifugation method. RNA blot hybridization was performed using 8ug total RNA and single-stranded [^{32}P] labled antisense RNA probes.

The yield of total RNA was similar for the wasting and control mice (290 v. 330 ug/gm tissue). Ethidium bromide stains of electrophoresed total RNA indicated intact RNA. RNA blot hybridization autoradiograms showed a 3-fold increase in glial fibrillary acidic protein (GFAP) mRNA signal, but no change in the signals for beta-tubulin, Thy-1 antigen, somatostatin, or glutamic acid decarboxylase. Degradation of RNA assessed by RNA blot hybridization was minimal. In a parallel study of mouse cortical samples, freezer storage up to 4 years had no effects on the quantity or quality of RNA.

In AD, we found a similar 3 fold increase in GFAP mRNA in frontal and temporal cortex compared to age-matched control samples (n=8 per group). We originally interpreted this increase in GFAP message as a glial reaction to the neurodegenerative events in AD. However, we now consider it possible that this increase in GFAP mRNA is a response to the premorbid conditions associated with AD, rather than a direct effect of the disease process. Supported by the John Douglas French Foundation (DGM) and the A.D.R.C. of Southern California (AG-05142 to CEF).

366.5 LEVELS OF CYTOSKELETAL mRNAs IN ALZHEIMER CORTEX. A.W. Clark, C.A. Krekoski*, I.M. Parhad, D.I. Hoar*, E.A. Swedberg* Depts of Pathology and Medical Biochemistry, Univ. of Calgary, Calgary, Alta, Canada, T2N 4N1.

Abnormal accumulations of cytoskeletal elements are present in cortical neurons of brains with Alzheimer disease (AD). These accumulations may reflect an abnormality in metabolism of the cytoskeleton. In this study we evaluated mRNA expression of specific cytoskeletal components in AD brain tissue. Postmortem brain tissue was studied in 6 cases (age: 74±2 yrs; brain weight: 953±33 gms) with a history of dementia and with neuropathological features of AD, and 6 age matched controls (age: 70±3 yrs; brain weight: 1306±108 gms). Counts of neurofibrillary tangles (Nft) and neuritic plaques (Np) in a $1mm^2$ section of parietal cortex in the AD cases were Nft:17±3; Np:25±5; in controls no Nft or Np were detected except in an 82 year old with Np but no Nft. Immunohistochemical studies with GFAP showed increased gliosis in the AD cases. At autopsy the parietal cortex was removed and rapidly frozen (AD: 8.2±2.9; Control: 9.8±2.6 hrs). Total RNA was isolated, and 20 µg samples from each brain resolved on 1.2% agarose/2.2 M formaldehyde gels, transferred to nylon membranes and hybridized with ^{32}P radiolabeled cDNA probes. The following probes were used: a 300 bp Pst I fragment of murine Nf-L (Lewis & Cowan, J Cell Biol, 1985) for the 68 Kd neurofilament protein, human bα1 tubulin (Cowan et al.,Mol Cell Biol 1983), and GFAP (Lewis et al., Proc Nat Acad Sci, 1984). Recovery of total RNA was decreased by 20% in the AD group as compared to controls (AD: 399±29; Control: 500±17 µg/gm tissue; Mann Whitney U p=0.01). Gel profiles were similar in AD and control cases with intact ribosomal bands. Northern blots showed bands at approximately 1.8Kb for bα1 tubulin, 3.0Kb for GFAP, and 2.5Kb for Nf-L. Some degradation of the mRNA was evident. Some nonspecific binding to ribosomal RNA was seen especially with the Pst I fragment of NF-L. No qualitative differences in the bands for mRNA of the cytoskeletal components studied were seen in AD as compared to control cases. Cytoplasmic dot hybridization was performed and quantitated using a densitometer. This system is sensitive enough to detect >= 30% change in RNA levels. Using this system no differences were seen between AD and control cases for any of the 3 probes. These results indicate 1) decreased recovery of total RNA from brains of AD cases as compared to age matched controls. 2)Based on Northern analysis and staining patterns on Northern gels, however, there is no evidence for differences in generalized degradation of RNA in AD as compared to controls, 3) and no marked change in the mRNAs of these 3 cytoskeletal components. (Supported by the Alberta Mental Health Council and the Alberta Heritage Foundation)

366.6 CLONING OF RNA SEQUENCES WHOSE PREVALENCE IS INCREASED IN ALZHEIMER CORTEX. S.A.Johnson* and C.E.Finch. Andrus Gerontology Ctr, USC. L.A. Ca. 90089.

To better understand the molecular basis for the selective cellular changes which occur in the Alzheimer Disease (AD) brain, we are analyzing AD and control (CTL) cortical poly (A) RNA for changes in RNA prevalence. We have prepared an AD cortex cDNA library in lambda gt10 and differentially screened it with cDNA probes from single individual AD and control(CTL) cortex poly(A)+RNA(Pair# 1 in Table). From a primary screen of ca. 30,000 clones, 50 clones showed detectable differences between AD and CTL on duplicate filters. Seventeen clones continued to show differential signals after two rescreenings at low plaque density (100/plate). To better assess the differential prevalence of these cDNA's between AD and CTL, recombinant phage DNA was bound to nylon membrane in a slot blot apparatus and hybridized to AD or CTL high specific activity cDNA probes. Five clones showed 1.5-2 fold greater signal in AD cDNA after 3 rounds of hybridization.

Five identical RNA gel blots each containing four pairs of age matched AD/CTL total RNA samples were each hybridized to one of the five AD differential cDNA clones (gel purified cDNA inserts were labeled by the random prime/hexamer technique).Signal intensities on the blots were quantitated by computerized image analysis. These data are shown in the Table.

	Insert		Prevalence Increase on RNA Blot (AD/CTL)			
Clone	Size	Gene Copy #	Pair 1	Pair 2	Pair 3	Pair 4
6-4	1.2kb	repeat	6.6	2.1	1.6	1.1
8-4	0.8kb	single copy	4.1	0.4	1.4	0.5
9-1	0.9kb	single copy	2.1	0.9	0.8	1.0
9-3	0.7kb	repeat	2.2	2.4	1.3	1.3
10-2	0.4kb	repeat	2.0	1.9	0.9	0.7

Clone 9-1 hybridizes to single RNA species of 1.5kb, while 8-4 hybridizes to two species of 1.2 and 2.0kb. Clones 6-4, 9-3 and 10-2 each give a smear upon hybridization to identical RNA gel blots, strongly suggesting the presence of repeated sequences in these clones . Southern genome blot analysis with human AD and CTL cerebellar DNA and rat liver DNA shows the presence of a high copy number repeated sequence in all three clones after high stringency hybridization . These three clones are only very weakly reactive with each other, suggesting they are divergent members of the same repeated sequence family. Similar analysis of clones 8-4, and 9-1 indicates these are each distinct single copy elements in the genome. This suggests that 8-4, which gives two bands on a RNA blot, is differentially spliced. However only the larger 8-4 transcript shows changes in RNA prevalence.

At present, we do not understand the variability in differential signal between individuals . These blots were done with our very best (undegraded) age-matched Total RNA samples to avoid differential poly(A)RNA yield. Further work is underway to see if large polymorphic differences are normal.

These data show that very few (3-5/10,000 detectable plaques) of the prevalent and/or moderately prevalent human cortical transcripts have modulated prevalence in AD vs CTL. Furthermore, we have found a family of human specific repeated sequences, members of which may be transcribed differentially in the AD cortex. SAJ was supported by the Samuel A Blank Research Grant through the ADRDA. Frozen cortex was obtained from Dr. Allen Roses at Duke U. and from the ADRC of SO. Cal.(AG-05142)

366.7 RADIOACTIVE URIDINE INCORPORATION INTO RNA BY POSTMORTEM HUMAN BRAIN TISSUE. EVIDENCE FOR POSTMORTEM TRANSCRIPTION IN THE ALZHEIMER BRAIN. E.M. Sajdel-Sulkowska and C.A. Marotta. Dept. of Psychiatry, Harvard Med. Sch.; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178.

The incorporation of [^{3}H]uridine into RNA has been studied in human postmortem brain incubated under standard tissue culture conditions. Brain tissues from 11 different control and Alzheimer's disease (AD) cases, 57-91 years of age, with postmortem intervals of 2.5 to 18 hours were examined. The incorporation of [^{3}H]uridine into RNA was observed in all cases and the reaction proceeded linearly for 60-90 minutes in both control and AD cultures. The extent of incorporation of the radioisotope in postmortem brain from a control case (73 years old, 10 hours postmortem) was compared with that of fresh brain and liver tissue from a 6 month old C57 mouse. Expressed per mg of DNA, the incorporation observed in the human case represented 39% of the fresh mouse brain and 5% of the fresh mouse liver. The specific activity of the human postmortem RNA was 1.0 x 10^4 dpm/mg RNA. The incorporation of [^{3}H]uridine into RNA was sensitive to inhibition by actinomycin or α amanitin. In a typical experiment the radioactive RNA could be extracted by the hot phenol method, and the specific activity recovered after extraction was 0.76 x 10^4 dpm/mg RNA. These results are consistent with the possibility that the transcriptional machinery of postmortem brain remains active for short periods of time. We previously established that postmortem control and AD brains contain structurally and functionally intact RNA that could be used for both in vitro protein synthesis studies and for the preparation of recombinant cDNA libraries (these Proceedings and reviewed in Prog. Brain Res. 70:303, 1986). Our findings indicated an altered RNA metabolism in AD and this may be contributed to by transcriptional as well as degradative factors. Since the present studies provide evidence for active transcription in the postmortem human brain, the factors that affect this process in AD may ultimately be amenable to direct investigation. Supported by AG02126, AG04522, AG05134, AHAF and McKnight Foundation.
