Previous work had shown that a 1 to 3 day preincubation of adrenal chromaffin cells in culture with the nicotinic antagonist d-tubocurarine resulted in a 5 to 10 fold increase in α-bungarotoxin (α-BGT) binding to the cells (Quik et al., 1987, Molec. Pharmacol. 31). Because the increase in α-BGT sites in chromaffin cells is so marked as compared to the size of the antagonist induced increase (~25%) in other neuronal cells in culture, this could infer that the α-BGT sites have a role in these cells. The molecular mechanisms responsible for the induced increase in the α-BGT sites were therefore studied. To determine whether the antagonist induced increase in the toxin binding sites can be modified by changes in the extracellular K^+ concentration, the chromaffin cells were incubated in the presence of varying KCl (2-50 mM); this treatment resulted in an increase in the α-BGT sites of similar magnitude as the nicotinic antagonist induced increase. D-tubocurarine in combination with high K^+ resulted in an increase in the sites only slightly greater than that with either agent alone; this suggests that the d-tubocurarine induced increase may occur at least in part by alterations in K^+. Further experiments with the phorbol ester 4β-phorbol 12-myristate 13-acetate (PMA) showed that this agent also enhanced α-BGT binding to the cells (10 fold); this increase was partially additive with the d-tubocurarine induced increase in the binding of α-BGT to the cells in culture. On the other hand, high K^+ together with PMA resulted in an increase in the toxin binding sites equivalent to that observed with either agent alone. These data suggest that one mechanism whereby nicotinic antagonists result in an increase in α-BGT sites involves activation of protein kinase C, possibly in response to changes in the K^+ concentration; however, alternate pathways must also exist as evidenced by the finding that the increase in the presence of d-tubocurarine plus PMA was greater than with either agent alone but less than additive. Regulation of the α-BGT sites by cAMP was also observed. Addition of dibutyryl cAMP to the cells in culture for 3 days led to a dose dependent reduction in both the d-tubocurarine induced and high K^+-induced increases in α-BGT binding to the cells.

Thus, these results show that various molecular mechanisms are available to allow for a finely regulated control of the α-BGT binding sites in adrenal medullary chromaffin cells. Supported by the MRC (Canada).

260.2 NICOTINIC-INDUCED TRANSLOCATION OF PROTEIN KINASE C IN PC12 CELLS DIFFERENTIATED WITH NERVE GROWTH FACTOR. R.O. Messing and A.M. Stevens*. Dept. of Neurology and Gallo Research Center, San Francisco General Hospital, University of California, San Francisco, CA 94110.

Activation of protein kinase C (PKC) is associated with increased PKC activity in the particulate fraction of cells. We studied activation of PKC in the neural cell line, PC12, by examining changes in the subcellular distribution of the enzyme in response to cholinergic agents. Cells grown for seven days with 2.5 S NGF were incubated in medium with indicated drugs at 37°C, and incubations were terminated by aspiration and one wash with ice-cold 250 mM sucrose, 1 mM EDTA, 1 mM EGTA, and 20 mM Tris-HCl (pH 7.5). Cells were homogenized in 20 mM Tris-HCl (pH 7.5, 4°C), 50 ug/ml leupeptin, and 1 mM PMSF, and sucrose was added to a final concentration of 250 mM just prior to centrifugation at 100,000 x g for 1 hr at 4°C. The supernatant (soluble fraction) and the Triton X-100 solubilized pellet (particulate fraction) were subjected to DEAE chromatography, and PKC in the eluates was measured by phosphorylation of H_1 histone in the presence of Mg^{2+}, ATP, phosphatidylserine, 1,2 diolein, and Ca^{2+}. In the absence of drugs, 13 ± 2% of total cellular PKC activity was found in the particulate fraction. Exposure to 1 mM carbachol increased particulate PKC activity to 50% of the total within five seconds. Carbachol's effect was concentration-dependent with a biphasic dose-response curve yielding approximate EC_{50} values of 10^{-7} and 10^{-4} M for the high and low affinity components respectively. In cells incubated with 100 uM 1,1-dimethyl- 4-phenylpiperazinium (DMPP), a selective nicotinic agonist, 39 ± 3% of total PKC activity was found in the particulate fraction whereas only 24 ± 1% was present in the particulate fraction of cells incubated with 300 uM muscarine. Since nicotinic stimulation of PC12 cells activates voltage-dependent Ca^{2+} channels, we examined the effect of Ca^{2+} channel blockade on PKC translocation. Preincubation for five minutes with the dihydropyridine Ca^{2+} channel antagonist nifedipine (1 uM) reduced PKC activity in the particulate fraction of DMPP-treated cells from 45 ± 1% to 32 ± 3% of total activity ($p < 0.03$). Thus, cholinergic-induced PKC translocation in PC12 cells is predominantly due to activation of nicotinic receptors and is partly dependent on Ca^{2+} influx through dihydropyridine-sensitive Ca^{2+} channels.

260.3 **PURIFICATION AND STRUCTURAL CHARACTERIZATION OF A HIGH MOLECULAR WEIGHT α -BUNGAROTOXIN BINDING PROTEIN FROM *APLYSIA CALIFORNICA*.** J. T. McLaughlin* and E. Hawrot.(Spon:R.G. Pellegrino) Dept. of Pharmacology, Yale Univ. School of Medicine. New Haven CT 06510.

An α-Bungarotoxin(Btx) binding protein was identified in membranes prepared from *Aplysia californica* cerebral, buccal, and pleural ganglia. The protein was initially characterized with a combination of SDS gel electrophoresis and electroblotting, using ^{125}I-α-Btx as a probe. The *Aplysia* toxin binding activity migrated with an apparent molecular weight of approximately 240 kD, similar to binding activity previously described in lower vertebrate CNS (Hawrot et al., 1986 Brain Res. 373:227-234); this observation distinguishes these high molecular weight (HMW) activities from the toxin binding α-subunit of the *Torpedo* nicotinic acetylcholine receptor (AChR), and other, previously characterized neuronal toxin binding proteins. A number of other unique physical characteristics of the *Aplysia* binding activity were revealed using the combination of SDS-PAGE and electroblotting. Unlike *Torpedo* binding, the *Aplysia* HMW binding activity is unaffected by alkylation, and is abolished by boiling, low pH, or exposure to 6 M Urea.

An important question that could not be addressed with the combination of electrophoresis and electroblotting was whether the mobility on SDS-PAGE was due to a multimeric protein resistant to SDS dissociation, or simply a reflection of monomeric structure.To distinguish between these two possibilities, the toxin binding protein was purified using α-bungarotoxin-coupled Sepharose 4B affinity chromatography. Purification was confirmed by silver staining of SDS gels,and the purified protein was then iodinated and subjected to treatments previously shown to abolish toxin binding activity. None of these treatments altered the mobility of the iodinated HMW protein. These results indicate that the binding activity in *Aplysia* resides on a HMW monomer which represents a previously uncharacterized α-bungarotoxin binding protein.

260.4 THE NICOTINIC ACETYLCHOLINE RECEPTOR IN THE CENTRAL NERVOUS SYSTEM OF MANDUCA SEXTA M. L. Perez and D. J. Prescott*. Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

In addition to efficient modes of excretion and/or detoxification of ingested nicotine, tobacco feeding insects may possess a variant of the cholinergic receptor which is less susceptible to this alkaloid (Morris, C., J. Exp. Zool. 229: 361-374, 1984). A receptor variant was isolated from nicotine fed Drosophila which differs in isoelectric point from that found in wild-type (Hall, L. M. et al., FEBS Lett. 95: 243-246, 1978).

We are characterizing the putative nicotinic acetylcholine receptor in Manduca sexta, the tobacco hornworm. This protein is solubilized from cerebral ganglia by Triton X-100. Binding is saturable and picomoles of alpha bungarotoxin binding sites per mg soluble protein are obtained. Both equilibrium and kinetic binding studies demonstrate a K_d of 0.5 nanomoles. The most efficient inhibitors of toxin binding are methyllycaconitine, lobeline, nicotine and curare. Atropine, muscarine, scopolamine and dopamine are ineffective as competitors. Studies on the structure of the multimer and its subunits are currently underway and show similarities to other neuronal nicotinic acetylcholine receptors.

260.5 CHARACTERIZATION OF AN ACETYLCHOLINE (ACh)-ACTIVATED CHANNEL IN LARVAL Drosophila NEURONS. J.L. Albert* and C.J. Lingle. Dept. Biol. Sci., Florida State Univ., Tallahassee, FL 32306

Recent isolation and functional incorporation into bilayers of a putative nicotinic ACh receptor (nAChR) protein from insects (Hanke & Breer, 1986,Nature) has led to the suggestion that the insect nAChR is a primitive form of vertebrate (v.) nAChRs (Breer et al, 1985,J.Neurosci 5). Proper evaluation of isolated, putative nAChRs requires an understanding of the behavior of nAChR channels in native insect neuronal cell membranes. As yet little is known about the properties of single AChR channels in insects. Using patch-clamp techniques we report here the properties of an ACh-activated channel from third instar Drosophila (D.) larval neurons in primary culture.

Using high K saline (140 mM) to short-circuit the high input resistance of these cells we observe two major classes of channel using 1-200 uM ACh in the pipette in cell-attached recordings. At 23-27 C, an infrequently occurring large amplitude channel has a conductance of 63.7+3.1 pS (n=3,+/-SD) and a single exponential on-time distribution with a mean open time of 0.35+0.09 ms (n=4). This channel will not be discussed further here. The small amplitude channel has a conductance of 34.9+8.1 pS (n=6,+/-SD) and a two component on-time distribution: Tfast=0.25+0.11 ms (n=5), Tslow=1.34+0.22 ms (n=5), when patches are compared at a similar single channel current amplitude.

We have explored the effects of [ACh] from 1 to 200 uM on the small amplitude channel. Above 10 uM, the grouping of repeated openings of a single channel into bursts can be observed. Unlike v. muscle nAChRs (max. P(o)>0.9), the probability of being open within a burst (P(o)) for the D. channel remains around 0.2-0.3 from 10-200 uM ACh. However, substantial heterogeneity among bursts is evident and limits our attempts to evaluate specific off-time components. Although other explanations are possible, we interpret the lack of dependence of P(o) on [ACh] over this range as indicative that at these [ACh] off-times are dominated by closed states other than unliganded and monoliganded closed states preceding channel opening. Although little is known about v. neuronal nAChRs, it appears that a low P(o) may also be characteristic of them (Takeda et al, 1986, Br. Res 378). Based on the biophysical characteristics of the D. channel we suggest that it is nicotinic and functionally resembles the v. ganglionic nAChR channel.

260.6 NICOTINE AND MUSCARINE EVOKE DIFFERENT RESPONSES IN ISOLATED, NEURONAL SOMATA FROM LOCUST THORACIC GANGLIA. J.A. Benson and R. Neumann*, Entomology Basic Research, Agricultural Division, CIBA-GEIGY Ltd., CH-4002 Basel, Switzerland.

The mechanically-separated neurones from the thoracic ganglia of Locusta migratoria remain electrophysiologically viable in vitro for many hours (Holden et al., J. Physiol. 276:4P, 1978; Lees et al., Brain Res. 401:267, 1987). These isolated somata respond to acetylcholine with a membrane potential depolarisation accompanied by a decrease in input resistance (Suter & Usherwood, Comp. Biochem. Physiol. 80C:221, 1985). Under voltage-clamp, pressure micro-application of 10^{-4}M nicotine for 10 to 100 ms evokes an inward current that decreases with membrane depolarisation and has a projected reversal potential of 0 to 20mV. Muscarine, applied at 10^{-3}M for 500 ms to 2 s, evokes a smaller, slower, inward current that increases with membrane depolarisation over the potential range -60 to -30mV. The receptors mediating these two distinct responses are referred to here as acetylcholine-1 (ACh1) and acetylcholine-2 (ACh2) receptors respectively. The response to 100 ms pulses of 10^{-4}M acetylcholine is dominated by the current activated via ACh1 receptors.

The ACh1 receptors are blocked in a dose-dependent manner by bath application of the vertebrate nicotinic receptor antagonists α-bungarotoxin (EC_{95} ca. 10^{-7}M), mecamylamine, hexamethonium, gallamine, chlorisondamine, lobeline and d-tubocurarine. All of these antagonistic effects are at least partially reversible, with α-bungarotoxin being slowest (total block 60% reversed in 2 hours). However, the ACh1 receptors are also blocked by some vertebrate muscarinic receptor antagonists such as atropine, scopolamine and benactyzine. In addition, these receptors are blocked by the vertebrate $GABA_A$ receptor antagonists, bicuculline and its methiodide salt (EC_{50} ca. 10^{-5}M), which do not affect the locust somal GABA response at concentrations up to 10^{-4}M (Lees et al., 1987).

The ACh2 receptors are activated by oxotremorine and blocked by atropine but not by α-bungarotoxin (10^{-7}M) or hexamethonium (10^{-4}M). The response mediated by these receptors resembles the effect of muscarine on crab stomatogastric neurones (Marder & Paupardin-Tritsch, J. Physiol. 280:213, 1978).

The data obtained so far suggest that the ACh1 and ACh2 receptors may correspond respectively to the "mixed" nicotinic/muscarinic and muscarinic receptors reported from numerous ligand-binding studies on insect neural tissue homogenates.

260.7 **NICOTINIC ACETYLCHOLINE RECEPTORS FROM BOVINE AND HUMAN BRAIN CHARACTERIZED USING MONOCLONAL ANTIBODIES.** P.J. Whiting* and J.M. Lindstrom. Receptor Biology Lab., The Salk Institute for Biological Studies, P.O. Box 85800, San Diego, CA 92138.

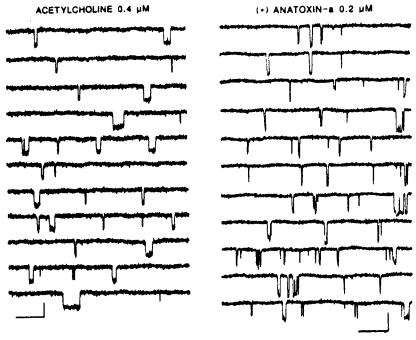
Using monoclonal antibodies (mAbs) prepared to nicotinic acetylcholine receptors (AChRs) from Torpedo electric organ AChR, we immunoaffinity purified nicotinic AChRs from chicken brain (Whiting and Lindstrom, Biochem. 25:2082, 1986). Subsequently, we prepared mAbs to AChRs from chicken brain and used them to immunoaffinity purify AChRs from rat brain (Whiting and Lindstrom, PNAS 84:595, 1987). Two subtypes of AChRs were identified in chicken brain, which apparently had the same subunit (Mr 49,000) but different β subunits (β=Mr 59,000 and β'=Mr 75,000). Rat brain AChR contained α (Mr 51,000) and β' subunits (Mr 79,000). N-terminal amino acid analysis showed that β' corresponded to the cDNA α_4 described by Goldman et al. (Cell 48:965, 1987). These AChRs exhibit nM binding affinities for nicotine and acetylcholine, but do not bind αbungarotoxin (αBgt). Their β or β' subunits are affinity labelled by the ACh binding site reagents MBTA and BAC, indicating that these subunits form the ACh binding site and contain the functional equivalent of cysteines α192, 193 of electric organ AChRs.

To obtain probes which crossreacted with human AChRs, we prepared a library of mAbs to AChRs from rat brain. Western blot analysis indicated that three of these rat mAbs bound to the β' subunit of rat AChRs. The other six mAbs were conformation-dependent, failing to bind to denatured AChRs. Several of the mAbs exhibited binding to the nicotinic AChR from both bovine and human brain, and were used as biochemical probes to characterize these AChRs. Sucrose gradient analysis indicated that these AChRs are approximately 10S in size, slightly larger than muscle AChRs. AChR was immunoaffinity purified from bovine brain AChR and found to consist of two subunits, Mr 50,000 and Mr 75,000, homologous to the α and β' subunits of chicken and rat brain AChR. Both bovine and human brain AChR exhibited high affinity binding for nicotine (K_I=15.8 nM and 5.4 nM, respectively) and for ACh (K_I=43 nM and 2.7 nM, respectively) as determined by inhibition of DL[^{3}H]nicotine binding, but neither AChR bound αBgt. The binding of [^{3}H]nicotine could be inhibited by reduction of these AChRs with dithiothreitol, and subsequent labelling with BAC and MBTA. The β' subunit was affinity labelled with [^{3}H]MBTA, indicating that it contains the ACh binding site.

Thus, the AChR from brain with high affinity for nicotine but no affinity for αBgt is formed from two types of subunits in brains of chickens, rats, cattle, and probably humans. In adult chickens, half of the AChRs are of the αβ subtype and half are of the αβ' subtype. In the mammalian species, greater than 90% appeared to be of the αβ' subtype.

260.8 PRESENCE OF NICOTINIC ACETYLCHOLINE RECEPTOR-ION CHANNEL (AChR) ON CULTURED RAT HIPPOCAMPAL CELLS. Y. Aracava*[1], H. Rapoport*[2], G. Lunt*[3], S. Wonnacott*[3], and E.X. Albuquerque*[1]. (SPON: T. Rogers). [1]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med. Baltimore, MD 21201; [2]Dept. Chem. Univ. California, Berkeley, CA 94720 & [3]Dept. Biochem. Univ. Bath, Bath BA2, U.K.

Using (+)anatoxin-a (*Mol. Pharmacol.* **29**: 250, 1986) and acetylcholine (ACh) as probes of AChR and employing the patch-clamp technique, we recorded channel activation in hippocampal neurons cultured from fetal rats (10 to 20-day-old culture). Both ACh (0.4 μM) and (+)anatoxin-a (0.1-0.4 μM) activated single channel currents whose amplitudes and durations were quite similar to those recorded at the perijunctional region of the muscle endplate. Figs. a and b show typical channel activity recorded from an area close to the axon hillock of the hippocampal neurons. Although some differences in agonist effects at central and peripheral receptors have been encountered (see abstracts of Rozental *et al.* and Lunt *et al.* at this meeting), the present study, still preliminary, disclosed marked homology between the putative hippocampal AChRs and those on the muscle. The hippocampal AChRs showed a similar sensitivity to histrionicotoxin, a probe for ion channel sites, as the muscle AChRs (*FEBS Lett.* 212:292, 1987). Additionally, AChRs activated by either ACh or (+)anatoxin-a were sensitive to α-bungarotoxin and dihydro-β-erythroidine. These studies suggest the presence of functional nicotinic AChRs on the neurons of rat hippocampus. (Support: NIDA Grant DA 02804 & U.S.Army Med. Res. & Devel. Comm. Contract DAMD17-84-C-4219).



Legend: Single channel currents activated by acetylcholine (a) and (+) anatoxin (b) recorded from cultured hippocampal neurons in the cell-attached configuration. Holding potential: -80(a) and -140 mV (b). Cal.: vert. 3 (a) and 8 pA (b); hor. 25 msec (a & b).

260.9 THE EFFECTS OF α-BUNGAROTOXIN AND MAGNESIUM ON THE ELECTROPHYSIOLOGICAL ACTIONS OF NICOTINE IN THE RAT CEREBELLUM. R. de la Garza, T.J. MCGUIRE,* B.J. Hoffer, R. Freedman. Univ. of Colo., Health Sci. Ctr., Dept. of Pharmacol. C236, 4200 E. 9th St., Denver, CO 80262 and Denver VAMC.

A recent study from our laboratory described the heterogenous electrophysiological actions of nicotine in the rat cerbellum. A curare-sensitive site was found to mediate the excitatory effects of nicotine on identified cerebellar inhibitory interneurons and a hexamethonium-sensitive site was found to mediate the inhibitory effects of nicotine on identified Purkinje cells. The experiments reported here investigated whether another more selective nicotine blocker, α-Bungarotoxin (α-BTX), would also antagonize the actions of nicotine on these neuronal populations. Additionally, we also investigated whether the actions of nicotine on either cell type are dependent on direct postsynaptic or indirect presynaptic actions by examing its effects in the presence of elevated concentrations of magnesium, ion which would reduce transmitter release.

Nicotine elicited reversible and dose-dependent effects on both cell types. The excitatory actions of nicotine on cerebellar interneurons were blocked by the simultaneous application of α-BTX in 17 of 18 cells tested. In some experiments, the antagonistic actions of α-BTX showed no recovery an hour after the removal of the toxin. In contrast, the inhibitory actions of nicotine on Purkinje cells were not blocked by similar applications of α-BTX in 17 of the 20 cells tested. A chi-square analysis of the data showed that the antagonistic effects of α-BTX depended on the type of cell studied in a statistically significant manner ($p < .0001$).

Additionally, the microiontophoretic application of magnesium ion failed to block the actions of nicotine on any of the 15 Purkinje cells and 10 interneurons tested. Student's *t*-tests for correlated samples showed that there were no statistically significant differences in Purkinje cell [$t(14) = -0.87$, $p > 0.05$] or interneuronal nicotine-induced responses [$t(9) = -1.67$, $p > 0.05$] in the presence and absence of magnesium ion.

The present data support the hypothesis of multiple nicotinic sites of action in mammalian brain (de la Garza et al., J. Pharmacol. Exp. Ther. 240: 689-695, 1987). Our findings also suggest that the pharmacological actions of nicotine on cerebellar cortex neurons are due to direct postsynaptic mechanisms (Supported by USPHS grant DA 07043 and the Veterans Administration).

260.10 **PURIFICATION AND CLONING OF THE MUSCLE-LIKE NICOTINIC ACETYLCHOLINE RECEPTOR FROM THE HUMAN MEDULLOBLASTOMA CELL LINE TE671.** M. Luther*, R. Schoepfer*, P. Whiting*, M. Montal+, and J. Lindstrom (SPON: D. Sakaguchi), Receptor Biol. Lab., The Salk Institute for Biol. Studies, P.O. Box 85800, San Diego, CA 92138 and +The Roche Institute of Molecular Biology, Nutley, NJ 07110.

Studies on the human muscle nicotinic acetylcholine receptor (AChR) have been difficult due to the low number of AChRs present on striated muscle, proteolysis, and the limited availability of tissue. Surprisingly, the AChR from the human medulloblastoma cell line TE671 exhibits electrophysiological, immunological, and pharmacological properties similar to those of AChRs from human muscle. Unlike AChRs from TE671 cells, the α bungarotoxin (αBgt) binding components from human brain do not bind monoclonal antibodies (mAbs) to AChRs from human muscle or autoantibodies to these AChRs from myasthenia gravis patients (Whiting and Lindstrom, J. Neuroimmunol., in press). Neither AChRs from TE671 cells nor brain αBgt binding components are bound by mAbs to brain AChRs which have high affinity for nicotine but do not bind α Bgt. Evidence suggests that AChRs from muscle and neurons and neuronal αBgt binding components are all members of a gene family. TE671 cells may derive from a precursor cell type whose mature form does not express muscle-like AChRs.

AChR protein from TE671 was purified 2,000-fold by toxin-agarose affinity chromatography, and its subunits were characterized by polyacrylamide gel electrophoresis, N-terminal amino acid analysis, and western blotting with subunit-specific mAbs to AChRs from fish electric organs or mammalian muscle. Sucrose gradients show that TE671 AChRs exist as both monomers and dimers. cDNA probes for all four subunits of mouse muscle AChR (a gift from J. Boulter) detect corresponding mRNA species in TE671 at high stringency. To determine the primary structure of the AChR, a cDNA library was made in λ-ZAP, a cloning vector furnishing an automatic excision procedure for the insert. Using a mouse muscle α subunit cDNA probe, several clones were obtained at high stringency, and sequence analysis was performed.

The expression of this AChR is enhanced by both nicotine (as previously reported by Siegel and Lukas, Neurosci. Abstr. 11.9, 1986) and calcitonin gene-related peptide (a putative neurotrophic factor reported to increase AChR synthesis in muscle by Fontaine et al., Neurosci. Letts. 71:59, 1986), while forskolin (which stimulates adenylate cyclase, increases phosphorylation of muscle AChR subunits and thereby causes desensitization as reported by Anthony et al., Neurosci. Abstr. 40.1, 1986) decreases both the expression and the level of mRNA for α subunits.

Thus, TE671 provides an excellent source for the study of human muscle AChRs at the protein and cDNA level.

260.11 IDENTIFICATION OF A GENE PROPOSED TO ENCODE A NON-ALPHA SUBUNIT OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS. E.S. Deneris*, J. Boulter*, J. Connolly*, K. Wada*, J. Patrick, and S. Heinemann. Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138.

We have taken a molecular genetic approach to isolate and characterize nicotinic acetylcholine receptors (nAChR) expressed in the brain. Through the isolation of rat cDNA clones we have identified three genes that are expressed in the nervous system and encode proteins with sequence and structural homology to the alpha subunit of the nAChR expressed at the mammalian neuromuscular junction. We have proposed that these genes encode alpha subunits (or ligand binding subunits) because they contain two adjacent cysteine residues that are the homologues of CYS 192 and CYS 193 of the *Torpedo* alpha-subunit. CYS 192 and possibly CYS 193 of the *Torpedo* alpha-subunit have been shown to be labeled with the affinity alkylating reagent 4-(N-maleimido) benzyltrimethylammonium iodide (Kao, P.N. et al., 1984, J. Biol. Chem. 259:11662) and therefore lie close to the binding site for acetylcholine. We have thus named these neuronally expressed genes: alpha2, alpha3 and alpha4.

Using the nAChR expressed at the neuromuscular junction as a model, we have hypothesized that the neuronal receptors contain non-alpha subunits as well. To test this hypothesis, we have screened cDNA libraries prepared from mRNA extracted from rat brain and the PC12 cell line. Screening with a radiolabeled alpha3 cDNA has resulted in the isolation of a novel set of cDNAs; one of which, PCX49 isolated from a PC12 library, encodes a full length protein. Nucleotide sequence analysis reveals that these cDNAs encode a protein with sequence and structural homology to the proposed neuronal alpha-subunits. However, the PCX49 encoded protein lacks the two adjacent cysteine residues found at position 192 and 193 in the *Torpedo* and muscle alpha-subunits. In this respect, this protein is similar to the non-alpha subunits found in the *Torpedo* and muscle nAChRs. Based upon this fact, we have hypothesized that the PCX49 encoded protein is a non-alpha subunit of a neuronal nAChR and have therefore named its gene beta2.

In situ hybridization histochemistry is being used to determine where the beta2 gene is expressed in the rat central nervous system. Preliminary results indicate a wide distribution of expression that includes the thalamus, medial habenula, the geniculate nuclei, and hypothalamus. These regions have been shown to express collectively, the alpha3 and alpha4 genes and raises the possibility that the beta2 gene product is assembled with either the alpha3 or alpha4 gene product at different synapses to form distinct nAChRs in the nervous system.

A *Xenopus* oocyte expression system has been used to determine if the beta2 gene encodes a functional nAChR subunit. We have found that acetylcholine and nicotine will elicit a depolarizing response in oocytes that have been injected with beta2 mRNA and either alpha3 or alpha4 mRNA. This response is blocked by toxin 3.1, but not alpha-bungarotoxin indicating that these genes encode proteins that produce a functional nAChR with the pharmacology of a ganglionic or neuronal nAChR.

260.12 ISOLATION AND CHARACTERIZATION OF A GENE CODING FOR A RAT BRAIN NICOTINIC ACETYLCHOLINE RECEPTOR α-SUBUNIT. K. Wada[1*], M. Ballivet[2*], J. Boulter[1*], J. Connolly[1*], E. Deneris[1*], E. Wada[3*], L. Swanson[3,4], S. Heinemann[1] and J. Patrick[1]. (SPON: G. Lemke) [1]Molecular Neurobiology Laboratory., [3]Neural Systems Laboratory. and [4]Howard Hughes Medical Institute, The Salk Institute, La Jolla, CA 92037, [2]Dept. of Biochemistry, University of Geneva, CH-1211, Geneva, Switzerland.

The molecular genetic approach we have employed has led to the identification of a family of nicotinic acetylcholine receptor α-subunit genes in rat. The genes thus far identified have been designated alpha1 through alpha4. Partial sequence data of the alpha2 gene were reported previously (P.Nef et al., in Nicotinic Acetylcholine Receptor:Structure and Function, Ed. A.Maelicke, Springer-Verlag, p417, 1986). Recently we have isolated rat genomic and cDNA clones encoding the mature alpha2 gene product. Partial sequencing of the genomic clones has shown that the alpha2 gene is composed of at least 6 exons and encodes a mature protein of 481 amino acids having characteristic features of nicotinic acetylcholine receptor α-subunits. Clones derived from the alpha2 gene were isolated from rat brain cDNA libraries. mRNA transcribed from one of the longest alpha2 cDNA clones was injected into *Xenopus* oocytes in combination with mRNA derived from a cDNA clone, PCX49. PCX49 was isolated from PC12 cell libraries and is encoded by the beta2 gene(E.Deneris et al., this meeting). The injection resulted in the synthesis of functional neuronal nicotinic acetylcholine receptors. Depolarising responses were recorded to perfused acetylcholine(1-5μM). The responses were blocked by d-tubocurarine and hexamethonium(0.1mM) but not by α-bungarotoxin(0.1μM, 30 minutes incubation) or atropine(1μM). These are the properties expected of neuronal nicotinic acetylcholine receptors. The localization of alpha2 gene transcripts in the rat brain was determined by *in situ* hybridization histochemistry using an ^{35}S-RNA probe encoding the 3'-untranslated sequence of the alpha2 gene. Transcripts were found in the interpeduncular nucleus and the hippocampus. Little or no signal was detected in other brain regions by this method.

260.13 ANATOXIN-a ACTS AT CENTRAL NICOTINIC ACETYLCHOLINE RECEPTORS. G. Lunt*[1], S. Wonnacott*[1], B. Thorne*[1], H. Rapoport*[2], Y. Aracava*[3], and E.X. Albuquerque*[3]. (Spon: L. Goldman) [1]Dept. Biochem., Univ. Bath, Bath BA2 7AY, U.K., [2]Dept. Chem., Univ. California, Berkeley, CA 94720 and [3]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Anatoxin-a, a neurotoxin produced by the algae *Anabaena flos-aquae*, is a potent and stereospecific agonist at the vertebrate neuromuscular juction, closely resembling acetylcholine in its channel conductance properties. We have investigated the effects of anatoxin-a isomers at nicotinic sites in the CNS. In binding experiments, (+)anatoxin-a was a potent competitor of [^{3}H](-)nicotine binding to rat brain membranes (K_i = 3 x 10^{-10}M); the (-)anatoxin enantiomer was two orders of magnitude less effective. To see if (+)anatoxin-a also acts as an agonist in the CNS, the toxin was tested in a model system based on the presynaptic nicotinic facilitation of transmitter release. Synaptosomes were prepared from rat hippocampus, and the intraterminal pool of acetylcholine was labelled by incubation with [^{3}H]choline. Perfusion of the labelled synaptosomes with Kreb's bicarbonate buffer into which pulses (100 μl; 50 μM) of (-)nicotine were introduced resulted in the release of discrete peaks of [^{3}H]acetylcholine, and this response could be partially blocked by the nicotinic antagonist dihydroβerythroidine (10 μM). Similarly, hippocampal synaptosomes loaded with [^{3}H]GABA responded to pulses of nicotinic agonist by releasing radiolabelled transmitter. The higher labelling [^{3}H]GABA allows lower agonist concentrations to be tested. In this case, 10 μM (-)nicotine and 1 μM (+)anatoxin-a released comparable amounts of [^{3}H]GABA. The results suggest that (+)anatoxin-a is at least 5 times more effective than (-)nicotine at presynaptic nicotinic receptors in mammalian brain. Additional evidence of the existence of nicotinic receptors in the CNS has been provided by electrophysiological studies (see abstract of Aracava *et al.* - this meeting). (+)Anatoxin-a and acetylcholine activated single channel currents from cultured hippocampal neurons disclosing the presence of nicotinic acetylcholine receptors which bore some functional and pharmacological homology with the neuromuscular nicotinic macromolecule. (Support: U.S. Army Med. Res. & Devel. Com. Contr. DAMD17-84-C-4219 and NIDA Grant DA 02804).

260.14 **BLOCKADE OF NICOTINIC ACETYLCHOLINE RESPONSES BY TOXIN F IN ISOLATED RAT RETINAL GANGLION CELLS AND BINDING OF RADIOLABELED TOXIN F TO RAT RETINAL HOMOGENATES.** E. Aizenman, R.H. Loring, R.E. Zigmond & S.A. Lipton. Depts. of Neurology and Pharmacology, Harvard Med. Sch., and Div. of Neurosci., The Children's Hosp., Boston, MA 02115.

Patch-clamp recordings from cultured retinal ganglion cells have revealed responses to acetylcholine that are blocked by classical nicotinic antagonists but not by alpha-bungarotoxin or atropine (Lipton et al., *Soc. Neurosci. Abstr.* 12: 635; 1986). In the present study we examined the antagonist and ligand binding properties of another fraction of the venom from *Bungarus multicinctus*, Toxin F (TXF), on retinal preparations. This toxin has been shown to block nicotinic responses in other neuronal systems (see Loring et al., *Soc. for Neurosci. Abstr.*; 1987). For the physiological studies, retinal ganglion cells were labeled *in vivo* by retrograde transport of a fluorescent dye and maintained in dissociated cultures (Leifer et al., *Science* 224: 303; 1984). Whole-cell patch-clamp recordings were performed on these cells. Currents induced by 50 micromolar acetylcholine (applied by pressure ejection from a micropipette in close apposition to the cell under study) were reversibly antagonized by 0.2 micromolar TXF. The toxin was introduced by rapid superfusion of the recording chamber; in this manner, responses were blocked within 2-4 minutes following toxin addition and partially recovered within 4-18 minutes after toxin washout. During the recovery phase from toxin block, single acetylcholine-induced channels were sometimes observed. Nicotinic channels obtained in this fashion had a slope conductance of 48 pS and a mean open time distribution with a TAU of 4.3 ms. Single nicotinic channels observed prior to toxin addition had a similar conductance.

For the binding studies, rat retinal homogenates were incubated in 3 to 100 nM radioiodinated TXF (500 Ci/mmol) in the presence and absence of cold TXF and/or alpha-bungarotoxin. We found that TXF specifically bound to two sites, one having a Kd of 14 nM and a Bmax of 18 fmol/retina, and a second having a Kd of 188 nM and a Bmax of 88 fmol/retina. We observed little or no TXF binding that was displaceable by alpha-bungarotoxin. Work by others has shown that the cholinergic pathway in the intact mammalian retina links "starburst" amacrine cells to ganglion cells and that this pathway participates in the response to slow motion of visual stimuli. Thus, the TXF binding sites may represent the TXF-sensitive cholinergic receptors on retinal ganglion cells that mediate this response.

261.1 INTRACELLULAR RESPONSES OF HUMAN CORTICAL BIOPSIES MAINTAINED IN VITRO. B.W. Strowbridge*, G.M. Shepherd, D.D. Spencer and L.M. Masukawa. Department of Neuroscience, Yale University School of Medicine, New Haven, CT 06510.

As part of a multidisciplinary study of the neural basis of human epilepsy, we obtained neocortical biopsies from twelve patients undergoing surgical procedures to treat intractable epilepsy. We compared intracellular responses in human neocortex with those of the rat and guinea pig, and probe for evidence of the differences which might throw light on the pathophysiology of epilepsy.

Biopsies of the cingulate, temporal and parietal cortices were taken as part of the normal surgical procedure. A portion of the biopsy was immediately placed in ice-cold Krebs buffer and removed to an antechamber outside the operating room where it was blocked and vibratomed into 400 um slices. The slices were left in the vibratome bath, which was gently bubbled with 95% O_2 /5% CO_2 and transported to the recording chamber, similar to a Haas chamber.

In most areas acceptable intracellular recordings were readily obtained after a 1-3 hour recovery period. We were able to classify the neurons encountered into the 3 categories that McCormick et al. (J. Neurophysiol. 54:782, 1985) proposed for guinea pig neocortex: regular firing, bursting and fast spiking, based on the cell's response to injected current. Regular firing cells accounted for 80% of our sample and were found in all layers except layer 1. Cells which responded to current steps with a burst of action potentials were encountered in 15% of the population and were concentrated in layers 4 and 5. Fast spiking neurons constituted only 5% of the population.

We used othrodromic electrical stimulation to analyse the synaptic physiology of the neurons in the biopsies, and found considerable variation in these responses. In 5 of our 12 cases, the orthodromic responses were similar to that of the rat and guinea pig neocortex: an initial EPSP followed by a long duration IPSP. Often the IPSP could be revealed by depolarizing current injection or by superimposing the orthodromic stimulus on a train of action potentials evoked by a current step. In 4 of the cases, there was evidence for a prolonged EPSP followed by a weak inhibition. Some cells, however, exhibited strong IPSPs to orthodromic stimuli, whereas other cells in the same slice responded with little or no IPSP. Three cases had orthodromic responses consisting of bursts of action potentials at a latency of 30-50 ms. In these cases, the latency of the burst could be altered by the membrane potential; in 2 of the 3 cases, hyperpolarization decreased the latency while increasing latency in one case.

Our studies indicate a number of similarities between the physiology of the human neocortex and the rodent neocortex. We have also observed orthodromic responses which are seldom seen in healthy animal neocortex, such as the long latency burst. We postulate that such responses may represent a physiological manifestation of the epileptic tissue. (Supported by NIH NS-07609 and the Office of Naval Research)

261.2 CONTENT OF PEPTIDES & AMINO ACIDS IN THE CEREBROSPINAL FLUID OBTAINED PRE & POST SEIZURE. O Devinsky*, RJ Porter, WH Theodore, NS Nadi. NINCDS, Bethesda, MD 20892.

Investigations of human epileptic foci have shown that the content of the amino acids glutamate, glycine and aspartate, the neuropeptides somatostatin and neuropeptide Y, as well as the catecholamines are increased when compared to non-focal tissue. We therefore studied baseline and post seizure cerebrospinal fluid (CSF) levels of amino acids and neuropeptides in patients with simple and complex partial, and generalized tonic-clonic seizures to determine if similar alterations occurred. Baseline CSF was obtained in 16 patients from 10 hrs to 3 days after the last seizure, and post ictal samples between 20 min and 75 min after a seizure. Amino acids were analyzed by fluorescence, catecholamines by HPLC with electrochemical detection, and peptides were determined by radioimmunoassay. Ten sequential 1 ml aliquots of CSF were collected. The same CSF fraction number was used for each separate analysis in order to avoid changes due to gradient formation. (All patients were on carbamazepine or phenytoin, but the levels did not change between baseline and post seizure CSF). There were no significant changes in the baseline and post seizure CSF for the following amino acids: glutamate, aspartate, glycine, GABA, taurine, alanine and leucine. Furthermore, there was no difference between the CSF amino acid levels in normal volunteers (n=10) and patients (baseline or post seizure). CSF levels of the following peptides were determined: somatostatin, ACTH, neuropeptide Y, neurotensin, cholecystokinin, βendorphin, vasoactive inhibitory peptide, and met-enkephalin. Significant differences ($p<.05$ by student t-test) between baseline and post seizure were found for ACTH (mean ± SD; n=16) (4.95 ± 1.1 pg/ml vs 2.90 ± 1.0 pg/ml), βendorphin (5.95 ± 1.0 pg/ml vs 7.9 ± 0.45 pg/ml), met-enkephalin (3.49 ± 1.1 pg/ml vs 6.92 ± 1.2 pg/ml), and somatostatin (84.1 ± 25.9 pg/ml vs 174.9 ± 41.8 pg/ml), but not neuropeptide Y, neurotensin, cholecystokinin, or vasoactive inhibitory peptide. Cortisol was not significantly altered in the post seizure CSF. No time dependence of the peptide alterations were observed in patients from whom sequential post seizure CSF samples were obtained. Earlier studies from our laboratory have shown that catecholamines are also increased in the post seizure CSF. The alterations of neuropeptides and catecholamines in brain as well as CSF may provide clues for a role of these compounds in the pathophysiology of seizures.

261.3 EVIDENCE OF AUGMENTED SEROTONIN AND DOPAMINE TURNOVER IN EPILEPTOGENIC FOCI RESECTED FROM HUMAN BRAIN. G.B. Glavin*, K.M. Kiernan* and G.R. Sutherland* (SPON: F. LaBella). Dept. Pharmacol. and Ther., Univ. of Manitoba, Winnipeg, Canada, R3E 0W3.

Temporal lobe and hippocampal specimens were obtained from patients undergoing surgical resection of their epileptic foci. Samples were analyzed in triplicate by HPLC/ED and levels of noradrenaline (NA), dopamine (DA), and 5-hydroxytryptamine (5-HT) as well as their major CNS metabolites MHPG (3-methoxy-4-hydroxyphenylethyleneglycol sulfate); HVA and DOPAC (homovanillic acid and dihydroxyphenylacetic acid); and 5-HIAA (5-hydroxyindoleacetic acid), respectively, were obtained. 3 out of 4 hippocampal specimens from actively spiking electrode sites showed huge (200-400%) increases in 5-HT turnover, compared to non-epileptic brain tissue. Analysis of actively spiking temporal cortical tissue revealed little evidence of exacerbated amine turnover, however, examination of less electrically active temporal cortical specimens showed both exaggerated 5-HT and DA turnover. Since 5-HT is known to exert anti-seizure activity, we suggest that the rise in 5-HT turnover observed in these samples reflects recruitment of 5-HT for endogenous anti-epileptic activity. The significance of the enhanced DA turnover remains to be determined, however, we suggest that our method, sensitive to picomolar concentrations of monoamines and their metabolites, is a useful addition to the research armamentarium investigating the epileptogenic focus.

261.4 GABAERGIC SYNAPSES IN THE HUMAN EPILEPTIC HIPPOCAMPUS: LIGHT AND ELECTRON MICROSCOPY OF GAD IMMUNOSTAINING. Babb, T.L., Kupfer, W.R.* and J.E. Pretorius*. Dept. of Neurology and Brain Research Institute, University of Calif. Los Angeles 90024

Glutamate decarboxylase (GAD) immunocytochemistry of resected epileptic temporal lobes has shown that the numbers of GABA cells and terminals are not significantly and selectively decreased in epileptic hippocampus compared to the severe hippocampal sclerosis characteristic of hippocampal epilepsy. (Babb, T. Neurotransmitters and Seizures and Epilepsy III pp. 293-302, N.Y. Raven Press, 1986) This relative preservation of inhibitory interneurons and their terminals as quantified by light microscopy of GAD-stained hippocampus suggests that GABAergic inhibition is intact in human epileptic hippocampus. The present study was performed to investigate the ultrastructure of the GABAergic synapses and examine the integrity of the pre- and post-synaptic profiles in epileptic tissue. To date, 6 epileptic hippocampi have been studied extensively by combined GAD staining and electron microscopy. The hippocampi were immersion-fixed in picric acid-aldehyde, GAD-immunostained, epon-embedded and examined with transmission E.M. in fields CA_1, CA_2, CA_3 and fascia dentata (FD). Synapses were defined as GABAergic if (1) the terminals had GAD on the vesicles and around mitochondria, (2) there was a wider cleft between the pre-synaptic membrane (with denser vesicles) and post-synaptic membrane (with adjacent density). Symmetric synapses were more frequent than the asymmetric type. GABAergic synaptic profiles appeared intact in all regions of epileptic hippocampus despite adjacent glial fibrils. Cell bodies had typical organelles such as ribosomes, endoplasmic reticulum and Golgi near the post-synaptic cytoplasm. We conclude that GABAergic synaptic structure is intact in human epileptic hippocampus. NIH Grant NS02802.

261.5 VARIATIONS IN THE DELAYS BETWEEN PEAKS WITHIN POPULATION BURSTS IN CA1 RECORDED WITH A 32 ELEMENT ARRAY. J. L. Novak*[1], B. C. Wheeler[2], and F. -L. Chang[2]. [1]Department of Electrical and Computer Engineering, University of Illinois, Urbana, IL 61801 and [2]Department of Psychology, University of Illinois, Champaign, IL 61820.

Epileptiform bursts recorded in the CA1 area of the rat hippocampal slice propagate in the direction of the afferent volley evoked in the Schaffer collateral pathway. These bursts appear to be composed of two types of population spikes: the first spike which may be mediated by fast receptors involving kainic acid, and secondary spikes via NMDA. Although propagation delays for the first spikes occur as a result of the conduction velocity of the Schaffer collaterals, the mechanism for the apparent propagation of the secondary spikes remains unclear.

A planar, photoetched microelectrode array of 4 by 8 electrodes spaced 200 μm apart was used to investigate propagation of an epileptiform burst through the CA1 region of hippocampal slices from male Sprague-Dawley rats. The media contained (in mM): 124 NaCl, 26 $NaHCO_3$, 10 glucose, 5 KCl, 2.0 $CaCl_2$, 1.25 NaH_2PO_4, 0.8 $MgSO_4$. Picrotoxin (100 μM) was added to induce epileptiform responses. The slices were positioned with the Schaffer collateral pathway parallel to the major array axis. Bipolar stimulating electrodes were positioned in the s. radiatum of CA1, either near CA3 or the subiculum.

To measure the propagation of active tissue within the slice, and not the passive spread of field potentials, a 2-D current source density (CSD) analysis was performed prior to measuring peak times. This prevented artifacts which may have resulted from treating passively generated field potentials as individual events with zero interchannel delay. The use of this technique with this electrode array and preparation has been reported (IEEE Trans. BME, BME-33:1024, 1986).

The interchannel delays between active sinks corresponding to the first population spike recorded over the 200 μm interelectrode intervals were fairly regular. However, delays for the second sink appeared much more variable, often with no delay between adjacent channels. To study the variability, an index of coefficients of variation was adopted. For the first spike, the coefficient is 0.314 $\pm$ 0.183 (n = 10), and the second is 0.841 $\pm$ 0.363 (n = 10). The two coefficients of variance are significantly different, ($t = 9.76$, $p < 0.001$), suggesting that epileptiform activity in CA1 does not consist of passively conducting serially activated stereotypical responses, but rather that active localized processing may exist.

261.6 THE PAUCITY OF BLOOD VESSELS IN THE TEMPORAL LOBE MAY ACCOUNT FOR ITS SUSCEPTIBILITY TO SEIZURE-INDUCED DAMAGE. J.P. Olson*, F.E. Samson, T.L. Pazdernik*, V.H. Gattone II* and S.R. Nelson Department of Anatomy and the R.L. Smith Center, Univ. of Kansas Medical Center, Kansas City, Kansas 66103.

Sustained seizures (kainic acid-induced) in rats result in ischemic infarction of temporal lobe (piriform-entorhinal cortex and amygdala). We hypothesize that the temporal lobe lesion may be the result of vascular insufficiency during the seizure caused by regional differences in tissue vascularity. A vascular casting technique was used to compare cortical vasculature of areas susceptible to damage (temporal cortex) with areas unaffected (parietal cortex) by seizures.

Normal rat brains were perfusion fixed with 2.5% buffered glutaraldehyde under physiological conditions and the cerebral vasculature injected with Microfil silicon casting medium. The brains were processed and cut into 4mm coronal sections for gross examination of the cerebral vasculature. Cortical regions were removed from the parietal and temporal lobes, paraffin embedded and sectioned for vascular quantitation. Quantitatively, the penetrating vessels were counted and their cross sectional areas measured. Regional vascular volume density was determined by point counting.

Gross examination of cerebral vascular casts revealed a rich supply of penetrating vessels and capillaries in parietal lobe with few penetrating vessels in the temporal lobe. This apparent difference in vascularity was confirmed by morphometric analysis of parietal and temporal cortex. Analysis revealed there were fewer and smaller penetrating vessels and less vascular volume density in temporal cortex. The temporal cortex vascular density was 0.024±0.001 compared to 0.045±0.003 mm^3/mm^3 in the parietal cortex (mean ± SEM, n=6). There were also one fourth (25.9%) the number of penetrating vessels (diameter >20um) in temporal cortex. Since blood flow is generally considered to be proportional to the vascular volume density, a 50% reduction in vascular volume would have functional significance. This paucity in vascularity may predispose the temporal lobe to ischemic damage during seizures because the blood flow cannot accommodate the increased metabolic need.

261.7 INCREASED EXTRACELLULAR POTASSIUM UNMASKS EXCITABILITY DIFFERENCES BETWEEN THE EPILEPTIC MUTANT TOTTERING AND CONTROL MOUSE HIPPOCAMPUS IN VITRO. P.A. Rutecki and J.L. Noebels. Dept. of Neurology, Section of Neurophysiology, & Program in Neuroscience, Baylor College of Medicine, Houston, TX. 77030.

The single locus mutant mouse tottering (tg/tg) displays spontaneous generalized spike-wave epileptiform discharges and absence seizures which can be abolished by reducing their abnormal central noradrenergic (NE) hyperinnervation originating from the locus coeruleus. In this study we tested the hypothesis that a difference in excitability between tg/tg and control (+/+) mice can be demonstrated in vitro. We also evaluated whether exogenous NE can modulate convulsant-induced epileptiform activity.

Extracellular recordings were made from the CA3 subfield of 400 µM thick hippocampal slices. Neither tg/tg, nor +/+ slices displayed spontaneous epileptiform discharges in control saline containing 5 mM $[K^+]_o$.

When $[K^+]_o$ was raised to 7.5 mM, spontaneous epileptiform discharges appeared in both genotypes. The discharge frequency increased in 10 mM $[K^+]_o$. The mean frequency of occurrence of spontaneous discharges was higher in +/+ than tg/tg slices, but the difference was not significant (0.106 vs 0.062 Hz for $[K^+]_o$=7.5 mM, 0.31 vs 0.26 Hz for $[K^+]_o$=10 mM; $P > 0.05$). The mean duration of a discharge was significantly longer in tg/tg compared to +/+ slices (106.5 [N=12] vs 86.8 ms [N=18] for $[K^+]_o$=7.5 mM, 111.1 [N=9] vs 84.8 ms [N=8] for $[K^+]_o$=10 mM; $P < 0.05$). Bath application of 10 µM 4-aminopyridine had a dissociative effect similar to high $[K^+]_o$ on discharge duration but not frequency between the two genotypes. In the presence of a different class of convulsant, 10 µM picrotoxin, discharge durations in both tg/tg and +/+ slices were longer than in elevated $[K^+]_o$, but there was no significant difference in duration or rate between the two. Bath application of 10 µM NE or 1 µM isoproterenol did not initiate spontaneous discharges in low $[K^+]_o$, but did produce an increase in the frequency of discharges induced by high $[K^+]_o$ in both +/+ and tg/tg slices. Neither agonist had an effect on discharge duration.

These results demonstrate an intrinsic difference in network excitability of an isolated region of the epileptic mutant tottering brain. Although exogenous NE agonists did not prolong discharge duration, our findings confirm that NE agonists exert a neuromodulatory effect on $[K^+]_o$-induced epileptiform discharge frequency. (Supported by NIH grants NS11535, NS01049, RR-05425, and the Bluebird Circle.)

261.8 DIFFERENCES IN THRESHOLD AND PATTERN OF ELECTROSHOCK-INDUCED SEIZURES IN GENETICALLY EPILEPSY-PRONE RATS. R. A. Browning, D. L. Patrick* and P. C. Jobe. Southern Illinois Univ. Sch. of Med., Carbondale, IL 62901 and Univ. Ill. Coll. Med., Peoria, IL 61656.

Previous studies from our laboratory have suggested that convulsions characterized by facial and forelimb (F&F) clonus depend on (and presumably emanate from) a forebrain (FB) substrate, while convulsions characterized by running-bouncing (R/B) clonus and tonus depend on a brainstem (BS) substrate for expression (Browning & Nelson, Exp. Neurol. 93 546, 1986). We have also reported that minimal electroshock stimulation preferentially produces F&F clonus when corneal (C) electrodes are used and R/B clonus when ear-clip (EC) electrodes are used (Browning & Nelson, Life Sci. 37 2205, 1985). Thus, it should be possible to preferentially activate either FB or BS driven convulsions depending on whether one uses C or EC electrodes. The present investigation was designed to compare the thresholds of the FB seizure substrate in genetically epilepsy-prone rats (GEPRs) and seizure resistant (normal) rats using the minimal electroshock seizure threshold (EST) test and C electrodes. Rats used in these studies were male and female GEPRs which display either severe (tonic) seizures (GEPR-9s) or moderate (R/B clonic) seizures (GEPR-3s) in response to sound (audiogenic) stimulation and Sprague-Dawley seizure resistant (SR) rats. Female SR rats displayed F&F clonus with a threshold of 15.8±0.8 mA in response to the EST test, whereas female GEPR-9 rats failed to exhibit F&F clonus at any stimulus intensity. Instead R/B clonus was observed in GEPR-9s at very low stimulus intensities, and the threshold for this response was 6.2±0.2 mA. Higher stimulating currents (7-10mA) caused tonic seizures with full hindlimb extension in GEPR-9s. Similar results were obtained when male GEPR-9 rats were compared with male SR rats. Unlike GEPR-9s, GEPR-3s displayed F&F clonus in response to the EST test, but their threshold was lower than that of SR rats (GEPR-3s=19.5±0.1 mA; SRs=23.2±0.04 mA, $p< 0.01$). These findings suggest that in GEPR-9s the EST of the BS is less than that of the FB, whereas in SR rats and GEPR-3s, the EST of the BS is higher than the FB. Thus, in GEPR-9s one cannot trigger the FB seizure (F&F clonus) without also triggering the BS seizure. Apparently when the BS seizure occurs, it gains control of the output (spinal cord) and precludes the expression of F&F clonus.

261.9 DECREASED POTASSIUM UPTAKE IN ASTROCYTES CULTURED FROM GENETICALLY EPILEPSY PRONE RATS. J.T. Neary, L.O.B. Norenberg*, and M.D. Norenberg, Laboratory of Neuropathology, Vet. Admin. Med. Ctr. and Univ. of Miami School of Medicine, Miami, FL 33101.

A key function of astrocytes is the uptake of potassium released during neuronal activity. Pollen and Trachtenberg (Science, 167: 1252, 1970) suggested that a defect in potassium buffering by astrocytes could lead to a lower threshold for neuronal excitability, thereby contributing to epileptogenesis. The use of primary astrocyte cultures from genetically epilepsy-prone rats (GEPRs) affords a unique opportunity to study mechanisms which may be related to seizure activity in these cells. Thus, we have investigated the potassium uptake system in cultured astrocytes derived from GEPRs.

Astrocytes were obtained from neonatal cortices of normal Sprague-Dawley rats, GEPR-3 (rats which display moderate, clonic seizures), and GEPR-9 (animals with severe, tonic seizures) which were kindly provided by Dr. J. W. Dailey, Univ. Ill., Peoria. Cells were maintained in primary culture and after two weeks were treated with 0.5 mM dibutyryl cyclic AMP to induce differentiation. The age of cultures used in these studies ranged from 6 to 10 weeks. Following a 30 min. preincubation in a balanced salt solution at 37°C, potassium uptake (using 86-rubidium as a potassium analog) was measured at 3 mM KCl for 1 min.

We found that potassium uptake was reduced by about 15% in astrocytes from GEPR-9 as compared to cells from Sprague-Dawley rats (control = 75.6 $\pm$ 2.55 nmol potassium/min/mg protein, mean $\pm$ SEM; GEPR-9 = 63.8 $\pm$ 1.6; $P<0.01$). Similar results were obtained with cultures from GEPR-3 (62.3 $\pm$ 1.8 nmol potassium/min/mg protein; $P<0.01$). The ability of the cells to respond to increased potassium levels (12 mM) for a prolonged time (10 min) was also investigated. In GEPR-3 cultures, potassium uptake was decreased by about 11%. However, in GEPR-9 astrocytes (derived from rats with a more severe form of seizures than GEPR-3), potassium uptake was decreased by 31% (control = 789 $\pm$ 66 nmol potassium/10 min/mg protein; GEPR-9 = 544 $\pm$ 23; $P<0.02$).

These studies indicate that astrocytes from GEPRs have a diminished ability to take up potassium and suggest that an astroglial defect in potassium homeostasis may contribute to epileptogenesis.

261.10 SERUM GROWTH HORMONE AND BODY WEIGHT ARE DECREASED IN DEVELOPING GENETICALLY EPILEPSY-PRONE RATS. S.A. Mills, C.E. Reigel, P.C. Jobe, and D.D. Savage. Dept. Pharmacol., U. of New Mexico Sch. of Med, Albuquerque, N.M., 87131 and Dept. of Basic Sciences, U. of Illinois Col. of Med. at Peoria, Peoria, IL., 65616.

The Genetically Epilepsy-Prone Rat (GEPR) is an animal model of epilepsy in which seizures occur in response to acoustic stimuli. Recently, GEPR rats have been found to be hypothyroid between days 5 and 45 of age (Soc. Neurosci. Abs. 12:72, 1986). Neonatal hypothyroidism produces a number of deficiencies in growth and development, including central nervous system abnormalities. Hypothyroidism causes a decrease in pituitary growth hormone (GH) content, serum GH, and weight gain. Because of the effects of hypothyroidism on GH and on growth and development, body weight and serum GH levels were determined in developing GEPR rats and age matched non-epileptic Sprague-Dawley controls.

GEPR-3 and GEPR-9 rats used in these studies were derived from breeding pairs which had previously demonstrated the ability to produce progeny susceptible to audiogenic seizures. GEPR-3, GEPR-9, and control rats were weighed and sacrificed by decapitation between 1300 and 1500 hours on 5, 9, 13, 16, 22, 31, 45, and 90 days of age. Trunk blood was collected and serum stored at -70°C until assayed. Serum GH levels were determined by radioimmunoassay.

Serum GH levels in both GEPR-3 and GEPR-9 rats were decreased relative to control rats at all time points studied, and were significantly lower than control levels on Days 9, 13, and 45 of life. Weight gain in the GEPR rats was significantly less than control at all time points studied. The difference in weight gain between control and GEPR rats was most striking from 9 to 16 days of age. GEPR-3 rat weight gain was less than control until Day 16, while GEPR-9 rat weight gain was less than control through Day 31.

These results indicate that weight gain in the GEPR rat remains below control weight gain up to 90 days of age. The difference in weight gain between control and GEPR rats is greatest between Days 9 and 16 of age. This period of time coincides with the interval of the most marked decrease in serum GH in GEPR rats as compared to control. Both the decrease in weight gain and serum GH level occur at a time when serum T_4 levels are most significantly decreased in GEPR rats compared to control. These results suggest that abnormalities in GEPR rat serum GH and weight gain may be functional consequences of neonatal hypothyroidism.
(Materials for the GH radioimmunoassay were provided by the NIADDK division of the NIH)

261.11 HIPPOCAMPAL MOSSY FIBER ZINC IS DIMINISHED IN THE GENETICALLY EPILEPSY-PRONE RAT. D.D. Savage. Dept. Pharmacol., U. New Mexico School of Medicine, Albuquerque, N.M., 87131.

The axonal projection (mossy fibers) of hippocampal formation (HPF) dentate granule cells are rich in histochemically detectable zinc. The role of mossy fiber zinc in neurotransmission between dentate granule cells and CA_3 pyramidal cells is not known. Depletion of HPF zinc in rodents has been associated with a decrease in long term potentiation and decreased performance in learning paradigms. Intraventricularly administered zinc produces seizures. Elevation of whole HPF zinc has been reported in several animal models of epilepsy including the photosensitive baboon, audiogenic mice, kindling and kainate-induced seizures.

The Genetically Epilepsy-Prone (GEPR) rat has been developed by the selective inbreeding of Sprague-Dawley rats susceptible to acoustic stimulus-induced seizures. Given the evidence of an association between whole HPF zinc and epilepsy, HPF mossy fiber zinc was measured in GEPR rats by a newly developed quantitative histofluorescence technique using 8-methoxy-p-toluenesulfonamide (TSQ).

Thirty one day old GEPR-9 and non-epileptic Sprague-Dawley control rats were sacrificed and their brains frozen. Eight micron thick horizontal sections were cut through the ventral HPF, thaw mounted onto microscope slides and vacuum desiccated for 24 hours prior to analysis. Zinc:TSQ histofluorescence was examined using an image analysis system at 32.5X magnification. Eighty microliters of TSQ solution (0.003% TSQ in barbital-acetate buffer, pH 10.2) were applied to the sections, the sections coverslipped and examined one minute later. Fluorescence, expressed as grey levels, was measured and compared to a standard curve of fluorescence obtained from analysis of water soluble plastic sections embedded with known amounts of zinc. Fluorescence measurements were made in the s.lucidum of HPF CA_3 and adjacent s. radiatum. Specific mossy fiber fluorescence, expressed as femtograms zinc/100 microns^2, was defined as the difference in fluorescence between these two regions.

Six sections of ventral HPF were analyzed from six animals of each group. The results indicated a 47% reduction in mossy fiber zinc in GEPR-9 rats compared to non-epileptic controls. Whether the decrease in mossy fiber zinc is an etiological factor in the development of epilepsy in GEPR rats is unknown. However, diminished mossy fiber zinc could be one consequence of thyroid and growth hormone deficiencies during critical stages of HPF maturation, particularly mossy fiber migration and subsequent innervation of HPF CA_3 pyramidal neurons.

261.12 ONTOGENY OF MONOAMINERGIC DETERMINANTS OF SEIZURE SUSCEPTIBILITY AND SEVERITY IN THE GENETICALLY EPILEPSY-PRONE RAT. C.E. Reigel, J.J. Joliff, P.C. Jobe and P.K. Mishra. **Dept. of Basic Sciences, Univ. of Illinois Col. of Med. at Peoria, Peoria, IL 61656.**

The adult Genetically Epilepsy-Prone Rat (GEPR) has been characterized by widespread regional deficits in central norepinephrine (NE) and serotonin (5-HT) levels. Regional defects in NE or 5-HT have been implicated in the regulation of seizure susceptibility in certain areas and seizure severity in others. Severity defects are those NE or 5-HT deficits present in the severe seizure colony (GEPR-9) and not the moderate seizure colony (GEPR-3). Behaviorally, GEPR-9s exhibit full tonic extensor convulsions and GEPR-3s exhibit generalized clonic convulsions in response to sound. Pharmacological manipulations of NE or 5-HT support a role for these deficits in the regulation of seizure susceptibility and severity in the GEPR.

As a further test of the involvement of NE and 5-HT deficits in seizure processes in the GEPR, we have examined regional monoamine levels developmentally at ages prior to sound-induced seizure susceptibilty through maturation to adult patterns of convulsion. Seizure susceptibility begins in GEPR-3s at 15 days and in GEPR-9s at 16 days of age. Both colonies reach 100 percent susceptibility at 19 days, maturing rapidly to near adult patterns of characteristic seizures (clonic versus tonic) at 30 days of age. Adult seizure patterns are present at 45 days of age. Monoamine levels were measured in the telencephalon, hippocampus, cerebellum and medulla of male, seizure naive GEPR-9s, GEPR-3s and non-epileptic controls at 13, 16, 19, 21, 23, 27, 30 and 45 days of age. Monoamine levels were also measured in the telecephalon, cerebellum and remaining brain of 5, 9 and 13 day old subjects. Monoamine levels were determined by the HPLC/electrochemical detection method of Co and associates (Pharmacol Biochem Behav 16: 641-646, 1982).

Deficits in 5-HT associated with seizure severity in adult GEPRs were present only in 45 day old GEPR-9s in contrast to the appearance of tonic seizures at earlier ages. Suceptibility deficits in 5-HT were present in GEPR-3s and GEPR-9s prior to and throughout their period of seizure susceptibility. Deficits in NE associated with seizure susceptibility were present in GEPRs prior to and throughout their period of seizure susceptibility in all areas except the medulla. Adult NE severity defects were present in GEPR-9s from the age of appearance of tonic seizures to 45 days in the cerebellum and hippocampus, but not medulla or telencephalon. NE levels lower than GEPR-9 or control were present in GEPR-3s during the period that they transiently exhibited tonic convulsions. Adult susceptibility deficits in NE and 5-HT were present developmentally whereas adult severity deficits were limited to NE in two brain areas. (Supported by BRSG grant SO7 RR 05369)

261.13 **POWER-SPECTRUM OF SURFACE EEG OF GENETICALLY-EPILEPTIC CHICKENS AND EFFECTS OF INTERMITTENT PHOTIC STIMULATION.** P.K. Mishra, E.C. Crichlow and R.D. Crawford, Department of Physiological Sciences, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0.

Intermittent photic stimulus (IPS) can induce epileptiform seizures in Genetically-Epileptic chickens. The seizures in these birds are controlled by an autosomal recessive gene 'epi'. Chickens that are homozygous for the epi gene have spontaneous seizures and can be driven into seizures by a number of external factors. The resting EEGs of the homozygous recessive birds show a slow-wave high-voltage rhythmic pattern with periodic spikes and spike-wave complexes which is characteristically different from their normal hatchmates. Upon IPS stimulus the EEG recording shows high-voltage spikes of the same frequency as the stimulus. The ictal phase is prolonged after the stimulus has stopped and in this phase a drastic reduction in amplitude is seen in the EEG.

Ten genetically epileptic (epi/epi) and ten normal chickens were implanted with stainless steel surface electrodes on their skulls. After complete recovery from surgery, EEG signals from differential as well as monopolar electrodes were recorded before during and after IPS on a FM tape recorder. These signals were later analysed by a digital computer. Fast fourier transformations of 104 sec. before IPS and 8-24 sec. after IPS were utilized to obtain the components of various physiological frequency bands in the resting and ictal phase respectively.

Slow frequency components (0-4 cps) of the interictal (resting) EEG of epileptic birds were significantly elevated (up from 37% in normal to 66% in epileptic) whereas the remaining three bands (4-8, 8-14, and 14-64 cps) were significantly reduced in the epileptic birds as compared to those of the normal birds. Although a statistically significant reduction was observed in all three high frequency components, the most significant reduction was observed in the 14-64 cps band. IPS stimulation caused a significant reduction in the 0-4 cps component and an elevation in the other three components of the power-spectrum. However, this effect was seen only in the recordings from the anteriorly placed electrodes. Recordings from the normal birds did not show any significant change in the EEG power-spectrum upon IPS stimulation. This technique may be useful in evaluating the neuropharmacological effects of various drugs, especially those, which cause no visually detectable changes in the EEG.

261.14 DEVELOPING NORMAL AND GENETIC EPILEPSY PRONE RATS HAVE A DIFFERENT SEIZURE THRESHOLD TO FLUOROTHYL. K.L. Ginter*, P.A. Schwartzkroin and J.E. Franck. (SPON: A.B. Harris) Dept. Neurological Surgery, Univ. of Washington, Seattle, WA 98195

The genetic epilepsy prone rat (GEPR) has generalized seizures in response to auditory stimuli and a lowered seizure threshold to non-auditory manipulations. We have been interested in these animals as a model of non-sensory generalized epilepsy and have examined the development of seizures in GEPRs and control rats to fluorothyl, an inhalant convulsant, which has been suggested to have a mechanism of action similar to that of pentylenetetrazol.

Sprague Dawley rats (n=46) and GEPRs (n=53; bred from progenitor stock obtained from Dr. Phillip Jobe) were individually placed in a plastic bell jar on postnatal day 10, 15, 20, 25 or 30 and fluorothyl was infused (20µl/min) onto a piece of filter paper suspended at the top of the jar. Latencies to clonic and tonic seizures were recorded. At 40 days of age all animals were tested for audiogenic seizures. Six GEPRs did not have audiogenic seizures and fluorothyl data from these animals were analyzed separately.

Control animals had clonic-tonic convulsions in response to fluorothyl with the onset of clonus showing no age dependence (all ages $\bar{X}\pm$S.D.=193±18 sec). Seizure progression to full tonic extension, however, did change with age. At 10 days, the tonic component occurred shortly following the onset of clonus (221±18 sec); by day 30, latency to tonus had increased to 291±26 sec.

The GEPRs also had generalized seizures, with a consistent, but significantly shorter, latency to clonus independent of age (all ages=162±15 sec; p=.038). Day 10 GEPRs looked much like control animals of the same age; convulsions progressed to tonus immediately following the onset of clonus. As these animals matured, however, this pattern didn't change; tonic extension consistently occurred shortly after clonus (day 30 clonic and tonic latencies 167±17 and 175±17 sec, respectively).

Six GEPRs failed to convulse to the audiogenic post-test and their fluorothyl data was examined separately to determine if GEPR seizures to different stimuli co-vary. These animals had respective clonic and tonic latencies (162 and 170 sec) almost identical to age matched audiogenic susceptible GEPRs (168 and 170 sec).

These data indicate that: 1)the GEPRs have a greater sensitivity, and different response pattern, to fluorothyl than do control animals; 2)during maturation, normal rats develop a perhaps protective mechanism which delays tonic seizures; 3)this mechanism does not mature in the GEPR, and 4) the substrates of audiogenic and non-audiogenic seizures in the GEPR can occur independently; audiogenic seizures may be a special case of a more general neural deficit which interacts with abnormalities in the auditory system. These data both support the position that the GEPR is a valuable model in the study of generalized epilepsy and raise interesting questions on the primary neural deficit involved in non-audiogenic seizures in these animals.

261.15 THE GENETIC EPILEPSY PRONE RAT HAS ALTERED GABA RECEPTOR BINDING IN SUBSTANTIA NIGRA BUT NOT INFERIOR COLLICULUS. J.E. Franck and P.A. Schwartzkroin. Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195.

The genetic epilepsy prone rat (GEPR) has generalized convulsions to loud auditory stimuli and a lowered seizure threshold to non-auditory convulsants. A primary site of pathology in these animals appears to be the inferior colliculus which has been reported to have decreased inhibition and an altered number of GABAergic inhibitory neurons. We have examined GABA binding in the GEPR colliculus and substantia nigra, hypothesizing that this feature of inhibitory function may also be compromised in colliculus and that the nigra may be similarly involved since it modulates generalized seizures.

Conventional in vitro autoradiographic techniques were used to examine the binding of both ^{3}H-muscimol (MUS), to the high affinity GABA recognition site, and ^{3}H-flunitrazepam (FLU) to the benzodiazepine (BZ) site on the GABA receptor complex. Slide mounted tissue sections (10µ) from audiogenic susceptible GEPRs (n=13) and normal Sprague Dawley rats (n=9) were incubated in either Tris citrate buffer (0 ^{0}C; .025M; pH 7.4) containing 10nM MUS (with or without excess cold GABA), or in Tris HCl buffer (0 ^{0}C; .17M; pH 7.4) containing .5 to 12 nM FLU (to allow Scatchard analysis) (with or without excess clonazepam). Labelled slides were apposed to LKB Ultrofilm with tritium brain mash standards; the central and cortical nuclei of the inferior colliculus and the substantia nigra pars reticulata were analyzed on the resulting autoradiograms using the DUMAS/BRAIN system (Drexel University). Binding characteristics of MUS and FLU were expressed as a mean percent (±S.D.) of co-incubated control rats over five replicates.

No differences were observed in specific MUS or FLU binding to either the cortical (MUS=113±19% of control; FLU=99±3%) or central nucleus (MUS=113±30%; FLU=108±8%) of the GEPR inferior colliculus. There was, however, a dramatic reduction in MUS binding in the GEPR substantia nigra (59±12% of control; p=.0012). The binding of FLU to the nigral GABA receptor complex was examined in detail to determine if the alterations observed were specific for MUS binding sites or if other features of GABA receptor function were altered. Scatchard analysis of FLU binding demonstrated that there was no change in receptor number (B_{max}=98±4% of control values). However, the affinity of FLU binding in the GEPR nigra was decreased (K_d=125±14% of control); this difference, while suggestive, was not significant (p=.07).

These data suggest that: 1)despite reports of GABAergic abnormalities in the GEPR inferior colliculus, there are no alterations in inhibitory high affinity GABA or BZ binding sites in this structure; 2)inhibition is compromised in the substantia nigra of the GEPR; and 3)altered inhibition in the substantia nigra may be a common mechanism in the induction of both audiogenic seizures (via demonstrated nigral-collicular pathways) and in the increased propensity of the GEPR to exhibit generalized seizures in response to non-auditory treatments.

261.16 SPECIFIC REGIONAL CHANGES IN THE CONCENTRATION OF PARVALBUMIN IMMUNOREACTIVITY IN THE EPILEPTIC (El) MOUSE. T.B. Anderson*, J.J. Miller and K.G. Baimbridge (SPON: N.W. Kasting). Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada. V6T 1W5

Parvalbumin (PV) is a soluble calcium-binding protein found associated with sub-populations of GABA containing neurons in the rat brain. We have previously shown that the concentration of a second calcium binding protein, Calbindin D28k (CaBP), is reduced in specific regions of the brains of both the kindled rat (Miller and Baimbridge, Brain Res. 278:322, 1983) and the genetically epileptic (El) strain of mouse (Mody et al, Epilepsy Res. 1:45, 1987). In the seizure sensitive gerbil, Peterson et al (Brain Res. 340:384, 1985) have demonstrated an increased number of GABAergic neurons in the dentate gyrus of the hippocampal formation. Using a specific radioimmunoassay we have now determined the regional PV concentrations of El mice in which seizures have been induced by mild vertibular stimulation and compared these values with those of a control (Swiss) strain.

With the exception of the ventral occipital cortex all other cortical regions of the El mice showed dramatically elevated levels of PV with the maximum increase being in the ventral frontal cortex (270% of Swiss strain controls). The striatum, in which PV is contained within a sparse population of GABAergic interneurons, also showed elevated levels (195%) while there were no changes in the hippocampal formationl, medulla, pons, midbrain or cerebellum. Preliminary immunohistochemical studies indicate that the number of PV-positive neurons is not significantly increased when compared to control mice. This suggests that the increased PV levels determined by RIA represents an increase in the concentration of PV within the PV-positive neurons.

The increased levels of parvalbumin in the El mice are dramatic and interestingly occur in all the brain regions where CaBP levels are decreased, with the exception of the hippocampal formation. For the most part these two proteins occur in separate populations of neurons, for example, in the cortical regions examined there are very few cells which contain both PV and CaBP. The function of these proteins is presently unknown. Both bind calcium with high affinity and neither has been shown to have any enzyme stimulatory role in either muscle of neural tissue. The changes seen in the levels of PV and CaBP in specific cortical regions of the El mice may prove to be an important factor in the predisposition of this genetic strain of mouse to seizures.

261.17 GABA WITHDRAWAL SYNDROME IN EPILEPTIC AND NON-EPILEPTIC BABOONS AND RATS. S. Brailowsky, H. Fukuda*, C. Menini*, C. Silva-Barrat* and R. Naquet. Laboratoire de Physiologie Nerveuse, C.N.R.S., 91190 Gif-sur-Yvette, France.

We have previously shown (Brailowsky et al., Neurosci. Lett., 74:75, 1987) that local application of GABA into the fronto-rolandic cortex of photosensitive baboons produces a complete blockade of both electrographic and behavioral signs induced by light stimulation, and that these anticonvulsant effects are followed by spontaneous epileptogenic activity originating in the infused areas. In this report, we confirm the presence of this "GABA-withdrawal syndrome" (GWS) in epileptic baboons infused in other cortical territories, in amygdala-kindled rats and in non-epileptic animals from these two species.

Chronic (7 days) infusion of GABA (100 ug/ul at 10 ul/hr) into the occipital cortex of photosensitive monkeys blocked the epileptic syndrome for the whole duration of GABA infusion. This effect was not observed when the aminoacid was delivered to the pre-frontal areas. In fully kindled rats (stage 5), bilateral GABA application (100 ug/ul/hr for 7 days) into the motor cortex produced a significant decrease in the motor component of the seizures without modifying the limbic after-discharge. In both epileptic and non-epileptic rats and monkeys, the interruption of GABA treatment was followed by focal epileptic activity localized to the infused areas. In all animals, EEG activity return to normal patterns after 1-2 days in rats and 2-4 days in monkeys.

The GWS is proposed as a useful model to study the participation of GABAergic mechanisms both in genetic and acquired epileptogenesis and its possible role in the convulsive syndromes observed after chronic, anticonvulsant medication in humans.

261.18 GABAERGIC MEDIATION OF PENTYLENETETRAZOL SEIZURES IN THE ANTERIOR THALAMUS. K.D. Holland*, J.W. Miller, C.M. Hall*, and J.A. Ferrendelli, Div. of Clin. Neuropharm., Depts. of Pharmacology and Neurology, Washington Univ. Medical School, St. Louis, MO 63110.

Recent studies have indicated that the anterior thalamus may play a role in the propagation of experimental generalized seizures induced by the convulsant drug pentylenetetrazol (PTZ). In this study we have examined how manipulations of GABAergic neurotransmission in the anterior thalamus affect gross behavior and PTZ seizure threshold in the rat.

In control animals, timed, continuous, intravenous infusions of PTZ via a jugular catheter led to generalized myoclonic jerks at a dose of 25.2 $\pm$ 2.2 mg/kg, clonic seizures at 30.7 $\pm$ 2.8 mg/kg, followed by a tonic seizure at 86.8 $\pm$ 4.1 mg/kg with forelimb, but not hindlimb, extension. Muscimol (30 nmol in 0.25 µl), primarily a $GABA_A$ agonist, was injected in the midline anterior thalamus through guide cannulas. This resulted in a reduction in the myoclonic (-54%) and clonic (-52%) seizure thresholds but increased the tonic seizure threshold (+19%) compared to control animals. Preliminary results revealed that piperidine 4-sulfonic acid, a specific $GABA_A$ agonist, produced effects identical to muscimol. In contrast, (+)-baclofen (150 nmol), a $GABA_B$ agonist, injected in the same fashion, increased the threshold for all PTZ seizure components (myoclonic +60%, clonic +94%, and tonic +28%) relative to controls. In the above experiments PTZ was infused 10-20 min after intracerebral injections of saline or drug. Animals were also treated with bilateral medial anterior thalamic microinjections of gamma-vinyl-GABA (GVG) (30 µg in 0.5 µl), which increases endogenous GABA levels by inhibiting GABA-transaminase. These animals tested with PTZ infusions 24 hrs later also had increased thresholds to all seizure components (myoclonic +129%, clonic +130%, and tonic +56%). Muscimol (30 nmol) and piperidine 4-sulfonic acid caused impaired postural reflexes, decreased spontaneous activity, and in some rats impaired respiration. In contrast, baclofen produced hypokinesia without altering postural reflexes or respiration. GVG produced very little or no effect on behavior.

Bicuculline methiodide, a $GABA_A$ antagonist, produced marked hyperactivity at low doses (300 pmol), and spontaneous clonic seizures at higher doses (> 1 nmol), but 300 pmol had no significant effects on PTZ seizure thresholds.

The results of this study lead to the conclusion that GABAergic neurotransmitter systems in thalamus influence both spontaneous behavior and convulsant actions of PTZ. In addition, the data indicate that $GABA_A$ and $GABA_B$ receptors have different roles in these processes.

261.19 INTRA-AMYGDALOID TETANUS TOXIN IN CATS: A MODEL OF LIMBIC EPILEPSY. D.S. Garant*, M.C. Mangione*, L.O. Simpson*, G.T. Golden, and R.G. Fariello (SPON: S.J. Potolicchio). VA Medical Center, Coatesville, PA 19320 and Jefferson Medical College, Philadelphia, PA 19107.

Five cats were each stereotaxically implanted with a guide cannula into one basolateral amygdala, and with epidural and depth electrodes for long-term EEG evaluation. After 1-2 weeks HPLC-purified tetanus toxin C was infused via the cannula, and EEG and behavioral observations were made daily thereafter. Infusion effects were variable. One cat given 100 pg toxin had seizures increasing in frequency and severity for 1 week, then decreasing until the cat was seizure-free by 2 weeks after infusion. Two cats given 200 pg had no seizures for 2 weeks, but within 48 hours after a second 200 pg infusion were both in limbic status epilepticus. Two cats given 200 pg were in status within 5 days. The EEG profile of each cat was, however, stereotypic. After infusion, all cats had independent multifocal spiking bilaterally in limbic nuclei: these isolated spikes were subsequently followed by recruiting afterdischarges of variable duration localized to the infused amygdala, ipsilateral hippocampus, and/or septum in 2 cats, and to leads in the vicinity of the claustrum in 3 cats. These afterdischarges propagated over time to become generalized limbic seizures in all cats, and became tonic-clonic seizures in all but the 100 pg cat. In 2 cats the initial EEG abnormality noted was bursts of fast beta activity in the infused amygdala.

These findings are similar to those obtained after limbic application of cobalt chloride (Fariello et al., Neurosci. Abstr. 11:384.17, 1985), and indicate that this technique is a potential model of limbic epilepsy. The mechanism of action of tetanus toxin remains unclear, but we plan to more fully document the electrographic and neurochemical changes in limbic function after infusion of the toxin into this and other species. The finding of seizures originating in the claustrum and this structure's early involvement in the development of the epileptic response was unexpected and deserves further study; this may be the first evidence implicating claustrum in seizure processes.

262.1 INTRANIGRAL GAMMA-VINYL-GABA SUPPRESSION OF ELECTROSHOCK SEIZURES: ROLE OF NORADRENERGIC NEUROTRANSMISSION. J.O. McNamara and D.W. Bonhaus. V.A. Med. CTR. and Depts of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC 27705.

The substantia nigra (SN) powerfully regulates seizure activity. In most seizure models the net effect of nigral output is to facilitate seizure propagation. Microinjection of the GABA mimetics muscimol and gamma-vinyl-GABA (GVG) into SN suppress tonic hindlimb extension (THE) in the electroshock (ES) seizure model. We have shown that the anticonvulsant action of intranigral muscimol, against ES seizures, is blocked by antagonism of alpha-2 adrenergic receptors; these receptors are almost certainly post-synaptic. Together with the finding that endogenous norepinephrine (NE) suppresses ES seizures, We postulated that intranigral injection of GABA mimetics produce an anticonvulsant action by increasing NE turnover.

The objectives of this work were twofold: 1) to determine whether the anticonvulsant action of GVG can be blocked by the alpha-2 receptor antagonist idazoxan (IDX); and 2) to test the hypothesis that intranigral GVG exerts its anticonvulsant action by increasing NE turnover.

Intranigral GVG produced a 37 % decrease in THE. IDX (1 mg/kg) abolished this anticonvulsant action.

	before GVG	with GVG	
vehicle	8.1 ± 0.5	5.1 ± 1.1	p<0.05
IDX	9.1 ± 1.8	10.9 ± 1.3	ns

Values are the mean ± S.E.M. of THE in seconds.

Contrary to our hypothesis, intranigral GVG did not increase NE turnover in any of the six brain or spinal cord regions tested. Using DOPA accumulation in the presence of a DOPA decarboxylase inhibiter as an index of catecholamine turnover, we found that intranigral GVG actually decreased catecholamine turnover by 28 % in the hippocampus ($p<0.05$). Intranigral GVG did not modify NE or dopamine content in any area tested.

These results suggest that, while activation of alpha-2 receptors is essential for the anticonvulsant effect of intranigral GVG on ES seizures, the mechanism of this effect does not involve increased NE turnover. Whether intranigral GVG enhances NE neurotransmission by a mechanism other than increasing NE turnover has not been tested. An alternative hypothesis is that while the basal level of interaction of NE with alpha-2 receptors is required for detection of nigral regulation of ES evoked THE, the SN and the NE systems regulate seizure activity by independent mechanisms.

262.2 ACTIVITY OF SUBSTANTIA NIGRA PARS RETICULATA (SNPR) NEURONS DURING KINDLED SEIZURES IN FREELY MOVING RATS. R.D. Russell, D.W. Bonhaus, and J.O. McNamara. Departments of Medicine (Neurology) and Pharmacology, Duke University and VA Medical Centers, Durham, North Carolina 27710.

Kindling is an animal model of epilepsy in which periodic application of an initially subconvulsive electrical stimulus results in progressively more intense seizures. The SNPR is a crucial structure in the propagation of kindled seizures activated by limbic stimulation (McNamara et al., J. Neurosci., 1984). Prior study with paralyzed-ventilated rats found that SNPR cells in kindled, but not naive (i.e., non-kindled), rats fired in bursts of action potentials which were time-locked to spike-wave complexes of afterdischarge (AD) recorded from amygdala EEG (Bonhaus et al., J. Neurosci., 1986). The objectives of the present experiment were: 1) to extend SNPR unit analysis to kindled seizures of freely moving rats; and 2) to correlate SNPR activity to behaviors which accompany the AD.

A bipolar electrode was placed in the amygdala of Sprague-Dawley rats. Single units were recorded during AD in non-kindled rats or during an AD elicited after at least three class 5 kindled seizures had been evoked. Single unit recordings were obtained in or nearby the SNPR with either a single microelectrode mounted on a microdrive or with a five-wire bundle of microwires (i.e., 25 micron diameter, teflon insulated platinum-iridium) directed at the SNPR under stereotaxic guidance.

In the non-kindled animals (n=6), neither the rate nor pattern of SNPR cell firing changed during the AD. In contrast, in kindled rats single units were recorded before and after AD but during the AD there were phasic increases in multiple unit activity which occurred time-locked to spike-wave complexes of the AD. This "population burst firing" occurred for both SNPR (4 of 5 rats) and non-SNPR recordings (10 of 12 rats) of kindled rats. The onset of clonic motor components of the seizure and the onset of burst firing varied considerably; however, once both burst firing and clonic motor activity were established, they were time-locked and terminated together.

These data extend the results of Bonhaus et al. (1986) to a more physiological preparation. The activity of cells in the SNPR, as well as nearby cells in the reticular formation, are time-locked to spike-wave complexes of the kindled seizure. Taken together, these data indicate that burst firing of SNPR is neither necessary nor sufficient for the clonic motor seizure in amygdala kindled rats.

262.3 EVIDENCE FOR ENHANCED N-METHYL-D-ASPARTATE RECEPTOR MEDIATED INHIBITION OF CARBACHOL-STIMULATED PHOSPHOINOSITIDE HYDROLYSIS FROM KINDLED RATS. R.A. Morrisett*, J.V. Nadler & J.O. McNamara (Spon: H. S. Swartzwelder); Duke Univ./V.A. Med. Ctr., Durham, N.C., 27705

Increasing evidence implicates NMDA (N-methyl-D-aspartate) receptor mediated processes in the development of plastic changes in neuronal activity. One example is kindling, in which repeated administration of initially subconvulsive trains of electrical stimuli eventually results in the development of intense behavioral and electrographic seizures. NMDA receptor antagonists suppress kindling development. Electrophysiologic studies of hippocampal slices from kindled animals have demonstrated two findings consistent with increased NMDA receptor mediated events: 1) iontophoresis of excitatory amino acid receptor agonists into CA1 produces greater reduction of $[Ca^{++}]_o$ in kindled slices (Wadman et al., Exp. Br. Res., 57:404(1985)); 2) synaptic activation of granule cells by perforant path stimulation is inhibited by an NMDA receptor antagonist in slices from kindled but not control animals (Mody and Heinemann, Nature 326:701 (1987)). To understand the molecular basis of these electrophysiologic findings, we have initiated studies of NMDA receptors and NMDA receptor coupled second messenger systems in kindled animals.

NMDA receptor activation potently inhibits agonist-stimulated PI hydrolysis in hippocampal slices (Baudry et al., Nature, 319:329 (1986)). We hypothesized that NMDA would inhibit carbachol-stimulated PI hydrolysis to a greater extent in slices prepared from kindled compared to control animals. Sprague-Dawley rats were implanted with a stimulating electrode in the right amygdala under Nembutal anesthesia. Five animals were stimulated twice daily until each had 4-6 stage 5 kindled seizures. Kindled animals were sacrificed 24 hours after the last seizure for determination of NMDA inhibition of carbachol-stimulated PI hydrolysis. Each experimental animal was paired with a sham-operated control. PI hydrolysis was measured by determining the synthesis of radiolabelled IP_1 using anion exchange chromatography in transverse hippocampal slices (400 µm) prelabelled with ^{3}H-inositol. NMDA (10 µM) alone did not alter basal PI hydrolysis in control or kindled animals. Carbachol-stimulation of PI hydrolysis was slightly but not significantly greater in slices prepared from kindled animals. NMDA (10 µM) inhibited carbachol-stimulation of PI hydrolysis to a greater extent in slices prepared from kindled animals (17 ± 4 % NMDA inhibition in control versus 54 ± 15% NMDA inhibition in kindled slices, $p<0.03$).

These findings provide direct biochemical evidence for enhanced NMDA receptor function in hippocampal slices of kindled animals. The molecular consequences reflected in this alteration of PI hydrolysis may underlie the enhanced NMDA receptor function measured electrophysiologically.
(Support: NIH NS 17771 & NS 16064).

262.4 BRAIN SITE OF ACTION OF CLINICALLY EFFECTIVE ANTICONVULSANTS

L.S.Chen* and J.O. McNamara (SPON: C. Shin). Department of Medicine (Neurology), Duke Univ. Med. Ctr. and VA Med. Ctr., Durham, NC 27710

The brain site(s) at which clinically useful anticonvulsants exert their therapeutic action is unknown. The substantia nigra (SN) is one site which promotes seizure propagation in animal models. Iadarola and Gale have observed that the SN is a site of anticonvulsant action of some drugs which presumably act by enhancing GABA transmission. We hypothesized that the SN is one site at which clinically used anticonvulsants exert their therapeutic actions. To test this idea, we examined the effects of microinjection of phenobarbital(PB), carbamazepine (CBZ) and phenytoin (PT) into the SN bilaterally on electroshock seizures in rats. The anticonvulsant efficacy was assessed by measuring the duration of tonic hindlimb extension (THE) before and after treatment. Intranigral application of PB suppressed THE in a dose-dependent manner. Significant ($p<0.05$, student t test) reduction of THE was observed after injection of 30 (35% reduction) or 150 (40% reduction) nmol but not after 3 (3% reduction) nmol. The magnitude of the effect with 150 nmol PB was equivalent to that obtained with 440 pmol of a GABA agonist, muscimol (47% reduction). Intranigral injection of vehicle alone did not suppress THE. The anticonvulsant effect of PB was spatially specific since THE was not suppressed after injection of 30 nmol of PB 2 mm dorsal to the SN. In contrast, neither CBZ (10 or 60 nmol) nor PT (3 or 30 nmol) modified THE. Measurement of PB and CBZ content in the SN showed that differences in concentrations in the SN did not account for the lack of efficacy of CBZ. The present findings with PB extend previous evidence that intranigral application of anticonvulsants which enhance GABA transmission suppresses seizures. This suggests that at least part of the anticonvulsant action of drugs which enhance GABA mediated transmission is exerted at the SN. By contrast, CBZ and PT, drugs postulated to block seizures by suppressing sustained repetitive firing, appear not to exert significant anticonvulsant action at the SN.

262.5 DECREASED PHOSPHORYLATION OF SYNAPTIC MEMBRANE PROTEINS ASSOCIATED WITH OLFACTORY BULB KINDLING. S. E. Tan* and R. F. Berman. Dept. of Psychology and the Neuroscience Program, Wayne State University, Detroit, Michigan 48202.

Kindling refers to the observation that low intensity, initially subseizure levels of electrical stimulation delivered to one of several brain regions gradually results in the development of a seizure focus. Kindling has been considered to be a model of both epilepsy and neuronal plasticity. The neuronal mechanisms underlying the development of kindling are currently unknown. However, the phosphorylation of specific synaptic membrane proteins has been linked with other models of synaptic plasticity (e.g., long-term potentiation), and recent studies have reported altered phosphoprotein metabolism following the development of hippocampal and amygdala kindled seizures. The present experiment examined synaptic membrane phosphoproteins isolated from olfactory bulb, frontal cortex, and hippocampus two weeks following the completion of olfactory bulb kindling in rats. Briefly, eighteen adult, male Long-Evans rats were stereotaxically implanted, unilaterally with a stimulating electrode into either the right or left olfactory bulb. After recovery from surgery the animals were divided into two groups; kindled and control (n=9 each). Animals in the kindled group were electrically stimulated once daily through the implanted electrode with a level of current initially sufficient to produce a brief (3-5 sec) afterdischarge (AD threshold). Animals were stimulated daily at the AD threshold until they reached a criterion of 3 consecutive Stage 5 kindled seizures. Control animals were not stimulated. Two weeks later all animals were decapitated, the brains rapidly removed and dissected into frontal cortex, olfactory bulbs, and hippocampus. Synaptic membranes were isolated from these brain regions, homogenized, and incubated with 10 μM (^{32}P)ATP for 2.0 min at 30 deg. C. The radiolabeled samples were then further fractionated on a 10% SDS-polyacrylamide gel. The gel was stained with Coomassie Blue, dried and placed in contact with X-ray film for autoradiography. The level of ^{32}P incorporation into synaptic membrane proteins was subsequently determined by spectrophotometric scanning of the autoradiogram. The phosphorylation of a specific phosphoprotein band at a molecular weight of approximately 45,000 was found to be significantly decreased ($p<.01$) in the frontal cortex of olfactory bulb kindled rats compared to controls. Phosphorylation of this protein band accounted for approximately 16.6% of total membrane phosphorylation in the frontal cortex of control animals, and decreased to 9.5% in kindled rats. These data support the involvement of protein phosphorylation in the development of kindled seizures. (Supported by NIH grant RR08167).

262.6 ELECTRICALLY-INDUCED STATUS EPILEPTICUS IN RATS:EFFECTS OF PARTIAL AND COMPLETE AMYGDALA KINDLING. D.D. Walczak* (SPON:C.W.Gorodetzky).Dept.Clinical Neurosciences, Burroughs Wellcome Company, Research Triangle Park,NC 27709

The characteristics of status epilepticus induced by amygdala stimulation were determined in rats that were either unkindled, partially kindled, and fully kindled. All subjects were male Hooded rats implanted with bipolar depth electrodes in the left basolateral amygdala and with bilateral extradural screw electrodes over the frontal cortex. Rats were rested one month from the last kindling stimulus before status induction. Status was induced during consecutive "induction periods" consisting of 8.0 minutes of repeated stimulus trains: 2.0 second trains of 1.0 msec biphasic pulses, 90 Hz, 700-800 μA peak-peak, 2.0 seconds on, one second off. Spontaneous EEG was recorded for 2-5 minutes after each period.

Rats were subjected to a maximum of six induction periods to produce characteristic repetitive electrographic spiking that was cyclic in frequency (electrographic status). Rats exhibiting this pattern were then observed for expression of nonconvulsive status, partial convulsive status (repeated Stage 1-2), generalized convulsive status (repeated stage 3-5), and for 24-hour survival.

Partial kindling had both a facilitatory effect on status induction and a protective effect against status-related mortality. Fully kindled rats were induced more easily than partially kindled but had a higher mortality rate at equivalent levels of status induction. Nonkindled rats were difficult to induce, but those few that exhibited convulsive status had equivalent mortality to fully kindled rats. This differential responsiveness to status induction may reflect differential involvement of limbic and extralimbic structures in partial vs complete kindling.

262.7 MORPHOLOGICAL CHANGES IN THE HIPPOCAMPAL DENTATE GYRUS ACCOMPANY KINDLING OF THE ENTORHINAL CORTEX. A.J. Cronin,* T.P. Sutula and N.L Desmond (SPON: John A. Jane). Dept. Neurosurgery, Univ. Virginia Sch. Med., Charlottesville, VA 22908 and Dept. Neurology, Univ. Wisconsin, Madison, WI 53792.

Long-term potentiation (LTP) of the synapses between entorhinal cortical (EC) axons and granule cell spines in the dentate gyrus (DG) correlates with various morphological changes suggestive of enhanced pre- and postsynaptic efficacy[1]. Kindling of the EC-DG pathway also induces potentiation of the EC-DG synapses, but synaptic potentiation induced during epileptogenesis may not be equivalent to LTP. The present study seeks to identify morphological changes of the EC-DG synapses after kindling stimulation. Previous studies have not demonstrated morphological changes after kindling stimulation of a monosynaptic pathway. Chronic stimulating and recording electrodes were implanted unilaterally in the angular bundle and DG hilus, respectively, of adult rats[2]. Here we report on a kindled group (N=5) and a sham group (N=4) of animals. Each animal in the kindled group was perfused with mixed aldehydes[1] 5 days after the 3rd class 5 seizure. Sham animals were perfused with mixed aldehydes at a survival interval matched with the kindled survival interval. Blocks from the DG were processed for electron microscopy, and montages were photographed as described previously[1]. We compared the incidence of dendritic spines connected to their parent dendrite (connected spines) for the kindling group and the sham group. Across the entire proximodistal extent of the molecular layer, kindling correlates with a 36% increase in the incidence of connected spines (sham mean 7.9±0.7%). This increase in the incidence of connected spines occurs in spite of the fact that the number of spine synapses per unit area of tissue does not increase with kindling. The increased incidence of connected spines with kindling reflects a particular subpopulation of the dendritic spines, those with concave spine heads. Note that Desmond and Levy previously[1] hypothesized that the concave spines represent the population of potentiated spines following LTP-inducing conditioning stimulation. In addition, with kindling stimulation, the heads of the concave connected spines enlarge (area increases 19%), and their spine stems increase in diameter by 27%. The spine head enlargement and stem diameter increase are consistent with previously reported correlates of LTP in the EC-DG system. These data provide evidence for morphological changes in the excitatory synapses of the monosynaptic pathway which received kindling stimulation and are consistent with the enhanced synaptic efficacy associated with kindling. 262.8 AN EXPERIMENTAL TEST OF THE GABA HYPOTHESIS OF KINDLING: GENERALIZED SEIZURES IN CORTICAL- AND AMYGDALA-PREKINDLED RATS FOLLOWING ACUTE ADMINISTRATION OF GABA-COMPLEX AND ADENOSINE ANTAGONISTS. N.S. Mingo* and W.M. Burnham. Dept. of Pharmacology, Univ. of Toronto, Canada, M5S 1A8.

The GABA hypothesis of kindling - as recently outlined by Burnham et al. - suggests that the development of secondary generalization in the kindling model is associated with a loss of GABA-mediated inhibition. If this is true, it follows that blockade of GABAergic function should produce secondary generalization even in subjects that have not been kindled.

The present study was designed to test this prediction of the hypothesis. Drugs were applied at appropriate intervals before the triggering of a focal seizure in a non-kindled animal, and electrographic and behavioural measures of secondary generalization were taken. Three different GABA complex antagonists were tested in a dose response paradigm: bicuculline, a specific antagonist for the GABA recognition site, picrotoxin, a drug that antagonizes GABA by binding to the associated chloride ionophore, and norharmane, a putative inverse agonist for the benzodiazepine receptor. In each case, the drugs were tested on both cortical and amygdala- implanted subjects, in order to assess possible differences related to the site of stimulation. For comparison, the adenosine agonist, aminophylline - already known to facilitate generalization in partially kindled subjects - was tested in the same paradigm. In line with the hypothesis, it was predicted that all GABA-complex antagonists would promote secondary generalization in prekindled rats.

Contrary to expectations, it was found that bicuculline and norharmane were ineffective at either site even at "near convulsant" doses. Picrotoxin was effective in facilitating generalization only in subjects implanted in the cortex. On the other hand, aminophylline was effective in promoting generalization in both the amygdala and cortically implanted prekindled subjects, although it was much more effective in animals with amygdala implants.

The failure of bicuculline and norharmane to produce "early trial" generalization raises serious questions about the GABA hypothesis of kindling. The contrasting actions of the different GABA complex antagonists raises corresponding questions concerning the current model of the GABA macromolecular complex. 262.9 THE TEMPORAL RELATIONSHIP OF AMYGDALOID AND HIPPOCAMPAL AFTER-DISCHARGE ACTIVITY DURING AMYGDALOID KINDLING. L. J. Burdette. Department of Neurology, Graduate Hospital, Philadelphia, PA 19146

Kindling is a process that involves repeated electrical stimulation of temporal lobe structures until a generalized motor seizure is elicited. For the kindling process to occur, current intensity must trigger an electroencephalographic spike train, called the primary afterdischarge (PAD). During amygdaloid kindling, PAD duration increases and a secondary afterdischarge (SAD) frequently occurs during middle or late kindling stages. The present objective was to assess the temporal relationship of the PAD and SAD recorded from the amygdala and hippocampus during amygdaloid kindling.

Male Long Evans rats (N=23) were implanted with chronic bipolar electrodes in basolateral amygdala and dorsal hippocampus. Following recovery, amygdala leads were stimulated daily with current (2 s train, .3 ms bipolar 50 Hz pulses) that was 400% of amygdaloid PAD threshold. Behavioral seizure development was scored according to Racine (1972). The kindled state was defined by the presence of three consecutive stage 5 seizures. PAD and SAD duration were measured as the time that spike amplitude was greater than half that of the prestimulation EEG. The duration of the intervening depression in spike activity was bounded in time by the termination and initiation of the PAD and SAD, respectively. Afterdischarge variables were averaged for each seizure stage prior to analysis.

The total duration of the PAD, spike depression and SAD was significantly shorter in the hippocampus than in the amygdala only during the first kindling stage. This effect is explained by the failure to observe a PAD in 25% of the hippocampal records early in the kindling process. When the analysis was restricted to only those trials in which an amygdaloid SAD was present, the pattern of afterdischarge activity varied by recording site and kindling stage. The incidence of amygdaloid SAD peaked during the middle kindling stages and remained constant until the kindled state was reached. In contrast, the hippocampal SAD rarely accompanied the amygdaloid SAD until late in the kindling process, and then was of shorter duration. The duration of the intervening spike depression decreased and increased in the amygdala and hippocampus, respectively, with each kindling stage. PAD duration did not differ between recording sites at any time. Together, these data suggest that the appearance of the amygdaloid SAD is not due to propagation of hippocampal afterdischarge activity.

262.10 **EFFECT OF CORTICAL KINDLING ON THE FUNCTIONAL ANATOMY OF CORTICAL CIRCUITS.** E.M. Santori and R.C. Collins Neurology and Neurological Surgery Dept., Washington U.,St. Louis, MO 63110

Electrical stimulation of the anterior neocortex in rat can trigger a focal clonic motor seizure. Repeated induction of such seizures results in a permanent increase in the strength and duration of the evoked seizure response. The present study was undertaken to determine whether the kindling of forelimb cortex alters its functional anatomy.

Rats were kindled within the forelimb sensorimotor cortex with 2 second trains of 1 msec pulses delivered at 50 HZ, at currents above the afterdischarge (AD) threshold applied once every other day. Animals were sacrificed after a mean of 32 stimulations. Mean AD duration increased from 5 seconds to 27 seconds and seizure responses changed from clonic forelimb movements and upper body bobbing to include rearing, tonic muscle contractions, and loss of balance.

In control and kindled subjects the pattern of functional metabolic changes induced by stimulation of the forelimb zone was studied. [14C]-Deoxyglucose (DG) was given during repetitive train stimulation: 0.1 sec. trains applied once/ two sec. consisting of 500 HZ bipolar pulses (0.1 msec and 1mAmp). Controls responded to these trains with discrete left arm jerks. During the later half of the 45 minute DG trace, stimuli would occasionally induce brief post-stimuli forelimb tremor or rarely a generalize seizure would occur. By contrast, kindled subjects responded to this stimulation with an almost immediate generalized seizure. This was followed by a period of simple or complex forelimb jerks eventually leading to another seizure. Several such cycles occurred during the course of the trace.

There were no consistent differences between control and kindled animals in either the size or magnitude of DG labeling within the focus. In three of the five kindled subjects, [14C] concentrations within the mirror focus and bilateral substantia nigra were more than two standard deviations greater that mean concentrations of controls (n=6). In addition, temporally averaged rates of glucose utilization within the nucleus of the lateral olfactory tract, ventral pallidum, entopeduncular nucleus, posterior thalamus were more than two standard deviations greater than the mean rates for control subjects. Finally, in two kindled subjects glucose utilization within the amygdala and hippocampus was markedly enhanced.

These studies indicate that cortical kindling results in new circuits participating in the functional response to cortical stimulation. Whether these pathways play any role in the mediation of kindling remains to be explored.

262.11 **POST-KINDLING REFRACTORINESS TO THE DEVELOPMENT OF STATUS EPILEPTICUS IN JUVENILE AND ADULT RATS.** H.B. Michelson and G.G. Buterbaugh. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, Maryland 21201.

Amygdala-kindled rats pretreated with pilocarpine nitrate (20 mg/kg i.p.) will, following stimulation, show prolonged seizures lasting at least four hours. We investigated the role of kindling in the development of status epilepticus (SE) in this model.

Adult rats were kindled with daily stimulations through two consecutive Stage 5 seizures and tested 24 hours, and at weekly intervals thereafter for the development of SE following pretreatment with 20 mg/kg pilocarpine. Rats were refractory to the development of pilocarpine-facilitated SE (pfSE) during the first week after kindling. Two weeks after kindling, 50% of rats tested developed pfSE; three weeks after kindling 80% of rats tested developed SE when electrically stimulated after pilocarpine administration. Stimulation of rats pretreated with higher doses of pilocarpine will elicit SE at shorter intervals after kindling in adult rats; 100 mg/kg pilocarpine will induce SE within 24-48 hours after kindling; 50 mg/kg will elicit SE within 1-2 weeks following kindling.

Twenty-eight day old rats were kindled with hourly stimulations and similarly tested for the emergence of SE. Juvenile rats are refractory to the development of SE during the first 5-6 weeks after kindling (until approx. 65 days of age). Nearly all juvenile-kindled rats developed SE when tested 6-7 weeks after kindling. Hourly-kindled adult rats will develop pfSE within 3-4 weeks after kindling, indicating that this difference in post-kindling refractoriness to pfSE is not a result of the use of a different kindling protocol. Juvenile rats will also develop SE after administration of high doses of pilocarpine (400 mg/kg) or lithium/pilocarpine coadministration, indicating that this maturational difference in the development of pfSE is not due to an inability of young rats to support prolonged seizure activity.

These findings suggest a state of relative enhanced post-kindling inhibition which steadily decays over time. This enhanced inhibition may be comparatively greater or may take longer to dissipate in juvenile-kindled rats. (Supported by USPHS MH09301.)

262.12 **PATHOLOGY AND 2-DEOXY-D-GLUCOSE UPTAKE ASSOCIATED WITH EARLY AND LATE STATUS EPILEPTICUS IN KINDLED RATS.** G.G. Buterbaugh, H.B. Michelson, D.O. Keyser and B.R. Jones*. Depart. of Pharmacol. and Toxicol., Univ. of Maryland School of Pharmacy, Baltimore, MD 21201.

Pilocarpine-facilitated status epilepticus (pfSE) is a model of status in which the seizures evoked by amygdala stimulation of amygdala kindled rats pretreated with pilocarpine (20 mg/kg, i.p.) continue for at least 4-5 hours. Stable, bilateral, 10-12/sec, spiking EEG discharge is characteristic of the first 2-3 hours of pfSE, while increasingly more severe convulsive behavior typically begins after 2-3 hours. This study correlated 2-deoxy-D-glucose (2-DG) uptake and neuropathology with this time-course of pfSE.

Rats received 2-DG (100 uCi/kg; i.v.), were killed 45 min later and brains removed and frozen sectioned for contact autoradiography. Rats injected after 10 min of seizures (minimal partial motor convulsions) showed extensive, bilaterally symetric 2-DG uptake throughout the brain, in particular the amygdala, hippocampus, lateral septum, most thalamic nuclei, substantia nigra, medial geniculate and all cortical regions. Rats injected after the appearance of more severe convulsions (2-2.5 hours) showed comparatively less bilateral 2-DG uptake in the hippocampus, medial geniculate and cortical regions. Uptake was notably absent in the thalamus and lateral septum and limited to the medial portion of the substantia nigra.

Seizures were pharmacologically terminated in separate rats which were killed 3-4 days later for histology. One hour of seizures was associated with cell loss in the ipsilateral hippocampus (CA1) and bilateral amygdala-pyriform regions and with bilateral necrosis of the substantia nigra. In some rats, damage was limited to the amygdala-pyriform region. Two or more hours of seizures, accompanied by increasingly severe convulsive behavior, were associated with bilateral damage in CA1/CA3 (ipsilateral CA4) hippocampal and amygdala-pyriform regions and in the paraventricular thalamic nuclei and substantia nigra.

The results indicate that the emergence of more severe motor convulsions during prolonged pfSE is associated with (1) diminished 2-DG uptake and (2) more extensive cell damage. (Supported by USPHS MH09301 and NS20670.)

262.13 ALPHA-2 ADRENERGIC RECEPTORS IN THE AMYGDALA ARE TRANSIENTLY ELEVATED DURING THE EARLY STAGES OF KINDLING. M.J. Chen, A. Vigil*, C. Laubert*, D.D. Savage and G.K. Weiss*. Departments of Pharmacology and Physiology, University of New Mexico School of Medicine, Albuquerque, New Mexico, 87131.

Our laboratory has recently demonstrated that the auto-inhibitory alpha-2 adrenergic receptors on the locus coeruleus (LC) neurons increase in number in the early stages of kindling. This enhanced inhibitory effect on the noradrenergic system may be important in allowing the progressive intensification and spread of amygdala kindling seizures. The purpose of this study was to determine if autoinhibitory alpha-2 adrenergic receptors are altered in other portions of the brain during the development of kindling.

Bipolar electrodes were stereotactically implanted in the right basolateral nucleus of the amygdala. Kindling stimulations (80-300 microampere biphasic square wave pulses, for 1 msec at 60 Hz for a total train duration of 1 sec) were administered three times per day at intervals of 90 minutes. Rats were kindled to either two Class 1 or one Class 5 kindled motor seizures. Ninety minutes after the last kindling stimulation, the rats were sacrificed and the brains frozen. Eight micron coronal sections were thaw mounted onto microscope slides and processed for in vitro autoradiography. Sections were incubated with 20 nM 3H-RX781094 in the absence or presence of 1 uM phentolamine. The sections were apposed to Ultrofilm and the film exposed for 15 days. Optical density measurements of 3H-RX781094 binding were made in the lateral septum, stria terminalis, substantia inominata, central nucleus of the amygdala, dorsal hippocampal s. moleculare and para-ventricular grey using computer-assisted microdensitometry.

Specific 3H-RX781094 binding was elevated significantly in the amygdala of Class 1 kindled rats compared to control. With the exception of the stria terminalis, binding was elevated, but not significantly, in the other brain regions analyzed. By contrast, there was a slight, but insignificant, decrease in binding in the brains of rats kindled to Class 5 motor seizures. Saturation of binding studies indicated that the elevation of 3H-RX781094 binding in the amygdala after two Class 1 kindled seizures was due to an increase in the number of binding sites with no change in affinity constant. This result is similar to the elevation in 3H-RX781094 binding in the LC reported previously. We speculate that a transient increase in the number of amygdaloid inhibitory alpha-2 receptors during the early stages of kindling would promote a progressive reduction in noradrenergic inhibition of kindled seizure spread. (Supported by the Minority Biomedical Research Support Program and NIH-NS23262.)

262.14 KINDLING OF SEIZURES WITH PROCAINE. G.A. Cottrell, B.K. Doane* and H.A. Robertson. Departments of Pharmacology and Psychiatry Dalhousie University, Halifax, N.S., CANADA B3H 4H7.

Several lines of evidence suggest that systemically administered procaine HCL has a selective limbic activating effect, i.e., it preferentially activates subcortical epileptic foci in animals and man. However, it is not known whether procaine can induce an epileptic focus. The following set of experiments addresses this issue by demonstrating that seizures can be pharmacologically kindled with procaine and by characterizing the kindling.

Male Sprague-Dawley rats were injected once daily with 150 mg/kg, i.p. procaine HCL (Sigma). Initially this dose produced no overt seizure activity. After an average of 13.4 injections, the rats exhibited mild front-paw clonus with hind-paw tonus. When only one of these seizures was induced and the rats were tested 2 weeks later, poor retention was observed. Only 3 of 8 rats responded to the procaine injection with a seizure. Further injections will induce a more severe seizure response characterized by front-paw clonus alternating with myoclonus almost continually for 30 min. These seizures are quite different from electrically kindled seizures. They also appear to differ from lidocaine-kindled seizures as neither omniphagia/coprophagia nor aggression was observed. Procaine kindling to this more severe stage took an average of 19.7 injections. Following 2-3 consecutive seizures, good retention was observed. On a 2 week retest, 7/7 rats exhibited seizures. Further, seizures have now been observed after 88 drug-free days. This dose of procaine does not induce seizures in age-matched controls. A group of rats with a single recording electrode in the amygdaloid complex, were kindled with procaine. During the kindling process, the amygdala EEG showed no seizure activity. The first after-discharge was observed at the time of the first behavioral seizure.

To summarize: Repeated daily administration of procaine HCL (150 mg/kg, i.p.) results in convulsive seizure activity of increasing severity. Thus, we have shown that procaine is a pharmacological kindling agent. Further, the phenomenon appears to be 'true' kindling as it is not observed on the first injection, the response gradually becomes more severe but once developed it can be reliably elicited and it is permanent or at least long-lasting. However, it does not appear to be caused by development of an epileptic focus in the amygdala.

This work was supported by the Canadian MRC and Department of Psychiatry, Dalhousie University.

262.15 FORMATION OF ABERRANT MOSSY FIBER PROJECTION BY LIMBIC KINDLING: EVIDENCE FOR SPROUTING INDUCED DURING DEVELOPMENT OF EPILEPTIC SEIZURES T. Sutula, He X.*, C. Hurtenbach*, Depts. of Neurology and Anatomy, and Neurosciences Training Program, University of Wisconsin, Madison, WI 53792

Kindling has been proposed as a mechanism for development of epileptogenesis after focal brain lesions. Lesions of CA3 are common in epilepsy (Ammon's horn sclerosis), and result in denervation of the dentate gyrus (DG), followed by sprouting of mossy fiber axons that form synaptic connections in the inner molecular layer (Laurberg, J. Comp. Neur. 200:433, 1981; Tauck, Nadler, J. Neurosci. 5(4):1016, 1985). The sprouted mossy fibers can be identified by supragranular staining in the DG with the Timm method.

To identify any relationships between CA3 lesions, sprouting, and rate of kindling, lesions of CA3 were prepared in rats by intraventricular kainic acid and electrolytic methods. Kindling was induced by daily 60Hz perforant path stimulation in lesioned groups and a matched unlesioned control group. After three Class 5 seizures, animals were perfused and adjacent horizontal sections were stained with the Timm method, and with cresyl violet.

Sprouting and reinnervation in the DG was observed in both lesion groups, as indicated by supragranular Timm staining with neuronal loss and gliosis in CA3-4. Unexpectedly, supragranular Timm staining was also observed in 7 of 8 kindled unlesioned control animals, and in four animals kindled by stimulation of the olfactory bulb. Phase contrast microscopy revealed clusters of Timm positive granules around cell bodies and radially oriented dendritic shafts in the inner molecular layer. There was no evidence of neuronal loss in CA3-4, and the hippocampal pyramidal layer appeared intact except for mild gliosis.

The results are evidence for a previously unrecognized anatomic plasticity associated with epileptic phenomena. The anomalous supragranular Timm staining in kindled animals is most likely an aberrant mossy fiber projection, and suggests that axonal sprouting and alterations in neuronal connectivity occur during development of kindling. These anatomical alterations may contribute to the development of kindling, and could have implications for emergence of neuronal dysfunction in response to repeated seizures. The findings also raise the intriguing possibility that abnormal patterns of activity can exert a potent influence on neural connectivity. (Supported by TIDA K07-NS00808, and the Epilepsy Foundation of America).

262.16 EFFECTS OF LESIONS OF THE CEREBELLAR CORTEX ON KINDLED SEIZURE DEVELOPMENT IN THE RAT. C.D. Applegate, M. Krieger* and J.L. Burchfiel. Departments of Neurology and Neuroscience, The Children's Hospital, Boston, MA 02115.

Previous work has suggested a role for the cerebellum (CB) in the behavioral and EEG expression of seizures. In general, results indicate an involvement of the CB in seizure suppression. Thus, CB stimulation has been shown to be capable of attenuating evoked cortical afterdischarge (AD) activity. Conversely, lesions of the CB have been reported to increase seizure durations following cortical application of epileptogenic agents and to increase AD durations following amygdala kindling. Preliminary data from our laboratory suggest that large radiofrequency lesions of the pontine brainstem which extensively damage the major output pathway of CB, the superior cerebellar penduncle, eliminate the development of seizure suppression typically observed at one focus following concurrent, alternate kindling stimulation of the septal nucleus and entorhinal cortex (kindling antagonism). Our data suggest that the CB may be involved in the development of patterns of site suppression in the kindling antagonism model and support earlier data indicating a role for the CB in the suppression of brain seizure activity. In the present study we have begun to examine the effects of lesions of the CB cortex on the development and subsequent expression of kindled seizures elicited from the septal nucleus.

The lateral CB cortex was removed bilaterally through aspiration in male, rats (N=6) under deep pentobarbital anesthesia. At the time of lesioning, animals were implanted with chronic stimulating-recording electrodes into the left septal nucleus. Control animals (N=7) were implanted unilaterally with electrodes into the septal nucleus as above. Following recovery from surgery, AD thresholds were established and daily kindling stimulations were administered until fully generalized stage 5 seizures were elicited.

Lesions resulted in a >50% loss of CB cortex bilaterally. The vermis and paraflocculi were largely spared. Lesions resulted in significant increases in focal AD durations. Increases in AD durations were present at initial trials (X=29.2 vs 18.1s;$p<.05$) and continued to be significantly longer when fully generalized seizures were elicited (X=80.5 vs 55.1s;$p<.01$). The latency to motor seizure as defined by the onset of bilateral forelimb clonus was also significantly increased (X=42.4 vs 12.0s;$p<.05$) following lesions of the CB cortex. Neither the rate of kindled seizure development nor thresholds for the elicitation of AD were significantly altered by CB lesions, although there was a trend toward lower thresholds in lesioned animals ($p=0.14$). These data suggest a complex role for the cerebellum in motor seizure development and expression.

Supported by NIH grant # NS20351 to JLB.

262.17 STUDIES OF BRAIN SPECTRIN (FODRIN) IN THE HIPPOCAMPUS AND CORTEX OF RATS WITH KINDLED SEIZURES. M Pintor*, KP Wayns-Lee*, NS Nadi. (Spon: PH Sheridan). NINCDS, Bethesda, MD. 20892.

Brain spectrin (fodrin) is a 220,000 - 240,000 MW dimer which lines the cell membrane and is suggested to play an important role in the maintenance of the cytoplasmic structure. Changes in the levels of the spectrin molecule have been associated with a variety of disorders ranging from muscular dystrophy (increased spectrin) to elliptocytosis (decreased spectrin). In the excitable tissues such as chromaffin cells release of catecholamines has been associated with the breakdown of fodrin (Perrin and Aunis, Nature, 315:589, 1987). When the breakdown of fodrin was prevented by pretreating the cells with fodrin antibody, release was blocked (Perrin et al., Nature, 326:498, 1987). Because the proteases involved in the breakdown of fodrin are calcium-dependent and there is a calcium flux into the cell during the state of seizure, we hypothesized that a breakdown of fodrin may occur during convulsions thus facilitating the release of transmitters and altering membrane structures at the seizure focus. To test this hypothesis rats were kindled to stage 5 using a bipolar electrode implanted unilaterally into the amygdala. Control rats were identically implanted with an electrode but were not stimulated. The rats were killed in mid seizure after having achieved at least 5 consecutive stage 5 seizures, and the brain was rapidly frozen and dissected into several parts including the hippocampus and cortex. The brains were then homogenized and run in SDS-containing buffer and analyzed in a 7.5% acrylamide-containing gel electrophoresis system. The gels which included purified fodrin were stained with coomassie-blue and read on a Biomedical Instruments densitometer. In the kindled rat hippocampus fodrin found in the 220,000 -240,000 MW range was decreased when compared with the sham operated rats. The cortex, on the other hand, showed an increase in the quantity of fodrin molecules in the kindled rat when compared with the sham operated rats. The decrease in the number of fodrin molecules in the hippocampus may imply an involvement of fodrin in the seizure process. The localization of this change and its involvement in transmitter interactions will be discussed.

262.18 RESPONSE PROPERTIES OF RAPIDLY RECURRING HIPPOCAMPAL SEIZURES. E.W. Lothman, J.B. Perlin, R. Salerno, Dept. Neurology, Univ. Virginia, Charlottesville, VA 22908.

Repetition of certain stimuli leads to a progressive enhancement of seizure responses (kindling) until a stereotyped convulsion occurs with each stimulus. The final kindled state, a model of chronic focal epilepsy, is typically achieved and studied with stimuli given many hours apart. With this standard approach, it takes days to weeks to reach a kindled state. Previously we have shown that rapidly recurring hippocampal seizures (RRHS) cause a kindling response over hours (Br. Res. 360:83, '85). We report here the epileptic responses to RRHS after completion of rapid kindling.

Adult albino rats stereotactically implanted with bipolar electrodes in the hippocampus were rapidly kindled with supramaximal tetani every 5 min for 6 hr. On alternate days thereafter, 14 afterdischarges were elicited at 30 min intervals. The first and last were produced by a series of tetani (50 Hz, 1 msec biphasic pulses for 10 sec) of increasing current until afterdischarge (ICTAD stimuli); the others were provoked with the same tetanus at current intensities suprathreshold for after-discharge production (STC stimuli). Behavioral seizure scores (BSS) and afterdischarge durations (ADD) were assessed according to convention and 4 STC responses were blocked together for analysis. For the first week kindled responses were seen, but BSS and ADD showed variability. Thereafter, responses stabilized so that kindled BSS and ADD responses were constant within and among separate test days. Afterdischarge thresholds (ADT) were stable throughout the experiment. This established the basic test protocol. Interposing blocks of 4 ICTAD stimuli in the test period increased the variability of BSS and ADD, but ADT remained unchanged. When the number of STC stimuli given on a test day was increased, mean BSS and ADD fell after 18 hours and ADT rose. Upon resumption of the basic test protocol, BSS, ADD, and ADT returned to stable, baseline kindled values over the next several days. Using the basic test protocol, but on consecutive days, BSS and ADD were lowered after 4-5 days. Returning to alternate test days normalized responses within a week.

These experiments show that with appropriate stimuli a kindled state can be established quickly with RRHS and that, after this, multiple stable responses can be elicited at a rate of every 30 minutes. With the basic test protocol the effect of various experimental manipulations can readily be studied, including their time course. However, even with the supramaximal stimuli used, repetitive seizures can eventually result in postictal "inhibitory" processes that can persist for several days.

262.19 RAPID KINDLING IN THE IMMATURE BRAIN. James L. Thompson and Gregory L. Holmes, Dept. of Neurology, Medical College of Georgia, Veterans Medical Center, Augusta, GA 30912-2366.

Kindling, the phenomenon whereby repeated administration of an initially subsconvulsive electrical stimulus results in progressive intensification of seizure activity culminating in a distinctive convulsion, is a widely used animal model of partial seizures. In immature rats the typical kindling paradigm used has been 1 sec., 60 Hz stimulations with a biphasic waveform of intensity sufficient to induce an electrical afterdischarge. Inter-stimulus intervals of 15 minutes to 24 hours are used. Lothman et al. (Brain Res. 360:83, 1985) reported that in mature animals, 10 sec. trains of low-frequency suprathreshold stimulations resulted in kindling in 2-3 hours. The purpose of this study was to determine whether rapid kindling could be achieved in immature animals using low frequency, long duration stimulations with a short inter-stimulus interval.

Bipolar electrodes, stereotaxically implanted in the hippocampus (CA3 region) or the amygdala of immature rats, were used to deliver 1 or 10 sec trains of suprathreshold (1000 μA) stimulations at frequencies of 10 or 60 Hz. The stimuli were administered every 5 minutes. Rapid kindling was achieved with 10 second but not 1 second stimulation with both 10 and 60 Hz frequencies. Ten second stimulations with a 60 Hz frequency resulted in more rapid kindling (mean number of stimulations to stage 5 seizures = 8.88±1.17) than 10 second stimulations with a 10 Hz frequency (mean = 14.93±1.54) ($t = 3.06$, $p<0.01$). When 10 sec., 10 Hz stimulations were administered hourly kindling also occurred although the animals required statistically more stimulations to reach their first stage 5 seizure (mean = 22.17±1.94) than in the animals stimulated every 5 minutes (mean = 14.93±1.54) ($t = 2.92$, $p<0.01$). The rate of kindling was similar in animals with hippocampal and amygdala electrodes. This study demonstrates that rapid kindling can be achieved with long duration stimulations and short interstimulus intervals in the immature animal.

262.20 CHRONIC CARBAMAZEPINE INHIBITS THE DEVELOPMENT OF COCAINE-KINDLED SEIZURES. S.R.B. Weiss*, M. Costello*, R. Woodward*, D. J. Nutt* and R.M. Post. BPB, NIMH, LCS, NIAAA, Bethesda, MD 20892.

Carbamazepine has been used to treat seizure disorders, paroxysmal pain syndromes and, more recently, manic-depressive illness. Its potency appears greatest for limbic system seizures but depends on the stage of development and the etiology of the seizure. Cocaine possesses both psychomotor stimulant and local anesthetic properties. In high doses, repeated administration produces increased motor responses (behavioral sensitization) as well as a convulsive response (pharmacologic kindling). Since the development of lidocaine-kindled seizures is blocked by carbamazepine, we evaluated the effects of carbamazepine on the development of cocaine-kindled seizures and stereotypic behavior, and on acute, high-dose cocaine seizures.

Rats were placed on a control or carbamazepine-containing diet for four days prior to the studies and were kept on these diets throughout the period of cocaine injections. In separate studies cocaine was injected once-daily at doses of 65 or 40 mg/kg and the animals were observed for one-half hour following treatment for stereotypy (40 mg/kg only), seizures, and death. By the third day of the experiment cocaine (65 mg/kg) produced seizures and deaths in all rats (N=15) on the control diet. In contrast, 12/15 rats treated with carbamazepine survived for three days and 7 survived nine days of cocaine injections.

At the 40 mg/kg dose of cocaine, carbamazepine markedly inhibited the development of cocaine-kindled seizures and lethality. While 80% (16/20) of control rats ultimately had seizures and 50% died, only 25% (5/20) of the carbamazepine-treated rats had seizures and only one animal died (5%) over the course of sixteen days of cocaine injections. Carbamazepine reduced the intensity of the stereotypy, but did not attenuate the overall pattern of sensitization of the response.

Carbamazepine (15, 25 or 50 mg/kg, i.p.), administered acutely, did not suppress seizures induced by high-dose cocaine (65 mg/kg), and lethality may have been potentiated. However, chronic pretreatment with carbamazepine (4 days) did decrease acute cocaine-induced seizures and associated lethality.

In summary, chronic dietary carbamazepine inhibits the development of lidocaine- and cocaine-kindled seizures and lethality. Chronic, but not acute pretreatment with carbamazepine inhibits high-dose cocaine seizures. The cocaine and the lidocaine findings suggest important interactions of carbamazepine with local anesthetic mechanisms mediating the progressive development of seizures. Effects at the type II sodium channels (batrachotoxin-sensitive) should be further explored since both carbamazepine and the local anesthetics potently interact at this site.

263.1 IMMUNOHISTOCHEMICAL LOCALIZATION OF BENZODIAZEPINE/$GABA_A$ RECEPTORS IN THE HUMAN AMYGDALOID COMPLEX. C.R. Houser, R.W. Olsen, J.G. Richards and H. Möhler*. VA Medical Center, West Los Angeles; Brain Research Institute, UCLA, Los Angeles, CA 90024; and Research Department, F. Hoffmann La-Roche, CH-4002 Basel, Switzerland.

Monoclonal antibodies to a purified $GABA_A$/benzodiazepine receptor complex from bovine cerebral cortex (Schoch, P. et al., Nature 314:168, 1985) have been used to determine the normal localization of this receptor in immunohistochemical preparations of the human amygdaloid complex. Within the basolateral group of amygdaloid nuclei, the densities of immunolabeling ranged from high to low. High levels of labeling were observed in the lateral amygdaloid nucleus, and this was the most heavily labeled nucleus within the entire amygdaloid complex. Moderate densities of labeling were present within the accessory basal nucleus. In contrast, the basolateral nucleus contained relatively low densities of receptor labeling. Within the corticomedial group of amygdaloid nuclei, the levels of staining were moderately high in the plexiform layer of the cortical nucleus but were moderate to low in other nuclei of this complex including the medial and central nuclei. The lowest levels of labeling were observed in the cortico-amygdaloid transition area that intervenes between the pyriform cortex and the amygdaloid nuclei.

The cellular localization of the benzodiazepine/$GABA_A$ receptor also varied among the different nuclei. In regions with high densities of receptor labeling, such as the lateral nucleus, immunoreaction product was distributed diffusely throughout the neuropil and could not be localized to specific cellular elements. However, in more lightly stained regions, labeled neuronal elements could be clearly distinguished. For example, in the basolateral nucleus, large multipolar neurons with long dendritic processes were outlined by reaction product. Similarly in the cortico-amygdaloid transition zone, neurons with elongated cell bodies and dendrites extending from both poles of the neuron were prominently labeled. In the anterior and central nuclei, many dendrities were enveloped with reaction product and merged with similarly labeled processes within the substriatal gray.

These findings indicate that different nuclei of the human amygdaloid complex have distinctive patterns of benzodiazepine/$GABA_A$ receptor localization. Knowledge of these patterns can now be utilized in studies of receptor localization in patients with neurological disorders that may involve the amygdala such as temporal lobe epilepsy. Supported by VA Medical Research Funds and NIH Grants NS21908 and NS22071.

263.2 AUTORADIOGRAPHIC LOCALIZATION OF GABA-A AND M1 MUSCARINIC RECEPTORS IN DEAFFERENTED PREPIRIFORM CORTEX OF RAT. A. P. Thomas*[1] and L. E. Westrum[2]. (SPON: P. D. Swanson). Depts. of Neurological Surgery[1,2] and Biological Structure[2], Univ. of Washington, Seattle, WA 98195.

The distribution of benzodiazepine (BZD) binding sites (which are complexed with the GABA-A receptor) and M1 muscarinic cholinergic receptors in the prepiriform cortex (PC) of deafferented rats were studied by in vitro autoradiography, using 3H flunitrazepam (FNZP), and 3H quinuclidinyl benzilate (QNB) respectively. The PC of Sprague-Dawley rats was deafferented by unilateral ablation of the olfactory bulb (OB) on the day of birth (PNO) or in adulthood. Deafferented rats were examined at 22 or 16 weeks survival respectively. Cryostat sections (10 μm) were incubated in 3H FNZP (3nM) with or without unlabeled diazepam, and adjacent sections in 3H QNB (3nM) with or without unlabeled atropine. This was followed by preparation for autoradiography using LKB Ultrofilm. The films were exposed for 3 or 4 weeks, and the resultant autoradiograms were referenced to co-exposed brain mash standards, and optical densities (OD) were measured using a computer-assisted Drexel-DUMAS densitometer. Adult deafferented animals showed significant increases in OD of BZD receptor binding in the superficial layer of PC ipsilateral to the lesion as compared to the control side. In PNO deafferented subjects the difference was not as pronounced as in adults. The adult deafferented subjects demonstrated very highly significant increases in M1 muscarinic receptor binding, while changes in PNO-operated ones appeared to be very subtle. This increase in muscarinic receptors may indicate an enhanced activity of subcortical cholinergic afferents to PC, to compensate for the reduced sensory input with OB removal, or increased concentrations of receptor proteins resulting from heightened activity of intracortical association systems that generate excitatory synaptic potentials. In neonates the deprivation of primary sensory input during the critical period of muscarinic and GABAergic synaptogenesis in layer 1 of PC may have influenced the observed change in these receptor densities. The increase in BZD receptor binding in adult deafferented subjects may be indicative of: a) compensatory proliferation of GABA contacts onto pyramidal cells from GABA cells; b) effects of shrinkage resulting from the OB removal; c) possibly some of the glial fraction of GABA showing some binding in layer 1. Thus GABAergic and muscarinic receptor bindings not only are affected by deafferentation, but are age-dependent.

263.3 ORGANIZATION OF THE GABAergic SYSTEM IN THE RAT HIPPOCAMPUS. W. Woodson*, L. Nitecka* and Y. Ben-Ari (SPON: N. Lugo-Garcia). INSERM U-029, Hopital de Port-Royal, 123 Boulevard de Port-Royal, 75014 Paris, France.

Specific antibodies against GABA were used to study the GABAergic system in the rat hippocampus. Both the number of GABA-Like (Li) immunoreactive somata and neuropil density was assessed in semi-thin sections. Cell counts revealed that 9% of the hippocampal neuronal population show GABA-Li immunoreactivity.

Each laminar region had a characteristic organization of GABA-Li elememts. In the Ammon's horn 80 to 95% of the neuronal somata within the apical and basal dendritic regions were GABA-Li postive. Within the pyramidal cell layer 5 to 8% of the cells were GABA-Li in the CA1 to CA3 sectors of Ammon's horn and only 3% were postive within that portion of the pyramidal cell layer which inserts into the hilus. Only slight differences were observed in the density of the GABA-Li neuropil within the CA1 to CA3 dendritic regions. A dense band of GABA-Li label was found in the stratum lucidum associated with many postive cells. Counts of immunoreactive grains localized on the perimeter of pyramidal (CA1 to CA3) and granule somata revealed more terminal boutons on the CA3 cells as compared to CA1 and granule neuronal somata.

A clear topographical distribution of GABA-Li somata and neuropil was found in the fascia dentata: There the label particularly concentrated in its suprapyramidal and rostro-lateral portions. Approximately 40% of neurons in the molecular layer, 60% in the polymorph layer, and 18% within the hilar region proper showed GABA-Li immunoreactivity. Within the granule cell layer only 2% of the neurons were GABA-Li postive. Distinct differences in the density of the GABA-Li neuropil were present in the molecular, polymorph and hilar regions of the fascia dentata.

While the morphology of GABA-Li neuronal somata varied according to their laminar region the most heterogeneous cell types were found in the inferior region of the hippocampus.

These data demonstrate a clear topography in the distribution of GABA-Li in the hippocampus. While little differences in both the percentage of somata and neuropil density were found in the Ammon's horn, distinct variations were observed in the fascia dentata. Moreover, these results suggest the presence of a unique GABAergic plexus aligned along the mossy fibers.

263.4 **DUAL ULTRASTRUCTURAL LOCALIZATION OF TYROSINE HYDROXYLASE AND GABA IN RAT NUCLEUS ACCUMBENS: PRE- AND POSTSYNAPTIC INTERACTIONS BETWEEN DOPAMINE AND AMINO ACID TRANSMITTERS.** V.M. Pickel, A.C. Towle, T.H. Joh and J. Chan, Divs. of Neurobiology and Molecular Biology, Cornell Univ. Med. Coll., New York, NY 10021.

Cellular substrates for known physiological interactions between dopaminergic afferents and neurons containing gamma-aminobutyric acid (GABA) were examined in the rat nucleus accumbens. Peroxidase-antiperoxidase labeling for GABA and immunoautoradiographic labeling for the catecholamine synthesizing enzyme, tyrosine hydroxylase (TH) were differentially identified within single sections examined by light and electron microscopy. The GABA-like immunoreactivity (LI) was seen in two distinct types of medium-sized (10-20 μm) perikarya. The first, characteristically spiny type, showed low intensity GABA-LI; whereas, the second, morphologically characterized as aspiny, showed more intense immunoreactivity. The GABA-LI was also seen in proximal dendrites, axons, axon terminals, and glia.

In dual labeled sections, terminals showing GABA-LI and immunoreactivity for TH exclusively formed symmetric synapses or appositions characterized by equally spaced, non-electron dense membranes. The two types of terminals differed in that the TH-labeled terminals were smaller (mean diameter 0.3 versus 0.6 μm) and less frequently detected (138 versus 300 terminals in an area of 2,400 um^2). The TH-labeled terminals also more frequently formed junctions with the soma (4% versus 1%) and proximal dendrites (14% versus 6%) of GABAergic neurons, and less frequently (8% versus 24%) formed junctions with unlabeled proximal dendrites. However, in some cases, both types of labeled terminals formed synapses on common proximal dendrites that were either with or without GABA-LI. They also formed junctions with common or separate unlabeled dendritic spines. Presynaptic interactions were seen between the TH- and GABA-labeled terminals and unlabeled terminals exhibiting asymmetric, typically excitatory, synapses on the common spine. We conclude that GABAergic and TH-labeled (principally dopaminergic) terminals have certain common post-synaptic sites of termination on soma and proximal dendrites, with GABA being the principal inhibitor of non-GABAergic neurons and dopamine interacting primarily with the GABAergic neurons. Furthermore, GABA and dopamine may selectively modify the output from the nucleus accumbens through convergence on common dendritic spines of known projection neurons or through axonic interactions with each other or with excitatory afferents.

263.5 IN VIVO IMAGING OF RAT C6 GLIOMAS BY [125-I] IODINATED BENZODIAZEPINES AND ISOQUINOLINES. B.J. Ciliax, S. Starosta-Rubinstein, D.M. Wieland, M.E. Van Dort, D.L. Gildersleeve, J.B. Penney and A.B. Young. Depts. of Pharmacology, Neurology, and Internal Medicine. University of Michigan, Ann Arbor, MI 48104.

The C6 rat glioma cell line has very high concentrations of the peripheral benzodiazepine binding site (PBS). The function of this site is unknown but it is distinct from the well known central/neuronal benzodiazepine receptor (CNR), which is coupled to the GABA-A receptor/Cl^- channel complex. The two benzodiazepine (BDZ) binding sites can be distinguished pharmacologically: diazepam and flunitrazepam bind to both sites, clonazepam binds only to the CNR, while Ro 5-4864 and the isoquinoline compound, PK 11195, bind only to the PBS. Intracranial C6 gliomas can be imaged in vitro and in vivo by PBS radioligand binding (Starosta-Rubinstein et al. PNAS 84:891, 1987). Several human tumors (two high grade glioma, one breast, one kidney, and one meningeal tumor) grown in athymic rodents also had high concentrations of the PBS. Thus, these tumor types might be imaged via positron emission tomography (PET) or single photon emission computed tomography (SPECT) if the appropriate ligands were available. To this end, we have synthesized and tested several iodinated [125-I]-labelled BDZ analogues ultimately for use in SPECT imaging in our rat C6 glioma model.

We examined [125-I]-7-iodo-diazepam, [125-I]-7-iodo-Ro 5-4864, [125-I]-4'-iodo-Ro 5-4864, and [125-I]-2'-iodo-PK 11195 for tumor imaging. Wistar rats were injected intracerebrally with 5 µl of a C6 glioma cell suspension. After two weeks, the animals were catheterized for i.v. injections of [125-I]-labelled compounds (400 µCi/250g body wt). (Animals receiving the diazepam analog were predosed with 5 mg/kg clonazepam to block binding to CNR). All compounds imaged tumor tissue, selectively binding to the PBS, with little background binding to normal brain. However, the time course for optimal signal-to-noise ratios differed substantially for each drug. For example, [125-I]-7-iodo-diazepam had its best in vivo binding ratio (tumor to brain) early (10 min post injection) while [125-I]-4'-iodo-Ro 5-4864 required approximately two hours to achieve optimal binding. The differences in the binding kinetics could be very important when selecting a ligand for human use in SPECT.

263.6 AUTORADIOGRAPHIC EVIDENCE FOR POSTSYNAPTIC GABA-B RECEPTORS IN RAT STRIATUM AND HIPPOCAMPUS. D.C.M. Chu, J.B. Penney and A.B. Young. Neuroscience Program and Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

Lesion techniques were combined with [3H]GABA quantitative autoradiography to examine the hypothesis that GABA-B receptors exist on presynaptic terminals of certain pathways where baclofen has been shown to block synaptic release of glutamate. We performed lesions in anesthetized rats of both pre- and postsynaptic elements of two glutamate pathways which are affected by baclofen: the corticostriatal pathway and the perforant pathway. The presynaptic corticostriatal pathway was disrupted by aspiration of frontoparietal cortex; intrinsic striatal neurons were destroyed by intrastriatal injection of ibotenic acid (126 nmol in 1.0 µl). Presynaptic input from the entorhinal cortex was disrupted by knife-cut lesions of the angular bundle; destruction of postsynaptic dentate granule cells was achieved with the selective toxin colchicine (2 injections, each 8 nmol in 0.7 µl). GABA-B and GABA-A binding in the striatum were evaluated one month after lesioning by quantitative autoradiography using [3H]GABA. All side-to-side comparisons were made by two-tailed paired Student's t-test.

There were no changes in striatal GABA-B nor GABA-A receptor numbers or affinities following unilateral decortication (n=7). However, destruction of striatal neurons with ibotenic acid (n=9) led to dramatic decline in the number of both GABA receptor types with no significant change in affinity. Four and 30 days after unilateral entorhinal knife-cuts (each n=6), GABA-B receptor numbers were significantly increased by 20-40% in dentate gyrus molecular layer ipsilateral to the lesion. This suggested that GABA-B receptors upregulate following removal of excitatory afferents. Conversely, unilateral colchicine lesions (n=12) of dentate granule cells led to total loss of both types of GABA receptors in the molecular layer of dentate gyrus two weeks later. It appears that GABA-B receptors are not on presynaptic nerve terminals of these glutamate pathways, but may have a postsynaptic neuronal localization. Upregulation of GABA-B receptors following removal of entorhinal inputs suggests that these excitatory inputs synapse directly on GABAergic neurons in the dentate gyrus and may mediate feed-forward inhibition of granule cells.

263.7 MULTIPLICITY OF BRAIN L-GLUTAMATE DECARBOXYLASE AND CHOLINE ACETYLTRANSFERASE. J.-Y. Wu, J.Y. Liu*, D.M. Evans*, H.S. Lin* and C.T. Lin. Dept. of Physiol., Penn State Univ. Col. of Med., Hershey, PA 17033.

It is generally accepted that the level of neurotransmitters such as GABA and acetylcholine (Ach) is normally governed by their synthetic enzymes e.g. L-glutamate decarboxylase (GAD) and choline acetyltransferase (CAT), respectively. Multiple forms of GAD differing in molecular weight [WU, SU, Lam, Brandon and Denner, Brain Res. Bull. 5 (Supp. 2) 63-70 (1980)], in affinity for pyridoxal phosphate [Denner and Wu, J. Neurochem. 44, 957-965 (1985)], in subunit structure [Denner, Wei, Lin, Lin and Wu, Proc. Natl. Acad. Sci. 84, 668-672 (1987)] and in hydrophobic properties [Spink, Wu and Martin, J. Neurochem. 40, 1113-1119 (1983)] have been reported. With the use of monoclonal antibody against GAD, we were able to obtain two distinct forms of GAD from rat brain. One appeared to have two identical subunits with a molecular weight of about 67,000-dalton and the other one appeared to have two subunits with a molecular weight of 40,000- and 80,000-dalton. The immunoaffinity purified GAD still retained GAD enzyme activity and GAD immunoreactivity as shown in the immunodot and immunoblot tests. In addition to GAD, we have also identified multiple forms of CAT in the rat brain. Two distinct forms of CAT were obtained by CM-cellulose column. One was eluted at relatively low ionic strength, about 30 mM potassium phosphate buffer, pH 7.2 containing 1 mM β-mercaptoethanol and 1 mM EDTA. The other one was eluted at much higher ionic strength, about 150 mM potassium phosphate containing the same amount of protectors. These two forms of CAT could be further distinguished by immunoblot test using monoclonal antibody against CAT. The former showed a single protein band corresponding to a molecular weight of 68,000-dalton, whereas, the latter showed two protein bands corresponding to lower molecular weight, 55,000- and 60,000-dalton in addition to the 68,000-dalton protein band. The 68,000-dalton form has been purified by immunoaffinity and the purified preparation still retained CAT enzyme activity and CAT immunoreactivity. We are currently using the same approach to purify the second form of CAT. Eventually, we plan to localize various forms of GAD and CAT at cellular and subcellular levels so that their functions, particularly those related to the regulation of GABA and Ach levels can be analyzed. (Supported in part by grants from NIH, #NS20978, #EY05385 and #NS20922.)

263.8 IMMUNOCYTOCHEMICAL LOCALIZATION OF L-GLUTAMATE DECARBOXYLASE AND CATECHOLAMINE-SYNTHESIZING ENZYMES IN THE RETROPERITONEAL SYMPATHETIC TISSUE OF NEWBORN RAT. L.Eränkö 1, M.Ahonen1, O.Häppölä 1, T.H. Joh 2 and J.-Y.Wu 3. 1Dep. of Anatomy, Univ. of Helsinki, Siltavuorenpenger 20, 00170 Helsinki, Finland, 2Lab. of Neurobiology, Dep. of Neurology, Cornell Univ. Med. College, New York, NY 10021, U.S.A., 3Dep. of Physiology, Pennsylvania State Univ., Milton S. Hershey Med. Center, Hershey, PA 170033, U.S.A.

All sympathetic cells, i.e., sympathetic ganglion cells, adrenal medullary cells and paraganglionic cells use catecolamine as neurotransmitter and/or hormone. The main retroperitoneal paraganglion of newborn rat consists of several kinds of catecholamine containing cells: 1) small, intensely tyrosine hydroxylase (TH) immunoreactive (paraganglion-type) cells, 2) larger, moderately TH-reactive (neuron-like) cells, 3) some small intensely TH- and phenylethanolamine N-methyltransferase (PNMT)-reactive cells and 4) some TH-negative cells. In addition to catecholamines, other neuroactive substances have been localized in sympathetic cells. γ-aminobutyric acid (GABA), which is known to function as inhibitory neurotransmitter in the mammalian central nervous system, has also been identified in mammalian peripheral tissues. L-glutamate decarboxylase (GAD) is the enzyme synthesizing GABA from glutamate. GAD has been shown to be present in chromaffin cells of the adrenal medulla, which also contain catecholamines. In this study, indirect immunofluorescence method and a specific GAD antiserum were used to localize GAD in newborn rat retroperitoneal sympathetic tissue.

The retroperitoneal paraganglia and the adrenal medullas of newborn rats were immersion fixed in 4% paraformaldehyde, pH 7.3, for two hours and indirect immunofluorescence method was applied using antisera to TH, PNMT and GAD. To study coexistence of GAD with catechoamines, consecutive sections and the method of Tramu et al. (1978) were used.

In the main retroperitoneal paraganglion all small intensely TH-reactive cells were also intensely reactive to GAD. Larger, neuron-like cells were moderately reactive to TH but non-reactive to GAD. PNMT immunoreactivity was localized in a small number of cranially situated small intensely TH- and GAD-positive cells. In the adrenal medulla a large number of chromaffin cells showed intense immunoreactivity to TH and they all were PNMT- and GAD-reactive, too. A subpopulation of chromaffin cells were only moderately TH-reactive and non-reactive to PNMT and GAD.

The results suggest that in the retroperitoneal paraganglion of newborn rat the small noradrenaline containing cells are also GAD-immunoreactive. Adrenaline containing cells in the paraganglion and in the adrenal medulla are GAD-positive. In addition to adrenal medulla, rat retroperitoneal paraganglionic tissue contains cells in which catecholamine-synthesizing enzymes and GAD are immunocytochemically colocalized.

263.9 EXPRESSION OF GLUTAMATE DECARBOXYLASE mRNA BY NEURONS OF THE CEREBRAL CORTEX. D.L. Benson*, P. Isackson, S.H.C. Hendry, E.G. Jones and A.J. Tobin. (SPON: R.S. Morrison). Departments of Anatomy and Neurobiology, and Biological Chemistry, University of California, Irvine and Department of Biology, University of California, Los Angeles.

A plasmid was constructed for the preparation of glutamic acid decarboxylase (GAD) RNA probes by inserting the 2.4 Kb EcoRI fragment of cat GAD cDNA (Kaufman et al., Science 232: 1138, 1986) into the EcoRI site of pBS (Stratagene). The resultant plasmids, pBS GAD-1 and pBS GAD-2, contain the GAD cDNA in opposite orientations flanked by the T_3 and T_7 RNA polymerase promoters. A 300 base RNA antisense probe has been prepared by transcription of Hind III linearized pBS GAD-1 with T_7 RNA polymerase. This probe, labeled with α^{35}S-thio-UTP, has been used for in situ hybridization experiments. Northern blot analysis shows that this probe, as well as a 2.4 Kbase antisense probe, reacts specifically and equally well with GAD mRNA from mouse, cat and monkey brain poly A^+ RNA preparations under the same hybridization conditions (65°C with 50% formamide) being used for in situ localization.

Autoradiographs from sections of fresh frozen cat and monkey cerebral cortex show hybridization of the GAD RNA probe to neurons in all layers of the sensory-motor and visual cortices. The same proportions of cortical neurons show hybridization as those stained immunocytochemically for GAD or gamma aminobutyric acid (GABA) and similar populations of large and small non-pyramidal neurons show hybridization as those stained immunocytochemically.

In situ hybridization of the GAD RNA probe is now being applied to the visual cortex of monocularly deprived animals in order to determine if activity dependent changes in GAD and GABA levels result from changes at the transcriptional level.

Supported by NIH grants, numbers NS 21377, EY 6432, NS 20356 and NS 22256.

263.10 AUTOANTIBODIES TO GLUTAMIC ACID DECARBOXYLASE IN A PATIENT WITH STIFF-MAN SYNDROME AND TYPE I DIABETES MELLITUS. F. Folli*, M. Solimena+,**, S. Denis-Donini+, G.C. Comi#, G. Pozza*,#, A. Vicari* and P. De Camilli+. *Clinica Medica VII and #Clinica Neurologica of the "Istitute S. Raffaele"; +Dept. of Medical Pharmacology, Univ. of Milano, 20129, Milano, Italy.

Stiff-man syndrome (SMS) is a rare CNS disorder of unknown etiology characterized by spontaneous muscle rigidity and painful spasms due to a simultaneous activation of agonist and antagonist muscles. A case of stiff-man syndrome associated with epilepsy and diabetes mellitus is described.

The patient is a 45 year-old woman whose HLA phenotype is: A 1/28, B 8/44, Cw 5/x and DR 3/4. DR 3 and DR 4 antigens are known to be associated with an increased incidence of autoimmune diseases. The diabetes is a type 1B diabetes (autoimmune diabetes) (Bottazzo, G.F. et al., unpublished observations). IgGs oligoclonal bands are present in the cerebrospinal fluid (CSF). These findings prompted us to search for signs of autoimmunity against the CNS. To do so we tested the serum and the CSF of the patient for the presence of antibodies directed against nervous system antigens both by light microscopy immunocytochemistry and by Western blotting. Both the serum and the CSF produced an identical prominent immunostaining of gray matter regions in sections of rat and human brains, and of a subpopulation of nerve cells in primary neuronal cultures from mouse brain. They also produced an identical staining of rat pancreatic islets. Double-immunofluorescence experiments revealed that in all cases the staining was identical to that produced by antibodies to glutamic-acid decarboxylase (GAD) (gift of Oertel and co-workers). High concentrations of both GAD and GABA in pancreatic β-cells had been previously reported (some evidence indicates that GABA may play a local regulatory function in the endocrine pancreas). Western blots of proteins from total homogenates of rat and human brain indicated that the major antigen recognized by both the serum and the CSF antibodies is a protein comigrating with GAD.

On the basis of pharmacological and clinical studies, it has been suggested that SMS is due to a disorder of GABA-ergic neurons. An abnormal function of GABA-ergic systems has also been implicated in at least some types of epilepsy. Although autoantibodies directed against GAD are probably not pathogenic since GAD is an intracellular antigen, our findings raise the possibility of a common primary autoimmune pathogenesis in a syndrome which appears to involve GABA-ergic neurons and GABA-ergic neuroendocrine cells. (Supported in part by an MDA grant and by grants from the Italian Ministry of Education to PDC).

263.11 DISTRIBUTION OF GAMMA-AMINOBUTYRIC ACID-POSITIVE NEURONS AND ACETYLCHOLINESTERASE IN THE MONKEY THALAMIC INTRALAMINAR NUCLEI. C.A. Hunt and E.G. Jones. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

To gain more knowledge about the organization of the primate intralaminar complex, we studied the precise distribution of gamma-aminobutyric acid (GABA)-immunoreactive neurons and acetylcholinesterase (AChE) in the monkey. Three adult Macaca fascicularis were perfused transcardially with either 10% formalin and 0.05% glutaraldehyde (one monkey) or with 2.5% paraformaldehyde and 0.25% glutaraldehyde (two monkeys). Frozen sections were stained immunocytochemically for GABA using a rabbit antiserum and the avidin-biotin-peroxidase technique. Adjacent sections were stained histochemically for AChE. Monkeys were not pretreated with colchicine. The distribution of GABAergic neurons and of AChE staining were plotted onto camera lucida drawings of frontal sections through the thalamus.

GABAergic neurons were present in all nuclei of the intralaminar complex. They were uniformly distributed in the central medial, rhomboid, centre médian and parafascicular nuclei. The latter two nuclei, particularly the centre médian nucleus, contained considerably fewer GABAergic neurons than neighboring thalamic nuclei. GABA-immunoreactive neurons in the paracentral and central lateral nuclei tended to be distributed in small clusters interspersed among the fibers of the internal medullary lamina.

The intralaminar nuclei could be clearly distinguished from adjacent nuclei by the presence of intense AChE staining. No AChE-positive somata were seen. The pattern of AChE staining varied somewhat among individual nuclei, in a manner approximately parallel to the distribution of GABAergic neurons. The centre médian nucleus contained the least intense AChE reactivity, and AChE staining in the paracentral and central lateral nuclei had a patchy appearance. Areas of darker staining could sometimes be superimposed upon clusters of GABAergic neurons.

These data show that the intralaminar nuclei of the monkey, like other thalamic nuclei, contain a discrete population of GABAergic neurons, and that the intralaminar nuclear complex can be characterized by a high level of acetylcholinesterase staining, which is distributed in a pattern similar to that of the GABAergic neurons.

263.12 DEVELOPMENT OF CORTICAL INHIBITION: AN IN VITRO HRP AND GABA-IMMUNOCYTOCHEMICAL STUDY IN TURTLE. M. Blanton and A. Kriegstein. Dept. of Neurology, Stanford U. Sch. of Med., Stanford, CA 94305.

Pyramidal cells in developing turtle cortex are generated in a brief time period (Goffinet, JCN 243:106, '86) and occupy a single layer. When mature, their dendrites receive GABAergic, inhibitory inputs from nonpyramidal cells and excitatory inputs segregated in distinct sublaminae of the molecular layer. These temporal and spatial features aid resolution of developmental events and encouraged us to study the anatomy and physiology of synaptic systems in developing turtle cortex. We used focal applications of horseradish peroxidase (HRP) and GABA-immunocytochemistry to follow cellular and synaptic differentiation. We found pyramidal and non-pyramidal neurons to be distinguishable early in corticogenesis and to later form distinct synaptic patterns.

Pseudemys scripta embryos were staged (Yntema, J. Morph. 125:219, '68), perfused transcardially with saline, and the brains vibratomed at 300-500 µm. HRP-coated electrodes were placed in desired locations in the brain slices, which were maintained in vitro for six hours, then fixed and processed with standard techniques.

Pyramidal cells develop from vertically or obliquely oriented bipolar cells that appear at stage 15. They differentiate in relative synchrony and acquire multiple ascending dendrites to become pyramidal-like at the time of cortical plate appearance (stage 20). In subsequent stages, pyramidal cells give rise to multiply branching axons, which issue recurrents containing varicosities and form an axonal network extending mediolaterally and rostrocaudally. Apical dendrites acquire spines over a similar time course. At hatching, these cells appear mature, except for the presence of spines more proximally than in adult neurons.

Horizontally oriented nonpyramidal cells, the first relatively differentiated cells to appear, are intensely immunoreactive for GABA from the earliest stages studied (stage 16), well before cortical plate formation (GABA antisera and protocol kindly provided by O. Ottersen and J. Storm-Mathisen). This population of cells is split by intercalation of the cortical plate, composed predominantly of GABA-negative somata (presumably pyramidal cells). HRP-filled and GABA-positive fusiform cells acquire multiple ascending secondary dendrites with development, and more heterogeneous nonpyramidal cell types, covered with numerous fine branches and growth cones, occupy all layers. Punctate structures (putative terminals), present at stage 20, increase in density to a nearly adult-like distribution by hatching.

GABAergic neurons are thus present and distinct from pyramidal cells at early stages of corticogenesis, prior to cortical plate formation and synaptogenesis. Analysis of postsynaptic effects of GABAergic neuronal circuits may be facilitated in this system because of sequential, synchronous pyramidal cell differentiation.

263.13 DEVELOPMENT OF CORTICAL INHIBITION: FUNCTIONAL $GABA_A$ RECEPTORS AT EARLIEST STAGES OF CORTICOGENESIS. J.M. Shen, J.R. Huguenard, and A.R. Kriegstein. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

The balance between excitation and inhibition is critical for normal cortical function and may be disordered in pathological states such as epilepsy. To understand how this balance may be attained during corticogenesis, one must first examine the time course of development of excitatory and inhibitory systems. Since GABA is the principal inhibitory neurotransmitter in cortex, we have begun by studying the development of GABA responsiveness in embryonic cortical neurons.

The whole-cell patch clamp technique was used to record from acutely dissociated cortical neurons from embryonic turtles (Pseudemys scripta). Animals between embryonic stages 16 (early corticogenesis) and 26 (hatching) were studied (staged according to Yntema, C.L., J. Morph. 125:219, 1968). This preparation holds several advantages: 1) turtles and mammals are phylogenetically related and their cortical structures share certain anatomical and physiological features; 2) the relatively simple organization and developmental pattern of turtle cortex facilitate the analysis and interpretation of results, and 3) patch clamp recordings are easily obtainable from embryonic turtle cortical neurons.

Neurons from the earliest stage tested (stage 16) were responsive to applications of 0.5 mM GABA; 96% of all neurons tested across all developmental stages responded (n=50). The response was accompanied by an increase in membrane conductance (mean increase across all ages = 7.4-fold). This GABA-mediated conductance became larger with developmental age, increasing 3-fold from stage 16 to 26. In cells from all stages, the GABA-mediated response inverted polarity at E_{Cl^-} and was reversibly blocked or greatly reduced by 10 μM bicuculline methiodide, suggesting that the receptors mediating the response were predominantly of the $GABA_A$ subtype. Analysis of current-voltage relationships revealed that a fast, transient, voltage-dependent inward current did not appear until stage 19/20.

These results indicate that $GABA_A$ receptors are present and functional in neuronal membranes at the earliest stages of corticogenesis (stage 16) before the formation of the cortical plate (stage 19/20), identification of synaptic profiles (stage 20), or appearance of a voltage-activated inward current (stage 19/20). Cells immunoreactive for GABA are also found in the cortex at stage 16 (see preceding abstract). The role of these precocious GABAergic elements and the time at which this inhibitory system becomes functional have yet to be determined.

263.14 DEVELOPMENT OF CORTICAL INHIBITION: APPEARANCE OF SYNCHRONIZED NEURONAL DISCHARGES. A.R. Kriegstein and J.M. Shen. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Agents that antagonize inhibitory function in cortex can produce spontaneous epileptiform activity. However, for drug-induced synchronized neuronal discharges to occur, functional excitatory circuits and inhibitory mechanisms that normally keep check on excitation must both be present. To determine the earliest stage at which both systems are functional, cortices of embryonic turtles (Pseudemys scripta) were exposed to bicuculline, a $GABA_A$ receptor antagonist, and the timetable for appearance of synchronized neuronal discharge was established.

The entire cortex was dissected out from brains of animals between embryonic stage 17 (early corticogenesis) and hatchlings 1 week of age. The cortical slab was placed in a recording chamber at room temperature perfused with 10 μM bicuculline methiodide in turtle ringer. Field potentials were recorded from the ependymal surface and stimulation was provided by tungsten electrodes placed in the molecular layer.

Cortex from embryonic stages prior to stage 21 (n=5) failed to develop spontaneous or evoked epileptiform activity even after 4 hours of bicuculline exposure. Epileptiform discharges were first apparent in stage 21 embryos and were observed in cortices obtained from all later stages (n=12). The mean amplitude of spontaneous population events increased 3-fold from stage 21 to hatchling animals, and the mean frequency of discharge decreased from 0.17 Hz to 0.12 Hz and became more regular. Data from adult cortex indicate that epileptiform discharges originate in the dorsomedial subfield (DMC) and spread to other cortical areas. Simultaneous recordings from the dorsal cortex (DC) and DMC in embryonic tissue revealed that discharges in DMC led those in DC, and the velocity at which discharges propagated nearly doubled from 14.8 mm/sec in stage 21 animals to 28.3 mm/sec in hatchlings. Furthermore, at younger stages, discharges recorded in DMC did not always propagate to DC, suggesting that the ability to generate repetitive synchronized neuronal discharge matures in advance of the mechanism underlying propagation of epileptiform activity.

Our data indicate that the mechanisms for synchronizing excitatory neuronal activity become functional at stage 21. This timetable parallels other events in corticogenesis: cortical plate formation, synaptogenesis (Goffinet, A.M., J. Comp. Neurol. 125: 219, 1983), and development of a voltage-dependent inward current. Our results do not exclude the possibility that functional GABA-mediated inhibition develops even earlier. The previous abstracts show that GABA-immunoreactive neurons and functional $GABA_A$ receptors are present by stage 16. This raises the possibility that GABA may play a non-transmitter role in early corticogenesis.

263.15 FURTHER EVIDENCE FOR A GABAERGIC PROJECTION FROM THE LATERAL HABENULA TO THE DORSAL RAPHE NUCLEUS: NEUROTRANSMITTER LABELING OF FASCICULUS RETROFLEXUS AXONS AND KAINIC ACID LESIONS. M.R. Park and H.T. Chang, Department of Anatomy and Neurobiology, University of Tennessee, Memphis, College of Medicine, Memphis, TN 38163.

Progress in understanding neuronal organization has been the greatest in the layered structures of the brain. In them, the segregation of individual neuronal elements provides additional criteria for characterizing components that is not available in more homogenous structures. While the habenular nuclei are not themselves layered, their afferents and efferents traveling in the fasciculus retroflexus are segregated in a way that allows conclusions to be drawn about the organization of habenular circuits from their patterns of labeling.

The fasciculus retroflexus is divided into a central core containing medial habenular axons and a surrounding mantle containing efferents from the lateral habenula (Herkenheim & Nauta, J. comp. Neurol., 187: 19, 1979). Afferents to the habenular nuclei also travel in the fasciculus retroflexus, as do some fibers from the stria terminalis. Little is know of the division habenular afferents between core and mantle.

We now report that immunohistochemical labeling for γ-amino butyric acid (GABA) labels axons in the mantle of the fasciculus retroflexus where efferents from the lateral habenula are confined. Substance P immunoreactivity is confined to axons lying in the core of the fasciculus retroflexus; the mantle is not labeled. GABA immunoreactivity is also found among axons of the stria terminalis. Since some stria terminalis axons course uninterupted through the habenular complex and join the fasciculus retroflexus, we performed kainic acid lesions in the lateral habenula to test the source of labeled axons. Lesions confined to the lateral habenula diminish the number of GABA positive fibers in the mantle of the fasciculus retroflexus. Substance P labeling is unaffected. Serotonergic immunoreactivity is present in axons of both the core and mantle. However, phaseolus vulgaris leucoagglutinin (PHAL) injections in the dorsal raphe nucleus label only mantle fasciculus retroflexus axons. The source of the serotonergic fibers found in the core could then well be the median raphe nucleus.

These results bear on our continuing efforts to clarify the nature of the lateral habenular-dorsal raphe projection. We have previously reported the presence of axonal terminal fields in the dorsal raphe nucleus from the labeling of lateral habenula efferents with the anterograde PHAL technique. Physiological evidence of a monosynaptic lateral habenula-dorsal raphe connection comes from our intracellular recording experiments of dorsal raphe neurons. The present findings indicate that at least some lateral habenular efferent axons are GABAergic. If these same axons reach the dorsal raphe nucleus, then they could account for a monosynaptic GABA mediated inhibition in neurons of that nucleus. On the other hand, the pattern of substance P labeling does not seem to permit the hypothesis of a substance P projection from lateral habenula.

263.16 GABA DISTRIBUTION IN A PAIN MODULATING ZONE OF TRIGEMINAL SUBNUCLEUS INTERPOLARIS. M. A. Matthews and T. V. Hernandez*. Dept. Anat., LSU Medical Center, New Orleans, LA 70119

Physiological and behavorial studies have shown that painful stimuli from the central face and oral cavity are retained following a trigeminal tractotomy at the obex and that many WDR and NS units with receptive fields in these same areas are located in subnucleus interpolaris (Vi). We have defined a subdivision of Vi rich in Substance-P, enkephalin and serotonin, together with those categories of cellular elements involved in pain modulation (Matthews et al., 1987).

A recent model for control of spinal and medullary nociceptive neurons (Basbaum and Fields, 1984) incorporates a GABA-ergic cell into this circuitry and indicates that such elements could act as one substrate for presynaptic inhibition of primary afferents. We therefore examined the distribution of GABA-ergic activity in Vi by focusing on the types of cells, together with dendritic and synaptic profiles, which are immunocytochemically labeled with an antiserum against glutamic acid decarboxylase (GAD).

GAD occurred throughout Vi but was most concentrated in the ventrolateral quadrant and interstitial nucleus. It was localized to groups of small neurons with two to three primary dendrites, and within numerous punctate profiles suggestive of synaptic elements. Electron microscopy revealed labeled dendrites, some of which were post-synaptic to scalloped terminals of presumptive primary afferents. Other labeled dendritic elements, which were quite variable in size, engaged both GAD-labeled and unlabeled synapses. Most GAD synapses displayed clear round vesicles and formed contacts with unlabeled perikarya and a variety of dendritic processes. Numerous GAD-positive synapses were also incorporated into axo-axonic clusters, in which the GAD element was presynaptic to scalloped terminals. Others engaged in serial arrays with other unlabeled terminals which, in turn, were presynaptic to dendrites. Occasionally, GAD synapses formed contacts with GAD-positive dendrites.

These data show that GABA-ergic neuronal elements occur in spatial arrangements providing an anatomical substrate for post-synaptic modulation of activity in this area. GABA terminals also appear to be involved in a pre-synaptic inhibitory mechanism which may, in some instances, affect transmission in primary afferents. Double labeling immunocytochemical studies are currently in progress to define this circuitry.

264.1 CHANGES IN EXTRACELLULAR POTASSIUM EVOKED BY GABA AGONISTS IN THE HIPPOCAMPAL SLICE. A.W. Barclet and M.E. Morris. Departments of Pharmacology and Anaesthesia and the Playfair Neuroscience Unit, University of Toronto, Toronto, Canada, M5S 1A1.

The effects of GABA (gamma-aminobutyric acid) and related compounds on extracellular potassium ion concentration ([K^+]o) were examined using isolated slices of guinea pig hippocampus. Double-barrelled K^+-selective microelectrodes were used to record from the CA1 region in 400 um slices mounted in a Haas tissue bath, perfused with physiological saline containing 4.25 mM K^+ at 33.5 °. Bath applications of GABA (0.5 - 10 mM) resulted in reversible dose-dependent depressions of field potentials evoked by stimulation (0.5 Hz, 100 uA, 100 us) of the Schaffer collaterals. These were accompanied by increases in [K^+]o which were followed by graded undershoots during wash-out. Changes in [K^+]o were greatest in the pyramidal cell layer at depths of 100 - 200 um and characterized by an apparent ED_{50} of 3 mM and mean maximal increase of 1.8 (SE ±0.36, n = 7) mM. The $GABA_A$ agonist THIP (0.1 - 1 mM) evoked changes of similar magnitude but shorter duration than those with GABA. Applications of baclofen (± racemic mixture, 0.01 - 1 mM), caused small (≤ 0.5 mM) but definite and prolonged accumulations of K^+. Potassium levels were also raised by beta-alanine and glycine (1 - 10 mM) but not with taurine (10 mM). Bicuculline methiodide (100 uM) or picrotoxin (100 uM) reduced the increases in [K^+]o evoked by 10 mM GABA by approximately 25 %. Pentobarbital (100 - 1000 uM) and ethanol (20 - 100 mM) also caused dose-dependent increases in [K^+]o (≤1.5 mM), and both GABA- and THIP-evoked changes in [K^+]o were strongly potentiated by pentobarbital (200 uM). The apparently greater potency of THIP (which is taken up less avidly than GABA) as well as the demonstrated antagonist sensitivy of the GABA-evoked [K^+]o increases suggests that there is a receptor-mediated increase in potassium conductance. However, the K^+ accumulations evoked by GABA agonists/analogs may also receive contributions from electrogenic Na/K pumping of GABA or K/Cl co-transport.

264.2 DESENSITIZATION AND CHANNEL OPENING OF γ-AMINOBUTYRATE (GABA) RECEPTORS FROM RAT BRAIN. D.J. Cash and K. Subbarao*. Neurochemistry Unit, Missouri Institute of Psychiatry and Department of Biochemistry, University of Missouri-Columbia, School of Medicine, St. Louis, MO 63139

GABA Mediated chloride ion exchange and receptor desensitization were measured using $^{36}Cl^-$ isotope tracer and quench flow technique. The responses of different receptors could be resolved from the kinetic measurements. Two major receptors differed in their rates of desensitization, their modulation by pentobarbital and their activity (concentration).

Cerebral cortex from male Sprague-Dawley rats were homogenized and centrifuged at 270 g, 4 min. The supernatant was pelleted, resuspended and centrifuged in a 4-12% Ficoll gradient at 110,000 g, 1 hr. The middle band was diluted, pelleted and resuspended to give a membrane suspension containing sealed vesicles. The measurement of GABA mediated chloride exchange was initiated by mixing the membrane with $^{36}Cl^-$ in the presence of GABA and terminated by mixing with bicuculline methiodide. Two major phases of chloride exchange limited by two phases of receptor desensitization were detected in two types of experiment. (a) The time course of the $^{36}Cl^-$ influx progressed in two phases. (b) The $^{36}Cl^-$ influx was decreased by preincubation with GABA in two phases.

The measurements supported the existence of two distinguishable receptors on the same membrane, which were desensitized with time constants τ (=1/k) = 47 ms and 740 ms and gave chloride exchange into the vesicles with τ = 105 ms and 444 ms respectively at saturation with GABA. The 1/2 response concentrations were similar for both receptors, 150 μM and 114 μM GABA for desensitization and 105 μM and 82 μM GABA for chloride exchange for the faster and slower desensitizing receptors respectively. The two receptors are present in a ratio circa 1:4, similar to the ratio of low affinity to high affinity sites in binding experiments. Desensitization rates and channel opening equilibria have different dependencies on GABA concentration. Minimal molecular models are presented which explain the results over a wide GABA concentration range.

264.3 INWARD Ca CURRENT REQUIRED TO OPEN GABA RECEPTOR Cl CHANNELS. M. Gyenes*, T.T. Gibbs*, and D.H. Farb Department of Anatomy and Cell Biology, SUNY Health Science Center, Brooklyn, New York 11203

Whole cell current recordings under voltage-clamp conditions were used on spinal cord neurons from 6 d chick embryos maintained in cell culture. GABA, drugs and extracellular solutions of varying ionic composition were applied by microperfusion from 7-barrel pipets. All experiments were carried out at 22°C.

Adding 10 mM Ca or 10 mM Ba augments the GABA-activated current at -60 mV by 23.8 ± 2.6% (N=7) and 143 ± 27% (N=11), respectively, whereas 100 uM Cd, 10 mM Mn or 10 mM EGTA inhibit the GABA response respectively by 71.4 ± 6.3% (N=8), 67 ± 7.8% (N=4) and 48 ± 6.1% (N=4). Similarly, the somatic currents induced at -60 mV by externally applied GABA are enhanced by elevated internal Ca or Ba and inhibited by internal Cd. While the expected reversal potential for the GABA response in our internal and external solutions is around 0 mV, the observed values were +3.7 ± 0.75 mV (N= 9), +7.4 ± 0.06 mV (N= 6) and +11.9 ± 0.9 mV (N= 13) with internal solutions that contained respectively, 1 mM Ca and 11 mM EGTA, 10 mM Ba and 11 mM EGTA and 11 mM EGTA. External picrotoxin (100 uM) reduces by 80% the Ba-enhanced GABA response both at -60 mV and +40 mV. Near the apparent reversal with 2 mM Ba added to the external solution, the GABA-activated current could be separated into two sequential components: a rapid inward current followed by a slow outward current.

The results indicate that GABA cannot activate the Cl channel when the inward Ca current is blocked. Two possible explanations seem the most likely: GABA activates a separate Ca channel close to the Cl channel or GABA activates a single channel that allows both Ca and Cl to pass through sequentially. Ca could act catalytically as cofactor changing the channel's selectivity filter, and thereby coordinating Cl permeation.

264.4 DESENSITIZATION OF THE GABA RECEPTOR-GATED CHLORIDE CHANNEL IN BRAIN: EFFECTS OF NON-COMPETITIVE BLOCKERS OF NICOTINIC RECEPTOR-GATED CATION CHANNELS. Rochelle D. Schwartz and Meredethe R.Cone*. Department of Pharmacology, Duke University Medical Center, Durham, NC 27710.

The functional activity of the GABA receptor complex was studied by measuring muscimol stimulation of ^{36}chloride ($^{36}Cl^-$) uptake in rat cerebral cortical synaptoneurosomes. The effects of muscimol were blocked uncompetitively by picrotoxin (IC_{50}=44uM), a blocker of the GABA receptor-gated Cl^- channel. The muscimol response was blocked non-competitively by several non-competitive inhibitors (NCI) of nicotinic receptor (nAChR)-gated cation channels such as quinacrine, triphenylphosphonium, phencyclidine and chlorpromazine (IC_{50}s=20, 50, 250 and 300uM, respectively). Other antagonists at the nAChR complex such as cocaine, propranolol, amantadine, mecamylamine and hexamethonium were ineffective up to concentrations of 1mM. Since many of these NCI inhibit nicotinic responses via enhancement of desensitization of the nAChR, their role in desensitization of the GABA receptor was investigated. We previously demonstrated that "desensitization" of the GABA receptor complex occurs following preincubation of synaptoneurosomes with GABA agonists, barbiturates or ethanol (Schwartz et al., Mol. Pharmacol. 30, 419-426, 1986). In the present study initial rates of $^{36}Cl^-$ uptake were measured so that desensitization of the GABA receptor could be studied in more detail. Analysis of the time course for muscimol-stimulated uptake (10uM, 1-10 sec, 30°C) indicated a decrease in the apparent dissociation rate constant (k_d) at the initial time points, consistent with a desensitization process, with a transition $t_{1/2}$ of 0.58±0.23 sec. In order to slow the rate of muscimol-induced desensitization, $^{36}Cl^-$ uptake was measured at 22°C, resulting in a relatively constant k_d over the first 5 sec. However, in the presence of triphenylphosphonium (50uM), the rate of desensitization was enhanced (transition $t_{1/2}$=1.04±0.15 sec). Similar results were obtained with phencyclidine. When Ca^{2+} was omitted from the medium, the inhibition of muscimol-induced $^{36}Cl^-$ uptake by each NCI except picrotoxin was significantly attenuated. Ca^{2+} also decreased muscimol-stimulated $^{36}Cl^-$ uptake in a concentration-dependent manner (IC_{50}=30uM) primarily via decreasing muscimol potency. These data suggest that the desensitization of the GABA receptor promoted by NCI could be mediated by Ca^{2+} mobilization. Under identical assay conditions, the NCI inhibited [^{3}H]t-butylbicycloorthobenzoate binding to synaptoneurosomes with the same IC_{50}s for inhibition of muscimol responses, indicating that these NCI of nAChR-gated cation channels also interact with convulsant sites on the GABA receptor-gated Cl^- ion channel.

264.5 DIFFERENTIAL ACTIONS OF PENTOBARBITAL AND PHENOBARBITAL ON GABA-ACTIVATED SINGLE CHANNEL CHLORIDE CURRENTS. R.E. TWYMAN, C.J. ROGERS AND R.L. MACDONALD. (Spon: S.Gilman) Department of Neurology, University of Michigan, Ann Arbor, MI 48104.

Barbiturates enhance GABAergic inhibition. To determine the mechanisms of pentobarbital (PB) and phenobarbital (PhB) enhancement of GABA-activated chloride (Cl^-) currents, we recorded single channel Cl^- currents from excised outside-out patches from mouse spinal cord neurons grown in dissociated cell culture.

Bathing and intrapipette recording medium consisted of a HEPES-buffered, equal Cl^- concentration solution. Strychnine (200 nM) was used in all solutions to block glycine-coupled Cl^- currents. Patches were held at the potassium equilibrium potential (-75 mV). Pressure ejection pipettes were used to apply GABA (2μM) alone or with PB (50 μM) or PhB (500 μM). Due to desensitization of GABA Cl^- currents, GABA applications were limited to 5 seconds. Responses were digitized at 8 kHz with 1 kHz Bessel filtering and analyzed by computer using the analysis program IPROC (Sachs et al., Pflugers Arch 395:331, 1982).

Two conductance states were recorded, but the larger, dominant state (~26 ps) was used for these analyses. Excised patches which were GABA sensitive had infrequent spontaneous, non-bursting Cl^- currents. GABA increased the probability of channel opening and evoked bursting currents. In the presence of PB or PhB, GABA-evoked currents had the same conductance but openings were more frequent, with an increase in burst number and a longer mean open time. In addition, PB, but not PhB, increased the mean number of openings per burst.

Both PhB and PB increased burst duration. However, PhB prolongation of burst duration was due to the prolongation of individual openings within the burst while PB prolongation of bursts was due to an increased duration of individual openings within the burst and an increased number of openings. Enhancement of GABA-activated Cl^- currents by PB and PhB may be due to 1) an increased number of channel openings, 2) an increased duration of individual channel openings and 3) an increase of burst duration. The effect of PB on burst duration was more pronounced than that of PhB and may account for the ability of PB to prolong GABA currents more effectively than PhB.

264.6 GABA-ACTIVATED CHLORIDE CURRENTS HAVE MULTI-STATE KINETICS IN CULTURED MURINE SPINAL CORD NEURONS. C.J.Rogers, R.E.Twyman and R.L.Macdonald. Dept. of Neurology, University of Michigan, Ann Arbor, Michigan, 48104.

Gamma aminobutyric acid (GABA) produces inhibition by increasing membrane chloride conductance. GABA-activated chloride currents have been shown to have three conductance states and to open in bursts (Bormann, Hamill and Sakmann, J. Physiol. (Lond) 385:243, 1987). We have studied the steady state gating properties of the largest (~26 pS) GABA-activated chloride conductance state. By analyzing frequency plots of open and shut durations we have determined that the GABA-activated chloride channel has multiple open and shut states.

GABA-activated Cl^- currents were studied using excised outside-out patches of mouse spinal cord neurons. Dissociated fetal neurons were cultured for 3-6 weeks prior to use. The medium used in the recording pipette contained in mM: KCl 153.33; $MgCl_2$ 1; Hepes 10; EGTA (EGTA 5, Ca^{++} .5, K^+ 12); NaOH 1; KOH 2; pH = 7.38. The bathing medium used for recording contained in mM: NaCl 142; $CaCl_2$ 1; KCl 8.09; $MgCl_2$ 6; glucose 10; Hepes 10; pH = 7.4. Strychnine (100 nM) was added to the bathing medium and to the GABA-containing solutions to block glycine-activated Cl^- currents. Patches were clamped at -75 mV. Micropipettes (tips broken to 20-30 μM were used to apply 2 μM GABA for periods of 5-10 seconds. Responses were digitized at 8 KHz with a 1 KHz 8 pole bessel filter. Data were analyzed using a modified version of the IPROC analysis program (Sachs et al., Pflugers Arch 395:331, 1982).

Two conductance states were recorded but the larger, dominant state (~26 pS) was used for these analyses. Excised patches which were GABA sensitive had infrequent spontaneous single opening, non-bursting currents. GABA (2 μM) increased the frequency of non-bursting currents and evoked bursting currents. Bursting was defined by periods of rapid channel opening and closings separated by designated longer shut periods. Frequency plots of open and shut durations were fit using the least squares method. The frequency plot of open durations could be fit by four exponentials and the frequency plot of shut durations could be fit by six exponentials. These data suggest that the GABA-activated chloride channel has at least ten states, four open states and six closed states. There may be also longer shut and open states which were not detected in our experiments due to the relatively short periods of GABA application. A method of burst analysis was developed using the shut state time constants. Four "burst terminators" were defined and burst properties were characterized using these burst terminators. These analyses have shown that the largest GABA-gated chloride channel has multi-state kinetics.

264.7 ACTIONS OF AVERMECTIN B_{1a} ON CHLORIDE CHANNELS IN RAT BRAIN SYNAPTONEUROSOMES. K. Matsumoto, M.E. Eldefrawi and A.T. Eldefrawi. Dept. Pharmacol. & Exp. Therap. Univ. Maryland Sch. of Med., Baltimore, MD 21201.

The macrocyclic lactone anthelmintics, avermectin B_{1a} (AVM) and ivermectin (dihydroavermectin), have been shown to interact with γ-aminobutyric acid (GABA) receptor-chloride channel complex in the central nervous system. These drugs not only stimulate GABA release from brain synaptosomes but also increase chloride channel conductance in cultured chick spinal neurons (Matsumoto et al., Neurosci. Lett. (1986) 69, 279). Preliminary data from our laboratory showed that AVM inhibited ^{35}S-*t*-butylbicyclophosphorothionate (^{35}S-TBPS) and ^{3}H-muscimol binding to rat brain synaptic membranes and also stimulated $^{36}Cl^-$ flux in rat brain microsac preparations (Abalis et al., (1986) 1,69). In the present study, we investigated the effects of AVM on $^{36}Cl^-$ efflux and ^{35}S-TBPS binding assays. Rat brain synaptoneurosomes were obtained by slightly modifying the method of Schwartz et al.(FEBS Lett., (1984) 175, 193). Whole brains were minced into small pieces and homogenized in 20 vol. of ice-cold Krebs-HEPES buffer. The homogenate was passed through 3 layers of nylon mesh (130 μm), then through a Millipore filter (10 μm). The filtrate was centrifuged at 1000 *x* g for 15 min. The pellet was washed by resuspension and recentrifugation to remove endogenous GABA, then used for efflux and binding assays. The time course of $^{36}Cl^-$ efflux from synaptoneurosomes was multiphasic. AVM (3 μM) significantly increased $^{36}Cl^-$ efflux compared to basal (control) efflux. The stimulatory effect of AVM on $^{36}Cl^-$ efflux was partly temperature-dependent (21° > 30° > 0°C). Muscimol (10^{-5}M) had no effect on $^{36}Cl^-$ efflux at various temperatures tested. Bicuculline methiodide, picrotoxinin and 4,4'-diisothiocyano-2,2'-stilbene disulfonic acid (DIDS) inhibited AVM-induced $^{36}Cl^-$ efflux. These agents also decreased basal $^{36}Cl^-$ efflux in the absence of AVM. AVM-induced $^{36}Cl^-$ efflux was not changed by other Cl^- transport blockers like anthracene 9-carboxylic acid and 2,4-dichlorocarboxylic acid (10^{-4} M). AVM-induced $^{36}Cl^-$ efflux was not decreased by pretreatment with 20 μM muscimol for 5 min. On the other hand, effects of AVM on ^{35}S-TBPS binding was biphasic: stimulating binding to a maximum at $3x10^{-8}$ M, with less stimulation up to 10^{-7} M and inhibition above 10^{-6} M. These results suggest that AVM directly activates chloride channels that are regulated by GABA and those that are not, through sites that are different from the GABA receptor.

(Supported in part by NIH grant ES 02594).

264.8 **MEMBRANE CURRENTS INDUCED BY GLYCINE IN NEURONS ISOLATED FROM *SPASTIC* AND CONTROL MICE.** D.L. Tauck, W.F. White and S.A. Lipton. Depts. of Neuroscience, Neuropathology & Neurology, Children's Hospital and Harvard Medical School, Boston, MA, 02115.

Behavioral and electromyographic abnormalities in the mutant mouse *spastic* suggest a decrease in inhibitory neurotransmitter function. Previous studies using receptor binding techniques have demonstrated an 80-90% decrease in the specific binding of ^{3}H-strychnine, a ligand for the post-synaptic glycine receptor, to the spinal cord, brainstem and midbrain of *spastic* compared with littermate control mice. Preliminary autoradiographic data indicate that the density of glycine receptors is decreased in the retina. Since mammalian retinal ganglion cells are known to be directly sensitive to glycine [Tauck et al., (1986) *Soc. Neurosci. Abstr.* 12(1):635], and since the cells can be labelled for unequivocal identification in culture, these are the neurons that were chosen for this study. Using the whole-cell mode of the patch-clamp technique, the present study compares the membrane currents induced by glycine in isolated central neurons from *spastic* and control mice.

The electrophysiological responses to glycine of cells isolated from *spastic* animals were indistinguishable from those of controls. Glycine, 100 μM, produced large increases in membrane conductance in all ganglion cells studied. The reversal potential of the current induced by glycine was dependent on the distribution of chloride ions across the membrane, consistent with chloride being the charge carrier of the glycine-induced current. The responses to 100 μM glycine were reversibly antagonized by 1 μM strychnine. Finally, the currents elicited by glycine decayed exponentially with a time constant of approximately 5 seconds.

These results demonstrate that the function of those glycine receptors which mediate inhibition in retinal ganglion cells is not compromised in the mutant mouse *spastic*. This discrepancy suggests that the receptors studied with autoradiographic techniques may be a different population than the ones that mediate fast synaptic transmission; alternatively, the discrepancy may indicate that only a small percentage of the glycine receptors studied with autoradiographic techniques are necessary to mediate the whole-cell currents measured with these techniques.

264.9 EFFECT OF AMMONIUM ON E_{GABA} IN CULTURED RAT HIPPOCAMPAL NEURONS. M.K. Walton*, W. Raabe and J.L. Barker.(SPON: J.M.H. ffrench-Mullen) Lab of Neurophysiology, NIH, Bethesda MD 20892 and Dept. of Neurology, VA Med. Ctr., Minneapolis, MN 55417

Ammonium levels are elevated in several clinical disorders and are believed to have a role in the pathophysiology of these disorders by effects on both inhibitory and excitatory pathways. In cerebral cortex, thalamus and spinal cord ammonium has been shown to readily shift the equilibrium potential of the IPSP by inactivation of extrusion of chloride from these neurons. However, there have been conflicting reports of the effect of ammonium on the IPSP equilibrium potential in mammalian hippocampus in vivo or in hippocampal slice. To re-examine the effects of NH_4^+ on hippocampal cells this study investigated the effect of NH_4^+ on the equilibrium potential for the GABA activated current (E_{GABA}) in cultured rat hippocampal neurons.

Hippocampal neurons from E19 rat embryos were grown in culture for 2 to 4 weeks. Cells were placed in a physiologic medium with 1uM TTX added to suppress spontaneous activity. Intracellular recording was carried out in control medium and in medium with NH_4Cl added (1-5 mM) using conventional sharp microelectrode pipettes filled with potassium acetate. GABA (20uM) was applied by brief pressure pulses from a pipette in close proximity to the recorded neuron. Intracellular current was used to briefly shift membrane potential to determine E_{GABA}, and to maintain a constant membrane potential between test pulses.

Ammonium shifted E_{GABA} in a depolarizing direction. NH_4^+, 1 mM, shifted E_{GABA} 2 mV, 2 mM NH_4^+ shifted E_{GABA} by 4 mV, and 5 mM NH_4^+ shifted E_{GABA} by 7 mV. NH_4^+ had no consistent effect on passive membrane properties.

In rat hippocampal neurons E_{GABA} is dependent on the chloride gradient across the neuron's membrane. The effect of NH_4^+ on E_{GABA} found in this study implies an increase in intracellular chloride. These results suggest that rat hippocampal neurons in tissue culture do have a mechanism for chloride extrusion that is sensitive to inactivation by ammonium.

264.10 **ALPHA ETHYL, METHYL THIOBUTYROLACTONE POTENTIATES GABA CURRENTS IN CHICK SPINAL CORD NEURONS.** C.F. Zorumski, J. Yang, K. Baker, D.F. Covey, D.B. Clifford; Departments of Psychiatry, Anatomy and Neurobiology, Pharmacology, and Neurology; Washington University Medical School, St. Louis, Missouri.

Alpha alkyl substituted thiobutyrolactones (TBLs) are heterocyclic molecules with anticonvulsant activity. Previously it was shown that these compounds are effective against pentylenetetrazole and maximal electroshock seizures. Binding, chloride flux and molecular modelling studies suggest that the anticonvulsant effects occur throughan action at the GABA chloride ionophore complex and specifically through an action at the picrotoxinin (PTXN) binding site. The present study was undertaken to investigate the electrophysiological effects of alpha ethyl, methyl thiobutyrolactone (aEMTBL),one of the most potent of the TBLs yet synthesized, on GABA currents in voltage clamped neurons.

Embryonic chick spinal cord neurons (SCN) were dissociated and grown in primary culture. Between 3-7 days after plating SCN were studied using gigaseal recording techniques. Pressure applications of aEMTBL produced a reversible dose dependent potentiation of GABA currents. The half maximal effective concentration was 7uM with saturation at 500uM. aEMTBL potentiated the response to all concentrations of GABA, increasing the response to a saturating GABA dose by 56%. The potentiation was not due to a GABA-mimetic effect as concentrations of aEMTBL up to 10mM failed to induce current.

Based on binding studies it is likely that TBLs interact with the PTXN site. The physiological consequences of an interaction of aEMTBL with this site was examined by attempting to reverse the block of GABA currents produced by 1mM PTXN. 500um aEMTBL produced a partial relief of PTXN block leading to a small inward current with a large increase in membrane noise during application of GABA. Neither phenobarbital (PB) nor diazepam (DZP) had any effect on PTXN block suggesting a difference between aEMTBL and other GABA potentiators. aEMTBL also enhanced GABA responses in the presence of saturating concentrations of either PB or DZP.

At a single channel level the potentiation of GABA currents by aEMTBl was manifest as an increase in the frequency of channel opening without a change in the single channel conductance (28-30ps for GABA alone and GABA+aEMTBL) or mean channel open time (8.3+/-1.7msec for GABA and 9.3+/-1.5msec for GABA+aEMTBL). In the presence of aEMTBL the GABA channel showed a near doubling of the probability that the channel is in an open state (17% vs. 9%).

In summary aEMTBL potentiates GABA currents in chick SCN. We propose that this potentiation occurs through an action at the PTXN binding site and that aEMTBL has features which differ from either barbiturates or benzodiazepines.

264.11 HETEROLOGOUS DESENSITIZATION OF THE GABA RECEPTOR COUPLED CHLORIDE ION CHANNEL BY ETHANOL: REVERSAL BY THE IMIDAZOBENZODIAZEPINE Ro15-4513. P.D. Suzdak, R.D. Schwartz and S.M. Paul*. Section on Molecular Pharmacology, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

The ability of ethanol, to "desensitize" the -aminobutyric acid (GABA) receptor-coupled chloride (Cl^-) ion channel was studied using a cell-free subcellular brain preparation (synaptoneurosomes) for measuring $^{36}Cl^-$ flux. Ethanol (20-100 mM) stimulates $^{36}Cl^-$ uptake into rat cerebral cortical synaptoneurosomes in a biphasic manner, with a maximal response at 50-70 mM (EC_{50} 30mM) [Suzdak et al., PNAS 83, 4071 (1986)] and a maximal stimulation of $^{36}Cl^-$ uptake of 11.5 nmole/mg protein/5 sec. Higher concentrations of ethanol (160 mM) resulted in a progressively smaller stimulation of $^{36}Cl^-$ uptake and blocked both muscimol (5 μM) and pentobarbital (500μM)-stimulated $^{36}Cl^-$ uptake. Following continuous exposure of synaptoneurosomes ($\leq$ 20 minutes) to ethanol (50mM), $^{36}Cl^-$ uptake diminished to a new steady state level with a $t_{1/2}$ of 1 minute. The decrement in response to ethanol was dependent upon both concentration and length of exposure, and was reversible. No decrement was observed in the ability of subthreshold concentrates of ethanol (10 mM) to enhance muscimol stimulated $^{36}Cl^-$ uptake following a 20 minute incubation. "Heterologous desensitization" to both muscimol and pentobarbital was observed in experiments where these agents were added following a 20 minute preincubation with ethanol (50 mM). The ability of ethanol to produce "heterologous desensitization" of the $GABA_A$ receptor was prevented by coincubation with Ro15-4513 (0.1 μM) but not with β-carboline inverse agonist DMCM (1 μM). By contrast Ro15-4513 did not block pentobarbital or muscimol-induced desensitization of the GABA receptor-coupled Cl^- ion channel confirming previous studies on its specificity in blocking ethanol stimulated $^{36}Cl^-$ uptake in vitro (Suzdak et al., Science 234, 1243, 1986). These data further suggest that ethanol, at pharmacologically relevant concentrations, interacts with brain GABA receptors and that Ro15-4513 is an antagonist of the action of ethanol at this receptor complex.

264.12 **IN VITRO SLICE PREPARATION AS A MODEL FOR INVESTIGATION OF GABA/BENZODIAZEPINE INTERACTIONS.** **S. Hussain,* J. Bagust,* C.R. Gardner*[1] and R.J. Walker. Dept. Neurophysiol., Southampton Univ. Southampton SO9 3TU, and [1]Roussel Labs., Swindon SN3 5BZ, England.**

In vitro brain slice preparations are a popular tool for neuropharmacological studies. Many areas of the mammalian brain have been used including the hippocampus, olfactory cortex, lateral geniculate nucleus and spinal cord (Kerkut, G.A. & Wheal, H.V., Electrophysiol. Isolated Mammalian CNS Preps., Academic Press, Lond., 1981). The cerebellum has been studied by a number of workers (Llinas, R. & Sugimori, M., J. Physiol. 305, 171, 1980) and its cellular organization is known. The pharmacological actions of Benzodiazepines (BDZs) are at least partly mediated by enhancing GABA transmission (Costa, E. et al., Life Sci., 17, 167, 1975) and certain clinically effective anticonvulsants interact with sites in the GABA-BDZ-chloride ionophore complex.

In the present study extracellular recordings were made from the Purkinje cell layer in the rat cerebellar slice (500 μm thick). Slices were continuously perfused with oxygenated Krebs at 25°C and a flow rate of 15 ml min^{-1}. The firing rate of the cells was in the range 5-80 Hz. Drugs were applied either by bath addition or ionophoretically using a multibarrel electrode placed in close proximity to the recording electrode.

GABA (0.1M in electrode) inhibited spontaneous activity in a current dose related manner (range, 5-100 nA, 15 sec duration). This inhibition was blocked by bath application of bicuculline salts, 0.5 μM. Pitrazepin and picrotoxin, both 5 μM, antagonised bath applied GABA inhibition of cell activity. Bath applied BDZs, eg. Flurazepam and RU 32007 also inhibited activity at mM concentration. At lower concentrations the BDZs produced a significant potentiation of submaximal GABA responses. For example, GABA, 50 nA, and Flurazepam, 50 nA, separately applied only caused slight inhibition of cell activity. When applied together they produced almost complete inhibition. This potentiation of GABA inhibition was blocked by the BDZ antagonist RO 15-1788 (0.1 M in electrode, 50 nA) All effects were readily reversed. Similar effects to flurazepam were obtained with RU 32007. The beta-carboline DMCM, a potent inverse agonist, did not appear to have any obvious effects. Bath application of up to 50 μM or ionophoretic application did not potentiate or inhibit GABA responses.

This work clearly demonstrates the modulatory effects of BDZs on GABA transmission. The use of cortical slice preparation and isolated spinal cord preparations for the analysis of GABA/BDZ interactions is also under investigation. In preliminary studies using isolated cord BDZs depress dorsal root afferent activity in a dose dependent manner but this depression is irreversible.

264.13 PHARMACOKINETICS OF FLURAZEPAM AND ITS METABOLITES IN RAT SERUM AND BRAIN. S. Dolan*, C.E. Lau*, M. Tang* and J. L. Falk. Dept. of Psychology, Rutgers Univ., New Brunswick, NJ 08903.

Flurazepam is a hypnotic agent used for the treatment of insomnia. Its pharmacokinetics and metabolic fate is known mainly from research with dogs, cats and humans but remains largely unknown in rodents. Since diazepam and its major metabolite desmethyldiazepam are eliminated differently in rats, compared to humans and other animals, flurazepam was studied to evaluate a similar possibility.

Groups of adult, male, albino rats were injected with flurazepam (16 mg/kg, i.p.). Brain and serum levels of flurazepam and its major metabolites were determined at various times between 15 min and 24 hr. Serum samples (50 ul) were buffered with borate buffer (pH 9) and extracted with diethyl ether. Following evaporation of the ether layer the residue was resuspended in mobile phase. Whole brain was homogenized in distilled water (1:4) and similarly extracted. Samples (20 ul) were analyzed by HPLC with UV detection at 230 nm on a 5 um Ultrasphere C18 2mm I.D. column. Mobile phase consisted of 0.03 M sodium acetate buffer (pH 2.9), acetonitrile and methanol (60:25:15 v/v). The flow rate was set at 0.3 ml/min.

This method identifies simulaneously flurazepam and the following metabolites: didesethyl flurazepam, monodesethyl flurazepam, N-1-hydroxyethyl flurazepam and desalkyl flurazepam, all of which were present in serum and brain with Tmax at 30 min. The elimination rates appear to be parallel for flurazepam and desalkyl flurazepam in both compartments with relatively short half-lives. In serum the t1/2 was 1.76 hr for flurazepam which is quite similar to the value for other species. In contrast, we found that the serum t1/2 for desalkyl flurazepam was 1.44 hr in the rat compared to values of 40 to 200 hours in dogs and humans. Hence, it appears that the pharmacokinetics of the major metabolites of both diazepam and flurazepam are quite different in rats and humans.

264.14 ALTERATIONS IN BRAIN CELLULAR METABOLISM OF RATS FOLLOWING IN UTERO EXPOSURE TO DIAZEPAM. M.C.K. KELLOGG AND R. MIRANDA. Dept. of Psychology, Univ. of Rochester, Rochester, N.Y. 14627.

Previous work has shown that exposure to diazepam (DZ) during the last week of gestation can induce alterations in the adult rat offspring that resemble the actions of DZ given acutely to naive adult rats. Additionally, concomitant exposure to DZ and the central benzodiazepine (BZ) antagonist RO15-1788 prevented the effects of DZ (Brain Res., 293:73 and 307:38,1984). While the central BZ receptor is considered to be associated with neural membranes, BZs also bind to a peripheral type receptor in the CNS that may be associated with subcellular membranes such as the mitochondrial outer membrane (Anholt, J.Biol. Chem. 261:576; 1986). The objective of the present study was to determine whether late gestational exposure to DZ altered cellular metabolism in the offspring, a possible consequence of a mitochondrial receptor location. To examine this possibility malondialdehyde(MDA)-like material was measured as an index of metabolic activity. MDA is an endproduct of a series of autocatalytic peroxidation reactions and of the synthesis of prostaglandins and thromboxines. Pregnant dams (Long Evans) were divided into groups and all injections were given subcutaneously once daily over gestational days 14-20. MDA was measured in 6 brain regions of exposed offspring at 3-4,16-18, and 24-26 months of age.MDA levels increased in most regions of uninjected and vehicle injected rats from 3 to 24 months; in the diencephalon and midbrain, however, the levels increased from 3 to 18 mo. and then decreased from 18 to 24 mo. Prenatal exposure to DZ elevated MDA levels at 3 months with the lower exposure dose (1.0 mg/kg) producing a larger increase than the higher dose (2.5 mg/kg). The pattern of aging-related changes in MDA levels was also altered by early DZ exposure in a dose-related manner. Exposure to 2.5 mg/kg induced an aging pattern in all regions similar to that seen only in control diencephalon and midbrain, whereas exposure to 1.0 mg/kg induced a profile similar to telencephalic regions and cerebellum of controls. Concurrent exposure to DZ (2.5 mg/kg) and RO15-1788 (10 mg/kg) did not prevent the effect of DZ and exposure to the antagonist alone produced an effect in young adults that was comparable to the effect of the low dose of DZ. The effect of the peripheral type antagonist PK-11195 is being evaluated. The results suggest an environmentally modifiable, dynamic, age-related involvement of BZ binding sites with intracellular metabolism. The central and peripheral sites may both be involved. Supported by grant MH-31850.

264.15 ALTERATION IN RAT BRAIN ^{31}P-NMR SPECTRA FOLLOWING IN UTERO EXPOSURE TO DIAZEPAM. R.MIRANDA, T.CECKLER*, R.GUILLET*, and C.K.KELLOGG. Depts of Psychology and Biophysics, Univ. of Rochester, Rochester, N.Y., 14627.

Exposure to diazepam (DZ) between gestational days 14-20 alters malondialdehyde (MDA) levels in young adult and aged offspring in a dose-dependent manner. The central antagonist RO15-1788 (RO) did not reverse this effect. Administered alone, RO induced an effect comparable to DZ. These findings suggest a dynamic age related involvement of benzodiazepine (BDZ) receptor subtypes with intracellular metabolism.

We analysed the effects of prenatal exposure to BDZs on intracellular metabolism using in vivo ^{31}P-NMR spectroscopy. Following prenatal exposure of Long Evans rats to vehicle, DZ(2.5mg/kg/day), RO(10mg/kg/day) or DZ+RO, ^{31}P spectra were acquired at 3-4, 16-18 or 24-26 months of age. A 2cm surface coil was placed over the head of a rat anesthetised with Ketamine and Xylazine. Spectra were acquired using a GE 2.0 Tesla CSI system (^{31}P-frequency 34.635 MHz). Parameters were: repetition rate, 3 sec; sweep width, 3 KHz; pulse width, 20 µsec. Convolution difference techniques were used to eliminate the broad lipid/bone resonance.

Intracellular pH (pHi) decreased with age in uninjected and vehicle controls, as did the ratio of phosphocreatine (PCr) to inorganic phosphate (Pi). The ratio PCr/ßATP did not change with age. At 3-4 mo. and at 24-26 mo. of age, DZ exposed animals showed a significant decrease in pHi from control levels. At 16 -18 months of age however, the differences in pHi were not significant. The 16-18 month period may be a critical period in the life span of the animal, representing a transition between late adulthood and old age that might involve changes in cellular energy metabolism.

Prenatal exposure to DZ did not alter PCr/Pi ratios from control values. The PCR/ßATP ratios differed between exposed and control groups only at 24-26 mo. If ßATP is relatively constant throughout the animal's lifespan, this could imply that there was an increase in PCr and Pi levels with treatment and age. One explanation of these results is that the cellular composition of brain tissue may change with age and be modified by prenatal drug exposure. At 3-4 months of age, pHi was also significantly reduced in animals exposed to RO alone, but not in animals exposed to DZ+RO. Also, RO administered alone or along with DZ, decreased PCr/Pi ratios in 3-4 mo. old animals without changing PCr/ßATP ratios. These results indicate that prenatal exposure to BDZs may alter relationships between PCr utiliztion and pHi. Alternatively, observed changes in ratios may be due to changes in relaxation rates of the different phosphate groups, indicating a change in their physical environment. Present research centers on the role of peripheral BDZ receptor ligands (PK11195), the effects of acute exposure to BDZs, and the relationship between PCr utilization and pHi. Supported by grant MH 31850.

264.16 MODULATION OF GABAERGIC FUNCTION IN THE SUBSTANTIA INNOMINATA BY THE MESOLIMBIC DOPAMINE SYSTEM. M.C. Austin and P.W. Kalivas, Dept. of VCAPP, Washington State University, Pullman, WA 99164.

It has been suggested that the behavioral hyperactivity produced by increased dopaminergic neurotransmission in the nucleus accumbens (NA) is mediated by inhibition of the GABAergic efferents from the NA to the substantia innominata (SI). Studies have demonstrated that pretreating the SI with the GABA agonist muscimol attenuates the locomotor activity elicited by dopamine injection into the NA. We evaluated whether the locomotor activity produced by cholinergic stimulation of the NA could be inhibited by pretreating the SI with muscimol. We also investigated the effect of 6-OHDA lesions of the VTA on GABA levels in the SI.

Male S.D. rats were implanted with chronic bilateral injection cannulae into the NA and SI. One week after surgery, rats were adapted to the photocell cages for one hour, pretreated with 2 or 5 µg/side muscimol intra-SI followed by an intra-NA injection of 0.33 µg/side carbachol and placed back into the photocell cages for 120 min. The carbachol-induced motor stimulant effect was significantly reduced by pretreating the SI with 2 or 5 µg/side muscimol.

To determine the effect of 6-OHDA lesions of the VTA on GABA levels in the SI, rats were unilaterally injected with 6-OHDA into the A10 region. Ten days following surgery, rats were sacrificed by head-focused microwave and the NA and SI dissected from the brain. Measurement of GABA was obtained by pre-column derivatization of the supernatant with t-butylthiol o-phthaldialdehyde for 6 min. and injection of the sample on HPLC. Lesion of the VTA significantly increased GABA levels in the SI compared to the nonlesioned side, whereas GABA levels were decreased in the NA. This may be explained as a disinhibition of GABA turnover in the SI by reducing DA inhibitory tone in the accumbens. These findings provide further support for the postulate that DA in the NA modulates GABAergic function in the SI. Studies are also planned to investigate the effect of direct stimulation of the NA on GABA levels in the SI.

264.17 COCAINE DECREASES GABA TURNOVER IN THE VENTRAL PALLIDUM AND NUCLEUS ACCUMBENS. A.J. Bordelais and P.W. Kalivas* (SPON: J.W. Wright), Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA.

It is known that GABAergic neurons in the nucleus accumbens (NA) project to the ventral pallidum (VP) (Br. Res. 177, 325, 1979). Furthermore, the increase in spontaneous motor activity produced by injection of dopamine (DA) agonists into the NA is prevented by pretreatment with a GABA agonist injection into the VP, which has led to the postulate that DA may be acting in the NA to inhibit tonic GABA modulation of neurons in the VP (Prog. Neurobiol. 14, 69, 1980). To more directly evaluate this hypothesis, GABA metabolism by GABA-transferase was inhibited by injection of aminooxyacetic acid (AOAA; 40 mg/kg, ip) which results in a linear increase in GABA levels over time that can be used as a measure of GABA turnover.

Male S.D. rats were injected with AOAA, and 15 min later injected with saline, ip, or cocaine (5, 10 or 20 mg/kg, ip). 45 min later, the rats were again injected with saline or the same dose of cocaine, and killed by head-focused microwave one hr later. The VP, NA, pedunculopontine region and A10 DA region were punched from the brain, and GABA levels measured with HPLC-EC using a t-butylthiol, o-pthaldehyde derivatization of GABA and 5-aminovaleric acid (internal standard). The derivatized GABA was separated on a C-18 reversed-phase column, and oxidized at +0.7 V. It was found that cocaine produced a decrease in the level of GABA in all brain areas examined. The decrease was dose-related in the VP, NA and A10 where only the highest dose of cocaine decreased GABA accumulation. This decrease was up to a 40% decline over control levels. In the pedunculopontine region, the lowest dose of cocaine was most effective at decreasing GABA accumulation. Since cocaine increases DA neurotransmission in the NA by preventing DA reuptake into the presynaptic terminal, these data support the hypothesis that DA release into the NA inhibits tonic GABAergic influence in the VP.

264.18 EFFECT OF GABA AGONISTS AND ANTAGONISTS ON EVOKED GABA RELEASE FROM PARS COMPACTA AND RETICULATA OF THE RAT SUBSTANTIA NIGRA. B. Floran *, I. Silva *, C. Nava *, and J. Aceves *. (SPON. H. Brust Carmona). Department of Physiology. Centro de Investigación del IPN. Apartado Postal 14-740. 07000 México, D.F.

In previous comunications we have presented data suggesting the presence of GABA "A" presynaptic autoreceptors on the GABAergic terminals of the pars compacta of the substantia nigra, and of GABA "B" receptors (autoreceptors?) probably on the GABAergic terminals of the pars reticulata. Continuing our characterization of these presynaptic GABA receptors, we are now reporting the results of a comparative study on the effects of muscimol, benzodiazepines (diazepam), baclofen, bicuculline and picrotoxin on the release of GABA from gabaergic terminals in nigra compacta and reticulata. Experiments were done in slices of either pars compacta or reticulata of the substantia nigra. To prevent the uptake by glial cells, the labelling with tritiated GABA was done in the presence of β-alanine (10 μM). To prevent part of the reuptake of the released GABA, the superfusion medium contained nipecotic acid (10 μM). The release was induced by continuous superfusion with high (15 mM) potassium. Muscimol inhibited in a dose-dependent manner the release from compacta, but had no effect on the release from reticulata. Diazepam (100 μM) potentiated the inhibitory effect of muscimol, without having any effect by itself on the release from compacta. Baclofen (100 μM) inhibited the release from reticulata without affecting the release from compacta. Both picrotoxin (100 μM) and bicuculline (10-100 μM) facilitated the release from compacta, but, in reticulata, picrotoxin had no effect and bicuculline inhibited the release. Confirming previous results the present ones strongly suggest the presence of two types of GABA receptors modulating the release of GABA from the gabaergic terminals of substantia nigra: the classical type "A" receptor (activated by muscimol, blocked by bicuculline, affinity increased by benzodiazepines) in pars compacta, and the type "B" receptors (activated by baclofen), where picrotoxin has no effect and bicuculline (surprisingly) behaves as an agonist. (Supported by CONACYT- México).

264.19 COMPARISON OF THE ACTIONS OF THE GABA-A AGONIST, MUSCIMOL AND THE BENZODIAZEPINE RECEPTOR AGONISTS, CGS 9896 AND DIAZEPAM ON GABA AND GLUTAMATE TURNOVER IN THE RAT CORTEX AND CEREBELLUM. G.A. Rowan, C.F. Flaherty, H.S. Kim, C. Cosi*, D.L. Cheney and P.L. Wood. Dept. of Psychology, Rutgers Col, New Brunswick, N.J., 08903 and Neuroscience Research, Research Dept., Pharmaceutical Division, CIBA-GEIGY Corp., Summit, N.J. 07901.

Studies of benzodiazepine receptor ligands in vitro have clearly indicated differences in both the affinity and efficacy of coupling between benzodiazepine and GABA receptors. There are, however, few detailed studies of the in vivo consequences of these differences in efficacy of coupling between these receptors at the synaptic level. We have, therefore compared the effects of the GABA-A receptor agonist, muscimol; the benzodiazepine receptor agonist, diazepam; and the agonist/antagonist benzodiazepine receptor ligand, CGS 9896, on GABA and glutamate turnover in the rat cerebellum and prefrontal cortex.

For these studies, rats were injected intravenously with infusions of [^{13}C]glucose and the incorporation of this label into CNS glucose, glutamate and GABA was monitored by gas chromatography-mass fragmentography. Using this approach, muscimol reduced both GABA and glutamate turnover in the cerebellum and prefrontal cortex. GABA turnover was also decreased in both brain regions by CGS 9896 and only in the prefrontal cortex by diazepam. The decrease in GABA turnover elicited both by muscimol and the benzodiazepine receptor agonists was greatest in the prefrontal cortex. In marked contrast to the direct GABA agonist, the benzodiazepine receptor ligands did not alter glutamate turnover in either brain region.

These data indicate regional differences in the efficacy of coupling of the benzodiazepine/GABA receptor complex regulating GABAergic tone. Also, with this method, no benzodiazepine modulation of basal glutamatergic tone was detected. However, the role of benzodiazepine/GABA receptor coupling in synaptically- or pharmacologically-activated glutamatergic neurons remains to be determined.

265.1 IN VIVO LABELLING OF CENTRAL BENZODIAZEPINE RECEPTORS WITH ^{3}H-RO 15-4513. Bernard Sadzot*, J. James Frost, and Henry N. Wagner, Jr.* (SPON: H. Mayberg). Division of Nuclear Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Ro15-4513 is a high affinity triazine derivative of the benzodiazepine (BZ) antagonist Ro 15-1788 and is classified as a partial inverse agonist. Ro 15-4513 has the unique property of antagonizing ethanol-stimulated GABA receptor-mediated uptake of $^{36}Cl^{-}$ and blocking the anticonflict and intoxicating actions of ethanol in vivo (P.D. Suzdak, et al., Science, 1243-1247, 1986). This unique property suggests that Ro15-4513 could be an interesting ligand to image benzodiazepine receptors in man using positron emission tomography. Current ligands for imaging BZ receptors in man include the nonbenzodiazepine agonist ^{11}C-suriclone and the agonist ^{11}C-Ro 15-1788.

Parallel in vivo binding experiments were carried out in mice using ^{3}H-Ro 15-4513 and ^{3}H-Ro 15-1788 (0.2-0.5 ug/kg). Some animals were pretreated with Ro 15-1788 (15 mg/kg, i.p.) or flunitrazepam (3 mg/kg, i.v.) 15 min. prior to the injection of each tritiated drug to define nonspecific binding. Mice were killed at 2-120 min. after ^{3}H- drug administration. The percent of the injected dose in the brain was high for both tritiated drugs (ca. 10%/g). The percent displacable binding for ^{3}H-Ro 15-4513 was greatest in the cerebral cortex and hippocampus (>90%) and lowest in the cerebellum (60-70%). For ^{3}H-Ro 15-4513, the relative regional distribution revealed particularly high specific binding in the hippocampus relative to the other regions. The ratio of specific binding for ^{3}H-Ro 15-4513 to ^{3}H-Ro 15-1788 at 15 min. post injection was computed for 11 brain regions. This ratio varied from 1.85 in the hippocampus to 0.27 in the cerebellum demonstrating that the regional binding is quantitatively different for the two ligands.

These results demonstrate that Ro 15-4513 can be used to determine the distribution of central BZD binding sites in vivo. The distribution of Ro 15-4513 binding is different from that of Ro 15-1788 which may relate to the unique ability of Ro 15-4513 in reversing the effects of ethanol. Ro 15-4513 is a ligand which could be used in PET studies to understand the receptor-mediated effects of ethanol.

265.2 MUSCIMOL BINDING DIFFERS IN KREBS-RINGER'S BICARBONATE AND TRIS-CITRATE BUFFERS: DISPLACEMENT WITH GABA. Geoffrey Fuller and Paul Madtes Jr. (SPON: V. Wahby). Departments of Biology and Chemistry, Point Loma Nazarene College, San Diego, CA 92106.

Characterization of the GABA receptor frequently involves the use of a TRIS-citrate (TRIS) buffer. This has allowed extensive analysis of the receptor. However, recent evidence suggests that this receptor is sensitive to the presence of various ions, such as sodium, bicarbonate, and chloride ions. Consequently, it has been suggested that a physiological buffer should be used to determine GABA binding. One ligand which often is used to measure GABA binding is muscimol, a potent agonist which binds to the GABA receptor. We previously reported the effect of different buffering conditions on ^{3}H-GABA binding, with displacement by GABA, and on ^{3}H-muscimol binding, with displacement by muscimol. We found that high-affinity GABA binding is maximal if measured under physiological conditions and is not dependent on the buffer used to prepare the tissue. In contrast, high-affinity muscimol binding is maximal if the tissue is prepared using TRIS and is not dependent on the assay buffer. Since apparently there are more muscimol receptors than GABA receptors, we studied whether the displacement of ^{3}H-muscimol by GABA differed from that by muscimol, depending on the buffering conditions. Fresh bovine retinas were isolated, homogenized in sucrose, and stored frozen until assayed for ^{3}H-muscimol, displacing with unlabelled GABA. Membranes were washed in either TRIS or Krebs-Ringer's bicarbonate (KRB) buffer and assayed in either the same or the opposite buffer. Both high- and low-affinity binding were higher when assayed in TRIS and lower when assayed in KRB. GABA-displaceable, high-affinity binding was low when membranes were washed and assayed in KRB. These data suggest that the conditions for muscimol binding which is displaceable by muscimol differ from those for muscimol binding which is displaceable by GABA. Therefore, the buffering conditions may reveal different subclasses of GABA receptors. Thus, the characteristics of GABA binding may depend upon the ionic environment during both tissue preparation and assay. This work was funded by a grant from Research Corporation.

265.3 BRAIN GABA-A RECEPTORS ASSOCIATED WITH CHLORIDE CHANNELS AND INNATE ALCOHOL SENSITIVITY. K. Nieminen, O. Malminen* and E.R. Korpi. Research Laboratories of the Finnish State Alcohol Company, Alko Ltd., POB 350, SF-00101 Helsinki, Finland.

Alcohol may enhance the actions of GABA, the main inhibitory neurotransmitter in the brain. In a series of studies on the role of GABAergic mechanisms in ethanol-induced motor impairment, we have now compared the brain GABA/benzodiazepine receptor-chloride ionophore complexes in two rat lines selectively bred for low (AT) and high (ANT) acute ethanol sensitivity.

In the cerebral cortex of naive ANT and AT rats the maximal stimulation of [^{3}H]flunitrazepam by GABA was slightly greater in the AT's than the ANT's, suggesting a larger number of GABA-A receptors associated with benzodiazepine receptors in the AT's. Scatchard analyses of [^{3}H]flunitrazepam binding in repeatedly washed cortical membranes, however, did not reveal any difference in the binding parameters between the lines. In solubilized (CHAPS) receptors from the cerebral cortices, GABA was found to enhance the binding of [^{3}H]flunitrazepam slightly more in the ANT's. In several AT samples, a clear GABA stimulation was observed, however, in the presence of ethanol.

We did not find any significant difference between the lines in cerebrocortical or cerebellar membranes in the binding parameters of a chloride channel ligand, t-[^{3}H]butylbicycloorthobenzoate ([^{3}H]TBOB). Also the GABA inhibition of [^{3}H]TBOB binding and the enhancement of this GABA effect by lorazepam was similar in both rat lines. Preliminary experiments using muscimol-stimulated $^{36}Cl^{-}$ flux assay in a preparation of cerebrocortical and cerebellar microsacs have not yet shown any meaningful differences between naive AT and ANT animals.

In conclusion, our present data do not suggest that any major modification in the rat brain GABA/benzodiazepine receptor-chloride ionophore complexes has occurred as a result of selective breeding for high and low sensitivity to the motor impairment produced by moderate doses of ethanol.

265.4 **METHYLXANTHINES DIMINISH GABA/BENZODIAZEPINE RECEPTOR FUNCTION THROUGH AN ADENOSINE RECEPTOR-LIKE MECHANISM.** D.J. Roca* and D.H. Farb (SPON: M. Halpern) Dept of Anatomy and Cell Biology, SUNY Health Science Center, Brooklyn, New York 11203

Benzodiazepines (BZDs) are thought to exert their behavioral effects by enhancing the activity of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). Biochemically, GABA-BZD interactions can be observed in binding studies, where it has been shown that BZDs enhance GABA binding and GABA enhances BZD binding. Chronic BZD exposure can diminish the ability of GABA to potentiate BZD binding. We refer to this reduction in the interaction between GABA and BZD binding sites as functional "uncoupling." Interestingly, methylxanthines (MXs), such as caffeine and theophylline, also bind to the BZD binding site and enhance GABA activity. Thus, we thought it would be of interest to examine the effects of prolonged methylxanthine treatment on BZD binding and its modulation by GABA. Seven day old primary chick brain cell cultures were treated for 36h with either theophylline, caffeine, or isobutylmethylxanthine (IBMX). Following treatment cells were harvested, homogenized and washed exhaustively. Reversible binding of 1 nM [^{3}H]flunitrazepam (FNZM) was determined by filtration in the presence and absence of GABA. Potentiation is expressed as the percentage increase of [^{3}H]FNZM binding over binding without GABA. Maximum enhancement of [^{3}H]FNZM binding by GABA was 70+3% (n = 31) in control cultures. In contrast, maximum GABA potentiation of [^{3}H]FNZM binding was reduced to 49+9% in theophylline treated cultures (EC_{50} = 0.89 nM, 25 pooled experiments), 45+9% in caffeine treated cultures (EC_{50} = 10 nM, 15 pooled experiments) and 55+3% in IBMX treated cultures (100 uM, n = 9). Chronic theophylline treatment did not significantly affect the B_{MAX} or K_D of [^{3}H]FNZM binding or the potency of GABA for potentiating [^{3}H]FNZM binding. Protein synthesis and degradation were unaltered after 36h exposure to theophylline, indicating that chronic treatment did not adversely affect cell viability. Chronic treatment of membranes did not result in uncoupling, suggesting that uncoupling requires active cellular function and is not due to a passive conformational change. Chloroadenosine (a stable adenosine receptor agonist) blocked the ability of chronic theophylline treatment to produce uncoupling, but did not alter the uncoupling induced by chronic treatment with flurazepam. This suggests that the MXs induce uncoupling through an adenosine-like receptor. In contrast the BZDs are thought to induce uncoupling through the BZD receptor. These results may help explain some of the side effects observed with chronic methylxanthine exposure.

265.5 THE CAGE CONVULSANT SITE OF THE LOCUST GABA RECEPTOR COMPLEX DIFFERS FROM ITS COUNTERPART IN MAMMALIAN BRAIN
M. J. Brown*, G. G. Lunt* and A. Stapleton*. (Spon. G. A. Bradfisch). Dept. of Biochemistry, University of Bath, England BA2 7AY and The Dow Chemical Company, Walnut Creek, CA. 94598.

We have described a GABA receptor complex in locust brain that has a basic organization of interacting binding sites similar to the well characterized receptor of mammalian brain (Robinson, T. N. et al J. Neurochem. 47, 1955, 1986). Nevertheless there are significant differences in the detailed pharmacology of the GABA/muscimol and benzodiazepine binding sites. We have now looked at the cage convulsant site of the locust receptor and some important differences have emerged.

Binding of [^{35}S]TBPS to locust brain membranes at equilibrium over the range 2 to 150nM gives a K_d of 10nM but such data produce Scatchard plots indicative of positive cooperativity. Such effects are not seen in parallel binding studies on rat brain membranes. Further examination of the kinetics of binding in the locust show that both the on and off rate constants vary with [^{35}S]TBPS concentration in a manner consistent with positive cooperativity.

The interaction of the TBPS binding site with other sites on the locust receptor complex was also examined. We observed enhancement of [^{35}S]TBPS binding by GABA, (+30-80%) diazepam (+20-40%) and pentobarbital (+25-50%) that is, the converse of what is generally seen in studies on mammalian brain GABA receptor. Additionally [^{35}S]TBPS binding in the locust was insensitive to picrotoxinin whereas in mammalian brain strong antagonism is seen. It has been reported that in housefly thorax preparations picrotoxinin is a weak inhibitor of TBPS binding and GABA enhancement of the binding is seen (Cohen, E. and Cassida, J. Pestic. Biochem. Physiol., 25, 63, 1986). In fly head membrane preparations [^{35}S]TBPS binding shows complex kinetics, is insensitive to muscimol but is inhibited by picrotoxinin (Szamraj, O. I., Miller, T. and Olsen, R. W. Abstr. Neurosci. 12, 656, 1986). Thus it seems that the cage convulsant site of the insect GABA receptor complex not only differs from the corresponding site in mammalian brain but differences between insect species may occur.

Supported by a grant from The Dow Chemical Company.

265.6 ALTERATIONS IN [^{35}S]TBPS BINDING BY HALIDE IONS.
K.M. Garrett*, M.S. Abel*, T. Popkave* and A.J. Blume. Molecular Neurobiology Group, Dept. of CNS Research, Medical Research Division of American Cyanamid Co., Lederle Laboratories, Pearl River, NY 10965

An integral component of the GABA-A receptor complex (GAR) is the chloride ionophore (CI). Other components of the GAR (i.e. binding sites for GABA, benzodiazepine and barbiturates) are known to allosterically interact with the CI as well as with each other. The "cage convulsant", [^{35}S]-t-butylbicyclophosphorothionate ([^{35}S]-TBPS), binds to a site associated with the CI. Previous studies have shown that [^{35}S]-TBPS binding is dependent on anions (Squires et al. 1983; Havoundjian et al. 1986). We have conducted experiments to further examine the mechanism by which halide ions stimulate [^{35}S]-TBPS binding in rat cortical membranes. Fluoride, Cl, Br and I produce a concentration dependent increase in [^{35}S]-TBPS binding. Binding at sub-saturating concentrations of [^{35}S]TBPS (2 nM) is greatest in Br followed by I > Cl > F. Iodide produces a biphasic response; increases at $\leq$ 100 mM and decreases > 200 mM. The EC_{50} values for F, Cl and Br are comparable (150-200 mM), however, that for I is much lower (16 mM). Scatchard analyses of [^{35}S]TBPS were conducted at various concentrations of the four ions. As the ion concentration increases the number of binding sites (Bmax) increases, whereas the KD for [^{35}S]TBPS is not altered. For example, the Bmax (pmol/mg prot) ranges from 2.3 in 25 mM to 5.6 in 100 mM NaCl. The KD is 138 nM over this range. For KI, the Bmax ranges from 4.5 to 6.6 in 25 mM and 100 mM, respectively. The KD under these conditions is 88 nM. It appears that the halide ions can affect [^{35}S]TBPS binding in two ways: 1) the affinity of the receptor is dependent on the specific halide ion and 2) the number of receptors is dependent on the concentration of the ion. Data will be presented on [^{35}S]TBPS binding for a number of other ionic conditions. The question as to whether all halide ions induce the appearance of the same maximal number of [^{35}S]TBPS binding sites will be discussed.

265.7 DIFFERENTIAL EFFECTS OF HALIDE IONS ON ALLOSTERIC INTERACTIONS OF THE GABA-A RECEPTOR COMPLEX.
M.S. Abel*, K.M. Garrett*, and A.J. Blume (SPON: B. Beer). Molecular Neurobiology Group, Dept. of CNS Research, Medical Research Division of American Cyanamid Co., Lederle Laboratories, Pearl River, NY 10965.

[^{35}S]t-butylbicyclophosphorothionate ([^{35}S]-TBPS) binds to a site on the GABA-A receptor complex (GAR) that is associated with the chloride ionophore. The GAR contains sites for other pharmacophores (i.e. benzodiazepines, barbiturates and GABAergic compounds) that are known to allosterically interact with each other. We have investigated the modulation of [^{35}S]TBPS binding by the above pharmacophores in the presence of various anions. Benzodiazepine (BDZ) agonists stimulate binding in F, Cl, and low Br (< 100 mM), but have no effect in I or high Br ($\geq$ 100 mM). Chloride allows the greatest stimulation (60%) followed by F and Br. The BDZ antagonist RO 15-1788 minimally stimulates binding in F and Cl (12% at 200 mM) and has no effect in Br or I. BDZ inverse agonists inhibit binding in F and Cl and have no effect in Br. Unlike BDZ agonists and antagonists, the inverse agonists stimulate binding in I (40% at 200 mM). GABA agonists and barbiturates produce biphasic effects in F, Cl and Br (< 50 mM), however, only the inhibitory phase is observed in I and high Br. Bicuculline, a GABA antagonist, stimulates binding in I, yet has no effect in F, Cl and Br. The stimulatory effects of bicuculline are similar to those seen for the BDZ inverse agonists and suggests an inverse agonist activity for bicuculline. RO 15-1788 specifically antagonizes the effects of BDZ agonists and inverse agonists and does not alter GABA and barbiturate effects. In addition, at concentrations with no intrinsic activity, bicuculline blocks GABA effects but not those of BDZs and barbiturates. These data suggest the following: 1) the effects of ligands for the GAR on [^{35}S]TBPS binding are qualitatively dependent on the specific halide ion and quantitatively dependent upon the concentration of the ion, 2) the effects of the various drugs are specific for the site of the GAR at which they interact, and 3) there is a continuum (inhibition → stimulation) of drug effects on [^{35}S]TBPS binding which correlates to the range (convulsion → sedation) of pharmacological responses for these drugs.

265.8 CHARACTERIZATION OF PERIPHERAL BENZODIAZEPINE BINDING SITES IN Nb2 NODE LYMPHOMA CELLS: EFFECTS ON PROLACTIN-STIMULATED ORNITHINE DECARBOXYLASE ACTIVITY AND PROLIFERATION.
H.E. Laird II, K.C. Duerson*, A.R. Buckley*, D.W. Montgomery*, and D.H. Russell*. Depts. of Pharmacol. & Toxicol. and Pharmacol., Colls. Pharmacy & Medicine, Univ. of Ariz.,Tucson, AZ, 85721.

^{3}H-Ro 5-4864, a specific ligand for the peripheral-type Benzodiazepine (P-BZ) receptor, binds to Nb2 Node Lymphoma cells in a specific saturable and reversible fashion. Scatchard analysis of the specific binding data reveals a single, homogeneous class of binding sites with an equilibrium dissociation constant of 3.941 ± 0.217 nM and a receptor density of 155 ± 11 fmol / 2 x 10^6 cells. Evaluation of the binding potencies of selected benzodiazepine (BZ) recognition site ligands showed a pattern characteristic of the P-BZ receptor (Ro 5-4864= PK11195>Diazepam>Flunitrazepam >>>>Clonazepam).

The range of high affinity ^{3}H-Ro 5-4864 binding paralleled the concentrations which enhance prolactin (PRL)-stimulated ornithine decarboxylase activity and ^{3}H-thymidine incorporation in Nb2 cells. Binding of Ro 5-4864 to high affinity P-BZ receptor sites (10^{-10},10^{-9} M) enhanced PRL-stimulated mitogenesis to values as high as 200% of PRL alone, whereas binding to low affinity binding sites (10^{-6} M) inhibited PRL-stimulated mitogenesis to values less than 80% of PRL alone, similar to the extent of inhibition reported in mouse thymoma cells in response to 10^{-6} M Ro 5-4864 (Wang et al., PNAS 81:753,1984). PRL and BZs may interact in the regulation of proliferation and/or differentiation in certain cell types. PRL and P-BZ receptors have similar tissue distribution patterns in rats. Interestingly, both have been reported to have tumor promotion properties in chemically-initiated rat liver, and both are implicated in nuclear oncogenic expression.

These data coupled with the known requirements for de novo RNA and protein synthesis for cell cycle pregression in response to a mitogenic stimulus, suggest a nuclear site of action for mitogenic or co-mitogenic properties. In support of this hypothesis, preliminary evidence has revealed high affinity binding sites for ^{125}I-PRL and ^{3}H-Ro 5-4864 in intact and functional nuclei from Nb2 Node Lymphoma cells. Studies are in progress to characterize these binding sites and to determine their function in regulating cell proliferation.

Supported in part by grants from the University of Arizona Foundation, the Office of the Vice-President for Research, the Arizona Disease Control Research Commission, and the Flinn Foundation.

265.9 CHARACTERIZATION OF PERIPHERAL BENZODIAZEPINE (P-BZ) BINDING SITES IN THE RAT LIVER. K. C. Duerson*, A.R. Buckley*, D.W. Montgomery*, D.H. Russell*, and H. E. Laird II (Spon: P. Consroe). Depts. of Pharmacol. & Toxicol. and Pharmacol., Colls. of Pharmacy & Medicine, Univ. of Ariz., Tucson, AZ, 85721.

Evidence suggests that the P-BZ binding site plays a role in the regulation of cellular proliferation (Wang, et al., PNAS 81:753,1984). Benzodiazepines (BZ) and Prolactin (PRL) may interact in the regulation of proliferation and/or differentiation in certain cell types. P-BZ and PRL receptors have similar tissue distribution patterns in rats. Interestingly, both have been reported to have tumor promotion properties in chemically-initiated rat liver, and both are implicated in nuclear oncogenic expression. The association between the P-BZ and PRL receptors in cellular proliferation has not been examined in this tissue.

The high affinity binding of ^{3}H-Ro 5-4864, the specific ligand for the P-BZ binding site, has been characterized in a crude membrane preparation from rat liver. ^{3}H-Ro 5-4864 binds in a saturable and reversible fashion to a single, homogenous class of binding sites with an equilibrium dissociation constant (Kd) of 4.9 + 0.3 nM and a receptor density (Bmax) of 658 ± 67 fmoles/mg protein. Evaluation of the binding potencies of selected benzodiazepine recognition site ligands showed a pattern characteristic of the P-BZ receptor: Ro 5-4864 = PK11195 > Flunitrazepam > Diazepam >>>> Clonazepam.

Examination of the subcellular distribution of P-BZ sites in the liver showed an increased density of sites in the nuclear fraction compared with the mitochondrial and microsomal fractions (Bmax = 1260, 938, and 936 fmoles/mg protein respectively). In order to characterize the P-BZ binding site, intact nuclei were isolated (Haddox and Russell, J. Cell Physiol. 109:447, 1981) from rat liver. Preliminary data using this preparation revealed a high affinity P-BZ binding site with Kd = 3.7 nM and Bmax = 1641 fmoles/mg protein. The binding in this preparation showed a two fold enrichment of P-BZ binding sites over the crude membrane preparation. In addition, there was an improvement in the degree of specific binding from 72% in the crude membrane preparation to 96% in the nuclear preparation.

Studies are in progress to characterize the nuclear P-BZ binding site and to explore its relationship to the PRL receptors in regulating cellular proliferation in the liver.

Suported in part by grants from the University of Arizona Foundation, the Office of the Vice-President for Research, the Arizona Disease Control Research Commission, and the Flinn Foundation.

265.10 RESPONSE TO VARIOUS BENZODIAZEPINE RECEPTOR LIGANDS FOLLOWING CHRONIC DIAZEPAM EXPOSURE IN RATS: SN RETICULATA SENSITIVITY AND GABA MODIFICATION OF RECEPTOR BINDING. M.A.Wilson, C.Heninger and D.W. Gallager, Dept. Psychiatry, Yale U.Sch.Med., Conn. Mental Hlth. Ctr., New Haven, CT 06508.

We previously reported that substantia nigra pars reticulata neurons (SNr) demonstrate reduced responses to systemically or iontophoretically applied benzodiazepines (BZ) following chronic diazepam (DZ) exposure(Wilson and Gallager,Eur.J.Pharm,1987). Such treatment also decreases the ability of GABA to enhance agonist binding. Following chronic agonist treatment, a shift in the spectrum of responsiveness of BZ ligands toward inverse agonists has been postulated (Little et al.,Br.J.Pharm.83, 1984; Peterson and Jensen, Eur.J.Pharm.133,1987). We have examined SNr responses to the antagonist Ro 15-1788 and the inverse agonist DMCM following chronic DZ exposure in rats. We have also examined the ability of chronic DZ treatment to alter GABA's effects on agonist, antagonist and inverse agonist binding.

Male rats were continuously exposed to constant levels of DZ (250 ng/g) for 3 weeks by the s.c. implantation of silastic capsules filled with crystalline DZ. Control animals received empty capsules. The administration of 1 mg/kg of the BZ antagonist Ro 15-1788 (i.v.) did not significantly alter the firing rate or iontophoretic sensitivity to GABA in control SNr. After chronic DZ treatment, Ro 15-1788 caused a significant increase in SNr firing rate to 42 ± 13 % above the pre-injection rate. GABA senstivity, however, was not altered by Ro 15-1788 administration (11 ± 8 % increase) and no GABA shift in Ro 15-1788 binding was observed in cortical membranes following chronic DZ exposure.

The systemic administration of the inverse agonist DMCM (0.05 up to 1.6 mg/kg,i.v.) induced a mean increase of 62% over basal firing rate in controls, which was reversed by Ro 15-1788. SNr responses to DMCM were apparently attenuated after chronic DZ treatment, at least in this dose range (6 ± 6 % vs 31 ± 9% in controls at 0.3 mg/kg). Ro 15-1788 administration following DMCM did not alter firing rate further. Although DMCM's effect on the GABA-induced shift in agonist binding was attenuated in cortical membranes from chronic DZ treated rats, this effect is complicated by a reduction in the GABA response after DZ treatment. We are currently analyzing GABA's effects on inverse agonist binding following chronic DZ exposure.

Thus, following chronic agonist administration, SNr responses to agonists and inverse agonists appear reduced. Reductions in both agonist and inverse agonist responses following chronic agonist treatment would suggest that such treatment modifies some common element coupling various BZ ligands with the GABA effector system.

Supported by USPHS Grant NS-23321, MH-13276 & State of Connecticut.

265.11 CHARACTERIZATION OF THE BENZODIAZEPINE/ALCOHOL ANTAGONIST RO 15-4513 BINDING SITES IN CEREBELLUM. D.M. Turner* and R.W. Olsen (SPON: A.K. Cho). Dept. of Pharmacology, Mental Retardation Research Center and Brain Research Institute, Univ. of California, Los Angeles,CA 90024.

The pharmacological properties of binding sites for the benzodiazepine and alcohol antagonist Ro 15-4513 were investigated. Several antagonist and inverse agonist ligands of the benzodiazepine receptor were found to inhibit binding to both those sites which were sensitive to diazepam and those unique sites which were insensitive to diazepam. The binding of [^{3}H]Ro 15-4513, described by Möhler, et al., Eur. J. Pharmacol. 102, 191-192 (1984) as a photoaffinity label for the benzodiazepine (BZ) receptor,was found to label a 51 kD band in various brain regions corresponding to the central BZ receptor labeled with [^{3}H]flunitrazepam, as well as a 57 kD band in cerebellar granular layer not labeled with [^{3}H]flunitrazepam and not blocked by 10 µM diazepam (Sieghart, et al.,J. Neurochem. 48, 46-52 (1987)). We measured reversible [^{3}H]Ro 15-4513 binding to cerebellar membranes and found two populations, diazepam sensitive (DZ-S) and diazepam insensitive (DZ-IS) sites. The DZ-S site had a K_d of 7 nM for Ro 15-4513 while the DZ-IS site had a K_d of 4 nM in frozen-thawed bovine cerebellum and in fresh rat cerebellum, with a four to five-fold greater abundance (B_{max}) of DZ-S sites to DZ-IS sites. Like cold Ro 15-4513 itself, several other benzodiazepine receptor ligands at 10 µM inhibited the [^{3}H]Ro 15-4513 binding to a greater extent than did 10 µM diazepam, demonstrating the binding of these compounds to the DZ-IS site. These compounds included Ro 15-1788, CGS-8216, DMCM and ZK93426, indicating that the DZ-IS site is inhibited by some antagonist and inverse agonist ligands including β-carbolines and a pyrazoloquinoline as well as the imidazobenzodiazepinones. Ro 15-4513 was reported (Suzdak, et al., Science 234, 1243-1247 (1986)) to antagonize the actions of ethanol in animal intoxication and in in vitro neurochemical activity involving potentiation of GABA-regulated ^{36}Cl- flux in synaptoneurosomes. However, in our studies at 0°C ethanol up to 100 mM did not affect the binding of [^{3}H]Ro 15-4513 to either the DZ-S site or the DZ-IS site; 200-500 mM ethanol inhibited only 5-15% of the control binding. Numerous drugs that modulate DZ-S (central BZ) receptors were tested on [^{3}H]Ro 15-4513 binding. Binding to DZ-S sites at 0°C was allosterically inhibited by etazolate, pentobarbital, muscimol and GABA, indicating a partial inverse agonist efficacy for Ro 15-4513. These ligands, however, did not appear to affect binding to DZ-IS sites, providing no direct evidence for association with GABA receptors. Thus the relevance of the DZ-IS binding sites to pharmacological actions of this unique imidazobenzodiazepinone drug remains to be explored.

265.12 GENETIC DIFFERENCES IN BENZODIAZEPINE RECEPTOR SENSITIVITY IN MICE. D. J. Nutt*, R. G. Lister*, M. Costello* (SPON: M. Eckardt) LCS/DICBR, NIAAA, Bldg. 10/3B19, 9000 Rockville Pike Bethesda, MD 20892.

The present studies investigate differences in benzodiazepine receptor function in inbred strains of mice using the partial inverse agonist FG 7142. In outbred mice FG 7142 is proconvulsant, producing a maximal effect at 40 mg/kg but does not cause seizures at any dose (1). When given at a dose of 40 mg/kg to inbred strains weighing approximately 30 gms (Jackson labs) it caused full seizures in varying numbers.

DBA/2J	7/7	C58/J	5/6
C57BL/6J	0/7	LP/J	0/8
C3H/HeJ	0/9	CBA/J	5/7
A/J	3/7	MA/MyJ	0/8

These results suggest that BDZ receptor efficiency may be increased in the inverse agonist direction in those strains having seizures. DBA/2 mice have been found to be particularly sensitive to the effects of other convulsants acting at the benzodiazepine receptor (2). An increased sensitivity to FG 7142 has been observed in mice tolerant to the anticonvulsant effects of benzodiazepines (3).

In 2 strains from Charles River CD_{50} measurements were made (4). These were: DBA/2N 10 ± 1.4 (mg/kg ± 95% confidence limits), C57BL/6N 20 ± 1.5; No seizures were observed in NIH Swiss mice at doses up to 40 mg/kg.

To explore receptor function in these strains further FG 7142 was administered daily at a dose of 1/2 the CD_{50} (40 mg/kg for the N.I.H. Swiss). In all groups a progressive increase in the number of mice having full seizures was seen (chemical kindling).

This sensitization to the convulsant effect of FG 7142 persisted after a 3 week drug-free period, with increased effects being noted in the C57's. Despite the different responses to the acute dose all 3 strains kindled roughly equally suggesting that this phenomenon is independent of the acute sensitivity to inverse agonists.

265.13 MIANSERINE, A NON-CONVULSANT ANTIDEPRESSANT, PARTIALLY REVERSES THE INHIBITORY EFFECT OF GABA ON ^{35}S-TBPS BINDING. R.F. Squires and E. Saederup.* The Nathan Kline Inst., Orangeburg, NY, 10962.

Most clinically used antidepressants can produce convulsions in overdosage and we have found that many of these antidepressants and/or their metabolites, reverse the inhibitory effect of GABA on ^{35}S-TBPS binding to rat brain membranes. Eleven clinically active antidepressants fully reverse 1 μM GABA, (Amoxapine, EC_{50} = 1.6 μM; SKF 10,810, 4.3 μM; Viqualine, 10 μM; Indalpine, 13 μM; Inkasan, 14 μM; Methylene Blue, 20 μM; Zimelidine, 24 μM; Dibenzepine, 54 μM; Minaprine, 44 μM; Viloxazine, 490 μM; and Deanol, 34 mM) and most of them are capable of producing convulsions. Imipramine, Amitriptyline, Nortriptyline,Trimipramine and Trazodone, although not GABA antagonists in this system, have metabolites that are: 2-hydroxy-imipramine, 10-hydroxy-amitriptyline, 10-hydroxy-nortriptyline, 2-hydroxy-trimipramine and 1-(m-chlorophenyl)-piperazine. In contrast, a group of 12 antidepressants only partially reverse the inhibitory effect of 1 μM GABA on ^{35}S-TBPS binding. (Mianserine, EC_{50} = 7.1 μM, 40% max. reversal; Fluotracene, 7.3 μM, 56%; Zometapine, 15 μM, 76%; Thiazesim, 16 μM, 79%; Quinupramine, 23 μM, 30%; Noxiptiline, 24 μM, 52%; Marplan, 29 μM, 23%; Doxepine, 34 μM, 31%; Citalopram, 140 μM, 22%; Tranylcypromine, 160 μM, 61%; MK 940, 330 μM, 53%; Fenmetozole (DH-524), 590 μM, 26%). Mianserine, the most potent of the partial reversers, is practically devoid of convulsant activity in humans, even after large overdosage (R.N. Brogden et al., Drugs, 16:273-301, 1978). Mianserine may, therefore, block a sub-set of GABA-A receptors, possibly involved in the clinical antidepressant effect, without blocking the GABA-A receptors involved in convulsions. Further, Mianserine has a pharmacological profile quite different from most other clinically effective antidepressants (R.M. Pinder and A.M.L. van Delft, Acta Psychiat. Scand., Suppl. 302, 59-71, 1983) (it is not a reserpine or tetrabenazine antagonist; it does not potentiate NE, DA or 5HT; it is not a muscarinic receptor blocker, and it is a strong 5HT antagonist), strengthening the hypothesis that it may exert its antidepressant effect by selectively blocking a sub-type of GABA-A receptors. Recently, 4 out of 5 novel partial reversers were found to act electrophysiologically as GABA mimetics on population spikes in the rat hippocampus, while one (pipazethate) was a potent GABA antagonist (Dalkara et al., Life Sci., 39:415-422, 1986). These results also tend to support the hypothesis of pharmacologically distinct GABA-A receptors with different distributions in the brain. It is proposed that some antidepressants may act by selectively blocking the inhibitory action of GABA on the brain's reward systems (J. Nazzaro and E.L. Gardner, Brain Res., 189:279-83 1980; H.C. Fibiger and A.G. Phillips, Science, 214:643-5, 1981).

265.14 **EFFECTS OF MEMBRANE FLUIDIZING TREATMENTS ON THE GABA-A RECEPTOR- CHLORIDE CHANNEL COMPLEX OF MOUSE BRAIN.** K.J. Johnson*, A.M. Allan, and R.A. Harris. Dept. Pharmacology, Univ. Colo. Hlth. Sci. Center, Denver, CO 80262; and VA Med. Res. Serv., Denver, CO 80222.

We found that the potencies of chemically diverse intoxicant - anesthetic drugs to inhibit [35S]TBPS binding and to enhance muscimol-dependent 36Cl uptake are correlated with their potencies as general anesthetics, suggesting that enhancement of GABA action is important for their anesthetic actions (Allan & Harris, JPET, in press). In the present experiments we investigated the ability of three diverse membrane fluidizing treatments to affect the GABA-A receptor-chloride channel complex.

ICR mice were sacrificed by decapitation and the whole brain was used in the preparation of membrane vesicles (microsacs). The microsacs were fluidized, as measured by the decreased polarization of 1,6-diphenyl-1,3,5-hexatriene (DPH), by temperature (24-36°C), 2-(2-methoxyethoxy)-ethyl 8-(cis-2-N-octylcyclopropyl) -octanoate (A2C; 2-600 uM), or benzyl alcohol (0.1-50 mM). [35S]TBPS (4 nM) binding and basal and muscimol-dependent 36Cl uptake were measured as previously described (Life Sci. 39: 2005, 1985).

Our results revealed that each of the three membrane fluidizing treatments reduced [35S]TBPS binding in a dose-dependent manner. At the highest concentration tested, benzyl alcohol (50 mM), A2C (600 uM), and temperature (36°C) reduced [35S]TBPS binding by 100%, 60% and 20%, and decreased DPH polarization by 0.035, 0.038 and 0.040, respectively. Although each of the treatments inhibited [35S]TBPS binding, as did anesthetic agents, their ability to reduce [35S]TBPS binding was poorly correlated with their ability to decrease DPH polarization. No change in nonspecific binding was observed with any of the membrane fluidizing treatments.

The anesthetic agents investigated previously enhanced muscimol-dependent 36Cl uptake. However, we found that increasing temperature had no pronounced effect on muscimol-dependent 36Cl uptake and increased basal 36Cl uptake; benzyl alcohol and A2C decreased muscimol-dependent 36Cl uptake with little effect on basal 36Cl uptake.

We conclude that the effects of membrane fluidizing treatments on muscimol-dependent 36Cl uptake do not mimic those of anesthetic agents, and effects of drugs on [35S]TBPS binding are not closely related to membrane fluidization. We suggest that the actions of general anesthetics on the GABA-A receptor-chloride channel complex are not due to changes in bulk membrane fluidity. Supported by the VA and AA06399.

265.15 THE EFFECT OF Ca, K, AND GUANYL NUCLEOTIDES UPON $GABA_B$ BINDING IN ADULT RAT CORTICAL MEMBRANES, AND CULTURED CHICK CEREBRAL NEURONS. M.I. Al-Dahan*, M.H. Jalilian Tehrani, E. M. Barnes Jr., and R.H. Thalmann. Depts. of Cell Biology, Biochemistry and The Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030.

We have examined several features of the $GABA_B$ receptor system in adult rat cortical neurons, and have begun to assay a culture of chick embryonic neurons for the same features. We have confirmed the findings of others that adult rat cortical neurons display $GABA_B$ binding in the presence of endogenous calcium only (15.1 ± 0.7 fmol/mg protein as inferred from exposure to 10nM [^{3}H]GABA in the presence of 100μM bicuculline). This binding was stimulated 2-3 fold in the presence of 2.5mM Ca (41.2 ± 6.2 fmol/mg). The GTP analogue GMPNP (0.5mM) reduced the binding of (^{3}H)GABA to membranes solubilized in 0.05% Triton X-100 (30.6 fmol/mg versus a control level of 79.6 ± 2 fmol/mg). Mg did not stimulate $GABA_B$ receptor binding to the same extent as did Ca (1.5-fold increase in the presence of 1.2-5mM Mg versus a 2.2-fold increase in the presence of 2.5mM Ca), suggesting that this stimulation of binding was to some degree related to an ion whose conductance is affected by $GABA_B$ receptors. However, we have been unable to find evidence for similar stimulation by another ion whose conductance is affected by $GABA_B$ receptors, namely, K. Indeed at K concentrations exceeding 5mM, binding was reduced by about 50%. The latter result may reflect the release of endogenous GABA by K. Cultures from embryonic chick cerebrum, cultured for 7-14 days, were found to have specific $GABA_B$ binding as assayed in the presence of 2.5mM Ca by [^{3}H] - GABA in the presence of 100μM bicuculline (11.8 ± 3.8 fmol/mg), or by [^{3}H] - baclofen (10.9 ± 5.1 fmol/mg). This binding density was 20-30% of that assayed under similar conditions in adult rat cortex or adult chicken cerebrum using [^{3}H] - GABA or [^{3}H] - baclofen. $GABA_B$ binding was stimulated about 2-fold by 2.5mM Ca with an EC 50 of less than 10μM, as in the case of adult rat cortical membranes. GMPNP also inhibited GABA binding. Thus far, then, several features of an adult mammalian $GABA_B$ receptor system appear to be expressed in the chick neuronal cultures, namely 1) the presence of $GABA_B$ receptors, 2) the regulation of these receptors by calcium and 3) evidence of $GABA_B$ linkage to a GTP-binding protein. Supported by NIH grants NS21713, DK17436 and NS11535.

265.16 SUBACUTE ADMINISTRATION OF BICUCULLINE ON GABA RECEPTOR CHARACTERISTICS IN RAT BRAIN. Yoshihisa Ito*, Dong Koo Lim*, Beth Hoskins* and Ing K. Ho. Dept. Pharmacol. & Toxicol., Univ. MS Med. Ctr., Jackson, MS 39216.

Effects of acute and subacute administration of bicuculline on [^{3}H]-muscimol binding to various brain regions of Sprague-Dawley rats were studied. In subacutely treated animals, rats received bicuculline, 2 mg/kg, ip, daily for 10 days. For acute treatment, rats received saline vehicle daily for 9 days and bicuculline, 2 mg/kg, ip, on the 10th day. The control group received saline vehicle once a day for 10 days. The volume of injection was .1 ml/100 g body weight. All animals were sacrificed 30 min after the last injection.

There was no significant change in growth rates in rats treated subacutely with bicuculline. However, in these rats there was a significantly increased [^{3}H]-muscimol binding in frontal cortex, cerebellum, striatum and substantia nigra. The increase in [^{3}H]-muscimol binding was 69% in frontal cortex, 38% in cerebellum, 16% in striatum and 49% in substantia nigra. Scatchard analysis of the binding isotherms revealed that the K_d of high affinity binding sites was significantly lower in rats treated subacutely with bicuculline as compared to that of the control animals in all the regions studied. A significant increase in the B_{max} of high affinity sites was observed in cerebella of rats treated subacutely with bicuculline as compared to that of control groups, with no change in frontal cortex, striatum and substantia nigra. As far as low affinity binding sites were concerned, a significantly lower K_d in frontal cortex and a significantly higher B_{max} in cerebellum were noted in rats treated subacutely with bicuculline.

Studies on the in vitro displacement curve of [^{3}H]-muscimol binding by bicuculline also revealed that the K_i of bicuculline was significantly lower in rats treated subacutely with bicuculline as compared with that of the control animals. The acute administration of bicuculline, however, affected neither K_d nor B_{max} of both high and low affinity binding sites of various regions studied.

These results suggest that $GABA_A$ receptors are upregulated after subacute administration of bicuculline. (This study was partially supported by grant 5/SO7 RR05386 awarded by the Biomedical Research Support Grant Program, Division of Research Resources, National Institutes of Health.)

265.17 MODULATION OF γ-HYDROXYBUTYRATE BINDING BY GABA RECEPTOR COMPLEX LIGANDS. A. C. Nichols and O.C. Snead, III, Neuropsychiatry Research Program and Pediatrics Department, Univ. of Alabama at Birmingham, Birmingham, AL 35233.

Gamma-hydroxybutyric acid (GHB) produces generalized absence seizures in rodents. Augumentation of GABAergic transmission appears to exacerbate this effect. In the present study, we explored what effects modulators of the GABA chloride ionophore have on the specific binding of ^{3}H-GHB in rat synaptosomal membrane preparations. It has already been shown that chloride and other anions that are permeable to the chloride ion channel inhibit binding of [^{3}H]-GHB (Snead,Epilepsia 25:671, 1984). Therefore the effect of various agonists, antagonists, and modulators of the gamma aminobutyric acid (GABA)-benzodiazepine - picrotoxin chloride ionophore on specific, high affinity ^{3}H-GHB binding in synaptosomal membranes was determined. These compounds included GABA, the $GABA_A$ agonist muscimol, picrotoxin, diazepam, and pentobarbital. In addition the $GABA_B$ agonist baclofen and the glycine antagonist strychnine were also tested to determine if these compounds affected [^{3}H]-GHB specific binding.

^{3}H-GHB was custom labeled from gamma-crotonolactone. After 3 months it was necessary to repurify the ^{3}H-GHB by TLC. Pentobarbital and picrotoxin strongly enhanced ^{3}H-GHB binding while diazepam produced a more modest enhancement of binding. The other compounds showed no effect. This binding enhancement of binding was seen both in the presence and absence of 100 mM chloride, and was not anion dependent. Our data suggests that the GHB binding site may in some way modulate the chloride ion channel.

Such a mechanism could explain the convulsive action of GHB, and account for the fact that GABA potentiates experimental generalized absence seizures (King, Neuropharmacology 18:47-55, 1979)

265.18 EMBRYONIC DEVELOPMENT OF TWO CLASSES OF BENZODIAZEPINE BINDING SITES IN THE CHICK. T.T. Gibbs*, L.A. Borden* and D.H. Farb (SPON: H.-S. Yin). SUNY Health Science Center, Brooklyn, NY 11203.

We have examined the embryonic development of 2 classes of benzodiazepine binding sites in the embryonic chick CNS. Binding was examined by competition and saturation, using as radioligands [^{3}H]flunitrazepam, a classical benzodiazepine anxiolytic, and [^{3}H]Ro5-4864, a convulsant benzodiazepine. High-affinity (K_d = 2.3 nM) [^{3}H]flunitrazepam binding sites (site-A) are present as early as embryonic day 5 (Hamburger and Hamilton stage 27) and increase throughout development (B_{max} = 0.3 and 1.3 pmol/mg protein in 7 and 20 d brain membranes, respectively). When either 7 or 20 d brain membranes are photoaffinity labeled with [^{3}H]flunitrazepam and ultraviolet light, the radioactivity migrates as 2 bands on SDS-PAGE (Mr 48000 and 51000), indicating that high affinity flunitrazepam binding sites are similar in early and late embryos. Potentiation of [^{3}H]flunitrazepam binding by GABA was evident at both 7 and 20 d of development, indicating that functional coupling between site-A and the GABA receptor is acquired early in development.

Importantly, we have also identified a novel site (site-B) that binds classical benzodiazepine agonists with low affinity (micromolar), but displays high affinity (K_d = 41 nM) for Ro5-5864. Site-B exhibits characteristics expected for a functional receptor, including stereospecificity and sensitivity to inactivation by heat or protease treatment. Saturation binding studies employing [^{3}H]Ro5-4864 indicate that levels of site-B are similar in 7 and 20 d brain (ca. 2.5 pmol/mg protein). The function of site-B is not known, but its early appearance in embryonic brain suggests that it may play a role in early embryonic development.

GABA AND BENZODIAZEPINE RECEPTORS: MOLECULAR CHARACTERIZATION

266.1 PREPARATION AND PROPERTIES OF PURIFIED PEPTIDE SUBUNITS OF THE HUMAN BRAIN GABA RECEPTOR COMPLEX. M.Bureau*, A.I.Dilber*, G.Smith* and R.W. Olsen (SPON:A.V.Delgado-Escueta). Dept. Pharmacology and Brain Research Institute, Univ.California, Los Angeles, CA 90024.

Peptide subunits from affinity column-purified GABA-benzodiazepine(BZ) receptor from human brain were prepared by preparative SDS-PAGE, identified by photoaffinity labelling and immunoblotting, and eluted for further chemical characterization. Frozen human brain (parietal,frontal cortex) obtained at autopsy from neurologically normal patients was provided by the Human Neurospecimen Bank, Wadsworth VAH, Los Angeles. GABA-BZ receptor binding properties in human brain membranes were similar to those of animal tissues. Triton X-100 solubilized receptor from 100 g brain was purified about 1000-fold on an immobilized BZ affinity column (Stauber et al.,Eur.J.Biochem. in press) and photoaffinity labeled (Deng et al., BBRC 138,1308,1986). Aliquots of 100 pmol [^{3}H]FLU binding sites were incubated for 60 min at 4°C with 10 nM [^{3}H]FLU, followed by UV irradiation for 10 min. Aliquots precipitated with TCA, centrifuged and washed, showed incorporation of large amounts of covalently incorporated protein-bound [^{3}H]FLU. SDS-PAGE, followed by radioactivity measurement on the sliced gel, revealed a major [^{3}H]-FLU labeled band at 52 kD and minor bands at 58 kD and 46 kD, corresponding to three of the major stained bands in the purified receptor. The major BZ binding subunit (52 kD) was similar to that observed in rat and cow brain preparations, recognized on immunoblots by a monoclonal antibody bd24 specific for the BZ-binding subunit of the GABA-BZ receptor (Schoch et al., Nature 314,168 1985). The 46 kD band was variable and appears to be a proteolytic break-down product of the 52 kD peptide. The 58 kD band lightly labeled with [^{3}H]FLU corresponds to the GABA-binding subunit photolabeled with [^{3}H]muscimol that binds Schoch antibody bd17. Two other stained peptides observed at 32 kD and 62 kD were not labeled with [^{3}H]FLU, [^{3}H]muscimol, or Schoch antibodies, and may represent contaminants, break-down products, true subunits, or cytoskeletal elements. Preparative gels were electrophoresed using mg amounts of purified receptor, and all 5 peptides were eluted from the gel for further chemical analysis and antibody production. The major subunits (52 and 57 kD) gave no N-terminal sequence, so are being fragmented and purified by HPLC for sequencing.

Supported by NIH Grant NS 21908.

266.2 PHOSPHORYLATION OF A SUBUNIT OF THE GABA/BENZODIAZEPINE RECEPTOR BY A RECEPTOR-ASSOCIATED PROTEIN KINASE. P.M. Sweetnam, J.F. Tallman, D.W. Gallager, and E. J. Nestler. Department of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Changes observed in the functional state of the GABA/benzodiazepine receptor in response to GABA and benzodiazepine exposure suggest that the receptor undergoes reversible modification. Yet, the molecular basis of such changes remain unknown. In the present study we investigated whether the GABA/benzodiazepine receptor undergoes phosphorylation.

Partially purified preparations of GABA/benzodiazepine receptor were obtained from rat brain by use of benzodiazepine affinity chromatography. Such preparations contain a major protein of M_r 50 kD, designated the α subunit of the receptor, plus a number of other proteins of unknown identity. The β subunit of the receptor has not yet been identified. Aliquots of the receptor preparation were incubated in the presence of standard phosphorylating conditions for 15 min at room temperature. The phosphorylated samples were then analyzed by one dimensional SDS polyacrylamide gel electrophoresis or two dimensional electrophoresis with isoelectric focusing in the first dimension.

Analysis of the samples by one dimensional electrophoresis revealed that a number of proteins in the receptor preparation are phosphorylated by an endogenous protein kinase activity present at high levels in the preparation. A major, broad phosphorylated band was observed with a M_r of about 52-50 kD. Two dimensional electrophoresis was employed to determine whether phosphorylated 50 kD receptor subunit was contained in this band. By two dimensional electrophoresis, it was found that a major phosphoprotein band comigrated with the coomassie blue-stained purified 50 kD receptor subunit; this band also comigrated on accompanying gels with the photolabeled and immunolabeled 50 kD receptor subunit. Peptide mapping and immunoprecipitation will be used to definitively identify this comigrating phospoprotein as the receptor. Another major phosphoprotein band was a highly acidic protein of M_r 52 kD; the identity of this protein, which did not correspond to a coomassie-blue stained protein band in this preparation, remains unknown.

Initial attempts to characterize the endogenous protein kinase activity present in the receptor preparation showed that it was not altered by cyclic AMP, cyclic GMP, calcium plus calmodulin or phosphatidylserine, protein kinase inhibitor, trifluoperazine, or EGTA under the assay conditions used. In addition, the protein kinase activity did not appear to be affected by various GABA and benzodiazepine agonists and antagonists.

Further studies are needed to characterize receptor phosphorylation and the associated protein kinase activity, as well as to determine their physiological significance.

266.3 BIOCHEMICAL PROPERTIES OF THE BENZODIAZEPINE-GABA RECEPTOR PROTEIN FROM CODFISH BRAIN. L. Deng *, R.W. Olsen, and M. Nielsen[1]. Dept. Pharmacology and Brain Research Institute, Univ. California, Los Angeles, CA 90024, and [1]Psychopharmacology Lab., Sct. Hans Hospital, Roskilde, Denmark.

The molecular weight of benzodiazepine (BZ) and GABA receptor proteins from brains of the North Atlantic codfish were estimated by photoaffinity labeling and irradiation inactivation target size analysis. Crude codfish brain homogenates bound [^{3}H]flunitrazepam (FLU) and [^{3}H]Ro 15-1788 with affinity, quantity, and pharmacological specificity similar to mammalian brain central BZ receptors. Crude membranes and receptor purified several hundred-fold on a BZ affinity column were photoaffinity labeled with [^{3}H]FLU and analyzed by SDS-PAGE as described in Deng et al., BBRC 138, 1308 (1986). A major radioactive band was observed in both cases at 53 kD, corresponding to the [^{3}H]FLU-labeled peptide from rat brain run in an adjacent lane. A minor peak about 10% as big was observed at 47 kD; labeling of both was prevented by 10µM diazepam. Irradiation of frozen intact codfish brains, preparation of membranes, binding assays, and target size estimations were performed as described in Nielsen et al., Biochem. Pharmacol. 34, 3633 (1985). Scatchard plots (7 concentrations) were employed to determine Bmax values for several radiation doses (0-20 Mrad). In contrast to photolabeling studies, the radiation target size for BZ receptor ([^{3}H]Ro 15-1788 binding) was 31,400 ±4000 daltons (n=6) and for GABA receptor ([^{3}H]muscimol binding to Ag+-activated membranes or [^{3}H]GABA binding to frozen-washed membranes) was 71,500 ±10,000 daltons (n=4). This contrasts with target sizes of 50-55 kD for both activities in rat brain, consistent with the photolabeled peptide bands on SDS-PAGE. The contribution of different subunits to these binding activities, as well as possible effects of proteolysis, on the codfish BZ-GABA receptor protein is being investigated with affinity column-purified samples. Comparison of different animal species may allow interesting structural insight into the evolution of the receptor-chloride channel complex.

Supported by NIH Grant NS 22071.

266.4 BENZODIAZEPINE AGONISTS PROTECT A HISTIDINE RESIDUE FROM DIETHYL PYROCARBONATE MODIFICATION WHEREAS PROPYL BETA-CARBOLINE DOES NOT. B. Lambolez* and J. Rossier. Laboratoire de Physiologie Nerveuse, CNRS, 91190 Gif-sur-Yvette, France.

The binding sites for both benzodiazepines and beta-carbolines (two competitive ligands of the benzodiazepine receptor) were studied in membranes of rat cerebral cortex in order to determine whether they are partially or completely overlapping.

A 57% decrease of the binding of the benzodiazepine antagonist (^{3}H)Ro 15-1788 was observed between pH 7.5 and 5.5. This suggested that a histidine residue, which has a side chain pK_a in this pH range, may be important in benzodiazepine binding.

An Eadie-Hofstee analysis of (^{3}H)Ro 15-1788 binding showed a 46% decrease in the number of sites (B_{max}) at pH 5.5 as compared to pH 7.5, the affinity (K_d) remaining unchanged.

This indicates that the protonation of a histidine residue within or close to the benzodiazepine binding site blocks the benzodiazepine binding. This was confirmed using diethyl pyrocarbonate, a quite selective reagent of histidine residues, under the following conditions: 1 mM diethyl pyrocarbonate in 20 mM sodium phosphate buffer containing 0.2 M NaCl at pH 6 was found, in 15 min at 20°C, to block 67% of (^{3}H)Ro 15-1788 binding sites without changing the K_d as revealed by Eadie-Hofstee analysis.

In order to assess whether this histidine residue is located inside or adjacent to the benzodiazepine and beta-carboline binding sites, experiments were performed using either benzodiazepine or beta-carboline to protect (^{3}H)Ro 15-1788 binding against diethyl pyrocarbonate treatment. It was found that flunitrazepam, a benzodiazepine agonist, completely protects the benzodiazepine binding site from diethyl pyrocarbonate modification, whereas the propyl beta-carboline does not.

This histidine residue may be a part of the benzodiazepine agonists binding site which is distinct from the beta-carboline binding site. In this case, this histidine residue would be sterically protected when benzodiazepine agonists are bound.

Alternatively, this histidine residue may be allosterically hidden away from diethyl pyrocarbonate modification in a conformation of the benzodiazepine receptor macromolecule which would be stabilised by the binding of benzodiazepine agonists but not by the binding of antagonist propyl beta-carboline.

266.5 PERIPHERAL-TYPE BENZODIAZEPINE RECEPTORS: ISOLATION FROM OUTER MITOCHONDRIAL MEMBRANES: PORPHYRINS AS ENDOGENOUS LIGANDS: HORMONAL ASSOCIATIONS. A. Verma*, R.R. Trifiletti*, E.M. Michael*, S.H. Snyder. Departments of Neuroscience and Obstetrics and Gynecology, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Besides interacting with "central type" receptors in the brain, benzodiazepines (BZ) bind with high affinity to receptors in peripheral tissues. Insight into their function derives from subcellular fractionation studies localizing the receptor to outer micochondrial membranes (Anholt et al. J. Biol. Chem. 261:576, 1986). After photoaffinity labeling with [^{3}H]flunitrazepam we have purified the peripheral receptors to apparent homogeneity and identified two SDS-PAGE bands at 30 KD and 35 KD. The 35 KD band appears identical to the voltage dependent anion channel of outer mitochondrial membranes, designated mitochondrial porin. In analyzing tissue extracts for substances competing for receptor binding, we have isolated porphyrins as endogenous ligands of high affinity (KI=15 nM for protoporphyrin IX) (Verma et al. PNAS 84:2256, 1987). The selective, intense localization of BZ receptors to Leydig cells of the testes and the glomerulosa cells of the adrenal cortex suggested a role in hormone synthesis and/or secretion (DeSouza et al., Endocrinol. 116:657, 1985). We now report autoradiographic localization of [^{3}H]PK11195 labeled BZ receptors in rat ovary selectively to theca interna cells and to the corpus luteum, which are steroidogenic, while granulosa cells of ovarian follicles lack receptors. Benzodiazepine and porphyrin effects on hormonal secretion may clarify receptor function.

266.6 PURIFICATION OF THE GABA/BENZODIAZEPINE RECEPTOR COMPLEX BY IMMUNOAFFINITY CHROMATOGRAPHY. D. Park*, J. Vitorica* and A.L. de Blas. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, NY 11794.

The $GABA_A$ receptor (GABAR) is a membrane protein functionally associated to benzodiazepine receptor (BZDR), the Cl^- channel and a receptor for the barbiturates. We have purified the GABAR/BZDR complex from bovine brain by affinity chromatography on the immobilized benzodiazepine Ro 7-1986/1 according to the method of Sigel et al.[1]. Monoclonal antibodies (mAbs) and antisera to the affinity purified GABAR/BZDR complex have been produced[2]. We have used the mAb 62-3G1 for the purification of the GABAR/BZDR complex by immunoaffinity chromatography. The mAb 62-3G1 immunoprecipitated the [^{3}H]flunitrazepam (FNZ) and [^{3}H]muscimol binding activities of the affinity purified receptor complex. In addition, the mAb 62-3G1 immunoprecipitated the [^{35}S]TBPS binding activity from CHAPS-solubilized membranes. The mAb 62-3G1 also reacted with the affinity purified receptor complex in a solid phase radioimmunoassay. In immunoblots using either affinity purified receptor complex or crude rat brain membranes, the mAb 62-3G1 bound to the 57,000 Mr peptide but it did not react with the 51,000 Mr peptide.

For immunoaffinity chromatography, the mAb 62-3G1 was coupled to Affigel-10. The GABAR/BZDR complex, either photoaffinity labeled or not with [^{3}H]FNZ, was solubilized from rat brain membranes and applied to the 62-3G1 Affigel-10 column. After several washes, the bound receptor was eluted with 50 mM citrate (pH 3.0)/ 0.05 % Triton X-100. Under these conditions, between 50% and 80% of the [^{3}H]FNZ binding activity was retained by the column, and between 60% and 80% of the retained activity was eluted from the column in a single peak. Therefore the yield of this procedure was 3-4 fold higher than the yield of the ligand affinity chromatography. The SDS-PAGE and silver staining of the immunoaffinity purified receptor, revealed peptides of 51,000 and 57,000 Mr.

266.7 COMPARATIVE ANALYSIS OF GABA/BENZODIAZEPINE RECEPTOR PROTEINS PURIFIED FROM RAT CEREBELLUM, SPINAL CORD, ADULT AND EARLY POSTNATAL CORTEX. Thomas N. Sato*, Alessandro Guidotti and Joseph H. Neale. Department of Biology and Fidia-Georgetown Inst. for Neurosciences, Georgetown University, Washington D.C. 20057.

The GABA/benzodiazepine receptors have been characterized as type I and type II, based upon a higher affinity of type I for β-carbolines and the triazolopyridazine compound, Cl 218872. We have analyzed GABA/benzodiazepine receptor diversity associated with the pharmacologically defined type I and type II receptors with 2-D gel electrophoresis of the protein constituents of purified (up to 2000-fold) receptor preparations from cerebellum and spinal cord, well as from postnatal day 8 and adult rat cortex.

The Triton X-100 solubilized GABA/benzodiazepine receptor complex was purified by Ro7-1986/001-agarose affinity chromatography and elution with clorazepate. The benzodiazepine was removed by DEAE-Sephacel chromatography and the purified receptor preparations assayed for benzodiazepine and GABA binding. The receptors purified from cerebellum exhibited maximal sensitivity to Cl 218872, indicating a high concentration of type I receptor, while the sensitivity of the cortical preparation was consistent with the presence of a greater concentration of type II. Purified spinal cord receptor as well as that from 8 day postnatal rat cortex were relatively insensitive to Cl 219972, indicating the presence of nearly exclusive populations of type II receptors. In contrast to the pharmacological differences exhibited by the purified adult cortex and cerebellum receptors, they had very similar protein constituents, when analyzed by IEF-SDS PAGE. Two-dimensional analysis of flunitrazepam photolabeled proteins in the two purified preparations further supported the conclusion that they were very similar. When the purified neonatal and spinal cord receptors were analyzed by SDS-PAGE, they differed from the cerebellum and adult cortex in the mobility of major proteins. Data on the properties of receptor complex proteins, as determined by IEF-SDS PAGE, together with 2-D TLC peptide maps of individual proteins will be useful in formulating more precise models of receptor structure, relatedness, diversity and development. (supported by NIDA grant, DA 02297)

266.8 A QUANTITATIVE EVALUATION OF THE RELATIVE AMOUNT OF SPECIFIC GABA-BENZODIAZEPINE RECEPTOR mRNA AFTER INJECTION OF TOTAL mRNA INTO XENOPUS OOCYTES. E. Zyzek*, B. Vimort* and J. F. Pujol* (SPON : A. Calas) Lab. de Neuropharmacologie - Fac. Medecine Alexis Carrel - Rue Guillaume Paradin - 69372 Lyon Cédex 2 - France.

GABA-benzodiazepine receptor-chloride channel complexes could be detected by electrophysiological recordings in Xenopus oocytes previously injected with messenger RNA extracted either from optic lobes of chick embryos or adult rat hippocampus. The oocyte's ability to translate correctly exogenous messengers was used to develop a routine method which could allow a quantitative evaluation of the specific mRNA coding for the GABA-benzodiazepine receptor proteins among total mRNA injected. The conditions for the validation of this method were determined. According to the equation describing the dose-response curves of the electrophysiological response to GABA as a function of the total mRNA concentration injected in oocytes, we concluded that total mRNA extracted from the optic lobes of chick embryos were more enriched in specific GABA-receptor mRNA than total mRNA from rat hippocampus. This method could be extended to others tissues and/or receptors messengers quantification.

GABA AND BENZODIAZEPINE RECEPTORS: BEHAVIORAL STUDIES

267.1 ALTERATIONS OF THE BEHAVIORAL EFFECTS OF BENZODIAZEPINE RECEPTOR LIGANDS DURING CHRONIC DIAZEPAM ADMINISTRATION. C.A. Sannerud*, J.M. Cook and R.R. Griffiths* (SPON: S.E. Lukas). The Johns Hopkins Univ. Medical School, Baltimore, MD 21205 and the University of Wisconsin, Milwaukee, WI 53201

Chronic administration of benzodiazepines (BZ) produce a number of physiological alterations including physical dependence on the drug which is manifest by the appearance of a withdrawal syndrome upon termination of drug administration. In order to more fully understand the functional changes produced by chronic BZ administration, the behavioral effects of several BZ receptor ligands which appear to exist on a continuum of efficacy were assessed in BZ-dependent baboons chronically receiving 20 mg/kg/day diazepam. Dose-effect functions for the behavioral effects of a BZ agonist (midazolam maleate MDZ; 0.32-100 mg/kg), an antagonist (Ro15-1788 Ro; 1-32 mg/kg), and an inverse agonist (ß-CCE HCl; 0.32-100 mg/kg) were determined in dependent baboons by scoring behavioral signs of sedation and excitation for 1 hour after intramuscular injections. The behavioral effects of ß-CCE (0.32, 3.2, 32 mg/kg) in combination with Ro (3.2, 10 mg/kg) were also determined in dependent baboons.

Compared to the effects of these compounds observed in non-dependent baboons (Sannerud et al., Fed. Proc. 46:1301, 1987), qualitative and quantitative differences in the expression of these signs were found in dependent baboons. ß-CCE produced dose-dependent increases in abnormal postures, limb tremor, vomiting and jerks/convulsions in both the dependent and non-dependent baboons, however ß-CCE was 3-10 times less potent in dependent baboons. MDZ produced sedation and ataxia in non-dependent baboons, but produced no such effects in dependent baboons, even at doses 100-fold higher than those producing effects in non-dependent baboons. Although Ro produced no behavioral signs in the non-dependent baboon, Ro produced an inverse agonist-like profile of behavioral effects in the dependent baboons: a dose-dependent increase in limb tremor, abnormal postures and jerks/convulsions. The Ro precipitated withdrawal syndrome in dependent baboons was similar to the behavioral effects produced by ß-CCE in non-dependent baboons. When given in combination, Ro potentiated the effects of ß-CCE producing increases in abnormal postures, limb tremor, twitches/jerks and vomiting. Taken together, these data show that physical dependence may quantitatively and qualitatively change the effects of BZ ligands. If the rightward shift of the ß-CCE curve in dependent baboons is assumed to reflect competition with diazepam at the receptor site, the remaining observations suggest that physical dependence appears to shift the effects of BZ ligands along a continuum of efficacy in the direction of the inverse agonist. Supported by DA-01147.

267.2 AN INCREASE IN LOCOMOTOR ACTIVITY PRODUCED BY CENTRAL ADMINISTRATION OF BETA-CARBOLINE-3-CARBOXYLIC ACID ETHYL ESTER IN RATS. L. J. Wichlinski and R. A. Jensen. Biopsychology Laboratory, Department of Psychology, Southern Illinois University, Carbondale, IL 62901.

Recently we reported that beta-carboline-3-carboxylic acid ethyl ester (B-CCE) produces a suppression of locomotor activity in rats when given at a dose of 10.0 mg/kg i.p. (Wichlinski, L.J. & Jensen, R.A., Soc. Neurosci. Abstr., 12:660, 1986. This effect is attenuated by the benzodiazepine receptor antagonist Ro 15-1788 suggesting an involvement of benzodiazepine-receptor systems. However, we cannot be sure that the B-CCE-induced suppression of locomotor activity is due to activation of central benzodiazepine/B-CCE recognition sites. The discovery that benzodiazepine receptors exist in peripheral tissues (Kataoka, Y. et al., Proc. Nat. Acad. Sci., U.S.A., 81:3218, 1984) raises the possibility that this suppression of locomotor activity may be the result of a peripheral site of action for this compound.

To confirm that B-CCE is suppressing locomotor activity via initial activation of central benzodiazepine/B-CCE recognition sites, we administered B-CCE (5.0 and 10.0 ug) directly into the lateral ventricles. Locomotor activity was assessed using automatic activity monitors for the next 30 minutes. Preliminary data indicate that both doses of B-CCE increase locomotor activity in rats. This finding stands in contrast to the reduction in activity seen after peripheral administration of this compound. The elevation in activity level is most apparent during the latter half of the 30 minute period. While vehicle-treated rats habituate, B-CCE-treated rats fail to do so during the latter portion of the activity period. Testing with a wider dose range of B-CCE is necessary to determine whether this compound produces distinct effects on activity depending on the route of administration. In addition, further studies must be undertaken using benzodiazepine receptor antagonists to verify that this increase in activity after central administration is in fact mediated by benzodiazepine receptor systems.

We thank G. D. Searle and Co. for their contribution of the B-CCE and Ro 15-1788 (E-909) used in these experiments.

267.3 GABA AGONISTS MODULATE THE BEHAVIORAL EFFECTS OF LORAZEPAM IN SQUIRREL MONKEYS. Joseph G. Wettstein* and Roger D. Spealman* (SPON: Peter B. Dews). Harvard Medical School and New England Regional Primate Research Center, Southborough MA 01772.

Benzodiazepines (BZs) bind to recognition sites on protein complexes that also contain receptors for GABA. Previous studies have shown that GABA agonists can enhance the binding of BZ agonists in vitro, but little is known about the consequences of such interactions in vivo. The purpose of this study was to assess how pretreatment with the GABA agonists SL 75102 (4-{[(chlorophenyl)-5-fluoro-2-hydroxyphenyl)methylene]-amino}butyric acid) and THIP (4,5,6,7-tetrahydroisoxazolo-[5,4-c]-pyridin-3-ol) modify the behavioral effects of the prototypical BZ lorazepam. Comparison studies were conducted with SL 75102 and THIP combined with pentobarbital, which also appears to act at the GABA/BZ complex. Two groups of monkeys responded under a fixed-interval schedule of food presentation; in one group, responding was suppressed by a superimposed fixed-ratio schedule of response-produced electric shock. Dose-effect curves were determined by giving cumulative doses i.v. during timeout periods that preceded sequential components of the fixed-interval schedule.

When given alone, lorazepam (0.01-0.3 mg/kg) produced dose-dependent increases in the rates of both suppressed and nonsuppressed responding, effects characteristic for BZ antianxiety drugs. Pentobarbital, in contrast, had little effect except at the highest dose (5.6 mg/kg), which decreased responding. Neither SL 75102 (1.0-10.0 mg/kg) nor THIP (0.03-1.0 mg/kg) markedly altered rates of either suppressed or nonsuppressed responding. Pretreatment with SL 75102 (1.0 or 10.0 mg/kg) enhanced the rate-increasing effects of lorazepam on both suppressed and nonsuppressed responding, resulting in leftward shifts in the lorazepam dose-effect curves. Pretreatment with THIP (0.3 or 1.0 mg/kg) did not enhance the rate-increasing effects of lorazepam. Instead, the lorazepam dose-effect curves were either unchanged or shifted downward and rightward. The effects of pentobarbital were not altered systematically by pretreatment with either SL 75102 (10.0 mg/kg) or THIP (1.0 mg/kg).

The finding that SL 75102 enhanced the behavioral effects of lorazepam suggests a biologically significant counterpart to the interaction between GABA agonists and BZs at the receptor level. Enhancement of the behavioral effects of BZs does not appear to be a necessary consequence of pretreatment with GABA agonists, however, as THIP altered the effects of lorazepam in a complex manner without producing enhancement. There was no evidence that either GABA agonist altered the effects of pentobarbital. (USPHS support: DA02658, DA00088, RR00168.)

267.4 THE BENZODIAZEPINE RECEPTOR SYSTEM IN LS AND SS MICE: BEHAVIORAL AND BIOCHEMICAL STUDIES. B. J. Martin*, R. J. Marley*, A. Stinchcomb*, and J. M. Wehner. Instit. for Beh. Genetics and School of Pharm., Univ. of Colorado, Boulder, CO 80309.

Previous studies from our laboratory have demonstrated that long sleep (LS) and short sleep (SS) mice do not differ in the affinity or number of benzodiazepine (BZ) receptors in forebrain and cerebellum. They do, however, differ in GABA and ethanol enhancement of BZ binding in these regions (Alc. and Drug Res. 7: 25-32, 1986 and Alcohol, in press), as well as in behavioral sensitivity to anticonvulsant, hypothermic, and sedative properties of benzodiazepines (data submitted). In current studies the Plus elevated maze was used to measure the anxiolytic effects of diazepam and ethanol. LS mice were more sensitive than SS mice to the effects of diazepam at 1 mg/kg, exhibiting a greater percentage of entrances into and amount of time spent in the open arm vs. the closed arm of the maze ($P < .05$). LS mice also demonstrated a greater anxiolytic response due to ethanol (1 g/kg), as indicated by a significant difference between the two lines for entrances in the open arm ($P < .01$).

In order to determine possible mechanisms that underlie differences in enhancement of ^{3}H-flunitrazepam (FNZ) binding between LS and SS mice, we have examined ^{3}H-GABA binding and patterns of heat denaturation of ^{3}H-FNZ binding in forebrain and cerebellar tissue from LS and SS mice. The two lines did not differ in either the affinity or number of high and low affinity ^{3}H-GABA binding sites in either region. They also did not differ in the degree of bicuculline competition of ^{3}H-GABA binding. However, significant differences were observed between LS and SS mice in the patterns of heat denaturation of ^{3}H-FNZ binding in the forebrain region ($P < .001$), but not in the cerebellum. Differences were also observed in the degree to which GABA (0.1 mM) protected the BZ receptor from heat denaturation in both regions ($P < .001$). Analyses of these denaturation curves suggested that the observed differences in half-life ($t_{1/2}$) for denaturation may be due to variations in the molecular structure of one subtype of BZ receptor, whereas differences in the degree of protection by GABA may reflect differences in the relative proportions of BZ receptor subtypes.

From these data we conclude that differential sensitivity of LS and SS mice to benzodiazepines may be explained by molecular differences in the GABA/BZ receptor complex or intregal membrane constituents associated with the receptor complex that result in differential denaturation of the benzodiazepine receptor. 267.5 THE EFFECTS OF Ro15-4513 ON GENERALIZED MOTOR ACTIVITY. L.T. Johnson,* H.L. June and M.J. Lewis. Dept. of Psychology, Howard University, Washington, D.C. 20059.

The imidazobenzodiazepine compound Ro15-4513 has been shown to block the behavioral effects of ethanol (ETOH). Published reports (Bonette, Burkard, Gabl, and Mohler, 1986) show that Ro15-4513 antagonizes both the sedation as well as the motor impairment induced by ETOH. More recently, consistent with the above findings, Suzdak, Glowa, Crawley,Schwartz, and Paul (1986) have reported that Ro15-4513 also blocks the anti-conflict and intoxicating effects of ETOH. While these preliminary reports address both the anti-conflict and intoxicating effects of Ro15-4513, the effect of Ro15-4513 on the depressive effects of ETOH on generalized locomotor activity has not been investigated. The purpose of this study was to investigate the effects of Ro15-4513 on generalized motor activity.

Generalized motor activity of 14 male Charles River rats was assessed by the Omnitech Digiscan activity monitor system. Daily sessions were 10 minutes each. Baseline activity measures were obtained for 3 days under drug-free conditions (4% tween-80 vehicle intraperitoneal injection). Each animal then received 2.5 and 1.25 mg/kg intraperitoneal injections of Ro15-4513 alone. Each was followed by at least 2 drug-free sessions. Animals were then divided into two groups. The first group (n=8) received 2.5 mg/kg Ro15-4513 i.p. Ten minutes later animals received .75 gm/kg ETOH i.p. The second group (n=6) received .75 gm/kg only. Neither dose of Ro15-4513 alone produced any significant difference in activity from baseline levels. Animals receiving both Ro15-4513 and ETOH also showed difference in activity from baseline. Only animals receiving ETOH, however, showed a significant depression in generalized locomotor activity. These results show that Ro15-4513 is effective in attenuating the depressive effects of ETOH on generalized locomotor activity. Furthermore, they are consistent with the previous reports of the effects of this compound on the behavioral effects of ETOH (Suzdak et al., 1986) in the literature.

267.6 THE PARTIAL INVERSE BENZODIAZEPINE AGONIST RO 15-4513 POTENTIATES ETHANOL INDUCED SUPPRESSION OF WHEEL-RUNNING IN THE RAT. M.A. Bixler and M.J. Lewis. Dept. of Psychology, Howard University, Washington D.C. 20059.

Evidence suggests the imidazobenzodiazepine Ro 15-4513 blocks both the anticonflict and behavioral intoxicating effects of ethanol (ETOH) (Suzdak, P.D. et al., Science, 234: 1243, 1986). In a series of experiments, the ability of Ro 15-4513 to block acute ETOH-induced (0.75 g/kg; 30% v/v; i.p.) suppression of wheel-running was assessed.

ETOH administration alone, in combination with Ro 15-4513 (2.5mg/kg in 4% Tween 80/saline; i.p.), and Ro 15-4513 alone all produced an approximately 70% decrease in wheel-running.

Ro 15-4513 administered at 2.5, 1.25, 0.625, 0.312, 0.156, and 0.078 mg/kg doses revealed a dose-dependent suppression of wheel-running . All except the 0.078 mg/kg dose produced significant suppression. Pretreatment with this dose also failed to block ETOH suppression of wheel-running . Moreover, a trend in the direction of greater suppression in the pretreated subjects was noted. In a subsequent experiment, pretreatment with Ro 15-4513 (3.0 mg/kg) produced greater suppression of wheel-running performance (90%) than ETOH administration alone (53%).

These data suggest that wheel-running behavior is particularly sensitive to both the effects of ETOH and Ro 15-4513, and that in this task this inverse benzodiazepine agonist does not block ETOH induced suppression.

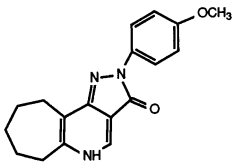
267.7 **CGS 20625: PHARMACOLOGICAL PROFILE OF A PYRAZOLOPYRIDINE ANXIOSELECTIVE ANXIOLYTIC WITH PARTIAL AGONIST/ANTAGONIST ACTIVITY.** M. Williams, D. A. Bennett, P. A. Loo*, A. F. Braunwalder*, C. L. Amrick, D. E. Wilson, N. Yokoyama* and J. W. F. Wasley*. Drug Discovery Division, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

CGS 20625 (2(4-Methoxyphenyl)-2,3,5,6,7,8,9,10-octahydrocyclohepta[b]-pyrazolo-[3,4-d]pyridin-3-one) is a potent and selective ligand at the central benzodiazepine (BZ) receptor (IC-50 =1.3 nM). The compound had a GABA ratio of 0.9 and stimulated TBPS binding to the chloride channel component of the BZ complex by 20%, a profile indicative of a partial agonist.



CGS 20625

In vivo, CGS 20625 blocked a pentylenetetrazol discriminative cue (ED-50 = 1.7 mg/kg p.o.) and selectively increased conflict responding with an MED of 0.3 mg/kg p.o. The compound generalized to both diazepam and CGS 9896 with ED-50 values of 9.7 and 0.9 mg/kg p.o. respectively. CGS 20625 had no effect on variable interval responding or rotorod performance, indicating a reduced tendency to cause muscle relaxation or sedation. The compound potentiated the actions of ethanol at a dose of 30 mg/kg, in contrast to diazepam which was active at 5.4 mg/kg p.o. CGS 20625 had no marked effects on rat locomotor activity and did not potentiate hexobarbital-induced sleep time until a dose of 100 mg/kg p.o. CGS 20625 antagonized diazepam-induced rotorod deficit (ED-50 = 7.2 mg/kg p.o.) indicating intrinsic antagonist properties.

CGS 20625 has a preclinical profile indicative of an anxioselective agent with minimal tendency for the side effects associated with the classical BZs. The partial agonist/antagonist profile of the compound is unique and may be responsible for its lack of side effects.

267.8 A COMPARISON OF THE DISCRIMINATIVE STIMULUS PROPERTIES OF CHLORDIAZEPOXIDE AND THE ß-CARBOLINE ZK 95 962.

D. N. Stephens and J. S. Andrews, Dept. of Neuropsychopharmacology, Schering AG, P.O.Box 65 03 11, D-1000 Berlin 65, F.R.G. (SPON: W. Kehr)

Classical benzodiazepines (BZ) are clinically effective anxiolytics, but the anxiolytic properties are confounded by unwanted sedative and muscle relaxant effects. Recently BZ-receptor ligands have been synthesised which possess only some BZ-like properties. The ß-carboline ZK 95 962 has been identified as a partial agonist at the BZ receptor. ZK 95 962 generalises to chlordiazepoxide (CDP) in drug discrimination procedures, has anxiolytic (Stephens, D.N. et al., Pharmacol. Biochem. Behav. in press) and antiepileptic properties but is non-sedative (Chapman, A.G. et al., Pharmacol. Biochem. Behav. in press).

Rats were trained to discriminate either CDP (5 mg/kg) from vehicle, or ZK 95 962 (10 mg/kg) from vehicle in a standard FR 10 food reinforced, 2-lever discrimination (Stephens, D.N. et al., Psychopharmacology 83 (1984) 233-239). Differences in the interoceptive properties of the two cues were investigated by comparing the effects of a range of BZ receptor ligands in generalising to, or antagonising the respective cues.

CDP and ZK 95 962 generalised to one another at similar doses (ED_{50}'s: CDP in CDP cue 2.5 mg/kg, CDP in ZK 95 962 cue 1.5 mg/kg; ZK 95 962 in CDP cue 1.6 mg/kg, ZK 95 962 in ZK 95 962 cue 1.5 mg/kg). However, there were striking differences in the dose effect curves for other BZ ligands. Ro 15-1788, a BZ antagonist with weak agonist properties, did not generalise to CDP in doses upto 40 mg/kg, but did generalise to ZK 95 962 (ED_{50} 2.3 mg/kg). CGS 9596, a weak partial agonist, generalised to CDP (2 mg/kg), but showed a bell-shaped response curve in the ZK 95 962 cue. The ß-carboline BZ receptor partial inverse agonist ZK 93 426 did not generalise to CDP but antagonised CDP stimulus effects (0.26 mg/kg) and generalised to the ZK 95 962 cue (20 mg/kg).

These results, as well as others to be presented, suggest that the stimulus properties generated in the two cues differ. The removal of sedative effects from a BZ ligand alters the discriminative stimulus in comparison to a classical BZ. These results may reflect the properties of different BZ receptor subtypes.

267.9 NO-05-0328: A new potent GABA-uptake inhibitor

E.B. Nielsen, K.H. Wolffbrandt, K.E. Andersen, L.J.S. Knutsen, U. Sonnewald and C. Braestrup

NOVO INDUSTRI A/S, Pharmaceuticals R&D, Departments of Medicinal Chemistry and Pharmacology, DK-2880 Bagsvaerd, Denmark.

R-(-)-1-(4,4-(3-Methyl-2-thienyl)-3-butenyl)-3-piperidine carboxylic acid (NO-05-0328) was identified as a selective and potent inhibitor GABA-uptake (IC_{50} = 75 nM in a rat brain synaptosomal preparation). The compound did not inhibit the binding of ligands to a variety of conventional neurotransmitter receptors and uptake sites. NO-05-0328 exerted marked and long-lasting anticonvulsant activity in a number of model systems. For example, the ED_{50} was 0.4 mg/kg for inhibition of convulsions in DBA/2 mice (ip, 30 min; diazepam 0.17, SKF 100330A 4.0 and valproic acid 31 mg/kg). In mice given DMCM, a full inverse agonist at benzodiazepine receptors, NO-05-0328 inhibited convulsions with an ED_{50} of 1 mg/kg (diazepam = 2.5). In pentylenetetrazol-treated animals, convulsions were inhibited with an ED_{50} of 6 mg/kg. In tests for sedation, NO-05-0328 exhibited effects in doses higher than those producing anticonvulsant effects. For example, exploratory behavior was reduced with ED_{50}'s of 15 (rearing) and 40 mg/kg (locomotion) in rats (diazepam 1.3 and 0.9 mg/kg, respectively).

These results indicate that NO-05-0328 is a promising candidate for a novel class of antiepileptic drugs with a selective mechanism of action.

267.10 BACLOFEN AND SOMATOSENSORY CORTICAL RESPONSE PROPERTIES.

T. Kaneko and T. P. Hicks. Department of Medical Physiology, The University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Many response properties of cells in sensory cortex are influenced by synaptically released GABA. Recent evidence (Hicks and Dykes, Brain Res. 274: 160-164; 1983; Oka et al., Brain Res. 376: 194-198; 1986) from somatosensory experiments has described how GABA acts in controlling certain response attributes of functionally distinct cortical cell types. Baclofen has been said to be a selective agonist for a postulated class of receptor, termed $GABA_B$ receptors. Accordingly, we sought to ascertain whether baclofen exerts actions similar to GABA on cell excitations induced by a variety of means of activation — both physiological and non-physiological. Cells in S1 cortex were excited synaptically by electrical stimulation of the VPL nucleus and naturally by hand-held probes or by computer controlled air puffers directed to the receptive field (RF).

Baclofen suppressed cell responses elicited by all experimental paradigms. When contrasted with the suppressant effects of GABA, relatively few cells showed differences in effect by the two inhibitory agents: one cell being GABA sensitive but baclofen insensitive, another two responding with a considerable difference in potency. Both compounds exerted similar effects upon puffer-induced responses irrespective of the air jet position within the RF. However, when the suppressions of air puffer induced activity were challenged by bicuculline methiodide (BMI), on 2 of 5 cells where complete tests including recovery could be obtained baclofen exerted BMI resistant suppressions. With both of 2 cells tested for BMI enlargements of RF size (Hicks and Dykes, 1983), baclofen produced RF size decreases despite the presence of BMI. Synaptic driving invariably was reduced by baclofen; in the one case where these excitations were challenged by BMI, the response suppressions remained unaltered. Differences in effect upon spontaneous firing also were noted between the two classes of agonist.

The experiments reveal a close functional similarity in overall effect of baclofen and GABA regardless of the method of excitation employed although it appears that there are important differences as well, some of which only become apparent through the use of BMI. Thus, the very interesting possibility is raised that there may exist a multiplicity of sites sensitive to GABA, which differentially underlie the various response properties exhibited by the distinctive cell types of S1 cortex. These sites provide two mechanisms — possibly the $GABA_B$ and $GABA_A$ receptors — by which RF size and cell responsiveness can be controlled. It is expected that the development and future testing of new classes of pharmacologically specific agonist (eg., THIP) and antagonist (phaclofen; Kerr et al., Brain Res. 405: 150-154; 1987) of the different classes of GABA receptor reported to date, will advance further our understanding of the role of the diverse types of inhibition extant in primary sensory cortex.

267.11 GABA IN THE NUCLEUS TRACTUS SOLITARIUS INCREASES BLOOD PRESSURE INDEPENDENT OF AN ACTION ON $GABA_A$ RECEPTORS. A.F. Sved and J.M. Catelli, Neurology Svc., VA Med. Ctr., East Orange, NJ 07019.

Previous studies in our laboratory have shown that ongoing GABAergic neurotransmission in the nucleus tractus solitarius (NTS) contributes to the maintenance of blood pressure (BP). Increasing the synaptic action of GABA by injection of a GABA uptake blocker (nipecotic acid; NIP) into the NTS increased BP. The current studies examined the GABA receptor subtypes involved in this process. These studies were carried out using chloralose-anesthetized (60 mg/kg iv), paralyzed (d-tubocurarine, 0.5 mg/kg iv), ventilated, Sprague Dawley rats. Microinjections (100 nl) of GABA agents were made into the right NTS at least 30 minutes following electrolytic lesion of the contralateral NTS. The pressor response to NIP injected into the NTS was not attenuated by pretreatment of the NTS with the selective $GABA_A$ receptor antagonist bicuculline (BIC). Injection of NIP (10 nmol) alone elevated BP 39±5 mmHg whereas when IP was injected immediately following BIC (10 pmol), BP increased 45±5 mmHg (n=6); these responses were not significantly different. In contrast, BIC (10 pmols) significantly attenuated the pressor response to injection of the GABA agonist muscimol (MUS), 2.5 pmol) into the NTS: BP increased 23±1 mmhg in response to MUS alone and 9±1 mmhg when MUS was injected following BIC (n=7, $p<0.01$). In addition, the pressor response to MUS in the NTS could be completely reversed by BIC: BP was increased 18±5 mmHg immediately following BIC injection (n=3). Selective stimulation of $GABA_B$ receptors with the specific $GABA_B$ agonist (-)baclofen (40 pmol) elicited a significant increase in BP (66±2 mmHg, n=4, $p<0.01$). These results demonstrate that the pressor response to enhanced synaptic action of GABA in the NTS can be produced independent of the involvement of $GABA_A$ receptors, and presumably is mediated via an action on $GABA_B$ receptors.

267.12 **INTEROCEPTIVE STIMULUS PRODUCED BY DIAZEPAM WITHDRAWAL IS POTENTIATED BY PICROTOXININ.** S.O. Idemudia* and H. Lal.(SPON: Martha A. Mann). Dept. of Pharmacology, Texas Coll. of Osteopath. Med., Fort Worth, TX, 76107.

Withdrawal from diazepam produces anxiety in man and a pentylenetetrazol-like interoceptive discriminative stimulus (PTZ-like IDS) in rats (Emmett-Oglesby, et al. Eur. J. Pharmacol. 92:127, 1983). We(Idemudia, et al. Soc. Neurosci. Abs. 12:484, 1986) recently showed that the PTZ-like IDS produced by diazepam(DZ) withdrawal was enhanced by the GABA-A antagonist bicuculline, suggesting that the withdrawal stimulus may be due to a decrease in the activity of the chloride ionophore complex modulated by binding at GABA, benzodiazepine, and/or picrotoxin receptors. We therefore tested the ability of a picrotoxin receptor agonist to enhance DZ withdrawal stimulus. Rats were trained in a two-choice, food reinforced operant task to discriminate PTZ (20 mg/kg) from saline (1 ml/kg). Thereafter, rats selected the saline-appropriate lever following saline, Ro 15-1788, or DZ, while no more than 50% of them selected the PTZ-appropriate lever following picrotoxinin (PTX; 0.02 to 0.64 mg/kg) or PTZ (2.5 to 10 mg/kg). DZ (120 mg/kg) was then administered in a liquid diet (Benjamin, et al. Fed. Proc. 46:712, 1987) twice daily for 3, 6, or 12 days. At 12hr after DZ, Ro 15-1788 produced a PTZ-like IDS. At 84hr, the rats were in spontaneous withdrawal, as 33% of them selected the PTZ-appropriate lever after either saline or Ro 15-1788. PTX (0.02 to 0.16 mg/kg) or PTZ (2.5 to 10 mg/kg) increased the withdrawal stimulus dose-dependently. The increase was the sum of the effects of the drugs and the withdrawal(i.e. additivity) in the 3- and 6-day groups. In the 12-day group, the PTZ-appropriate lever selection increased from 33% to 70% following 0.04 mg/kg PTX. This was a supra-additive effect, as only 10% of control rats selected this lever following this dose. Thus, chronic DZ produced a PTZ-like IDS which was enhanced by the GABA antagonists PTZ and PTX. The degree of enhancement depended upon the length of DZ treatment. Therefore, these data support the hypothesis that the PTZ-like IDS produced by withdrawal from chronic DZ may be due to an increase in the sensitivity of receptors for GABA antagonists resulting in an overall decrease in GABAergic activity. (Supported by NIDA Grant # RO1 DA 03521).

267.13 CHANGES IN PRESYNAPTIC INHIBITION IN THE CUNEATE NUCLEUS OF THE RAT PRODUCED BY DIAZEPAM, THIP, AND SKF 89976A. P.S. Blum (SPON: R. Shank). Department of Biological Research, McNeil Pharmaceutical, Spring House, PA 19477.

Presynaptic inhibition in the cuneate nucleus is mediated by GABA (Polc, P and W. Haefley, Naunyn-Schmiedebergs Arch. Pharmacol., 294:121, 1976). The mechanism for presynaptic inhibition in the cuneate nucleus is the depolarization of primary afferent fibers, and this primary afferent depolarization (PAD) can be measured using the Wall method of excitability testing (J. Physiol., 142:1, 1958). In the present study, the measurement of PAD in the cuneate nucleus of the urethane anesthetized rat was used to assess GABAergic properties of three drugs. The compound antidromic action potential evoked by stimulation in the cuneate nucleus (single pulses 0.1 ms duration, 2-5 V intensity) was recorded using a bipolar hook electrode on the median nerve (test response). The amplitude of the test response was compared to the amplitude of the response when the cuneate stimulus was preceeded (4-160 ms) by a conditioning stimulus to the ulnar nerve (single pulse, 0.5 ms duration, 7-100 V intensity). Increases in the peak height caused by either conditioning stimulus or drug effects were taken as evidence of PAD. In the absence of drug, PAD evoked by ulnar stimulation was stable for up to 3 hrs. Diazepam (0.5 mg/kg i.v.) produced a 40% increase in ulnar-evoked PAD, without any change in the amplitude of the test response. THIP (3 mg/kg i.v.), a GABA receptor agonist, blocked ulnar-evoked PAD without changing the amplitude of the test response. SKF 89976A [N-(4, 4-diphenyl-3-butenyl)-nipecotic acid] (1 mg/kg i.v.), a GABA uptake inhibitor, produced a third effect. No change was seen in PAD evoked by ulnar stimulation, but there was a 35% increase in the amplitude of the test response. Diazepam, THIP, and SKF 89976A, three compounds that interact with different aspects of GABA function, also affected presynaptic inhibition. Each of these compounds, however, produced a different effect. These studies suggest that excitability testing of primary afferent fibers can be used to assay the in vivo effects of test compounds on GABA neurotransmission.

267.14 DOES CHRONIC, VARIED STRESS EFFECT PICROTOXIN-INDUCED SEIZURES? T.D. Wolinsky* and E.E. Coons* (SPON: M.S. Gizzi) Dept. of Psychology, New York University, New York, NY 10003.

Evidence is accumulating for the involvment of GABA in both the pharmacology and treatment of depression. After exposing rats to a protocol based on the animal model of depression of R.J. Katz (Neurosci. and Biobehav. Rev, 5(2) p.231) we evaluated central GABAergic activity by examining the severity of seizures induced by the GABA antagonist, picrotoxin.

Rats underwent a three week regimen of chronic, varied and unpredictable stress. One or two days later, they were injected with picrotoxin (7.5 mg/kg, i.p.). All seizures were video-taped for later analysis. The latency and duration for each episode of the following seizure stages were measured: myoclonic jerks and twitches, writhes, clonus that occurred alone and in association with writhes and tonic extension, tonic extension of fore- and hindlimbs, and bouts of status epilepticus characterized by prolonged periods of alternating tonic and clonic activity. The order of these categories represents progressive stages of seizure severity.

In Experiment 1, two groups of 6 rats were used. One was exposed to chronic stress; the other was not. It appeared that the control animals experienced more severe seizures than the stressed group. For example, this was evidenced by a greater incidence of tonic activity in the control group, suggesting that the chronic stress provided partial protection from this form of seizure activity. However, because the stress regimen involved periods of food or water deprivation, the two groups differed in mean body weight; the control animals weighed significantly more. Therefore, we could not eliminate the possiblity that the above findings were due to differences in weight.

Experiment 2 consisted of three groups of 10 animals: a chronic stress, an acute stress group which was exposed to the same stressor given on the last day of the chronic stress, and a food-yoked control group. Using this more appropriate control, we were unable to replicate the results of Experiment 1. Moreover, the seizure severity and mean weight of the acute group were not radically different in comparison to those of the chronically stressed animals.

These data suggest that: 1) chronic, varied stress does not effect picrotoxin-induced seizure severity as assessed by this method; 2) great caution must be excercised when interpreting between-group differnces that may be due to experimental artifact (in this case, weight differences); and 3) while it has been reported that weight does not influence latency to the first occurrence of a variety of convulsive endpoints, we have demonstrated that the examination of the entire seizure profile does reveal weight effects.

267.15 INJECTION OF BENZODIAZEPINES, BUT NOT GABA OR MUSCIMOL INTO SUBSTANTIA NIGRA PARS RETICULATA SUPPRESSES PENTYLENETETRAZOL SEIZURES. H. Zhang*, H.C. Rosenberg and E.I. Tietz (SPON: T.H. Chiu). Dept. of Pharmacol., Med. Coll. of Ohio, Toledo, OH 43699.

In an earlier study (Soc. Neurosci. Abst. 11:272) it was found that the benzodiazepine (BZ) midazolam injected into the pars reticulata of the substantia nigra (SNpr) can suppress seizures produced by pentylenetetrazol (PTZ). The present study was done to determine if PTZ seizures could also be suppressed by the water-soluble BZ flurazepam (FZP), GABA or muscimol.

Male, Sprague-Dawley rats (275-300 g) were deeply anesthetized and guide cannulas with close-fitting obturators were implanted. A week later, 1 µl FZP, GABA or muscimol was infused over 1 min, bilaterally. The injectors were left in place another min, then withdrawn slowly and replaced with the obturators. PTZ, 70 mg/kg was injected i.p. 5 min after the start of FZP or GABA infusions, or 20 min after muscimol infusion. These times were based on the time-course of the circling response reported after unilateral injection of these drugs into SNpr (Fed. Proc. 45:806). Control rats received 1 µl of saline 5 or 20 min before PTZ. All injection sites were verified histologically.

5 rats with no prior surgery were given PTZ; all had tonic-clonic (TC) seizures. Five rats were given PTZ a week after surgery, but with no intranigral injection; 4 had TC seizures. 14 rats received intranigral saline before PTZ; 8 of these had TC seizures. This suggested that the saline infusion itself had some anticonvulsant effect. FZP, 50 µg bilaterally, produced a clear anti-PTZ action; 0 of 5 rats had TC seizures. In contrast, GABA doses of 20 and 100 µg had no clear effect. After 20 µg, 3 out of 8 had TC seizures; after 100 µg, 4 of 5 had TC seizures. Muscimol also failed to suppress PTZ seizures; 4 of 9 rats had TC seizures after 25 ng, 5 of 7 had TC seizures after 50 ng, and 2 of 5 had TC seizures after 100 ng muscimol.

Intranigral injection of BZ's suppressed PTZ seizures. Neither GABA nor muscimol did, which is similar to the results found by Mirski et al (1986) using intranigral gamma-vinyl GABA. GABA and muscimol doses were as great as those reported to block various types of experimental seizures, and to cause behavioral responses. If only 1 injector was in the SNpr, all drugs caused circling behavior. 50 and 100 ng muscimol produced self-injurious behavior in some rats. Thus, GABA and muscimol were producing actions expected of GABA-A agonists. Their failure to block PTZ seizures suggests that the anti-PTZ effect of intranigral BZ's is not mediated through GABA-A receptor-linked mechanisms. The same conclusion was reached by Chweh et al (1985) using systemically administered drugs. The SNpr may be the site of anti-PTZ action of systemically administered BZ's.

267.16 FLURAZEPAM TREATMENT CONFERS TOLERANCE TO THE ANTI-PENTYLENETETRAZOL ACTION OF SEVERAL, BUT NOT ALL, BENZODIAZEPINES. H.C. Rosenberg, J.M. Duggan*, E.I. Tietz and T.H. Chiu. Dept. of Pharmacology, Medical College of Ohio, Toledo, Ohio, 43699.

Benzodiazepines produce several pharmacologic effects by virtue of their actions at brain benzodiazepine (BZ) receptors. Studying the pharmacologic activity of a series of BZ agonists may reveal differing profiles that could be related to varying patterns of BZ receptor activation. The purpose of this experiment was to study patterns of tolerance and cross-tolerance among agonists of differing structures. Tolerance was studied in rats treated with a saccharin-flavored solution of the water-soluble BZ flurazepam, which was offered as the sole source of water. The concentration was adjusted so that rats could consume up to 100 mg/kg daily for 3 days, then up to 150 mg/kg daily for 4 days. Consumed in this fashion, the dose was sub-threshold for producing overt signs of intoxication. Flurazepam is quickly metabolized to active products, notably desalkyl-flurazepam, which is longer lasting and much more potent. Tolerance was sought by studying the activity of BZs against pentylenetetrazol (PTZ). Rats were tested 48 hrs after stopping the 1 week treatment. At this time, there is no measurable change in sensitivity to PTZ, and brain level of active flurazepam metabolites (as determined by radio-receptor assay) is very low. Benzodiazepines were administered before PTZ, 100 mg/kg, i.p. The injection interval was based on previous observations of the time-action characteristics of each BZ. Each rat was assigned a seizure score based on the most severe seizure observed: 0=none; 1=myoclonic jerks; 2= forelimb clonus; 3=clonus of all legs and loss of upright posture; 4=lethal tonic-clonic seizure. Results were evaluated by the Kruskal-Wallis test. Tolerance was seen, but only if the appropriate dose of BZ was chosen. Thus, too large a dose protected both control and 1 week treated rats against PTZ seizures. By adjusting doses accordingly, tolerance was observed for diazepam, clonazepam, desalkyl-flurazepam, and the 1,5-BZ clobazam. In contrast, tolerance was not seen with the imidazo-benzodiazepine, midazolam, even though a wide range of doses was examined. Furthermore, there was no tolerance to the anti-PTZ action of flurazepam. These data show that measuring tolerance, using this experimental design, can reveal differences between BZs that may be related to variations in their interactions with BZ receptors. The lack of tolerance to midazolam and flurazepam may be related to the imidazo ring in midazolam and the large N-containing side-chain of flurazepam.

267.17 A COMPARISON OF THE ANTICONVULSANT EFFECTS OF 1,4 AND 1,5 BENZODIAZEPINES IN THE AMYGDALA-KINDLED RAT AND THEIR EFFECTS ON MOTOR IMPAIRMENT. E. I. Tietz, H. C. Rosenberg and Ted H. Chiu. Dept. of Pharmacology, Medical College of Ohio Toledo, OH 43699.

The benzodiazepines (BZ's) are effective for the treatment of a variety of epilepsies but their usefulness is limited by psychomotor impairment and the development of tolerance. Clinical and animal studies suggest that the anticonvulsant 1,5 BZ, clobazam (CBZ) produces minimal neurotoxicity. The anticonvulsant efficacy of CBZ, diazepam (DZP) and clonazepam (CZP) was evaluated in the kindling model and was compared by dose-response analysis to the motor impairment produced by these BZ's.

Male, Sprague-Dawley rats (n=25) were deeply anesthetized and implanted with amygdaloid and contralateral cortical electrodes. After 1 week recovery, afterdischarge (AD) thresholds (79.6 ±6.3 µA) were determined. Rats were stimulated once daily for 1 sec at 400 µA (60 Hz, biphasic symmetrical square wave, 2.0 msec total pulse duration) until a criterion of 5 consecutive Stage 5 seizures was reached. Baseline responses were averaged over the next 2 days. Drug effect was calculated as a percent of baseline for motor seizure latency (3.5 ±0.4 sec) and duration (94.3 ±3.5), forelimb clonus latency (9.5 ±1.4) and duration (65.8 ±2.6), amygdala AD duration (82.3 ±3.5), and cortical AD latency (2.6 ±0.5) and duration (81.5 ±3.7). Doses of CBZ (0.5-15.0 mg/kg), DZP (0.1-2.0 mg/kg) and CZP (0.02-1.5 mg/kg) or vehicle were administered, i.p., 30 min before test stimulations in a single-blind crossover design with 3 days between each test dose. Motor impairment and muscle relaxation were measured 5 min before stimulation by evaluating ability to stay on a vertical screen, impairment of gait, and abdominal and hindlimb muscle tone.

The relative order of potency for all actions was CZP > DZP > CBZ. Each drug limited seizure spread, suppressing motor and EEG measures of kindled seizures. Forelimb clonus duration was the most sensitive predictor. The slope of the dose-response curve of CZP for this measure was significantly shallower than that of DZP. Though the CBZ dose-response curves for tests of motor impairment appeared steeper, they were not significantly different from those of DZP. Comparing ED50's for suppression of forelimb clonus with those for motor impairment revealed differences among the drugs. CBZ was relatively less potent than the other drugs for causing ataxia, while CZP was relatively more potent for causing muscle relaxation. Both CBZ and CZP were more likely to impair vertical screen performance than equi-effective anticonvulsant doses of DZP. Quantitative description of the acute anticonvulsant actions of the 1,4 and 1,5 BZ's in the kindling model will serve as a stable baseline for the study of tolerance development during chronic treatment.

267.18 INTRACEREBROVENTRICULAR 4,5,6,7-TETRAHYDROISOXAZOLO[4,5-C]PYRIDIN-3-OL (THPO) PROTECTS AGAINST PENTYLENETETRAZOL SEIZURES IN RATS. S.F. Gonsalves, B. Twitchell*, A. Schousboe*, and R.E. Harbaugh*. Depts. of Surgery and Pharmacology, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756 and Dept. of Biochemistry, Univ. of Copenhagen, Copenhagen, Denmark.

Previous studies suggest that at least some seizures may be ameliorated by enhancing GABAergic neurotransmission. THPO selectively inhibits high affinity uptake of GABA into astrocytes (Schousboe et al., Epilepsia 24:531, 1983). Theoretically, this action should increase the amount of GABA available for neuronal uptake. Evaluation of the anticonvulsant potential of this substance has been hampered by its inability to penetrate the blood-brain barrier. We assessed the anti-pentylenetetrazol (PTZ) activity of THPO following injection directly into the CSF. For comparison, the anticonvulsant activity of intracerebroventricular muscimol was also evaluated.

THPO (0.1-0.75 mg), muscimol (0.1-1.0 µg) or mock CSF was infused into the lateral ventricles of Sprague-Dawley rats 30 min to 3 hrs prior to PTZ administration. Maximal clonic-tonic seizures were elicited by injecting 25 mg/kg PTZ iv. Endpoints were tonic forelimb extension and death. To determine seizure threshold, PTZ was administered as a continuous iv infusion, and doses of PTZ producing various seizure components were calculated. THPO, at 0.3 mg and above, protected all animals (n=9) against a suprathreshold PTZ challenge for at least 1 hr. THPO did not elevate the seizure threshold dose. In contrast, muscimol (0.3 and 1.0 µg) protected against forelimb extension in only 33% of animals and against death in 58%. Low doses of muscimol did not affect seizure threshold; the threshold decreased following the 1.0-µg dose [TWITCH (mg/kg): Control=24.7±2.0; 1.0 µg muscimol=16.9±1.4, $p<0.05$]. Both THPO and muscimol exhibited neurotoxic effects at anticonvulsant doses. Initially, a reduction in locomotor activity and an impaired positional sense were observed. At the highest doses, effects included spontaneous twitches (THPO) and loss of righting reflex (muscimol). Our data suggest that THPO may protect against maximal PTZ seizures. Thus, glial GABA uptake inhibitors may suppress mechanisms involved in seizure spread. (Support: American Health Assistance Foundation and Hitchcock Foundation).

267.19 IN VIVO LABELING DEMONSTRATES BENZODIAZEPINE RECEPTOR MEDIATION OF RAT PUP ULTRASONIC ISOLATION CALLS. T.R. Insel, L.P. Miller*, and R.E. Gelhard*. Lab. of Clinical Science, NIMH, Poolesville, MD 20837.

Rat pups from 1-14 days of age emit ultrasonic (35-40 kh_z) calls when isolated. These isolation calls are a potent stimulus for maternal retrieval and may be a behavioral index of separation distress. Pups from a rat strain genetically selected for fearfulness show an increased rate of calling (Insel & Hill, Biol. Psychiatry, in press). The benzodiazepine (BZD) diazepam, in clinically anxiolytic doses, decreases the rate of calling whereas pentylenetetrazol, a drug with clinically anxiogenic properties, increases calling during a 2-minute separation test. (Insel et al., Pharm. Biochem. Behav. 24:1263, 1986). The BZD receptor antagonist, RO 15-1788, which generally lacks intrinsic effects was also found to decrease isolation calls at a dose of 5 mg/kg.

To investigate if the BZD receptor is involved in the mediation of these ultrasonic isolation calls, in vivo binding of ^{3}H-RO 15-1788 (3 μCi/pup) was compared in 10-day-old pups either (a) unseparated from their littermates, (b) separated for 5 minutes or (c) separated for 25 minutes. Twenty minutes after IP injection with ^{3}H-RO 15-1788, pups were sacrificed by decapitation, brains were immediately removed and either dissected for a regional analysis of binding or frozen for cryostat sectioning (24 μ) with subsequent autoradiography of slide-mounted sections (8 week exposure). Non-specific binding was assessed by preinjecting a subset of each group with diazepam (5 mg/kg).

Calling rate (calls/min.) was higher in both separated groups (unsep. = 1.9 ± 0.6, sep (5) = 41.5 ± 5.3, sep (25) = 28.0 ± 8.9). In three independent studies of macro-dissected tissue, sep (25) pups showed a 30% decrease in specific binding to cortex, but not to olfactory bulb, midbrain, or cerebellum. Autoradiographic binding in the separated groups was decreased significantly in the cingulate and pyriform cortex, increased in the inferior colliculus, but not affected in nine other brain regions analyzed.

These results are consistent with the hypothesis that the BZD receptor participates in the neural response to separation in the rat pup. Ongoing studies are investigating whether endogenous ligands for this receptor can alter the behavioral response to separation.

267.20 STUDIES OF CENTRAL NEUROTRANSMITTER FUNCTION IN EXPERIMENTAL HEPATIC ENCEPHALOPATHY. R.F. Butterworth, J.F. Giguère, A.M. Besnard*, H. Fournier*, G. Girard* and M. Bergeron*, Lab. of Neurochemistry, André-Viallet Clin. Res. Centre, Hôpital St. Luc, Montreal, Qué. H2X 3J4.

It has been repeatedly suggested that modifications of cerebral neurotransmitter function may be important in the pathogenesis of hepatic encephalopathy. Data to be presented is derived from an ongoing study in our laboratory, to evaluate this hypothesis. Four weeks following surgical construction of an end-to-side portocaval anastomosis, rats are chronically hyperammonemic and display neurological symptoms of encephalopathy. Measurement of cerebral amino acids by HPLC of their o-phthalaldehyde derivatives in shunted and sham-operated rats yielded the following:

(i) Region-selective increases in brain glutamine ranging from 1.7 times normal values in spinal cord to 3.5 times normal values in cerebral cortex.

(ii) Selectively decreased glutamate in cerebral cortex and brainstem.

(iii) No changes of brain GABA in any region studied.

Activities of the GABA nerve-terminal marker enzyme GAD were found to be within the normal range; activities of the cholinergic marker enzyme CAT were likewise unchanged. However measurement of the astrocytic enzyme glutamine synthetase gave values that were significantly decreased in several brain structures. High affinity binding of ^{3}H-GABA, ^{3}H-muscimol and ^{3}H-flunitrazapam to synaptic plasma membranes from cerebral cortex of shunted rats was unaltered. Taken together, this data does not support the much subscribed-to hypothesis that cerebral GABA dysfunction plays a pathogenetic role in hepatic encephalopathy. On the other hand, ^{3}H-glutamate binding was found to be significantly altered in cerebral cortex of shunted rats, the density of binding sites (B_{max}) being found to be increased from 9.2 to 14.6 pmol.per mg. protein ($p<0.01$) without changes in binding affinity (Kd). Such alterations of central glutamatergic function and the concomitant predominance of inhibitory (GABAergic) neurotransmission may be of pathophysiological importance in hepatic encephalopathy associated with chronic liver disease and portal-systemic shunting.

REGENERATION: LOWER FORMS

268.1 GASTROPOD GANGLION TRANSPLANTS: NEURON SURVIVAL IN SWAPS BETWEEN CLOSELY AND DISTANTLY RELATED SNAILS. S.B. Moffett. Dept. of Zoology, Washington State University, Pullman, WA 99164-4220.

In the pulmonate snail Melampus bidentatus, cerebral ganglia implanted into the hemocoel of host snails form connections with the host CNS and can induce the formation of supernumerary eyes or tentacles (Moffett and Austin, J. Exp. Zool. 216:321-325, 1981). An alternative approach used in this study has been to remove one of the host's cerebral ganglia and to implant another cerebral ganglion either from the same species or a different species in the same genus (Melampus species: M. bidentatus, M. castaneus, and M. olivaceus) or from a different genus in the same family (Ovatella myosotis).

Incorporation of implanted ganglia into the nervous system of the host can be evaluated using the animal's behavior, electrophysiological recordings, nerve and connective backfills, and immunohistochemistry. Snails with intraspecific swaps regain normal tentacle withdrawal responses much more rapidly than snails recovering from removal of a single cerebral ganglion (described in Moffett and Snyder, J. Neurobiol. 16:193-209, 1985). In many instances the implanted ganglion assumes the position and role of the excised ganglion, forming connections with the central ganglia and periphery. There are also regions of accessory neuropil development at the confluence of the host's cut nerves and connectives that secondarily contact the implant. Interspecific ganglion swaps within the genus Melampus also exhibit ganglion incorporation and support behavioral recovery. Whole mount immunofluorescence methods are being used to examine the fate of identified serotonergic cells and cell clusters in the implanted ganglia. Ganglion swaps between Melampus and Ovatella exhibit differential survival: ganglia from Melampus survive for up to 5 years in Ovatella and sometimes form connections with the host CNS or induce supernumerary sensory structures. In contrast, ganglia from Ovatella rarely survive for more than two weeks in the hemocoel of Melampus. These results suggest that whereas homologous neurons are able to find their places within the neural circuitry of closely related snails, phylogenetic closeness alone is unable to account for the regeneration success of implanted ganglia. (Supported by NIH grant RO1 NS 22896).

268.2 ALTERED SYNTHESIS OF SPECIFIC PROTEINS DURING REGENERATION OF AN IDENTIFIED APLYSIA NEURON IN VIVO. M.J. Savage and D.J. Goldberg. Department of Pharmacology, Columbia University College of P&S, New York, NY 10032.

After axotomy, neurons undergo many metabolic changes leading to either regeneration and synapse formation or death of the neuron. One change demonstrated to occur in a variety of regenerating nerve preparations is an altered synthesis of specific proteins. We have identified proteins whose synthesis is consistently increased or decreased in the identified giant cerebral neuron (GCN) of the marine slug, Aplysia californica during regeneration. With this cell we are investigating which aspects of axotomy or regeneration could act as signals for the changes in protein synthesis.

We have used one- and two-dimensional gel electrophoresis to visualize proteins in the cell bodies of GCNs which were labeled for 5 hours with ^{35}S-methionine. These cells had been axotomized and allowed to regenerate for one week in vivo. We identified three proteins with apparent molecular weights and isoelectric points of 66K,5.7, 116K,5.5, and 150K,5.5, whose incorporation of ^{35}S-methionine was significantly increased during regeneration. The latter two proteins are known to undergo fast axonal transport in other neurons of Aplysia. We found a second group of proteins whose incorporation of ^{35}S-methionine was reduced after one week of regeneration. This group consisted of six proteins: two proteins, 89K,4.9 and 104K,4.9, that are known to undergo fast axonal transport, one protein, 60K,5.6, that is thought to be a neurofilament subunit, another protein, 78K,6.1, whose synthesis has been shown to be synapse-dependent in another neuron of Aplysia, and two other proteins, 67K,5.5 and 66K,6.3.

Experiments are in progress to determine signaling events for the changes in synthesis of these proteins after axotomy. Using in vitro and in vivo methodology, we are assessing the importance of the loss of target cells, the type of target cell lost, and growth itself.

268.3 REPAIR OF BRAINSTEM-SPINAL PATHWAYS AFTER THORACIC SPINAL CORD TRANSECTION IN THE CHICK EMBRYO. B.H. Nelson* and J.D. Steeves. Dept. of Zoology, University of British Columbia (UBC), Vancouver, B.C., V6T 2A9.

The purpose of this study was to determine the exact stages during embryonic development in the chick when descending brainstem-spinal tracts lose the capacity for anatomical and functional repair after complete thoracic spinal cord transection. Transections and sham-operations were performed on embryonic days (E)3 through E13. The post-operative recovery period varied from 4 to 19 days, with some of the embryos being allowed to hatch.

The extent of anatomical repair was assessed by injecting 0.1 - 0.4 ul of a 10% solution of the retrograde tracer, wheat germ agglutinin-horseradish peroxidase (WGA-HRP), into the spinal cord, caudal to the transection site. The CNS tissue was then processed using a tetramethylbenzizdine (TMB) technique. The brainstem nuclei were examined for WGA-HRP positive cells and plotted using computerized camera lucida drawings .

Results indicate similar distributions of retrograde labelled cell bodies within the brainstems of both sham operated controls and embryos transected prior to E9. A few embryos transected on E3 actually hatched, and demonstrated complete restitution of motor function. In contrast, embryos transected on E9 through E13 never hatched and exhibited deficits in the labelling of certain supraspinal cell groups, including the reticulospinal, , rubrospinal, coeruleospinal and raphe-spinal nuclei.

The repair of spinal cord damage in early transected embryos may be due to either the regeneration of previously axotomized fibers, or to subsequent axonal projections from later developing supraspinal neurons. In an attempt to differentiate between these two possibilities, double labelling experiments, using two different retrograde tracers, injected immediately before and 4-7 days after spinal cord transection are currently in progress.

Supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada.

268.4 FURTHER CHARACTERIZATION OF A REGENERATION-SPECIFIC CYTOSOLIC PROTEIN IN THE GOLDFISH VISUAL SYSTEM. G.R. Wilmot*, T.H. Ford-Holevinski* and B.W. Agranoff. Neuroscience Lab Building, University of Michigan, Ann Arbor, MI 48104-1687.

The synthesis of a number of proteins is initiated or greatly increased following optic nerve crush in the goldfish. We have previously reported that incorporation of [^{35}S]Met into a retinal cytosolic protein doublet (68 and 70 kDa, pI 4.9 and 4.8, respectively) increases dramatically between 4 and 36 d postcrush (PC), and that these proteins reach the tectum in the newly regenerated nerve via slow axonal transport. Both the slow rate of transport and localization in a high speed supernatant fraction suggest strongly that the protein is associated with cytoskeletal elements. However, techniques for microtubule aggregation do not co-purify the doublet proteins, nor does preparation of neurofilaments by detergent sedimentation procedures. The doublet proteins have been partially purified by ion exchange and lectin affinity chromatography. While the doublet appears to be essentially absent from all non-neural tissues, a co-migrating doublet has been seen in silver stained gels of goldfish egg supernatant fraction. Following further purification of goldfish brain doublet via one- and two-dimensional PAGE gels, the electroblotted protein was administered to rabbits by subcutaneous implantation of nitrocellulose strips containing the doublet. The antibodies produced were used to probe Western blots of purified egg doublet, which indicated that the doublets from the two sources were immunologically cross-reactive. Further analysis by limited proteolysis within 1D SDS-PAGE gels (Cleveland mapping) confirmed that the egg and brain doublets are similar. The results also indicated considerable homology between the 68 and 70 kDa components. Because of the above-mentioned characteristics and presence in eggs and nervous tissue, we entertained the hypothesis that the 68-70 doublet is related to a 65-70 squid brain doublet thought to be associated with kinesin. Tubulin did not bind the 68-70 doublet in the presence of AMP-PNP and furthermore, our antibodies were not cross-reactive with a squid kinesin preparation. Efforts to sequence the goldfish doublet proteins thus far have been hampered by apparent NH_2-terminal blocks. (Supported by NEI Grant EY 05947.)

268.5 OBSERVATIONS ON ADULT APTERONOTUS SPINAL CORD FOLLOWING TRITIATED THYMIDINE INJECTIONS IN VIVO. M. J. Anderson[1], A. Reed[2], and S. G. Waxman[3]. [1]Dept. of Anatomy, Colorado State Univ., Fort Collins, CO 80523; [2] Dept. of Neurology, Stanford Univ. and VA Med. Ctr., Palo Alto, CA 94304; [3] Dept. of Neurology, Yale Med. Sch., New Haven, CT 06510.

Spinal cord of the adult teleost, Apteronotus albifrons, can regenerate new nerve cells bodies and fibers after injury. Normal adult Apteronotus cord also continues to grow in length and add new neurons in a small region at its caudalmost tip. It has been suggested that adult Apteronotus cord may continue to add neurons all along its length and that this low level of continued neurogenesis is the basis for the remarkable degree of regeneration possible in this species. We have therefore injected normal Apteronotus with ^{3}H-thymidine in order to look for addition of new neurons in spinal cord rostral to the caudalmost region of on-going growth.

Mature adult Apteronotus were injected I.P. with 0.5-1.0mCi (20μCi/g. body wgt) of ^{3}H-thymidine, sp. act. 78 Ci/mmol. Some fish were given three injections over the incubation period rather than just one injection. After an incubation period of 7 das. to 4 months, the fish were sacrificed and spinal cord was dissected out. Tissue was also taken from liver and stomach, as a control for tritium incorporation. Tissue was processed in two ways. Some tissue was fixed in 2.5% glutaraldehyde in 0.1 M sodium phosphate buffer with 0.08M sucrose (pH7.3; 300 mOs), postfixed in 2% OsO_4, and embedded in epon-araldite. Other tissue was fixed in 10% buffered formalin and embedded in paraffin. Sections of tissue were mounted on glass slides, deparaffinized, dipped in Kodak NTB-2 emulsion (diluted 1:1), stored in light-tight boxes at 4°C for 7-30 days, then developed with D-19.

Examination of autoradiographs from 7 different fish revealed no incorporation of ^{3}H-thymidine into cells of the spinal cord. In each fish, sections of spinal cord were taken at 5 different levels along the length of the cord; all levels were rostral to the caudalmost (normally-growing) tip. Even in fish with repeated tritium injections and a 4-month incubation period, tritium labelling was not observed in any of the levels of rostral spinal cord examined. The present experiments also confirmed our previous work that there is not an increase in number of neurons in spinal cord of older Apteronotus, as has been observed in some other fish (J.Comp.Neur.179:13 and 194:291). The absence of ^{3}H-thymidine incorporation in rostral Apteronotus spinal cord has important implications. It suggests that rostral Apteronotus spinal cord is quiescent and not a site of on-going neurogenesis. Since neurogenesis can be elicited following injury to rostal regions of cord, the present results emphasize the importance of mechanisms that modulate neurogenesis in this species. Supported by the Veterans Administration and NS-15320.

268.6 SEROTONIN AXONS IN THE SPINAL CORD OF XENOPUS TADPOLES: DEVELOPMENT AND REACTION TO SPINAL CORD TRANSECTION. M.S. Beattie, J.C. Bresnahan, and G.L. Lopate. Depts. of Surgery and Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH. 43210.

Antibodies to serotonin (5-HT) were used to trace the development of selected brainstem spinal axons and their reaction to spinal transection in Xenopus laevis tadpoles.

5-HT-positive cells are observed as early as stage 29 in the ventral, medial brainstem. Others have recently reported such neurons as early as stage 25, about 28 hours after first cleavage (Van Meir et al., Int. J. Develop. Neurosci, in press). At stage 29, 5-HT positive axons are not yet seen in the spinal cord; they are present at about stage 32 in the lateral funiculuis of the rostral cord, and rapidly reach the most caudal levels.

Low thoracic spinal cord transections were made in tadpoles at stages 48-56. Animals were sacrificed at varying periods following the transection, including a number of cases which were allowed to proceed through metamorphic climax. These long-term survivals produced animals with apparently normal neurological status, and reconstituted spinal cords, as we have reported previously (Lopate et al., Neurosci. Absts, '85). In these post-metamorphic cases, 5-HT-positive fibers were frequently observed crossing the lesion site, which could be distinguished by its disorganized structure, reduced size, and often, the appearance of ependyma-lined cavities. In addition, a column of 5-HT-positive cells were found located around the central canal rostral to the lesion, and occasional, scattered cells caudal to the lesion.

The short-term response to transection was characterized by a clearing of the neuropil staining caudal to the lesion, 5-HT-positive axonal swellings at the lesion site, and the appearance of 5-HT positive cells in the cord rostral to the lesion site. Within 3-5 days, a bridge of tissue was present, and 5-HT axons with swellings and varicosities could be seen entering the region of the lesion. Within 11 days, axons could be traced well caudal to the lesion in the funiculi, and had begun reinnervating the spinal gray.

Some of the fibers which are able to bridge a spinal transection during metamorphic climax in Xenopus appear to contain 5-HT. Studies are currently underway to determine the development and reaction to injury of tyrosine hydroxylase immunopositive axons in this model of spinal cord regeneration. (Supported by NS-10165)

268.7 **THE EFFECT OF TEMPERATURE ON THE CHRONOLOGY OF THE RECOVERY OF BEHAVIOR FOLLOWING SPINAL CORD TRANSECTION IN METAMORPHOSING SEA LAMPREY.** C. Wilbur*, L. Margolin* and J. Ayers. (*Spon: Norman Boisse*). Dept. of Biology and Marine Science Center, Northeastern University, East Point, Nahant, MA 01908.

It is generally accepted that larval and juvenile animals recover from CNS injury much better than their adult counterparts. In a previous investigation (*Soc. Neurosci. Abstr. 12: 1574*), we found that ithe latency to criterion of recovery is significantly longer at lower temperatures (13°C) than in larvae which recovered at room temperature (21°). In the present experiments, we investigated how metamorphosis affects the chronology of recovery from spinal transection and whether development or temperature has a greater influence on the time course of recovery.

Complete spinal cord transections were performed on experimental animals at 25% of total body length. Specimens were then placed in individual aquaria where they were allowed to recover at either 13° or 21°C. Specimens were scored weekly for behavioral recovery. We have been able to identify five stages of functional recovery of swimming in adult lamprey. We have determined the latency from the time of the lesion to the achievement of criteria for each of these stages, as well as for crawling, burrowing and withdrawal behaviors.

There is little difference in the time to recovery between pre- and post-metamorphic specimens when held at the same temperature. In contrast reduced holding temperature (13° vs. 21°) causes a significant increase upon the time course of the recovery of swimming and other behaviors. In general, specimens held at 13° take about 30% longer to reach criterion than those held at room temperature.

Acutely transected adult lampreys are known to exhibit a behavior not displayed by acutely transected ammocoetes: spinal undulations (*Science 221: 1312*). We also examined influence of temperature upon the time course of spinal undulations. Higher holding temperatures hasten the onset of attached undulations and epochs of spontaneous undulations tend to alternate with quiescent periods more frequently than at lower temperatures. Temperature appears to have little no effect on the overall duration of the attached undulations. *Supported by NSF Grant BNS-8406880.*

268.8 REGENERATION OF AXONS AND ASSOCIATED NEUROPIL IN CLAWS OF DEVELOPING LOBSTERS. (HOMARUS AMERICANUS) P. Cauwenbergs and C.K. Govind, Life Sciences Division, Scarborough Campus, Univ. of Toronto, 1265 Military Trail, Scarborough, Ontario, Canada M1C 1A4.

Developing tissue is much more plastic than adult tissue, a phenomenon also evident during regeneration in crustaceans. In one intermolt after limb autotomy adult lobsters regenerate entire limbs which are smaller than original (intact) limbs. During subsequent intermolts these newly regenerated limbs hypertrophy to reach pristine proportions. However, early juvenile lobsters regenerate entire limbs of pristine proportions in one intermolt. Whether such robustness in regenerative capacity extends to nervous tissue was studied by comparing nerve roots and hemiganglia between regenerated and opposite claws in developing juvenile lobsters. Unilateral autotomy of a cheliped was performed at various stages in juvenile animals, and the nerve supply to the regenerate and original limbs was analysed after one intermolt.

In early juveniles axon numbers in regenerated nerve roots slightly exceeded that of original roots, while in later juveniles, axon numbers in regenerated nerves were fewer than in controls. This robust regenerative capacity in early juveniles resulted in a two fold increase in synaptic density in hemiganglia of the regenerated versus original side. No differences were noted between regenerated and original hemiganglia in early juveniles when either the types (excitatory, inhibitory and neurosecretory) or diameter of nerve terminals were compared. Thus, the regenerative capacity in early juveniles is very robust with a slight overproduction of axons and a dramatic overproduction of central synapses.

In a second series of experiments, regeneration was delayed over several intermolts with repeated removal of the regenerate. As these experimental animals aged, increasingly fewer axons were counted in regenerated versus original roots and a corresponding decrease in synaptic density in hemiganglia on the regenerated side was observed. Nerve terminals, however, were markedly larger in regenerated versus original ganglia. Such a hypertrophy denotes a compensatory mechanism by existing terminals to occupy available space in the neuropil in the absence of the normal complement of sensory axons from the periphery. Subsequent reinvasion of the ganglionic neuropil by regenerating sensory fibres must entail a down-scaling of existing terminals in order to accommodate the full complement of axons. Clearly the nerve roots and ganglionic neuropil undergo considerable remodelling during claw regeneration in juvenile lobsters.

268.9 ACCELERATION OF SLOW TRANSPORT IN AXONS OF REGROWING NEWT LIMBS BY A NERVE CONDITIONING LESION MADE PRIOR TO AMPUTATION. C. Eberhardt Maier* and I.G. McQuarrie) Dept. of Devel. Genetics and Anat., Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

Forelimb regeneration in the newt (Notophthalmus viridescens) is a nerve-dependent phenomenon. After a limb is amputated, all the tissues of the replacement limb (except nerve axons) are formed from cells of the limb bud. Neurons innervate the new limb by regenerating axons that had been severed by amputation. Axonal sprouting and elongation is the result of the transport of cytoskeletal elements to the distal end of the axon. Previous studies have shown that the rate of axonal elongation coincides with the transport rate of the labeled cytomatrix proteins (e.g. actin, calmodulin, fodrin) and the fastest moving microtubules, representing Slow Component b (SCb) of axonal transport.

Studies were undertaken to determine whether a correlation exists between SCb and limb regrowth. The first requirement was to establish the rate of SCb in brachiospinal nerves. A laminectomy was performed to expose the cervical spinal cord. 35S-methionine was injected into the motor columns of spinal segments 3, 4, and 5. Injection-sacrifice intervals of 7, 14, 21, 28, and 42 days were employed, and serial 1 mm nerve segments were homogenized in SUB (0.5% SDS, 8M urea, 2% beta-mercaptoethanol). The supernatants were subjected to SDS-PAGE followed by fluorography. Fluorograms were used as templates to identify proteins to be removed from gels for solubilization and liquid scintillation counting. These included neurofilament proteins, microtubule-associated proteins, tubulins, actin, calmodulin, and fodrin. The peak of labeling for SCb proteins was found to advance at approximately 0.25 mm/d in normal nerves. The peak of labeling for neurofilament proteins, which identify the slowest moving rate component (SCa), advanced at less than 0.1 mm/d.

We have previously demonstrated that a conditioning lesion of newt brachiospinal nerves, made 2 weeks before amputation, will accelerate axonal sprouting and limb regrowth (Maier et al., J Exp Zool 232:181-6, 1984). We now show that the analysis of SCb transport patterns after amputation indicates a 2-fold increase in the rate of SCb during accelerated limb regrowth.

268.10 FRAGMENTS MADE FROM FULLY DIFFERENTIATED XENOPUS EYES REGENERATE TO FORM PATTERN DUPLICATED VISUO-TECTAL PROJECTIONS. L. Wunsh* and C.F. Ide. Dept. of Biology, Tulane University, New Orleans, LA 70118

In previous studies, removal of the temporal 2/3 of the stage 32 Xenopus eye bud resulted in restoration of an intact eye which formed pattern duplicated projections to the midbrain optic tectum. Restoration of the eyebud may have involved true regenerative growth, or merely a reassignment of uncommitted embryonic cells (e.g., optic stalk cells) to become part of the eye. To determine if Xenopus is capable of "true" retinal regenerative growth, we removed the temporal 2/3 of the retina of progressively older larval eyes (stages 38 and 48). Ten animals from each stage were injected with tritiated thymidine at one day post surgery and prepared for autoradiography one day later. Other animals were reared through metamorphosis and assayed for visuo-tectal projection type via electrophysiology techniques. More than 60% of eye fragments from both stages regenerated to form a normal sized eye.

Stage 38 fragments analyzed histologically at stage 43 showed a large mass of undifferentiated, heavily labeled cells in the naso-ventral region of the fragment. Similar fragments reared through metamorphosis showed pattern duplication of the visual projection to the medial tectum, the normal site of innervation of naso-ventral retinal cells. Thus, stage 38 fragments were similiar to embryonic stage 32 fragments with regard to healing mode, location of undifferentiated, labeled cells in the naso-ventral retina, and pattern duplication of naso-ventral map values. Stage 48 fragments on the other hand analyzed two days post surgery resembled normal, differentiated retina except for "ciliary margin-like" cells found throughout most of the dorsal part of the fragment which folded back upon themselves during healing and were heavily labeled with tritiated thymidine. Fragments mapped after metamorphosis showed partial duplication of the viso-tectal projection in the lateral tectum, the normal site of innervation from dorsal retina.

Stage 48 fragments represent a true "regenerating" system in that the retina is fully differentiated at the time of ablation and during subsequent regeneration. It may be, in these older fragments, that the remaining ciliary margin is the source of cells involved in retinal regeneration and that local growth in oddly juxtaposed regions of the margin correlate with partial pattern duplication of visuo-tectal map values. Supported by NSF Grant PCM-8316142.

268.11 REGENERATION AND NEURAL PLASTICITY FOLLOWING AXOTOMY OF AN IDENTIFIED GASTROPOD NEURON. R.P. Croll, M.W. Baker*, R.C. Swetnam* and R.Y.S. Lo*. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The nervous systems of several gastropod molluscs have been shown to be capable of regeneration and plasticity following injury. This study examines the axonal regeneration of an identified, serotonergic cell within the cerebral ganglion following a crush of its 2-5 collateral axons within the cerebrobuccal connective (CBC). In vitro, axonal regeneration of a homologous cell in Helisoma has previously been reported (Murphy et al., 1985, J. Neurobiol. 16:137). Our study examined this phenomenon using an in vivo preparation. Use of a much larger snail, Achatina, facilitated surgery and resulted in survival rates of near 90%. Following paralysis by injection of succinyl choline, a dorsal incision in the body wall permitted access to the paired CBC's. A single CBC in each subject was then crushed near the buccal ganglion and after closure of the incision, the subjects were maintained for up to 120 days. Regeneration was examined following the lesion using histochemical localization of serotonin-like immunoreactivity (SLIR), intracellular dye injections and backfilling techniques. Within 2-3 days following crush, blebs appeared along all SLIR fibres in the CBC ipsilateral and distal to the crush and in all ipsilateral buccal roots. These blebs became separated from each other and then decreased in number over the first 7 days post-lesion leaving little or no ipsilateral SLIR distal to the lesion. Also within the first week a number of small neurites were seen sprouting from the several axons proximal to the lesion site. These small neurites increased in number during the next two weeks at which point the first fibres were seen traversing the lesion site. The number of neurites which regenerate past the lesion gradually increased and by 8-10 weeks hundreds of very small fibres reached the buccal ganglia and exit the ganglion via the buccal roots.

Use of this preparation has also proved advantageous in another regard. In Achatina the buccal projection of the serotonergic cerebral cell is mostly unilateral. Unilateral axonal crush therefore results in nearly complete depletion of serotonin from the buccal ganglion ipsilateral to lesion. The buccal ganglia were therefore examined for evidence of compensatory sprouting of the contralateral, uninjured cell into denervated area. Sprouting of new fibres across the buccal commissure and out contralateral buccal roots were detected within a week following axonal crush. The number of contralateral fibres appeared to remain stable for at least several weeks following the lesion.

This study was supported by an NSERC (Canada) grant to RPC.

NEURAL PLASTICITY IN ADULT ANIMALS: HIPPOCAMPUS

269.1 A FREQUENCY-DEPENDENT THRESHOLD-LIKE EFFECT CONTROLS BOTH LTP AND LTD. Barbara Burger & W.B Levy. Dept. of Neurosurgery, Univ. of Va., Charlottesville, Va 22908.

The accompanying abstract (Levy & Burger) shows that the number of active afferents can control the production of entorhinal cortex-dentate gyrus LTP and LTD through a highly nonlinear, presumably postsynaptic process. The same interpretation explains the results here where frequency of ipsilateral (ipsi) afferent activity is used to control the event permitting contralateral (contra) LTP and LTD.

6 rats, prepared similarly to Levy et al.'83, received a series of unilateral conditioning trains at frequencies varying from 50-400Hz (2-9 pulses/20ms). 9 rats, prepared similarly, received bilateral conditioning stimulation in which the ipsi pathway received conditioning stimulation at frequencies varying from 25-400Hz (2 pulses/40ms or 2-9 pulses/20ms) while, simultaneously, the converging contra pathway received 400Hz (9 pulses) conditioning stimulation. The contra response is tested alone for 10-15' after each conditioning set.

For the train lengths and intensities used, ipsi conditioning of 100Hz or less does not support significant contra LTP or LTD, regardless of the concurrent contra afferent activity. However, ipsi conditioning at 200Hz or more results in LTD or LTP, depending on the concurrent contra afferent activity. 127 trains of 200Hz ipsi conditioning stimulation alone depresses the unconditioned, converging contra response to 76% of its previous baseline; p=.04. 63 trains of 200Hz ipsi conditioning paired with trains of 400Hz contra conditioning, increases the contra response to 126% of its previous baseline; p=.01. Importantly, 200Hz ipsi conditioning requires only 3 trains (i.e. just 15 stimulation pulses) to induce significant LTD or LTP; ipsi conditioning at lower frequencies fails to produce significant changes after 63 or 127 trains (i.e. 254-635 pulses).

These results indicate that: (1) There is a nonlinear relationship between presynaptic activity, varied as frequency here, and the postsynaptic event that permits synaptic modification. (2) Postsynaptic cell firing is not sufficient for supporting synaptic modification since lower frequencies fail to support LTP or LTD even though conditioning stimulation evokes population spikes. (3) LTD and LTP can be viewed as two parts of a single modification process since equivalent ipsi conditioning stimulation permits either LTP or LTD. Supported by NIH NS 15488 and NIMH RSDA MH00622 to W.B Levy.

269.2 AN INTENSITY-DEPENDENT THRESHOLD-LIKE EFFECT CONTROLS BOTH LTP AND LTD. W. B Levy & Barbara Burger. Dept. of Neurosurgery, Univ. of Va., Charlottesville, Va 22908.

Although somatic discharge of the postsynaptic cell is neither necessary nor sufficient to produce long-term potentiation (LTP), there is clear evidence that induction of LTP requires a permissive event with threshold characteristics (McNaughton et al.'78; Wilson,'81) Using the monosynaptic, bilateral input from the entorhinal cortex to the dentate gyrus this report separates presynaptic requirements from the event permitting long-term modification. The results are consistent with a highly non-linear postsynaptic event that permits either contralateral (contra) LTP or contra long-term depression (LTD).

8 rats, prepared as in Levy et al.'83, receive 3 ipsilateral (ipsi) alone conditioning sets of different intensities, followed by 3 sets of bilateral conditioning in which the ipsi pathway receives different intensity conditionings while the converging contra pathway receives conditioning stimulation of constant intensity. The contra response is tested for 15' after each of the 6 conditioning sets. Though cell firing is neither necessary nor sufficient for LTP, there is often a good correlation between the existence of a population spike and induction of LTP. Thus, 3 ipsi conditioning intensities are used: a low intensity evoking a 1-2 mV ipsi response; a medium intensity evoking a 10-15 mV ipsi response without a population spike; and a high intensity evoking a 10-20 mV ipsi response with a population spike.

With unilateral conditioning, neither low nor medium intensity ipsi conditioning significantly depresses the contra response. However, high intensity conditioning significantly depresses the contra response to 73% of its preconditioning values; p=.02. Likewise, with bilateral conditioning, neither low nor medium intensity ipsi conditioning permits potentiation of the contra response. However, high intensity ipsi conditioning paired with contra conditioning induces significant LTP of the contra response (142% of its pre-bilateral conditioning value; p=.02).

These data suggest that active afferents sum to control a nonlinear, or perhaps, a threshold-like process which permits the induction of either LTP or LTD. The accompanying abstract, Burger and Levy, shows a similar result using frequency instead of intensity as the experimental variable.

269.3 CHANGES IN DENDRITIC SPINE DIMENSIONS CAN CONTRIBUTE TO LTP IN THE HIPPOCAMPAL DENTATE GYRUS. N. L Desmond, R. E. Williams*, and W. B Levy. Dept. Neurosurgery, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

There is some controversy as to the role dendritic spines play in controlling excitatory synaptic drive. Some investigators, following Rall's '74 proposal, argue that changes in the dimensions of long, thin spine stems could significantly alter current flow from an activated spine synapse to the parent dendrite. That is, as a spine stem shortens and widens, its longitudinal resistance (R_{SS}) decreases. With this decrease, current flow into the parent dendrite would increase. Another group essentially argues that spine synapses are indistinguishable from shaft synapses because changes in stem dimensions have little or no effect on current flow from an activated spine synapse. The argument hinges on the actual spine stem dimensions and the resistance to ground (R_{BI}) at the intersection of the parent dendrite with the spine stem. Using morphometric values (Desmond and Levy, '82, '84, '85) from Golgi-impregnated granule cells of the dentate gyrus (DG) and a steady state model of the granule cell, this report finds that spine stem alterations can contribute significantly to LTP in the DG. A computer program solved the usual second order partial differential equation $[(\lambda^2\delta^2V/\delta X^2)-V=0$; Rall, '77] to calculate steady-state R_N (resistance to ground at the soma), R_{SS}, and R_{BI} values for 7 cells. The model used an R_M of 8000 ohm·cm^2 and an R_i of 70 ohm·cm. Values obtained for R_N (mean=83 Mohm) are somewhat higher than those reported from electrophysiological analyses (40-60 Mohm). The following example uses a dorsal leaf granule cell. A spine stem with a diameter of 0.1 um and a length of 1.2 um has an R_{SS} of roughly 107 Mohms. In the middle third of the molecular layer, R_{BI} ranges from 70-180 Mohms, with an average of 118 Mohm. Such a spine has a R_{SS}/R_{BI} ratio of 0.91 "before" LTP. Our LTP experiments find that spine stems shorten 15% and widen by 21%. If the exemplar spine stem dimensions are changed as suggested by these percentages, the dimensions become 0.12 um (diameter) and 1.02 um (length), producing an R_{SS} of 63 Mohms. With LTP then, the R_{SS}/R_{BI} ratio becomes 0.53, a decrease of 42% in the ratio of spine stem resistance to branch input resistance. This decrease produces a current increase of 24% (18-33% depending on R_{BI}). Thus, these data support Rall's original proposal so that the mechanisms underlying LTP may include spine stem modification as well as increased transmitter release (Dolphin et al., '82) and postsynaptic changes (Desmond & Levy, '86; by inference, more receptors). Supported by NS15488 and NIMH RSDA MH00622 to WBL.

269.4 INDUCTION OF HIPPOCAMPAL LONG TERM POTENTIATION IN THE AWAKE RAT USING PHYSIOLOGICALLY PATTERNED STIMULATION. D.M. Diamond and G.M.Rose. Medical Research Service, VAMC and Dept. of Pharmacology, UCHSC, Denver, CO 80262

Long term potentiation (LTP) has been described extensively as a mnemonic model. However, in most studies the stimulation required to induce LTP exceeds normal physiological activity. Recently, Rose and Dunwiddie (Neurosci. Lett., 69:244, 1986) reported that the threshold to induce LTP was reduced when the stimulation parameters more closely mimicked hippocampal discharge activity. They incorporated two well known characteristics of physiological activity in the hippocampus into a pattern of electrical stimulation: 1) hippocampal neurons discharge in a burst of activity, and 2) rhythmic activity at approximately 6 Hz (170 msec period) is observed during exploration (theta rhythm). Using the in vitro preparation, they stimulated the commissural input to CA1 with a single pulse, followed 170 msec later by a high frequency burst of 4 pulses (primed burst, PB). This pattern of stimulation, combining the timing of the theta rhythm with the bursting activity intrinsic to hippocampal neurons, resulted in a long term increase in the amplitude of the population spike (PB-LTP). In contrast, a high frequency train of 5 pulses (unprimed burst) did not induce long lasting effects. In this report, we have extended the findings of the in vitro study by using patterned stimulation to induce PB-LTP in the awake rat.

Data were obtained from 9 rats in 26 recording sessions. Under barbiturate anesthesia, the subjects were implanted with a stimulator in the hippocampal commissure. Contralateral to the stimulation site, a microdrive base was implanted over CA1. A miniature microdrive was then attached to the base after the subject recovered from the surgery. The removable microdrive allowed for accurate localization of the recording electrode in the CA1 cell body layer. Responses were recorded in CA1 following stimulation of the commissure. Population spike amplitude was just above threshold (.5-1 mV). The subjects were either asleep or in a quiet awake state during all baseline and post-high frequency recordings. Immediately prior to patterned stimulation (1+4 pulses), the subjects were awakened. Lasting increases (>20 min) in population spike amplitude occurred in 65% (17/26) of the recordings. In 13 sessions in which an initial EPSP was evident, increases in the slope occurred in 54% (7/13) of the recordings. There were no changes (0/17) in response to a train of 5 pulses.

Studies using patterned stimulation have provided an initial understanding of the relationship between endogenous rhythms and synaptic plasticity. By replicating the earlier in vitro work, we can now apply a two-tiered approach towards understanding both the mechanisms and behavioral basis of LTP.

269.5 CHARACTERISTICS OF CROSSED AND MULTISYNAPTIC PATHWAYS FROM THE ENTORHINAL CORTEX TO THE CONTRALATERAL DENTATE GYRUS IN UNANESTHETIZED RATS. R.L. Wilson*, K. Pang and G.M. Rose. Dept. of Pharmacology, UCHSC and Medical Research, VAMC, Denver, CO 80262

Previous studies have described a sparse monosynaptic connection from the entorhinal cortex to the contralateral dentate gyrus, termed the crossed temporodentate pathway (CTD). Since previous electrophysiological descriptions of this connection are from work in anesthetized animals, we re-examined this pathway in unanesthetized, behaving rats.

Sprague-Dawley rats were bilaterally implanted with stainless steel electrodes for chronic neurophysiological experiments. Recording electrodes were placed in the ilar region of the dentate gyrus and stimulating electrodes were placed in the angular bundle to allow activation of the entorhinal afferents. Input-output curves were constructed by stimulating an individual perforant path from 1 to 20 volts and recording the responses in the contralateral dentate gyrus. High frequency stimulation (HFS) consisting of 150 stimuli (10 trains of 15 pulses at 500 Hz; 5 sec. intertrain interval) was delivered to a single perforant path (HFS-PP).

Two evoked potentials were observed in response to perforant path stimulation which could be discriminated by differing onset latencies. The early (about 4.2 ms) potential corresponded to the previously described CTD response. The long latency (about 7.2 ms) of the second response suggested that it resulted from activation of a di-synaptic pathway (entorhinal->entorhinal->dentate; DS). Both responses, when recorded from the dentate hilus, displayed a positive field EPSP and a population spike. The CTD response was observed at higher stimulation voltages than the DS response.

After HFS, the following results were observed: 1) When recording ipsilateral to the HFS-PP, the direct perforant path-dentate (PP-DG) response was significantly increased. In contrast, the PP-DG response recorded contralateral to the HFS-PP was NOT increased. 2) The CTD response recorded ipsilateral to the HFS-PP was NOT significantly increased. However, a significant increase was seen in the CTD response recorded contralateral to the HFS-PP. 3) The DS responses recorded both ipsilateral and contralateral to the HFS-PP were significantly increased. In all cases where the response was elevated, it remained so for at least 24 hours.

In conclusion: 1) A population spike was elicited in the CTD pathway in the absence of anesthesia. 2) A longer latency, presumably DS, response was also recorded following contralateral PP stimulation. 3) HFS to a single perforant path produced LTP of the CTD and DS responses. 4) LTP of the DS response resulted from the potentiation of the first synapse (entorhinal -> entorhinal) and/or the second synapse (entorhinal -> dentate). These results demonstrate that information from a single entorhinal cortex is transferred to both the ipsilateral and contralateral dentate gyrus.

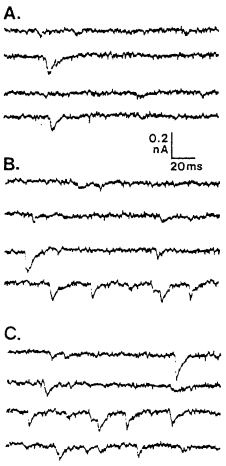
269.6 SINGLE QUANTAL CURRENTS IN HIPPOCAMPAL NEURONS. X.-W. Rong*, C. L. Keenan, and T. H. Brown (SPON: E. Roberts). Div. of Neurosci., Beckman Res. Institute, City of Hope, Duarte, CA 91010.

Application of the single-microelectrode clamp (SEC) technique to synapses in hippocampal brain slices (Brown and Johnston, J. Neurophysiol. 50: 487, 1983) enabled studies of conductance mechanisms responsible for long-term synaptic potentiation (LTP) in this tissue (Barrionuevo, Kelso, Johnston and Brown, J. Neurophysiol. 55: 540, 1986). Further elucidation of the mechanism responsible for LTP expression in hippocampus requires a quantal analysis (Barrionuevo, et al, 1986). This is best done using voltage-clamp techniques under conditions in which the quantal currents are larger than the noise.

Single quantal events have been detected in CA3 pyramidal neurons under both current- and voltage-clamp conditions (Brown, Wong and Prince, Brain Res. 177: 194, 1979; Johnston and Brown, Brain Slices, Plenum, 1984). The purpose of the present study was to improve the signal-to-noise ratio in our measurements of single quantal currents in these cells using a better SEC.



Hippocampal slices were prepared and maintained in the usual fashion. To the normal bathing medium was added tetrodotoxin (1 μM, to block evoked release), picrotoxin (10 μM, to block inhibitory quanta--see Johnston and Brown, 1984), and CsCl (2 mM, to block anomalous rectification at hyperpolarized holding potentials). Microelectrodes (25 - 40 MΩ) were beveled and the switching rate of the SEC was 5 - 8 kHz. Spontaneous miniature excitatory postsynaptic currents (MEPSCs) were recorded from a holding potential of -120 mV. Illustrated MEPSCs were recorded at three different time periods (A - C) over the course of an hour. Assuming a reversal potential near 0 mV (Brown and Johnston, 1983; Johnston and Brown, 1984), the larger currents represent a measured conductance increase (see Barrionuevo, et al, 1986) of about 10^{-9} S.

If the larger MEPSCs are produced by the mossy-fiber inputs--a possibility that we are now testing--then these synapses should be suitable for performing a quantal analysis of LTP.

269.7 MANIPULATION OF PITUITARY-ADRENAL ACTIVITY AFFECTS NEURAL PLASTICITY IN RODENT HIPPOCAMPUS. M.R. Foy, J.G. Banghart, S. Levine and R.F. Thompson. Departments of Psychology & Psychiatry, Stanford University, Stanford, CA 94305.

Stress can both improve or impair learning, and many of the hormones secreted during stress (ACTH, glucocorticoids, opioids, epinephrine, NE and vasopressin) can affect learning and memory processes. A marked impairment of long-term potentiation (LTP) in hippocampal explants taken from rats exposed to acute stress (inescapable tail-shock) has recently been reported (Foy et al., Behav. & Neural Bio., 1987, in press). In the present study, we examined the effects of acute stress (inescapable tail-shock) on LTP in rats given water or in rats pretreated with dexamethasone (dex, a synthetic glucocorticoid which blocks the pituitary-adrenal response to stress). We also examined the time-course of the stress response on LTP impairment.

Adult male rats (300-450g) were pair-housed in climate controlled facilities on a 12 hr light/dark cycle with food and water available ad lib. One animal in each pair (water x stress) was placed in a restraining tube and received tail-shocks (1 mA, 1 sec) every minute for 30 min. The other animal in each pair (water x control) was taken directly from the home cage and received no restraint or tail-shock. Dexamethasone was administered in drinking water (20 ug/ml) for 48 hr prior to experimental conditions mentioned above, i.e., (dex x stress) and (dex x control). In vitro hippocampal slices (400 um) were then prepared from these animals according to standard methods. Extracellular recordings of the population field potential were taken from the CA1 cell body layer in response to stimulation (0.1 msec pulses) of Schaffer collateral afferents, before and after tetanus (100 Hz for 1 sec). A stable response potentiation following the decline from maximal potentiation (PTP) occurred sooner in the dexamethasone treated groups, regardless of experimental condition (stress vs control). However, a stress-induced impairment of LTP was observed, regardless of dexamethasone treatment, from 5-30 min post-tetanus (LTP).

Our data suggest that dexamethasone might facilitate the time course from PTP to LTP; some variable(s) in the temporal pattern of the PTP/LTP interaction may be modulated by dexamethasone. These data replicate our previous findings that stress impaires LTP in the in vitro hippocampal slice. In addition, manipulation of the pituitary-adrenal axis by dexamethasone treatment appears to influence temporal patterns in the PTP/LTP interaction.

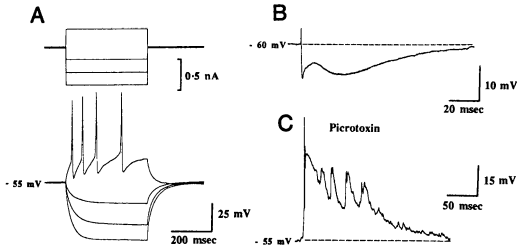
269.8 SYNAPTIC PLASTICITY AND THE ROLE OF NMDA RECEPTORS IN EPILEPTIFORM DISCHARGES IN TURTLE HIPPOCAMPUS *IN VITRO*. Linda J. Larson-Prior and N. Traverse Slater. Departments of Physiology and Psychiatry, Northwestern University Medical School, Chicago, IL 60611

The turtle telencephalon has provided a useful *in vitro* model for comparative studies of the physiology of the hippocampus and visual cortex due to the resistance of this tissue to anoxia and simplified intrinsic circuitry [1,2,3]. Intracellular recordings were made in pyramidal neurons of the turtle hippocampus (ventromedial cortex; VMC) identified by their characteristic firing properties (Fig 1A; refs 1&2). The intact VMC was maintained *in vitro* at 22 °C as previously described [1,2,3]. Stimulating electrodes were placed on the margin of the VMC adjacent to the lateral ventricle, and pyramidal neurons were impaled within 0.5 mm of the site of stimulation. Synaptic stimulation evoked either a monophasic or a biphasic ipsp (Fig 1B). Ipsps were transiently reduced by 1-2 Hz stimulation, and were irreversibly reduced (30-100%) by high frequency tetani (50 Hz, 2s), as observed in mammalian hippocampus [4,5]. Following the application of the GABA antagonist picrotoxin or 3-mercaptopropionic acid (3-MP) ipsps were reduced and synaptic stimulation produced epileptiform discharges (Fig 1C) which were not affected by the NMDA receptor antagonist ±AP5. In many cells 1 Hz stimulation or perfusion with magnesium-free medium revealed a slow epileptiform epsp which was reversibly blocked by the NMDA receptor antagonists ±AP5 and ketamine.



These results demonstrate a tetanus-induced plasticity of GABAergic inhibition in the turtle VMC which is similar to that described in the mammalian hippocampus [4,5]. However, the lack of sensitivity of epileptiform discharges induced by GABA antagonists to ±AP5 suggest a less prominent role is played by NMDA receptors in mediating epileptiform activity in the turtle VMC than has been previously demonstrated in the mammalian hippocampus *in vitro*.

269.9 LONG-TERM POTENTIATION IN CA3 NEURONS: CHANGES IN EFFICACY OF UNTETANIZED INPUTS. J. E. Bradler* and G. Barrionuevo. Departments of Behavioral Neuroscience, Psychiatry, and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Intracellular recordings were made from pyramidal neurons in the CA3b subfield of the in vitro rat hippocampal slice. EPSPs were reliably elicited by stimulation of three different sites in the slice: 1) the s. radiatum of the CA1 region; 2) the fimbria (Fi); and 3) the s. granulosum of the dentate gyrus to activate the mossy fibers (MF). Picrotoxin (8-15 M) was present in all experiments to block concomitant synaptic inhibition. During a control period the synaptic inputs were tested for 30 min at 0.16 Hz. If the EPSP amplitudes proved stable, tetanic stimulation was delivered to one of the stimulation sites to induce long-term potentiation (LTP). The tetanus consisted of eight 100 Hz 50 ms duration bursts, delivered at 0.16 Hz. LTP was defined as a nondecremental increase in EPSP amplitude of at least 25% 15 min posttetanus.

In experiments in which LTP was induced in the tetanized CA1-evoked EPSP (N=4), the amplitude of the untetanized MF-evoked EPSP underwent a depression (-20%) for the duration of the recording epoch. No consistent changes were observed upon the untetanized Fi-evoked EPSP. In experiments in which LTP was induced in the tetanized Fi-evoked EPSP (N=2), the untetanized CA1- and MF-evoked EPSPs were reduced in amplitude (-30%) during the posttetanus period. During the control period in experiments in which LTP was induced in the tetanized MF-evoked EPSP (N=6), stimulation of the MF site was simultaneously paired first with the CA1 site, and then with the Fi site. These pairings were designed to verify independence of the three inputs generating EPSPs in the impaled cell, and did not result in long term changes in the EPSPs. If independence was not confirmed, i.e., if the amplitude of the "paired" EPSP was smaller than the algebraic sum of the amplitudes of each individual EPSP, the data was not considered for analysis. In three neurons in which this criterion was fulfilled for the MF-and Fi-evoked EPSP, the untetanized Fi-evoked EPSP exhibited profound LTP (238%) considerably exceeding that induced in the tetanized MF-evoked EPSP (129%). In only one of these neurons was independence confirmed between the MF- and CA1-evoked EPSP. Upon induction of LTP in the MF-evoked EPSP, the untetanized CA1-evoked EPSP underwent LTP of considerable magnitude, reaching action potential threshold within 10 min posttetanus.

269.10 EFFECTS OF NMDA RECEPTOR ANTAGONISTS ON NOREPINEPHRINE-INDUCED LONG-LASTING POTENTIATION (NELLP) OF POPULATION SPIKE AND EPSP IN RAT DENTATE GYRUS. E.C. Burgard*, G. Decker*, and J.M. Sarvey, Department of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

NELLP is a long-lasting increase in both population spike amplitude and EPSP slope induced in rat dentate gyrus granule cells by bath application of norepinephrine (NE) to the in vitro hippocampal slice (Stanton & Sarvey, Brain Res. Bull. 18:115, 1987). The role that N-methyl-D-Aspartate (NMDA) receptors play in this phenomenon is intriguing since it has been demonstrated that these receptors play a regulatory role in the induction of long-term potentiation in the hippocampal slice (Dingledine, TINS 9:47, 1986). Here we investigate the susceptibility of NELLP to two selective NMDA antagonists: D-2-amino-5-phosphonovaleric acid (APV) and 3-[(+)2carboxypiperazin-4-yl]-propyl-1-phosphonic acid (CPP).

Medial perforant path stimulation in the rat hippocampal slice evoked a population spike recorded in the granule cell layer of dentate gyrus along with a dendritic EPSP recorded 100-200 µm from the cell body layer. In control experiments, bath application of (-)NE (50 µM) for 30 minutes reliably induced NELLP of both population spike amplitude and initial negative slope of the EPSP. This potentiation persisted after a subsequent 30 minutes of drug-free wash. In other experiments, APV and CPP were administered via the bath 15 minutes prior to, during, and 15 minutes following NE application. The responses were then followed through a 30 to 60 minute wash with drug-free buffer.

Application of CPP (1 or 10 µM) reversibly depressed the population spike 3-55% as well as the EPSP slope 0-31% recorded 15 minutes following administration of the drug. D-(-)-APV (10 µM) also reversibly depressed the population spike 4-15% but did not affect the EPSP slope. All concentrations of both drugs completely blocked potentiation produced in the presence of NE as well as NELLP of both the EPSP and population spike.

We conclude that (1) NMDA receptors are involved in the regulation of NELLP of both population spike and EPSP in rat dentate gyrus, and (2) NMDA receptors may be involved in normal synaptic transmission in medial perforant path. (Supported by USUHS Grant No. C07514)

269.11 EFFECTS OF SELECTIVE FORNIX-FIMBRIA LESIONS ON SUBSTANCE P, SOMATOSTATIN, AND CHOLECYSTOKININ CONCENTRATIONS IN THE RAT HIPPOCAMPUS. U.E. Gasser*, A.R. Dravid and R.A. Siegel*. Preclinical Research, Sandoz Ltd., Basle, Switzerland and Dept. Pharmacology, New York Univ. Med. Ctr., New York, NY 10016, U.S.A.

The neuropeptides substance P (SP), somatostatin (SST), and cholecystokinin (CKK) are present in the mammalian Hippocampus (HI). The SP projection to the HI likely arises in the medial septum-diagonal band (MS). CKK neurons appear to be intrinsic to the HI whereas SST-positive cells and fibers have been reported in the HI and fornix-fimbria (FF), respectively. We determined the activity of choline acetyltransferase (ChAT), and SP, SST and CKK levels (RIA) in 3 septotemporal regions of the HI in intact rats and in rats with partial FF lesions (medial/lateral). In control rats, the three peptides, like ChAT, exhibited an ascending concentration gradient along the septotemporal axis of the HI. One week postlesion, the marked loss of SP manifested in a lesion- and HI region-specific manner; an almost complete loss of SP in the dorsal region after medial lesion, and a marked reduction in the ventral region after lateral lesion. Thus the mediolateral organization of SP efferents from the MS appears similar to that of cholinergic fibers. The contribution of the dorsal pathway to hippocampal SP-innervation was estimated to be about 65% (complete FF lesion). The complete recovery of SP levels in all HI regions, and an overshoot in dorsal and medial regions, 8 weeks after either lesion may be due to collateral sprouting and/or accumulation of SP in the spared afferents. The mechanism(s) involved in similar changes in the contralateral HI are unclear. The decrease of SP in the MS at 8 weeks may indicate axotomy-induced retrograde degeneration of SP neurons. The lack of lesion effect on SST content at 1 week suggests the absence of septo-hippocampal innervation whereas the decline in SST in both hippocampi at 8 weeks probably reflects retrograde degeneration of SST neurons in the HI whose efferents course through both ipsi- and contralateral dorsal pathway. CCK levels in HI were not influenced by either lesion supporting the view that CCK containing neurons are intrinsic to the hippocampus.

269.12 **POSSIBLE ROLE OF INHIBITION IN LTP INDUCTION.** G. J. Pacelli, F. Naghdi and S. R. Kelso. Dept of Biological Sciences and Committee on Neuroscience, University of Illinois at Chicago, Chicago, IL 60680.

Brief activation of afferent pathways to region CA1 of the hippocampus can lead to a long lasting increase in synaptic transmission that has been termed long-term potentiation (LTP). Several studies have shown that separate sets of afferent fibers may be used to associatively induce LTP, using paradigms that in some cases are analagous to classical conditioning paradigms. One recent study reported that optimal associative interactions occur when brief trains of stimulation (40 msec at 100 Hz) are delivered to two separate afferent inputs at about theta frequency, i.e., when stimulation of the two inputs is separated by 200 msec. These patterns of stimulation are also accompanied by a "priming" effect, in which the stimulation of one pathway causes a prolongation of the synaptic response elicited in the second pathway 200 msec later. We wished to examine the suggestion (Larson and Lynch, Science 232:985, 1986) that this could be due to a lack of inhibitory synaptic activation during the second, "primed", synaptic stimulation.

Hippocampal slices were prepared from male Sprague-Dawley rats and maintained in oxygenated nutrient medium at 33-36 ^{0}C. Bipolar wire stimulating electrodes were placed on either side of region CA1 to stimulate separate sets of afferent fibers in stratum radiatum. Electrophysiological recordings were then made from stratum radiatum and stratum pyramidale in CA1 one half way between the two stimulating electrodes.

Our results indicate that brief stimulation (40 msec at 100 Hz) that does not normally elicit LTP can be made to do so when preceeded by 200 msec with a single shock to a separate "priming" synaptic input. Similarly, a single priming shock can lead to a prolongation of the synaptic response of the second "primed" input. When slices are bathed in picrotoxin to block inhibitory synapses, the priming effect is blocked and synaptic responses appear prolonged even in the absence of a priming stimulus. In addition, the brief stimulation is capable of eliciting LTP without a preceeding priming pulse.

These data are consistent with the hypothesis that the priming effect is due to a use-dependent depression of inhibitory synapses (Mcarren and Alger, J.Neurophysiol. 53:557, 1985) that allows the later stimulation of the primed pathway to be more effective in depolarizing the postsynaptic cell and in turn, more effective in eliciting LTP (Kelso, Ganong and Brown, PNAS 83:5326, 1986).

269.13 LOW-FREQUENCY SYNAPTIC DEPRESSION RECORDED INTRACELLULARLY FROM HIPPOCAMPAL GRANULE CELLS. P.C. Rinaldi, A.H. Ganong and T.H. Brown. Dept. of Surgery, Div. of Neurosurgery, Univ. California, Irvine, CA. 92717 and Div. of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA. 91010.

Low-frequency synaptic depression (LFD) may play an important role in modulating the flow of information through adaptive neural networks. Previous studies have used extracellular field potential recordings to demonstrate LFD (Teyler & Alger, Brain Res. 115, 413-25, 1976) in the perforant pathway synaptic inputs to granule cells. The parametric features of this response depression resemble those that characterize behavioral habituation (cf. Thompson & Spencer, Psyc. Rev., 173, 16-43, 1966). Little is known about the biophysical mechanisms for LFD in the hippocampal formation. As part of an effort to understand the underlying mechanisms, we have begun to study LFD using intracellular recording techniques.

Hippocampal slices from male rats were maintained in oxygenated, warmed, artificial CSF to which 10 μM picrotoxin was added to block synaptic inhibition. Bipolar electrodes were used to stimulate the perforant inputs. The postsynaptic responses were measured using 3 M KCl-filled intracellular micropipettes (50-100 M Ohms). During both the control and recovery periods, the synapses were stimulated at 30 sec. intervals. LFD was examined during the intervening period in which the synapses were stimulated at intervals of 2.5 or 5.0 sec.

Preliminary results suggest that the time-curve and magnitude of LFD observed in our intracellular measurement are similar to those previously reported based on field potential recordings. Within a restricted range of parametric values, the magnitude of LFD appeared to be inversely related to the stimulus intensity and directly related to the stimulus frequency. We are currently using the single-electrode voltage clamp (Brown & Johnston, J. Neurophys., 50, 487-505, 1983) to explain possible biophysical mechanisms of LFD.

269.14 AUTORADIOGRAPHIC AND HISTOCHEMICAL ANALYSIS OF DENTATE GYRUS FOLLOWING UNILATERAL ENTORHINAL CORTEX LESIONS. J.W. Bekenstein*, C.A. Tansey*, G.F. Wooten, O. Steward (SPON: H.R. Brashear). Departments of Neurology and Neuroscience, University of Virginia, Charlottesville, VA 22908.

Binding of [^{3}H]hemicholinium-3 (HC-3), a presynaptic cholinergic terminal marker, and of [^{3}H]3-quinuclidinyl benzilate (QNB), a muscarinic receptor ligand, was analyzed with autoradiography to examine the time course and extent of putative sprouting of the cholinergic septohippocampal pathway following unilateral entorhinal cortical lesions in the rat. Electrolytic lesions were made, and HC-3 and QNB binding studies were performed 3, 9, and 15 days post lesion. Binding results were compared to acetylcholinesterase (AChE) histochemical staining patterns of unfixed tissue.

Histochemistry: AChE histochemistry demonstrated a dual banded pattern in the molecular layer of the dentate gyrus ipsilateral to the lesion at 9 and 15 days post lesion, but not at 3 days. This dual banding consisted of the normal band located immediately external to the granule cell layer and a second band of intensified staining in the denervated zone. The amount of shrinkage of the ipsilateral molecular layer of septal dentate gyrus was 0-6% at 3 days, 14% at 9 days, and 20% at 15 days post lesion. These results are consistent with previous studies (Matthews, et al., Brain Res. 115:1-21, 1976).

Autoradiography: Densitometric laminar analysis of QNB binding at 3, 9, and 15 days post lesion showed no change from the pattern observed in unoperated rats except for shrinkage of the molecular layer. Analysis of HC-3 binding at 9 and 15 days post lesion revealed a rearrangement in the pattern of binding, with an increase in binding in the outer 2/3 of the molecular layer ipsilateral to the lesion. The binding of HC-3 at 3 days post lesion was no different from controls. Shrinkage of the molecular layer comparable to that seen with QNB and AChE was observed at all time points with HC-3. With a conservative correction for shrinkage of the molecular layer (Steward and Vinsant, J. Comp. Neurol., 214:370-376, 1983), the increase in binding in the outer 2/3 of the molecular layer was 10-20% at both 9 and 15 days post lesion.

Because HC-3 binding reflects the distribution of cholinergic terminals, the present results suggest that a rearrangement of cholinergic terminals occurs in the molecular layer of the ipsilateral dentate gyrus following unilateral entorhinal cortical lesions. The HC-3 findings extend AChE and tract tracing studies by allowing quantitation of terminal redistribution. QNB results suggest that functional muscarinic synapses are not formed by 15 days post lesion.

269.15 **NOREPINEPHRINE (NE) MODULATION OF DENTATE GYRUS SYNAPTIC PLASTICITY: INTERACTIONS WITH N-METHYL-D-ASPARTATE (NMDA) RECEPTORS AND KINDLING-INDUCED ALTERATIONS IN NORADRENERGIC SENSITIVITY.** P.K. Stanton, I. Mody and U. Heinemann*, Dept. of Neurophysiology, Max Planck Institute for Psychiatry, Martinsried, West Germany.

Depleting brain norepinephrine (NE) impairs long-term potentiation (LTP) of perforant path (PP)-dentate gyrus (DG) synapses, promotes induction of kindled epilepsy, and NE elicits long-lasting potentiation of PP evoked potentials. However, mechanism(s) underlying these actions remain unclear. Therefore, we employed ion-selective microelectrodes, extra- and intracellular recordings from dentate granule neurons to examine actions of NE on granule cells, and changes in these actions after the induction of long-term kindling plasticity.

Bath applying NE (50 μM) to rat hippocampal slices markedly enhanced both Ca^{2+} influx and K^+ efflux (measured with ion-selective electrodes) evoked by high-frequency PP stimulation of a type which elicits LTP (20 Hz/ 10 s). The β_1-antagonist metoprolol blocked this action, as did the NMDA receptor antagonist 2-amino-5-phosphonovalerate (APV 30 μM). Experiments where extracellular [Ca^{2+}] was lowered to 0.1 mM to block synaptic transmission revealed that NE specifically enhances postsynaptic Ca^{2+} influx while not affecting presynaptic influx. Furthermore, NE potentiated Ca^{2+} influx induced by iontophoresing NMDA onto granule cells, but not influx induced by quisqualate.

In intracellular recordings, NE depolarized control granule cells with an increase in input resistance (R_N), blocked accomodation of firing to depolarizing current injection or synaptic tetanus, and blocked the late after-hyperpolarization - all actions antagonized by metoprolol. NE also produced an α_1-receptor mediated block of regenerative Ca^{2+} potentials (after injecting Cs^+ to block K^+ currents and QX314 to block Na^+ spikes). Interestingly, the depolarization and increase in R_N were both long-lasting after washout of NE, similar to long-lasting potentiation of PP evoked field potentials elicited by NE.

Additionally, we have found that the NMDA receptor antagonist APV (30 μM) specifically blocked the long-lasting phase of NE-induced potentiation of PP evoked population potentials, as well as the persistent phase of depolarization and R_N increase recorded intracellularly. Furthermore, after the induction of kindled epilepsy (a form of long-term neuronal plasticity which we have shown enhances NMDA receptor participation in dentate synaptic transmission), NE lost all actions on dentate granule cells.

These results show that NE likely modulates DG granule cell long-term plasticity via β_1-receptor action to activate normally quiescent NMDA receptors. Furthermore, kindling is associated with down-regulation of sensitivity to NE. Physiologically, this may represent a "write-protect" mechanism by which neuronal networks prevent over-writing of stored information, and changes in noradrenergic sensitivity may also contribute to epileptogenesis.

BASAL GANGLIA: ELECTROPHYSIOLOGY AND BEHAVIOR

270.1 MOTOR FUNCTIONS OF THE CAIMAN BASAL GANGLIA. S.E. Brauth, Dept. of Psychology, Univ. of Maryland, College Park, MD 20742.

In the reptile Caiman crocodilus, the homologue of the mammalian corpus striatum is considered to be the ventrolateral area (VLA) of the telencephalon. In caiman, the VLA consists of two major cell fields, a small-celled field (VLA s.c.) containing a dense dopamingeric fiber plexus derived from the substantia nigra, and a large-celled field (VLA l.c.) in receipt of input from neurons located in the small-celled field, and which gives rise to an extensive fiber system, the ansa lenticularis (AL). On these bases, the VLA s.c. of the caiman has been compared to the caudate nucleus and putamen of mammals, while the VLA l.c. of the caiman has been compared to the globus pallidus of mammals.

Despite these histochemical and anatomical similarities, the pathways by which the reptilian and mammalian basal ganglia control motor functions differ in important ways. The principal targets of the AL in mammals are ventral tier thalamic nuclei which project back to motor and premotor cortices. In the caiman, the principal target of the AL is a pretectal nucleus which projects to the optic tectum. In order to gain insight into the behavioral functions of the caiman basal ganglia, the effects of ibotenic acid lesions placed within portions of the VLA l.c. (i.e., the globus pallidus) on prey-catching behaviors were assessed using computer quantification of videotaped behavioral sequences.

Juvenile caiman were videotaped while catching goldfish in a small enclosure. Prey-catching is fairly stereotyped in caiman. Normally, caiman orient toward their prey, then strike during which the jaws open and eyes close. Pallidal lesions result in excessive and poorly directed movements including inaccurate orientation movements. Strike accuracy was generally reduced from prelesion levels of 30-50% to between 10 and 30%. Many excess movements, including repetitive and apparently involuntary jaw movements were also observed. These excessive movements were most likely to occur if the lesions invaded the most ventral portion of the VLA, including the ventral pallidum.

These results are consistent with the view that motor functions of caiman basal ganglia involve modulation of tectal orientation and visually guided behaviors. In contrast to mammals, which are believed to have evolved from small burrowing insectivores and possess well developed somatosensory systems, many behavioral sequences such as prey-catching and nest building involve visually guided movements in birds and reptiles. The behavioral functions of the basal ganglia reflect these differences. Thus while the overall organization of the afferent and efferent pathways of the basal ganglia show many similarities among extant amniote species, the specific pathways by which motor functions are controlled, however, differ between vertebrate groups, reflecting the development of other sensory and motor systems as well.

270.2 RETICULAR AND CEREBELLAR STIMULATION MIMIC AMPHETAMINE ACTIONS ON AMPLITUDE AND TIMING OF FRONTAL CORTEX EVOKED NEOSTRIATAL RESPONSES IN RATS. Lawrence J. Ryan*, Stephen J. Young*, and Philip M. Groves. (SPON: Harry Klemfuss) Dept.Psychiatry, M-003,University of California San Diego, La Jolla, CA 92093.

Electrical stimulation of frontal cortex evokes a stereotyped sequence of extracellular potentials in rat neostriatum. Wave P1 corresponds temporally to the initial intracellularly recorded depolarization. The subsequent 80-150 ms duration hyperpolarization overlaps two extracellular waves: N2, which may reflect collateral inhibition, followed by P2, which may reflect thalamo-cortical disfacillitation. A late wave, N3, corresponds to rebound depolarization (Ryan, et al., 1986, Brain Res Bull 17: 751-758). Amphetamine (0.1-5.0 mg/kg, iv, d-amphetamine sulfate) reduces P1 amplitude and shortens the latency to N3 onset in a dose-dependent manner. These effects may be mediated extrastriatally, via noradrenergic mechanisms. First, these two effects of amphetamine are mimicked by repetitive stimulation (60 Hz, 0.1-0.3 mA square waves through 75u bipolar twisted teflon coated stainless steel electrodes) of the mesencephalic reticular formation and the deep cerebellar nuclei. Furthermore, mesencephalic reticular formation stimulation and amphetamine reduce the latency to the late rebound wave of cortico-cortical evoked responses. Second, kainic acid lesion of the medial thalamus, which eliminates wave N3, reduces or eliminates the amphetamine-induced reduction in P1 amplitude. Third, the beta noradrenergic drugs propranolol (5.0 mg/kg) and metoprolol (10.0 mg/kg) reverse these effects of amphetamine, whereas the dopamine antagonist, haloperidol (0.03 mg/kg) does not affect P1 amplitude and further shortens N3 latency. The alpha-2 antagonist yohimbine (1.0 mg/kg) strongly magnifies the amphetamine-induced reduction in N3 latency, but, paradoxically, reverses the reduction in P1 amplitude. The alpha agonist, clonidine (0.01-0.10 mg/kg) had inconsistent effects on P1 amplitude and N3 latency. Lastly, direct infusion of amphetamine (5uM) unilaterally into the contralateral deep cerebellar nuclei (N=2) reduced N3 latency. Taken together, these results suggest amphetamine strikingly alters cortico-striatal interactions via noradrenergic mechanisms acting on the medial thalamus and its afferents. Thus, one function of thalamostriatal projections may be to modulate corticostriatal relations.

270.3 RETICULAR FORMATION STIMULATION MODIFIES CORTICALLY EVOKED INTRACELLULAR POTENTIALS IN NEOSTRIATUM OF RAT. L.J. FISHER, S.J. YOUNG*, J.M. TEPPER AND P.M. GROVES. Dept. Psychiatry, UCSD, San Diego, La Jolla CA 92093.

We have previously demonstrated a correspondence between components of the neostriatal extracellular field potential and intracellular events elicited by stimulation of cortical white matter (Ryan, et al., 1986, Brain Res Bull:751-758). An initial intracellular depolarization occurs concurrent with an initial positive wave (P1) in the field potential, while the subsequent hyperpolarization parallels waves N2 and P2 which may reflect collateral inhibition followed by cortico-thalamic disfacilitation. A late wave, N3, occurs during the intracellularly observed late rebound depolarization.

In another abstract (Ryan, et al.), we report that systemic administration of d-amphetamine sulfate reduces the amplitude of P1 and decreases the latency to N3. These effects also occur with high frequency stimulation of the mesencephalic reticular formation (RF) or deep cerebellar nuclei. The present study was designed to examine the intracellular events associated with these effects.

Intracellular recordings were obtained from neostriatum in urethane anesthetized rats. A field potential electrode was placed within 1mm of the intracellular recording site. Bipolar stimulating electrodes were positioned in cortical white matter, RF and within the deep cerebellar nuclei.

Preliminary results indicate that high frequency stimulation (20-60 Hz) of RF consistently resulted in a reduction of the peak amplitude of the cortically evoked initial polarization and an exaggeration of an inflection observed during the rising phase of this potential. Additionally, there was an apparent reduction in the magnitude and duration of the after-hyperpolarization. These effects persisted for up to 1 minute following RF stimulation and were accompanied by a decrease in resting membrane potential.

These results suggest that alterations in field potentials associated with RF stimulation are mirrored by temporally corresponding intracellular events. Reticular activation may modify the level of thalamic or cortical input to the striatum to effect both tonic and phasic aspects of striatal processing.

270.4 MEASUREMENT OF LOCOMOTOR PATTERNS IN THE RAT: EFFECTS OF AGE AND N-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP). M.E. Melnick, L.D. Ford*, and M.K. Shellenberger. Departments of Physical Therapy Education and Pharmacology, The University of Kansas Medical Center, Kansas City, Kansas 66103.

We have reported that MPTP causes alterations in the motor activity and gait pattern of rodents. (Melnick, M.E. et al in MPTP: A Neurotoxin Producing a Parkinsonian Syndrome, 1986; M.K. Shellenberger and M.E. Melnick, Neurosci Abst., 1984) However, it has been difficult to demonstrate a significant persistence of these effects in the rat for more than 10 days after cessation of injections. Therefore, we have been considering techniques for a more sensitive measure of the effects of MPTP on locomotion and muscle tone. We had noted that MPTP-treated rats tended to walk with the entire foot-pad in contact with the supporting surface (i.e. a flat-footed gait) in contrast to the more typical pattern of weight supported on the metatarsals only.

We have used the Zeiss Interactive Digital Analysis System to assess the perimeter of the foot-pad in contact with the surface as well as the area of the footprint. The footprints of young adult (6-month-old), 1-year old and 18-month-old animals were analyzed after receiving either solvent or MPTP treatment. The data indicate that the aging process produces a significant increase in the area of the foot in contact with the supporting surface during locomotion. Furthermore MPTP-treatment causes an increase in this area in the young adult and year-old animals which makes the footprints of these animals appear to be like those of the 18-month-old rat. Because of the natural tendency towards a flat-footed gait with aging, it is more difficult to utilize this technique to assess MPTP-induced motor impairment in older animals.

270.5 DOPAMINERGIC INVOLVEMENT IN STRIATAL NEURONAL ACTIVITY DURING LOCOMOTOR BEHAVIOR AND ITS ENHANCEMENT BY COCAINE. N. Shimizu*, M.O. West, R.-S. Lee, J.K. Chapin, and D.J. Woodward. (SPON: G.A. Mihailoff) *Dept. of Cell Biology and Anatomy, The University of Texas Health Science Center at Dallas, TX 75235.*

Our previous studies demonstrated that a substantial population of the striatal neurons , considered to be important in motor function, increased their firing rate during locomotion. Also cocaine has been reported to elevate monoamines by inhibition of uptake. The objective of the present study was to clarify the following: (1) whether dopamine (DA) is involved in the excitatory response of striatal neurons during locomotor behavior, (2) whether cocaine modulates the striatal neuronal response to locomotion.

Adult Long-Evans hooded rats were prepared for chronic recording with a detachable microdrive positioned over the striatum. Four-barrel micropipettes were used for recording extracellularly the spontaneous activity of striatal neurons and for applying drugs. Single neuron activity was recorded through one of the barrels which was filled with a carbon fiber (7 μm in diameter, extending 20 μm beyond the tip of the glass capillary). Animals were trained to walk on a treadmill (TM) (30 sec on / 30 sec off) and a tone (800 Hz, 0.2 sec, 60 dB) served as a cue (0.5 sec before TM-onset) for the onset of TM locomotion.

Sixty-five percent of striatal units (n=185 neurons) increased firing rate during locomotion (185.8±26.7% increase, during locomotion vs. resting). Iontophoretic application of trifluoperazine (DA receptor blocking agent) significantly attenuated the locomotion-evoked excitatory response. Alpha-methyl-para-tyrosine (an inhibitor of tyrosine hydroxylase) blocked the TM-response 3-h post-injection (200 mg/kg, i.p.) in conjunction with the prolongation of the reaction time (latency to the first footfall after treadmill onset). In contrast, cocaine (1 mg/kg, i.p.) augmented the TM-response by 90±20% compared to the pre-injection values. This effect was observed within 10 min and reached to the maximum level at 30 min after injection. The response recovered within 1-h. The spontaneous firing rate did not alter, and little observable behavioral change occurred during resting at this dose. Our view is that the enhancement of the response may be elicited by the augmentation of dopaminergic neurotransmission. Furthermore, iontophoretically applied DA increased the spontaneous firing rate in 50 % of the neurons tested in the striatum (n=60), while inhibited 23 % of the neurons. Out of 60 neurons tested for DA sensitivity, 29 neurons were also analyzed for their response to TM-locomotion. Eighty percent of the neurons which increased the firing rate during locomotion were also excited by DA (significant $P \leq 0.05$, χ^2 test).

These observations suggest that DA participates in neural processes in striatum during locomotion, and its effect is excitatory in nature either through direct or modulatory actions. *(Supported by grants AA-5901, DA-02888 to DJW and awards from the Biological Humanics Foundation, and the RJ Reynolds Tobacco Co.)*

270.6 SINGLE UNIT CORRELATIONS WITH SPECIFIC MOVEMENTS IN LATERAL STRIATUM OF FREELY MOVING RATS. M. West, R, Carelli*, N. Shimizu, J. Chapin and D. Woodward. Dept. Psychology, Rutgers University, New Brunswick, NJ and Dept. Cell Biology & Anat., Univ. Texas Health Science Ctr., Dallas TX.

The objective of these experiments was to determine whether phasic patterns of neuronal activity correlated with discrete sensory and motor events are compartmentalized in the striatum, resulting in a functional "map." Long-Evans (hooded) rats of either sex, aged 90-120 days, were surgically prepared for chronic single-unit recording via a detachable, miniature microdrive positioned above specific areas of the striatum. Microelectrodes were advanced daily along vertical recording tracks through the striatum. Stereotaxic coordinates were referenced to Bregma, using a level skull. Videotape recordings of motor behavior were synchronized with computer-acquisition of neuronal firing patterns. Using stop-frame video analysis (30 frames/sec), raster displays and peri-event histograms (PEH) depicting striatal unit activity could be constructed around any observable movement. As previously reported (West et al, Neurosci. Abstr. 12:652, 1986), in central and medial regions of the striatum (A-P +0.2 to -0.2, M-L 2.5 to 3.5, D-V 3.0 to 7.0 mm), units showed no correlations with specific movements. Approximately 70% of these units significantly increased their firing rates during whole-body movements such as locomotion on a treadmill (TM). Over half the units exhibited short-latency (20 msec) sensory responses to a conditioned auditory tone stimulus signalling the onset of TM locomotion. We now report that highly specific correlations with discrete limb movements were exhibited by single units in the most lateral regions of the striatum (A-P 0.0, M-L 3.5 to 4.5, D-V 3.0 to 4.0 mm). Robust, short-duration (50-150 msec) bursts of activity were correlated with particular portions of the stance or swing phases of locomotion. In preliminary studies, these firing patterns were present during rhythmic, straight-ahead locomotion but not during backwards locomotion nor during exploratory locomotion composed of rapid shifts in posture and direction. Some units responded to passive manipulation of the limb with which they were correlated, while others fired only during active (voluntary) movement. Thus, variables related strictly to motor behavior did not appear to fully account for the magnitude of variations in unit activity observed under all conditions. The significance of these results is that they provide important neural substrates in a freely moving animal for evaluating factors such as behavioral context in studying striatal involvement in sensorimotor integration. 270.7 DIFFERENTIAL INVOLVEMENT OF THE STRIATUM AND ITS MAJOR EFFERENTS IN A REACTION TIME PERFORMANCE IN RATS.

Amalric M. Percy L*§. and G.F.Koob§ (SPON: European Neuroscience Association). Lab. de Neurobiologie et Neuropharmacologie du Développement. Bât. 440. Université de Paris-Sud. Orsay 91405 (France).§Div. of Preclinical Neuroscience and Endocrinology, Scripps Clinic and Research Fd., La Jolla, CA 92037 (USA).

A major function of the dopamine in the striatum is to control the activity of its efferent systems which contains primarly GABAergic neurons. The purpose of the present study was to examine 1) the effects of a dopamine receptor blocker (haloperidol) in the striatum and 2) the effects of a GABA receptor agonist (muscimol) injected in the globus pallidus (GP) or in the substantia nigra reticulata (SNr) in an operant reaction time task in rats.

Rats were trained to depress a lever, to hold it until the presentation of a visual conditioned stimulus (CS) then to release it within 500 ms. Responses within 500 ms were reinforced by a food pellet. Daily sessions ended after 100 trials (for details, see Amalric and Koob 1987). Results were expressed as a percentage of correct responses (CR) or incorrect ones: either premature responses (PR: release of the lever before the CS) or long responses (LR: over 500ms). Reaction time (RT) was measured from the CS to the lever release.

Haloperidol (25 and 50 ug) injected intraperitoneally impaired reaction time performance. For the highest dose, rats stopped pressing the lever after 10 to 40 trials. When injected bilateraly in the striatum, haloperidol (2.5 and 5.0 ug) disrupted the performance by increasing reaction time. Percentage of PR was significantly reduced as compared to pretest controls. Percentage of correct responses were also decreased after perfusion of muscimol (2.5, 5.0 and 10.0 ng) in the SNr or the GP. Interestingly the two structures were differentially affected by the drug. Rats perfused with muscimol in the SNr showed an increase in the number of premature movements. Reaction time were shortened with no change in the number of longer RT. In contrary, muscimol in the GP did not induce any change in the number of PR but did increase the number of long RT.

These results show that blockade of the dopamine receptors in the striatum increased response duration, while stimulation of the GABA receptors either shortened reaction time and movement in the SN, or increased RT in the GP. Interactions between DA and GABAergic efferent neurons seem to be essential to trigger a reaction time motor task. Informations on the motor programm could be processed differently at the different levels of the basal ganglia.

270.8 EFFECTS OF GLOBUS PALLIDUS LESIONS IN RATS ON SUSTAINED, RESTRICTED FORELIMB FORCE EMISSION. J.V. Harrell, E.S. Hall*, and R.C. Hicks*. Dept. of Psychology, Hampden-Sydney College., Hampden-Sydney, VA 23943

We have examined the effects of globus pallidus lesions in rats on ability to perform a force-band/duration task with their forelimbs. The task required rats to reach through an opening in a Skinner box and press with their forepaw upon an isometric force transducer with a force between 20 and 50 g and to hold that limited force for 1.5 sec in order to receive water reinforcers. Five rats received bilateral, electrolytic lesions of the globus pallidus (GP), two rats received bilateral sensorimotor cortex lesions (SC), one rat received a bilateral sham lesion (SL), and two rats were unoperated. These last three groups served as contols.

Rats were trained on the required task for approximately four months. A baseline of 20 days data was then collected. Surgeries were performed and on the following day preoperative criterion testing resumed. The initial postoperative testing period lasted approximately three weeks. Thereafter followed, in order, a two week hiatus, five testing days, a two week hiatus, and five testing days. A total of 68 days elapsed from initial surgeries to the conclusion of the experiment.

Four of the five GP rats showed extensive effects of the lesions. These effects were characterized by an inability in the immediate postoperative period to initiate responses. Only with prompting were these rats able to be retrained to preoperative criteria. The number of reinforced responses decreased markedly for these rats. Strip chart recordings revealed a dramatic change in force emission characteristics, indicating a more variable pattern of force emission. Moreover, stereotyped behaviors (sniffing, head movement, exploration) also increased. Controls showed no effects of lesions or sham procedures.

Results, overall, are in agreement with those of a previous study which showed essentially the same effects from caudate nucleus lesions. Together, these data strongly support the notion that the basal ganglia are important contributors to fine motor control, particularly of the type that requires significant sensory feedback and or sustained performance. (Supported in part by a grant from the Gwathmey Foundation in Virtinia.)

270.9 DOUBLE DISSOCIATION OF ASSOCIATIVE AND MOTOR FUNCTIONS IN THE ROSTRAL STRIATUM OF THE RAT. M. Pisa. Dept. Neurosciences, McMaster University, Hamilton, Ont., Canada L8N 3Z5.

The aim of this study was to examine the hypothesis of regional specificity of both motor functions and modality-specific associative functions in the rostral striatum of rat. Wistar rats were assigned to groups (N=16) for bilateral control injections (.4 ul PBS) or ibotenate injections (6ug) into either the medial, dorsolateral or ventrolateral regions of the rostral striatum. Postoperatively, half the rats of each surgical group were assigned to turn discrimination (left vs. right) and the other half to brightness discrimination (white vs. black) in a cross maze, for the motive of food. After reaching the learning criterion of 90% correct on the original discrimination, the animals were tested for discrimination reversal (intradimensional shift). Then, the rats were trained to retrieve food pellets from a feeding tube, and their forelimb reaching performance was evaluated in terms of number of reaching attempts made before retrieving the pellets. At the end of testing, the sizes and locations of the ibotenate-induced, somatodendritic lesions were verified histologically. The results were as follows: 1) None of the regional striatal lesions reliably affected original learning of the discriminations or reversal of the brightness discrimination; 2) medial striatal lesions significantly impaired spatial discrimination reversal but not forelimb reaching; 3) lateral striatal lesions significantly impaired forelimb reaching but not spatial discrimination reversal; 4) lateral striatal lesions with attendant, substantial damage to the adjacent cortex impaired both spatial discrimination reversal and forelimb reaching. These results indicate selective roles of the rostromedial striatum in flexible use of spatial cues and of the lateral striatum in forelimb motor control. However, the results also indicate that the selectivity of regional effects on behavior can be lost if the cortex is also damaged. The demonstration of double behavioral dissociation is fresh evidence for a topographically organized and task-specific role of the rostral striatum in both motor programming and cognition.

270.10 ATTENTIONAL VERSUS INTENTIONAL NEGLECT: CONTRASTING EFFECTS OF UNILATERAL STRIATAL AND CORTICAL LESIONS IN A VISUAL REACTION TIME TASK. V.Brown*, G.Mittleman* and T.W.Robbins*(SPON:E.Wong). Dept. of Exp. Psychology, University of Cambridge, Cambridge, CB2 3EB, UK.

Unilateral lesions of the cortex and the striatum produce syndromes of 'contralateral neglect' which may result from disruption of different processes. A paradigm for studying visual neglect has been developed for rats, which varies the response requirements for reporting the detection of brief visual stimuli in order to separate response related effects from those due to possible sensory or attentional deficits. Carli et al (Nature, 313;679, 1985) showed that unilateral dopamine (DA) depletion of the striatum impairs the capacity to initiate responses contralateral to the side of the lesion and enhances the tendency to respond ipsilaterally, regardless of the side of stimulus presentation. The present experiments compared the effects of hemidecortication and ibotenic acid (0.06M/lul) lesions (IBO) of the striatum in three visual reaction time tasks, in order to clarify the nature of the neglect syndrome associated with these lesions.

Rats were trained to make a sustained nose-poke in a centrally located, lit hole, until a brief (200ms), temporally unpredictable, visual stimulus was presented to either side of the head. Different groups were trained to report the detection of the stimulus by withdrawing from the central hole (measured as Reaction Time- RT) and completing the response by making a lateralised head movement either towards (Discrimination 1), or away from (Discrimination 2) the stimulus, or by opening a panel located at the rear of the test chamber (Discrimination 3).

The effects of the lesions on performance in Discriminations 1 and 2 were qualitatively similar to those following unilateral DA depletion of the striatum. There was a significant lengthening of RT in both cases when a contralateral response was required and an enhanced ipsilateral response bias. However, there were qualitative differences between the groups in their performance on Discrimination 3. Following hemi-decortication, rats showed a significant impairment in both accuracy and latency to report the presence of contralateral stimuli. Their performance on trials in which one or other of the stimulus lights was occluded is also consistent with the interpretation that they were failing to use the contralateral stimulus to mediate the discrimination. In contrast, the IBO group continued to use both stimulus lights postoperatively, as confirmed by tests of occlusion of the stimuli. In this group there was a general decline in the accuracy of detection but, if anything, this was less pronounced on the contralateral side.

270.11 SPONTANEOUS ACTIVITY OF TYPE II BUT NOT TYPE I STRIATAL NEURONS IS CORRELATED WITH RECOVERY OF BEHAVIORAL FUNCTION AFTER DOPAMINE-DEPLETING BRAIN LESIONS. E.S. Nisenbaum, M.J. Zigmond, E.M. Stricker, and T.W. Berger. Departments of Behavioral Neuroscience and Psychiatry and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Two types of extracellular waveforms, Type I and Type II, can be recorded from the rat striatum (Skirboll and Bunney, Life Sci., 25, 1979). Previously they have been shown to represent two functionally distinct subpopulations of neurons (Nisenbaum et al., Soc. Neurosci. Abstr., 12, 1986). One week after near-total destruction of the dopaminergic (DA) innervation to the striatum produced by intraventricular (ivt) administration of 6-hydroxydopamine (6-HDA), both Type I and Type II neurons exhibit increased spontaneous firing rates in association with severe ingestive and motor deficits (Orr et al., Soc. Neurosci. Abstr., 12, 1986). Despite the permanent loss of greater than 90% of striatal DA, animals can gradually recover from these behavioral dysfunctions. In association with behavioral recovery, the spontaneous activity of Type II neurons has been shown to return to pre-lesion levels (Nisenbaum et al., Brain Res., 398, 1986). The present study examined whether, similar to Type II neurons, the spontaneous firing of Type I neurons has returned to control levels in animals that have recovered from the effects of a 6-HDA-induced lesion.

Rats were injected ivt with 200 ug of 6-HDA, dissolved in 0.9% NaCl and 0.1% ascorbic acid, and extracellular single unit activity of Type I striatal neurons was recorded 4-6 weeks post-lesion from animals exhibiting behavioral recovery. A control group of animals was injected ivt with just the vehicle solution, and Type I firing rates were recorded 4-6 weeks later. Tissue punches subsequently were taken from the striatum and analyzed for DA content.

The spontaneous firing rates of Type I neurons recorded 4-6 weeks post-lesion from animals with striatal DA depletions of greater than 90% were significantly elevated relative to control levels. Thus, although Type I neurons exhibit increased activity in association with behavioral deficits after a 6-HDA-induced lesion, firing rates of Type I neurons do not return to normal levels in recovered animals. These results demonstrate that only the activity of Type II striatal neurons is positively correlated with behavioral recovery, and provide further evidence demonstrating the existence of two functionally distinct subpopulations of striatal neurons.

270.12 SINGLE UNIT NEURONAL ACTIVITY IN PUTAMEN: ROLE IN THE TERMINAL PHASES OF MOVEMENT

E. B. Montgomery, Jr. and S.R. Buchholz*. Department of Neurology and Neurological Surgery (Neurology). Washington University School of Medicine. St. Louis MO 63110

Earlier notions regarding the role of the basal ganglia in motor control emphasized a feedforward or "pre-programing" mechanism where motor programs are generated in the basal ganglia then relayed to the motor cortex for execution. However, single unit studies have failed to show changes in basal ganglia activity prior to that of the motor cortex or movement onset.

Of 111 units studied in the putamen of a monkey performing wrist extension and flexion movements, 19 had neuronal activity changes associated with the tasks. Tasks included fast step or slow tracking movements between two mechanical stops separated by 90 degrees either in response to a go signal or self-initiated. Neuronal discharges were temporally correlated with the go signal, movement onset and attainment of final target.

Most of the units which changed their activity with the tasks did so at or after the time of movement onset. Only one unit showed an increase in neuronal activity prior to any EMG or movement. Only 2 units showed a more consistent relationship to the go signal, usually for the fast tasks. Two units demonstrated a more consistent relationship to either flexion or extension. Only one unit was related most strongly to the pattern of muscle involvement.

In 8 of the 19 putamenal units, the most consistent relationships were those associated with attainment of the final target. This was most evident for the fast tasks and consisted of an increase in neuronal firing. For 6 of the 8 units the increased activity occurred from 100 to 400 msec before reaching the final target. For example, one unit changed from a tonic to a bursting pattern of discharge approximately 190 msec after the go signal and 300 msec before attainment of the final target for a fast flexion task. When trials were lined up on the attainment of the final target, there was a synchronization of the bursting pattern.

While the amount of data in this continuing study is small, there is a clear tendency of putamenal units to be better related to the final phases of movement rather than to the go signal or movement initiation. Even so, the time of onset of change in neuronal activity before attainment of the final target, suggests a role in anticipation of task termination and preserves the notion of a feedforward "pre-programing" mechanism. Thus, disorders of the basal ganglia may have greater effect on task termination and be reflected in abnormalities of movement time or duration rather than reaction times from go signal to movement onset. Studies in humans afflicted with Parkinson's disease and various experimental lesions of the basal ganglia in animals have shown normal reaction times but prolonged movement times. It is unclear whether this role is involved in the stopping of movement or in continuing the movement to its proper termination at the proper pace, although the latter is more likely the case.

270.13 CROSS-CORRELATION ANALYSIS OF GLOBUS PALLIDUS AND ENTOPEDUNCULAR UNIT ACTIVITY IN THE AWAKE CAT AND THE EFFECTS OF LESIONING NEOSTRIATUM. D. Jaeger, R.N.S. Sachdev*, G.W. Dauth, S. Gilman and J.W. Aldridge. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48104

The cross-correlation technique was used to assess the functional interactions between pairs of simultaneously recorded neurons in cat globus pallidus (GP) and entopeduncular nucleus (EP). Recordings were obtained from awake, quietly sitting cats (N=4) before and after ibotenic acid lesions of ipsilateral neostriatum. Spontaneous extracellular spike activity of 2-3 units was discriminated from the signal of a single microelectrode by using peak amplitudes and peak to peak time as discrimination parameters. Cross - correlograms were constructed from spike trains and significant interactions were determined by visual inspection.

In GP 31 unit pairs from controls and 49 unit pairs from lesioned cats were analyzed. Overall 49% of unit pairs showed significant functional interactions. In 44% of these interactions a 2-3 ms increase in the probability of activity of one unit 1-3 ms **either** before **or** after the second unit of the pair fired was seen (unilateral peak in correlogram). All other interactions (46%) consisted of an increase in the activity of units before **and** after the other unit fired (bilateral peak in correlogram). Both types of interactions were present in lesioned and control cats but the proportion of unilateral peak correlograms was significantly **increased** after the lesion (chi square test $p < 0.01$).

Similar interactions were seen in EP where 27 unit pairs before and 27 unit pairs after lesioning were analyzed. Here 30% of unit pairs had a significant interaction. The proportion of bilateral peak correlograms was unchanged compared to GP but there were significantly fewer correlograms with a unilateral peak ($p < 0.05$). In lesioned cats the proportion of significant interactions was higher. A significant increase ($p < 0.01$) in the proportion of unilateral peak correlations was most prominent.

The finding of unilateral peak correlations in GP and EP suggests a non - reciprocal functional excitatory interaction between neurons in these structures. An excitatory interaction between GABA'ergic neurons might be caused by a phasic rebound of spike activity after a short period of inhibition in tonically active neurons. Indeed our data show evidence of a short inhibitory interaction before the onset of excitation. The bilateral peak correlations we saw were quite symmetrical and on each side closely resembled the time course of unilateral peak correlations. This suggests a similar mechanism of generation which could be a reciprocal functional excitatory connection. Unilateral and bilateral peak correlations were also observed in GP but not putamen of quietly sitting awake monkeys. This suggests to us that these interactions are typical of mammalian GP. The finding of an increased number of correlations in GP and EP after removal of a major inhibitory input can be explained by a number of mechanisms. For example, the efficacy of remaining terminals could increase or new terminals could be formed through collateral sprouting.

270.14 EFFECT OF STRIATAL LESIONS ON SPONTANEOUS UNIT ACTIVITY RECORDED FROM THE GLOBUS PALLIDUS, ENTOPEDUNCULAR NUCLEUS AND VENTRAL PALLIDUM. R.N.S.Sachdev*, J.W.Aldridge, Dept. of Neurology, Univ. of Mich., Neuroscience Lab Bldg., 1103 E. Huron, Ann Arbor, 48104

The goal of this study was to determine the effects of unilateral striatal lesions on unit activity in the ipsilateral pallidum. Lesioning striatal inhibitory GABAergic projections to the globus pallidus (GP), entopeduncular nucleus (EP), and ventral pallidum (VP) might be expected to increase firing rate of neurons in these structures. Spontaneous unit activity was recorded from awake and quietly sitting cats (N=4). Two cats were studied both before and after the lesion. In two other cats one had no lesion, and the other cat was studied in all tracks after the lesion. Lesions were produced by injecting ibotenic acid into the caudate and putamen. Data collection resumed 10 days after injections and lasted for up to one year. Single units were discriminated and analyzed off-line and spike trains were scanned for bursts using a quantitative procedure developed by Legendy and Salcman (J. Neurophysiol. 53:4, 1985). Data were collected from 139 GP control, 172 GP post lesion, 65 EP control, 62 EP post lesion, 52 VP control and 31 VP post lesion units.

The lesion resulted in a significant decrease in the mean interspike interval duration (increased firing rate) in GP alone: GP 59ms to 33ms, EP 47ms to 39ms, and VP 53ms to 42ms. The median interspike interval durations also decreased significantly in GP, but not in VP or EP: GP 34ms to 25ms, EP 28ms to 30ms and VP 37ms to 32ms. The coefficient of variation changed significantly only in EP: GP 1.33 to 1.03, EP 1.43 to 0.79 and VP 1.17 to 0.86. The classification of units by burst properties established that all segments of the pallidum have units which exhibit bursts. The percentage of units which exhibit bursts decreases significantly after the lesion in GP and EP but not VP: GP 24% to 14%, VP 27% to 6%, and EP 40% to 9%.

This study demonstrates that striatal lesions can affect the firing rate and pattern in post synaptic pallidal neurons. Although all pallidal structures exhibited qualitatively similar changes, only GP had a significant change in both rate and pattern of activity. EP was affected in bursting but not rate. No changes were significant in VP. The differential effects on the pallidal structures after the striatal lesion could be related to the proportion of afferents lost and/or the characteristic pattern of striatal peptidergic projections.

270.15 RESPONSES OF MONKEY GLOBUS PALLIDUS CELL S DURING TARGETED REACHING MOVEMENTS. R. S. Turner* and M. E. Anderson (SPON: June L. DeVito) Dept. of Physiol. and Biophysics, University of Washington, Seattle, WA. 98195

Neurons in the internal pallidal segment (GPi) and reticular portion of the substantia nigra (SNr) are the output neurons of the basal ganglia. In awake monkeys, cells in both nuclei have high tonic firing rates in the absence of movement and they exert an inhibitory synaptic action on their target neurons. Nigral neurons typically exhibit a simple decrease in firing rate in association with saccadic eye movements in a specific direction (Hikosaka and Wurtz '83 J. Neurophysiol. 49:1230)

Pallidal neurons, however can show increases and/or decreases in firing rate with movements of the arm or leg (DeLong, Crutcher & Georgopoulus '85 J. Neurophysiol. 53:530). The limb movements used in these studies of the GP however, have always been unidimensional push-pull, side-to-side or reach-retract movements.

In order to better study the relationship between pallidal cell firing and limb movement we have examined the discharge of pallidal neurons in a monkey during horizontal arm reaching movements of 3 amplitudes (1", 2", & 3") made in one of 8 radial directions from a center start position. Under these conditions, of pallidal neurons showing a significant change in firing associated with the task, the majority of them (17/22) showed a response that changed with the direction of the movement performed.

Few of these cells showed a simple modulation in response magnitude depending on movement direction. Most directionally sensitive cells had responses composed of complex modulations in firing rate that changed with direction of movement. Few cells showed a simple reciprocal response relationship with movements in opposite directions.

Most behaviorally related neurons, however, (16/22) showed a decrease in firing rate as a first response with movements in at least one direction. These responses had an average onset time of ~100ms before movement initiation. The directional sensitivity of some cell reponses changed with the amplitude of the movements performed. However, no responses were found to have a linear relationship with movement amplitude.

Quantification of these results will allow a comparison of cell response with measured limb movement under different behavioral conditions.

270.16 THE EFFECT OF PALLIDAL INACTIVATION ON TRAINED WRIST MOVEMENTS IN THE MONKEY. J.W. Mink and W.T. Thach. Departments of Anatomy & Neurobiology and Neurology & Neurosurgery and The McDonnell Center for the Study of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110

What aspects of movement do the basal ganglia control? Theories include 1) initiation of stimulus-triggered or 2) self-paced movement, 3) scaling of velocity and/or amplitude and/or 4) agonist EMG, and 5) control of maintained posture as distinct from volitional movement.

Previous studies had shown that most pallidal units changed after the earliest EMG activity (Mink and Thach, Soc. Neurosci. Abst., 1986). Most pallidal neurons (> 90%) were best related to step-tracking (Mink and Thach, Soc. Neurosci. Abst., 1985). Some of these (50-75%) were slightly related to ramp- and sinusoid-tracking but with peak changes occurring at the initial step-like movement in ramp-tracking and at the direction change (stop-start) in sinusoid-tracking. A smaller fraction (25%) were related, albeit poorly, to self-paced rapid alternation.

This study was designed to further test the above hypotheses by inactivating the globus pallidus in monkeys during these tasks. Movement direction and muscle activity were dissociated with torque loads in such a way that, e.g., a flexion movement could be made by turning on loaded flexor muscles or by turning off loaded extensor muscles.

Following pallidal inactivation with muscimol or ablation with kainic acid, step-tracking reaction time was normal but movement time was slower by 50-300 msec. Ramp-tracking reaction time was normal, but the velocity of the initial step component of ramp-tracking was slower. Visually guided sine-tracking was near normal, but there was tonic agonist-antagonist cocontraction with a flexor positional bias. Self-paced rapid alternation was also performed from a flexed posture with tonic cocontraction and was further hindered by phasic cocontraction. Movement was invariably slower (by 35-50%) when made by decreasing activity of the loaded antagonist than when increasing activity of the loaded agonist.

Because of in normal animals 1) the late onset of unit activity, and in pallidal inactivated animals 2) the normal reaction time but prolonged movement time, 3) the agonist-antagonist cocontraction and 4) the inability to turn off antagonist muscles, these data suggest that the inhibitory pallidal output acts to reduce existing postural or other maintained muscle activity that would interfere with voluntary limb movement initiated and controlled by other neural mechanisms. (This work was supported by NIH grant 2 RO1 NS12777-12 and The McDonnell Center.)

270.17 EVIDENCE FOR SELF-INHIBITION OF NIGROSTRIATAL DOPAMINE NEURONS MEDIATED BY ANTIDROMICALLY ELICITED SOMADENDRITIC AND INITIAL SEGMENT SPIKES. R.F. Gariano*, S.J. Young* and P.M. Groves. Depts. Neuroscience and Psychiatry, Univ. California, San Diego, La Jolla CA 92093.

Antidromic stimulation of nigrostriatal dopamine (DA) terminals in the striatum typically elicits an initial segment (IS) response at the cell body, though occasionally the full somadendritic spike (FS) is seen. We have utilized these distinctive antidromic responses to study the nature of the inhibition of DA cell activity that follows electrical stimulation of the neostriatum.

Single-unit extracellular recordings were obtained from electrophysiologically identified nigrostriatal DA neurons in the substantia nigra of urethane-anesthetized rats. Monophasic square wave stimuli were delivered to the dorsolateral striatum at 0.6 Hz with a constant current (30-500 μs, 1-3 mA), adjusted to elicit antidromic responses on approximately 50-80% of stimulus trials. Post-stimulus time histograms of impulse events were separately constructed for stimuli that resulted in either a FS antidromic response, an IS response, or no antidromic response.

Striatal stimulation was followed in all three cases by a post-stimulus inhibition (PSI). For all cells tested (n=10), the PSI was longest following an FS antidromic response, intermediate for the IS response, and least when no antidromic response was elicited. The greater inhibition following the FS may be secondary to FS-dependent afterhyperpolarization and/or somadendritic autoreceptor activation by FS-dependent dendritic release of DA. The greater PSI for the IS response than for the case of no antidromic response may be secondary to DA release following electrotonic spread of the IS spike to adjacent dendritic membrane, electrical coupling of DA neurons, or some unknown factors. Since inhibition due to activation of striatonigral fibers or to antidromic activation of neighboring DA cells should be equivalent in the three cases, the greater PSI for FS and IS responses implies self-inhibition by individual DA neurons subsequent to both FS and IS responses. Preliminary evidence using the DA receptor antagonist haloperidol indicates that a portion of the PSI for the FS and possibly the IS cases is mediated by DA receptors. The role of DA autoreceptors in mediating PSI will be further examined in rats pretreated with alphamethylparatyrosine to deplete endogenous DA.

270.18 ELECTROPHYSIOLOGICAL EFFECTS OF NICOTINE AND GLUTAMATE INJECTIONS INTO THE TARGET REGIONS OF MIDBRAIN DOPAMINE NEURONS. K.W.P. Yoon*, G.P. Mereu and T.C. Westfall (SPON: S. Horenstein). Departments of Pharmacology and Neurosurgery, St. Louis University School of Medicine, St. Louis, MO 63104.

We have previously observed that the systemic administration of nicotine produces a dose-dependent increase in the firing rate of nigral pars compacta dopamine cells (A9) as well as ventral tegmental area dopamine cells (A10) of the rat (Soc. Neurosci. Abs. 12:1515, 1986). The purpose of the present study was to further investigate the effects of nicotine on midbrain dopamine neurons.

The changes in the action potential firing frequency and pattern of neurons in the substantia nigra dopaminergic (A9), pars reticulata (SNR), ventral tegmental area dopaminergic (A10), and ventral tegmental area non-dopaminergic cells of rats were recorded by extracellular single units during the microinjection of glutamate and nicotine into the respective striatal target regions of the dopaminergic projections: caudate nucleus for A9 and nucleus accumbens for A10.

Glutamate injections into the caudate nucleus most consistently caused a cessation of firing of SNR neurons and increased the firing rate of the A9 neurons. Nicotine injections into the caudate nucleus also caused a momentary cessation of the firing of SNR neurons but were frequently followed by excitation. The effect of nicotine injections into the caudate on A9 neurons was excitatory but in spite of the subsequent excitation of SNR neurons, the firing rate usually returned to the baseline.

Glutamate injections into the nucleus accumbens were most consistently followed by cessation of firing of ventral tegmental area non-dopaminergic neurons and excitation of the A10 cells. Nicotine injections into the nucleus accumbens also caused inhibition of ventral tegmental area non-dopaminergic neurons and excitation of the A10 cells. However, in contrast to the SNR neurons, no post-inhibitory excitation of the non-dopaminergic neurons was observed.

The results obtained suggest that the pharmacological stimulation of striatonigral or nucleus accumbens ventral tegmental area output cells by glutamate or nicotine influences dopaminergic neurons by removing the tonic inhibitory influence from the adjacent non-dopaminergic neurons. In spite of the well demonstrated inhibitory striatonigral (Precht, W. and Yoshida, M., Brain Res., 32:229, 1971) or nucleus accumbens-ventral tegmental area (Wolf, P., et al., Experientia, 34:72, 1978) outputs that directly inhibit the dopaminergic neurons, the overall excitation of the striatal regions caused excitation of the dopaminergic neurons. These results are consistent with the concept that nicotine produces multiple excitatory effects on midbrain dopamine neurons.

270.19 EFFECTS OF ADENOSINE 3', 5' MONOPHOSPHATE (cAMP) ON RAT NEOSTRIATAL NEURONS: INTRACELLULAR STUDY IN AN *IN VITRO* SLICE PREPARATION. T. Kita, H. Kita and S. T. Kitai. Dep. of Anatomy and Neurobiology, Univ. of Tenn. Sch. of Medicine, Memphis, TN 38163

It is well known that a number of neuroactive substances (e.g. dopamine) stimulate adenylate cyclase in the neostriatum (Str). The neuropharmacological actions of cAMP on Str, however, are not well understood. We studied the effects of cAMP and forskolin, an adenylate cyclase activator, on rat Str neurons in an *in vitro* slice preparation. Brain removed from decapitated rats were blocked to contain Str and were sectioned (400μm) in a parasagittal plane using a Vibratome. The slices were placed in a recording chamber and continuously superfused with oxygenated Krebs solution (composition in mM: NaCl 124, KCl 5.0, $MgSO_4$ 2.0, KH_2PO_4 1.25, $CaCl_2$ 2.0, $NaHCO_3$ 26 and glucose 10, pH 7.2-7.4). Local stimulation was applied through bipolar electrodes placed on the surface of the slice. Glass pipettes filled with 2 M K-methylsulfate were used for intracellular recordings. 8-bromo cAMP (10^{-7} - 10^{-4} M) and forskolin (10^{-7} -10^{-4} M) were applied to the superfusing solution. In experiment using intracellular injection of cAMP, the microelectrodes were filled with 10mM cAMP in either 2 M K-methylsulfate or 2 M K-acetate.

Extracellular applications of 8-bromo cAMP or forskolin and intracellular cAMP injections consistently resulted in a membrane depolarization, a decrease of the membrane conductance, and a decrease of the anomalous rectification in a dose-dependent manner. The responses were not affected by the addition of TTX in the superfusing medium. However, they were attenuated when recorded neurons were injected with TEA prior to the application of 8-bromo cAMP or forskolin. Moreover, the application of 8-bromo cAMP at higher concentration (10^{-4}M) or intracellular injection of cAMP resulted in an increase in the spike threshold and a decrease the spike afterhyperpolarization. These results suggest that elevation of cAMP in Str neurons result in (1) a decrease of potassium conductance and (2) a suppression of sodium spike generation.

Application of cAMP had complex effects on the synaptic responses (i.e., fast EPSP, IPSP and slow EPSP) to local stimulation. The details of these effect are currently under investigation. Preliminary observations show, however, that (1) generation of sodium spikes from fast EPSPs is decreased and (2) the duration and amplitude of slow EPSP are increased. These results indicate that activation of adenylate cyclase may act primarily to modify voltage dependent conductance in Str neurons.

SUBCORTICAL SOMATOSENSORY PATHWAYS

271.1 SOMATOSENSORY AND VISUAL REPRESENTATIONS IN THE CLAUSTRUM: TOPOGRAPHY AND COLLATERALIZATION OF CLAUSTRO-CORTICAL CELLS IN THE CAT. D. Minciacchi*, A. Granato*, A. Antonini* and G. Tassinari* (SPON: M. Bentivoglio). Inst. of Neurology and Inst. of Anatomy, Catholic Univ., Rome and Inst. of Physiology, Univ. of Verona, Italy.

The wide cortical distribution of claustral projections and the existence of sensory maps in the claustrum points out that this structure is a highly organized source of cortical input. After previous studies on the topography and collateralization of claustral projections to different cortical areas (Macchi et al., J. Comp. Neurol., 215, 121, 1983; Minciacchi et al., Neurosci., 16, 557, 1985) the present study was aimed at analyzing the organization of claustral projections to a single cortical area. A multiple retrograde fluorescence strategy utilizing Fast Blue, Diamidino Yellow, Evans Blue and Fluoro Gold was here employed. In all of the experiments these four tracers were injected under electrophysiological control in four cortical regions: the forepaw (S1fp) and face (S1fa) representation fields of the first somatic sensory area, the vertical meridian (V1vm) and periphery (V1pe) representations of the first visual area.

The claustral cell populations labeled from the S1 injections were located in the anterodorsal part of the claustrum while those labeled from the V1 injections were placed in its posterodorsal part. Thus, the claustral projections to S1 and V1 were mainly segregated and no claustral cells simultaneously projecting to S1 and V1 were found. Within the claustral region projecting to S1, the cell populations labeled from S1fa and S1fp were intermingled with a certain degree of topographical arrangement: the S1fa labeled neurons were located ventrally, partially surrounding the more dorsal S1fp labeled cells. Approximately 5% of the entire S1-projecting claustral population was simultaneously labeled from both the S1 injections. As for the visual projecting population, cells labeled from the V1pe and V1vm injections were clearly segregated: the cells labeled from V1pe were located dorsally, surrounding a central core of neurons labeled from V1vm. Cells simultaneously labeled from both V1 injections were also present (approximately 10% of the entire V1 projecting cell population).

Altogether, these data provide the first anatomical demonstration of a somatotopic arrangement of the claustro-S1 projections and confirm the retinotopical organization of the claustro-V1 projections in the cat. Furthermore, these results indicate that a certain degree of collateralization is present in the claustral projections to different fields within primary sensory areas, whereas no collateralization is present in the claustral projections to different primary sensory areas.

271.2 GABA-ergic INNERVATION OF IDENTIFIED THALAMO-CORTICAL NEURONS IN THE VENTROBASAL COMPLEX OF THE CAT. C. N. Honda, H. D. Schwark, and E. G. Jones. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

A confluence of functional, morphological and immunocytochemical studies suggests that many of the inhibitory interactions in the dorsal thalamus are mediated by the putative neurotransmitter gamma aminobutyric acid (GABA). In the cat ventrobasal complex GABA is generally believed to derive from two sources: (1) presynaptic dendrites and axon terminals of intrinisic neurons, and (2) axonal projections of neurons located in the somatic sensory regions of the nucleus reticularis. The present study combines immunocytochemical and intracellular recording and staining techniques to demonstrate GABA-ergic innervation of individual thalamocortical neurons in the ventral posterolateral (VPL) nucleus.

In the anesthetized cat, antidromically identified thalamocortical neurons in VPL were functionally characterized then intracellularly injected with horseradish peroxidase (HRP). Following fixation with 3% paraformaldehyde / 0.25% glutaraldehyde, frozen or Vibratome sections were processed for HRP using cobalt-intensified DAB to yield a black reaction product. Sections containing portions of intracellularly stained neurons were then processed for GABA immunoreactivity using standard immunoperoxidase techniques to yield an amber-colored reaction product. Under oil immersion (1000X) HRP labeled neurons (black) and GABA-containing elements (amber) were clearly distinguishable in the same section. Appositions between GABA-containing terminals and HRP-labeled neurons were judged to be "contacts" when no gap appeared between the two elements, and when both lay in the same plane of focus.

Small GABA-positive perikarya were found homogeneously distributed in VPL and intermingled among unlabeled large neurons. GABA-containing profiles resembling both *en passant* and terminal axonal enlargements were densely distributed throughout VPL. GABA contacts were found to occur on all portions of thalamocortical neurons, but were predominantly localized to primary and secondary dendrites. The GABA contacts identified to date were found mostly on dendritic shafts and not on spinous processes. At the present time, it is not possible to distinguish between GABA-containing axonal terminals and presynaptic dendrites. Hence, we cannot yet assess the relative contribution of GABA-ergic inputs originating from intrinsic or reticular nucleus sources.

Supported by NIH grants NS 22317 and NSO 7650

271.3 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF SINGLE NEURONS OF THE NUCLEUS RETICULARIS THALAMI (RTN) ON RAT SLICES. G.Avanzini*, M. De Curtis*, R.Spreafico* (Spon. E.Parati), Ist. Neurol. C.Besta 20133 Milano, Italy.

RTN is the most lateral nucleus interposed between the external medullari lamina and the internal capsule.It is known to receive collaterals both from cortico-thalamic and thalamo-cortical fibers arising from the dorsal thalamic nuclei. Immunocytochemical studies demonstrated the presence of GABA-positive terminals contacting cell bodies and dendrites of GABAergic RTN neurons. Aim of the present work is to investigate the physiological properties of RTN neurons. Experiments were performed on 350-400 um thick diencephalic orizontal slices of the rat, maintained in vitro. RTN neurons recorded with 4 M K acetate filled electrodes were activated by stimuli from the ventrobasal complex and from the internal capsule. All of the recorded neurons showed common electrophysiological properties: in resting conditions a single spike response followed by a short lasting hyperpolarizing potential was activated by synaptic or direct stimulations. When an hyperpolarizing steady current was injected intracellularly the response pattern changed to an all-or-none burst firing on a slow depolarizing potential, activated by both synaptic and direct stimuli; this response was followed by an afterhyperpolarizing potential showing a reverse potential around -80 mV. A non synaptic K^+-dependent nature of this hyperpolarizing potential is supported by the following facts. The block of synaptic transmission by lowering (Ca^{2+}) from 2 mM to 0,2 mM did not affect its amplitude. The selective block of GABAergic transmission by bicuculline mathiodide (10^{-5M}) mixed to perfusion fluid induced a gradual hyperpolarization of the membrane potential with a parallel transformation from single spike to burst response. In these conditions however a post-spike after hyperpolarization could still be detected by depolarizing the membrane potential to the resting level, thus restoring the single spike response pattern. The increase of the (K^+) from 3.5 to 7.5 mM decreased the amplitude of the hyperpolarizing potential and shifted its reversing point in depolarizing direction.

271.4 RESPONSE CHARACTERISTICS AND MORPHOLOGY OF VIBRISSA-SENSITIVE NEURONS IN THE VENTRAL POSTEROMEDIAL, THALAMIC RETICULAR AND POSTERIOR NUCLEI OF THE RAT. G.R. Belford, H.P. Killackey, N.L. Chiaia and R.W. Rhoades (SPON: R.K. Josephson). Dept. of Psychobiology, University of California, Irvine, CA 92717 and Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Many diencephalic nuclei receive input from the trigeminal (V) brainstem complex and a number of thalamic structures have been shown to contain vibrissa-sensitive neurons. We have employed intracellular recording and horseradish peroxidase (HRP) injection techniques in an effort to relate differences in the responses of vibrissa-related neurons in three portions of the thalamus, the ventral posteromedial nucleus (VPM), the thalamic reticular nucleus (TRN) and the posterior nuclear group (PO), to the morphology of these cells.

Thus far, we have recovered 31 VPM cells, 8 TRN cells and 4 PO neurons that were responsive to vibrissa stimulation. Five VPM cells, 4 TRN cells, and one PO neuron have been subjected to detailed anatomical analysis. Vibrissa-sensitive cells in VPM were usually excited by deflection of only one or two vibrissae, but several cells that we have recovered responded to as many as four whiskers. These neurons had either bitufted or multipolar dendritic trees. The average soma area was 205 μm^2, the total dendritic arbor averaged 7,234 µm in length and the cross-sectional area encompassed by the dendritic field was 62,761 μm^2. The TRN cells were also generally responsive to only one or a few vibrissae, but three of these neurons had responses that were qualitatively different from those of VPM cells. They had high and regular spontaneous discharges that were suppressed by vibrissa deflection or electrical stimulation of the V brainstem complex. This suppression was associated with a long-lasting ipsp. The somas of the TRN cells had an average diameter of 228 μm^2. These neurons were essentially bipolar and their dendrites followed the contours of the nucleus. The average dendritic length for these cells was 4,118 µm and the average cross-sectional area of the dendritic tree was 26,675 μm^2. All of the PO cells we recovered were excited by deflection of >10 vibrissae. These neurons had sparse, but widespread dendritic arbors. The one cell that has been completely analyzed had a soma area of 278 μm^2 and a total dendritic length of 5,651 µm. The cross-sectional area of the dendritic tree was 110,381 μm^2.

Supported by BNS 84-18715 (H.P.K.), BNS 85-15737 and DE07734 (R.W.R.). N.L.C. was supported by NRSA NS 07774.

271.5 THE RESPONSE PROPERTIES OF MEDIAL THALAMIC NEURONS TO TECTAL AND SENSORY STIMULATION BEFORE AND AFTER LESIONS OF THE SUPERIOR COLLICULUS. B. Grunwerg* and G. M. Krauthamer. Department. of Anatomy, UMDNJ-Robert Wood Johnson Medical School at Rutgers, Piscataway, NJ 08854

The medial thalamus receives a massive projection from the deeper layers of the superior colliculus. In previous studies we determined the peripheral response properties of tectothalamic projection neurons. In the present study we examined the sensory responses of medial thalamic neurons activated by deep tectal stimulation (0.5 msec. pulses, 250-500 uA) in chloral hydrate anesthetized, flaxedil immobilized rats. Thalamic unit activity was recorded extracellularly with tungsten microelectrodes.

Results indicated distinct differences in the response properties of anterior neurons, largely confined to paralamellar MD and posteroventral CL, and neurons located more posteriorly in Pf. Anterior neurons responsive to tectal stimulation were spontaneously active and tended to have complex peripheral response properties, responding to light tapping, noxious stimuli and auditory stimulation. Receptive fields were large and bilateral but responses were more intense to contralateral inputs. More posteriorly, in Pf, complex units were rarely encountered; most units responded exclusively to tail pinch or other painful stimuli and spontaneous activity was low.

Following unilateral destruction of tectal neurons with kainic acid (3.5 nM/0.5 ul) the rats displayed typical ipsiversive circling. Thalamic neuronal activity, recorded 2-3 days later, was strikingly altered. On the side ipsilateral to the tectal lesion, no spontaneous activity was seen whereas spontaneous activity remained high on the intact side. Responses to peripheral stimuli could no longer be elicited on either side.

These results indicate that the excitability level of medial thalamic neurons is regulated by tectothalamic projection neurons. The absence of sensory responses on both sides may reflect changes in bilateral intrathalamic information processing.

Supported by NSF BNS85-21333 and NIH NS206-26.

271.6 SOMATOSENSORY-VISUAL NEURONS IN CAT SUPERIOR COLLICULUS SHOW PARALLEL SOMATOSENSORY AND VISUAL VELOCITY TUNING. H.R. Clemo, M.A. Meredith and B.E. Stein. Depts. Physiol. & Anat., Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

There are many parallels between the somatosensory and visual representations in the deep layers of the superior colliculus (SC), both in their physiological properties and their involvement in localizing and orienting behaviors. However, it is not known whether there is a correspondence between functional properties of these modalities that may underlie such behaviors. Velocity of stimulus movement influences neuronal responsiveness and various velocities are optimal among SC neurons of either modality. Since the majority of somatosensory neurons are also responsive to other sensory stimuli (visual and/or auditory), we sought to determine the relationship of velocity tuning for each modality in somatosensory-visual neurons.

Cats (n=5), prepared 1 week prior to the initial recording session, were anesthetized (ketamine HCl), paralysed and respired with a mixture of N20 and O2. The somatosensory and visual receptive fields of 23 bimodal neurons in the intermediate layers were mapped and their responses to a variety of stimulus velocities for each modality were recorded. A mechanical probe was used to deliver stimuli in the cutaneous receptive field at different velocities (5-450 mm/s) and a galvanometer-driven mirror was used to move a bar of light across the visual receptive field at velocities ranging from 1-550°/s.

Of the neurons that showed velocity tuning (18/23; 78%), the majority (16/18; 89%) showed corresponding velocity tuning in both modalities. Thus, neurons (11/18; 61%) that were optimally activated (greatest number of spikes) by high velocity hair or skin displacement were optimally activated by high velocity visual stimuli. Similarly, those neurons (5/18; 28%) that responded best to slowly-moving somatosensory stimuli were also best activated by slowly-moving visual stimuli and the 5 neurons that showed no, or very broad, velocity tuning did so for both modalities.

To investigate the possible behavioral significance of this somatosensory-visual correspondence, stimulating electrodes were placed in the tecto-spinal tract of 3 cats. Forty percent (9/23) of all somatosensory-visual neurons were antidromically activated but no (0/27) unimodal somatosensory neurons could be activated in this way. It seems likely, then, that the correspondence of velocity sensitivity across somatosensory and visual modalities reflects parallel organizational schemes that underlie the behaviors mediated by the tectospinal pathway.

271.7 SOMATOSENSORY PROJECTIONS FROM SIV AND ADJACENT CORTEX TO THE THALAMUS AND SUPERIOR COLLICULUS IN THE NEWBORN CAT.
J.G. McHaffie, L. Kruger, H.R. Clemo and B.E. Stein. Dept. of Physiol., Med. Coll. of VA., Richmond, VA 23298 and Dept. of Anatomy, UCLA Ctr. Health Sci., Los Angeles, CA 90024.

A fourth somatosensory representation (SIV) has been described in the anterior ectosylvian sulcus (AES) of the cat (Clemo & Stein, Brain Res. 235:162, 1982). Unlike SI-SIII, SIV sends a direct projection to the superior colliculus (SC) while its thalamic projection skirts the ventrobasal complex to terminate in the posterior complex (Stein et al., J. Neurophysiol. 50:896, 1983). Since fetal and neonatal SC neurons respond to tactile stimuli (Stein et al., J. Neurophysiol. 36:667, 1973), we sought to determine if these corticofugal projections from AES also were present in the newborn cat.

Corticofugal projections from the AES were studied with autoradiography and retrograde HRP. When the injection was restricted to the walls and fundus of the AES, heavy ipsilateral thalamic label was seen in the medial subdivision of the posterior complex, the suprageniculate nucleus, and the external medullary lamina. No label was seen in the contralateral thalamus although the homotopic cortex was labeled. In the ventrobasal complex (VB) dense axonal label was seen traversing VB, but only sparse label was observed in VB proper. However, in those cases with marked spread of tracer into adjacent SII, terminal label in VB was much more pronounced. Thus, the corticothalamic projection in neonates is consistent with observations in the adult.

Rostral AES injections produced predominantly ipsilateral terminal label in the SC that was distributed in two tiers: a discontinuous band in the intermediate gray lamina and a second, more diffuse band in deep gray lamina. Caudally, dense terminal label was seen in the intercollicular zone and the dorsolateral periaqueductal gray. After injections of HRP into the SC, retrogradely labeled neurons were found throughout the ipsilateral AES. The cytoarchitecture characteristic of the adult SII-SIV region was apparent in the newborn. Retrogradely labeled neurons were found in SIV but never in SII. Thus, the corticotectal projection in neonates also parallels that seen in the adult.

These data show that the elaboration of a major descending somatosensory pathway to the thalamus and midbrain is largely a prenatal event. The in utero anatomical maturation of descending corticofugal projections from SIV cortex to the SC contrasts with the protracted postnatal development of the corticotrigeminal projection from SI cortex (Tolbert et al., J. Comp. Neurol. 228:478, 1984) but is consistent with the mature anatomical state of ascending trigeminotectal projections (McHaffie et al., J. Comp. Neurol. 249:411, 1986). Supported by NIH Grant EY05554.

271.8 RESPONSE PROPERTIES AND ORGANIZATION OF NOCICEPTIVE NEURONS IN THE RAT SUPERIOR COLLICULUS.
C. Q. Kao*, J.G. McHaffie and B.E. Stein. (Spon: K. Corley) Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

Numerous somatosensory neurons are present in the deep laminae of the superior colliculus (SC) and are topographically organized. Generally, both the response properties and spatial organization of such neurons are remarkably similar among species. Recently, we have quantitatively evaluated the response properties of nociceptive neurons in the hamster's SC (Larson, M.L. et al, J. Neurosci. 2:547, 1987). However, neither their properties nor their distributions in other species are known. The present study was an attempt to determine (a) whether nociceptive neurons are present in the SC of rat, if so, (b) whether they can be further catoragorized into nociceptive subtypes, and (c) whether they have any systematic organization.

Single- and multiunit activity was recorded in urethane anesthetised hooded rats. Neurons were first qualitatively characterized with manually presented innocuous (brushes, von Frey hairs, air puff) and noxious (pinch, glowing ember) stimuli. The stimulus-response relationships of nociceptive neurons were then evaluated quantitatively with an electronically controlled contact thermode placed on the skin.

In addition to those activated by low threshold (LT) tactile stimuli, many somatosensory neurons in the SC of rat responded preferentially, or soley, to frankly noxious stimulus. Two subtypes of nociceptive neurons were found: wide dynamic range (WDR- responsive optimally to noxious stimuli but also responsive to LT stimuli) and nociceptive specific (NS- responsive solely to noxious stimuli). The stimulus-response relationships of both WDR and NS neurons to noxious thermal stimuli appeared to be a positively accelerating power function. WDR receptive fields had two subregions: one in which LT and noxious stimuli were both effective and another, surrounding the first, in which noxious stimuli were more effective. NS receptive fields were significantly smaller than WDR receptive fields.

Several organizational features were evident. Regardless of subtype, nociceptive neurons had their heaviest concentration in the rostral one-half of the SC, and many had receptive fields on, or including, the face. A general dorsal to ventral segregation of somatosensory neurons was also noted, such that in a given electrode penetration, LT neurons were usually the most superficial, WDR neurons were just below these, and NS neurons were deepest of all.

These data indicate that nociceptive neurons are not a peculiarity of the hamster SC and that they have well-defined receptive field properties that are selectively distributed within the structure. Supported by NIH Grant EY05554.

271.9 SYNAPTIC ORGANIZATION OF THE VENTROBASAL COMPLEX IN THE PRIMATE.
P.T. Ohara, G. Chazal[1] and H.J. Ralston III. Anatomy Department, University of California San Francisco, San Francisco, CA 94143. USA. [1]I.N.S.E.R.M., U-6, 280 Bd. Ste Marguerite, 13009 Marseille, FRANCE.

Most mammalian thalamic nuclei have a common organization and, in some cases, particular morphological features have been correlated to functional parameters. This paper is concerned with delineating the features of the synaptic organization of the monkey ventrobasal complex (VB) in order to provide a basis for experimental studies of the primate somatosensory thalamus.

Adult Macaca fascicularis were perfused under deep barbiturate anaesthesia with 2% paraformaldehyde/ 2% glutaraldehyde in 0.1M phosphate buffer pH 7.6. The thalamus was sectioned on a vibratome at 50um and the slices osmicated, stained with uranyl acetate, dehydrated and embedded in Epon. Serial thin sections were cut through different regions of the VB and examined with the electron microscope.

Terminal types and the contacts they establish are similar to those found in other thalamic sensory nuclei. Four vesicle containing profiles were identified. Large axon terminals (RL-type) containing spherical synaptic vesicles and establishing asymmetric synaptic contacts. Small terminals with densely packed spherical synaptic vesicles and establishing asymmetric synaptic contacts (RS-type). Terminals containing moderately packed flattened or cylindrical synaptic vesicles and establishing symmetrical synaptic contacts (F-type). Finally, vesicle filled dendritic appendages (PSD) containing pleomorphic synaptic vesicles with synaptic contacts intermediate between symmetrical and asymmetrical.

In the extra-glomerular neuropil RL terminals contact larger dendrites; RS terminals contact small dendrites; F terminals contact neuronal cell bodies and large or medium size dendrites. PSDs are presynaptic to neuronal cell bodies, dendrites and other PSDs and are postsynaptic to RS, F and PSD profiles. Within glomeruli, dendrites, RL, PSD and F terminals are present and triadic arrangements involving dendrites, RL terminals and PSDs are common. Three dimensional computer-aided reconstructions of glomeruli have been made (program supplied by the High voltage Electron Microscopy Laboratory, Boulder Colorado) to analyze the organization of components within the glomeruli and the number of synaptic contacts.

271.10 THE PROJECTION OF THE DORSAL COLUMN NUCLEI AND THE SPINAL CORD TO NEURONS OF THE PRIMATE VENTROBASAL (VB) THALAMUS.
H.J. Ralston III, P.T. Ohara, D.D. Ralston and G. Chazal.[1] Dept. of Anatomy, Univ. of California, San Francisco and [1]Neurobiological Research Unit, INSERM-U6, 13009 Marseille.

The ventrobasal thalamus (VB) of the monkey is the major region of the thalamus concerned with somatic sensation. Some VB neurons have been found to respond specifically to a particular somatic stimulus; others respond to both noxious and nonnoxious stimuli. That region of VB representing the contralateral body receives projections from the dorsal column nuclei (DCN) and the spinal cord via the spinothalamic tract (STT). This study examines the two projection systems to determine the nature of their terminations upon VB neurons.

Macaca fascicularis monkeys were anesthetized and monitored during the entire surgical procedure. Using sterile neurosurgical techniques, the dorsal column nuclei and rostral cervical spinal cord were exposed. Unilateral lesions of the DCN were made, and microinjections of 0.1 ul of 10% WGA-HRP were made into the dorsal horn of the cervical enlargment on the same side as the DCN lesion, and into the contralateral DCN. The wound was closed, the animals survived for 2 or 3 days, then were reanesthetized and perfused intravascularly with aldehyde solutions. Thalamus, DCN and cord were cut in serial sections with a vibratome and alternate sections reacted for light microscopy using TMB-nitroprusside at pH 3.3, or for electron microscopy using TMB-ammonium molybdate at pH 6.6 (Olucha et al. J. Neurosci. Meth. 13:131,'85) followed by slow osmication at pH 5.0 (Henry et al. J. Histochem. Cytochem. 33:1256, '85). In some cases, DCN lesions were combined with GABA immunocytochemical studies to examine DCN projections to interneurons.

The molybdate-TMB/slow osmication method provides an excellent retention of reaction product combined with good quality fixation. Both DCN and STT projections to VB end as large profiles with round synaptic vesicles (RL), the DCN terminations being the most numerous, even in zones of overlap of the two projections. Both projections contact large dendrites in the extraglomerular regions, and medium dendrites and dendrites with vesicles (presynaptic dendrites - PSD) within glomeruli. In some cases, both DCN and STT-RL profiles contacted the same dendrite, indicating a convergent input of the 2 systems on single VB neurons. DCN projections to PSD's were more commonly found to contact PSDs than were STT projections, suggesting different degrees of inhibitory mechanisms for the 2 systems. Combined degeneration and immunocytochemical techniques demonstrated that the DCN projects to GABAergic neurons. (Supported by NS23347 and NS21445; and INSERM).

271.11 TERMINAL ARBORS OF INDIVIDUAL G HAIR FIBERS IN THE CAT CUNEATE NUCLEUS VISUALIZED WITH INTRAAXONAL HRP. J. Pierce, R. Weinberg, and A. Rustioni. Departments of Anatomy and Physiology, University of North Carolina, Chapel Hill, NC 27514.

Neurons in the dorsal column nuclei typically exhibit small, modality-specific receptive fields. Fibers innervating G hairs comprise a major part of the forelimb cutaneous input to the cuneate nucleus (CN). This study examined the pattern of collateral arborization of individual G hair fibers in the CN, stained by the intraaxonal iontophoresis of HRP; these findings bear upon the mechanisms that account for place- and modality-specificity in the lemniscal system. Cats were anesthetized with pentobarbital and α-chloralose. Microelectrodes containing HRP (Sigma Grade 1, 10% solution in TRIS-buffered KCl) were advanced through the dorsal columns, using stimulating cuff electrodes placed on the superficial radial and median nerves to provide a hunting stimulus. The modalities and receptive fields of cutaneous units were characterized with handheld probes. When a G hair fiber was identified, intra-axonal penetration and HRP injection were attempted. At the end of each experiment, animals were perfused with 2.5% glutaraldehyde/0.5% paraformaldehyde in phosphate buffer. Serial Vibratome-cut sections were reacted with DAB, and mounted for light microscopic examination. Fifteen collaterals from four identified G hair fibers were reconstructed in the transverse plane, using an immersion objective and a camera lucida attachment. In one case, the reconstruction of a series of collaterals was projected onto the longitudinal plane. Collaterals were spaced an average of 600 µm apart, with the closest spacing found between obex and 4 mm caudal to obex. In this region, adjacent collaterals tended to overlap, forming a relatively continuous rostrocaudal tube of terminations. In the transverse plane, the terminal fields had an oval shape, occupying on average 55,000 μm^2. Primary collateral branches would often spread out, and then bend back into the region in which most of the boutons were found. Arrangement of the terminal fields was generally consistent with cuneate comatotopic mapping studies. However, the large cross-sectional area of individual terminal fields suggest a high level of convergence. From published data one can calculate that roughly 5000 G hair fiber terminal fields could fit in the middle CN. The degree of anatomical convergence suggested by these experiments implies that intrinsic mechanisms are involved in generating place- and modality-specificity in the CN.

271.12 INTRACELLULAR STAINING OF INTERNEURONS IN CAT CUNEATE NUCLEUS. R.J. Weinberg, C.Y. Wen, R.E.W. Fyffe*, R. Giuffrida*, and A. Rustioni. Depts. of Anatomy and Physiology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27514.

Prior work from this laboratory has demonstrated a population of GABAergic interneurons in the cuneate nucleus. In the present study, interneurons from the cuneate core region have been intracellularly recorded and stained to further characterize them electrophysiologically and morphologically. Cats anesthetized with pentobarbital and α-chloralose were used. An array of stimulating electrodes was placed in the medial lemniscus at the level of the inferior colliculus. Cuneo-thalamic projecting neurons were identified by antidromic stimulation from this array, as shown by a short (<2 msec) constant-latency response. Previous work indicates that only few, if any, neurons in the cuneate core project to non-thalamic targets; therefore, cuneate neurons failing to respond antidromically were tentatively identified as interneurons and selected for further study. Modality and receptive fields were identified, as well as responses to stimulation of three major forearm nerves. Intracellular penetration was then attempted; following successful penetration, the neuron was intracellularly stained with HRP (Sigma Grade 1, 10% solution in TRIS-buffered KCl). Following intracardiac perfusion with 2.5% glutaraldehyde and 0.5% paraformaldehyde in phosphate buffer, Vibratome sections of the medulla were reacted with DAB and mounted for microscopic examination. In favorable cases, sections were osmicated and wafer-embedded in epon-Spurr resin for electron microscopy.

To date, five neurons have been recovered that a) match electrophysiological criteria for identification as cuneate interneurons, and b) correspond in size and location to cuneate neurons that are labeled by GAD immunocytochemistry (Rustioni et al., 1984). These neurons are all small (cell body 10 x 20µm diameter), with only a thin rim of cytoplasm surrounding the nucleus. They tend to lie at the periphery of cell clusters. Their dendrites extended several hundred µm from the cell body and branch only sparsely. In no case, could a clearly-defined axon be identified. The best characterized neurons respond to hair deflection, and exhibit short-latency excitatory responses to stimulation of more than one peripheral nerve. Immunocytochemical and electronmicroscopic study of this material is now in progress. Several other neurons of heterogeneous morphologies and not resembling the cuneo-thalamic neurons previously described by Fyffe et al. (1986), have also been recovered.

271.13 MORPHOLOGICAL CHANGES IN THE RAT DORSAL COLUMN NUCLEI FOLLOWING PRENATAL LIMB REMOVAL. J.R. Norris, D.R. Dawson, and H.P. Killackey, Dept. of Psychobiology, University of California, Irvine, CA. 92717

Tangential sections of the primary somatosensory cortex of the rat stained for succinic dehydrogenase (SDH) activity exhibit an anatomical map of the entire body surface. Recently, it has been shown in the rat that, following forelimb amputations on embryonic day 16 or 17, the hindlimb portion of the SDH staining pattern exhibits an increase in size of as much as 100%. The extent to which these cortical changes reflect morphological changes in the subcortical somatosensory nuclei is not known. In the present study, cytoarchitectural and tract-tracing methods were used to analyze the morphological organization of the dorsal column nuclei (DCN) following prenatal limb amputations.

Forelimb or hindlimb amputations were performed in utero between embryonic day 16.5 and 19.5. Natural birth occurred on day 22 or 23. Animals were weaned after three weeks and raised until early adulthood. Some animals with forelimb amputations received complete lower thoracic spinal transections, were sacrificed and processed for Fink-Heimer staining. Some animals received bilateral injections of WGA-HRP, were sacrificed and reacted with TMB. Some animals were sacrificed and processed using Nissl staining methods.

In the DCN of adult rats which received limb amputations prenatally, three anatomical changes were observed. First, the ipsilateral nucleus associated with the amputated limb is reduced in size and is less distinct than the contralateral equivalent, despite a relatively normal location and shape. The reduction in size is most noticable with earlier amputations but is present in each of the animals observed. Second, the border between the two ipsilateral dorsal column nuclei is blurred in regions where the nuclei are in close approximation. Third, the termination pattern of the afferent projections to the ipsilateral DCN (associated with the intact limb) exhibits a slight increase in size which corresponds in location to the blurred border regions between the two ipsilatersal dorsal column nuclei.

271.14 PROJECTIONS FROM GLABROUS SKIN OF SINGLE FOREPAW DIGITS TO THE CUNEATE NUCLEUS IN THE RACCOON. D.D. Rasmusson, Dept. of Physiology & Biophysics, Dalhousie University, Halifax, N.S., CANADA B3H 4H7

The anatomical and physiological organization of the cuneate nucleus in the raccoon has been described by Johnson et al. (J. Comp. Neurol. 132:1-44, 1968). The middle, cluster region of the cuneate is characterized by enlarged representations of the forepaw digits. These digit "columns" are elongated rostrocaudally and separated by dense myelin bundles. The purpose of the present experiment was to determine if the anatomical projection pattern from single digits corresponds precisely to these boundaries. Alternately, afferents from adjacent digits might overlap, requiring filtering to produce the restricted receptive fields seen at the single unit level.

Transganglionic transport of HRP was used to produce labeling of primary afferent terminals. A total of eleven digits were studied in 8 raccoons. HRP (20%) or WGA-HRP (2%) was injected into both ventral nerves of the digit (about 95% of the innervation of the glabrous skin travels in the ventral nerves: Somatosen. Res., 4:43-62, 1986). The animals were perfused three days after the injections and 50 µm thick horizontal sections of the medulla were taken. The tissue was reacted with TMB and in some cases counterstained with neutral red. Alternate sections were stained with thionin.

The projection patterns in every case consisted of dense labeling in long rostro-caudal columns extending throughout the cluster region of the cuneate with the 5th digit represented medially and successive digits more laterally. Within such a column, the labeling was dense over clusters of cells and considerably lighter between clusters. The mediolateral extent of the labeling was restricted to the somatotopically appropriate column and did not overlap into adjacent digit columns. This pattern broke down in the non-cluster regions (both rostral and caudal cuneate) where the labeling was more diffuse.

This pattern of projection indicates that the primary afferents are strictly segregated in the cluster region of the cuneate nucleus according to the digit of origin. The restricted terminal labelling seen here makes it possible to test the idea that these primary afferent terminals might sprout into adjacent digital regions of the cuneate nucleus after peripheral denervation.

271.15 CLUSTERS OF AFFERENT TERMINALS FROM DIGITS AND PADS OF THE HAND RELATE TO DISCRETE CLUSTERS OF CELLS IN THE CUNEATE NUCLEUS OF MACAQUE MONKEYS AND PROBABLY HUMANS. S. L. Florence, J. T. Wall, and J. H. Kaas. Dept. of Psychology, Vanderbilt Univ., Nashville, TN 37240.

The present experiments demonstrate that clusters of primary afferents from specific digits and pads of the hand of macaque monkeys terminate in discrete clusters of cells in the cuneate nucleus that react densely for cytochrome oxidase and are outlined by myelinated axons.

To demonstrate the termination pattern of afferents, small subcutaneous injections of WGA-HRP or cholera toxin sub-unit B-HRP were made into one or more localized foci of the palm or digits of the hands of five macaque monkeys (Macaca fascicularis). Following survivals of 3-4 days, the brain stem of each perfused monkey was cut coronally and alternate sections were processed with tetramethylbenzidine, cytochrome oxidase (CO), myelin stain, or Nissl stain.

The middle two thirds of the cuneate nucleus (pars rotunda) was found to be parcellated into numerous CO-dark regions separated by CO-light septa-like zones. Careful alignment of adjacent brain sections revealed that CO-dark regions are relatively free of myelinated axons and correspond to cell clusters, while intervening CO-light septa correspond to bundles of myelinated fibers. The rostral and caudal poles of the cuneate nucleus and the pars triangularis were found to be structurally more homogeneous. The terminal fields of primary afferent fibers from individual digits were concentrated primarily within individual CO-dense regions of the pars rotunda and a CO-dense region could be related to each digit. Injections of the palm often involved more than one palmar pad and a group of CO-dense patches were usually associated with these injections. At the rostral and caudal poles of the nucleus, afferent fibers terminated more diffusely. A comparison of the brain sections from macaque monkeys and myelin-stained brain sections from humans revealed a parcellation pattern in the pars rotunda of the cuneate nucleus of humans that was very similar to that found in monkeys.

We conclude that the pars rotunda of the cuneate nucleus of macaques, and probably other primates including humans, has a somatotopic map that is anatomically apparent and precisely organized in a manner comparable to the "barrel field" of rats. The results also suggest that additional, less discrete maps exist at the rostral and caudal poles of the cuneate nucleus and perhaps also in the pars triangularis. The separate maps may relate to different submodalities.

271.16 DORSAL COLUMN STIMULATION PRODUCES PRIMARY AFFERENT DEPOLARIZATION IN NUCLEUS CAUDALIS VIA A BRAINSTEM LOOP. N.E. Saadé, S.F. Atweh# and S.J. Jabbur#. Fac. of Sci., Lebanese Univ., Hadath-Beirut and #Fac. of Med., Amer. Univ. of Beirut, Beirut, Lebanon.

Dorsal column stimulation inhibits n. caudalis activity through a brainstem loop (Brain Res. 348:401, 1985). The inhibition begins 15-20 ms after stimulation, peaks at 35-50 ms, and lasts about 200 ms. A similar inhibition of dorsal horn activity through a similar loop is, in part at least, presynaptic (Brain Res. 310:180, 1984). We now show that primary afferent depolarization is produced in n. caudalis through a dorsal column-brainstem loop.

Anesthetized decerebrate/decerebellate cats were used, in which the ventral and lateral spinal funiculi were sectioned bilaterally at C1/C2 and C3/C4 levels. The presence of primary afferent depolarization was ascertained by changes in the positive wave recorded from the surface of n. caudalis in response to test stimulation of infraorbital nerve and changes recorded from infraorbital nerve to test stimulation in n. caudalis. A 30 ms train of shocks at 300 Hz was applied to the ipsilateral dorsal columns rostral to the cuts, and both forepaws were stimulated with single shocks. The areas of the positive wave of n. caudalis and the two components comprising the nerve response were measured with a waveform calculator.

Dorsal column stimulation depressed the positive wave evoked in n. caudalis by infraorbital nerve stimulation, the peak depression occurring 10-30 ms after stimulation and lasting about 150 ms. The positive wave decreased to 30% of control after the dorsal column stimulus and to 60% of control after contralateral forepaw shock. The nerve response consisted of an inital spike due to activation of infraorbital nerve terminals and a later complex spike related to the dorsal root reflex and due to antidromic activation of the nerve fibers by interneuron activity in n. caudalis producing presynaptic inhibition. Dorsal column stimulation increased the first spike to 150-180% of control, but decreased the later spike to 40-50% of control, both effects peaking at 30-50 ms and lasting about 100 ms. These changes, and their time course, provide the evidence that the inhibition of n. caudalis activity produced by the dorsal column-brainstem route is mediated, in part at least, by a presynaptic mechanism.

271.17 SPINOCERVICAL TRACT NEURONS RESPONSIVE TO LIGHT TACTILE STIMULATION OF THE RACCOON FOREPAW. Harumitsu Hirata, Sherri L. Provencal*, Cecilia H. Yu*, and Benjamin H. Pubols Jr. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

Response properties of single neurons activated by light mechanical stimulation of the glabrous surfaces of the forepaw have been extensively studied at the several levels of the raccoon dorsal column-medial lemniscal system (Pubols & Warren, 1985). The present investigation was undertaken in order to compare these findings with data obtained from the cells of origin of the raccoon spinocervical tract (SCT). Stainless steel microelectrodes were used to detect the extracellular electrical activity of SCT neurons in raccoons anesthetized with pentobarbital sodium.

A total of 29 antidromically identified SCT neurons with low threshold excitatory receptive fields (RFs) restricted to the glabrous surfaces of the ipsilateral forepaw have been studied. Of 8 neurons tested, none displayed enhanced response to noxious stimuli. All 29 neurons were histologically verified as falling within Rexed's laminae III-IV of dorsal horn segments C_7-C_8. Conduction velocities ranged between 8.3 and 56.8 $m.s^{-1}$.

Units were classified according to their response to a maintained mechanical stimulus as either rapidly adapting (RA; N = 25), or slowly adapting (SA; N = 4). The proportions of RA and SA do not differ significantly from those found in the clusters region of the main cuneate nucleus (MCN; Rowinski, Haring, & Pubols, 1985).

RF areas are significantly smaller ($P < .05$) on digits (N = 12; range = 0.4-45.0 mm^2) than on palm pads (N = 6; range = 8.8-56.4 mm^2). These values are slightly less than those previously seen in the MCN (Rowinski, et al., 1981). The median digital RF area (6.6 mm^2) is approximately 27 X that for primary afferents of the median nerve (Pubols, Pubols, & Munger, 1971), while the median palmar RF area (19.7 mm^2) is approximately 56 X that for median nerve fibers.

For 5 RA units, the range of exponents of the power function relating instantaneous spike frequency during displacement ramp stimulation to ramp velocity was .51-1.08. These values are comparable to those previously observed in the MCN (Rowinski, et al., 1985), In addition, 2 RA units displayed a discontinuous, or step, function, previously seen only in raccoon RA neurons of the thalamic ventrobasal complex (Warren, Kelahan, & Pubols, 1986).

Thus, the ability of the raccoon SCT to convey information from the glabrous skin of the forepaw regarding submodality, spatial, and dynamic characteristics of light mechanical stimuli appears to be at least as precise as that of the dorsal column-medial lemniscal system. (Supported in part by research grant NS-19486, USPHS, and by the Coleman H. Wheeler Jr. Memorial Fellowship Program of the Neurological Sciences Institute.)

272.1 INHIBITORY EFFECTS OF ANTERIOR PRETECTAL NUCLEUS STIMULATION ON JAW-OPENING REFLEX AND TRIGEMINAL (V) BRAINSTEM NEURONAL RESPONSES IN RATS. C.Y. Chiang*, I.C. Chen*, J.O. Dostrovsky and B.J. Sessle, Dept. of Physiology, Fac. of Medicine, and Fac. of Dentistry, Univ. of Toronto, Toronto, Ontario.

It has been recently reported that low-intensity stimulation of the anterior pretectal nucleus (APT) of the rat results in an increased tail-flick latency lasting for more than 45 min without causing escape behaviour or motor deficits (Roberts & Rees, Pain 25:83, 1986). The present study aimed to test the possible modulatory role of APT on the jaw-opening reflex (JOR) and neuronal responses in the trigeminal (V) brainstem sensory complex.

Experiments were performed on male Wistar rats anaesthetized with chloralose-urethane. Digastric activity was recorded intramuscularly with a pair of fine insulated stainless-steel wires. The JOR was elicited by test stimulation of the maxillary skin (0.1-0.2 ms, 0.5 Hz). In the experiments in which V neuronal activity was recorded, the animals were paralysed and artificially ventilated and the field potential (FP) evoked by facial skin (test) stimulation and the activity of single neurones in subnucleus caudalis of the V complex were recorded with tungsten microelectrodes (10-20 Mohms). The same type of electrode was also used for stimulation (8 pulses, 0.2 ms, 400 Hz, cathodal current) in APT (P:-4.3 to -4.8; L:1.6 to 1.8; V:5.0 to 6.0; with reference to Bregma) to test for conditioning effects on the JOR and caudalis activity at conditioning-test (C-T) intervals of 30 - 800 msec.

Conditioning stimulation of APT had an inhibitory effect on the JOR. This was manifested as a reduction of EMG amplitude, decreased incidence of single motor unit evoked discharges, and lengthening of JOR latency. The most effective stimulating loci were in the ventral APT, and currents as low as 35 uA often induced a 25 - 50% reduction in JOR amplitude. The APT-induced inhibition was usually noted at C-T intervals of 30 - 200 msec, and this period of inhibition was often preceded and followed by a period of facilitation. In addition, APT stimulation produced a 10-20% reduction in the caudalis FP and inhibited the evoked activity of low-threshold mechanoreceptive neurones and nociceptive neurones. APT stimulation inhibited the JOR and the neuronal responses bilaterally, but was more effective ipsilaterally.

These findings indicate that the APT exerts a modulatory influence on the JOR that is predominantly inhibitory in nature. Our findings of inhibitory effects also on V brainstem neuronal activity suggest that the inhibitory effect on the JOR may be at least partly due to modulatory influences on neurones in parts of the V brainstem sensory complex that subserve reflex and somatosensory functions. (supported by NIH)

272.2 MICROINJECTION OF GLUTAMATE INTO THE NUCLEUS TRACTUS SOLITARIUS PRODUCES ANALGESIA IN THE RAT. M. M. Morgan, J.-H. Sohn and J. C. Liebeskind. Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

The nucleus tractus solitarius (NTS) is a medullary structure known to contain high levels of opioid peptides and receptors. Recently, Lewis and co-workers (in press) demonstrated that electrical stimulation of the nucleus tractus solitarius (NTS) could produce naloxone-reversible analgesia. In the present study, microinjections of glutamate, an excitatory amino acid, were made into the NTS to determine if activation of cell bodies of the NTS mediate this analgesic effect as opposed to fibers of passage.

Male Sprague-Dawley rats (200-400 g) were anesthetized with pentobarbital (55 mg/kg) and a guide cannula was stereotaxically positioned just dorsal to the obex. A monopolar electrode was inserted through the guide, extending 1 mm ventrally. The threshold for stimulation-produced analgesia was then determined using the tail-flick test to assess pain sensitivity. Once the threshold was determined, the electrode was removed and an injection cannula filled with glutamate (30 or 60 mM) or saline was inserted in its place. All injections were made in a volume of 0.5 µl over a 90 s period. Tail-flick tests were carried out 30 s after the end of the injection and at 1 min intervals thereafter for 5 min. If analgesia persisted, additional tail-flick tests were performed at 5 min intervals until response latencies returned to baseline values. All electrode sites were histologically verified following completion of the experiment.

Microinjections of glutamate into the NTS produced analgesia lasting approximately 5 to 10 min. Injections outside the NTS, or injections of saline into the NTS were ineffective in producing analgesia. In contrast, many sites outside the NTS supported analgesia during electrical stimulation, although the threshold for SPA was generally higher. This analgesia could be mediated by current spread activating NTS neurons or by activation of fibers of passage arising from rostral pain inhibition centers. Our glutamate microinjection data demonstrate that activation of cell bodies in the NTS can produce analgesia. (Supported by NIH grant NS07628).

272.3 EFFECTS OF MONOAMINE DEPLETION ON ANALGESIA PRODUCED BY ELECTRICAL STIMULATION OF THE NUCLEUS TRACTUS SOLITARIUS. A.M. Lohof, M.M. Morgan, and J.C. Liebeskind, Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024-1563

Electrical stimulation of the nucleus tractus solitarius (NTS) causes analgesia in the rat. The NTS is rich in opioid peptides and their receptors, and stimulation-produced analgesia (SPA) from the NTS is attenuated by naloxone. The role of other transmitter systems has not been studied. Akil & Liebeskind (1975) showed that depletion of monoamines by tetrabenazine (TBZ) attenuated SPA from sites in and around the dorsal raphe nucleus. This study sought to determine whether TBZ would also interfere with NTS stimulation-produced analgesia.

Male Sprague-Dawley rats (200-350 g) were anesthetized with pentobarbital (55 mg/kg) and a bipolar stimulating electrode was stereotaxically positioned in the NTS. Pain sensitivity was measured using the tail-flick test. After determination of SPA threshold intensity, TBZ (10 mg/kg, i.p.) or 0.9% saline was administered. SPA threshold intensity was determined again 30 min later. In other rats, electrodes were aimed at the dorsal raphe nucleus; SPA thresholds were determined before and after TBZ as described above.

Unlike SPA from dorsal raphe sites, that from the NTS was not consistently affected by TBZ. Serotonin, found in high concentrations in the dorsal raphe nucleus, is known to be involved in a descending pain inhibition system. Our results confirm the importance of this transmitter in the production of SPA from the dorsal raphe nucleus. Monoamines do not appear to mediate SPA from the NTS. (Supported by NIH grant NS 07628)

272.4 STIMULATION OF NUCLEUS TRACTUS SOLITARIUS CAUSES ANALGESIA BY ACTIVATING PERIAQUEDUCTAL GRAY MATTER IN THE RAT. J.-H. Sohn, A. Lohof, M. M. Morgan, and J. C. Liebeskind. Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

Electrical stimulation of the nucleus tractus solitarius (NTS) produces opioid-mediated analgesia (Lewis et al., in press). The NTS has extensive reciprocal connections with higher brain structures. Notable among these are connections with the periaqueductal gray matter (PAG), itself known to be involved in pain inhibition. This study sought to determine whether NTS stimulation-produced analgesia (SPA) relies on connections with the PAG.

Male Sprague-Dawley rats were anesthetized with pentobarbital (55 mg/kg) and mounted in a stereotaxic apparatus. Pain sensitivity was measured using the tail-flick test. In the first experiment, a stimulating electrode was stereotaxically positioned in the NTS and holes were drilled in the lateral aspect of the skull so that a guide cannula could be lowered into the hole. Through this cannula a wire was inserted projecting 10 mm laterally allowing coronal brain sections to be made. Thresholds for SPA were determined before and after coronal sections. Sections were made rostral to the PAG and between the NTS and PAG. In the second experiment, similar procedures were followed except selective electrolytic lesions (2 mA DC, 15 sec) of the PAG were made rather than transections. Stimulation and lesion sites were histologically verified.

Transections between the NTS and PAG increased the threshold for SPA in the NTS. Thresholds were doubled in most rats, and in some animals SPA could no longer be obtained below intensities causing motor effect (i.e. tail movement). In some rats, transection also caused an increase in baseline tail-flick latency, but this effect disappeared after one or two minutes. Cuts made rostral to the PAG had no effect on SPA threshold. Selective PAG lesions also increased SPA threshold. In this experiment, baseline tail-flick latencies were always increased for approximately 2 to 5 minutes after the lesion.

Taken together, these results suggest that stimulation of the NTS produces analgesia via a descending system arising in the PAG. In related work, Morgan et al., (this volume) have shown that NTS analgesia is due to stimulation of cell bodies and thus not attributable to stimulation of descending PAG fibers. (Supported by NIH grant NS 07628).

272.5 SUPPRESSION OF THE HINDLIMB FLEXOR REFLEX THROUGH MEDIAL THALAMIC STIMULATION IN THE LIGHTLY ANESTHETIZED RAT. J. Duysens and J. Gybels*. Lab. of Experimental Neurology, University of Leuven, B-3000 Leuven, Belgium.

Although the descending control of flexor reflex pathways has been documented extensively, the nociceptive flexor reflex has been rarely used in studies of stimulation produced analgesia (SPA). The lightly anesthetized rat (Nembutal 10-20 mg/kg/hr) is a suitable preparation for testing the flexor reflex, as elicited by electrical stimulation of the pad. This model was used to further explore the analgesic effects obtained on the tail-flick and hot plate test in response to stimulation of the medial thalamic nuclei. Both the timing of the pad stimulation (interstimulus interval of 10 s) and the sampling of the integrated EMG responses of the pretibial flexors from the stimulated leg, were controlled by a small computer.

Provided the anesthesia was sufficiently light, a reliable complete suppression of the nociceptive flexor reflex was obtained with the same central stimuli which were previously shown to be effective in producing SPA in awake rats (1000 ms train at 100 Hz, 0.1 ms pulses at 50 μA). Such stimuli were sometimes effective over distances of more than 2 mm. Optimal sites were located near the midline, 1.8 mm behind the bregma and at depth of 4.5-5 mm and 7-7.5 mm below the cortical surface. Depending on the stimulus parameters a total train duration of minimum 300 to 500 ms was required with a pulse frequency exceeding 20 Hz. The suppression occurred during the period of stimulation and was sometimes followed by a rebound contraction after the completion of the stimulation.

Since the amount of suppression remained constant at different reflex amplitudes an additive inhibitory mechanism is postulated. Intravenous injection of naloxone (0.05 mg/kg) or methysergide (15 mg/kg) failed to reverse the suppression.

It is concluded that the hindlimb withdrawal reflex of the lightly anesthetized rat is suppressed by the same stimulus parameters and at the same sites yielding effective SPA in the awake rats. Moreover, the automated testing of the flexor reflex allows a rapid and detailed characterization of these sites.

272.6 EFFECTS OF INTRATHECAL (IT) THYROTROPIN-RELEASING HORMONE (TRH) ON IT SEROTONIN (5HT) ANALGESIA AS MEASURED BY THE TAIL FLICK (TF) AND HOT PLATE (HP) TESTS. E.S. Culhane*, C.L. Thurston, D.K. Douglass*, I.G. Campbell*, E. Carstens and L.R. Watkins. (SPON: S.N. Suberg) Dept. Animal Physiology, UC Davis, Davis, CA 95616.

TRH has been reported to have a modulatory effect on analgesia systems. IT TRH blocks IT morphine analgesia and ICV TRH potentiates both opiate and nonopiate stress induced analgesias. Recent anatomical evidence suggests a possible interaction between TRH and 5HT in the spinal cord. TRH and 5HT are colocalized in raphe-spinal neurons projecting to the ventral horn, while TRH containing cell bodies and terminals appear to be separate from, but do overlap, the descending 5HT projections to the dorsal horn. The present study investigated the possible modulatory effects of TRH on IT 5HT analgesia using the TF and HP tests.

Forty-six male Sprague Dawley rats (450-600g) were implanted with IT catheters terminating at the lumbosacral enlargement. After post-operative recovery and habituation to the restrainers used during testing, baseline TF and HP latencies were measured, and equivolume IT injections of either saline, 5HT (125 ug), TRH (10, 50 or 500 ng), or 5HT (125 ug) + TRH (10 or 50 ng) were made. Following injection, TF latencies were tested every 5 min for 40 min, and HP latencies were tested immediately following the 5, 15, 30 and 40 min TF tests.

5HT alone produced a rapid and significant analgesia for 15 min on the TF test which was significantly attenuated by 10 ng TRH. Conversely, 5HT did not produce analgesia on the HP test, but 10 ng TRH + 5HT caused significant analgesia for 15 min post-injection. 50 ng TRH did not affect 5HT analgesia on either test. TRH alone produced a significant dose dependent hyperalgesia 25-40 min post-injection on the TF test. No hyperalgesia occurred when both 5HT and TRH were injected.

These data indicate that TRH may affect 5HT analgesia in an inverted dose dependent manner. In addition, TRH appears to modulate a spinally mediated reflex (TF) differently than a supraspinally organized behavior (HP). A more complete dose response is currently being investigated. The slow-onset, dose dependent TRH hyperalgesia on the TF reflex may be due to its excitatory effect on motoneurons. Attenuation of TRH hyperalgesia by 5HT at times when 5HT alone is not analgesic suggests that 5HT may antagonize TRH's actions in the ventral horn.

272.7 ANALGESIA INDUCED BY MICROINJECTION OF ARGININE VASOPRESSIN INTO THE LATERAL HABENULA OF CONSCIOUS RATS. K.D. Lake*, C.L. Thurston, E.S. Culhane*, E. Carstens, and L.R. Watkins. Dept. of Animal Physiology, University of California, Davis, Ca. 95616.

In a previous study, Lake et al. (FASAB, 1987) showed that microinjections of arginine vasopressin (AVP) into the lateral habenula (LHb) of anesthetized rats elicited an immediate and significant increase in mean blood pressure and heart rate for over 30 min. Since acute and genetically hypertensive rats can display elevated plasma AVP levels, high AVP content in certain brain nuclei, and a reduced sensitivity to painful stimuli, these data raise the possibility that the LHb may be involved in pain modulation secondary to its hypertensive effects. In order to study the possible role of the LHb in pain processing, we investigated the effect of AVP injection into the left LHb or control site just dorsal to LHb [dorsal hippocampus (Hi)] on the tail flick latency (TFL) in conscious rats.

Male Sprague Dawley rats, 450-520 grams, were surgically implanted with a 27-gauge guide cannula 10 days prior to testing. The rats were habituated to the restrainers used in testing. Baseline TFL values were recorded prior to injection with a 0.5 ul volume of either 20, 50, or 100 ng AVP. TFL were tested at 3, 6, 10, 15, 20, 25, 30, 35, and 40 min post-injection (PI). Correct placement of the injections was confirmed by histological examination of dye-injected brain sections. During our pilot studies, we observed these AVP-induced behaviors: circling, barrel rotations, scratching, partial flaccidity and hypnotic staring as well as potential seizure indices (piano playing and wet dog shakes). The rats were placed in an observation area at 5, 10, 20, 40 min. PI for behavioral observation.

Our preliminary results have indicated no dose dependency for analgesia or behavior. No analgesia or abnormal behavior occurred in rats injected with saline. Of the behaviors noted, the clearest differences between groups were for analgesia and "seizure". 5 of 12 LHb rats showed both "seizure" and 100% analgesia (TFL = 8.0 s). 1 of 5 Hi rats showed "seizure"; 0 of 5 showed analgesia.

These data suggest a potential interrelationship between analgesia, "seizure" and hypertension elicited from the LHb. While we have not yet tested whether AVP can elicit hypertension from the Hi, the data to date strongly indicate that neither analgesia nor "seizure" are readily elicited from this region. In contrast, AVP clearly can induce analgesia, "seizure" and hypertension when injected into the LHb. Whether AVP-induced "seizure" and/or hypertension from the LHb cause, or are simply correlated with, analgesia is yet to be determined.

Supported by NIH grant NS 20037.

272.8 DEVELOPMENT OF TOLERANCE FOLLOWING INTRATHECAL (IT) INJECTIONS OF ARGININE VASOPRESSIN (VAS). C.L. Thurston, R.J. Jones*, E.S. Culhane*, E. Carstens, and L.R. Watkins, Dept. Animal Physiology, Univ. of California, Davis, CA 95616

IT VAS produces analgesia, scratching bouts, and motor suppression. Repeated injections of VAS have been shown to result in tolerance to the scratching and motor effects (Long, J.B., et al., Neurosci. Abs. 12:1496, 1986). The purpose of the present study was to determine if rats develop tolerance to VAS-induced analgesia and, if so, to compare the time course of tolerance development to the analgesic, scratching, and motor effects of IT VAS.

Nineteen male Sprague Dawley rats were implanted with lumbosacral IT catheters. Following habituation to the restrainers used during test sessions, each rat was assigned to a drug group (25 ng VAS or saline) and then subjected to the following protocol on 7 consecutive days. Baseline tail flick latencies (TFL) were measured prior to drug injection. Following IT injection, TFL were measured every 15 min for 90 min on Day 1, and at 5, 15, 60, and 90 min on subsequent days. Motor ability of the rats was assessed from 5-15 and at 30 min post-injection. Throughout the 90 min test time, rats were observed for any signs of abnormal behavior.

On Day 1, 7/11 rats receiving 25 ng VAS reached the 8 sec TFL cutoff throughout the 90 min test; saline produced no significant change in TFL. The 4 nonanalgesic VAS rats were not tested after Day 1. The remaining VAS rats exhibited tolerance to the analgesic effects of VAS on Days 2-5, with the mean TFL across time varying between 4 and 6 sec, as opposed to 8 sec on Day 1. On Days 2-4, the baseline TFL were significantly higher than Day 1 (5 sec compared to 3.5 sec on Day 1). On Days 6 and 7, VAS again produced analgesia with mean TF latencies between 6.2 and 8 sec. Tolerance also developed to the scratching and motor effects of IT VAS. Scratching bouts occurred in 3 rats receiving VAS on Days 1 and 2, but did not occur in any rats on Day 3. However, on subsequent days, one or two rats would show scratching bouts (not always the same rat across days). Motor dysfunction occurred in 6/7 rats receiving VAS on Day 1, with the severity of motor dysfunction decreasing on subsequent days. Two rats developed barrel rotations with repeated injections.

This study shows that tolerance develops to repeated IT injections of VAS, but this tolerance reverses after a few days. This suggests the possibility that non-opiate analgesics such as VAS may be used for long term pain management without the problem of tolerance that accompanies opiate analgesics. The tolerance to analgesia, motor suppression, and scratching bouts follow different time courses showing a dissociation of these effects.

272.9 **DECEREBRATION BLOCKS THE ANALGESIA OBSERVED AFTER VERY BRIEF BUT NOT LONG SHOCKS.** M. W. Meagher and J. W. Grau. Dept. of Psychology, UNC, Chapel Hill, NC 27514 and Dept. of Psychology, Texas A & M University, College Station, Texas 77843.

We have suggested that the memory of an aversive event may activate the brainstem systems which modulate the flow of nociceptive information at the level of the spinal cord (Grau, J. W., Beh. Neurosci., 101: 272, 1987). Supporting this hypothessis, we have shown that factors which should speed the decay of the memory also speed the decay of analgesia. On the basis of this behavioral evidence we have suggested that forebrain systems may mediate the activation of the analgesic systems when an organism is exposed to mild aversive events. By contrast, others (e.g. Watkins, L. R. et al., Brain Rsch., 276:317, 1983) have suggested that the analgesic systems may be directly activated at the level of the brainstem and that forebrain systems are not essetial. Supporting this notion, they have shown that decerebration has little impact on the magnitude of shock induced analgesia. However, the duration of shock exposure employed in these studies (90 sec) is considerably longer than the shock duration (2.25 sec) we typically use. Thus, it is possible that forebrain systems do mediate the analgesia observed after very brief shocks, whereas long shocks may directly activate the brainstem analgesic systems. The present experiemt tests this hypothesis.

The subjects were 48 male Sprague-Dawley rats (100-120 days old). One-half of the subjects experienced sham surgery under Pentothal anaesthesia. The other half received mid-collicular decerebrations. Eight to ten hr later the subjects were placed in restraining tubes and allowed to acclimate for 15 min. Baseline pain reactivity was then assessed. One third of the subjects then recieved 3 very brief (0.75 sec) 1.0 mA shocks spaced 20 sec apart. Another third received 3 long (25 sec) 1.0 mA shocks spaced 20 sec apart. The remaining subjects served as unshocked controls. Five tail-flick tests were then administered at 2 min intervals.

No significant differences existed between the groups prior to shock exposure. Both the very brief shocks and the long shocks induced significant analgesia in the sham controls. However, the very brief shocks did not induce analgesia in decerebrate subjects. By contrast, exposure to long shocks did induce a strong analgesia. In fact, exposure to long shocks induced a greater analgesia in decerebrate subjects than it did in the sham controls.

This study shows that forebrain systems mediate the activation of the analgesic systems when subjects are exposed to very brief shocks. It also shows that long shocks are capable of directly activating the brainstem analgesic systems. The fact that decerebration potentiated this analgesia suggests that forebrain systems may actually inhibit the direct activation of the analgesic systems by long shocks.

272.10 **LESIONS OF THE FRONTAL CORTEX ATTENUATE THE ANALGESIA OBSERVED AFTER VERY BRIEF BUT NOT LONG SHOCKS.** J. W. Grau and M. W. Meagher. Dept. of Psychology, Texas A & M University, College Station, Texas, 77843 and Dept. of Psychology, University of North Carolina, Chapel Hill, NC 27514.

Considerable evidence exists that neural systems in the brainstem can modulate the flow of nociceptive information at the level of the spinal cord. Elsewhere we investigated whether neural systems in the forebrain play a role in activating these brainstem systems (see the abstract by M. W. Meagher and J. W. Grau). We showed that decerebration blocks the analgesia observed after very brief shocks, which suggests that forebrain systems mediate the activation of the analgesic systems in this situation. By contrast, decerebration potentiated the analgesia observed after long shocks. This suggests that long shocks can also directly activate the analgesic systems in the brainstem, and if anything, neural systems in the forebrain may inhibit the direct activation of the analgesic systems by long shock. The present study assesses whether lesions of the frontal cortex would have a similar impact on the analgesia observed after very brief or long shocks.

The subjects were 48 male Sprague-Dawley rats (100-120 days old). One-half of the subjects experienced sham surgery under Pentothal anaesthesia. The other half received lesions of the frontal cortex. The subjects were then tested 24 to 30 hr later. The subjects were placed in restraining tubes and allowed to acclimate for 15 min. Baseline pain reactivity was then assessed with the tail-flick test. One third of the subjects then received 3 very brief (0.75 sec) 1.0 mA shocks spaced 20 sec apart. Another third received 3 long (25 sec) 1.0 mA shocks spaced 20 sec apart. The remaining subjects served as unshocked controls. Five tail-flick tests were then administed at 2 min intervals.

No significant differences existed between the groups prior to shock exposure. Both the brief and the long shocks induced significant analgesia in the sham controls. In lesioned subjects exposure to brief shocks did not induce analgesia. By contrast, exposure to long shocks induced a strong analgesia. However, unlike decerebration, lesions of the frontal cortex did not potentiate this analgesia.

These findings suggest that neural systems within the frontal cortex play a critical role in mediating the analgesia observed after very brief shocks. This finding is of particular interest since others have shown that electrical stimulation of cells in this region can elicit analgesia on the tail-flick test (e.g. Hardy, S. G. P., Brain Rsch, 339:281, 1985). The fact that lesions of the frontal cortex did not affect the analgesia observed after long shocks suggests that neural systems in this region may not play a role in modulating the direct activation of the analgesic systems.

272.11 SACCHARIN INTAKE DIFFERENTIALLY CORRELATES WITH THE ANALGESIC STATES ELICITED BY TWO FOOTSHOCK PARAMETERS. J.T. Cannon, K.H. Gunn*, B.J. Cannon*[1], B.L. Thomas* and J.P. Utz*. Depts. of Psychology, University of Scranton, Scranton, PA 18510 and [1]SUNY Binghamton, Binghamton, NY 13901

Increasing the severity of relatively brief stressors can change an opioid form of stress-induced analgesia (SIA) into one that is nonopioid (Terman et al., 1984). For example, 3 min of 3.0mA pulsed footshock produces SIA that is diminished by naloxone, whereas, SIA elicited by 3 min of 3.5mA is naloxone insensitive (Missar and Cannon, 1986).

Opioids appear to be involved in the hedonic qualities of several motivational states, among them the response to sweets (e.g., Lieblich et al., 1983). Previously, we observed a negative relationship (r = -.77) between consumption of a 3mM saccharin solution and the analgesic response to morphine (2.5mg/kg) that appeared to depend upon individual differences across subjects, altering both preference for saccharin and the analgesic effectiveness of morphine (Gogas et al., 1985).

Here we examined the relationships between saccharin intake and analgesia elicited by footshock parameters that previously have been found to generate either naloxone sensitive or naloxone insensitive forms of SIA. We expected to find a significant negative correlation between saccharin intake and, at least, the naloxone sensitive form of SIA.

Thirty adult, male, albino rats (350-450g) were studied during the dark phase of a 12-12 hr light-dark cycle. The animals were exposed to pulsed footshock (1 sec pulse every 5 sec) for 3 min at 3.0 or 3.5mA in a counterbalanced fashion on two consecutive days. Tail-flick latencies were determined at 1 min intervals for 5 min preceding footshock and for 10 min following footshock. Vocalizations emitted between shock pulses were recorded for all animals. On the third day after stress, saccharin intake was determined by providing the animals with a 3mM saccharin solution as their only fluid source for 24 hr.

ANOVAs on tail-flick latencies and vocalizations revealed significant effects of repeated testing and significant interactions between test day and footshock intensity. Consequently, correlations between saccharin intake and either tail-flick latencies or vocalizations (none of the latter were significant) were performed separately for each stress day.

As predicted, saccharin intake and post-3.0mA tail-flick latencies exhibited a significant negative correlation in previously unstressed animals (r = -.84). In contrast, a significantly different correlation existed between saccharin and post-3.5mA tail-flick (r = .19). Surprisingly, saccharin intake and post-3.0mA tail flick latencies showed a significant positive correlation on the second stress day (r = .57). Once again, the correlation between saccharin and post-3.5mA tail-flick latencies was significantly different (r = -.44).

These findings, once again, suggest a linkage between the hedonic value of a sweet substance and opioid analgesic mechanisms. In some situations, a relationship also may exist between saccharin intake and nonopioid SIA, however, this relationship appears to be independent from the preceding.

272.12 HISTAMINE H_2-RECEPTOR MEDIATED FOOTSHOCK-INDUCED ANALGESIA (FSIA) IS DEPENDENT ON NEITHER PITUITARY NOR ADRENAL ACTIVATION. K. R. GOGAS AND LINDSAY B. HOUGH. DEPARTMENT OF PHARMACOLOGY AND TOXICOLOGY, ALBANY MEDICAL COLLEGE, ALBANY, NY 12209.

Evidence suggests that the putative neurotransmitter, histamine, is involved in the mediation of non-opiate FSIA. We previously showed that H_2-receptor antagonists, such as cimetidine and ranitidine, but not the opiate antagonist, naloxone, significantly inhibit the analgesia elicited by exposure to 3 min of 3.5 mA FS (e.g., Gogas et al, Brain Res., 370:370, 1986). More recently, we found that the brain-penetrating H_2-receptor antagonist, zolantidine also significantly antagonizes this FSIA (Gogas and Hough, submitted). In order to determine whether stimulation of the pituitary-adrenal cortical axis is necessary for activation of this pain inhibitory system, we have determined the effect of adrenalectomy and hypophysectomy on H_2-receptor mediated FSIA.

Hypophysectomy and adrenalectomy were performed by the breeder (Taconic Farms) on male Sprague-Dawley rats (150-175 g). Sham operated animals served as controls. All animals were housed 2 to a cage at 27.5 °C with free access to food and water. Dextrose (5%) and NaCl (1%) served as water for hypophysectomized and adrenalectomized animals, respectively. Pain sensitivity was assessed using a modified version of the D'Amour tail-flick test, with a 7 sec upper limit of exposure. Three hrs into their dark cycle, animals received blinded injections of either naloxone HCL (10 mg/kg, i.p.), zolantidine dimaleate (5 mg/kg, s.c.) or saline vehicle. The intervals between injection and the first post-stress test were 10 and 30 min for naloxone and zolantidine, respectively. Following injection, animals were tested for baseline pain sensitivity, exposed to 3 min of 3.5mA FS, and tested for 15 min post-stress as previously described (Gogas et al, Brain Res., 370:370, 1986). Difference scores (obtained by subtracting each animal's mean baseline from its post-stress latencies) were analyzed by 3-way repeated measures ANOVA.

Neither adrenalectomy nor hypophysectomy had any effect on baseline or FSIA when compared to sham controls. Zolantidine significantly attenuated the FSIA in both the surgery and sham treated groups ($p < .0001$), indicating that the pharmacological nature of the response was unaffected by the surgical treatments. Likewise, naloxone had no effect on FSIA in any of the groups tested, showing that the naloxone-insensitivity of the FSIA was maintained following surgery. The present results show that neither hypophyseal nor adrenal mechanisms are necessary for the expression of the H_2-receptor mediated FSIA, and imply that the response is mediated by neural and not hormonal pathways. (Supported by DA-03816 and a grant from Sterling Winthrop Research Institute).

272.13 RESPONSES OF RVM NEURONS TO NOXIOUS STIMULI ARE BLOCKED BY FOOT-SHOCK STRESS. M.W. Friederich and J.M. Walker, Department of Psychology, Brown University, Providence, RI 02912.

It is now well established that several distinct endogenous pain inhibitory systems exist within the brain and spinal cord. These systems can be activated by noxious and physically or psychologically stressful stimuli. Much evidence suggests that brainstem structures in the rostral ventral medulla (RVM), especially the serotonin containing nucleus raphe magnus (NRM), are part of the descending pain control system that mediates environmentally induced analgesias. Most of the evidence for the involvement of general anatomical areas in stress analgesia has come from lesion studies. The effects of these stressors on neurons that respond to noxious input are unknown.

Previous work has demonstrated that some types of stress analgesia can be induced in anesthetized rats. We have used anesthetized rats to study the functional role of RVM neurons in stress analgesia through extracellular unit recordings. The change in rate of electrical discharge of neurons in the RVM, particularly in the NRM, was recorded in response to noxious mechanical pressure (2.8 kg/cm^2) to the tail before, and after, exposure to a stressor (5 or 7 mA of electrical current to the hindlimb). Recording sites were histologically verified to be within the RVM.

Our findings indicate that, for the majority of cells, exposure to the stressor for two minutes temporarily blocks the neuron's responses to the noxious stimulus. More specifically, neurons that evidence a decreased rate of discharge in response to noxious mechanical pressure (off-cells) tend to be disinhibited after two minutes of stress. Neurons that are excited by noxious mechanical pressure (on-cells) tend to be inhibited following exposure to the stressor. In some cells, this effect can be replicated by administration of morphine (i.v., 4mg/kg). Naloxone administration (i.v., 1 mg/kg or less) reverses this morphine effect. In other cells, in which stress is effective in blocking the response to pain, morphine (i.v., 4 mg/kg) remains without effect. These latter cells appear to be part of a non-opioid analgesia system. Whether naloxone or naltrexone can block the effect of stress on these neurons is currently under investigation to clearly determine the opioid or non-opioid involvement in this system.

272.14 DIFFERENTIAL EFFECTS OF INTRATHECAL ADMINISTRATION OF PHENTOLAMINE AND METHYSERGIDE ON ANALGESIA INDUCED BY CONTINUOUS VERSUS INTERMITTENT COLD WATER SWIM IN THE RAT. J.Rochford* and J.L.Henry Dept. of Psychiatry, McGill Univ., Montreal, Quebec, H3A 1A1

Continuous cold water swim elicits analgesia that is partly mediated by noradrenaline, but is independent of both serotonin and endogenous opioid peptides. In contrast, intermittent cold water swim elicits analgesia that is partly mediated by an opioid mechanism. Because the contribution of the monoamines in intermittent cold water swim analgesia is not known, the present study was conducted to determine whether the analgesia elicited by intermittent cold water swim is dependent upon noradrenaline and/or serotonin. Male Sprague-Dawley rats (225-250 g) were implanted under anaesthesia with chronic intrathecal catheters (Intramedic PE-10 tubing) via the atlanto-occipital junction so that the inner tip lay at the fifth lumbar vertebral level. Two weeks after surgery the rats were randomly divided into 6 groups (N=8 per group). Following determination of baseline pain sensitivity using the tail flick test (3 trials at 5 min intervals), two groups received intrathecal administration of artificial cerebrospinal fluid (CSF; 20 µL), two received phentolamine mesylate (30 µg in 10 µL CSF followed by 10 µL CSF to flush the catheter) and two received methysergide bimaleate (30 µg). Fifteen minutes later, one group within each drug condition was subjected to continuous cold water swim (3.5 min in 4° C water). The other group received intermittent cold water swim (10 s in, 10 s out for 6 min). Tail flick latency was determined 30 and 60 min after the swim. In CSF-treated animals, continuous cold water swim elevated tail flick latencies to 29.76% (SEM = 7.43) of the maximum possible effect (MPE). Intrathecal phentolamine produced a nearly complete blockade of continuous cold water swim analgesia (MPE = 5.53% ± 3.33, $p < .05$), but methysergide was without effect (25.37% ± 3.15, $p > .05$). In contrast to continuous cold water swim analgesia, intermittent cold water swim analgesia was more pronounced (MPE in CSF-treated animals = 67.06% ± 8.84), and was significantly attenuated by both phentolamine (34.36% ± 7.91) and methysergide (20.72% ± 4.31; both ps < .05). The difference between the phentolamine and methysergide groups was not significant ($p > .05$). These data suggest that noradrenaline is involved in both continuous cold water swim and intermittent cold water swim analgesia, whereas serotonin is involved only in the analgesia elicited by intermittent cold water swim.

272.15 ENHANCEMENT OF SYMPATHETICALLY EVOKED ACTIVITY IN SENSITIZED WDR NEURONS IS DEPENDENT ON CONDITIONING STIMULUS MODALITY. W.J. Roberts, M.E. Foglesong* & R.C. Kramis*. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, Oregon 97209, USA.

Earlier, we hypothesized that a persistent sensitization of spinal wide-dynamic-range (WDR) neurons subsequent to noxious input is the essential dysfunction in sympathetically maintained pains such as causalgia and reflex sympathetic dystrophy (Pain 24:297-311, 1986). The present study was designed to test this hypothesis by determining whether noxious stimulation results in a persistent enhancement of the responsiveness of WDR neurons to sympathetically evoked afferent activity in anesthetized cats.

We recorded from single WDR neurons with cutaneous receptive fields on the hindlimb. The responsiveness of these neurons to afferent input was assessed with two types of test stimuli: non-noxious pressure applied to the receptive field; and electrical stimulation of the sympathetic trunk. Two types of noxious conditioning stimuli were used to sensitize WDR neurons: pinching small folds of skin with serrated forceps; or heating 1 sq cm of skin to 50°C for 10 sec.

In preliminary experiments, we have found that noxious pinch increased the responsiveness of WDR neurons to non-noxious pressure, but it did not increase their responsiveness to sympathetically evoked afferent activity. In contrast, noxious heat enhanced their responsiveness to sympathetically evoked afferent activity but not to non-noxious pressure. The increases in responsiveness persisted well beyond the period of discharge of nociceptors activated by the conditioning stimuli.

The finding that noxious pinch has different effects than noxious heat on the sensitization of WDR neurons to afferent input suggests that multiple mechanisms are involved.

272.16 MIDBRAIN SUPPRESSION OF SIMULTANEOUSLY RECORDED LUMBAR DORSAL HORN NEURON (DHN) AND BICEPS FEMORIS MOTOR UNIT (MU) RESPONSES DURING THE HINDLIMB FLEXION WITHDRAWAL REFLEX (WR). E. Carstens, Dept. of Animal Physiology, Univ. of California, Davis, CA 95616.

Stimulation in midbrain periaqueductal gray (PAG) or lateral reticular formation (LRF) suppresses DHN responses to noxious hindfoot heating in deeply anesthetized rats; this suppression is phasic (restricted to the midbrain stimulation period). In contrast, initial PAG or LRF stimulation frequently suppresses WR and MU responses for prolonged periods in lightly anesthetized rats. This study addressed whether there are different time courses for PAG or LRF suppression of DHN and MU/WR responses to noxious heat recorded simultaneously in the same rat.

In pentobarbital-anesthetized rats, the lumbar spinal cord was exposed to record single DHNs with a tungsten microelectrode, the left biceps femoris was exposed to record single muscle fiber (ie., MU) action potentials using a single-fiber EMG electrode, and the left hindfoot was attached to a force transducer to record isometric withdrawal force. WR force and DHN and MU responses to noxious heat (50-54 deg. C, 10 s duration, 2 min intervals) on the volar hindfoot surface were recorded simultaneously.

To date, 43 paired DHN and MU recordings were made in 15 rats. Mean latencies to onset and peak of response were shorter for DHNs (1.9 and 4.6 s, respectively) than MUs (3.5 and 5.9 s). Mean response magnitude was higher for DHNs than MUs (301 vs. 247 impulses/10 s). DHN were larger than corresponding MU responses in 19 cases, the reverse was seen in 12, and 12 were about equal. MU spikes never followed those of the DHN in a 1:1 correspondence.

In 7/14 rats, WR and MU responses were markedly suppressed for prolonged periods (5 to >40 min) following stereotaxic placement of PAG and LRF stimulating electrodes; DHN responses were stable before and after electrode placement in each case. Neither MU nor DHN responses were affected by electrode placement in the other 7 rats. Initial PAG or LRF stimulation (3 100 ms, 100 Hz trains/s, 25-400 uA) induced a prolonged suppression of WR and MU but only phasic suppression of DHN responses in 4 rats. Only phasic suppression of WRs, MUs and DHNs was seen in 8 rats. Phasic suppression of DHNs and MUs was recruited at lower current intensities by LRF compared to PAG stimulation. Equal PAG or LRF stimulation more effectively suppressed responses of MNs than DHNs in 11/15 and 4/10 cases, respectively. MN and DHN responses could also be dissociated by (1) habituation (12/42 cases) of MU but not DHN responses to the initial 2-4 heat stimuli, and (b) abolition of MU but not DHN responses following supplemental pentobarbital.

These results indicate that MUs contributing to the WR are more susceptible to prolonged suppressive effects than are DHNs (some of which might serve as interneurons in the WR pathway).

Supported by NIH grant NS 20037.

273.1 PEPTIDE-CONTAINING NEURONS IN THE ENTERIC NERVOUS SYSTEM OF PRIMATES. K. Anderson* and C. Sternini (SPON: D. Aures-Fisher). Dept. of Medicine and Center for Ulcer Research and Education, UCLA School of Medicine, Los Angeles, CA 90024.

Numerous biologically active peptides have been reported to innervate the enteric nervous system (ENS) of mammals. The aim of this study was to examine the distribution of peptide containing neurons in the ENS of the Macaca monkey, using rabbit antisera directed to [Tyr] rat calcitonin gene-related peptide 23-37 (CGRP), neuropeptide Y (NPY; provided by Dr. McDonald), vasoactive intestinal peptide (VIP; provided by Dr. Walsh), galanin (GAL; from Peninsula) and a rat monoclonal antibody to substance P (SP; from Pel-Freeze). Specimens of the gut were fixed with a paraformaldehyde-picric acid solution and processed as whole mount preparations or cryostat sections for immunohistochemistry using either immunofluorescence or avidin-biotin methods. Peptide-containing nerve fibers were present in ENS along the entire length of the gastrointestinal tract with a differential distribution in the different layers. The muscle coat, particularly the circular layer, harbored numerous SP, VIP and GAL immunoreactive fibers, a smaller number of CGRP positive processes and only a few NPY fibers. CGRP axons in the smooth muscle were more numerous in the pyloric region than in other areas of the gut. A great number of peptide (particularly CGRP, SP and VIP) immunoreactive fibers was associated with the myenteric plexus. In the submucosa, peptide-containing processes were mainly found in the ganglia and associated with the vasculature. Blood vessels received a rich supply of CGRP, NPY and SP fibers, whereas the number of perivascular VIP and GAL processes was much lower. In the mucosa, SP innervation was the most abundant, especially in the intestine, where SP fibers surrounded the glands, often running close to the lumen. VIP mucosal fibers were also numerous, with a similar distribution as those immunoreactive for SP. CGRP and GAL processes were usually restricted to the base of the mucosa, being more numerous in the intestine than in the stomach. In some cryostat preparations, CGRP fibers were also observed running parallel to the duodenal villi. Only a few, thin NPY fibers were visualized in the mucosal layer. Ganglion cells positive for VIP, GAL and SP were observed in the myenteric plexus of the stomach and intestine as well as in the submucosal plexus of the intestine. CGRP ganglion cells were restricted to the intestinal plexuses. No positive NPY somata were observed. Co-localization studies have demonstrated that the majority of CGRP fibers in the enteric ganglia also contained SP immunoreactivity.

273.2 N-ACETYLASPARTYLGLUTAMATE IMMUNOREACTIVITY IN NEURONS OF THE MONKEY'S VISUAL PATHWAY. S.B. Tieman, C.R. Hamilton, B.A. Vermeire, M.A.A. Namboodiri and J.H. Neale. Dept. of Biol. Sci., State Univ. of New York, Albany, NY 12222, Div. of Biol., Calif. Inst. of Technol., Pasadena, CA 91125, and Dept. of Biol., Georgetown Univ., Washington, D.C. 20057.

The neurotransmitters used by the major projection neurons of the mammalian visual system remain unknown, although there is some evidence implicating receptors for the acidic amino acids, aspartate and glutamate. N-acetylaspartylglutamate (NAAG) is an endogenous brain peptide thought to act at an acidic amino acid receptor. We have previously identified NAAG-like immunoreactivity in retinal ganglion cells and lateral geniculate neurons in both rat and cat, and in visual cortical neurons in the cat. We now report the immunohistochemical localization of NAAG in the visual pathway of the monkey. Frozen sections through the retina, lateral geniculate nucleus (LGN), superior colliculus and visual cortex of one adult female Macaca mulatta (approx. 10 yrs old), who had undergone midsagittal section of the optic chiasm at the age of 4 yrs, were reacted for the presence of NAAG. In temporal, but not nasal retina (where the ganglion cells had degenerated because they were axotomized by the optic chiasm section), we observed staining of retinal ganglion cells, their dendrites in the inner nuclear layer, and their axons in the optic nerve fiber layer. In both temporal and nasal retina we also observed stained amacrine cells, including some displaced amacrines. We also saw staining in the target regions of the retinal ganglion cells, the superior colliculus and the LGN, where both neuropil and cell bodies were stained. In LGN, staining was confined to layers 2, 3, and 5, that is, to the layers innervated by the intact ipsilateral pathway. Immunoreactivity was also seen in the pyramidal cells of layer V, upper layer II, and lower layer III of occipital cortex (including areas 17 and 18). This staining was not observed when normal rabbit serum was substituted for NAAG antiserum, or when the antiserum was blocked by preabsorption with NAAG coupled to bovine serum albumin (BSA). In retina and cortex, NAAG-BSA was more effective than conjugates of BSA with either N-acetylaspartate or aspartylglutamate, whereas in LGN, AG-BSA blocked staining of the cells as effectively as did NAAG-BSA. Thus, in retina and cortex, it is likely that the antisera are recognizing NAAG, whereas, in LGN, they may be recognizing some other, related peptide. These results are very similar to those in cat, and demonstrate the presence of NAAG and/or related compounds in neurons of the monkey's visual pathway. A determination of the role that these compounds play in mammalian visual neurotransmission must await further study. Supported by NSF grant #BNS 8217479 to SBT, NIMH grant #MH 34770 to CRH, and NIDA grant #DA 02297 to JHN.

273.3 SUBSTANCE P-LIKE IMMUNOREACTIVITY IN SUPERFICIAL LAYERS OF CHICK OPTIC TECTUM: DEPENDENCE UPON RETINAL INPUT. W.J. Crossland, G.R. Ten Eyck,* D.J. Goebel* and R.H. Granda* (SPON: R. Pourcho) Dept. of Anatomy and Cell Biology, Wayne State Univ. Schl. Med., Detroit, MI 48201.

Substance P-like immunoreactivity (SPLI) has been reported in retinal ganglion cells and retinal terminals in mammals and amphibians as well as in several layers of the avian optic tectum. We undertook this study to determine if substance P might be present in the retinofugal projection of the chick by observing the distribution of SPLI in normal chicks and those which had undergone unilateral eye removal at hatching.

Newly hatched chicks were unilaterally enucleated under deep halothane anesthesia. After eight weeks survival two enucleated and two normal chicks were perfused transcardially with phosphate-buffered paraformaldehyde. Two other enucleated chicks were perfused with 0.1% glutaraldehyde added to the fix. Frozen sections of the brains and retinae were reacted with a monoclonal antibody to Substance P (Pel Freez) then reacted with PAP (Polysciences). Sections fixed with glutaraldehyde were embedded in epon for electron microscopy.

The brain sections contained many regions of intense SPLI in fibers although relatively little of it was associated with the visual centers, optic nerve, chiasm or optic tract. However, a prominent band of SPLI was clearly demonstrated in sublaminae a-c of the stratum griseum et fibrosum superficiale of the optic tectum as well as a dense network of SPLI fibers in the deeper tectal layers. The superficial band was most dense dorsomedially and least dense lateroventrally. In retinal sections some SPLI cell bodies were found in the retinal ganglion cell layer. Whether these are ganglion cells or displaced amacrine cells (many cells in the inner plexiform layer also reacted) is yet to be determined. Electron microscopic observation of the superficial SPLI-containing layer in the tectum revealed densely labeled profiles of synaptic terminals contacting small dendrites or spines.

After contralateral eye removal the SPLI in the superficial tectal laminae completely disappeared although staining in the deeper layers was not affected.

The dramatic alteration of SPLI in the superfical tectum suggests that the SPLI is either contained in retinal terminals or that the production of the peptide is closely regulated by the retinal afferents.

This study was supported in part by a grant from the Michigan Eye Bank (W.J.C.) and by a Core Equipment Grant for Vision Research (EY-04068). R.H.G. was supported by a Fellowship from the Neuroscience Program at Wayne State University.

273.4 A CRF SYSTEM IN THE RAT RETINA: DISTRIBUTION AND EFFECT ON RETINAL NEURONS. Hermes H. Yeh and John A. Olschowka, Dept. Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

The demonstration of the presence of peptides in the mammalian retina has presented a unique challenge to research in CNS peptidergic systems. Whereas their localization in discrete retinal cell types favors a neurotransmitter role in the retina, their neuronal effects remain largely unexplored. Here, we present an immunohistochemical demonstration of a system of corticotropin releasing factor(CRF)-containing cells in the rat retina and, based on their anatomical disposition, report results of an ongoing electrophysiological study to elucidate the effect of CRF on cholinergic retinal neurons.

Retinal wholemounts, prepared from adult female Long Evans rats anesthesized with chlorpent and perfused intra-aortically with 4% paraformaldehyde, were incubated in rabbit-anti-CRF in the presence of Triton X-100 and visualized using the unlabeled peroxidase-anti-peroxidase procedure. One wholemount from each animal was subsequently embedded in epon to obtain 2- to 10-um transverse sections. Serial sections of the entire retina were obtained from 2 epon-embedded specimen.

Wholemount preparations revealed that the CRF-labeled cells could be found in two separate layers. The great majority of them were situated in the ganglion cell layer. These cells were predominantly displaced amacrine cells based on their soma diameter (8-12 um), their overall morphology, and on one preliminary double labeling experiment which indicated that the distribution pattern of ganglion cells, retrogradely labeled with fluorogold, did not overlap with that of the CRF-immunopositive cells in the ganglion cell layer. A small portion of the CRF-labeled cells were amacrine cells found in the vitreal aspect of the inner nuclear layer. Seen to better advantage in transverse sections, processes of CRF-labeled cells from both layers elaborated densely within sublamina 4 and 5 of the inner plexiform layer. Some amacrine cells in the inner nuclear layer also emitted a thin process which ramified within sublamina 1 and, on rare occasions, processes emanating from some cells in the ganglion cell layer were found to ascend across the inner plexiform layer toward sublamina 1.

We are using a cell culture system to assess electrophysiologically the effects of CRF on cholinergic retinal neurons. This experimental system permits continuous monitoring of neuronal release of acetylcholine. Our results indicate that CRF (0.1-1.0 um), dissolved in recording medium and ejected by pressure near cholinergic retinal neurons, had a potent effect on evoking acetylcholine release. Typically, when compared to that of pressure-ejected glutamate, the excitatory response to CRF had a longer onset and response duration. Most of the cholinergic neurons examined in this culture system were responsive to micropressure-ejected CRF.

273.5 ULTRASTRUCTURE OF SOMATOSTATIN IMMUNOREACTIVE CELLS IN THE DEVELOPING VISUAL CORTEX OF THE RAT. B.W. Bakkum*, R.S. Cohen and L.A. Benevento. Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60612.

Somatostatin (SRIF) has been implicated as a trophic factor. Light microscopic studies have shown that somatostatin-immunoreactive cells (SRIF-cells) are present in the visual cortex of the rat as early as embryonic day 20 (Laemle et al., 1982). The number of postnatal SRIF-cells progressively increases in layers V and VI until postnatal day 7 (PND=7) at which time SRIF-cells in the superficial layers begin to appear. Up to PND=13, SRIF-cells in layer V and VI remain constant in number or may even decline. In order to add to the knowledge of the cytological development of the cortex, we monitored the development of this dynamic population of SRIF-cells in areas 17, 18 and 18a of the early postnatal rat. Rats (PND=4, 7, 10 and 13) were anesthetized and perfused with 5% acrolein, 4% paraformaldehyde and 0.5% glutaraldehyde in 0.1M phosphate buffer at pH 7.4 and the brains were removed immediately and placed in a similar solution, omitting the acrolein, overnight at 4°C. Vibratome sections (40 µm) were processed with Immunonuclear antibody #20H2T and the Avidin/Biotin immunoperoxidase procedure. Tissue pieces from the visual cortex containing SRIF-cells were then postfixed in osmium tetroxide and embedded in Epon according to standard procedures. At PND=4 and 7, when SRIF-cells are increasingly present in layers V and VI, SRIF-immunoreactivity was ubiquitously distributed throughout the cytoplasm. It surrounded, but was not contained within the cisternae of rough endoplasmic reticulum. At this stage, developing axosomatic synaptic profiles appeared immature and it was not possible to classify them into specific synaptic types. The pre- and postsynaptic densities appeared symmetrical with little development of the postsynaptic density. Synaptic vesicles were sometimes present in the presynaptic endings. At PND=10 and 13, (during the time when light microscopy shows SRIF-cell number leveling off or decreasing in layers V and VI and appearing in layer II/III), the synaptic profiles on SRIF-cells in layers V and VI could be differentiated into symmetric and asymmetric types, with the former being the predominant type. The distribution of the reaction product was similar to that seen in the younger cells. From this qualitative data, no correlation could be made as to the relationship of the appearance of SRIF and the initiation of synaptogenesis. Therefore, SRIF-cells in layers V and VI of the visual cortex during the dynamic developmental phase (4-13 days) showed (1) typical morphologic patterns of synaptic development and (2) similar patterns of distribution of SRIF reaction product to those seen in the adult.

273.6 LHRH NEURONAL SYSTEM IN THE ACCESSORY OLFACTORY BULB OF THE PRAIRIE VOLE, MICROTUS OCHROGASTER. R.L. Reger*, A.A. Gerall, C.J. Wysocki, C.S. Carter, Dept. of Psychol., Tulane U., New Orleans, LA 70118, Monell Chem. Senses Ctr., Philadelphia, PA 19104, and Dept. of Zool., U. of Maryland, College Park, MD 20742.

Olfactory stimulation derived from male urine is necessary for estrous behavior and ovulation in the prairie vole (Carter, et al., Biol. Reprod. 23:1038, 1980). These and other reproductive processes are mediated by the vomeronasal-accessory olfactory system (Wysocki, Neurosci & Biobeh. Rev. 3:301, 1979). The present research studied the contribution of the vomeronasal organ (VNO) to the LHRH neurons in the accessory olfactory bulb (AOB) and whether male urine affects them.

Ten virgin females whose VNO had been unilaterally extirpated were exposed to male odor through a wire mesh cage divider for 36 hr. Male and dividers were then removed and 200 µl of either male urine or water was applied to the females' noses. One hr later they were perfused with 1%-4% paraformaldehyde. Their brains were sectioned, and LHRH was visualized by the Sternberger PAP method (a-LHRH H16; S.Vigh, Hungary). Complete VNO elimination was verified by H&E stain. Fiber densities in the AOB were determined using computer-aided image analysis.

Extirpation of the VNO results in degeneration of the glomerular layer of the ipsilateral AOB. LHRH-containing immunoreactive fibers seen looping among the glomeruli and forming contacts within or between them on the intact side are absent on the extirpated side. Male odor present for 36 hr increases LHRH immnoreactive fiber density in the deep layers of the AOB more than 1 hr exposure used in our previous studies. The lesioned side of females receiving male odor for only 36 hr had more LHRH fibers, especially in the deep layers of the AOB, than the intact side. The additional 1 hr of direct urine application non-significantly increased LHRH immunoreactive density on the intact side. Several LHRH-immunoreactive cell bodies were seen in the AOB; of all animals regardless of treatment or side.

Extirpating the VNO diminishes or redirects LHRH from the glomerular region and increases the density of LHRH fibers coursing along the AOB dorsal surface. The increase in LHRH fibers density which must be due to sources other than the VNO might include the Nervus Terminalis or centrifugal fibers. Olfactory cues apparently modify these as well as the vomeronasal system.

273.7 IMMUNOCYTOCHEMISTRY OF NEUROPEPTIDES IN THE CEPHALIC NEUROENDOCRINE SYSTEM OF THE LUBBER GRASSHOPPER, ROMALEA MICROPTERA. C.A. Zahnow*, K.R. Rao, C.J. Mohrherr* and J.P. Riehm*. Dept. of Biology, Univ. of West Florida, Pensacola, FL 32514

Pigment-dispersing hormones (PDHs) are a family of arthropod neuropeptides. Recently a pigment-dispersing factor (PDF), NSEIINSLLGLPKLLNDA-amide, which shows 78% sequence homology with ß-PDH from the crab Uca, has been isolated from lyophilized heads of the lubber grasshopper Romalea microptera (Rao et al., J. Biol. Chem., 262: 2672-2675, 1987).

In the present study we examined the localization of PDH/PDF in the cephalic neuroendocrine system of Romalea, utilizing an antiserum raised against ß-PDH (Dircksen et al., Cell Tissue Res., in press, 1987). Additional immunocytochemical work was carried out utilizing antisera for FMRF-amide (O'Donohue et al., Peptides, 5: 563-568, 1984) and adipokinetic hormone (N-terminal specific antiserum 433; Schooneveld et al., Cell Tissue Res., 243: 9-14, 1986). Immunocytochemistry was done utilizing the PAP method on sections of tissues (supraesophageal ganglia, optic lobes, and corpora cardiaca) embedded in Paraplast.

PDH-positive perikarya were found only in the optic lobes, whereas cell bodies reacting to FMRF-amide antiserum were located in the optic lobes, various parts of the brain, and the glandular lobes of the corpora cardiaca. Immunostaining of successive sections revealed co-localization of FMRF-amide and PDH reactivity in two clusters of somata, located dorsally and ventrally, between the medulla and lamina of the optic lobe. The PDH positive cells situated between the medulla and lobula were distinct from the FMRF-amide reactive cells in this region; the latter were more abundant and more widely distributed. An extensive network of immunoreactive fibers was found in the optic lobes and supraesophageal ganglion. The PDH and FMRF-amide reactivities in these fibers and plexuses were co-localized mainly in the lamina and, to a lesser extent, in the medulla. Marked differences were noted between the PDH-positive and FMRF-amide immunoreactive elements in the supraesophageal ganglion. The corpora cardiaca showed no reactivity to PDH antiserum, although strong staining was evident for AKH and FMRF-amide. The PDH immunoreactivity noted here seems to be attributable to the octadecapeptide PDF of Romalea, as preincubation of antiserum with the latter peptide abolished the staining. The function of PDF in insects and the chemistry of AKH-like and FMRF-amide-like substances in Romalea remain unknown.

(Supported by NSF Grant DCB-8314737).

273.8 DETECTION OF VASOPRESSIN MESSENGER RNA IN CELLS WITHIN THE BED NUCLEUS OF THE STRIA TERMINALIS BY IN SITU HYBRIDIZATION HISTOCHEMISTRY. D.M. Dorsa, M.A. Miller*, and R.T. Zoeller, GRECC, VA Medical Center, Seattle, WA 98108 and Laboratory of Cell Biology, NIMH, Bethesda MD 20892

Vasopressin (VP)-immunoreactive neurons have been reported to be present in several extrahypothalamic sites including the medial amygdala and the bed nucleus of the stria terminalis (BNST). Cells in the BNST have been suggested to be the primary source of vasopressin fibers in the lateral septum, habenula, and periventricular grey. Using in situ hybridization techniques, we have confirmed the presence of VP synthesizing cells within the BNST by identifying individual neurons which contain VP mRNA.

Adult male Sprague-Dawley rats were decapitated, their brains frozen, and 12µm sections obtained. In situ hybridization was performed on post-fixed sections using a synthetic 48-base oligonucleotide probe complementary to the VP mRNA encoding the last 16 amino acids of the glycopeptide region. ^{35}S-dATP and terminal deoxynucleotidyl transferase were used to 3'-end label the probe (SA=6000 Ci/mmol). Hybridization was carried out for 20h at 37°C. Tissues were washed in 2X SSC/50% formamide at 40°C. The sections were dehydrated, dipped in NTB3 nuclear emulsion, and exposed for 2 to 3 weeks. After developing and counterstaining, the sections were examined microscopically for evidence of hybridization.

Scattered cells within the BNST were found to be labeled by the DNA probe. Between 10 and 20 cells were visible per section. The cells, located almost exclusively in the medial aspects of the nucleus, were parvocellular in appearance (mean diameter was approximately 10µm). These cells differed clearly in size from magnocellular VP neurons which were labeled in the paraventricular n. Quantitative in situ hybridization methodologies will prove useful in studying the factors which modulate the activity of these extrahypothalamic vasopressin producing neurons.

Suppported by NIH NS 20311 and the Veterans Administration.

273.9 ONTOGENIC STUDY OF THE GENE EXPRESION OF PREPROENKEPHALIN IN THE RAT FOREBRAIN. Y. Morita, H. Kiyama*, K. Noguchi*, A. Wang*, and M. Tohyama*, Dept. of Anatomy and Neuroanatomy, Osaka Univ. Med. Sch., Osaka 530, Japan

Enkephalins (methionine- and leucine- enkephalins: met-ENK and leu-ENK) are endogenous pentapeptides which bind to the same sites as opiates. Biochemical and immunocytochemical studies have demonstrated the extensive but differential distribution of these endogenous opiate-ligands in the central nervous system as well as other organ systems, indicating that these opioid peptides play various roles in different tissues. Recent recombinant DNA technology have revealed that the proenkephalin contains 6 copies of met-ENKs and one copy of leu-ENK. In the present study, the cellular localization of the precursor mRNA of proenkephalin, preproenkephalin (PPE), was first examined in the rat forebrain by means of in situ hybridization histochemistry, and secondly our attempt was directed to the ontogenic changes of the PPE gene expression in the brain tissues. The complementary DNA (cDNA) of the PPE mRNA (generous gift from Dr. K. Yoshikawa et al., JCB., 259:14301, 1984) were labeled with ^{32}P or ^{35}S according to nick translation protocol.

Neurons containing the PPE mRNAs were observed in various cerebral structures; piriform cortex, ventral tenia tecta, nuclus accumbens, pyramidal and polymorph layers of the olfactory tubercle, caudate-putamen nucleus, lateral septum, lateral and posterior bed nuclei of the stria terminalis, diagonal band of Broca, medial and lateral preoptic areas, amygdala complex (central nucleus), anterior hypothalamic nucleus, perifornical area, lateral hypothalamus, premamillary nucleus, medial mamillary nucleus, ventral lateral geniculate nucleus. Among these structures, part(s) of the amygdala complex, central nucleus, exhibit(s) the high level of hybridization signals throughout ontogenic stages. This may provide additional data to understand the function of enkephalins in the central nervous system. While, other cerebral structures containing PPE gene expressing neurons show the gradual increase of the hybridization signals during ontogeny.

273.10 CELLULAR LOCALIZATION OF RAT GAMMA-PREPROTACHYKININ A mRNA IN THE RAT DORSAL ROOT GANGLION AND TRIGEMINAL GANGLION BY IN SITU HYBRIDIZATION HISTOCHEMISTRY. K. Noguchi*, H. Kiyama*, Y. Morita, A. Wang*, and M. Tohyama*. (SPON: E. Semba). Dept. of Anatomy and Neuroanatomy, Osaka Univ. Med. Sch., Osaka 530, Japan

Substance P (SP) is one of the most characterized neuropeptides belonging to the tachykinin family, and regarded as a transmitter candidate involved in the pain sensation in the central and peripheral nervous tissues. It has been demonstrated that substance P and related peptide, substance K (Neurokinin K), are coded on a single gene by sequence analysis. This tachykinin gene produces three types of precursor mRNAs, alpha-, beta-, and gamma-preprotachykinin A (PPTA). Alpha-PPTA mRNA codes for only SP, while although beta- and gamma-PPTA mRNAs have different sizes they yield both SP and SK as final products. The present study uses the complementary DNA (cDNA) of the rat gamma-PPTA mRNA (generous gift from Prof. S. Nakanishi; Kawaguchi et al., BBRC, 139:3, 1986), and demonstrates the cellular localization of PPTA mRNAs in the trigeminal and dorsal root ganglia by means of in situ hybridization histochemistry. The gamma-PPTA cDNAs (-600bp, containing the coding region of SP and SK) were labeled with ^{35}S according to nick translation protocol.

After the autoradiographic exposure from one to two weeks, silver grains were observed on and in the close vicinity of neurons in the trigeminal and dorsal root ganglia. In the two ganglia, labeled neurons are small to medium in size. The population of the gamma-PPTA gene expressing neurons in the trigeminal and dorsal root ganglia are about 6.0% and 11.0% respectively. The size of the gamma-PPTA gene expressing neurons appears to be comparable to the previous data drawn from immunocytochemical studies.

273.11 ONTOGENY OF SUBSTANCE P AND ELEDOISIN BINDING SITES IN RAT BRAIN: A COMPARATIVE AUTORADIOGRAPHIC STUDY. T.V.Dam, E.Escher* and R.Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, Verdun, Québec. H4H 1R3 and Departement de Pharmacologie, Faculté de Medecine, Université de Sherbrooke. Sherbrooke. Québec. J1H 5N4.

The existence of various classes of tachykinin receptors in peripheral tissues and brain has been proposed. We previously reported that the distribution of Substance P (SP)-NK-1 receptor binding sites undergoes major redistribution during postnatal ontogeny. (Quirion and Dam. J. Neurosci. 6:2187-2199, 1986). For example, high densities of [^{125}I]BH-SP binding sites are present in most brain stem nuclei at post-natal days 1 and 4 (P1 and P4) while it is not the case in adults. In the striatum, [^{125}I]BH-SP binding sites are distributed in "patches" early after birth but not in adults. We now report on the comparative ontogenic development of two putative tachykinin receptor classes namely NK-1 and NK-3 using [^{125}I]BH-SP and [^{125}I]BH-Eledoisin (ED) as respective ligands. The development of those two sites has been studied both pre- and post-natally in E3, E1, P1, P6, P14, P28 and P35 days old rats of either sexes. Brain sections were prepared and incubated with 100 pM [^{125}I]BH-SP or 50 pM [^{125}I]BH-ED as described before (Quirion and Dam, ibid). Our data indicate that the distribution of [^{125}I]BH-ED binding sites is discrete and different from that of [^{125}I]BH-SP. The distribution of [^{125}I]BH-ED binding sites also undergoes major modifications during brain development. High densities of sites are present in certain brain stem nuclei at E3 to P6 while it is not the case in older animals. Moreover, dense cortical [^{125}I]BH-ED labelling in layer IV and V does not become apparent until P14. Finally, [^{125}I]BH-ED binding sites are fairly homogeneously distributed in striatum thoughout brain development. These data clearly indicate the differential ontogeny of NK-1 and NK-3 receptora binding sites in rat brain.

(Supported by a research grant from the Scottish Rite Foundation for Schizophrenia).

273.12 SUBSTANCE P TERMINALS IN THE RAT CUNEATE NUCLEUS. C.Y. Wen, S. DeBiasi*, S.L. Van Eyck, P. Petrusz* and A. Rustioni. Dept. of Anatomy and Physiology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27514.

Substance P-positive fibers and terminals have been demonstrated in the cuneate nucleus of rats and cats by light microscopic immunocytochemistry (ICC); Double-labeling experiments have suggested that substance P (SP) may be present in non-primary (post-synaptic) afferents to the dorsal column nuclei (Conti and Rustioni, 1986).

In this work substance P-positive terminals in the cuneate nucleus of rats were investigated by electron microscopy (EM). Both pre- and post-embedding EM ICC were used for this purpose. Rats were perfused with 4% paraformaldehyde and 0.5% to 1% glutaraldehyde. The caudal brainstem was subsequently post-fixed overnight in 4% paraformaldehyde (for pre-embedding procedure) or for five hours in 1% paraformaldehyde (for post-embedding procedure). Forty micrometer-thick sections were cut with a Vibratome and post-fixed in osmium tetroxide. For pre-embedding procedure, sections were pre-treated with alcohol. Antibodies for substance P were prepared in our laboratory (post-embedding) or obtained from Immunonuclear (pre-embedding). For pre-embedding staining peroxidase ICC was used, while in the post-embedding material substance P was revealed by 20 nm colloidal gold particles coated with goat anti-rabbit IgG.

Substance P-positive terminals are mostly of small size, dome-shaped, and contain dense-core vesicles interspersed among round, clear vesicles. They form asymmetric synapses with dendrites of various sizes and are not involved in axo-axonic synapses. In the post-embedding material, gold particles are found predominantly over dense-core vesicles. Given their morphology, substance P-positive terminals are likely to be endings of non-primary afferents to the dorsal column nuclei (Rustioni and Ellis, 1978). This is supported by the sharp reduction in number of substance P-positive terminals in the cuneate nucleus after spinal cord transection but not after dorsal rhizotomy.

Experiments currently in progress aim to verify the origin of these terminals by a double-labeling technique employing the anterograde transport of horseradish peroxidase, revealed by TMB histochemistry and post-embedding ICC for substance P.

273.13 GALANIN-CONTAINING SOMATA IN THE PRIMATE NUCLEUS BASALIS/DIAGONAL BAND COMPLEX. L.C. Walker†, V.E. Koliatsos†, C.A. Kitt†, R.T. Richardson§ and D.L. Price†. †Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Neurophysiology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The nucleus basalis/diagonal band complex in primates is characterized by large, basophilic neurons that innervate amygdala, hippocampus, neocortex, and other regions in the central nervous system. Most neurons forming the major subdivisions of this basal forebrain complex are cholinergic [Mesulam et al., J. Comp. Neurol. 214:170-197, 1983]. Furthermore, recent studies in rats have shown that many neurons in the medial septum/diagonal band contain both the neuropeptide, galanin, and choline acetyltransferase (ChAT), whereas cholinergic cells of the nucleus basalis magnocellularis lack galanin [Melander et al., Brain Res. 360:130-138, 1985]. In the owl monkey, a nocturnal New World primate, galanin and acetylcholinesterase coexist in neurons in all parts of the basal forebrain complex [Melander and Staines, Neurosci. Lett. 68:17-22, 1986]. However, the extent to which galanin and specific cholinergic markers, such as ChAT, coexist within neurons of the primate basal forebrain complex is not yet known. To address this issue, colchicine was injected into the lateral ventricle of an anesthetized rhesus monkey (Macaca mulatta) to enable visualization of galanin-containing somata. After 24 hours, the animal was perfused with 4% paraformaldehyde for immunocytochemical analysis. In 40 µm-thick frozen sections, galanin-immunoreactive neurons (mean size approximately 14 µm x 27 µm) were present throughout the rostro-caudal extent of the basal forebrain complex. In adjacent sections, ChAT-immunoreactive neurons of a similar size were present in the same locations as galanin-immunoreactive cells. Many neurons in the basal forebrain complex contained both markers, as demonstrated by double immunostaining with diaminobenzidine and benzidine dihydrochloride. Intense galanin immunoreactivity of cells in the nucleus of the diagonal band could be used to segregate these neurons from large cells of the nucleus accumbens and olfactory tubercle, which stained for ChAT but showed little or no galanin immunoreactivity in this preparation. These results show that, unlike the case in rodents, galanin coexists with ChAT in neurons throughout the nucleus basalis/diagonal band complex of the rhesus monkey. Basal forebrain neurons containing other peptides, such as somatostatin, neuropeptide Y, and leu-enkephalin, were generally small and sparse compared to ChAT- and galanin-containing neurons. The extensive coexistence of galanin and ChAT in neurons of the nucleus basalis/diagonal band complex in primates suggests that galanin could act as a cotransmitter with acetylcholine in areas innervated by these cells.

273.14 DISTRIBUTIONS AND RELATIONSHIPS TO EACH OTHER OF CLUSTERS OF NEUROTENSIN- AND SUBSTANCE P-IMMUNOREACTIVE NEURONS IN THE CAUDATE-PUTAMEN AND VENTRAL STRIATUM OF THE SPRAGUE-DAWLEY RAT IN THE EARLY POSTNATAL PERIOD. K.W. Eggerman*, R.F. Sprung*, D.E. Wesche*, E. Payne* and D.S. Zahm (SPON: R. Walsh). Department of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Neurotensin (NT)-immunoreactive (IR) neurons can be demonstrated in vibratome sections through the striatum in adult S-D rats in the absence of pretreatments, but they are present in greater numbers following exposure of the sections to H_2O_2, and are most numerous 48 hours following ICV injection of colchicine in clusters in n. accumbens and ventromedial caudate-putamen (c-p) (Zahm, 1987; Zahm and Heimer, 1987). They are not observed, however, in the dorsolateral quadrant of the c-p, where the striosomal (Graybiel and Ragsdale, 1983) organization of the striatum is distinct. Evidence from cat suggests that dense NT-IR terminal stain (Goedert et al., 1984) and, perhaps, neuron clusters (Sugimoto and Mizuno, 1987) correspond to striosomes in that species. We sought to determine, using a reported striosomal marker (Gerfen, 1985), substance P (SP)-IR, if striatal NT-IR neurons might be more apparent in striosomes in the immature rat. Anesthetized pups collected on postnatal days 1, 3, 5, 12, and 20 were perfused through the left ventricle first with a saline rinse and then with phosphate buffered aldehydes. Brains were sectioned at 50µm. Adjacent series of sections were treated with sodium borohydride (1%, 15 min.) and appropriate normal sera (2%) prior to incubation in anti-NT (1:3000, Immunonuclear), anti-SP (1:000, Sera), carrier buffer alone or one of the two antibodies preabsorbed with the appropriate antigen. Immunostaining was produced using biotinylated second antibodies (1:200), the ABC kit (Vector), and DAB. Controls resulted in absence of staining. On P1 NT-IR neurons were present in the subiculum, amygdaloid complex, endopiriform region, lateral hypothalamus, the septal area and, in the striatum, only along the caudal dorsolateral margin of the c-p. The latter were very numerous, however, extending ventrally toward ventral striatum by P5. At P12 NT-IR neurons were distributed in conspicuous clusters throughout lateral parts of the c-p and in ventral striatum. Dense patches of SP-IR terminal stain which contained clusters of SP-IR neurons were located more medially in the c-p, however, and where the distribution of NT-IR and SP-IR cell clusters did overlap the positions of NT-IR and SP-IR clusters themselves almost never corresponded. To the contrary, they appeared to be distributed in an inverse or complementary fashion. By P20 the arrangement observed was that of the adult, with NT-IR striatal neurons being few in the absence of section pretreatment. Support: NS-23805 and the American Parkinson Disease Association.

273.15 **THYROTROPIN-RELEASING HORMONE (TRH) IN SUBREGIONS OF THE HIPPOCAMPAL FORMATION: IMMUNOCYTOCHEMICAL LOCALIZATION AND QUANTITATION BY RADIOIMMUNOASSAY (RIA).** M.J. Kubek, J. Roepke, M. Zaphiriou, S.H. Murphy, T.G. Hill, A. Sattin, and W.C. Low, Depts. of Anatomy, Psychiatry, Physiology and Biophysics, and Program in Medical Neurobiology, Indiana University School of Medicine, Indianapolis, IN 46223.

Previous studies from our laboratories have demonstrated that TRH afferents project to the hippocampal formation by way of the fornix pathway (Neurosci. Abs. 11:680). Radioimmunoassay of TRH indicated that the ventral hippocampal formation is more densely innervated by TRH afferents than the dorsal hippocampus. In addition, fornix lesion studies sugggested that intrinsic sources of TRH existed within the hippocampal formation (Neurosci. Abs. 12:300). To determine the source of intrinsic hippocampal TRH, immunocytochemical methods were used to stain TRH-containing neural elements. TRH quantitation in microdissected subregions of the hippocampus was also determined using RIA.

In the immunocytochemical study, rats were perfused with phosphate buffer and lysine-periodate fixative. Hippocampal sections were cut 10 um thick using a cryostat at -20°C and mounted on glass slides. Tissue sections were incubated in primary antisera (1:3200) containing polyclonal antibodies raised in rabbits against BSA-conjugated TRH. Antibody localization was visualized using the peroxidase-anti-peroxidase method. TRH-positive staining was observed in pyramidal cells of regions CA1, CA3, and hilus. Granule cells of the dentate gyrus were also stained along with neurons in the subiculum. TRH-positive staining also displayed a unique laminar pattern: stratum oriens was moderately stained throughout the CA fields while strata radiatum and moleculare were sparsely stained. Within the dentate gyrus, stratum moleculare of the lower blade was more densely stained than the upper blade. Tissue incubated in preimmune sera at the same dilution and from the same rabbit exibited no staining.

In the RIA study, hippocampal subregions were microdissected on an ice-cold wax plate using low power magnification. Tissues were extracted by sonication using 90% methanol. TRH radioimmunoassay revealed that the CA3 region of the hippocampal formation contained the highest amounts of TRH (152 ± 5.8 pg, n = 8), followed by intermediate levels in region CA1 (116 ± 8.8, n = 9) and the dentate gyrus (76.5 ± 7.7, n = 7). The subiculum (38.4 ± 5.6, n = 9) and the hilus (26.6 ± 3.9, n = 7) contained the lowest levels. These TRH levels appear to correlate well with our immunocytochemical findings.

The results from this study suggest that (1) the intrinsic sources of hippocampal TRH appear to be pyramidal and granule cells, and (2) a discrete laminar distribution of TRH exists within subregions of the hippocampal formation. Finally, although the terminal zones of the extrinsic TRH afferents to the hippocampus have yet to be identified, we hypothesize that they will include projections to stratum oriens of cornu ammonis and stratum moleculare of the dentate gyrus.

273.16 THE LOCALIZATION OF SUBSTANCE P, CHOLINE ACETYLTRANSFERASE, LEU-ENKEPHALIN, AND ACETYLCHOLINESTERASE IN THE NORMAL AND DEAFFERENTATED INTERPEDUNCULAR NUCLEUS OF THE RAT. M.D. Kawaja*, B.A.Flumerfelt and A.W. Hrycyshyn*. Dept.of Anatomy, University of Western Ontario, London, Canada N6A 5C1.

The major afferent pathway to the interpeducular nucleus (IPN) arises from the medial habenula (mHb) and projects via the fasciculus retroflexus (FR). The purpose of this study was to examine the distribution of immunohistochemically demonstrable substance P (SP), choline acetyltransferase (ChAT), and leucine-enkephalin (l-Enk) reactivity, and acetylcholinesterase (AChE) in the normal IPN and following lesions of the FR. Neurons of the mHb exhibited moderate to weak AChE activity, SP reactivity dorsally, and ChAT reactivity ventrally. Within the IPN SP reactivity was localized in the lateral subnuclei (IP-L) and in the dorsal cap of the rostral subnucleus (IP-R); l-Enk is found in the central subnucleus (IP-C) and the IP-R; ChAT reactive axons were present in the rostral portion of the IP-R, and further caudally in the IP-C and intermediate subnuclei (IP-I); AChE staining was heaviest in the entire IP-R and in the IP-L. One week following unilateral electrolytic lesions of the FR, a significant decrease in SP reactivity was demonstrated ipsilaterally in the IP-L and in the dorsal cap of the IP-R; ChAT activity declined within the IP-C, IP-I, and in the rostral portion of the IP-R. Bilateral FR lesions substantially reduced SP reactivity in the IPN, while ChAT activity was moderately decreased. A perceptible decrease in AChE staining was observed bilaterally in the IP-L, while activity in the IP-R was unchanged. l-Enk reactivity was not altered following lesions to the FR. IPN afferents arising from the dorsal mHb projected predominantly to the IP-L and possessed both SP and AChE activity, while those axons that arise from the ventral mHb possessed high levels of ChAT activity and projected to the IP-C, IP-I and the rostral IP-R. AChE activity in the IPN appeared to be mainly intrinsic with only a moderate response in IP-L to FR lesions. Also, the distribution of AChE and ChAT activities overlapped the rostral portion of IP-R, while in ChAT-positive IP-C and IP-I AChE staining was weakest. Since l-Enk reactivity was unaffected following FR lesions, a habenular source for the enkephalinergic terminal fields in the IPN is unlikely.

273.17 ORIGIN OF ATRIAL NATRIURETIC PEPTIDE-CONTAINING FIBERS IN THE RAT INTERPEDUNCULAR NUCLEUS: A COMBINED IMMUNOCYTOCHEMICAL AND FLUORESCENT RETROGRADE LABELLING STUDY IN THE RAT. G.S.Hamill (SPON: W.P.Bartlett).Department of Anatomy, Penn State University College of Medicine, Hershey, PA 17033.

Recent studies have reported a widespread distribution of atrial natriuretic polypeptide (ANP) within the CNS by radioimmunoassay and immunocytochemical techniques. ANP is heterogeneously distributed within the rat interpeduncular nucleus (IPN) principally within axon terminals localized in the rostral (R), dorsal medial (DM), dorsal lateral (DL) and lateral subnuclei (L). In this study, the origin of ANP-positive fibers identified in the IPN was determined using a technique combining retrograde fluorescent labelling and immunocytochemistry on the same tissue section.

Sprague-Dawley adult rats were anesthetized with Nembutal (40mg/kg), and 125-250 nl of fast blue dye (0.05%) stereotaxically injected into the IPN. Following 8 days survival and an intraventricular injection of colchicine (200ug/25ul H20), the rats were perfused through the heart with 4% paraformaldehyde. 14-18um cryostat sections were cut coronally through the entire brain prior to processing for immunocytochemistry. The ANP antiserum (1:250 dilution) used in this study was raised in rabbits against rat atriopeptin III (Zamir et al., Brain Res.365:105-111,1986). Preabsorption of the ANP antiserum with 1uM atriopeptin III resulted in a complete absence of immunostaining.

Preliminary data revealed that ANP-positive cell bodies projecting to the IPN were localized in the medial habenula (MH) and dorsal tegmental region (DTR). Most ANP-positive cell bodies within the (MH) were labelled with fast blue, and were confined to a narrow, vertically-oriented band adjacent to the lateralmost margin of the nucleus. In the (DTR) region, cells positively stained for ANP only, fast blue only, and ANP + fast blue, were localized on the midline just ventral to the fourth ventricle, in a narrow zone encircling the dorsal tegmental nucleus, and within the dorsal lateral tegmental nucleus.

The results of this study indicated that the IPN receives ANP-positive afferents from both the (MH) and dorsal tegmental region. The (DTR) also contained ANP-positive cells that projected to other brain regions, and contained cells that projected to the IPN that were not ANP-positive. In light of previous studies demonstrating reciprocal projections between the (R), (DM), (DL), and (L) subnuclei of the IPN and the (DTR) and raphe, the present data suggests that ANP may have some role in modulating the physiological activity within this feedback loop.

This study was supported by a grant from the American Heart Association, South Central PA chapter.

273.18 ULTRASTRUCTURAL LOCALIZATION OF CHOLECYSTOKININ-8 LIKE IMMUNOREACTIVITY IN THE CAT NUCLEUS SOLITARIUS. B.E. MALEY,Dept. of Anatomy and Neurobiology, Univ. Kentucky Med. Ctr., Lexington, KY. 40536

Cholecystokinin-8 like immunoreactivity (CCK) has been reported to be present in neuronal cell bodies and fibers in the cat nucleus solitarius at the light microscopic level. The nucleus solitarius is known to be involved in the central regulation of cardiovascular functions. CCK plays a role in this regulation, although the morphological basis for its action is not understood yet. The present study was undertaken to define the specific synaptic circuitry involving CCK in the nucleus solitarius.

All animals used in the present study were perfused with 4% paraformaldehyde and 0.5% glutaraldehyde in Sorenson's phosphate buffer, pH 7.4. The nucleus solitarius was isolated, cut on a vibrating microtome and immunostained with antiserum to CCK.

CCK was localized to specific synaptic terminals, dendrites, axons and neurons of the nucleus solitarius. The CCK reaction product was generally associated with synaptic vessels in terminals as well as the cytoplasmic side of other membrane bound structures. Immunolabelled synaptic terminals contained a mixture of clear and dense core vesicles in addition to mitochondria and other presynaptic structures. The majority of CCK labelled terminals contacted spines and smaller, distal dendrites, although CCK labelled terminals were also present on larger dendrites and occasionally on the neuronal cell body.

Results of this study indicate that CCK is present in presynaptic terminals in the cat nucleus solitarius, suggesting a possible role for it in the synpatic circuitry of this neural region. The morphological characteristics of CCK immunolabelled terminals is very similar to that of other peptidergic immunolabelled terminals in the cat nucleus solitarius. However, its pattern of distribution along the neuron is different than that of enkephalin and similar to that of substance P. This suggests that the pattern of termination on neurons is critical component of the synpatic circuitry in the nucleus solitarius.

273.19 IMMUNOCYTOCHEMICAL STUDIES OF PROENKEPHALIN-DERIVED PEPTIDES IN THE RAT CEREBELLUM. D. Zhao* and J. S. Hong (SPON: M. Ng Cheong Ton). Lab. of Neurobehav. Toxicol., NIEHS/NIH, Research Triangle Park, NC 27709.

Radioimmunoassay studies revealed that the cerebellum contains little amount of enkephalin immunoreactivity. Previous immunocytochemical studies either failed to identify the subpopulation(s) of neurons that contain the enkephalin-like immunoreactivity or only demonstrated a few positively stained Golgi cells. The existance of considerable amount of messenger RNA coding for proenkephalin prompted us to investigate this discrapancy by re-examining the distribution of the enkephalin-like immunoreactivity at cellular level.

Forty adult Fisher-344 rats were used. Purfused brains were sliced at either 10 or 20 um on the cryostat and further post-fixed in paraformaldehyde. Three different antisera raised against methionin-enkephalin (ME) conjugated with either thyroglobulin or BSA, one antibody directed against methionin-enkephalin-Arg-Phe (MEAP) were employed as the parimary antibodies in the immunostaining (these antibodies have been used by several laboratories and their specificities have been examined). All 3 antibodies against ME and the one against MEAP yielded identical staining pattern, i.e. outlayer stellate cells, basket cells, some Golgi cells and all Purkinje cells were positively stained while granule cells were not stained. The neurons in the deep cerebellar nuclei (DCN) and the fiber tracts from Purkinje cells to the DCN were also demonstrated to contain enkephalin-like immunoreactive substances. These indicate that the proenkephalin-derived peptides may exist in most, if not all, cerebellar inhibitory neurons and interneurons. Since all these neuronal components are known to use GABA as inhibitory neurotransmitter, it is extremely interesting that inhibitory proenkephalin-derived peptides coexist with GABA in these cells. Because the architecture of the cerebellum is relatively simple and the circuits between the cerebellar neurons are well defined, our finding may offer a unique model to study the fuctional significance of colocalized neurotransmitters and neuromodulators.

274.1 EFFECTS OF FENFLURAMINE ON LANGUAGE PRODUCTION IN CHRONIC SCHIZOPHRENIA. A.A. Rejzer*, R.O. Elliott*, B.D. Marshall*, and H.V.Soper. Camarillo State Hospital and UCLA-NPI Research Program, Camarillo, CA 93011.

Reported behavioral improvement among the autistic following fenfluramine treatment and high serotonin levels among certain chronic schizophrenic patients suggest that fenfluramine may be beneficial to schizophrenic patients. In particular, such control of serotonin level might improve expressive language.

The subjects, 8 (7 male) chronic schizophrenic (DSM-III diagnosed) patients, received minimal optimal neuroleptics and either a placebo or fenfluramine through the duration of the study. The first linguistic evaluation was conducted toward the end of a staggered baseline (placebo) period. Then the fenfluramine was introduced at 60 mg/day. The levels were titrated up 20 mg/day at 2-week intervals to a peak of 120 mg/day where they were maintained for 6 weeks, except for 1 subject who received the sequence 60, 80, 100, 80 mg/day. The second evaluation was performed at the end of the last dosage interval.

All evaluations were tape-recorded and the subject was asked 3 open-ended questions ("Tell me about"). The first 25 spontaneous utterances were rated by 2 experts on 2 scales - 14 factors of a pragmatic usage (PU) scale and 17 factors of a thought, language, and communication (TLC) scale. The PU scale included ratings of intonation variation, turn taking, topic maintenence, presuppositions, referencing, organization, fragments, pauses, repetitions, revisions, dysfluencies, vocal level, and rate. The TLC scale included ratings of poverty of speech, poverty of content of speech, pressure of speech, distractible speech, tangentiality, derailment, incoherence, illogicality, clanging, neologisms, word approximations, circumstantiality, loss of goal, perseveration, echolalia, blocking, and stilted speech.

The results suggest not only no beneficial effect from fenfluramine on language, but in fact an overall impairment in function. On the PU scale 5 subjects showed overall deterioration in linguistic functioning and 3 showed very little change. Overall performance deteriorated on most of the pragmatic variables assessed. The results were similar for the TLC scale. Although the deterioration was not as severe, 1 subject showed mild improvement, 1 showed no change, and the rest become more impaired.

The results of this study - lack of any beneficial effect from fenfluramine on linguistic functioning - are very similar to those obtained for neuropsychological functioning reported previously (Soper & Marshall, neurosci. Abstr. 12:480, 1986).

We would like to thank the staff of the Clinical Research Unit at Camarillo State Hospital for their help with the subjects, and Philip R. A. May, M.D., and Kamal Midha, Ph.D., for their help with the design.

274.2 EFFECTS OF A NEW SERENIC DRUG, DU 28853, IN EXPERIMENTAL MODELS FOR AGGRESSIVE BEHAVIOUR. B.Olivier and J.Mos*. Dept. Pharmacology, Duphar b.v., P.O.Box 2, 1380 AA Weesp, Holland.

DU28853 (1-(2,3-dihydro-1,4-benzodioxin-5-yl)piperazine hydrochloride) is a new drug from the class of serenics, which has been developed as specific anti-aggressive compounds. DU28853 was tested in various animal experimental aggression models in different species.

Isolated male mice confronted with a group housed partner rapidly attack. DU28853 very effectively inhibited this behaviour (ED_{50}=0.4 mg/kg p.o.) and even at doses 25 times the ED_{50} the behavioural effects were specific, i.e. animals were not sedated.

In a resident-intruder paradigm, aggression by male resident rats was dose-dependently (ED_{50}=1 mg/kg po) decreased by DU28853, whereas at the same doses social interest and exploration were not affected, neither were animals sedated. After chronic treatment with DU28853 (10 mg/kg once per day for 14 days orally) no tolerance was observed for its anti-aggressive action in a resident-intruder paradigm. In a large colony, in which a dominant (α) male, a subordinate male and a female were permanently housed, introduction of a strange male rat evoked aggression largely from the α-male. DU28853 reduced this aggression not only in the α-male but also in the subordinate (ED_{50}=2.5 mg/kg po).

Lactating female rats very rapidly attack intruders placed into their home cage during the first two weeks postpartum. DU28853 inhibited aggression (ED_{50} ~1 mg/kg po) against male intruders without interference with pupcare. Social interest remained intact while exploration increased.

In a paradigm of brain-stimulation induced aggression in rats, DU28853 at doses from 2 to 8 mg/kg po, enhanced the threshold currents to induce attacks whereas threshold currents to evoke locomotion via the same electrode were even decreased. This points to the very specific influence of this drug on aggression.

DU28853 inhibited a juvenile form of agonistic behaviour, play fighting in rats, but had no influence on locomotor activity.

Aggression resulting from mixing piglets from different litters was markedly reduced by DU28853 without sedation.

Defensive behaviour and flight, behaviours very important for species survival were unaltered by DU28853; this also held for shock-induced fighting, another commonly used model for defence.

DU28853 exerts a specific anti-aggressive activity in all species and models tested so far. This serenic property is characterized by decreases in offensive aggression which are not directly caused by behavioural interference from sedation or senso-motoric impairment. The latter may heavily interfere with the proper performance of behaviour. The specificity of the behavioural effects is further supported by the absence of effects on defence and flight.

The specific and unique profile of DU28853 warrants further testing of the drug in certain human disorders in which aggression is one of the symptoms.

274.3 ROLIPRAM-INDUCED INCREASE IN SENSORIMOTOR REACTIVITY MEASURED WITH ACOUSTIC STARTLE: SITES OF ACTION AND POSSIBLE MONOAMINERGIC MECHANISMS; J.H. Kehne, N. Boulis, and M. Davis, Dept. Psychiat., Yale Univ. Sch. Med., 34 Park St., New Haven CT 06508.

Previous work demonstrated that the phosphodiesterase inhibitor rolipram (4-(3-cyclopentyloxy-4-methoxy-phenyl-2-pyrrolidone)) increased sensorimotor reactivity manifested as elevated startle responses to auditory stimuli (Kehne et al., 1986, J. Neurosci., 6, 3250-3257). The present study further investigated sites of action and possible monoaminergic mechanisms underlying this behavioral effect of rolipram. For all systemic studies an ED_{50} dose of 0.5 mg/kg (IP) was used.

Two lines of evidence indicate that rolipram increases startle by enhancing neurotransmission on the motor (output) side of the startle reflex: (1) IP rolipram increased startle responses elicited by single-pulse, bilateral electrical stimulation of the nucleus reticularis pontis caudalis. Because stimulation of this relay nucleus directly activates the reticulo-spinal limb of the neural circuit mediating startle, the startle-enhancing effect of rolipram must be expressed, at least in part, at the level of the reticular formation or spinal cord. (2) Direct spinal (intrathecal) infusion of rolipram increased startle amplitude (Kehne et al., ibid.), though supraspinal infusions were not tested. In the present study, a 5 μg dose increased startle after intrathecal but not after supraspinal (lateral ventricle) infusion, implicating the spinal cord as a site of action.

Biochemical studies have demonstrated that compounds that elevate intracellular levels of cAMP can increase the evoked release of monoamine neurotransmitters. However, in the present study, the startle-enhancing effect of rolipram was not blocked by a variety of treatments which interfere with presynaptic monoaminergic function or which block postsynaptic monoamine receptors. These treatments included: (1) α-methyl-para-tyrosine (100 mg/kg; 3.5 hr before rolipram) + reserpine (10 mg/kg; 4 hr before); (2) para-chlorophenylalanine (400 mg/kg; 24 hr before) + reserpine (10 mg/kg; 4 hr before); (3) the noradrenergic neurotoxin DSP4 (50 mg/kg; 3 wks before); (4) pretreatment 30 min before with high doses of several monoamine antagonists: (i.e. β-adrenergic antagonist propranolol (20 mg/kg), α_1-adrenergic antagonist prazosin (5 or 10 mg/kg), dopaminergic antagonist haloperidol (1 mg/kg), serotonergic antagonists cyproheptadine (10 mg/kg) or cinanserin (10 mg/kg). These data indicate that a direct release of monoamines does not account for rolipram's enhancement of the startle response.

In summary, the increase in startle amplitude produced by the phosphodiesterase inhibitor rolipram is mediated, at least in part, by an action at the spinal level, and this effect is not attributable to increased release of monoamines.

274.4 RADIATION- AND DRUG-INDUCED EMESIS IN THE FERRET. G. L. King, Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

Emesis is the most prominent prodromal symptom in man following low-level (300-1000 cGy) radiation. The ferret, Mustela putorius furo, has been recently introduced as an alternative species to dogs and non-human primates for studying this phenomenon (Gylys & Gidda, Gastroent. 90:1446, 1986; Andrews, Davis & Hawthorn, J. Physiol. 378:16P, 1986). Present work describes my findings on radiation-induced emesis in the ferret and preliminary results on those compounds that may act via the area postrema to induce emesis. For all studies, I used adult male ferrets (Fitch strain, castrated, descented, 1-1.5 kg, Marshall Farms), fed ad lib. For the radiation studies, a total of 48 animals were head-shielded and radiated (bilateral ^{60}Co, 100 cGy/min) at the following calculated midline absorbed doses (in cGy): 601 (n = 6), 401 (n = 6), 201 (n = 6), and n = 30 for steps between 49 and 127. Emetic latencies were standardized as T_0 = time that radiation ended. The emetic threshold is about 70 cGy and the ED_{50} = 95 cGy. This latter value becomes 79 cGy if retching (nonproductive emesis) is included as an emetic episode. The latency to first emesis decreased with increasing radiation dose (68.9 cGy = 40 min [n = 1]; 601 cGy = 8.5 min) whereas the duration of the prodromal response increased (68.9 cGy = 0.5 min, 601 cGy = 57 min). Increasing the dose also increased the number of both (a) emetic "bouts" within the prodromal episode (68.9 cGy = 1; 601 cGy = 2-7), and (b) expulsions (68.9 cGy = 2; 601 cGy = 7-15). For the chronic drug studies, animals were anesthetized and implanted with sterile jugular catheters. Compounds were injected under aseptic conditions 2-3 times weekly as a bolus, followed by a bolus of saline. Compounds were injected at various doses on a dose-weight basis, in volumes that never exceeded 1 ml. At least 48 hr passed between drug injections. Compounds tested thus far (on 3-6 animals) include: apomorphine, WR-2721 (a radioprotectant with emetic properties), peptide YY, and several opioid peptides (Leu- and Met-enkephalin, DADLE, DAGO, DPDPE, DSLET, and DTLE). WR-2721 produces an emetic episode that lasts for about 10 min; responses to all other emetics are brief (0.5-2.0 min). Of all compounds tested, peptide YY and the μ receptor agonist DAGO produce emesis at the lowest dose (3 μg/kg); DAGO-induced emesis is 100% at 5 μg/kg (n = 3). In contrast, the threshold dose for emesis induced by the δ-receptor agonists DADLE and DSLET is 100 μg/kg. Studies with opioid-receptor antagonists and other μ-, δ- or κ-receptor-selective agonists are in progress to determine the relative contribution of each receptor type to opioid-induced emesis.

274.5 INTRACRANIAL SELF-ADMINISTRATION OF NEUROHUMORS. J. E. Smith, K. H. McAllister*, C. A. Van Osdell*, G. F. Guerin, N. E. Goeders and S. I. Dworkin, Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Intracranial self-stimulation experiments indicate that specific neuronal circuits may mediate the neurobiological consequences of reinforcer presentation. Neurobiological investigations of intravenous drug self-administration further indicate reinforcing neuronal activity to be initiated through receptors in discrete brain regions which activate neuronal circuits that mediate these processes. Furthermore, these studies imply that continued reinforcing neuronal activity results from the release of neurohumors that interact with discrete receptors at specific sites. Experiments were initiated to identify such neurohumors and brain loci using intracranial self-administration procedures.

Adult male F-344 rats were implanted with intracranial guide cannulae into either the nucleus accumbens (NA), medial prefrontal cortex (MPC), preoptic nuclei (PO), ventral pallidum (VP) or ventral tegmental area (VTA). Following recovery from surgery the rats were allowed to self-administer 100 nanoliter infusions of either aspartate (Asp), dopamine (DA), glutamate (Glu), gamma aminobutyric acid (GABA), oxotremorine (OXT) or serotonin (5-HT) into one of these regions in 150-1500 picomole doses using electrolytic microinfusion transducer systems. Each animal was exposed to several doses of the neurohumor and vehicle twice per week during 3 to 8 hour sessions.

Animals self-administered DA and Glu significantly greater than vehicle at some brain sites. Presentation of DA into the NA and Glu into the PO and VP maintained responding in a number of animals at rates significantly above vehicle, while 5-HT into the NA or Asp into the VTA did not. OXT infusions into the VTA and MPC and GABA infusions into the VP may also maintain lever pressing but these data are less consistent at this time. Two lever discrimination and pharmacological blockade experiments are currently in progress for DA self-administration in the NA and Glu self-administration into the PO and VP. Intracranial self-administration may be useful in further characterizing and delineating the neuronal receptors and circuits that initiate and mediate reinforcement processes activated by drugs of abuse. (Supported in part by USPHS Grant DA-03832).

274.6 DOSE-DEPENDENT AND BASELINE-DEPENDENT CONDITIONING IN THE PLACE PREFERENCE PARADIGM. N.L. COSTELLO*, J.N. CARLSON AND S.D. GLICK. (SPON: J.S. DEITCH) Department of Pharmacology and Toxicology, Albany Medical College, Albany, NY 12208

The place conditioning paradigm has been used extensively as an animal model for the evaluation of drug reinforcement. Previous studies have demonstrated that a wide range of doses of d-amphetamine (d-A) which when consistently paired with an initially non-preferred environment will induce a significant increase in the total time spent in that environment (place preference). This laboratory recently reported that when compared to saline control rats, female Long-Evans rats exhibited a 'relative place aversion' to a dose of d-A (1.25 mg/kg) which was within the range of doses previously reported to induce a place preference in male rats (Costello et al. Neurosci. Abst. 1986). The present study was conducted to determine the dose dependency of this phenomenon.

Six doses (0 to 5 mg/kg) of d-A were given i.p. to female Long-Evans rats. These doses produced an inverted U-shaped function in place conditioned behavior. Contrary to the reports of similar studies, which have reported larger effects with a 5 mg/kg dose of d-A in male rats, the present study revealed that this dose failed to produce a significant place preference in females. In contrast to our previous findings, a 1.25 mg/kg dose now induced a place preference. It was noted that overall baseline preference for the conditioned side, as determined in a pre-conditioning phase, ranged from 20 to 360 sec. On this basis the control and drug groups were seperated into low [< 200 sec] or high [>200 sec] initial preference sub-groups. We evaluated the ratio of post-conditioning / pre -conditioning time spent on the drug paired side to determine if baseline preferences interacted with d-A preference induction. Place preferences were more readily induced when high initial baseline preferences were present at preconditioning. An initially low baseline preference with 1.25 mg/kg group may account for our previous findings.

After three post-conditioning test days we conducted a reinstatement test. All subjects were given a 1.5mg/kg dose of d-A, prior to placement in the testing chamber. All groups which exhibited a preference on the first three test days continued to do so when tested with the drug. Although the 5 mg/kg group did not exhibit a preference over the first three test days, when a dose of 1.5 mg/kg was administered on the fourth test day, a significant preference for the drug paired environment was observed. This suggests that this dose, elicits competing rewarding and aversive effects and that the former generalized to the effects of the 1.5 mg/kg dose. (Supported by NIDA grant DA03817 to S.D.G.)

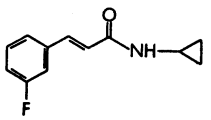
274.7 EFFECTS OF IONIZING RADIATION ON FIXED-RATIO ESCAPE PERFORMANCE IN RATS. P.C. Mele*, C.G. Franz* and J.R. Harrison* (SPON: S. Kandasamy). Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

This laboratory recently reported that acute, sublethal doses of ionizing radiation produced reversible, dose-related disruptions in responding when maintained by fixed-ratio (FR) and fixed-interval schedules of milk presentation (Toxicologist 7: 250, 1987). The present study extended these findings by irradiating rats responding under an FR schedule of termination of electric foot-shock (FR escape).

Adult male rats pressed a lever to terminate scrambled foot-shock under an FR20 schedule; shock-off duration was 30 sec. Test sessions occurred Mon-Fri and were 60 min in duration. Separate groups of rats (n=6/group) were exposed to 0, 4.5 or 7.5 Gy of 60Co gamma radiation. Over 6 wk of testing after exposure, there were no consistent changes in performance of the 0 and 4.5 Gy exposure groups. In the 7.5 Gy exposure group, response rates were reduced over the first 30 days after exposure; individual rats had response rates falling below their control range during 16, 15, 12, 11, 8 and 4 of the 22 test sessions that occurred during this time. For each rat, response rates were almost completely reduced during some of these sessions and only slightly or moderately reduced during others. Subsequently, recovery of preirradiation control rates occurred in all rats. Thus, radiogenic disruption of FR escape performance was reversible and dose-related though variable both within and between animals. Next, rats of the 0 Gy exposure group received 150 Gy/day for 5 consecutive days. Over 6 wk of testing response rates were moderately reduced in only 1/6 rats (wk 4-5), indicating that dose-fractionation was less effective in disrupting performance than a single, acute dose. To evaluate the relative sensitivity of the FR escape baseline, chlorpromazine (C, 0.1-3.0 mg/kg) and d-amphetamine (A, 0.3-5.6 mg/kg) were used as reference compounds. C and A typically decreased response rates in a dose-dependent manner to 15 and 30% of control at the highest doses tested, respectively, although the lowest dose of A increased rates slightly (by 25%). Thus, FR escape responding was disrupted by these prototypical drugs at doses that have been shown to disrupt a variety of other schedule-controlled behaviors.

274.8 CINFLUMIDE, A CHEMICALLY NOVEL CENTRALLY ACTING SKELETAL MUSCLE RELAXANT. F.E. Soroko*, B.T. Kenney*, E. Grivsky+, R.A. Maxwell and B.R. Cooper. Department of Pharmacology, +Department of Chemistry (Retired), Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Cinflumide was compared with the clinically-used central muscle relaxants, chlorzoxazone, carisoprodol and methocarbamol in rodents using weakness of the abdominal muscles, ataxia and loss of righting reflex as indices of skeletal muscle relaxation. Cinflumide was found to be more potent or of equal potency to the above clinically-used muscle relaxants depending on species and routes of administration. The duration of action of cinflumide compared favorably to the three standards.



In the conscious cat cinflumide produced signs of skeletal muscle relaxation. It was found to be more potent than methocarbamol and approximately equal in potency to chlorzoxazone and carisoprodol. No evidence was obtained in the rodent or the cat that cinflumide produced sedation as a side effect at doses equal to the ED_{50} for muscle relaxation. Electrophysiological studies show that cinflumide acts on the spinal cord to depress selectively polysynaptic reflexes. Clinically, cinflumide is in Phase 2 studies.

274.9 LOCOMOTOR ACTIVITY PATTERNS INDUCED BY DESIGNER DRUGS. H.D Christensen, D.A. Christensen*, W. Cao*, R.A. Brumback* and J.M. Carney*. Depts. of Pharmacol. and Pathol., Col. Med., OUHSC, Oklahoma City, OK 73190

Locomotor activity effects of 3,4-methylene dioxymethamphetamine (MDMA) was compared to saline controls in five strains of inbred mice where recombinant sets exist. In the SWR mouse there was a progressively greater stimulation as the dose of MDMA was increased. In contrast in the C57L mouse, MDMA at 5 and 10 mg/kg i.p. stimulated locomotor activity to twice control values with a slight decrease at 30 mg/kg, compared to the 5 and 10 mg/kg dose levels. The response of AKR mice to MDMA was a four-fold depression in activity at 5 and 10 mg/kg while 30 mg/kg induced stimulation. The BALB/cBy mouse, which is not stimulated by amphetamine, had an activity depression of four-fold after 5 and 10 mg/kg and two-fold after 30 mg/kg MDMA. One of the four mice receiving 30 mg/kg daily showed stimulation on day 3 and 4. The C57BL/6By mouse showed no change at 5 mg/kg and a mild stimulation at 30 mg/kg. Thus, five mg/kg MDMA would be an appropriate dose to study genetics since locomotor activity for AKR and BALB/cBy is a depression, C57L stimulation and SWR and C57BL/6By are not significantly different from saline treated animals.

Locomotor activity was measured after daily administration of four designer drugs, MDMA, MDA, MDEA and methamphetamine 5 mg/kg in A/J and C57BL/6J mice. MDMA showed a depression on day 1 for A/J mice, but no change from saline values on days 2-4. MDA and methamphetamine did no differ from saline on day 1 but progressively stimulated activity on day 2-4 reaching a 4 to 5 fold increase from day 1. MDEA did not vary from saline. In C57BL/6J mice there were no differences on day 1, small but significant depression for MDMA, MDA and MDEA on day 4, while methamphamine caused stimulation. When these drugs were given daily for 15 days, MDMA induced a decrease in A/J but not in the C57BL/6J or C57BL/10J mouse. In the two F1 generations, B6AF1 and B10AF1, MDMA caused a decrease like the A/J sire, although their basal rates are more like their dams. One day post administration there was a relative rebound and by seven days post administration control values were found. Fifteen days of MDA and MDEA treatment resulted in an activity decrease in C57BL/10J but not in A/J or C57BL/6J mouse.

Depending upon the inbred strain MDMA, MDA and methamphetamine elicit different responses suggesting separable CNS mechanisms. One approach to the identification and characterization of these separable mechanisms is to utilize recombinant inbred mouse strain sets (AKXL, CXB/By and SWXL).

274.10 THE EFFECT OF INTRACEREBROVENTRICULAR INJECTIONS OF VEHICLE SOLUTIONS ON LOCOMOTOR ACTIVITY IN THE HAMSTER. P. Schnur and C.M. Archuletta*. Dept. of Psychology, University of Southern Colorado, Pueblo, CO 81001.

A series of experiments investigated the effects of 5 µl intracerebroventricular injections of commonly used physiological vehicle solutions on running wheel activity in six female golden Syrian hamsters, Mesocricetus auratus. Stainless steel cannulas were implanted in the left lateral ventricle (1.1 mm anterior to bregma, 1.7 mm lateral to the midline, 2.7 mm below the dura) under sodium pentobarbital anaesthesia. Animals were given at least one week to recover from surgery before testing commenced. The solutions studied (and their compositions in grams/liter) were as follows: bacteriostatic saline (9 g sodium chloride (NaCl), 9 g $C_6H_5CH_2OH$ (benzyl alcohol)), saline (9 g NaCl), artificial cerebrospinal fluid 1 (7.46 g NaCl, 0.19 g potassium chloride (KCl), 0.14 g anhydrous calcium chloride ($CaCl_2$), 0.19 g magnesium chloride ($MgCl_2 \cdot 6H_2O$), 1.76 g sodium bicarbonate ($NaHCO_3$), 0.18 g sodium biphosphate, (Na_2HPO_4), 0.61g glucose ($C_6H_{12}O_6$)), artificial cerebrospinal fluid 2 (1.8 g NaCl, 0.093 g KCl, 0.088 g calcium chloride ($CaCl_2 \cdot 2H_2O$), 0.042 g potassium dihydrogen phosphate, (KH_2PO_4), 0.04 g magnesium sulfate ($MgSO_4$), 0.55 g $NaHCO_3$), Ringer's solution (7 g NaCl, 0.14 g KCl, 0.13g $CaCl_2$, 0.20 g $NaHCO_3$) and deionized water. All solutions were freshly prepared and filtered prior to injection. Following the injection, animals were placed in the running wheels for a three hour test session and the number of wheel revolutions was recorded at 20-min intervals. Compared with no injection or sham injection controls, which did not differ from one another, all solutions except Ringer's solution produced a temporally-specific decrement in running wheel activity: Little or no effect was evident for one hour after the injection, but activity decreased dramatically thereafter for the next two hours. The mechanism(s) underlying this effect is under investigation.

274.11 REPEATED ADMINISTRATION OF MURINE-RECOMBINANT INTERFERON-GAMMA (murIFN-gamma) PRODUCES DECREASED LOCOMOTOR ACTIVITY IN MICE. S.B. Weinberger, G. Schulteis, A.G. Fernando*, C. Bakhit, and J.L. Martinez, Jr. Psychology Department, University of California, Berkeley, CA 94720 and Genentech, Inc., South San Francisco, CA 94080.

In addition to their important immune augmenting effects, the interferons may modulate, either directly or indirectly, neuronal and central nervous system function. In some human patients, interferons may cause several presumably centrally-mediated, but reversible, effects, including lethargy, anorexia, psychomotor retardation, and cognitive changes that persist throughout the treatment period. Although several investigators studied the effects of interferon-alpha in animals, the behavioral effects of peripherally administered interferon-gamma have not been characterized, nor are the biochemical changes that may underlie these effects known. We report here the effects of treatment with murIFN-gamma on spontaneous locomotor activity in mice.

All studies were done in male Swiss-Webster mice. Locomotor activity was measured in an open field chamber, the floor of which was divided into 16, 3-inch square sections. The number of lines crossed during a 60 min observation period was tabulated in one-min intervals.

The acute effects of murIFN-gamma injection were evaluated both immediately after and 4 hrs after a single 30 µg i.p. injection. In both studies total crossovers over the 60 min observation period were not significantly different in animals treated with murIFN-gamma or saline.

The locomotor effects of repeated daily treatment with murIFN-gamma were evaluated over a 60 min period commencing 4 hrs after the fifth daily i.p. injection of 30 µg of murIFN-gamma. As compared to the saline-treated mice, a decrease in locomotor activity was seen in the murIFN-gamma animals (total crossovers for mins 25-60: murIFN-gamma, 90 +/- 29, n = 7; saline, 230 +/- 28, n = 8; p = 0.035 [Mann-Whitney U-Test]). Additionally, the murIFN-gamma-treated animals gained significantly more weight over the 5-day treatment period than did the saline-treated controls.

The observed decrease in locomotor activity suggests a centrally mediated effect of murIFN-gamma. Biochemical experiments following murIFN-gamma treatment in mice (Bakhit et al., in preparation) suggest changes in striatal dopaminergic and serotonergic activities, which may contribute to the observed murIFN-gamma effect on locomotor activity.

274.12 THE EFFECTS OF ADENOSINE AGONISTS ON DISCRETE TRIAL AVOIDANCE BEHAVIOR IN RATS. P.M. Fritz* and D. Luttinger. Department of Pharmacology, Sterling-Winthrop Research Institute, Rensselaer, NY 12144

Adenosine agonists have been suggested to produce effects in animals that are similar to those produced by antipsychotic drugs (e.g. Heffner et al., The Pharmacologist 27:293, 1985 and 28:89, 1986 and Luttinger and Patton, Society for Neuroscience 12:911, 1986). The present studies were conducted to further explore the effects of adenosine agonists in a procedure that detects antipsychotic activity. Thus, the ability of adenosine agonists to selectively inhibit discrete trial avoidance responding was assessed as well as the effects of theophylline on adenosine agonist induced effects.

Male Sprague-Dawley rats were trained on an avoidance schedule to press a lever to avoid (or escape) electric footshock. The schedule consisted of a 30-second intertrial interval. During the intertrial interval, the number of lever presses were recorded but had no programmed consequences. Following the 30-second intertrial period a 10-second interval during which a continuous tone was presented ensued. When the tone was on, a lever press would result in termination of the tone and initation of another 30-second intertrial interval. A response during this component of the schedule is considered an avoidance response. If the rat did not press the lever during the 10 seconds when the tone was on, then the tone remained on and electric current (0.60 mA) was applied through the grid floor resulting in the rat being shocked. This component continued until the rat pressed the lever or 5 seconds elapsed. If the animal pressed the lever to terminate the shock, the response was considered an escape. Each session consisted of 50 such trials. Adenosine agonist and antipsychotic compounds were administered orally one hour (theophylline -45 min) before the session in a volume of 1 ml/kg.

The two antipsychotic drugs tested, chlorpromazine and clozapine, produced dose-related inhibiton of avoidance responding without affecting escape responding. Similarly, administration of the adenosine agonists 5'-N-ethylcarboxyamidoadenosine (NECA), 5'-N-methylcarboxyamidoadenosine (MECA) N^6-cyclohexyl adenosine (CHA), 2-chloroadenosine (CLA), N^6-cyclopentyladenosine (CPA) and the R- and S- isomers of phenyl isopropyladenosine (RPIA and SPIA) inhibited avoidance responding without affecting escape responding. Except for CLA (active at 55 mg/kg) and SPIA (inactive at 3 mg/kg), the other agonists were active at 3 mg/kg. Theophylline antagonized RPIA-induced inhibition of avoidance responding without affecting clozapine or chlorpromazine induced inhibition of avoidance responding.

These results extend the observations that adenosine agonists produce effects similar to antipsychotic drugs in a variety of procedures. Furthermore, the effects of the adenosine agonists, but not the antipsychotic drugs are antagonized by theophylline.

274.13 BEHAVIORAL AND BIOCHEMICAL EVIDENCE FOR NORADRENERGIC INVOLVEMENT IN THE STIMULANT EFFECTS OF AMFONELIC ACID. G.L. Robinson, B.K. Koe, and P.A. Seymour. Central Research Division, Pfizer, Inc., Groton, CT 06340

Tests that evaluate the ability of drugs to antagonize the behavioral effects of d-amphetamine, have become important preclinical tools for the evaluation of potential antipsychotic agents. D-amphetamine, however, has been shown to release norepinephrine (NE) as well as DA from central catecholaminergic neurons, and to enhance the metabolism of both NE (Kalisher et. al., J. Pharmac. Exp. Ther., 193:64, 1975) and DA (German et. al., J. Neural Trans. , 44:39, 1979). These nonspecific effects of d-amphetamine can pose problems when this agent is used for the measurement of in vivo DA antagonism, especially when the agents in question posess alpha1-antagonist properties. The psychostimulant amfonelic acid, however, has been reported to be selective for DA (McMillen, B.A. and Shore, P.A., J. Pharm. Pharmac., 30:464,1978), and may present an advantage over the use of d-amphetamine. The present studies examined the effects of the alpha1-adrenergic antagonist, prazosin (PRA), on d-amphetamine vs. amfonelic acid-induced locomotor stimulation in rats. D-amphetamine and amfonelic acid both induced dose-related stimulant effects from .32 - 1.78 mg/kg, s.c., and a mixed stimulant/stereotypy effect at 3.2 mg/kg, s.c., with remarkable similarity in all respects. It was found that PRA significantly attenuated d-amphetamine-induced (ID50 < 1 mg/kg) and amfonelic acid-induced (ID50 < 1 mg/kg, s.c.) locomotor activity at doses that had no effect on spontaneous locomotor activity. These findings are in agreement with those of Menon and Haddox (Neuropharm., 23:555, 1984) who reported that PRA antagonizes amfonelic acid-induced stimulation in mice. Finally, in contrast to the aforementioned selective dopaminergic effects of amfonelic acid, it was found that amfonelic acid inhibited the uptake of both DA and NE from rat brain synaptosomes (IC50=.05 and .09 uM respectively) more potently than did d-amphetamine (IC50=1.5 and .4 uM). These data do not support the hypothesis that amfonelic acid is more selective for dopaminergic systems than d-amphetamine.

274.14 CEREBRAL ACTIVITY IN THE DECORPORATE RAT: DRUG EFFECTS. C.H. Vanderwolf, G. Buzsaki, D.P. Cain, R.K. Cooley* and B.J. Robertson*. Dept. of Psychology, Univ. of Western Ontario, London, Canada, N6A 5C2.

Mikeska and Klemm (Lab Anim. Sci., 1975, 25, 175-179) suggested that decapitation of conscious animals causes pain and distress. In a reinvestigation of this, we implanted chronic recording electrodes transcortically in the hippocampus and neocortex in 29 rats. Polygraphic recordings were taken before and during decapitation. Hippocampal activity was filtered (usually 6-12 Hz), rectified and integrated as a measure of rhythmical slow activity (RSA). In waking rats atropine-resistant forms of hippocampal RSA and neocortical low voltage fast activity (LVFA) occur during voluntary movement. These patterns appear to depend on central serotonergic pathways (Vanderwolf, C.H., and Baker, G.B. Brain Research,1986, 374, 342-356). Atropine-sensitive forms of RSA and LVFA appear to depend on central cholinergic pathways and may occur during waking immobility and during anesthesia (Vanderwolf, C.H., and Robinson, T.E. Behav. Brain Sci., 1981, 4, 459-514). Thus, atropine-resistant (serotonergic) activation could be said to be restricted to the conscious state but atropine-sensitive (cholinergic) activation is not so restricted.

After decapitation at C1 in undrugged rats, neocortical activity (sometimes clear LVFA) persisted for 6-9 s. Hippocampal activity (usually some clear RSA) persisted for about 15 s. Following decapitation of ether anesthetized rats, similar patterns occurred but hippocampal activity persisted for about 24 s. When rats pretreated with atropine (50 mg/kg, i.p.) or scopolamine (5 mg/kg, s.c.) were decapitated, some RSA was present for 1-3 s but at a level of only 35% of what was seen during locomotion prior to decapitation. Hippocampal activity persisted for about 11 s. Clear LVFA was not observed. These results suggest that rats lose consciousness almost immediately when decapitated.

Further, previous anatomical studies have shown that dorsal root fibers from C1-C3 terminate no higher than C2. Trigeminal pain fibers terminate as low as C4 in rats (Torvik, A. J. Comp. Neurol. 1956, 106, 51-142). Therefore, following section at C1, little or no pain input can reach the brain.

Conclusion. Decapitation is probably virtually painless.

This research was supported by NSERC grants to D.P. Cain and C.H. Vanderwolf.

274.15 CENTER TIME: A TEST FOR ANXIOLYTIC ACTIVITY IN RATS. N.F.Nichols* and P.J.K.D.Schreur (SPON: L.T.Rutledge). CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

In a novel enclosure, rats and mice spend more time near the walls than in the exposed central space. Anxiolytic compounds increase the "center time," the amount of time spent away from the walls.

Method. Male Sprague-Dawley rats (10/group), 170-190g, were injected s.c. 20 min before the test. Activity was recorded for 5 min in the light in 16-beam Omnitech Digiscan Activity Monitors (16" x 16") with 16 regularly-spaced 1" holes in the plastic floors. Center time is the amount of time the rat spends more than 1/2" from the walls of the cage. Groups were compared by Student's t-test.

Results. Center time was significantly increased by diazepam and the proposed 5-HT1a agonists, buspirone and 8-OH-DPAT (8-hydroxy-dipropyl-aminotetralin). Chlordiazepoxide (10 mg/kg) tended to increase center time, but the effect did not reach statistical significance. Sodium pentobarbital increased center time at 10 mg/kg; haloperidol (0.1 -1 mg/kg) did not increase it at all.

In conclusion, center time is a predictor of anxiolytic efficacy of drugs.

274.16 PHENCYCLIDINE-INDUCED ATAXIA: COMPARISON OF MOVING BELT AND GAIT ANALYSIS. G.C. Haggerty and J.M. Johnson*, Battelle Columbus Division, Columbus, OH 43201 and College of Pharmacy, Ohio State University, Columbus, OH 43210.

Phencyclidine is a psychotomimetic agent which has experienced continual and increased popularity as a drug of abuse since the mid 1960's. Its effects in animals vary according to the species and dosage of drug used. In rodents, phencyclidine appears to exert a biphasic effect on behavior. Investigators have found that administration of phencyclidine to rats in the dose range of 2 - 7.5 mg/kg primarily produces excitation, while higher doses cause gross motor ataxia and central nervous system depression (Murray et al., Life Sci., 24:2217-2226, 1979; Haggerty et al., Toxicol. Appl. Pharmacol., 75:444-453, 1984). The objective of the present work was to determine the feasibility of measuring ataxia in rats following doses of phencyclidine lower than those which induce severe functional impairment and depression. Two methods were used: 1) Performance of a moving belt task, a well documented method for the measurement of ethanol-induced gait impairment, and 2) The assessment of footprint patterns during forward locomotion.

Phencyclidine at a dose as low as 2 mg/kg impaired performance of the moving belt task, suggesting the presence of drug-induced ataxia. At 4 mg/kg, impairment was present, but performance was also adversely affected by hyperexcitability and moderate stereotypy. Phencyclidine did not induce abnormal gait patterns, as measured by footprint analysis, although at the higher doses tested, an increase in step length was observed. This effect was attributed primarily to an increase in the walking speed of the animals due to the excitatory effects of phencyclidine. An ethanol-treated group, included in the study for comparison purposes, showed a clear increase in step width and a concomittant decrease in step angle, indicating a wider gait.

In summary, the results of this study showed that phencyclidine produced ataxia in the rat at doses that were clearly excitatory. Phencyclidine-induced ataxia was detected using a moving belt task, but not by gait analysis suggesting that the moving belt was a more sensitive technique for assessing drug-induced ataxia.

276 SYMPOSIUM. NEUROPEPTIDES/NEURAL SYSTEMS IN FEVER, INFLAMMATION AND IMMUNE RESPONSES. J.M. Lipton, Univ. of Tex. Hlth. Sci. Ctr. at Dallas (Chairperson); D.G. Payan, Univ. of California, Sch. of Med.; San Francisco, J.E. Blalock, Univ. of Alabama Med. Sch., Birmingham; D.L. Felten, Univ. of Rochester Sch. of Med.; T.L. Roszman, Univ. of Kentucky Sch. of Med.

Bidirectional interactions between the nervous system and the immune system were suggested initially by research on brain lesions and immunity and on immunologic modulation of neural function. Such interactions are now widely accepted, although the details remain to be established. Terms such as "neuroimmunomodulation", "immunotransmitters", "neuroendocrine-immune axis" reflect the recent development of ideas about parallels, shared chemical mediators and homeostatic relations between the nervous and immune systems.

Neuropeptides are believed to form a link between the two systems. For example, α-MSH, a naturally occurring CNS peptide, alters host responses such as fever and inflammation. Substance P, somatostatin and VIP are believed to be important to modulation of local immunological responses by the peripheral nervous system, via interaction between immunocompetent cells and the neuropeptides. Receptors for certain peptides, previously associated primarily with neuroendocrine function, occur on macrophages, lymphocytes and other tissues of the immune system. Lymphoid tissues such as the spleen, thymus and lymph glands are innervated by autonomic fibers. There is recent evidence that destruction of specific hypothalamic regions markedly alters immune function and that central administration of agents that impair neurotransmitter function can depress antibody responses. The aim of the symposium is to broaden understanding of relations between neuropeptides, neural structures and host responses through a review of these and other concepts. Investigators from several disciplines will outline this rapidly developing field of research.

277 SYMPOSIUM. DYNAMIC CHANGES OF SYNAPTIC STRUCTURE UNDER NORMAL AND EXPERIMENTAL CONDITIONS. D. Purves, Washington University (Chairperson); S. Smith, Yale University; C.H. Bailey, Columbia University; W.T. Greenough, University of Illinois.

The purpose of this symposium is to review recent work which indicates that synaptic connections in the mature nervous system are normally subject to substantial structural change. Steve Smith will begin the session by discussing the observation that the application of neurotransmitters (and other agents that alter levels of second messengers) can have marked effects on the structure of cultured mammalian neurons. These changes are particularly apparent among the growth cones and dendrites of such cells. Dale Purves will then describe the gradual changes in the configuration of synapses that have been observed in the peripheral nervous system of living mice when the pre- or post-synaptic elements of identified neurons are monitored over long periods (weeks to months). These observations, like those of Smith, depend on video-enhanced light microscopy and digital image processing; these techniques will also be discussed. Craig Bailey will then review recent work on the structural correlates of simple forms of learning in Aplysia. The emphasis of his talk will be on a specific set of identified synapses that he and his colleagues have used as a model system to explore a possible anatomical basis for the relationship between short- and long-term memory in Aplysia. Finally, Bill Greenough will discuss changes in synaptic numbers and dendritic branching patterns in the rat cerebral cortex elicited by exposure of adult animals to a complex environment, or to maze or motor training. He will also consider the possible relationship of these effects to long-term memory. These several lines of evidence suggest that structural changes in the arrangement of synaptic connections play an important part in the normal function of the mature nervous system.

OPIATES, ENDORPHINS AND ENKEPHALINS: PHYSIOLOGICAL EFFECTS IV

278.1 INTERACTIONS OF PROGLUMIDE WITH MORPHINE ANALGESIA. G.W. Pasternak and R.J. Bodnar. Dept. of Neurol. Memorial Sloan-Kettering Cancer Ctr., New York, NY 10021.

Proglumide (PRO) antagonizes cholecystokinin (CCK) receptors and blocks CCK effects. The demonstration that CCK acts as a physiological antagonist of opiate analgesia led to the subsequent finding that PRO potentiates analgesia induced by morphine and other opioid manipulations, effects which are blocked by naltrexone, but which do not display monotonic dose-response relationships. PRO also potentiated analgesia in morphine-tolerant rats. The following four experiments explored PRO-opiate interactions further. First, PRO (10 mg/kg, IP) potentiated morphine (2.5-20 mg/kg, SC) analgesia on the tail-flick test in mice both in terms of peak effects and duration of action without affecting basal latencies. Further, PRO (5 and 10 mg/kg, but not 1 mg/kg) potentiated morphine (5 mg/kg) analgesia. PRO dose-dependently reinstated morphine analgesia in mice 48 h after morphine pellet implantation, and increased morphine analgesia in mice 24 h after morphine pellet implantation. Naloxone (0.01-1.0 mg/kg, SC) eliminated analgesia induced by both morphine (5 mg/kg) and morphine paired with PRO (10 mg/kg). Naloxonazine (35 mg/kg, SC) eliminated morphine (5 mg/kg) analgesia and the PRO-induced potentiation. As the morphine dose was increased (20 & 30 mg/kg), naloxonazine antagonized both morphine analgesia and the PRO-induced potentiations; the former effect was more pronounced. Finally, PRO (5 ug) potentiated d-ser$_2$-thr$_6$-leucine enkephalin (DSTLE, 5 ug) analgesia following administration of both into the periaqueductal gray. Again, central PRO failed to alter baseline latencies. These data indicate that the ideal circumstances under which PRO-induced potentiations occur is when the opiate system is active, and that PRO is an effective enhancer of opiate actions without possessing intrinsic analgesic activity itself. (Supported by ACS Grant PDT 169).

278.2 CHANGING PATTERNS OF ANALGESIA INDUCED BY LATERAL VENTRICLE OR SPINAL INJECTIONS OF MORPHINE OR KETOCYCLAZOCINE IN DEVELOPING RATS. G. A. Barr, D. Miya and W. Paredes. Biopsychology Doctoral Program, Dept. Psychology, Hunter College, CUNY, NY, NY 10021, USA and Dept. Psychiatry, Albert Einstein College of Medicine, Bronx, NY 10461, USA.

Morphine and ketocyclazocine, prototypic but non-specific μ and k opioid receptor agonists, produce changing and different patterns of analgesia during development. Morphine's effects first appear at 3 days of age when a noxious stimulus is applied to the forepaw of a pup but not until 4-10 days later (depending of the stimulus and its intensity) when the same stimulus is applied to the tail. Ketocyclazocine's analgesic actions do not show this strong caudad pattern of development and emerge at about 5-7 days for both the forepaw and tail. Further, analgesia produced by morphine, but not ketocyclazocine, to a thermal noxious stimulus was attenuated by intraspinal depletion of serotonin by 5,7 DHT. It was proposed that morphine acts at a μ opioid receptor in brain that in turn activates some descending system (e.g. serotonin) in spinal cord to mediate its analgesic actions and that this descending system develops in a rostral to caudal direction postnatally. In contrast, ketocyclazocine may act at local spinal k receptors that mature at the same age at different segmental levels. To test this model and to further understand the anatomical organization of morphine (μ) and ketocyclazocine (k) induced analgesia, we injected each drug into the lateral ventricle or subdurally into the spinal cord. Lateral ventricle injections were done free hand by penetrating the cartilaginous skull with a 30 ga. needle. Accuracy of the injection was verified by dye. For the intraspinal injections, a catheter constructed of dialysis tubing was implanted under the dura on the dorso-lateral surface of the spinal cord. Morphine or ketocyclazocine were injected in doses that ranged from 1 to 10 μg. Pups were tested at various ages beginning at three days. Both thermal and pressure noxious stimuli were used. In each case, the stimulus produced a quick (< 1 second) and consistent withdrawal response at each age tested. When injected into the lateral ventricle of 3 day olds, morphine, but not ketocyclazocine, produced a potent analgesia for the forepaws. No increase in latency was seen for the hindpaw or tail. In 10 day olds, morphine's effects were seen in all three appendages but only when the mechanical stimulus was used. No analgesia was noted in the hindpaw or tail when the thermal stimulus was tested. Intraspinal injections of ketocyclazocine or morphine produced a different pattern. Neither drug produced a consistent developmental pattern of analgesia until 14 days of age. At this age, ketocyclazocine began to produce analgesia in the tail flick test, but at a relatively high dose (30 μg). The data from both sets of experiments imply that analgesia produced by intracerebroventricular administration of morphine acts through descending spinal circuits that are mature at the level of the rostral spinal cord by three days of age and develop caudally over several weeks. Further, the circuitry for mechanical and thermal stimuli differ with the latter maturing more slowly. In contrast, spinal segmental opioid receptors mediating opiate induced analgesia develop relatively late since neither drug produces much analgesia until into the second week of life.

278.3 EFFECTS OF STRESS AND β-FUNALTREXAMINE (β-FNA) PRETREATMENT ON MORPHINE (MS) ANALGESIA AND OPIOID BINDING IN RATS. J.U. Adams*[1], J.S. Andrews*[1], J.M. Hiller[2], E.J. Simon[2] and S.G. Holtzman*[1] (SPON: F.J. Gordon). [1]Dept. of Pharmacology, Emory University, Atlanta, GA 30322 and [2]Dept. of Psychiatry, New York University, New York, NY 10016.

Stress has been hypothesized to induce the release of endogenous opioids, which in turn may mediate such phenomena as stress-induced analgesia and stress-induced potentiation of MS analgesia. β-FNA is an irreversible opioid antagonist that presumably acts by alkylating the mu-opioid receptor. Receptors can be protected from alkylation in vitro if occupied by reversible receptor ligands. This study was essentially an in vivo protection experiment designed to provide further evidence for the stress-induced release of endogenous opioids and their subsequent action at opioid receptors. Adult male rats that were either subjected to restraint stress or unstressed were injected ICV with β-FNA (2.5 µg) or saline. Twenty-four hours later, subjects were tested unstressed for MS analgesia using the tail-flick assay or were sacrificed and numbers of opioid binding sites in brain were determined. [^{3}H]D-Ala^2-NMePhe^4-Gly(ol)enkephalin (DAGO) served as a specific ligand for mu-opioid receptors, and [^{3}H]bremazocine as a general ligand for all opioid receptors.

Pretreatments did not affect baseline tail-flick latencies 24 hr later but markedly altered the analgesic response to MS (3.0-17.5 mg/kg SC). Rats injected with saline while stressed were significantly less sensitive to MS than were their unstressed counterparts. β-FNA pretreatment antagonized MS analgesia in an insurmountable manner, as characterized by a downward shift to the right of the MS dose-effect curve when compared to the curve for saline-pretreated controls. Animals pretreated with β-FNA while stressed were significantly more sensitive to the analgesic effect of MS than were animals that received β-FNA while unstressed. This is consistent with the hypothesis that stress induces release of endogenous opioids which would protect opioid receptors from alkylation by β-FNA. β-FNA caused small and similar decreases in ^{3}H-DAGO binding in brain of both stressed and unstressed animals. Stressed rats injected with saline tended to have an increased number of [^{3}H]DAGO and [^{3}H]bremazocine binding sites compared to the other groups. This outcome may be revelant to the tolerance to MS analgesia caused by stress. Stress-induced tolerance probably served to limit the magnitude of the difference in the analgesic effect of MS between the stressed and unstressed animals treated with β-FNA. (Supported in part by Grants DA0017 and DA00541 and by RSA DA00008.)

278.4 THE ANALGESIA OF PREGNANCY INVOLVES A SPINAL OPIOID MECHANISM. A.R. Gintzler, W. C. Chan* and H.W. Sander*, SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203.

It has been demonstrated that during pregnancy and labor in rats and humans there is an opioid mediated elevation in the threshold for responsiveness to aversive stimuli which reaches a maximum at term. Acute administration of the opiate antagonist, naltrexone, into the lumbar intrathecal space of pregnant rats (day 20 of gestation) significantly reduces the threshold for reflexive jumping in response to electric footshock. The intrathecal administration of the inactive stereoisomer of a closely related narcotic antagonist, (+)naloxone, is devoid of any effect on pain threshold. No effect on pain threshold is observed following intrathecal saline administration to pregnant rats, intrathecal naltrexone administration to non-pregnant rats or following systemic administration of an intrathecally effective dose of naltrexone to pregnant rats. These data indicate that the analgesia observed during gestation is mediated, at least in part, via spinal opioid receptors which are activated by some aspect of the pregnant condition. Recent experiments suggest that this phenomenon involves both uterine and hormonal components. The former is suggested by experiments in which hypogastric neurectomy reduced by a factor of five the analgesia of pregnancy. A hormonal component is inferred by the observation that during pseudopregnancy jump thresholds are significantly higher than that observed in the period prior to its induction or following its offset.

278.5 EFFECTS OF NALOXONE AND U69593, A KAPPA OPIOID, ON HIBERNATION INDUCTION IN SUMMER ACTIVE GROUND SQUIRRELS BY "HIBERNATION INDUCTION TRIGGER" (HIT). T.-P. Su[1], D.B. Bruce*[2] and P.R. Oeltgen*[3]. [1]Neuropharmacol. Lab, NIDA Addiction Research Center, Baltimore, MD 21224, [2]Wheaton College, Wheaton, IL 60187 and [3]VA Hospital and Univ. of Kentucky, Lexington, KY 40511.

HIT is an endogenous plasma factor isolated from winter hibernating animals which, when injected, can induce hibernation in summer active ground squirrels (Dawe,A.R. and Spurrier,W.A., Science, 163:298, 1969; Oeltgen,P.R. et al., Prep. Biochem., 8:171, 1978). It was also observed that HIT, when given to monkeys, could induce inhibitory activities. Some of the inhibitory activities could be reversed by naloxone, raising a possibility that the action of HIT, at least in part, may involve opioid receptors. The present study examined this possibility by studying the effects of naloxone and a selective kappa opioid agonist U69593 (Lahti,R.A. et al., Europ. J. Pharmacol., 109:281, 1985) on HIT-induced hibernation in summer active ground squirrels (Citellus tridecemlineatus).

Drugs were delivered through osmotic minipumps which were implanted subscapularly into ground squirrels. Delivery rates were 1 mg/kg body weight/h for naloxone and 0.457 mg/kg/day for U69593. HIT was dissolved in saline and given to animals intrasaphenously. Animals were put into separate cages in the hibernaculum at 7°C. Hibernation frequency was determined by measurement of core temperature, respiratory rate and bouts of activity.

Injection of HIT caused summer active ground squirrels to hibernate. However, animals receiving naloxone hibernated four times less frequently than controls. After removal of pumps which were deliverying naloxone, reinjection of HIT into naloxone-treated animals caused them to hibernate in a frequency equivalent to controls receiving HIT. U69593 was tested to see if kappa receptors may be involved in the HIT-induced hibernation since naloxone is known to block mu, kappa and delta opioid receptors. U69593 did not cause hibernation in summer active animals, indicating that kappa opioid receptors may not be involved in the HIT-induced hibernation. However, unexpectedly, U69593 antagonized HIT-induced hibernation in summer active ground squirrels.

HIT depressed electrically stimulated twitches in a guinea-pig ileum myenteric plexus-longitudinal muscle preparation. However, the depression was not reversed by naloxone even at high doses (≥3000 nM).

Taken together, our results indicate that HIT may not by itself have opioid properties, but may induce hibernation as a potent precursor or releaser of endogenous opioid ligands.

278.6 MODULATION OF MESOLIMBIC DOPAMINERGIC PROJECTIONS BY BETA-ENDORPHIN IN THE RAT. S. Iyengar, H.S. Kim and P.L. Wood, Neuroscience Research, Research Dept., Pharmaceutical Division, CIBA-GEIGY Corp., Summit, N.J. 07901.

The basal forebrain limbic regions are known to receive a dense innervation of beta-endorphin from the arcuate N. and of dopamine from the ventral tegmental area. In addition, receptor autoradiography with [^{3}H]beta-endorphin has demonstrated a high density of putative epsilon or beta-endorphin binding sites in the N. accumbens. To study the interactions of these systems, we examined the potential modulation of the dopaminergic nerve endings in the N. accumbens and olfactory tubercle by beta-endorphin.

Intraventricular beta-endorphin stimulated dopamine metabolism in the N. accumbens and olfactory tubercle as evidenced by increased levels of DOPAC. These actions were dose dependent and reversed by the opiate antagonists naloxone and WIN 44441.

Since beta-endorphin has high affinities for mu, delta and epsilon receptors, we performed tolerance experiments to determine if a specific epsilon receptor was involved in the actions of beta-endorphin on DOPAC levels in the N. accumbens. For these experiments, 2 groups of animals were prepared: 1) tolerant to ascending doses of ip morphine and intraventricular DADLE; and 2) tolerant to an ascending dose of intraventricular beta-endorphin. Using this design, in the beta endorphin tolerant animals, morphine was still active while the actions of beta-endorphin were reduced. In the morphine/DADLE tolerant animals, beta-endorphin was still active while the action of morphine and DADLE were reduced.

These data are therefore suggestive of an epsilon mediated action of beta-endorphin in the rat N. accumbens.

278.7 **MU ANTAGONIST PROPERTIES OF KAPPA AGONISTS IN CENTRAL CONTROL OF BLADDER MOTILITY IN RATS.** Frank Porreca, Linda Nunan and Russell J. Sheldon. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724

Previous studies have shown that intracerebroventricular (i.c.v.) mu and delta opioid agonists inhibit volume initiated, spontaneous micturition contractions in the rat, while kappa agonists do not. (Dray and Metsch, Eur. J. Pharmacol. 104: 47, 1984). Recent findings from a number of laboratories have shown that kappa agonists block some, but not all, of the pharmacological actions of agents that have been classically termed mu agonists (Wood, Drug Dev. Res. 4: 429, 1984; Holaday et al., Fed. Proc. 44: 2860, 1985). In the present study, possible mu antagonist properties of 3 putative kappa agonists, U50,488H (U50), tifluadom (TIF) and ethylketocyclazocine (EK), as well as dynorphin-(1-17)(DYN) were tested against 9 mu agonists of various structure. Female, Sprague-Dawley rats were anesthetized with ketamine HCl (100 mg/kg, i.p.) and supplemented with urethane (1.2 g/kg, i.p.) as needed. The bladder was catheterized via the urethra and filled with warm saline until spontaneous contractions occurred as a result of central reflex activity. All compounds were were given i.c.v., with antagonists given 15 min prior to agonists. Administration of mu agonists [D-Ala^2, NMPhe^4, Gly-ol]enkephalin (DAGO, 0.01 nmol), [NMPhe^3, D-Pro^4]enkephalin (PL017, 0.03 nmol), morphine (0.08 nmol), normorphine (0.3 nmol), sufentanil (0.002 nmol), etorphine (0.004 nmol), phenazocine (17 nmol), meperidine (176 nmol) or the delta agonist, [D-Pen^2, D-Pen^5]enkephalin (DPDPE, 15 nmol) all inhibited contractions for periods of 20-30 min. The i.c.v. kappa agonists U50 (22 nmol), EK (3 nmol), TIF (3 nmol) and DYN (0.23 nmol) were unable to alter bladder activity. Unlike U50, higher doses of EK, TIF and DYN produced consistent suppression of bladder contraction. Pretreatment with sub-agonist doses of the kappa agonists consistently blocked the agonist effects of morphine and normorphine, but failed to antagonize DAGO, PL017, phenazocine, meperidine and DPDPE. Mu agonist effects of etorphine and sufentanil were antagonized by U50 and DYN but unaffected by EK and TIF. In addition, administration of U50 during a morphine-induced bladder shutdown resulted in either an immediate recovery of bladder activity or a shortened duration of action. Furthermore, pretreatment with U50 produced a parallel, rightward shift of the morphine dose-response curve with similar efficacy, suggestive of a competitive interaction. These findings may reflect either (a) the presence of mu-receptor subtypes (isoreceptors) within the central nervous system that are differentially antagonized by kappa agonists, or (b) differences in intrinsic activity of mu agonists at a common receptor, such that less efficacious compounds are more susceptible to antagonism by kappa agonists. Supported by NS 23710 and DK 36289.

278.8 ACTION OF OPIOIDS ON PERIPHERAL SENSORY NERVES: STUDIES USING THE RAT INFRAORBITAL NERVE MODEL. H.G. Hassan, H. Renck and C.W.T. Pilcher (SPON: S.R. Choudhury) Depts. of Surgery and Pharmacology, Faculty of Medicine, P.O. Box 24923 - Safat, Kuwait.

Opiates exert their profound analgesic effects by activating specific receptors in the CNS at spinal and supraspinal loci. Recent studies have shown that opiates can produce intense and prolonged analgesia following intrathecal and epidural administration but of the opioid drugs used clinically, only pethidine has been shown effective as a sole agent for surgery. This opioid is relatively selective for kappa-receptors, which are richly distributed in the spinal cord. However, at high doses pethidine also has a local anaesthetic action in peripheral nerves. Thus its spinal efficacy may result from conduction block, activation of opioid receptors or a combination of the two. Using the rat infraorbital model (Haggag, H.G. et al Acta Anaesthiol. Scan. 29: 375 - 379, 1985) we have examined further the ability of pethidine and selected opioids to produce peripheral nerve block. Pethidine rapidly produced abolition of nociceptive responses, the duration and degree of which was dependent on opioid doses over the range 1.0 - 5.0 mg/kg. Doses below 1.0 mg/kg did not produce a significant effect whilst at 5.0 mg/kg inhibition of responding was complete. Neither intravenous nor local administration of naloxone at 0.25 - 1.0 mg/kg had any effect on the pethidine-induced analgesia. All of the other opioid agonists examined were without effect in this model. It was concluded that the pethidine-analgesia was not mediated by an opioid receptor mechanism but by inhibition of conduction in the infraorbital nerve by a local anaesthetic action.

This work was supported by Grants MDS 181 and MR 015 from Kuwait University Research Council.

278.9 OPIATE DRUGS ALTER OPIOID PEPTIDE GENE EXPRESSION. J. Ryan*, R. Hanig*, J. Schwartz[1], J. Douglas[2] and G.R. Uhl. (SPON: R. Ackerman). Dept. of Neurology and Howard Hughes Medical Institute, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114. [1]LNGR, NINCDS, Bethesda, MD 20892. [2]IABS, Portland, OR 97201.

Opiate drug-induced alterations in function of brain circuits utilizing opioid peptides have been sought to explain the sequelae of long-term administration of opiate agonists, including tolerance and dependence. Nevertheless, there is still not agreement about the mechanisms responsible for these time-dependent concomitants of opiate drug administration. Since expression of several neuropeptide genes can vary in response to drug-induced alterations in neural function, we have examined the influences of opiate drugs on regional expression of the principle brain opiate peptide genes.

Animals were treated for 5 days with a regimen of increasing doses of morphine free base pellets implanted subcutaneously, brains rapidly removed, total striatal RNA prepared and subjected to quantitated Northern analyses. Blots were hybridized with cRNA probes directed against enkephalin, dynorphin, and somatostatin mRNAs, and with oligonucleotide cDNAs complementary to endogenous actin and tubulin mRNAs as well as B-globin mRNA added as a recovery marker.

Levels of both preproenkephalin and preprodynorphin mRNAs in the rat striatum are reduced by 30-40% following treatment with a 5 day schedule of ascending doses of morphine administered as subcutaneously-implanted pellets. These mRNA levels remain below normal during the animals' expression of withdrawal symptoms. Normal levels of methionine-enkephalin immunoreactivity are found at the end of treatment. Conversely, treatment with the opiate antagonists naloxone or naltrexone increased expression of preproenkephalin and preprodynorphin mRNAs to more than 200% of control levels. These changes in gene expression display the appropriate directions and temporal features to fit with a model of opiate tolerance and dependence.

278.10 **STUDIES ON THE PERIPHERAL ANTISECRETORY EFFECT OF OPIOIDS IN THE MOUSE SMALL INTESTINE.** R.J. Sheldon*, M.E. Malarchik*, F. Porreca and T.F. Burks. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

In recent years, the intestinal epithelia of several species have been suggested to be a possible site of opiate antidiarrheal actions. In the present study, we have investigated the actions of receptor-selective opioids on transepithelial potential difference (PD) and short-circuit current (Isc) in the small intestine of the mouse. Whole jejunal segments from male ICR mice (30-40 g) were cut open into flat sheets and mounted in Ussing chambers: mucosal and serosal surfaces were bathed in standard Krebs-Ringers media (pH 7.4, aerated with 95% O_2/5% CO_2) containing 10 mM mannitol or 10 mM glucose, respectively. Initially, PD and Isc gradually decreased with time, reaching a plateau after 30 min. Basal values (mean $\pm$ s.e.m.; N=30) at 30 min were: PD (-2.4 $\pm$ 0.2 mvolt; serosal positive), Isc (76.7 $\pm$ 4.6 uamp/cm^2) and tissue resistance (Rt)(30.6 $\pm$ 1.3 ohms·cm^2). Most tissues exhibited slow oscillations in PD (0.1-0.3 mvolt amplitude) and Isc (15-20 uamp/cm^2 amplitude) after 10 min in vitro. Tetrodotoxin (TTX) (0.1 uM; serosal media) caused a rapid reduction in basal PD and Isc, and eliminated the spontaneous oscillations of PD and Isc, suggesting tonic neural control of basal intestinal transport. In TTX-pretreated tissues, carbachol (10 uM) and theophylline (1 mM) produced prominent secretory responses (ΔIsc > 100 uamp/cm^2 increase), indicative of intact epithelia. Serosal addition of atropine (1-10 uM), however, had no effect on basal PD or Isc. The delta-selective opioid agonist [D-Pen^2, D-Pen^5]enkephalin (DPDPE) (0.003-1 uM) produced a sustained concentration-related decrease in PD and Isc when added to the serosal media. At higher concentrations, [D-Ala^2, NMePhe^4, Gly-ol]enkephalin (DAGO) (0.1-3 uM), a mu receptor agonist, and U50,488H (>3 uM), a kappa receptor agonist, caused similar reductions in PD and Isc when added to the serosal media. All of the opioid agonists abolished spontaneous oscillations in PD and Isc. Antisecretory effects of DPDPE (0.1 uM) and DAGO (1 uM) were reversed by naloxone (1 uM) and ICI 174,864 (1 uM), a delta receptor antagonist; effects of U50,488H were not reversed at these antagonist concentrations. Pretreatment of tissues with TTX (0.1 uM; serosal media) abolished the effect of DPDPE (10 uM). In contrast, DPDPE (1 uM) produced a prominent antisecretory effect in the presence of atropine (10 uM); 10 uM carbachol was completely blocked by this dose of atropine. These data suggest that delta opioid receptors are involved in the regulation of fluid and electrolyte transport processes in the small intestine of the mouse. Furthermore, peripheral regulation of transport by opioids appears to be mediated through non-cholinergic neuronal mechanisms. (Supported by NS 23710, DA 02163 and DK 36289.)

279.1 CHOLINERGIC MECHANISMS IN MOTONEURONS OF LOBSTER CARDIAC GANGLION. Joseph E. Freschi and David R. Livengood. Neurology Dept., Emory Univ., Atlanta, GA 30322 and Physiology Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814.

We studied the post-synaptic effects of acetylcholine (ACh) and nicotinic and muscarinic agonists on large motoneurons in the cardiac ganglion of Homarus americanus. Neurons were penetrated with one or two microelectrodes and studied under current- and voltage-clamp. To improve space-clamp, axons were ligated within several hundred micrometers of the soma (Tazaki & Cooke, J. Neurophysiol., 56:1739, 1986). At resting membrane potentials of -50 ± 5 mV, ACh caused a dose-dependent membrane depolarization at concentrations between 0.01 and 1 mM. Nicotinic responses were variable among ganglia. Concentrations between 0.1 and 1 mM were required to cause maximum depolarization, and these responses were invariably less than half the amplitude of the responses elicited by similar doses of ACh. Muscarine, however, in the same dose range, caused depolarizations 60-90% as large as those caused by ACh. Under voltage-clamp, muscarinic agonists caused inward currents of 1-3 nA. The response became larger at more positive and smaller at more negative holding potentials; no response to muscarinic agents could be obtained at potentials negative to -100 mV. We were unable to demonstrate a reversal potential for the agonist-induced current, even after shifting E_K to more postive potentials by increasing $[K]_o$ to 50-150 mM (normal 15 mM). The response amplitude was increased when $[K]_o$ was decreased to 1.5-5 mM. We examined the effect of cholinergic agonists on voltage- and time-dependent currents and could not identify a specific current uniquely affected by the drugs. Often no change in membrane conductance could be seen; the I-V curves before and after agonist were parallel. When a change was seen, it appeared to involve a reduction in leak current. The net effects of this change were a reduction in amplitude of total inward current following hyperpolarizing steps, and an enhancement of inward calcium current and reduction of total outward current following depolarizing steps. The agonist-induced inward current was blocked by 50 mM tetraethylammonium and 10 mM barium, but not by 10 mM 4-aminopyridine, 5 mM cesium, or 5 mM manganese.

We conclude that in motoneurons of lobster cardiac ganglion (1) ACh acts on both nicotinic and muscarinic receptors, but the muscarinic effect is predominant; (2) the muscarinic agonist-induced inward current is caused in part by a reduction of a resting potassium conductance; and (3) either the affected potassium conductance may not be voltage- and time-dependent or it may be generated in unclamped regions of the dendrites not excluded by axonal ligation. (Supported by NIH grant NS22628).

279.2 VASOACTIVE INTESTINAL POLYPEPTIDE MOBILIZES INTRACELLULARLY BOUND CALCIUM BY GENERATING INOSITOL TRISPHOSPHATE TO CAUSE EXOCYTOTIC SECRETION OF CATECHOLAMINES FROM RAT ADRENAL GLAND. R.K. Malhotra*, T.D. Wakade* and A.R. Wakade (SPON: K. Koizumi), Department of Pharmacology, SUNY Health Science Center at Brooklyn, N.Y. 11203

Secretion of catecholamines from the rat adrenal gland has been believed to be regulated by the activity of splanchnic neurons. Splanchnic neurons release acetylcholine, a principal transmitter, which activates cholinergic receptors of the chromaffin cells to secrete catecholamines. Our most recent study shows that in addition to acetylcholine some other non-cholinergic substance(s) might be released from splanchnic neurons to induce catecholamine secretion (Malhotra & Wakade, J. Physiol. 383, 639, 1987). At present the biochemical nature of such substance(s) has not been identified. Among various peptides tested (enkephalin, enkephalinamide, etorphine, etc.) vasoactive intestinal polypeptide (VIP) proved to be as potent as acetylcholine in evoking the secretion of catecholamines by directly stimulating the chromaffin cells (Malhotra & Wakade, J. Physiol., in press) Present study was aimed at determining the role of Ca in VIP-induced secretion of catecholamines. We now show that omission of Ca from the perfusion medium had almost no effect on VIP-induced secretion; however, addition of 1 mM EGTA to Ca-free medium abolished the secretion. Stimulation with VIP did not result in a net increase in Ca^{45} uptake, and the uptake was not modified by phorbol 12,13-dibutyrate, a protein kinase C activator. All these results were very similar to those obtained with muscarine. In contrast, nicotine-evoked secretion was associated with an increase in Ca^{45} uptake and this effect was further enhanced by the phorbol ester. VIP (0.3 to 10 μm) and muscarine (30-100 μm) produced time- and concentration-dependent increase in the production of ^{3}H-inositol phosphates. A VIP antagonist, Ac-Tyr-hGRF (10 μM), reduced VIP-induced ^{3}H-inositol phosphates production by about 70%. The production of ^{3}H-inositol phosphates by VIP and muscarine occured in Ca-free and EGTA medium. Although nicotine produced a brisk secretory response, there was no increase in ^{3}H-inositol phosphates. These findings suggest that inositol 1,4,5-trisphosphate generated upon activation of VIP or muscarine receptors is linked to exocytosis through mobilization of intracellularly bound Ca ions.

279.3 PROTEIN KINASE-C SUPPRESSES OUTWARD K^+ CURRENTS IN ISOLATED RAT VENTRICULAR MYOCYTES. M. Apkon, R. Miyake*, R. Gross*, J.M. Nerbonne. Departments of Pharmacology and Internal Medicine, Washington Univ. Sch. of Med., St. Louis, MO 63110

Previously, we reported the specific suppression of depolarization-activated outward K^+ currents in rat ventricular myocytes by α_1-adrenergic agonists. As phorbol esters and diacylglycerol analogues mimicked the effects of α_1-agonists, we postulated that protein kinase-C (PKC) activation underlies K^+ current suppression. In order to evaluate the involvement of PKC, we have examined the effects of exogenously supplied PKC on outward K^+ currents directly. PKC was purified from rat brain (Kitano et. al. (1986) Meth. Enzym. 124:349-353) and stored at -80°C in 10% glycerol with (in mM): 20 Tris; 0.5 EGTA; 0.5 EDTA; 10 β-mercaptoethanol. For physiological experiments, the PKC solution was dialyzed for 4 hours at 4°C against Tris (2mM) buffered KCl (135 mM) with 0.5 mM EGTA; after enzyme activity was assayed, the kinase was diluted 1:1 in pipette recording solution (see below) to a final PKC concentration of 15 μg/ml.

With Co^{2+} (5 mM) and TTX (20 μM) in the bath to block voltage-gated inward Ca^{2+} and Na^+ currents, whole-cell K^+ currents were measured during depolarizations to potentials positive to -30 mV from a holding potential of -60 mV; recording pipettes contained (in mM): 135 KCl; 10 EGTA; 10 HEPES; 5 Glucose; 3 Mg-ATP; 0.5 Tris-GTP. After control K^+ currents were measured, a whole-cell recording was established with a second pipette, which contained the diluted PKC solution, and K^+ currents were remeasured. The waveforms of K^+ currents after introduction of the PKC-containing pipette were then compared with the control K^+ currents measured in the same cell. In all experiments, the accuracy of the voltage clamp was monitored with the PKC-containing pipette and only data obtained from cells in which this pipette faithfully recorded a 20 mV voltage-step applied to the first pipette were accepted; this criteria minimized errors caused by damage from the second pipette. In all cells examined (n=3), peak outward K^+ currents, evoked by depolarizations to +50 mV, were reduced following introduction of the PKC-containing pipette. The absolute magnitude of the current suppression, as well as the timecourse of this effect, however, varied markedly among cells; mean K^+ current suppression was 22%. In contrast, no effects on K^+ currents were seen when the second pipette contained heat-inactivated PKC (n=2). We conclude that the direct intracellular application of (brain) PKC, at least in a qualitative sense, mimics the effect of α_1-agonists on outward K^+ currents in rat ventricular myocytes. These results, therefore, lend additional support to our postulate that the effects of α_1-adrenergic receptor activation in ventricular myocytes are mediated via a mechanism involving PKC-dependent protein phosphorylation. 279.4 SELECTIVE EFFECTS OF PHORBOL ESTERS ON CA AND K CURRENTS IN HIPPOCAMPAL NEURONS. D. Doerner, T.A. Pitler and B.E. Alger, Dept. Physiol., Univ. Maryland Sch. Med., Balto., MD 21201.

Several neurotransmitters induce polyphosphoinositide breakdown and activation of protein kinase C (PKC). PKC regulates a number of ionic conductances in peripheral and invertebrate nervous systems, but there is less evidence regarding its effects in mammalian CNS. The hippocampus is rich in PKC and is therefore a good model for studying its role in the brain.

We have used the whole-cell voltage-clamp technique to study the effects of PKC activation on K and Ca currents in hippocampal neurons acutely dissociated from guinea pig (Kay and Wong, 1986, J. Neurosci. Meth. 16:227-38) and tissue cultured from fetal rat (Segal, 1983, J. Neurophys. 50:1249-64). Using phorbol esters to activate PKC, we have asked whether specific current components are subject to PKC regulation.

Electrodes filled with $CsMeSO_3$, ATP and leupeptin were used to identify distinct Ca current components in pyramidal cells. Ca current was identified as a TTX- and low-Na-insensitive inward current also carried by Ba and blocked by Cd. We observed a low-voltage-activated, transient current and a high-voltage-activated current with a large, rapidly inactivating phase and a smaller, slowly inactivating phase. The low-voltage-activated current was seen reliably in tissue culture. Both phases of high-voltage-activated current were seen in acutely dissociated and tissue-cultured neurons, and may correspond to the N and L currents identified in other preparations. Phorbol esters markedly reduced the N-like component, but reduced the L-like component only slightly. The low-voltage-activated transient current, which resembles the T current identified by others, was unaffected.

Using $KMeSo_4$-filled electrodes, we observed large outward currents with both rapid transient and late components. The late current had a large, voltage-dependent component (IK), and a cadmium-sensitive, slowly developing late component (I_{AHP}). When depolarizing voltage-clamp pre-pulses were used to inactivate the rapid transient current, I_K was seen to activate rapidly. Phorbol esters reduced both I_K and I_{AHP} without affecting transient current. Leakage and holding currents were unchanged.

All effects of phorbol esters could be reversed with washing.

We suggest that these effects are due to block of I_K rather than enhancement of calcium influx or block of other currents. I_{AHP} reduction may be due in part to reduction of I_{Ca}, although a direct effect of phorbol esters on IAHP cannot be excluded at present. (Supported by NIH grant NS22010)

279.5 THE LATE IPSP OF HIPPOCAMPAL NEURONS MAY BE CONTROLLED BY A GTP-BINDING PROTEIN THAT IS NOT COUPLED TO ADENYLYL CYCLASE. R.H. Thalmann, D. Grenet* and L. Birnbaumer*. (Spon: B. Lonsbury-Martin) Depts. of Cell Biology, Physiology and Biophysics and Program in Neuroscience. Baylor College of Medicine, Houston, TX 77030.

Orthodromic synaptic stimulation of hippocampal and other forebrain neurons is followed by an early IPSP (peak within 20msec following the stimulus) and then by a late IPSP (peak within 200 msec) that is associated with a potassium conductance and may be mediated by GABAb receptors. We report that the potassium conductance of the late IPSP is blocked by pertussis toxin, an inactivator of one or more GTP-binding proteins (G-proteins) other than Gs. Synaptic potentials were elicited in CA3 neurons of the rat hippocampal slice by an electrical pulse (50usec) to the mossy fiber pathway. When the stimulus was at threshold for elicitation of a postsynaptic action potential the early IPSP conductance was 140 nano Siemens (nS) and reversed at -75 mV, while the late IPSP conductance was 15nS and reversed at -97mV. When the hippocampus was injected with pertussis toxin (2.5ug, 1-3 days prior to recording), no change in the early IPSP could be detected, but the late IPSP conductance was reduced to 2.5nS, and reversed at -76mV. Mossy fiber EPSP's that exceeded control values did not reinstate that late IPSP in toxin treated cells. For example, in control cells, when the membrane potential was set at -95mV, a threshold stimulus was associated with a EPSP slope of 20mV/msec, while the most intense stimulus produced an EPSP with a rise time of 40mV/msec. The late IPSP conductance varied from 15 to a maximum of 30nS over this same range of EPSP slopes. By contrast, in toxin treated hippocampi, the EPSP slope varied similarly from 20-40mV/msec, but the late IPSP conductance increased from 2nS to only 6nS. The toxin treatment also reduced the response to the GABAb ligand baclofen (5um perfused 5-15 mins) but failed to affect the response to THIP (20um), a ligand for the GABAa receptor mediating the early IPSP. Control and toxin treated slices adjacent to those used for recording were frozen immediately after slicing for a subsequent assay of ADP ribosylation of G-proteins The toxin treatment had ADP-ribosylated a significant, but not total, portion of the total toxin substrate. Although pertussis toxin inactivates Gi, perfusion of forskolin (25um for 30-200mins) under conditions that increase cyclin AMP several fold in slices had no effect upon the late IPSP, suggesting that the late IPSP did not depend upon inhibition of cyclic AMP synthesis. By analogy with more direct observations on a similar potassium conductance that is gated by muscarine in cardiac cells (Yatani et al., Science 1987, Vol. 123-207) the late IPSP could depend upon a G-protein (Gk) that is directly linked to the potassium conductance of the late IPSP. Supported by NIH grant NS21713 and DK-19318.

279.6 PIRENZEPINE BLOCKS CALCIUM- AND PI-TURNOVER-RELATED MUSCARINIC ACTIONS IN RAT HIPPOCAMPUS. B. E. Alger and M. McCarren. Dept. Physiol., Univ. Maryland School of Medicine, Baltimore, MD 21201.

Muscarinic cholinergic agonists have a variety of effects on mammalian CNS neurons. Different receptor-effector mechanisms are probably involved, but there are few physiological data on this topic. Some muscarinic agonists may act via protein kinase C. Group A agonists (e.g., carbachol) dramatically increase PI turnover; group B agents (e.g., oxotremorine) are only weak partial agonists for this effect. Phorbol esters that activate protein kinase C and group A muscarinic agonists block the actions of adenosine and other G-protein-linked neurotransmitters; group B agonists are much less effective (Worley et al., PNAS, 1987, in press). Groups A and B are equipotent on other measures. Muscarinic receptors also differ in their sensitivity to block by pirenzepine (PRZ).

We are investigating the relationship between muscarinic effects associated with PI turnover and PRZ sensitivity. We now report that PRZ (1 uM) prevents or reverses carbachol's (50 uM) blockade of adenosine. At 1 uM, PRZ does not affect the plateau of carbachol-induced depolarization, whereas 10-20 uM PRZ strongly antagonizes the depolarization.

In control saline plus TTX, the bath-applied carbachol depolarization has an initial rapid rise. PRZ (1 uM) markedly slows dV/dt. "Low Ca" (nominally zero mM)/2 mM Mn saline slows dV/dt to the same extent as PRZ. The dV/dt of the oxotremorine depolarization is slow in control saline and is hardly affected by either low Ca/Mn or PRZ. Carbachol and oxotremorine produce similar plateau depolarizations.

We conclude that PRZ-sensitive muscarinic actions are associated with PI turnover. They are also associated with a transient Ca-dependent membrane depolarization. PRZ-insensitive receptors mediate maintained membrane depolarization. (Supported by NIH grant NS22010)

279.7 $GABA_A$ RECEPTORS OF HIPPOCAMPAL NEURONS: INTRA- AND EXTRACELLULAR REGULATORY FACTORS. Armin Stelzer* & Robert K.S. Wong (SPON: L.W. Haynes) Dept. Neurology, CPS Columbia University New York, N.Y. 10032.

There is evidence that GABA functions as a neurotransmitter in the CNS and that the GABAergic transmission is highly modifiable. We examined the postsynaptic action of GABA in acutely isolated cells prepared from the CA1 region of the guinea-pig hippocampus (Kay & Wong 1986). Whole-cell voltage-clamp experiments were carried out using low resistant pipettes (2-5 MOhm). K+-currents were suppressed by external TEA, Cs & 4AP, and internally by Tris. GABA (100 uM) was applied by short pressure pulses (10-25 ms) of low frequency (0.01 Hz) to prevent accumulative desensitization. We observed that the GABA-induced outward-current progressively decreased during intracellular recording down to about 10% of the control value after 10 minutes. This spontaneous run-down of the GABA-current was probably caused by alteration of the intracellular content by dialysis and exchange through the recording pipette. The inclusion of a suitable level of free Mg++ and ATP was critical for the maintainence of stable GABA responses.

The stabilized GABA current allowed us to examine the interaction of the GABA receptor with other transmitter agents. Glutamate (10 uM in the perfusate) increased the peak amplitude of the GABA-current to up to 160% over control. Other structurally related compounds such as NMDA and, surprisingly, the NMDA receptor antagonist APV produced a similar enhancement of the GABA-current with comparable efficacy. Short duration hyperpolarizing voltage-pulses applied to estimate the leak conductance showed that the GABA-induced conductance was also proportionally increased in the presence of the modulating agent . Thus the enhancement of GABA-current cannot be attributed to changes in the reversal potential.

The results show that the efficacy of the GABA receptor can be modified by physiologically-occurring agents at both extra- and intracellular membrane sites. The data are particularly interesting in that the modification of GABA-ergic transmission may contribute to long-term changes in the activities of the neuronal circuit following tetanic stimulation.

279.8 BLOCKADE AND DESENSITIZATION OF A RAPID SEROTONIN RESPONSE IN NG108-15 CELLS AND MOUSE HIPPOCAMPAL NEURONS, Jerrel L. Yakel* & Meyer B. Jackson, Dept. of Biology, UCLA, Los Angeles, CA.

Serotonin(5-HT) produces a rapid depolarizing and desensitizing inward current in NG108-15 cells(a neuroblastoma X glioma hybrid cell line) [Christian et al, Brain Res. 147:261(1978)]. A similar fast desensitizing inward current is one of 3 different 5-HT responses observed in primary cultures of mouse striatum [Yakel et al, Soc. Neurosci. Abstr. 12:726, 1986] and hippocampus, being observed in less than 10% of these neurons.

5-HT produced a fast inward current in 86%(148 cells) of NG108-15 cells. This inward current is associated with a large conductance increase with a reversal potential of 6.5$\pm$4.1 mV(7 cells). Metoclopramide(1 μM), curare(1 μM), and spiperone(20 μM) reversibly blocked this response. 200 μM methysergide reduced this response by 42$\pm$7% (3 cells), while 20 μM methysergide had no effect. The 5-HT agonist 5-methoxy-N,N-dimethyltryptamine did not activate this response. Cobalt (1 mM) was found to reduce the amplitude by 67$\pm$9% (6 cells). This effect probably is not due to a decreased calcium influx, because a 0 mM calcium/2 mM EGTA bath solution did not alter the response. Therefore, the cobalt effect may be the result of a direct block of the 5-HT-gated channel. The pharmacology of this response in NG108-15 cells and cultured hippocampal neurons was found to be similar in the following respects: 1) metoclopramide and curare(both at 20 μM) are antagonists; 2) methysergide(20 μM) has no effect; 3) 5-methoxy-N,N-dimethyltryptamine(10 μM) has no effect. In addition, the time course and reversal potential of these two responses is quite similar. Thus, NG108-15 cells appear to be an excellent system for studying an apparent neuronal response.

The time course of desensitization during continuous 5-HT application(50 μM) in NG108-15 cells was found to be variable between cells, the mean time to 50% desensitization averaging 2.0$\pm$2.6 sec(64 cells). The rate of desensitization during individual experiments usually decreased with time, possibly due to intracellular dialysis by the patch electrode. The time course of desensitization at the beginning of an experiment was usually biphasic, with a fast and a slow component. Several minutes into an experiment, desensitization was monophasic, with only a slow component. Forskolin (30 μM), an adenylate cyclase activator, was found to increase the rate of desensitization; the time to 50% desensitization decreased by 28$\pm$10% (4 cells) after forskolin treatment. The rate of desensitization of the 5-HT response in these cell types may be regulated by phosphorylation.

279.9 PHARMACOLOGICALLY DISTINCT ACTIONS OF 5-HT ON SINGLE NEURONS IN RAT HIPPOCAMPUS. R. Andrade and R.A. Nicoll. Dept. of Pharmacol., St. Louis Univ. Sch. of Med., St. Louis, MO 63104 and Depts. of Pharmacol. and Physiol., Univ. of Calif., San Francisco, San Francisco, CA 94143.

While multiple receptors for 5-HT have been postulated to exist on the basis of binding studies, their relationship to the electrophysiological actions of this amine at the cellular level remain unclear. We have reexamined the actions of 5-HT in the hippocampus using intracellular current-and voltage-clamp recordings in in vitro rat brain slices.

Administration of 5-HT to pyramidal cells of the CA1 region elicits a hyperpolarization which sags during prolonged administration. This hyperpolarization subsides upon removal of the 5-HT and is followed by a longer lasting depolarization which is associated with a decrease in the calcium-activated afterhyperpolarization (AHP). The hyperpolarization exhibits the pharmacological profile of a 5-HT_{1A} binding site and results from a selective increase in potassium permeability. Upon blockade of the hyperpolarization with spiperone or pertussis toxin, the remaining actions of 5-HT could be examined in isolation. The depolarizing action of 5-HT, exhibited a dose-response curve similar to that of the hyperpolarization but the response had a slower time course, and was mediated by the closure of an as yet unidentified potassium conductance. The decrease in the AHP was closely associated temporally with the depolarization. It did not involve reductions in the calcium spike and, as previously reported, it decreased the ability of the cells to show spike frequency adaptation. Both the depolarization and the decrease in the AHP were mediated by 5-HT receptors which do not appear to conform to any of the previously described 5-HT binding sites.

When cell excitability was examined using weak depolarizing current pulses, 5-HT causes an initial decrease in excitability which was followed by a long lasting increase in excitability upon removal of the 5-HT. With strong depolarizing pulses, however, only excitatory actions of 5-HT were evident despite the hyperpolarization. This is due to the blockade of spike frequency adaptation which occurs during and after the hyperpolarization. Thus the overlapping and opposing actions of 5-HT results in an unusual alternation in the input-output curve of the pyramidal cell.

279.10 PERTUSSIS TOXIN BLOCKS AUTORECEPTOR-MEDIATED INHIBITION OF DOPAMINERGIC NEURONS IN SUBSTANTIA NIGRA AND SEROTONERGIC NEURONS IN DORSAL RAPHE NUCLEUS. R.B. Innis and G.K. Aghajanian. Dept. of Psychiatry, Yale University Sch. of Med., New Haven , CT 06508.

Guanine nucleotide binding proteins (G or N proteins) not only act as signal transducers resulting in stimulation (G_s) or inhibition (G_i) of the synthesis of the classical second messenger cAMP but may also have direct actions on ion channels which are independent of cAMP. Pertussis toxin inactivates the α subunit of at least two G proteins, G_i and G_o. Because the dopamine somatodendritic autoreceptor (of the D_2 subtype) and the serotonin somatodendritic autoreceptor (of the 5-HT_{1A} subtype) may be linked to the inhibition of adenylate cyclase, we have examined the effects of pertussis toxin on electrophysiological inhibtion mediated by these two receptors.

To examine the role of G proteins in receptor-mediated inhibtion of 5-HT neurons, we injected pertussis toxin (0.5-1.0 μg) into rat midbrain in a region immediately rostral to the dorsal raphe nucleus, and we recorded extracellularly from 5-HT neurons 1-15 days after injection. The baseline firing rate of 5-HT neurons in chloral hydrate anesthetized animals was not significantly affected by pertussis toxin. However, in comparison to saline-injected animals, toxin-treated animals showed markedly blunted sensitivity to agonists that act at 5-HT autoreceptors (ipsapirone, 5-HT, and LSD) and to baclofen, a $GABA_B$ agonist. This effect was demonstrated in vivo (with intravenous and iontophoretic application of drugs) and in vitro in the dorsal raphe brain slice preparation. The sensitivity to GABA itself was not significantly decreased with pertussis toxin treatment, consistent with evidence that GABA administered in this manner acts on dorsal raphe cells mainly through $GABA_A$ receptors.

To examine the role of G protein(s) in DA autoreceptor function, rat substantia nigra was injected with 1 μg pertussis toxin, and zona compacta DA neurons were recorded extracellularly 1-7 days after injection. In comparison to saline-injected animals, the toxin-treated animals showed almost no inhibition of DA neurons in response to DA applied iontophoretically or the dopamine agonist (-)-apomorphine given intravenously, although they maintained almost normal inhibitory responses to iontophoretically applied GABA.

This study is part of a series of experiments in which pertussis toxin has been shown to block inhibition mediated by the somatodendritic autoreceptors of the three major monoaminergic systems in rat brain: the α_2-adrenoceptor on norepinephrine-containing cells of the locus coeruleus (Aghajanian and Wang, Brain Res., 371:390, 1986); the D_2 receptor on DA-containing neurons of the substantia nigra (present study); and the 5-HT_{1A} receptor on 5-HT-containing neurons of the dorsal raphe nucleus (present study).

279.11 NEUROMODULATORY ACTIONS OF NOREPINEPHRINE IN THE THALAMUS: POSSIBLE CONTRIBUTION TO THE ASCENDING CONTROL OF AROUSAL? David A. McCormick and David A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Medicine, Stanford, CA 94305.

The mammalian thalamus is richly innervated by noradrenergic axons and terminals arising from the locus coeruleus. Activation of this ascending noradrenergic system in vivo has been previously shown to enhance the firing of lateral geniculate neurones to other inputs (Rogawski and Aghajanian, Nature, 287:731; Kayama et al., Neurosci. 7:655). Here we investigate the ionic mechanisms by which NE modulates the excitability of thalamic neurones.

Local application of NE to intracellularly recorded thalamic neurones maintained in vitro and located in the guinea pig lateral geniculate (dorsal division), medial geniculate, anteroventral, reticular, and parataenial nuclei resulted in a slow depolarization and decrease in input conductance of 2 to 15 nS. This was a direct effect since block of synaptic transmission by bathing the slices in 0.5 mM Ca^{++}, 5.0 mM Mn^{++} did not block the NE response. I-V plots performed before and during application of NE indicated that the equilibrium potential varied as a Nernstian function of $[K]_o$. Similarly, changing $[K]_o$ from 0.5 to 5.0 mM or visa versa affected the amplitude of the NE response as expected for a K-mediated event. These results indicate that the NE-induced slow depolarization is due to a decrease in K conductance.

Parataenial (Pt) neurones are electrophysiologically distinct from other thalamic neurones in that they display prominent accomodation and slow afterhyperpolarizations. Application of NE to Pt neurones not only caused the slow depolarization mentioned above, but also completely blocked the slow ahp and reduced accomodation without affecting fast ahps.

The NE-induced slow depolarization appears to result from the activation of α_1 receptors since it was activated by the α_1 agonist phenylephrine but not by the α_2 agonist clonidine or the β agonist isoprenaline. The subtype of adrenoceptor mediating the block of the slow ahp in Pt neurones is not yet known.

Thalamic neurones possess three possible excitability states: they generate single spike discharges at membrane potentials above approximately -55 mV, burst discharges at membrane potentials below -65 mV, and are silent when V_m is in between. The NE-induced slow depolarization completely inhibited burst discharges and promoted the occurrence of single spike activity by depolarizing V_m towards -55 mV, inhibiting the slow ahp, and by increasing the slow membrane time constant. These effects allow the ascending noradrenergic system to potently control the prevalence of single spike versus rhythmical burst firing in the thalamus and thereby influence the pattern and excitability of basal neuronal activity throughout the forebrain. Supported by NIH grants NS 12151, NS 06477 and NS 07331.

279.12 WHOLE CELL VOLTAGE CLAMP STUDIES OF ENZYMATICALLY DISSOCIATED DORSAL LATERAL GENICULATE NEURONS. S. Suzuki* and M.A. Rogawski, Neuronal Excitability Section, Medical Neurology Branch, NINCDS, NIH, Bethesda, MD 20892.

We have developed an isolated cell preparation from guinea pig thalamus that is suitable for gigohm seal patch clamp recording. The dorsal lateral geniculate nucleus (LGNd), a brain region that consists of a relatively homogeneous population of principal neurons with well characterized transmitter sensitivity and a small number of intrinsic interneurons, was chosen as a model system. Slices of guinea pig LGNd (1×1×0.6 mm) were exposed to trypsin, mechanically dissociated and plated on polystyrene dishes essentially as described by A.R. Kay and R.K.S. Wong (*J. Neurosci. Methods* 16: 227-238, 1986). Neurons isolated in this manner exhibited roughly spherical morphology with amputated, "stump-like" processes. Patch electrodes, filled with (in mM) 140 K gluconate, 1 $MgCl_2$, 10 HEPES, and 1.1 EGTA, were used for current clamp and voltage clamp recording. Current clamp recordings demonstrated that isolated LGNd neurons had resting potentials of -40 to -50 mV and fired tetrodotoxin (TTX)-sensitive action potentials (AP). In the presence of TTX (2 μM) and tetraethylammonium (20 mM), the cells exhibited longlasting Cd^{2+}-sensitive APs (100 msec) that were followed by slow afterhyperpolarizations (500 msec). Superfusion with GABA (100 μM) produced a rapid hyperpolarization, whereas norepinephrine (10 μM) or the α_1-agonist phenylephrine (25-50 μM) caused a slow depolarization in association with rapid spike firing as expected from previous *in vivo* studies (M.A. Rogawski and G.K. Aghajanian, *Nature* 287:731-734, 1980).

Under whole cell voltage clamp conditions, step depolarization elicited a TTX-sensitive fast inward current and two kinetically distinct outward currents, I_K and I_A. I_K, a slowly rising voltage-dependent outward current demonstrated a tail current that reversed about -70 mV, near the expected equilibrium potential for K^+. When LGNd neurons were depolarized from holding potentials negative to -50 mV, I_A, a rapidly activating and inactivating (transient) outward current, was observed. GABA stimulated a large picrotoxin-sensitive conductance increase with reversal potential about -50 to -60 mV. When KCl was substituted for K-gluconate in the pipette solution, the reversal potential of the GABA activated current shifted to about 0 mV, as expected of a Cl^- current. We conclude that acutely dissociated LGNd neurons exhibit excitability characteristics expected of neurons in the intact brain and are a suitable preparation for studying voltage-sensitive currents and transmitter responsiveness using the patch clamp technique.

280.1 FORMS OF GROWTH AND RETRACTION AT MOUSE NEUROMUSCULAR JUNCTIONS REVEALED BY A NEW NERVE TERMINAL STAIN AND CORRELATIVE ELECTRON MICROSCOPY. N. Robbins and J. Polak*. Dept. of Dev. Genetics & Anatomy, Case Western Reserve School of Medicine, Cleveland, Ohio 44106.

The extent to which adult motor nerve terminals engage in sprouting and remodelling is controversial. To address this issue, we combined a new stain for nerve terminals in whole mounts (Tetanus toxin C fragment coupled to Texas Red) with a stain for acetylcholine receptors (FITC-alpha-bungarotoxin) and used 100x oil objectives. Sprouts were then seen as fine protrusions from terminal branches, with no underlying acetylcholine receptors. In addition, tracings of video-recorded whole-nerve-terminal images were used to determine the extent of nerve terminal protrusion or retraction with respect to post-synaptic folds. Ultrastructure and immunocytochemistry were used to characterize sprouts and protrusions in parallel.

In mature (6-7 mo.) CBF-1 mice, fast twitch muscles had 0-1 sprout per endplate and slow muscles had 2-3. In slow muscle from 1 mo. old mice, sprouts were even more numerous and prevalent. In all muscles, sprouts often occurred in clusters and were always located at the upper (Schwann-cell associated) plane of the nerve terminal. Sprouts were also seen when fixation preceded staining. In young muscle, a 30 min. exposure to 0.1-to 5 ug/ml cytochalasin D decreased the percentage of endplates with sprouts from 81 to 32% (control). In whole mounts of mature soleus muscle, the majority of synapses showed one or more lamellar or angular protrusions of the nerve terminal beyond the receptor region as well as retractions. Such forms usually occupied no more than about 5% of the nerve terminal area.

In about 20% of 117 random sections, EM revealed nerve terminal protrusions at gaps between Schwann cell and muscle, extending about 0.5 um. Semi-serial sections indicated that at least some of these protrusions were lamellar, extending up to 2.3 um along the terminal branch. The protrusions were devoid of vesicles or mitochondria, contained fine filaments, and stained with anti-actin. Retraction of nerve terminals away from post-synaptic folds were also noted.

Thus, mature nerve terminals have filapodia-like sprouts which apparently do not last long enough to induce receptors (at least in young mice) and are readily withdrawn upon exposure to cytochalasin D. In addition, lamellipodia-like protrusions and retractions are additional forms of plasticity. The possible role of these forms in neuromuscular plasticity will be discussed.

Supported by NIH AG00795 and AG 06641.

280.2 TRANSIENT FILOPODIAL-LIKE STRUCTURES OBSERVED AT THE LIVING MAMMALIAN NEUROMUSCULAR JUNCTION. Hill, R.* and Robbins, N. (SPON: R.J. Lederman). Department of Developmental Genetics and Anatomy, Case Western Reserve University, Cleveland, Ohio 44106.

Static observations of the neuromuscular junction (NMJ) in slow twitch muscle has indicated that remodelling may occur at this much studied synapse. Recent observations, utilizing tetanus toxin C fragment conjugated to texas red (TT-TR) as a nerve terminal stain indicate that fine sprouts protrude from terminal branches (Robbins & Polak, this volume). Such sprouts possess no underlying acetylcholine receptors and thus may be newly formed. The purpose of the present research was to examine the possibility that these filopodia-like sprouts have only a transient existence, and as such, would represent a dynamic component of the NMJ.

To address this issue, the slow twitch pectineus muscles of anesthetized young (3-5 wks.) Swiss Webster mice were stained in situ with TT-TR and in final experiments with FITC-alphabungarotoxin as well to visualize underlying acetylcholine receptors. High fluorescence resolution was obtained with a 100x oil objective specially shielded from the preparation. Images were visualized by a SIT camera and recorded onto VCR tape. The incisions were then closed and the animals allowed to recover. The following day, the same procedure was repeated and the same NMJ relocated. Tracings of the recorded NMJ, from day one and day two were then overlaid. In some of the junctions, the number and location of sprouts had not changed while in other day 1 animals, sprouts were absent while new sprouts were generated in different parts of the nerve terminal. Two other stains - 4Di 2Asp and $DIOC_2(5)$ were evaluated for comparison to TT-TR, but neither stained the sprouts described above nor revealed some of the more detailed architecture of the nerve terminal.

This study is the first to identify filopodia-like structures in the living mammalian NMJ and to demonstrate that they are transient and dynamic entities. Studies are currently in progress to determine the fate of these structures as well their role in normal synaptic remodelling and in circumstances such as aging. (Supported by NIH grant AG 06641).

280.3 DYNAMIC ASPECTS OF CORNEAL INNERVATION VISUALIZED IN LIVING MICE. L.W. Harris* (SPON: D. Purves), Departments of Anatomy and Neurobiology and Neurological Surgery, Washington University School of Medicine, St. Louis, Missouri 63110.

Repeated visualization of identified neural elements in living mammals has recently been accomplished using non-toxic fluorescent dyes (Purves et al., J. Neurosci. 6:1051-1060, 1986; Purves et al., Soc. Neurosci. Abstr. 12:390, 1986; Lichtman et al., J. Neurosci. 7:1215-1222, 1987). Here I report the adaptation of these methods to test the anatomical stability of sensory nerve endings in the corneas of adult mice.

Topical application of a dilute solution of the fluorescent dye 4-(4-diethylaminostyryl)-N-methylpyridinium iodide (4-Di-2-ASP, Molecular Probes) labeled neural processes throughout the cornea. Images were acquired with a fluorescence microscope system coupled to a SIT camera and an image processor (op. cit.). Neural staining, which faded within one to two hours, could be repeated after an arbitrary interval.

Vital staining with 4-Di-2-ASP demonstrated the corneal innervation as completely as conventional stains (e. g., methylene blue, gold chloride). Nerves could be seen to enter the cornea radially from the sclera. Within the corneal stroma these nerves ramified to form a plexus, from which finer nerve fibers branched upward and divided dichotomously among the cells of the superficial layers of the corneal epithelium.

Observations of the same region of the cornea were made at intervals of up to two months. Stromal nerves maintained a constant position relative to the iris during this time. Thus, identified stromal nerves could be used to precisely localize superficial nerve endings. Over periods of a few hours, little or no change in the appearance of the same superficial sensory endings was noted. After 24 hours, however, changes in terminal arborizations were apparent (though an overall similarity to initial configuration was retained). After one week, terminal branching patterns bore little or no resemblance to those seen initially; indeed, the position of individual groups of sensory terminals relative to stromal nerves was often totally different. Thus, marked rearrangement of the surface terminals occurs over a period of several days.

These observations suggest that sensory endings within epithelial tissues in adult mammals may be quite dynamic under normal circumstances.

280.4 REPEATED IMAGING OF NEUROMUSCULAR JUNCTIONS IN MOUSE SOLEUS MUSCLES IN VIVO. Donald J. Wigston, Department of Physiology, Emory University School of Medicine, Atlanta, GA 30322.

Although it has been suggested that neuromuscular junctions (NMJs) in adult skeletal muscle are continually remodelled, the evidence for this is rather indirect. Epi-illumination fluorescence microscopy makes it possible to study a particular NMJ several times in the same animal, separated by arbitrary intervals, to see directly if any changes occur in its shape. Using this approach, Lichtman et al. (J. Neurosci. 7:1215, 1987) have found that NMJs in mouse sternomastoid muscles do not change their shape significantly over several months. However, much of the earlier evidence for remodelling of NMJs in mammals was obtained in soleus muscles. Since it is possible that intrinsic differences between muscles might influence synaptic reorganization, I have monitored identified NMJs in soleus muscles of adult mice by viewing them in living animals.

In preliminary experiments, fluorescent dyes that stain nerve terminals were used, but these stained soleus muscle fibers too heavily to be used routinely. However, the arrangement of postsynaptic acetylcholine receptors (AChRs) provides a reliable indication of the shape of the presynaptic nerve terminal: there is normally an exact correspondence between the shape of a nerve terminal and the arrangement of AChRs, and changes in the configuration of a nerve terminal produce corresponding alterations in the pattern of AChRs. To label AChRs, soleus muscles were exposed in anesthetized mice and bathed for 1 hr with rhodamine-conjugated α-Bungarotoxin (5 μg/ml). This clearly delineated superficial NMJs in the absence of any detectable effect on neuromuscular transmission. Labeled junctions were examined with epi-illumination using a 50X water-immersion lens (NA = 1) and an intensified video camera (SIT) operated at maximum gain so that low levels of incident light could be used. Images were digitally enhanced and recorded on videotape.

Staining and viewing were repeated 7-131 days later. Individual NMJs were easily identified from the original recordings as the overall morphology of each NMJ was remarkably similar each time. Minor rearrangements were detected in some NMJs viewed several months apart, however. Occasionally small parts of the original NMJ were not apparent at the second viewing (deletions); sometimes, extension of existing branches or their appearance de novo (additions) was observed. I have not so far observed such changes in NMJs studied at the shortest times after the initial viewing. The modest changes observed suggest that NMJs in adult mouse soleus muscles undergo only a minor degree of spontaneous remodelling.

280.5 OBSERVATIONS ON THE ASSOCIATION OF SATELLITE CELLS AND SYNAPSES IN AN AUTONOMIC GANGLION. S.L. Pomeroy and D. Purves, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

Neurons in mammalian autonomic ganglia are associated with satellite cells (glia) whose function is not yet understood. Recently, gradual changes in the arrangement of synaptic terminals on the surfaces of neurons in mouse salivary duct ganglia have been described in normal adults (Purves et al., Soc. Neurosci. Abstr. 12: 390, 1986). Here we report some observations on the relationship of satellite cells and synapses in these ganglia which may be pertinent to ongoing synaptic rearrangement.

Both light microscopic observations of adult mouse salivary duct ganglia after methylene blue staining in vivo, and electron microscopical examination of fixed ganglion cells, indicate that the position of glial nuclei on the surfaces of these neurons tend to mark sites of increased numbers of preganglionic endings. Although this relationship is not strict--synaptic boutons are often observed on regions of the neuronal surface away from the satellite cell nuclei--the association is significant. Furthermore, the neuronal surface near glial nuclei often bears increased numbers of finger-like extensions, which are the usual sites of synaptic contact.

In the course of observing individual ganglion cells over time in living mice (Purves et al., J. Neurosci. 6: 1051-1060, 1986), it became evident that satellite cells can be seen in vivo with the same techniques (video microscopy and image processing) used to monitor nerve cells. In order to determine whether glia change their relationship to the nerve cells they invest, we made repeated observations of identified neurons and their associated satellite cells in unstained ganglia over periods of several weeks. In some of the cases that we followed, the position of a glial nucleus changed substantially within 1-3 weeks. In other cases, we observed the disappearance of an earlier identified nucleus, or appearance of a nucleus not previously seen.

Although these findings admit a number of explanations, our observations indicate that the position of satellite cell nuclei may be a useful marker of synaptic sites in living animals. They also raise the possibility that satellite cells play a specific role in the maintenance or rearrangement of synapses on these neurons.

280.6 THE ROLE OF NMDA RECEPTORS IN LONG-TERM POTENTIATION IN THE PYRIFORM CORTEX: EFFECTS OF KETAMINE. D. K. Patneau and J. S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Previous research from our laboratory has demonstrated a selective long-term potentiation (LTP) of the pyriform cortex (PC) potential evoked by olfactory bulb (OB) stimulation which appears to be functionally inhibitory (Soc. Neurosci. Abstr. 11:780, 1985). Period 1 of the evoked potential, representing both a mono- (A1) and di-synaptic (B1) EPSP in PC pyramidal cells, remains unchanged, while period 2, which is temporally associated with IPSPs, is dramatically increased by repeated high-frequency stimulation. The selective potentiation observed cannot be produced by stimulation restricted to the lateral olfactory tract (LOT), indicating that other pathways, activated either alone or in concert with the LOT, are involved in LTP produced by OB stimulation (Soc. Neurosci. Abstr. 12:508, 1986).

An extensive association fiber system in the PC, whose level of activation is reflected by B1 in the field potential, is a strong candidate for involvement in the production of LTP. Activation of N-methyl-D-aspartate (NMDA) receptors by glutamate has been implicated in the development of LTP in the hippocampus. Glutamate or an analogue is presumed to be the neurotransmitter of the association fibers in the PC. The present study therefore utilized an NMDA antagonist, ketamine, to investigate the role of NMDA receptors, presumably activated by association fibers, in the development of LTP in the PC.

Male Long-Evans rats were chronically implanted with electrodes in the OB and PC and an intravenous catheter. The effects of ketamine (5 mg/kg) on the PC evoked potential and on the induction and expression of LTP were examined. Half of the animals received ketamine immediately before thirty 100 Hz trains of 10 pulses each, and half received ketamine following the trains.

A number of measures were used to assess differential changes in the LOT volley, A1, B1, and period 2 of the PC evoked potential. Ketamine's primary effect was inhibition of B1, with no alteration of the LOT volley, indicating that input from the OB was unaffected. Ketamine significantly retarded the development of LTP when given prior to the potentiating trains. When given following the trains, it temporarily antagonized the expression of LTP, but did not block its development.

These results indicate a role for NMDA receptors in pyriform cortex LTP, and are consistent with a model for its development involving coactivation of LOT and association fibers.

280.7 LONG-LASTING POTENTIATION IN TRANSMISSION DEVELOPS IN CHRONIC PREPARATIONS FOLLOWING SYSTEMIC ADMINISTRATION OF KAINIC ACID. N. W. Milgram, C. Sawicki*, J. Rick* and G. O. Ivy. Life Science Division, Scarborough Campus, U. Toronto, Scarborough ONT, M1C1A4.

Systemic administration of kainic acid (KA) produces sustained activation of limbic system structures which can lead to repeated afterdischarge and eventually to convulsive seizures. This treatment also has long lasting consequences as indicated by cognitive deficits, hyperactivity (Milgram, N. W., Soc. Neurosci. Abstr., 12, 1375, 1986) and the development of spontaneous seizures. The present work illustrates some physiological correlates of these long lasting changes in rats implanted with chronic stimulating electrodes in the angular bundle and with recording electrodes in the the dentate gyrus. Testing involved three phases: an initial period of stabilization, a treatment phase which involved a subcutaneous injection of KA (10mg/kg) and a post-treatment phase during which field potentials were monitored for up to 4 months. One group of animals received KA only, while a second group was also administered sodium pentobarbitol.

The immediate response to KA was a progressive decrease in field potentials and by two hours post-injection, they were virtually gone. Over subsequent days field potentials exhibited substantial growth resulting in both a potentiation in amplitude and a decrease in threshold compared with the pretreatment interval. The animals which were not administered pentobarbitol showed a similar growth, except that it occurred over a much longer interval and was preceded by a longer period of suppression. Tests using paired-pulses indicated that these results were not due to a selective suppression of inhibition. Histological analysis revealed extensive cell death in the animals given KA alone but not in the animals which were also treated with pentobarbitol.

The phenomenon we describe provides a possible neural correlate of memory which differs in two important respects from the long-term potentiation(LTP) induced by electrical stimulation. First, the KA-induced potentiation shows a growth which may continue over an extended interval of time while LTP is maximal shortly after the treatment. Second KA produces a permanent potentiation while LTP decays by a few weeks.

280.8 LATENT EXCITATORY SYNAPTIC PATHWAYS REVEALED AFTER TETANIC STIMULATION IN THE HIPPOCAMPUS. R. Miles* and R.K.S. Wong Dept. of Neurology, Columbia University, New York NY 10032.

Plasticity of hippocampal synapses is usually studied by stimulating a fibre pathway and monitoring changes in responses evoked in a single neuron or in the post-synaptic population. This technique precludes a direct examination of the possibility that changes occur at synapses between post-synaptic cells. We recorded from pairs of CA3 cells in slices from guinea pig hippocampus to examine whether tetanic stimulation affects recurrent excitatory or inhibitory synaptic circuits.

Two pathways which synapse with CA3 cells were stimulated repetitively (20-50 Hz, 5-10 sec x 2). 1. mossy fibres in transverse slices. 2. longitudinal association fibres in longitudinal slices from the CA3 region. Recordings were made from cell pairs where no interaction was detected initially. In 5 of 48 cases in transverse slices and in 3 of 22 cases in longitudinal slices latent excitatory interactions were revealed several minutes after tetanisation and persisted for at least 20 minutes. The latency and probability that post-synaptic events failed suggested that new pathways were poly-synaptic.

Since pharmacological disinhibition increases functional excitatory connectivity in the CA3 region (J. Physiol. 388, 1987) we asked whether tetanic stimuli modified recurrent inhibitory interactions. Recordings were made from pairs of burst firing cells, one of which could evoke inhibitory post-synaptic potentials in the other. The strength of di-synaptic inhibitory coupling was assessed by averaging post-synaptic responses to pre-synaptic bursts. It was reduced by more than 20% from its control level in 15 of 20 cell pairs when tested at 12-20 minutes after tetanic stimulation.

These modifications at intrinsic synapses changed activity in the post-synaptic population. In 21 of 36 cell pairs from both transverse and longitudinal slices simultaneous synaptic events of amplitude greater than 5 mV emerged after tetanic stimulation. They could be triggered by a single cell and probably reflect simultaneous activity in small groups of CA3 cells. The formation of groups of associated cells after tetanic stimuli and the ability of some cells to initiate simultaneous firing in a group via recurrent excitatory pathways may represent a mechanism for information storage and recall.

280.9 SUBCELLULAR DISTRIBUTION OF PROTEIN KINASE C (PKC) IN RAT BRAIN REGIONS SUGGESTS THAT HIPPOCAMPUS HAS THE HIGHEST CAPACITY FOR KINASE TRANSLOCATION, AND THAT THIS CAPACITY MAY BE DIURNALLY REGULATED. F-S. Sheu*, K. Murakami*, and A. Routtenberg. (SPON: M. deJonge). Cresap Neurosci. Lab., Northwestern Univ., Evanston, IL 60201.

PKC is active when present at the plasma membranes and its activation may occur by translocation from cytosol to membrane [Nature (1985) 317 546, J. Biol. Chem. (1985) 260 15718]. The subcellular PKC distribution in a given brain region may thus indicate the level of PKC activity in that region as well as its capacity for futher activation in response to extracellular signals. We thus assayed cytosol/membrane distribution of PKC activity in eight regions of adult rat brain.

Preliminary experiments indicated that: (1) maximum PKC activity could be extracted by 1% and 2% of Triton X-100 from membrane and crude homogenate fractions respectively; (2) a minimal amount of divalent cation chelator (0.1 mM EDTA) in homogenization buffer was sufficient to prevent proteolysis of PKC and minimized PKC extraction from membranes. Thus we used these conditions during tissue preparation in our studies of PKC distribution.

We observed a significant difference in the total PKC activity (cytosol plus membrane fraction, C+M) across the eight regions examined ($F=5.09$, $df=7,63$, $p<0.001$). The order of total PKC activity among the eight brain regions was: hippocampus>frontal cortex>neostriatum> septal area>cerebellar cortex>thalamus>entorhinal cortex >hypothalamus. In addition, there were significant differences in cytosol and membrane PKC activity among these eight brain regions ($F=5.68$ $df=7,63$ $p<0.001$ for cytosol; $F=2.21$ $df=7,63$ $p<0.05$ for membrane). The hippocampus had the highest level of cytosol PKC activity of the brain regions. Moreover, the mean proportion of cytosolic PKC activity (C/C+M) in hippocampus (0.53 ± 0.04) was consistently higher than that of other brain regions, such as neostriatum (0.39 ± 0.07), thalamus (0.40 ± 0.04) and cerebellum cortex (0.40 ± 0.06). Hippocampus may thus have the highest capacity for PKC translocation in response to transmembrane signals. In a separate experiment, we found that rats sacrificed at midnight when behavioral activity was high, had a significantly lower C/C+M ratio in hippocampus (0.447 ± 0.022) than that of rats sacrificed at noon when behavioral activity was low (0.520 ± 0.016) ($t=2.71$, $df=6$, $p<0.025$). The subcellular PKC distribution in rat hippocampus might thus display a diurnal rhythm possibly related to the animals' arousal state. (Supported by MH25281-13, and AFOSR-0042).

280.10 COOPERATIVE ACTION OF Zn(II) AND Ca(II) IN THE REGULATION OF PROTEIN KINASE C ACTIVITY FROM RAT BRAIN K. Murakami*, M.K. Whiteley*, and A. Routtenberg. Cresap Neurosci. Lab. Northwestern Univ. Evanston, IL 60201

Recently, PKC has been shown to have a cysteine repeating sequence which could be a potential metal binding site(s). We have reported that purified protein kinase C (PKC) can be fully activated by cis-fatty acid in the absence of Ca2+ and phospholipid. This suggests that PKC may be activated by another signaltransduction pathway, possibly cis-fatty acid liberation by Ca2+-dependent phospholipase A2 (PLA2) in addition to PLC/PI breakdown mechanism (FEBS Lett. (1985) 192:189, J.Biol. Chem. (1986) 261:15424). Since cis-fatty acid does not require Ca2+ for PKC activation, it is possible to examine the effects of metal ions on protein kinase C independently of Ca2+. Here we show a specific interaction of Zn2+ with protein kinase C and a positive and negative cooperativity with Ca2+.

At low concentrations (~5uM) of Ca2+, Zn2+ (~300uM) shows significant augmentation of PKC induced both by cis-fatty acid and by PS/diolein. In contrast, 300uM Zn2+ inhibits PKC activity at high concentrations (over 50uM) of Ca2+. In the absence of Ca2+, Zn2+ neither inhibits PKC activity induced by cis-fatty acid nor activates PKC with phospholipid and diacylglycerol. The dual and opposite effect of Zn2+ indicates that PKC has high and low affinity Ca2+ binding sites and at least one Zn2+ binding site and that Zn2+ does not interact with PKC unless Ca2+ occupies its high affinity site(s).

Our laboratory has proposed that PKC play an important role in synaptic plasticity in rat hippocampus: 1) an increase in membrane associated PKC activity following long-term potentiation (LTP)(Science (1986) 231:587) 2) an increase in phosphorylation of protein F1 (Behav. Neural. Biol. (1985) 43:3, Brain Res. (1986) 399:205), a PKC substrate (Brain. Res (1985) 334:147, Exp. Neurol.(1985) 89:213, J. Neurosci. (1986) 6:3618) 3) prolonging effects of LTP by PKC activators (Brain Res (1986)378:374, 379:358). Zn2+ concentration has been known to be high in hippocampus, especially in mossy fiber system (~490uM in wet tissue). Interestingly, chronic Zn2+ deficiency alters neural activity in the same system. Thus, it is possible that the cooperative action of Zn2+ and Ca2+ plays a role in synaptic physiology in mossy fiber system. (MH25281-13 and AFOSR 87-0042 to A.R.)

280.11 THE IDENTIFICATION OF PROTEIN F1 IN MAMMALIAN NERVOUS TISSUE USING AFFINITY-PURIFIED ANTIBODY AGAINST CALF PROTEIN F1. S.Y. CHAN, C. HASKELL* AND A. ROUTTENBERG. Cresap Neuroscience Laboratory, Northwestern University, Evanston, Ill. 60201.

The *in vitro* phosphorylation of protein F1 (Mr=47K, pI=4.5) has been found to be directly correlated with synaptic plasticity of long term potentiation (*Behav. Neural Biol.*,1985,43,3-11). Protein F1 has recently been co-identified with neuronal growth-associated proteins GAP43, pp46 and B-50, and as such may play a role in nerve growth and regeneration as well.

Protein F1 has been purified from rat synaptosomal membranes using column chromatography methods (*J. Neurosci.*, 1986, 6, 3618-3627). It was found to be phosphorylated by purified protein kinase C (PKC) but by no other kinases tested. Using the same purification method, protein F1-like molecules can be isolated from rat, calf and human but not from Aplysia. Aside from a slightly different molecular weight (rat=47K, human=53K, calf=55K), these molecules have very similar physical and biochemical properties to rat F1 including pI, PKC phosphorylation, V8 protease map and cross-reactivity by F1-specific antibodies. Such results indicated that protein F1 is generally present in mammalian nervous tissues.

Rabbit antisera were raised from purified calf F1 and subsequently purified by a calf F1-conjugated affinity column. This affinity-purified antibody specifically immunoprecipitated F1 from human, monkey, calf and rat but no cross-reactivity was observed using Aplysia nervous tissue. Initial results suggested that the antibody was capable of blocking F1 phosphorylation by PKC in a dose-dependent manner.

Preliminary immunolocalization studies using paraffin-embedded rat hippocampal and cortical sections showed staining by the F1-antibody in the hippocampus and frontal cortex. In the hippocampus, the heaviest staining was found in the stratum radiatum near the hippocampal fissure. Other areas of staining included the molecular layer of dentate gyrus, CA3 cell area, entorhinal cortex and subicular complex. Staining seemed to be confined to lamina containing neuronal projections of the hippocampal formation and no specific staining was observed in the pyramidal and granule cell bodies. (This work was support by MH25281-13 and AFOSR-0042)

280.12 ULTRASTRUCTURE OF DENDRITIC SPROUTS SEEN FOLLOWING CLOSE AXOTOMY OF GIANT CENTRAL NEURONS IN THE LAMPREY G.F. Hall, A. Poulos and M.J. Cohen. Dept of Biology, Yale University, New Haven, CT 06520

Axotomy of anterior bulbar cells (ABCs), a group of giant Muller interneurons in the hindbrain of the sea lamprey (Petromyzon marinus), results in dendritic sprouting if the site of axotomy is located close to the cell body (<500 um) (Hall & Cohen, Science 222 pp. 518-521 1983). In order to determine whether dendritic sprouts evoked by axotomy are intrinsically dendritic or axonal in nature, we have examined the ultrastructure of the dendrites, axon and dendritic sprouts of ABCs 2 months following close axotomy and compared it with the dendritic and axonal ultrastructure of intact ABCs.

The dendrites and axons of intact ABCs were distinguished by the following ultrastructural criteria: (1) the predominance of microtubules in the dendritic cytoskeleton and of neurofilaments in that of the axon, (2) the presence of polyribosomes and large numbers of mitochondria in the dendrites and their respective absence and scarcity in the axon, and (3) the exclusively postsynaptic status of the dendrites versus the presynaptic status of the axon.

We found that all neuritic sprouts evoked by axotomy resembled axons rather than dendrites whether they originated from the axonal stump or the dendrites. The dendrites of axotomized ABCs with dendritic sprouts possessed a mixture of dendritic and axonal characteristics, having the dendritic pattern of synaptic relations combined with axonlike cytoskeletons.

We conclude that axotomy of ABCs close to the soma causes axonal regeneration to occur from ectopic sites in the dendrites. Our results also suggest that the materials needed for axonal regeneration (such as axonal cytoskeletal elements) may be transported through the dendrites to dendritic sprouts following close axotomy, displacing the dendritic cytoskeleton while leaving dendritic synapses intact. Supported by NIH # NS-10174

281.1 CALCIUM CHANNELS IN TWO TYPES OF ANTERIOR PITUITARY CELLS IDENTIFIED BY A PLAQUE ASSAY. S.A. DeRiemer. Dept. of Biological Sciences, Columbia Univ., New York, NY 10027.

The presence of multiple types of calcium channels in many cells raises the question of what impact the existence of any one of these has on a cell's physiology. To address this question we have examined the calcium channels present in two cell types from the anterior pituitary gland, growth hormone secreting somatotrophs and prolactin secreting lactotrophs (DeRiemer & Sakmann, Exp. Brain Res. Ser. 14:139-154, 1986).

Primary cultures of rat anterior pituitary cells were prepared and maintained using standard techniques. Cells of a given type were identified using the reverse hemolytic plaque assay of Neill & Frawley (Endocrinol. 112:1135-37, 1983). Hormone secretion was measured by radioimmunoassay on fractions collected from a perifused cell column with materials supplied by the NIADDK. Patch clamp recordings of ion channels in identified cells were carried out according to standard methods.

Preliminary results indicated that these cells contained two classes of calcium current, low-voltage activated (Type I, T) and high-voltage activated (Type II, L), and that lactotrophs and somatotrophs had different relative amounts of the two currents. In further examination, it appears that both cell types have aproximately the same amount of the high-voltage activated current when records are normalized to cell capacitance, while the absolute level of low-voltage activated current is significantly higher in the lactotrophs, both with respect to the somatotrophs and to the other calcium current. The high-voltage activated current in these cells is sensitive to dihydropyridines, both BAY K8644 and antagonists such as nifedipine. The low-voltage activated current is selectively inhibited by alcohols as was shown in inferior olive cells by Llinas & Yarom (Soc. Neurosci. Abstr. 12(1):174, 1986).

Three functions are likely candidates for selective involvement of calcium channels: patterned electrical activity, basal or stimulated secretion, and modulation by neurotransmitters. The high-voltage activated current can be modulated by the adenylate cyclase activator, forskolin (1-10 μM), while no effect has been observed on the high-voltage activated current to date. Effects of dihydorpyridines on secretion suggest that basal release in lactotrophs is relatively insensitive to both BAY K8644 and nifedipine, but is inhibited by Cd^{++} (1 mM) suggesting that the low-voltage activated calcium channel may be involved in this process. These effects are being examined further as well as the involvement of these channels in electrical activity.

Experiments were begun at the Max-Planck Institut für biophys. Chemie, Göttingen with the support of Dr. Bert Sakmann and a Hoffmann-LaRoche fellowship from LSRF. Supported by NSF #8615840.

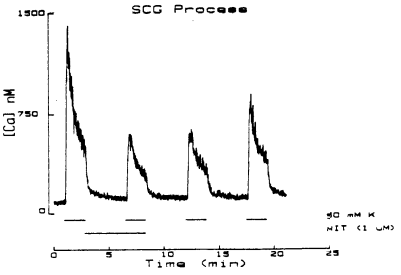
281.2 DISTRIBUTION OF MULTIPLE Ca^{2+} CHANNEL TYPES AND INTRACELLULAR Ca^{2+} STORES IN SINGLE CENTRAL AND PERIPHERAL NEURONS. S.A. Thayer*, L.D. Hirning*, K.M. Harris* and R.J. Miller Dept. of Pharmacological and Physiological Sci., Univ. of Chicago, Chicago IL 60637.

A rise in intracellular Ca^{2+}, $[Ca^{2+}]_i$, serves as a trigger for many neuronal processes, including the release of neurotransmitter. We investigated two means by which this rise in $[Ca^{2+}]_i$ can be produced. The influx of Ca^{2+} through voltage-sensitive Ca^{2+} channels and the release of Ca^{2+} from intracellular stores were measured with the Ca^{2+}-sensitive dye fura-2 in neurons grown in primary culture from the hippocampus (H) and the superior cervical ganglion (SCG) of the rat. The fura-2 fluorescence signal was measured with a microfluorimeter capable of alternating the excitation wavelength at a frequency of 60 Hz. Recordings were obtained from either a single or small bundle of neuronal processes and compared to recordings from single cell bodies.

In SCG and H neurons depolarization with 50 mM K^+ produced a rapid increase in $[Ca^{2+}]_i$ composed of both transient and sustained components. This response was seen in recordings from both the soma and processes of the cells. The entire response could be reversibly blocked by 30 μM La^{3+} and partially inhibited by 1 μM nitrendipine (NIT) as shown in the figure below. The transient component was blocked by predepolarization in Ca^{2+}-free solution and the remaining sustained component was substantially inhibited by 1 μM NIT. These data show that both dihydropyridine (DHP) sensitive and insensitive Ca^{2+} channels are present in processes as well as cell bodies of central and peripheral neurons.

Intracellular stores of Ca^{2+} can also be mobilized in these neurons. Both central and peripheral neurons responded to perfusion with 10 mM caffeine in Ca^{2+}-free bathing solution with small transient increases in $[Ca^{2+}]_i$. Multiple responses to caffeine could be produced only if these stores were allowed to replenish by either prolonged incubation or depolariztion in medium containing Ca^{2+}.

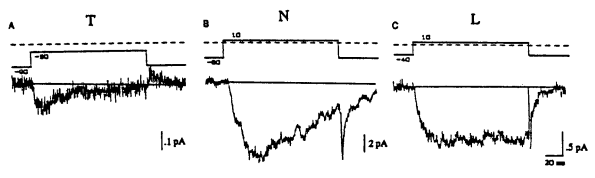
Neurotransmitter release from SCG and H neurons, when evoked by the same method of depolarization as used in these studies, is not sensitive to DHP Ca^{2+} channel blockers. Therefore, the DHP-insensitive portion of the rise in $[Ca^{2+}]_i$ seen in these recordings must be responsible for triggering neurotransmitter release. However our studies demostrate the presence of DHP-sensitive as well as insensitive Ca^{2+} channels in both the soma and processes of these neurons. This suggests that the DHP-insensitive channels may be clustered around release zones giving them a relative advantage for the initiation of neurosecreation (Miller, R.J., Science, 235:46, 1987). The contribution of Ca^{2+} released from intracellular stores to neurotransmitter release remains to be determined.



281.3 MULTIPLE TYPES OF CALCIUM CHANNELS IN HIPPOCAMPAL NEURONS: CHARACTERIZATION AND LOCALIZATION. *K.R. Bley*, D.V. Madison, and R.W. Tsien (SPON: R.D. Blakely), Dept. of Physiology, Yale Medical School, New Haven, CT 06510.*

We have studied Ca currents in cultured neurons of the CA3 region of the rat hippocampus using patch-clamp techniques. Both whole-cell and cell-attached recordings suggest the presence of three types of Ca channels in these cells, corresponding to those termed T, L, and N in other preparations (e.g. DRG neurons or dentate granule cells). In whole-cell recordings with 10 mM Ca outside and internal Cs-EGTA, weak depolarizing pulses from negative potentials elicit a transient Ca current (T) which decays with a time constant of approximately 50 msec and is nearly completely inactivated positive to -60 mV. In cell-attached patch recordings (110 mM Ba in the pipette), openings with a slope conductance of 7 pS give average currents with kinetics like whole-cell T current (panel A). L-type channels display a slope conductance of 25 pS, are evoked in isolation by strong pulses from relatively depolarized holding potentials, and inactivate very little in 150 msec (panel C). L-current responds to dihydropyridines: nifedipine potently reduces the whole-cell current while Bay K 8644 produces mixed agonist and antagonistic effects, with higher concentrations being more antagonistic. A third component of Ca current (N-type) is evoked with negative holding potentials and strong test pulses, and shows marked inactivation with a $\tau \sim 100$ ms. Unitary openings with a slope conductance of 11-16 pS show kinetics corresponding to whole-cell currents (panel B).

We have recorded activity of all three channel types on processes and somata of pyramidal-shaped neurons in culture, as well as acutely dissociated neurons from hippocampi of juvenile rats. This indicates that high-voltage activated Ca channels (L and N) are not confined to dendritic membranes as previously postulated.



281.4 CHARACTERIZATION OF BA^{++} CURRENTS THRU VOLTAGE-GATED CA^{++} CHANNELS IN IDENTIFIED MAMMALIAN CORTICAL NEURONS. K. Giffin*, J.P. Doyle* and J.M. Nerbonne, Dept. of Pharmacology, Washington University Medical School, St. Louis, MO. 63110.

In spite of the presumed importance of voltage-dependent Ca^{++} influx in the regulation and modulation of neuronal excitability, little is known about voltage-gated Ca^{++} channels in mammalian central neurons. The cortex, in particular, has remained largely intractable to cell physiologists apparently because of its complexity, cellular diversity and the difficulties associated with identifying specific cortical cell types. Here, we report the results of experiments aimed at characterizing the properties and distributions of voltage-gated Ca++ channels in cortical neurons, identified based on their projection targets. Callosal-projecting neurons are identified in vitro following retrograde labelling in vivo with rhodamine-labelled "beads". In neonatal (3-15 days) Long Evans rat pups, multiple bead injections are made into the primary visual cortex (Area 17). Following 2-15 days survival, neurons are dissociated from the contralateral area 17 and plated on monolayers of cortical astrocytes; dissociated cells prepared in this manner are viable for up to three weeks in vitro. Using the whole-cell variation of the patch-clamp recording technique, we have examined the waveforms of Ba^{++} currents through voltage-gated Ca^{++} channels in callosal-projecting cortical neurons within 6 hrs of isolation. Ba^{++} currents are recorded in bath solutions containing (in mM): NaCl, 140; $BaCl_2$, 5; KCl, 4; $MgCl_2$, 2; HEPES, 10; glucose, 5; pH 7.4 with 1 μM TTX added to suppress voltage-activated Na^+ currents; pipet solutions contain (in mM): CsCl, 140; EGTA, 10; HEPES, 10; glucose, 5; Tris-ATP, 3; Tris-GTP, 0.1; pH 7.4. In voltage-clamped cells, depolarizations, from holding potentials (hps) of -40 to -100 mV, evoke inward Ba^{++} currents which begin to activate at -30 mV, peak between 0 and +10 mV and are blocked by Co^{++} (5mM) or Ni^{++} (2mM). Ba^{++} current amplitudes in callosal-projecting neurons are uniformly small with peak amplitudes in the range 100-300 pA; this contrasts markedly with voltage-gated Na^+ and K^+ currents, which average 10 to 50 times larger. Although the amplitudes of Ba^{++} currents evoked from depolarized hps are reduced, normalized, peak current-voltage (IV) relations appear to be independent of hp over the range -40 to -100 mV. The waveforms of Ba^{++} currents evoked on depolarizations from -80mV suggest the presence of two kinetically-distinct components: one that is inactivating and another that is sustained during 250 ms depolarizations; no differences are observed, however, in normalized IV plots for these two components. In dissociated callosal-projecting neurons examined after 1-5 days in vitro, however, Ba^{++} currents peak at more hyperpolarized potentials. Present efforts are devoted to the further evaluation of developmental variations in voltage-gated Ca^{++} channels and to examining the possibility that these channels are regulated and/or modulated by cortical neurotransmitters. 281.5 CROSSLINKING BY ^{125}I-ω-CONOTOXIN: EVIDENCE SUGGESTING MULTIPLE NEURONAL CALCIUM CHANNEL SUBTYPES. L. J. Cruz*, J. S. Imperial*, D. S. Johnson* and B. M. Olivera* (SPON: J. W. Conlee). Department of Biology, University of Utah, Salt Lake City, UT 84112.

The peptide toxin ω-conotoxin GVIA, isolated from the fish-hunting cone snail Conus geographus, has been shown to inhibit voltage-sensitive Ca channels. The receptor targets of this toxin are found in neuronal tissue; voltage-sensitive Ca channels from skeletal muscle T- tubules, or from cardiac muscle are not high affinity sites for the toxin (Cruz et al., Biochemistry 26: 820, 1987). Initial crosslinking studies indicated that a single band was radiolabeled by the toxin, with a M_r of 135,000-140,000 in chick brain membrane preparations.

We recently carried out more extensive crosslinking studies; these data suggest multiple ω-conotoxin receptor targets in chick neuronal tissue. Crosslinking of solubilized receptor preparations with bivalent crosslinking agents (such as disuccinimidyl suberate) yields two pairs of radiolabeled bands after SDS PAGE, one highly labeled pair with M_r = 140,000 and 193,000, and two lightly labeled bands with M_r of 160,000 and 216,000. Based on the recent results with purified T-tubule Ca channels, the two pairs suggest we may be crosslinking two different types of Ca channel complexes by this procedure. However, if photoactivatable derivatives of ^{125}I-ω-conotoxin are crosslinked to synaptosomes, instead of the two radiolabeled pairs of bands, three other bands are specifically crosslinked, with M_r = ~ 308,000, ~ 230,000 and 96,000. The high MW bands are rather broad.

At present, we are correlating these crosslinking data to the different types of Ca channels inhibited by ω-conotoxin. In addition to the physiological types of Ca channels that have been defined (L and N) as targets of ω-conotoxin (McCleskey et al., PNAS, in press), within the N class there may be two distinct subtypes. Inhibition of one of these (the N_A subtype) causes paralysis and death; inhibition of the second subtype (N_B) in the CNS causes a shaking syndrome. At present, we are attempting to assign which crosslinked bands correspond to the L, N_A, and N_B Ca channel subtypes. Crosslinking studies have been carried out in additional systems; the patterns in most vertebrates can be correlated to the pattern obtained with chick brain receptors. In Torpedo electric organ, two bands of significantly lower molecular weight (68 and 56 K) are crosslinked. (This research was supported by grant GM22737.)

281.6 ω-CONOTOXIN BINDING SITES IN DEVELOPING CHICK BRAIN. M. J. Litzinger, J. S. Imperial*, A. Azimi*. Depts. of Neurology and Biology, University of Utah, Salt Lake City, UT 84123.

ω-Conotoxin (ω-CgTx) binding in whole chick brain preparations as a function of development shows a relatively constant level until embryonic days 18-20 (the period just before hatching) when it increases dramatically and then levels off (Litzinger et al., Soc. Neurosci. Abstr. 12:1229, 1986). Similarly, ^{45}Ca uptake studies in synaptosomes from chick brain show a 4-fold increase between embryonic days 18-20; ω-CgTx blocks 38% of the uptake on embryonic day 17 and 86% on day 20 (Litzinger et al., Neurology 37, Supl. 1:346, 1987). On the other hand, nitrendipine (NTP) binding in chick brain preparations indicates a slow gradual increase during development (Marangoes et al., J. Neurochem. 42:1338, 1984) and NTP does not block synaptosomal ^{45}Ca uptake at any age (Litzinger et al., Neurology 37, Supl. 1:346, 1987). ω-CgTx has been shown to act at both the N- and L-type voltage-sensitive calcium channel (VSCC) while NTP acts only on the L-type (McCleskey et al., PNAS, In press). The N-type VSCC, believed associated with transmitter release, has been suggested as responsible for ^{45}Ca fluxes (Reynolds et al., PNAS, 83:8804, 1986).

Crosslinking of ^{125}I-ω-CgTx to chick membrane preparations using the bivalent crosslinker disuccinimidyl suberate (DSS) indicates the target to be a polypeptide with a M_r of 135,000-140,000 (Cruz et al., Biochemistry 26:820, 1987). Recent data on more extensive crosslinking using DSS suggest multiple ω-conotoxin receptor targets in chick neuronal tissue (Cruz et al., Soc. Neurosci. Abstr., 1987). With the modified method, brain preparations from chicks at embryonic day 16, post natal day 2 and adult stage all showed the same crosslinking pattern on SDS PAGE. However, preliminary data using photoactivatable derivatives of ^{125}I-ω-CgTx showed a difference in the relative intensities of specifically crosslinked bands for 16-day old embryos and 2 to 7-day old chicks. The most obvious difference is in a radiolabeled band at a M_r of ~ 96,000 which is very intense in preparations from newly hatched chick but barely visible in the embryo preparations. Whether the apparent increase in amount of the 96 K protein corresponds to the appearance of more N-type VSCC or not remains to be investigated. (Supported by a grant from Miles Laboratories, Inc.)

281.7 SOLUBILIZATION AND PARTIAL PURIFICATION OF ω-CONOTOXIN BINDING SITES FROM RAT BRAIN SYNAPTOSOMES. R.L. Rosenberg*, J.S. Isaacson*, B.M. Olivera*+, W.S. Agnew, and R.W. Tsien. Dept. of Physiology, Yale Univ. Sch. of Med., New Haven, CT 06510 and +Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

The peptide ω-CgTx VIA from Conus geographus blocks N- and L-type calcium channels of neuronal cells (McCleskey et al., PNAS 1987), and ^{125}I-labelled toxin binds specifically to high-affinity sites in chick brain synaptosomes (Cruz and Olivera, JBC 261:6230, 1986). We are using [^{125}I]ω-CgTx VIA as a marker for the solubilization and purification of Ca channels from rat brain.

The binding of [^{125}I]ω-CgTx to rat brain synaptosomes was measured in a standard glass fiber filtration assay. Saturable binding to a single class of sites was observed, with K_d 0.2-0.4 nM and B_{max} 0.4-0.5 pmol/mg protein.

Specific, saturable binding of [^{125}I]ω-CgTx was also observed in detergent extracts of rat brain synaptosomes using a rapid gel filtration assay. Efficient solubilization was obtained with a mixture of Triton X-100 and CHAPS (1:1) at a concentration of 0.5-1.0% (w/v) for 15 mg/ml membrane protein. Binding affinity was not markedly changed by solubilization (K_d 0.2-0.3 nM). B_{max} was 0.2-0.3 pmol/mg protein; overall recovery of binding activity in the detergent extracts averaged 40%. Binding to detergent extracts, unlike that to the intact synaptosomes, was inhibited by NaCl, with half-maximal inhibition at a concentration of 150 mM.

Partial purification of [^{125}I]ω-CgTx binding sites in detergent extracts was achieved with three different methods. When detergent extracts were fractionated on sucrose density gradients (12-30% w/v), [^{125}I]ω-CgTx binding peaked at 19% sucrose, well-separated from the bulk of protein (peak at 15% sucrose). Maximum specific activity was approximately 0.5 pmol/mg protein, indicating a purification of approximately 2-fold. Elution of detergent extracts through Sepharose 6B also gave a significant purification; [^{125}I]ω-CgTx binding activity eluted earlier than did the bulk of the protein, yielding a purification of 2-4 fold. A significant fraction of the binding sites eluted in the void volume, indicating a tendency for the sites to remain or become clustered upon solubilization. [^{125}I]ω-CgTx binding protein was bound by wheat germ agglutinin-Sepharose 6B, and could be eluted by addition of 200 mM N-acetylglucosamine to the column buffer, with a resultant 5-fold enrichment of binding sites. Unlike dihydropyridine binding activity from skeletal muscle, functional [^{125}I]ω-CgTx binding sites could not be recovered after adsorption to DEAE Sephadex.

These results show that the [^{125}I]ω-CgTx binding protein from rat brain can be solubilized from membranes without loss of activity, and that standard techniques for protein purification can lead to significant enrichment in [^{125}I]ω-CgTx binding activity.

281.8 FORMATION OF CELL-FREE PATCHES UNMASKS A LARGE, DIVALENT-PERMEABLE, VOLTAGE-INDEPENDENT CHANNEL IN APLYSIA NEURONS. J.A. Strong, A.P. Fox, R. W. Tsien, and L.K. Kaczmarek. Depts. of Pharmacology & Physiology, Yale Med. School, New Haven, CT 06510

Recent work has shown that excitable cells contain a number of different kinds of voltage-activated calcium channels, which differ in their conductances, voltage dependence, and kinetic properties. We now report that Aplysia neurons contain a voltage-independent divalent-permeable channel whose activity is prominent in cell-free patches but virtually undetectable in cell-attached recordings. For most experiments, we recorded from cell-free, inside-out membrane patches taken from bag cell neurons maintained in primary culture, using Ba as the extracellular charge carrier, and K-aspartate (with 15 mM EGTA, 15 mM HEPES (7.8)) on the intracellular side. Under these conditions, an inward channel is observed which has several unusual properties:

(1) a strong selectivity for divalent cations. In 370 mM Ba/535 mM K (or Na), the reversal potential is >75 mV, indicating a selectivity on the order of 1000:1 for Ba over K or Na.

(2) a surprisingly large single channel conductance. With 185 mM Ba, the single channel conductance is 85 pS; the open channel current at -70 mV is 8 pA. As has been found for several voltage-activated calcium channels, the open channel current-voltage relation becomes less steep near the reversal potential.

(3) a lack of voltage-dependent activation and inactivation. Although depolarization does increase the open time, channel openings can be readily observed within the entire voltage range studied (-120 to +150 mV).

(4) a ubiquitous distribution. Virtually every patch, taken from either the soma or from processes, contains at least 2-4 channels.

Based on these 4 characteristics, the channel is almost certainly the same as that which has been extensively characterized by Chesnoy-Marchais (J. Physiol. 367:457) in outside-out patches taken from Aplysia neurons in situ.

(5) We have found that, despite this ubiquitous distribution, channel openings are virtually never observed during cell-attached recordings. In a typical 20 minute cell-attached recording (used to study 2 smaller, voltage activated calcium channels present in these cells) we would see the channel open once or not at all. This suggests that an unknown cytoplasmic regulator acts either to keep the channel closed or to markedly alter its characteristics. We are presently attempting to characterize this regulation. Application of ATP or Mg.ATP (2 mM), GTP (0.2 mM), Ca (up to 10 uM) or glucose (5 mM) to the intracellular side of cell-free patches failed to close the channel. We have noted that openings are sometimes seen in cell attached patches in cells following prolonged exposure to low-Ca solutions. The channel is unlikely to be activated by cellular aspartic acid receptors, as we obtained similar results with K-methane sulfonate. We are also investigating the possibility that the channel subserves an influx of calcium into rapidly retracting processes. In 2 cell-attached patches we observed transient openings of the channel when a process just distal to the patch began to retract following acute mechanical injury.

281.9 LOW THRESHOLD CALCIUM CONDUCTANCE IN PARABRACHIAL RETICULAR NEURONS STUDIED *IN VITRO* AND ITS BLOCKADE BY 1-OCTANOL. C. S. Leonard and R. Llinás. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

The electrophysiological properties of dorsolateral pontine reticular formation neurons belonging to the lateral parabrachial and pedunculopontine nuclei were studied in guinea pig brain slices. Intracellular recordings from these neurons revealed two groups of cells. One group demonstrated action potentials followed by a long lasting afterhyperpolarization (AHP). Current clamp analysis and blockage of the AHP by bath application of 5 mM 4-aminopyridine indicated that an "A" current is responsible for this AHP. The other group of cells, in addition to fast, TTX-sensitive spikes, demonstrated "low-threshold" calcium-dependent spikes (LTSs) similar to those observed in thalamic (Jahnsen & Llinás: J. Physiol., 349: 205, 1984) and inferior olivary (Llinás & Yarom: J. Physiol., 315: 549, 1981) neurons. Indeed, the LTSs were insensitive to 10^{-4}M TTX, but were blocked by bath application of 0.5 mM Cd, suggesting that the LTSs are mediated by a Ca current. Also, in the above neurons the conductance underlying the LTS was usually inactivated at resting potential and became de-inactivated upon membrane hyperpolarization. In addition, 1-octanol which was recently reported to block low-threshold Ca currents in inferior olivary cells (Llinás & Yarom: Soc. Nsci. Abst., 12:174, 1986), almost completely blocked this low-threshold spiking when added to the bath at concentrations of 10^{-5} to 10^{-6}M. The location of these neurons overlapped that of neurons labelled retrogradely by injections of fluorescent microspheres into the thalamus *in vivo*. This finding is of interest as it is known that neurons of the lateral parabrachial nucleus projecting to the thalamus fire a burst of action potentials during the PGO waves and rapid eye movements of paradoxical sleep (Sakai: in Brain Mechanisms of Sleep, ed. D. McGinty et al., Raven, 1985). Since the LTS cells described here produce a burst of fast Na spikes when the LTS is activated, it is reasonable to hypothesize that the LTSs play an important role in the production and control of PGO waves and in the activation of thalamic systems involved with the generation of eye movements accompanying the dream state. [Research was supported by grants NS-07848 and NS-13742 from NINCDS.]

281.10 PHARMACOLOGICAL DIFFERENCES BETWEEN INFERIOR OLIVE AND THALAMIC LOW THRESHOLD CALCIUM CONDUCTANCES. E. Geijo-Barrientos* and R. Llinás (SPON: S. M. Simon). Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

An *in vitro* study of guinea pig olivary neurons, using voltage clamp techniques, recently demonstrated that 1-octanol at doses of 1 μM reversibly and almost completely blocks the low-threshold Ca conductance in those neurons (Llinás & Yarom: Soc. Nsci. Abst., 1986). We designed a similar study to test whether the low threshold Ca conductance seen in thalamic neurons (Llinás & Jahnsen, Nature 297: 406, 1982; Jahnsen & Llinás, J. Physiol. 349: 205, 1984) is also equally affected by the alcohol. Adult guinea pigs weighing 150-200 gm were utilized and the cells in different thalamic nuclei (including nucleus reticularis thalami) were studied intracellularly using a single electrode voltage clamp (Axoclamp Instruments). Results demonstrated that 1-octanol at doses of 10-50 μM reduces only partly the low-threshold Ca current. Also, as previously reported for the inferior olive, it did not affect the high-threshold dendritic Ca conductance. These results suggest that two different low-threshold Ca conductances may in fact exist in CNS neurons. However, because the octanol blockage of the low-threshold Ca conductance may not occur by direct action on the low-threshold Ca channel, the possibility that octanol may be used to differentiate the two low-theshold Ca conductances must remain open. Nevertheless, the effects of octanol in the *in vivo* preparation also indicate that doses sufficiently high to block physiological as well as harmaline tremor are insufficient to block cortical spindling of thalamic origin (Llinás, Paré, Deschênes & Steriade, Soc. Nsci. Abst. 1987). This indicates that octanol may be utilized as a drug capable of differentiating these two types of neuronal oscillation. [Supported by a fellowship from Generalidad Valenciana (Spain) and Program Grant NS13742 from NINCDS.]

281.11 DIFFERENCES BETWEEN THALAMOCORTICAL SPINDLING AND PGO WAVE GENERATION DEMONSTRATED BY LOW-THRESHOLD CALCIUM CURRENT BLOCKAGE BY OCTANOL. R. Llinás, D. Paré, M. Deschênes and M. Steriade. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016, and Laval Univ. School of Med., Quebec G1K 7P4, Canada.

Recent studies *in vitro* have demonstrated that octanol at concentrations of 10^{-6} g/ml (7.6 μM) can specifically block the low threshold calcium conductance underlying calcium spikes in the inferior olive (Llinás & Yarom, Soc. Nsci. Abst. 1986). Further studies with this compound indicate that, by contrast, the thalamic low threshold spike is only partly blocked in concentrations of 10-50 μM (Geijo-Barrientos & Llinás, Soc. Nsci. Abst., 1987). However, neurons in the nucleus parabrachialis (which projects to the thalamus) seem to have a similar sensitivity to octanol *in vitro* (1-10 μM for almost complete block; Leonard & Llinás, Soc. Nsci. Abst., 1987) as do inferior olivary cells *in vitro*. The possibility exists, therefore, that octanol may differentiate the mechanisms which generate the thalamo-cortical oscillations, known as spindling, from the so-called PGO (ponto-geniculo-occipital) waves which accompany eye movement in the dreaming state. This hypothesis was tested in anesthetized cats after high collicular transection. Under these conditions, spontaneously occurring spindles and related spike bursts were abolished and replaced by tonic single spike discharge for 15 to 20 min by intravenous injections of octanol at a concentration of 15 to 18 mg/kg. On the other hand, PGO waves induced by Reserpine, as well as the PGO-like waves evoked in the lateral geniculate neurons, were blocked for 12 min by concentrations of only 5 mg/kg octanol. In agreement with these results is the fact that alcohol in general is known to reduce REM sleep in man (Gross et al., J. Nerv. Ment. Dis. 142:493, 1966). These results point out the relevance of biophysical studies *in vitro* in the understanding of the mechanisms that ultimately generate brain function. (Supported by Program grant NS13742 from NINCDS and MRC grants MT-3689 and MT-5877).

282.1 **NEUROTROPHIC ACTION OF GLYCYL-L-GLUTAMINE IN PRESERVING ACETYLCHOLINESTERASE OF PREGANGLIONICALLY DENERVATED CAT SUPERIOR CERVICAL GANGLION.** **G.B. Koelle, N.S. Thampi, and U.J. Sanville*. Dept. of Pharmacology, Med. Sch., Univ. of Pennsylvania, Philadelphia, PA 19104-6084.**

The fall in acetylcholinesterase (AChE; EC 3.1.1.7) of the cat superior cervical ganglion (SCG) that follows preganglionic denervation is opposed by intracarotid infusion of an aqueous extract of cat central nervous system or its dialysate, or of glycyl-l-glutamine (GlyGln), glycyl-l-glutamic acid, or l-glutamic acid (Koelle, G.B. et al., Proc. Natl. Acad. Sci. USA, 80:3106; 81:6539; 82:5213; 83:2751, 1983-1986). Infusions were given via the right common carotid artery from 24 to 48 hr following bilateral preganglionic denervation.

In contrast to the other preparations, the effect of GlyGln was confined to the circulatory remote left SCG and not detectable at the directly infused right SCG; this suggested that a metabolite of GlyGln, formed in the blood, is an active neurotrophic factor. An alternative explanation has now been tested: that GlyGln must combine slowly with some component of plasma to allow its penetration to the cytoplasm of ganglionic neurons.

GlyGln was incubated overnight at 5°C with fresh or heat-treated (60°C for 60 min) plasma, then infused as usual for 24 hr via the right common carotid artery; ganglia were excised and assayed 48 hr post-denervation. Infusion of GlyGln had a marked neurotrophic effect in preserving AChE in both right and left SCG at 3 µM following incubation with either fresh or heat-treated plasma; lower positive effects were detectable at 1 and 0.3 µM; at concentrations of 100 µM or higher, GlyGln had an inhibitory effect on AChE contents of SCG. Results indicate that GlyGln has a direct, potent neurotrophic action. Preliminary findings suggest that it acts by regulating the conversion of G_1 to G_4 AChE.

282.2 **DEOXYCYTIDINE MAY HAVE A CRITICAL ROLE IN THE SURVIVAL OF POSTMITOTIC PERIPHERAL NEURONS THAT IS INDEPENDENT OF DNA SYNTHESIS.** T. L. Wallace and E. M. Johnson, Jr. Center for Biotechnology, Baylor College of Medicine, and Houston Biotechnology, Inc., The Woodlands, TX 77381 and Department of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

The molecular mechanism by which neurotrophic factors maintain the survival of neurons is not well understood. We have found that deoxycytidine is critical for the KCl and insulin-stimulated survival of postmitotic ciliary parasympathetic ganglion neurons, and the nerve growth factor-stimulated survival of postmitotic dorsal root ganglion sensory neurons in vitro. Cytosine arabinoside (ARA C), a competitive inhibitor of 2'-deoxycytidine, caused a concentration-dependent inhibition of survival of both neuronal types with an $IC_{50} = 2 \times 10^{-8}$ M after four days in culture. This cytotoxic effect of ARA C was blocked by 2'-deoxycytidine and its 2'-deoxynucleotides, but not by cytidine, cytosine, 2'-deoxyadenosine, 2'-deoxyguanosine, or 2'-deoxythymine, showing that ARA C interfered with a deoxycytidine-specific survival process. 2'-Deoxycytidine, by itself, was not survival-promoting. That is, it acted to block the effects of ARA C, but could not by itself stimulate survival. Other antimitotic agents, such as adenine arabinoside, thymine arabinoside, 5-fluorodeoxyuridine, and aphidicolin had no effect on neuronal survival at a concentration 5,000 times the IC_{50} of ARA C, indicating that inhibition of deoxyribonucleic acid (DNA) synthesis was not the cause for the inhibition by ARA C of neuronal survival. This also showed that other 2'-deoxynucleosides were not involved in the survival process. Nitrobenzylthioinosine, an inhibitor of 2'-deoxycytidine and ARA C membrane transport in other cell types, inhibited the cytotoxic effect of ARA C, suggesting that ARA C entered the neurons through a similar transport mechanism and that ARA C needed to gain access to the inside of the neuron to be effective. These results indicate that ARA C, in addition to being an antimitotic agent for dividing cells, is also cytotoxic for postmitotic neurons. This inhibition of neuronal survival by ARA C is hypothesized to be due to inhibition of a 2'-deoxycytidine-dependent pathway, but one, however, that is independent of DNA synthesis. This suggests that 2'-deoxycytidine may be a common mediator of the survival-promoting effects of several trophic factors on peripheral neurons. Thus, 2'-deoxycytidine's role in cellular function appears to be not simply limited to that of a metabolic precursor of DNA. 2'-Deoxycytidine may have an important and previously unrecognized role in postmitotic neurons that is critical for neuronal survival.

282.3 PARTIAL PURIFICATION AND CHARACTERIZATION OF A MEMBRANE-DERIVED FACTOR REGULATING TRANSMITTER PHENOTYPIC EXPRESSION. J.E. Adler, L.S. Schleifer and I.B. Black. Division of Devel. Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021.

We have previously reported that cell membrane contact induces de novo expression of choline acetyltransferase (CAT) activity in virtually pure cultures of neonatal rat dissociated sympathetic neurons. To define underlying molecular mechanisms, we have begun to isolate and characterize the membrane-associated component(s) that stimulates CAT expression. Cultures were first exposed to membranes derived from a variety of adult rat tissues to define specificity. Membranes from spinal cord, as well as sympathetic and dorsal root sensory ganglia contained substantial CAT-inducing activity. Spinal cord membranes were employed as a source for purification due to the large quantities of tissue available and the high CAT-inducing activity.

After spinal cords were homogenized in low ionic strength buffer and centrifuged at high speed, CAT-inducing activity was predominantly localized to the membrane pellet. Using increased ionic strength, we were able to extract more than half of the total CAT-inducing activity from the membranes in a soluble form.

The solubilized extract was applied to a variety of chromatographic columns. Activity was eluted from a DEAE ion exchange column in a sharp peak containing less than 10% of the applied protein. Gel chromatography also resulted in a single sharp peak of activity containing 10% of the applied protein. Sequential application of the extract to these two columns yielded substantial purification. The activity peak from the gel column correlated with an approximate Mr of 27 KD. Activity eluted from a heparin affinity column at very low salt concentrations, suggesting that the factor is not a heparin binding protein. Our studies suggest that cell contact-mediated regulation of phenotypic expression may be governed by a discrete membrane factor. We are presently continuing isolation and characterization. (Supported by NIH grants HD 12108, NS 10259, the Dysautonomia Foundation Inc. and the American Heart Assoc. L.S.S. is a recipient of a Cornell Scholars Award. I.B.B. is a recipient of a McKnight Research Project Award).

282.4 SCHWANN CELLS SHED A TRUNCATED FORM OF THE NERVE GROWTH FACTOR (NGF) RECEPTOR. P.S. DiStefano and E.M. Johnson, Jr. Neuroscience Research Unit, Abbott Laboratories, Abbott Park, IL 60064, and Department of Pharmacology, Washington University, St. Louis, MO 63110.

Recent studies have demonstrated the rapid appearance of NGF receptors on Schwann cells due to the loss of axon-Schwann cell contact. This phenomenon has been demonstrated both in vivo and in vitro. We report here that cultured rat Schwann cells, as well as a schwannoma cell line (JS-1 cells), secrete a truncated form of the NGF receptor (NGF-Rt) into their culture medium. Cell surface NGF receptors and NGF-Rt from conditioned media were assayed by crosslinking specifically bound ^{125}I-NGF with EDAC. Cell surface receptors were then solubilized with octyl glucoside. NGF-NGF receptor species were immunoprecipitated from cell extracts or media with the anti-rat NGF receptor monoclonal Ab, 192-IgG. Labeled receptor species were visualized using SDS acrylamide gel electrophoresis/autoradiography. Conditioned media from primary Schwann cell cultures and JS-1 cells showed a distinct immunoprecipitable band at 65 kD (subtracting a monomer of NGF yielded a fragment of ~52 kD). Conditioned media from PC12 cells and brain septal neurons were devoid of NGF-Rt, as was naive medium.

To demonstrate an in vivo correlate of this phenomenon, urine and plasma samples were collected from various aged rats and assayed for NGF-Rt as described above. In urine, NGF-Rt levels were high in 1 day old rats and decreased approximately 50 fold by adulthood (4-8 wks). NGF-Rt was also detected in amnionic fluid of E15 and E19 rats. A similar developmental pattern of NGF-Rt was seen in plasma samples, although plasma concentrations appeared lower than urinary NGF-Rt levels. If the NGF-Rt observed in early development was a product of Schwann cells, we predicted that sciatic nerve section, which dramatically increases NGF receptor levels on Schwann cells, would result in increased urinary and plasma NGF-Rt levels. It was found that bilateral sciatic nerve transection increased NGF-Rt significantly in urine and plasma as early as 1 day post lesion; NGF-Rt levels remained elevated at 14 days post lesion.

The shedding of cell surface NGF receptors by Schwann cells may reflect a mechanism by which the cell eliminates or turns over NGF receptors. Alternatively, the NGF-Rt may subserve a secondary function once it is cleaved from the cell surface.

282.5 REDUCTION OF NATURALLY OCCURRING MOTONEURON DEATH IN VIVO BY A PUTATIVE TARGET-DERIVED NEUROTROPHIC FACTOR. R. W. Oppenheim, L. J. Haverkamp, D. Prevette* and S. Appel. Dept. of Anatomy, Wake Forest Univ. Sch. of Med., Winston-Salem, NC 27103 and Dept. of Neurology, Baylor Coll. of Med., Houston, TX 77030.

Between embryonic day 6 (E6) and E10 approximately one-half of the motoneurons (MNs) in the lumbar lateral motor column (LMC) of the chick embryo that normally innervate hindlimb musculature degenerate and die by a process known as naturally occurring neuronal death. It is generally believed that neurons in the LMC compete for a target-associated entity that is limited in amount relative to the total number of neurons present prior to cell death. A number of in vitro studies have, in fact, demonstrated that crude or partially purified factors derived from target muscles can influence the growth, differentiation and survival of dissociated spinal cord neurons. We now report that target derived factors can also markedly increase the survival of MNs in vivo.

In our initial experiments, we found that treatment of embryos for several days (E5-8) with 250 µl (3-4 mg protein/ml) of crude muscle homogenates taken from E8-9 hindlimbs reduced LMC-MN death by 20-30%. Kidney or lung extract or heat inactivated muscle extracts were ineffective. Embryonic motility, an index of neuromuscular activity, was normal in the treated embryos. Because most of the survival activity was retained in a 25-75% ammonium sulfate fraction ($AmSO_4$) all subsequent experiments were done with this partially purified extract. The survival effect of the $AmSO_4$ fraction on MNs was found to be dose-dependent. The partially purified extract had no effect on the survival of neurons in either dorsal root (DRG) or sympathetic ganglion (SG) whereas treatment with NGF (20 µg daily) increased the survival of DRG and SG neurons but had no effect on MN survival. Furthermore, whereas NGF treatment resulted in increased cell size of DRG and SG neurons (but not MNs), the muscle-derived factor did not affect MN, DRG or SG cell size. Treated embryos had reduced numbers of pyknotic MNs in the LMC. Enhanced MN survival occurred along the entire length of the lumbar LMC as well as in non-limb innervating (thoracic) regions. The massive MN death that occurs following early (E2) limb-bud removal was partly ameliorated by treatment with the $AmSO_4$ fraction. Preliminary results from treatment with three different components of the $AmSO_4$ fraction (< 30,000 MW, 30,000-75,000 MW and > 75,000 MW) indicate that most of the survival activity is contained in the < 30,000 MW component. Experiments are in progress to further purify and characterize this putative MN survival factor and to examine its primary or secondary effects on muscle development and innervation.

282.6 THYROTROPIN RELEASING HORMONE DE-AMINATION OBLITERATES ITS TROPHIC EFFECT IN NEURONAL CULTURES.

R.W. Banda*, E.D. Means, and H. Scherch*
Department of Neurology, Veterans Administration Medical Center and University of Cincinnati Medical Center, Cincinnati, Ohio 45267

The role of thyrotropin releasing hormone (TRH) in neuronal growth and survival has been the subject of several recent investigations. It has been localized to the ventral horn of the spinal cord in several mammalian species. We have shown in the past a trophic effect for this peptide in murine ventral horn neuronal cultures in terms of perikaryal size and complexity of neurites. We have also demonstrated its protective effect on neuronal loss following peripheral nerve section. The present study was undertaken to examine the possible effect of TRH-OH, the de-aminated metabolite of TRH formed via the proline endopeptidase pathway on neuronal cultures.

Ventral horn neurons from 12- to 14- day old mouse embryos were cultured using standard techniques. Two groups of cultures were fed daily a final concentration of 0.1 mM and 0.01 mM TRH respectively. Two more groups were similarly fed a final concentration of 0.1 mM and 0.01 mM TRH-OH. One group received vehicle only, and a final group was left untreated. At 18 days the cultures were fixed and stained with cresyl violet. Neuronal perikaryal area and maximal diameter were computed using a Leitz Dialux 22 microscope with camera lucida attachemnt and a Zeiss Videoplan semiautomatic image analyzer. Available software allowed for the construction of histograms and statistical analysis. The results revealed no significant difference in neuronal area and maximal diameter between the untreated controls, the vehicle treated controls and the TRH-OH treated cultures at both concentrations. As expected perikaryal area and maximal diameter were significantly increased in the TRH treated cultures at both concentrations employed ($p<0.01$).

These results suggest the lack of a neurotrophic effect for TRH-OH in this experimental paradigm. Whether the proline endopeptidase pathway leading to the formation of TRH-OH is significant in the inactivtion of TRH in these neuronal cultures merits further investigation.

282.7 AXONAL SPROUTING IN LISSAUER'S TRACT IN ANTI-NGF TREATED RATS. C.E. Hulsebosch, R.E. Coggeshall and J.R. Perez-Polo. Marine Biomedical Institute, Departments of Anatomy and Neurosciences, Physiology and Biophysics, Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX 77550.

We previously reported more unmyelinated primary afferents in dorsal roots of the operated side compared to controls after unilateral spinal cord denervations. We interpreted this to mean that neurons emitted more branches as a result of spinal denervation. In an effort to manipulate this phenomenon, Nerve Growth Factor or antisera to Nerve Growth Factor (ANTI-NGF) were given in daily subcutaneous injections (1.5 µl/gm body weight of NGF at 10 ng/ml PBS and undiluted antisera, 3 µl/gm body weight, respectively) from birth for a period of one month. We previously reported a significant increase in the number of unmyelinated fibers in dorsal roots (T4, T5, T6) of the ANTI-NGF rats compared to denervated, NGF treated, preimmune sera treated or untreated littermate animals despite a concomitant 38% decrease in the number of small diameter dorsal root ganglion cells in the same segments of the ANTI-NGF rats. The present study presents preliminary data on the number of unmyelinated (UN) and myelinated (MY) fibers in Lissauer's tract, a tract in the white matter in which unmyelinated and small diameter myelinated primary afferents as well as propriospinal fibers are found, in the T3-T4 segment in ANTI-NGF rats compared to normal littermates.

	ANTI-NGF			NORMAL		
	MY	UN	TOTAL	MY	UN	TOTAL
	1833	15685	17518	1711	10259	11970
	1584	10256	11840	2226	10566	12792
	2037	13776	15813	1522	8289	9811
	1908	10171	12079	418	8007	8425
Mean	1841	12470	14310	1469	9280	10750
± S.E.	± 95	±1361	±1403	±380	±659	± 998

Since the same ANTI-NGF rats demonstrated a 38% decrease in small diameter neurons and small diameter neurons are thought to give rise to small diameter fibers, one would predict a significant decrease in the number of fibers in Lissauers tract unless sprouting occurred in either the primary afferents or the propriospinal neurons. Since the total means are 14,310 for the ANTI-NGF rats and 10,750 for the normal rats. This data supports the hypothesis of increased branches or axonal sprouting in the white matter as a result of NGF deprivation.

Supported by NIH grants NS20091, NS11255, NS17039, NS18708 the Spinal Cord Research Foundation of PVA and the Florence and Marie Hall Endowment for Programs of Excellence in Education in the Medical Sciences.

282.8 NGF IMMUNOREACTIVITY AND BIOLOGICAL ACTIVITY IN THE PITUITARY GLAND. S. Soinila, J. Lakshmanan* and T. Lahtinen*
Hatfield Marine Science Center, Oregon State University, Newport, OR 97365; Growth Factor Laboratory, Center for Neurologic Study, San Diego, CA; Dept. Anatomy, University of Helsinki, Finland.

A physiological role for NGF in the normal development of the peripheral sympathetic and sensory cells has been clearly demonstrated. There is also evidence that NGF has potent effects on various central neurons. However, the endogenous sources and routes of NGF supply to the neurons are not completely understood. We have studied various endocrine organs (pituitary, thyroid, parathyroid glands, adrenal medulla and gonads) as possible NGF sources and recently reported evidence that the pituitary gland might be one (Soinila et al., Soc. Neurosci. Abstr., 12, 1986).

In the present study we have investigated the biological NGF activity in the pituitary gland by coculturing each lobe at various ages with newborn rat sympathetic ganglia (for method see Lahtinen et al., Dev, Brain Res. 27:51, 1986).

Explants of the anterior, intermediate and posterior pituitary lobes taken from newborn, 2- and 3-week-old and adult rats stimulated nerve fiber growth from newborn superior cervical ganglia. This effect was completely abolished by antiserum to NGF. Freezing of the pituitary lobes for 7 days did not inhibit their growth-promoting effect, suggesting that biologically active NGF or an NGF-like factor is present in vivo in each lobe during the entire postnatal period.

NGF immunoreactivity in the adult gland is localized exclusively in the intermediate lobe (Soinila et al., Soc. Neurosci. Abstr.,12, 1986). We therefore tested the hypothesis that NGF levels in the anterior and posterior lobes remain low due to rapid retrograde axonal transport. The superior cervical ganglion, which is known to send axons to both anterior and posterior lobes, was bilaterally extirpated. This operation failed to produce immunohistochemically detectable NGF in either anterior or posterior lobe, but, surprisingly, it decreased the fiber growth stimulation by both lobes.

We suggest that pituitary NGF is a potential source of circulating NGF, and its levels are neurally controlled. It could also serve as a trophic factor for the innervating neurons or as a local neuromodulator.

282.9 NGF FACILITATES THE SURVIVAL OF RETINAL GANGLION CELLS AFTER OPTIC NERVE SECTION. G. Carmignoto*, P. Candeo*, R. Canella*, C. Comelli*, L. Bigon*, G. Vantini and L. Maffei*°. (SPON: G. Calderini). Fidia Research Laboratories, 35031 Abano Terme (PD), Italy. °Istituto di Neurofisiologia del CNR, Pisa, Italy.

In adult rats, intracranial transection of the optic nerve leads to degeneration of retinal ganglion cells, which is almost complete after 2 months. We here report that repetitive intraocular injections of βNGF (from male mouse submaxillary glands; 5 μg/injection every 48 hours) prevents, at least in part, the degeneration of a class of rat ganglion cells for a period as long as 2 months post-transection. Ganglion cells were retrogradely labelled with HRP pellets applied to the proximal stump of the optic nerve at 5-7-9 weeks after sectioning. After 24 hours, rats were perfused and the retinae dissected, post-fixed and reacted for HRP. The outlines of HRP-filled ganglion cell bodies were drawn with a camera lucida and measured with an IBAS-1 computer. In the same animals, the number of apparently normal myelinated axons of the optic nerve was estimated in semithin sections taken at 1 and 2 mm from the globe. Analysis of whole-mounted retinae shows that HRP filled ganglion cells of large size are more numerous in the retinae of the eyes treated with NGF, with respect to control retinae treated with cytochrome c. In particular, ganglion cells above 15 μm in mean diameter are present only in the retinae treated with NGF. Counting of myelinated optic nerve fibers shows that the number of morphologically intact fibers in the experimental optic nerves is about twice that of the controls. Hence, the intraocular injection of NGF has an effect on the survival of ganglion cells after section of the optic nerve. Whether this is due to a direct or indirect (via cholinergic amacrine cells) effect of NGF on the ganglion cells is currently under investigation.

282.10 MODULATION OF IN VITRO NEUROTROPHIC INTERACTION BY GANGLIOSIDE. F.J. Roisen, H. von Hoesslin*, S.P. Mahadik[1], M.M. Rapport[1], and G. Yorke*. Dept. of Anatomy, Sch. of Med., Univ. of Louisville, Louisville, KY 40292 and [1]Div. of Neurosci, New York State Psychiatric Inst., New York, NY 10032.

Gangliosides are glycosphingolipids that are more abundant in neuronal membranes than those of other tissues. They stimulate neuritic differentiation of Neuro-2a neuroblastoma and chick embryonic sensory ganglia (DRG) in culture. They potentiate some of the morphological and biochemical actions of Nerve Growth Factor (NGF) on DRG and the NGF-responsive rat pheochromocytoma cell line PC-12. We have demonstrated that monoclonal antibodies (mAbs) against the monosialoganglioside GM1 can diminish both NGF-mediated and NGF-independent neuritogenesis in DRG. The present study examines further the role of gangliosides in the regulation of neurotrophic interactions. Two neuritogenic models, DRG and PC-12, were cultured in the presence of either heart conditioned media (HCM) (Helfand et al, Exp. Cell Res., 113:39, 1978) or NGF. The effect of exogenous GM1 (150 ug/ml) on HCM or NGF mediated neuritogenesis was evaluated microscopically as neurite number and length and biochemically as changes in ornithine decarboxylase activity. For DRG and PC-12, the morphological and biochemical actions of NGF were potentiated by simultaneous treatment with GM1. Equivalent results were obtained by pretreating cultures with GM1 for 24 h prior to washing and refeeding with growth promoting medium. The neuritogenic action of HCM on DRG was enhanced by GM1. GM1 alone increased ODC levels, while HCM reduced ODC activity of DRG. Simultaneous exposure of DRG to HCM and GM1 resulted in further reduction of ODC activity. In contrast, although HCM elevated ODC activity of PC-12 cells, exogenous GM1 had no effect. Five mAbs against GM1 (Mahadik et al, J. Neurochem., 47:1172, 1986) were used to probe the role of endogenous ganglioside in DRG and PC-12 neurite formation. The antibodies were incorporated into the media at 20% and applied in the presence and absence of HCM or NGF. The mAbs reduced the actions of both HCM and NGF on DRG and PC-12. The mAb A2B5, which recognizes several neuronal gangliosides except GM1, had no effect. These studies suggest that GM1 can regulate neuronal development. Supported by NIH grant NS 24524.

282.11 SURVIVAL OF AXOTOMIZED SEPTAL CHOLINERGIC NEURONS: COMPARISON OF THE EFFECTS OF NERVE GROWTH FACTOR AND GM1 GANGLIOSIDE TREATMENTS. Lawrence F. Kromer, Dept. of Anatomy & Cell Biology, Georgetown University, School of Medicine, Washington DC 20007.

Several recent studies have indicated that the intraventricular administration of exogenous nerve growth factor (NGF) can prevent retrograde neuronal degeneration of septal cholinergic neurons after partial or complete transections of the dorsal septo-hippocampal pathways (Hefti '86, J. Neurosci. 6: 2155; Williams et al. '86, PNAS 83: 9231; Kromer '87, Sci. 235: 214). Peripheral administration of exogenous ganglioside GM1 also is reported to prevent retrograde changes after partial lesions of the basal forebrain cholinergic projections to hippocampal and neocortical areas (Cuello et al. '86, Brain Res. 376: 373; Sofroniew et al. '86, Brain Res. 398: 393). At present it is uncertain whether GM1 has a direct effect on cell survival or whether its effect is mediated by enhancing the ability of injured neurons to respond to low levels of their appropriate neurotrophic factor, such as NGF. The present experiments, therefore, were undertaken to compare the effects of exogenous GM1 and NGF on the survival of septal cholinergic neurons which received complete bilateral aspiration lesions of their axonal projections to the dorsal hippocampus. For this study lesioned animals were treated for 14 days beginning immediately after surgery with either a daily intraperitoneal administration of GM1 (30 mg/kg) or a continuous intraventricular infusion of NGF (2.5 ug of 2.5s NGF/day). Immunocytochemical staining for choline acetyltransferase (CAT) was used to identify surviving cholinergic neurons within the dorsal medial septum. Results from these experiments indicated that only about 20% of the CAT+ neurons in the medial septum survive bilateral lesions of the dorsal septo-hippocampal pathway. In contrast, approximately 85% of these neurons are present 2 weeks after this lesion when NGF is administered intraventricularly. Current data indicate that only 32% of the cholinergic neurons in the dorsal medial septal survive when GM1 is administered intraperitoneally. These preliminary results suggest that treatment with GM1 alone (in contrast to NGF) is not as effective in rescuing septal cholinergic neurons when there is a complete bilateral transection versus a partial lesion of the dorsal septo-hippocampal pathways. This difference in cell survival in the two paradigms may be associated with greater levels of endogenous trophic factors being available to the septal neurons after partial fornix/fimbria lesions. Further experiments are being conducted to resolve this issue. However, the present data are consistent with the hypothesis that the effect of GM1 on cholinergic neuronal survival requires the presence of at least low levels of endogenous trophic factor. (Supported by NIA grant #AG-06648)

282.12 GM1 GANGLIOSIDE FACILITATES NEURONOTROPHIC FACTOR EFFECTS BOTH IN VIVO AND IN VITRO. A. Leon, S.D. Skaper, G. Vantini and G. Toffano. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy.

An increasing number of studies are now available indicating that the systemic administration of monosialoganglioside GM1 is effective in ameliorating outcome following experimentally induced brain damage to adult rodents. In addition, cultured neuronal cells, both primary and clonal, are known to respond to the ganglioside with pronounced morphological changes characteristic of cell differentiation. In cells with an absolute neuronotrophic factor requirement for survival and/or neurite outgrowth, the GM1 effects are associated with amplification of the trophic factor action on its target neuronal cells. For example, it has been reported that exogenously supplied GM1 is capable of potentiating the nerve growth factor (NGF)-induced neurite outgrowth of embryonic dorsal root ganglionic neurons and sympathetic ganglia. A similar situation was recently observed in vivo and suggests that GM1 effects in vivo, as in vitro, may be related to modulation of neuronal cell responsiveness to neuronotrophic factors. Studies conducted utilizing neuronal cell cultures indicate that the GM1 ganglioside stably associated to the cell surface is most probably responsible for the observed effects. There is now evidence that gangliosides may affect the production of second messengers involved in the membrane-mediated transfer of information. Hence, the capability of GM1 to facilitate neuronotrophic factor effects may involve amplification or modulation of the membrane-mediated transduction and/or translation of the trophic signal(s).

283.1 **HYPERALGESIA FOLLOWING NALOXONE-PRECIPITATED WITHDRAWAL FROM MORPHINE IS ASSOCIATED WITH INCREASED ON-CELL ACTIVITY IN THE ROSTRAL VENTROMEDIAL MEDULLA (RVM).** **J. B. Bederson*, N. M. Barbaro*, and H. L. Fields.**
Departments of Neurosurgery, Neurology, and Physiology, University of California, San Francisco, 94143

Two physiologically defined classes of cells in the rostral ventromedial medulla, on- and off-cells, have been implicated in modulation of nociceptive transmission and morphine (MS)-induced analgesia. On-cells burst just prior to withdrawal reflexes such as the tail flick or paw pinch withdrawal, and are inhibited by systemically administered MS. Off-cells pause just prior to tail flick and paw withdrawal, and are excited by MS. There is extensive evidence indicating that off-cell discharge inhibits spinal nociceptive transmission, but the role of the on-cell is less clear. On- and off-cells have reciprocal patterns of activity: on-cells are silent during periods of off-cell activity and vice-versa. Baseline tail flick latency (TFL) is shorter when on-cells are active and off-cells silent. The reciprocal relationship between on- and off-cell firing raises the possibility that the on-cell facilitates nociceptive transmission.

One sign of naloxone-precipitated opiate withdrawal is hyperalgesia. If MS-induced changes in on- and off-cell activity are important in analgesia then hyperalgesia may be the result of changes in the opposite direction in these cells. The present studies examine this hypothesis by studying the relationships between tail flick, paw withdrawal, and on- or off-cell activity after naloxone-precipitated withdrawal from MS.

Rats were anesthetized with chloral hydrate followed by continuous i.p. infusion adjusted to achieve stable TFL and paw withdrawal threshold (PWT), without signs of discomfort. Activity of on- and off-cells was continuously recorded. Saline or MS (1.25 mg/kg, i.v.) administration was followed by naloxone (1.0mg/kg, i.v.). TFL and PWT were correlated with cell activity.

Morphine eliminated tail flick and paw withdrawal (cutoff = 10 sec and 500 gm, respectively) as well as both spontaneous and reflex-related on-cell activity. Off-cell activity increased and the nocifensive-related pause was eliminated. When naloxone was given after MS, tail flick and paw withdrawal were consistently reduced to values significantly below baseline (hyperalgesia). On-cell activity was consistently increased above baseline during the period of hyperalgesia and returned to pre-MS levels 10-20 min later, along with the tail flick and paw withdrawal values. Off-cell activity abruptly decreased following administration of naloxone, returning to pre-MS levels as the period of hyperalgesia ended. In control (saline treated) animals, naloxone had no effect on any variable measured.

These results demonstrate a period of hyperalgesia after naloxone-reversal of morphine analgesia which is temporally correlated with increased on-cell activity. The hyperalgesia was observed following a single dose of morphine, and was not produced by naloxone alone. 1. The findings suggest that on-cells are part of a system which facilitates spinal nociceptive reflexes. 2. The results raise the possibility that certain aspects of opiate dependence and withdrawal are explainable by changes in the circuitry of the RVM.

283.2 CHARACTERIZATION OF ANTINOCICEPTION PRODUCED BY INTRATHECAL SEROTONIN. G.F. Gebhart and R.E. Solomon. Department of Pharmacology, University of Iowa College of Medicine, Iowa City, IA 52242.

This study investigated the mechanisms by which intrathecal (i.t.) serotonin (5-hydroxytryptamine; 5-HT) produces antinociception by examining the effects of agents selective for 5-HT_1 receptor subtypes, the development of tolerance to 5-HT chronically administered i.t., and cross-tolerance between i.t. 5-HT and i.t. morphine. Rats were initially deeply anesthetized with pentobarbital (45 mg/kg i.p.) for placement of femoral arterial and venous and 7.5-8 cm i.t. catheters. Under light pentobarbital anesthesia (3-6 mg/kg/hr), the spinal nociceptive tail-flick (TF) reflex was evoked by radiant heating of the tail. Cumulative i.t. doses of drugs were administered in 7.5 µl volumes at 6 min intervals, and TF latencies were determined at 1, 3 and 5 min after each dose. Mean arterial pressure (MAP) was continuously recorded. Dose-response functions for 5-HT were determined 30 min after pretreatment with pargyline (5 mg/kg i.v.). 5-HT (10-320 µg) produced a dose-dependent inhibition of the TF reflex (ED_{50}=100.0 µg; 95% C.L.=47.6-210.0 µg), and a dose-dependent decrease in MAP (-17.0± 5.1 mm Hg at 320 µg). In the presence of the 5-HT antagonist methysergide (30 µg i.t.), the dose-response function for antinociceptive effects of 5-HT was shifted significantly to the right (ED_{50}=460.0 µg; 95% C.L.=164.2-1288.0 µg), whereas the depressor effects of 5-HT were not significantly changed. The selective 5-HT_{1A} agonist, 8-hydroxy-N,N-dipropyl-2-aminotetralin (8-OH-DPAT; 1-320 µg) and the selective 5-HT_{1B} agonist, 5-methoxy 3-(1,2,3,6-tetrahydro-4-pyridinyl) 1 H indole (RU 24969; 1-320 µg) did not increase TF latencies at any dose; rather, both agonists produced 10-20% decreases in TF latencies at the greatest doses tested (100-320 µg). 8-OH-DPAT and RU 24969 also produced dose-related depressor effects that were maximal at 320 µg (8-OH-DPAT: -46.0± 4.3 mm Hg; RU 24969: -28.7±5.0 mm Hg). These results suggest that the depressor, but not the antinociceptive, effects of i.t. 5-HT are mediated by spinal 5-HT_1 receptors. In rats treated chronically with i.t. 5-HT (320 µg/day x 7 days) and tested while awake, 5-HT initially produced significant increases in TF and hot-plate reaction latencies. These effects were significantly diminished on day 7, indicating the development of tolerance to the antinociceptive effects of i.t. 5-HT. Chronic i.t. morphine (32 µg/day x 7 days), which has been found to produce tolerance to the antinociceptive effects of i.t. morphine and cross-tolerance to i.t. clonidine, did not affect the dose-response function for antinociceptive effects of i.t. 5-HT in lightly-anesthetized rats. These results are not inconsistent with reports that opioids and α_2-adrenoceptor agonists, but not 5-HT, share the ability to inhibit release of putative nociceptive transmitters from primary afferents. Supported by DA 02879 and T32 GM 07069.

283.3 ROLE FOR THE HIGH-AFFINITY MU_1 OPIOID BINDING SITE IN CENTRAL OPIATE AND OPIOID ANALGESIA. R.J. Bodnar, C.L. Williams*, S.J. Lee* and G.W. Pasternak. Dept. of Psych. Queens College, CUNY, Flushing NY 11367 and Dept. of Neurol., Memorial Sloan-Kettering Cancer Ctr., NY, NY 10021.

The intracerebral microinjection technique has localized central sites of analgesic action for opiates and endogenous opioids, including the periaqueductal gray (PAG), locus coeruleus (LC), nucleus raphe magnus (NRM) and nucleus reticularis gigantocellularis (NRGC). Multiple opiate receptor subtypes (mu, delta, kappa, epsilon) have been implicated in opiate analgesia elicited from spinal and brainstem loci. Binding studies indicate that many of the ligands used in subtype determinations share a common high-affinity (mu_1) for which selective irreversible antagonists (e.g., naloxonazine) have been developed. Mu_1 sites have been implicated in a number of opiate actions, including supraspinal, but not spinal analgesia elicited by either systemic or intracerebroventricular administration of opiates or opioids. The present study evaluated whether the mu_1 binding site was involved in analgesia elicited by morphine injected into either the PAG, LC, NRM or NRGC. Rats were stereotaxically implanted with guide cannulae (28 gauge) aimed at one of the four loci and microinjected with morphine through a 33 gauge internal cannula 24 h following naloxonazine (20 mg/kg, IV) or vehicle. Latencies were assessed every 15 min for 60 min; naloxone (10 mg/kg, SC) was administered and latencies were then assessed 15 and 30 min after this injection. Morphine (5 ug) elicited analgesia from all four sites which was reversed by naloxone and naloxonazine. Naloxonazine produced a rightward shift in morphine analgesia dose-response curves from the PAG and LC. We then evaluated the analgesic effects of two delta receptor agonists, d-ser_2-thr_6-leucine enkephalin (DSTLE) and d-pen_2-d-pen_5 enkephalin (DPDPE); the former but not the latter interacts with mu_1 sites. Like morphine, DSTLE analgesia from all four sites was blocked by naloxone and naloxonazine. In contrast, DPDPE failed to produce and analgesic response at doses up to 15 ug when injected into either the PAG or LC. These data indicate that the high-affinity mu_1 opioid binding site mediates opiate and opioid analgesia elicited from these integral brainstem loci involved in opiate forms of pain inhibition. (Supported by ACS Grant PDT 169).

283.4 **THE RAT VISCERAL PAIN MODEL (VPM) IN THE ASSESSMENT OF TOLERANCE TO MORPHINE SULFATE (MS).** R.W. Colburn*, D.W. Coombs*, C.C. Degnan*, and L.L. Rogers*
(SPON: S. Velez) Dept. of Anesthesia Research, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756

The Acetic Acid Writhing (AAW) test in the rat (Collier et al, Br J Chemother 32:295,1968) is a classic tool for visceral pain assessment. In the AAW model, intraperitoneal administration of noxious chemical agents induces an inflammatory effect and a quantifiable writhing response. We recently reported a new visceral pain model (VPM) to provoke a reproducible and reversible visceral insult in rats (Coombs et al, Anesthesiology: Submitted 1987) by duodenal distention via inflation of a surgically placed intraduodenal balloon catheter. This distention provokes a writhing-like activity (WLA) characterized by profound contraction of abdominal musculature, body stretching and posturing to right or left. Serial tests potentially allow acute and chronic assessment of analgesic agents and narcotic tolerance.

Under halothane anesthesia, 200 gram Sprague-Dawley rats were implanted with balloon catheters. The rats recovered 72 hours prior to testing nociception. A minimum threshold volume (MTV) to elicit WLA without destroying gut integrity was established (range 0.5-1.0 ml). Five MTV balloon pulses were given over 30 seconds. Rats were observed for 10 minutes to record WLA. Fifteen rats who exhibited WLA were grouped as follows: Group I = Saline Control and Group II = Morphine, 1 mg/ml. One ml/kg of saline or morphine was injected subcutaneously every 12 hours for 5 days. WLA was assessed on Days I and V, 30 minutes after the morning injection. Catheter position and gut integrity were confirmed at post-mortem. Association was analyzed by chi-square (see table below).

Results: On Day I, WLA was observed in 86% of controls and in no morphine-treated rats. On Day V, WLA was seen in 29% of control and 25% of morphine-treated rats.

	Saline Control (n=7)	Morphine (n=8)
Day I	6/7 (86%)	0/8 (0%) p 0.01
Day V	2/7 (29%)	2/8 (25%)p=NS

Conclusions: 1. Acutely morphine yields significant antinociception against mechanical visceral stimulation. 2. Reduced writhing (WLA) in controls at day 5 may result from stress-induced analgesia or from altered MTV over time; this requires further study. 3. On day 5 morphine-treated rats were not uniformly tolerant (25% WLA). This finding with 2 (above) may suggest inadequate morphine duration/magnitude to yield tolerance in the VPM or partial tolerance protection by stimulation/stress in the morphine group (Colpaert et al, Eur J Pharm 49:335, 1978). Further work is in progress.

283.5 SPINAL AND SUPRASPINAL INTEGRATION OF THE VISCERAL AFFERENT INPUT TO THE THORACIC SPINAL CORD OF THE CAT. B.M. Lumb* and F. Cervero* (SPON: A.D.Smith). Department of Physiology, University of Bristol Medical School, Bristol BS8 1TD, U.K.

The diffuse nature of visceral sensations may be attributed, at least in part, to the relatively sparse visceral afferent input to the spinal cord and subsequent extensive central divergence. We have shown that the divergence of the visceral afferent input to the lower thoracic spinal cord of the cat involves supraspinal looped pathways under phasic and tonic descending inhibitory controls from the brain stem. We have now investigated further the extent of this central divergence by studying whether single thoracic neurones are influenced by bilateral visceral stimulation and whether this information is modulated by descending controls.

Extracellular recordings were made in the T9-T11 segments of the spinal cord of anaesthetized cats. Viscero-somatic neurones were distinguished by their responses to electrical stimulation of the dorsal roots and of the ipsilateral splanchnic nerve (iSPLN). These cells were then tested for bilateral visceral inputs with electrical stimulation of the contralateral splanchnic nerve (cSPLN). Descending influences were tested by reversible spinalization at T7 and by electrical stimulation in the nucleus raphe magnus (NRM) and the adjacent reticular formation (Ret.F.)

Viscero-somatic neurones could be divided into 2 groups on the basis of the presence or absence of a contralateral visceral input.

i) More than 90% of the neurones could be excited by stimulation of both the iSPLN and cSPLN, i.e. had bilateral visceral inputs. The majority of these cells were located in the ventral horn with the remainder distributed in the superficial and deep dorsal horn. The visceral responses of these cells were generally reduced or abolished in the spinal state which suggests that their visceral inputs were mediated or reinforced by supraspinal loops. More than 80% of these cells could be driven by stimulation in NRM and Ref.F. In every case tested the initial excitatory response to brain stem stimulation was followed by a period of inhibition.

ii) A small minority of units (less than 10%) showed no response to stimulation of the cSPLN, i.e. had an ipsilateral visceral input only. All these cells were located in the superficial dorsal horn and only 1 cell could be driven by electrical stimulation in NRM and Ret.F although, when tested, the visceral inputs to these cells were inhibited by brain stem stimulation.

These results show that the divergence of the visceral afferent input in the cat's thoracic cord includes a bilateral input to a large proportion of viscero-somatic neurones and that the visceral inputs to these cells may be mediated by supraspinal loops. We have also obtained evidence for the existence of a small population of viscero-somatic neurones in the superficial dorsal horn with an exclusively ipsilateral visceral input.

283.6 DIFFERENTIAL ENCODING OF PROLONGED NOXIOUS MECHANICAL STIMULI BY DORSAL HORN NEURONES OF THE RAT'S SACRAL SPINAL CORD. J.M.A. Laird*, F. Cervero* and H.O. Handwerker*+ (SPON: European Neurosci. Assoc.). Department of Physiology, University of Bristol Medical School, Bristol BS8 1TD, U.K. and (+) Institute of Physiology & Biocybernetics, University of Erlangen, D-8520 Erlangen, F.R.G.

When a fold of human skin is squeezed for 2 minutes at an intensity just above the pain threshold, the sensation becomes more and more painful throughout the stimulus period. However, microneurographic studies of human nerves and electrophysiological recordings from rat's single nerve fibres have shown that all types of cutaneous receptor, including nociceptors, exhibit adaptation to such stimuli (Adriaensen et al 1984, Human. Neurobiol. 3:53-58; Handwerker et al 1987, Exp. Brain Res. 65: 493-504). We have now examined the responses of dorsal horn neurones of the rat's sacral spinal cord to identical noxious mechanical stimuli in an attempt to establish the central mechanisms responsible for the increasing pain sensation that occurs in parallel with a decreasing afferent inflow from nociceptors.

Extracellular recordings were made from dorsal horn neurones in the S1-S2 segments of the spinal cord of rats anaesthetized with pentobarbitone. All neurones responded to noxious mechanical stimulation of the rat's tail and were tested with mechanical stimuli ranging from 4 to 8N (350-700 KPa) and lasting for 2 minutes. These stimuli were delivered by a feed-back controlled device previously used to examine the discharge patterns of cutaneous afferent fibres from the rat's tail.

All dorsal horn neurones studied were excited by these stimuli throughout the 2 min period and showed little evidence of adaptation. Most cells responded with a sustained discharge after an initial phasic response and in some cases increased their responses throughout the stimulus. Two broad categories of neuronal response could be distinguished:

i) Nociceptor specific neurones of the superficial dorsal horn encoded the intensity of the stimulus so that more intense stimuli produced greater sustained responses.

ii) Most multireceptive ("wide dynamic range") neurones of the deep dorsal horn did not show the same encoding properties. However, their excitability increased during and after the application of the stimulus and this resulted in an increase in the levels of background activity for several minutes after the end of the stimulus. The magnitude of their sustained discharges during stimulation was not correlated with the stimulus intensity.

These results provide initial evidence for a central component of the tonic pain sensation that results from prolonged noxious stimulation and show differential encoding properties between nociceptor specific and multireceptive neurones of the dorsal horn.

283.7 OPIATES SUPPRESS CARRAGEENAN-INDUCED INFLAMMATION. K. Hargreaves* and J. Joris (SPON: S. Pretel). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Although opiates inhibit neurogenic plasma extravasation (Lembeck & Holzer, Arch. Pharmacol. 312:175, 1979), their peripheral effects in models of actual inflammation have not been determined. Therefore, we examined the effects of opiates on suppressing carrageenan (CARRA)-induced edema, hyperthermia and plasma extravasation, in addition to their well-recognized effects on blocking hyperalgesia. The dorsal-plantar paw thickness, measured by a caliper to 0.1 mm, was taken as an index of edema. Local hyperthermia of the plantar surface of the inflamed paw was measured with a contact thermocouple. Plasma extravasation was quantitated by measuring (at 620 nm) Evans blue dye extracted (by formamide) from paw tissue (6 mm punch biopsies) after i.v. injection. For noxious thermal stimulation, rats in a chamber had their paws exposed to a beam of radiant heat applied through a glass floor; paw withdrawal latency (PWL) was taken as an index of the nociceptive threshold. All observations were collected by investigators blind as to treatment allocation. Six to twelve rats/group were employed with data analyzed by ANOVA and Duncan's test. In the first study, CARRA was injected into a hindpaw and 60 min later rats received either i.p. morphine (0.2, 1.0 or 5.0 mg/kg) or saline injection. Morphine caused a dose-related (ANOVA: $p<0.01$) blockade of CARRA hyperalgesia at 0.2 mg/kg (4.2 ± 1.5 sec), 1.0 mg/kg (5.1 ± 1.8 sec, $p < 0.05$) and 5.0 mg/kg (6.8 ± 1.3 sec, $p < 0.01$) as compared to the PWL of saline-treated rats (2.8 ± 1.4 sec). Inflammatory hyperthermia was also reduced by morphine at 0.2 mg/kg (29.5 ± 0.2°C, $p < 0.05$), 1.0 mg/kg (29.8 ± 0.3°C, $p < 0.01$) and 5.0 mg/kg (29.4 ± 0.3°C, $p < 0.01$) in comparison to saline-treated rats (31.6 ± 0.4°C). Similar results were observed with edema; morphine administered at 0.2 mg/kg (8.2 ± 0.4 mm, $p < 0.05$), 1.0 mg/kg (7.9 ± 0.3 mm, $p < 0.05$) and 5 mg/kg (7.7 ± 0.3 mm, $p < 0.05$) had significantly less edema than saline-treated rats (9.2 ± 0.4 mm). This effect is stereospecific, since 1 mg/kg levorphanol decreased edema (7.9 ± 0.1 mm, $p < 0.05$) as compared to saline (8.8 ± 0.3 mm), while 1 mg/kg dextrorphan had no effect (8.7 ± 0.5 mm). Administration of 2 mg/kg i.v. morphine significantly inhibited CARRA-induced plasma extravasation (10.4 ± 1.5 µg dye/biopsy, $p < 0.01$) as compared to i.v. saline (17.8 ± 2.5 µg dye/biopsy). These results indicate that systemic opiates exert anti-inflammatory effects in the CARRA model of inflammation either through a peripheral mechanism or via activation of centrifugal CNS processes. (J. Joris, supported by an FNRS Belgium Fellowship, is on leave from the Department of Anesthesiology, University of Liege).

283.8 INVOLVEMENT OF THE PERIPHERAL NERVOUS SYSTEM IN CARRAGEENAN-INDUCED INFLAMMATION. J. Joris*, R. Dubner and K. Hargreaves* (SPON: M.A. Ruda). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Recent studies have demonstrated that substance P (SP) and calcitonin gene-related peptide (CGRP), 2 neuromediators present in C fibers, have peripheral inflammmatory activity (Lembeck et al., Eur J Pharmac 85:171, 1982; Brain & Williams, Br J Pharmac 86:855, 1985). We investigated whether the peripheral nervous system contributes to carrageenan (CARRA)-induced inflammation by examining the effect of denervation and a SP antagonist on this inflammation. Three signs of inflammation were assessed. Cutaneous hyperthermia was measured with a thermocouple. Paw thickness, measured with a caliper to 0.1 mm, was used as an index of edema. Hyperalgesia was determined using thermal stimulation: rats in a chamber had their paws exposed to a beam of radiant heat applied through a glass floor. Paw withdrawal latency (PWL) was taken as an index of the nociceptive threshold. All observations were collected by investigators blind as to treatment allocation. Six to eight rats/group were employed with data analyzed by ANOVA and Duncan's test. In a first experiment, one group of rats had a hindpaw denervated by sciatic and saphenous nerve section 8 days before testing. Another group was sham operated. In each of these 2 groups, half of the rats received either CARRA (2 mg) or saline (SAL) into the operated paw. Denervation significantly inhibited the inflammatory hyperthermia by 88.4% at 2 hr ($p<0.01$) and 38.1% at 3.5 hr. ($p<0.05$) after CARRA injection. Similar results were observed with edema: denervation inhibited CARRA-induced edema by 31.1% at 2 hr. ($p<0.01$) and 21.8% at 3.5 hr. ($p< 0.01$). On the other hand, denervation had no effect on the SAL-treated paw with respect to temperature and edema. In a second experiment, rats injected in one hindpaw with CARRA (2 mg) received 60 min later a second injection into the paw of either SAL or an SP antagonist, ($DPro^{2}$,$DTryp^{7,9}$)substance P (25, 50, 100 or 200 µg). As compared to the SAL treated paws (PWL = 2.6 ± 0.3 sec.), the SP antagonist produced a significant dose-related (ANOVA: $p<0.05$) blockade of CARRA-induced hyperalgesia at 25 µg (3.3 ± 0.8 sec.), 50 µg (3.4 ± 0.2 sec.), 100 µg (4.4 ± 0.6 sec.) and 200 µg (5.6 ± 1.3 sec.). These results indicate that CARRA-induced inflammation has a significant neurogenic component possibly involving the release of substance P. (J. Joris, supported by an FNRS Belgium fellowship, is on leave from the Department of Anesthesiology, University of Liege).

283.9 D-BACLOFEN ANTAGONIZES L-BACLOFEN AT LOW DOSES BUT NOT AT HIGH DOSES. G. H. Fromm, T. Shibuya*, C. F. Terrence*. Dept. of Neurology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

D-baclofen (D-BCF) antagonizes L-baclofen (L-BCF) in the feline trigeminal nucleus [Terrence CF et al., Pharmacology 27:85, 1983] and in the rat spinal cord [Sawynok J, Dickson C. Pharmacology 31:248, 1985], but not in hippocampal slices [Haas HL et al. Neurosci Let 55:1, 1985] . We have also found that L-BCF is more effective than five times as much racemic baclofen in the treatment of trigeminal neuralgia, suggesting that D-BCF antagonizes L-BCF in humans too [Fromm GH, Terrence CF. Neurology in press].

We have now investigated the effect of iontophoretic application of L-BCF and D-BCF to single neurons in the trigeminal nucleus of Sprague-Dawley rats anesthetized with halothane. 10-20 nA of 0.1 M L-BCF depressed excitatory transmission similar to the effect of 0.1-0.4 mg/kg L-BCF given i.v. The concommittant application of 10-20 nA 0.1 M D-BCF antagonized the effect of L-BCF. However, 40-50 nA D-BCF facilitated the action of L-BCF. We also found that 30-40 nA L-BCF had a much stronger effect than previously obtained with parenteral L-BCF, and D-BCF was not able to block it. The iontophoresis of 240-350 nA D-BCF produced an effect similar to that 10-20 nA L-BCF.

An antagonistic action by one enantiomer of a drug on the effect of the other is rather unusual, but has been reported for apomorphine and some Ca channel blockers. Our observations indicate that D-BCF has a similar effect as L-BCF but is one to two orders of magnitude less potent. The weak effect of D-BCF therefore probably interferes with the stronger effect of L-BCF when both are administered in equimolar low concentrations, comparable to those used in the treatment of trigeminal neuralgia. The failure to observe an antagonistic effect in the hippocampal slice experiments was probably due to the fact that a high dose of L-BCF was administered, as well as that the dose of D-BCF was twice that of L-BCF. Our experiments therefore also indicate that drug action in humans can only be predicted when therapeutic concentrations are administered in an appropriate model.

283.10 DIFFERENT TYPES OF PAIN ARE REGULATED DIFFERENTLY IN THE CNS. A NEW MODEL OF PAIN REGULATION IS NEEDED. K.Hole, P.K.Eide*, O.B.Fasmer* and O.-G.Berge*. Dept. of Physiol., University of Bergen, N-5000 Bergen, Norway.

It is well established that the serotonergic raphe-spinal pathways may tonically inhibit nociception. When the tail flick test is used as a measure of nociception in rats and mice, lesioning of these pathways with intrathecal 5,6-dihydroxytryptamine (5,6-DHT) or blocking spinal 5-hydroxytryptamine (5-HT) receptors with receptor blockers injected intrathecally, reduce the tail flick latency. On the other hand, antinociception is observed when spinal 5-HT receptors are stimulated with 5-HT agonists or when 5-HT is released from spinal terminals using parachloroamphetamine injected intrathecally.

However, when the formalin test was used in mice, 5,6-DHT induced lesion reduced pain sensitivity in the early phase of the test, while the late phase remained unchanged. Thus, one may conclude that the serotonergic raphe-spinal pathway may tonically inhibit, tonically enhance, or have no tonic activity depending on the test used to measure nociception. The early phase in the formalin test is probably related to a direct chemical stimulation of nociceptors, the late phase related to inflammatory pain, while the tail flick test measures a spinally integrated nociceptive reflex.

Similarly, the putative 5-HT receptor antagonist metitepin injected systemically in mice increased the sensitivity in the tail flick test and reduced the sensitivity in the increasing temperature hot plate test.

These and similar observations show that the role of the 5-HT system in control of nociception is complex, possibly different for different types of pain (different simulus modalities, intensities and duration). As a working model one may postulate that the nociceptive control system has a set point value, similar to several other control systems. This set point may vary, during the night-day cycle, depending on behavioral state and stress, and may be influenced by a variety of external and internal stimuli. The consequences of manipulations of serotonergic functions may thus depend on the stimulus and the set point value and the state of the control system at the time of stimulation.

283.11 GONADAL STEROIDS MODULATE SWIM ANALGESIA IN INTACT AND GONADECTOMIZED RATS. M.-T. Romero, M.L. Cooper*, B.R. Komisaruk and R.J. Bodnar. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367 and Inst. of Animal Behavior, Rutgers Univ., Newark, NJ 07102.

Female rats a significantly smaller magnitude of analgesia following morphine, opioid-mediated intermittent cold-water swims (ICWS) and nonopioid-mediated continuous cold-water swims (CCWS) than age-matched and weight-matched males. Normal gonadal function modulates these gender-specific effects since castration reduces CCWS and ICWS analgesia to levels observed in female rats, and ovariectomy reduces these analgesic magnitudes further in females. The present study evaluated the roles of the gonadal steroids, testosterone proprionate (TP) and estradiol benzoate (EB) upon CCWS and ICWS analgesia in intact and gonadectomized male and female rats. Age-matched rats received castration, ovariectomy or sham surgery. Four weeks later, intact and gonadectomized males and females (range: 8-10 rats/group) received either TP (2 mg/kg, SC) for 14 days, EB (5 ug/kg, SC) for seven days or sesame oil vehicle (VEH) for 14 days; each treatment continued through behavioral testing. All animals were exposed to CCWS (2°C for 3.5 min) and ICWS (2°C, 18 10-sec swims and 10-sec rests) in a counterbalanced fashion with a one-week interval elapsing between conditions. Tail-flick latencies, jump thresholds and core body temperatures were assessed for up to 2 h following each swim. Gonadectomy reduced both CCWS and ICWS analgesia. The magnitude of swim analgesia was reinstated by TP treatment in castrated males and ovariectomized females for CCWS analgesia on both tests and for ICWS analgesia on the jump test. TP potentiated CCWS analgesia in intact males on the tail-flick test. EB attenuated CCWS analgesia in intact females and reinstated ICWS analgesia in ovariectomized females on the jump test. Hypothermia could not account for the altered analgesic effects or the effects of the steroids. These results suggest that TP, but not EB plays an important role in the gonadal modulation of both opioid-mediated and nonopioid-mediated forms of swim analgesia, but supplements of neither steroid to intact rats consistently alters these analgesic responses. (Supported by PSC/CUNY Grant 6-66351 and NIH BRSG RR 07064).

283.12 HISTAMINE AND CONTINUOUS COLD-WATER SWIM ANALGESIA IN RATS: EFFECTS OF CIMETIDINE. J.A. Robertson, L.B. Hough and R.J. Bodnar. Dept. of Psych., Queens College, CUNY, Flushing, NY 11367 and Dept. of Pharmacol. & Toxicol., Albany Medical College, Albany, NY 12208.

Cimetidine, a histamine H_2 receptor antagonist, produces differential effects upon analgesic responses. While cimetidine fails to affect morphine analgesia, it reduces a nonopioid form of footshock analgesia, and potentiates an opioid form of footshock analgesia. The antagonist effects upon footshock analgesia were presumed to occur centrally since neither of the two forms of footshock analgesia was mediated by neurohormonal factors. Since it was not known how cimetidine affected neurohormonally-mediated forms of environmentally-induced analgesia, the present study evaluated the effect of this H_2 receptor antagonist upon the nonopioid and neurohormonal analgesic response elicited by acute exposure to continuous cold-water swims (CCWS) in rats. Sprague-Dawley rats received cimetidine (10, 50 and 100 mg/kg dissolved in phenol (5 mg/ml), IP) or a phenol vehicle 30 min prior to CCWS (2°C for 3.5 min). Tail-flick latencies, jump thresholds and core body temperatures were assessed 30, 60 and 90 min thereafter. CCWS analgesia on both nociceptive measures was significantly potentiated by 50 to 100% across the post-swim time course by the 100 mg/kg, but not the 50 or 10 mg/kg doses of cimetidine. The 100 mg/kg dose of cimetidine also potentiated CCWS hypothermia; the two lower cimetidine doses were ineffective. In contrast, none of the cimetidine doses affected baseline tail-flick latencies jump thresholds or core body temperatures. The associated potentiations of both CCWS analgesia and CCWS hypothermia by the same cimetidine dose range suggests that H_2 antagonist effects upon this manipulation may be altering the stressful consequences of the swim rather than specific effects upon the activated nonopioid neurohormonal pain-inhibitory system. (Supported by PSC/CUNY Grant 6-66351 and BRSG NIH Grant RR 07064).

283.13 POTENTIATION OF CONTINUOUS COLD-WATER SWIM ANALGESIA BY YOHIMBINE. K.L. Kepler and R.J. Bodnar. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

The analgesic response following continuous cold-water swims (CCWS) is mediated through a nonopioid, but neurohormonal and hypothalamo-hypophysial mechanism of action. Norepinephrine (NE) has been postulated as a possible modulator of CCWS analgesia since this stressor promotes NE release. In this regard, CCWS analgesia is reduced following lesions placed in the noradrenergic locus coeruleus and is potentiated following pretreatment with either clonidine, an alpha$_2$-NE receptor agonist or desipramine, a NE reuptake blocker. The present study evaluated whether yohimbine (YOH) an alpha$_2$-NE receptor antagonist altered CCWS analgesia on the tail-flick and jump tests in rats, and whether any effects correlated with YOH-induced changes in CCWS hypothermia or basal thresholds. YOH (0.1-2.0 mg/kg, IP) dose-dependently increased jump thresholds, but failed to alter basal tail-flick latencies or core body temperature. YOH (0.1 and 2.0 mg/kg) potentiated CCWS (20C for 3.5 min) analgesia for 60 min on the jump test; this potentiation was additive relative to YOH and CCWS effects alone. YOH dose-dependently potentiated CCWS analgesia on the tail-flick test at 30 min after the swim, an effect not accountable by basal changes. Since CCWS hypothermia failed to be affected by YOH, the analgesic potentiations could not be explained by this variable. Together with our previous determination that clonidine pretreatment potentiated CCWS analgesia, these data indicate that both agonists and antagonists of the alpha$_2$-NE receptor potentiate this form of analgesia, suggesting that such NE-induced effects may be orthogonal to intrinsic pain-inhibitory mechanisms subserving CCWS. These data confirm previously-established analgesic efficacies of alpha$_2$ NE antagonists and agonists administered peripherally. Further, these effects dissociate CCWS analgesia from the YOH-induced decreases of neurally-mediated autoanalgesia and neurally and opioid-mediated footshock analgesia. These results may be explained by differential NE-induced changes in nociception at different levels (e.g., brainstem, spinal cord) of the neuraxis. (Supported by PSC/CUNY Grant 6-66351 and NIH BRSG RR07064).

PEPTIDE: RECEPTORS I

284.1 NEUROPEPTIDE MODULATION OF PHOSPHOLIPASE C ACTIVITY IN BRAIN SLICES AND NG108-15 NEUROBLASTOMA-GLIOMA HYBRID CELLS. S.J. Fluharty, C.V. Nicchitta & J.R. Williamson. (SPON: C.R. Gallistel) Depts. of Animal Biology and Biochemistry, Institute of Neurological Sciences, University of Pennsylvania, Phila., PA 19104.

Several neurotransmitter receptors are coupled to the hydrolysis of inositol phospholipids through the stimulation of a polyphosphoinositide specific phospholipase C (PLC) in neural cells. This receptor-mediated release of inositol phosphates (IPs) and the subsequent rise in cytosolic calcium is presumed to play an important role in the regulation of neuronal function. The present report compares the effects of angiotensin II (ANG II), a neuropeptide which is known to stimulate PLC in a variety of peripheral cells, with Substance P (SP) and the alpha-adrenergic agonist phenylephrine (PE) in brain slices, and with bradykinin (BK) in a culutred neuron-like cell line, NG108-15.

Male SD rats were sacrificed and slices of the hypothalamus-thalamus-septum (HTS) region were prepared. Slices were incubated under constant gassing in KRH containing 10 uCi/ml of (^{3}H)-myoinositol for 1 hr in the presence of 10 mM LiCl. After labelling, ANG II (10 uM), SP (1 uM) or PE (100 uM) was added and samples were quenched with 1 M TCA 30 min later, neutralized and applied to Dowex 1X-8 columns. Experiments involving cultured NG108-15 cells were similar except that labelling was for 24 hr and samples were quenched 30 sec after addition of ANG II or BK (10 uM). IPs were eluted sequentially with 0.2 - 1.0 M NH_4 formate/0.1 M formic acid. In some cases, membranes were prepared from HTS or NG108-15 cells for radioligand binding studies using (^{125}I)-ANG II.

In HTS slices, both PE and SP increased IPs by 140% and 74%, respectively. In contrast, ANG II had no effect on IPs nor did it alter the response to PE despite the presence of ANG II receptors in this region (B_{max} = 7.4 fmols/mg prot: K_D = 548 pM). ANG II receptors also are present in NG108-15 cells (B_{max} = 12.8 fmols/mg prot; K_D = 331 pM) yet this peptide did not appear to stimulate PLC in these cells. On the other hand, BK increased IP_1, IP_2 and IP_3 levels from 200-400%.

In summary, our results are consistent with the suggestion that the properties of neuronal and peripheral ANG II receptors may differ particularly with regard to their coupling to inositol phospholipid metabolism. Therefore, the precise intracellular second messenger system(s) utilized by these receptors in the brain remains to be established. Supported by NS 23986, DK 15120 and the University of Pennsylvania Research Foundation.

284.2 PHOSPHOLIPASE A2, A KEY ENZYME IN THE PRODUCTION OF ARACHIDONIC ACID, BINDS BRADYKININ (BK) WITH HIGH AFFINITY AND SPECIFICITY. C. R. Mantione Miami Valley Laboratories,
Health & Personal Care Technology Division
The Procter & Gamble Co., Cincinnati, Ohio 45247

Quinacrine, a phospholipase A2 (PLA2) inhibitor, prevents BK-induced prostaglandin formation without affecting basal activation of prostaglandins in guinea pig lung (Vargaftig and Dao Hai, J. Pharm Phamacol 24, 159, 1972). Also, quinacrine blocks BK-stimulated cGMP formation in murine neuroblastoma cells (Snider, M. R. and Richelson, E., J. Neurochem 43, 1749, 1984). This led to an investigation of whether quinacrine was acting by inhibiting BK binding directly to a site on PLA2.

For these experiments, bee venom PLA2 (25-250 ng) was incubated with [3H]BK in 25 mM TES buffer, pH 6.8, with 0.05% BSA for 90 min at 25° C. [3H]BK bound with 85% specific binding over the concentration range of 0.05-10 nM. The pH optimum lies between 6.5-7.2, then slowly declines at higher pH. The association rate constant was determined to be 0.0074 min-1 at 25° C, whereas the dissociation T1/2 was greater than 180 min. Under binding conditions described above, a Scatchard analysis yielded a Kd of 3.8 nM and a Bmax of 1328 pmoles/ng enzyme. Pharmacologically, this binding site represents neither a B1 or a B2 receptor. Both the B1 specific antagonist, Leu8,desArg^9-BK, and the B2 antagonist, [Thi5,8 D-Phe7]-BK, inhibits binding with a Ki between 7-9 nM. The agonist, MetLys-BK is about 3 times more potent than BK. Substance P, a neurokinin, was equivalent to that of BK and Lys-BK. The algesic agent capsaicin was inactive. Quinacrine had a Ki of 62 µM. L-Phosphatidylcholine, a PLA2 substrate, was inactive, as were PAF and various prostaglandins.

These data provide evidence that PLA2 and other phospholipases has a high affinity site which specifically binds the kinin family of peptides. PLA2 may represent an important in vivo binding site for regulating inflammation and pain generation mediated by bradykinin, and possibly certain neurokinins.

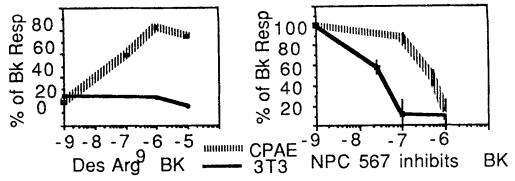
284.3 **TWO DISTINCT BRADYKININ RECEPTORS DISTINGUISHED BY DIFFERENTIAL COUPLING TO PHOSPHOLIPASE A_2 AND PHOSPHOLIPASE C**

B.R. Conklin, R.M. Burch, L.R. Steranka, J. Axelrod, Laboratory of Cell Biology, National Institute of Mental Health, Bethesda MD 20892 and Nova Pharmaceutical Corp., Baltimore MD 21224

Bradykinin (BK) is a nonapeptide with potent actions in mediating vasodilation, pain, and smooth muscle contraction in a variety of biological systems. Many of these actions are thought to be mediated by arachidonic acid and its metabolites. Phospholipase A_2 (PLA_2) and Phospholipase C (PLC) are rate limiting enzymes in receptor mediated arachidonate release and its metabolism to eicosanoids. We have investigated the coupling the BK receptor to these two lipases in Swiss 3T3 fibroblasts and CPAE bovine pulmonary artery endothelial cells, and have found striking differences in their respective sensitivity to several bradykinin analogs and their receptor coupling to PLA_2 and PLC.

The BK receptor in CPAE cells has been shown to be coupled to PLC while PLA_2 activation was not observed (Clark et al JBC, 261:23,10713, 1986). In contrast, we have evidence that in the 3T3 cells, BK receptor mediated arachidonate release is coupled to PLA_2 (Burch, Axelrod, PNAS in press). We have measured receptor function by release of ^{3}H-arachidonic acid as well as RIA for the primary eicosanoid end product of BK stimulation in each cell line (prostaglandin E_2 in the 3T3 cells, and 6-keto-prostaglandin $F_{1\alpha}$ in the CPAE cells). The dose response curves for bradykinin in the two cell lines are similar with EC50s of 3T3: 200 pM and CPAE: 210pM. Des-Arg^9-BK is a full agonist in the CPAE cells with a EC50 of 40nM while it is completely inactive in the 3T3 cells up to a concentration on 10μM. NPC 334 (p-chlorophe^6-Pro^7-BK) is a full agonist in the 3T3 cells but is only a partial agonist in the CPAE cell reaching maximum of 56% of the bradykinin response at 250 nM and dropping to 10% at 10μM. NPC 567, (DArg-(Hyp^3,DPhe^7)-BK a BK antagonist, is 10-fold more potent in blocking the effects of 10 nM BK the 3T3 cells than in the CPAE cells. Des-Arg^9-Leu^8-BK is a weak antagonist with effects seen at 10 μM in both cell lines.

These findings indicate that there are at least two distinct bradykinin receptors, one represented in the CPAE cells coupled to PLC and the other in the 3T3 cells coupled to PLA_2 for release of arachidonate.



284.4 VASOPRESSIN-STIMULATION OF PHOSPHATIDYLINOSITOL HYDROLYSIS IN THE RAT BRAIN: ENHANCED RESPONSIVENESS TO VASOPRESSIN IN THE HOMOZYGOUS BRATTLEBORO RAT. L.M. Shewey* and D.M. Dorsa, (SPON: W. Catterall). GRECC, VA Medical Center, and Depts. of Medicine and Pharm., Univ. of Washington, Seattle, WA 98108.

We have previously reported characterization of vasopressin (AVP) receptors in the septum of the Brattleboro (BB) rat. Animals homozygous for this trait have a near complete inability to synthesize AVP in the brain. Binding studies of AVP receptors using membranes prepared from the septum of heterozygous (HE) and homozygous (HO) Brattleboro rats revealed an increased number of AVP receptors with a lower affinity for [^{3}H]-AVP in HO animals when compared to those in the HE animals. The present studies were undertaken to determine the effect of this apparent "up-regulation" in the absence of endogenous AVP in the HO-BB rat septum on the post-receptor responsiveness of the tissue to AVP. We have recently reported that AVP stimulates phosphatidylinositol hydrolysis as measured by the accumulation of [3H]-inositol-1-phosphate (IP_1) in septal slices from Long-Evans rats. This response was maximal at 0.5μM AVP with a 64.9±6.6% (n=7) stimulation of [3H]-IP_1 levels relative to basal values, and could be completely inhibited by d(CH_2)$_5$ Tyr(Me)AVP, a specific V_1 antagonist. For the present study, septal slices from age-matched, adult male HE- and HO-BB rats were prelabeled with [3H]-inositol in the same assay, and AVP-stimulated accumulation of [3H]-IP_1 was measured in the presence of lithium. A dose-dependent accumulation of [3H]-IP_1 in response to AVP was seen in both HE and HO septal slices, but at all concentrations, the response was greater in the HO than in the HE. In the HO, a maximal response of 48.4± 5.9% stimulation over basal was observed at a concentration of 5μM AVP (n=7), while in the HE, only a 17.9±4.6% response was seen at a comparable protein concentration (n=7). Interestingly, the HO-BB septal slices also demonstrated an increased [3H]-IP_1 accumulation in response to oxytocin (0.1μm) (26.4± 3.3%, n=7) when compared to HE (3.8±2.1%, n=8). These results indicate that BB rats do possess functional AVP receptors in the septum that are able to hydrolyze inositol phospholipids in response to AVP. In accordance with their altered receptor characteristics compared to the HE animal, the post-receptor response in the septum of HO-BB rats is much larger than in HE, and the maximal response occurs at a concentration of AVP that is one order of magnitude higher than for HE or LE animals. Thus, the Brattleboro rat represents a potentially useful model for the study of CNS AVP receptor regulation and subsequent alterations in target cell sensitivity.

284.5 BINDING OF A TRITIATED VASOPRESSIN ANTAGONIST TO BRAIN VASOPRESSIN RECEPTORS: FURTHER EVIDENCE FOR A V_1 RECEPTOR. M.D. Brot*, L.M. Shewey*, K. Myers*, C. Blamick*, and D.M. Dorsa, (SPON: T. KENNEDY) GRECC, VA Medical Center, and Depts of Medicine, Pharmacology, Psychology and Psychiatry, Univ of Washington, Seattle, WA 98108.

[^{3}H]-arginine^8-vasopressin (AVP) receptors have been localized in various regions of the rat brain, including the septum. Functionally, septal AVP receptors have been implicated in mediating vasopressin's effects on memory, thermoregulation, and neuronal excitation. Pharmacologic studies have suggested that these AVP binding sites have similar characteristics to peripheral V_1 receptors present in liver and smooth muscle.

For this study, a specific V_1 antagonist, [^{3}H]d(CH_2)^5-Tyr(Me) AVP, (Manning Compound, MC) was used to further characterize septal vasopressin binding sites. Saturation experiments using both [^{3}H]-AVP and [^{3}H]-MC (over a concentration range of 0.25 to 10nM) were performed using membranes prepared from septal tissue from Long-Evans rats. The specificity of [^{3}H]-MC for the binding sites was assessed by measuring the displacement potency of various competitor peptides including oxytocin (OXY), AVP, MC, and dDAVP (deamino-D-arginine^2-vasopressin), a specific V_2 agonist, and compared to that for [^{3}H]-AVP.

The results from saturation experiments using [^{3}H]-AVP as a ligand indicated the presence of a single class of binding sites with a Kd of 1.7 ± 0.34nM, and B_{max} of 22.6 ± 4.2fmol/mg protein in septal membranes. When [^{3}H]-MC was used, saturation analyses on the same membrane preparations yielded a Kd of 0.72 ± 0.12nM and a B_{max} of 23.9 ± 10.25fmol/mg protein, suggesting a higher affinity interaction of the antagonist with the binding site.

The results of studies of the specificity of [^{3}H]-AVP and [^{3}H]-MC binding to septal membranes are summarized in the table below. The numbers represent the inhibition constants (Ki, nM) for each of the competing ligands tested.

Labeled Ligand	AVP	MC	OXY	dDAVP
[^{3}H]-AVP	0.40	0.25	289.5	>1000
[^{3}H]-MC	1.46	0.18	>1000	>1000

For both tritiated ligands, the displacement potencies of OXY and dDAVP are much lower than those of AVP and MC. These findings indicate that both [^{3}H]-AVP and [^{3}H]-MC label a binding site which is similar in specificity to peripheral V_1-type receptors and provide additional support for the existence of these receptors in the brain. Furthermore, [^{3}H]-MC does not appear to label oxytocin receptors in this brain region. These data also suggest that MC may be a useful ligand for studies of brain vasopressin receptors.

284.6 DIFFERENT DISTRIBUTIONS OF INSULIN-LIKE IMMUNOREACTIVITY AND INSULIN RECEPTOR IN THE MAMMALIAN SPINAL CORD. N.B. Reddy,* W.K. Engel, and V. Askanas, USC Neuromuscular Center, USC Sch. Med., Los Angeles, CA 90017.

The distribution patterns of insulin-like immunoreactivity (ILI) and insulin receptor (IR) have been previously mapped in mammalian brain but not in spinal cord.

We have isolated and frozen immediately on dry ice, spinal cords from rat, cat and monkey. Cryostat transverse sections of cervical, thoracic and lumbar levels were collected on gelatin-subbed glass slides. ILI was identified utilizing a PAP immuno-histochemical reagent kit containing polyclonal anti-human insulin antibodies (DAKO Corp.). As controls, adjacent sections were incubated either in normal serum or in preabsorbed primary antibody solution. IRs were identified by autoradiography using 0.1-0.5 nM ^{125}I-insulin. Nonspecific ^{125}I-insulin binding in the presence of 1 uM unlabeled insulin was determined in adjacent sections. Autoradiographs were quantitatively analyzed with computerized densitometry (RAS System, Amersham Corp.) using optical density standards obtained from Amersham.

ILI was observed in the cytoplasm of neurons of both the dorsal and ventral horns. In the large ventral horn neurons, the amount of staining per neuron was much more prominent than in the small dorsal horn neurons, and probably more per unit of cytoplasmic area, although the latter comparison was difficult to quantitate in the sections. The nuclei and extracellular spaces did not have any significant staining. ILI was also observed in the axonal processes originating from neurons, especially in the ventral horn, suggesting possible transport of insulin-like substance (ILS) from the cell body. When the sections were incubated with normal serum or with preabsorbed primary antibody, no ILI was observed in the neurons, suggesting the specificity of immunocytochemical procedure for insulin-like substance. The patterns of ILI distribution was similar in cervical, thoracic and lumbar segments of spinal cord, and between the 3 species studied.

The distribution of IRs was distinctly different in various regions of the spinal gray matter. Computerized densitometry of the monkey spinal cord revealed that the density of IR in dorsal horn (laminae 1-3, +4) was 45+2 fmoles/mm^2 compared to 19+4 fmoles/mm^2 in ventral horn (laminae 7-9), and 24+1 fmoles/mm^2 in dorsal part of lamina X. Corresponding nonspecific binding values in the dorsal and ventral horns were, respectively, 2+0.6 and 3+1 fmoles/mm^2. Similar patterns of IR distribution were observed in the cervical, thoracic and lumbar segments, and between the 3 species. (Neither ILI nor IR was found in the spinal cord white matter.)

Thus, IR density is more than twice as high in the dorsal horn as it is in the ventral horn, but ILI is greater in ventral horn neurons, indicating that ILI and IRs are differently distributed. Physiologic roles of the spinal ILS and IRs remain to be defined. Speculatively, ILS might be a transported-exported trophic peptide interacting with post-synaptic IRs; e.g., ventral horn neuronal ILS may interact with muscle IRs and dorsal horn IRs may receive ILS from axons of dorsal root ganglia and intraspinal afferents.

284.7 PEPTIDE MAPPING AND NORTHERN BLOT ANALYSIS OF INSULIN RECEPTORS IN BRAIN AND ADIPOCYTES. K.A. Heidenreich, P.R. Gilmore*, and E. Hatada* Department of Medicine, Division of Endocrinology and Metabolism, M-023E, University of California, San Diego, La Jolla, CA 92093.

We have previously shown that insulin receptors in the central nervous system are structurally distinct from insulin receptors of more classic target tissues like adipocytes and liver. The receptor subunits in brain have smaller apparent molecular weights (M_r) than the subunits in other tissues and the size discrepancy involves differences in N-linked glycosylation of the proteins. In this study, we examined the degree of homology in the protein backbones of insulin receptors in rat brain and adipocytes by peptide mapping and compared the mRNAs encoding the receptors by Northern blot analysis. Insulin receptors in both tissues were photoaffinity labeled by ^{125}I-B2(2-nitro-4-azido-phenylacetyl)-des-Phe-B1-insulin and isolated by SDS gel electrophoresis. The labeled receptors were removed from the gel by electroelution and treated with endo-B-N-acetyl-glucosaminidase F, an enzyme that cleaves N-linked oligosaccharides at the core. The deglycosylated receptors were then subjected to partial proteolysis by five proteases with differing substrate specificities, and the intact receptors and proteolytic fragments were analyzed by electrophoresis. In brain, the intact α-subunit had an apparent M_r of 115,000; whereas, in adipocyte, the α-subunit had an apparent M_r of 125,000. After deglycosylation, both subunits were reduced to 100kDa. Treatment of the deglycosylated subunits with each of the five enzymes yielded a unique pattern of fragments ranging from 70kDa to 11kDa. For each enzyme, there was a striking similarity in the peptide maps generated from receptors in brain and adipocytes. Thus, both subunits contain similar protease-sensitive sites exposed at discrete intervals from the labeled hormone binding site including loci for aromatic amino acids (chymotrypsin data), glutamic acid residues (S. aureus V8 protease data), and lysine and arginine residues (trypsin data). Northern hybridization experiments were carried out using poly(A)$^+$ RNA isolated from rat brain, rat adipocytes and human hepatocarcinoma (HEPG2) cells, and an Eco R1 fragment of the human insulin receptor cDNA encoding most of the α-subunit and all of the β-subunit. In rat brain, two bands of 9.5 and 7.4kB were detected. In rat adipocytes, the same two bands were observed. The mRNA bands observed in rat tissues represented only two of the five mRNA species seen in human HEPG2 cells. The results indicate that the protein domains and the mRNAs encoding insulin receptors in brain and adipocytes are very similar, if not identical. We conclude that the structural heterogeneity of insulin receptors may result from differences in post-translational processing of the same gene product. The variation in receptor structure may contribute to the tissue-specific differences in insulin action.

284.8 INSULIN-LIKE GROWTH FACTOR-1 RECEPTORS IN BOVINE RETINA: HIGH LEVELS OF IGF-1 BINDING ARE ASSOCIATED WITH LOW LEVELS OF BETA SUBUNIT AUTOPHOSPHORYLATION. R. J. Waldbillig, NEI, D. LeRoith, NIDDK and G. J. Chader, National Eye Institute, NIH, Bethesda, MD 20892

It was found that bovine retina contains high affinity specific receptors for insulin-like growth factor-1 (IGF-1). Tracer binding studies with WGA-purified receptors reveal that ^{125}I-IGF-1 binding exceeds ^{125}I-insulin binding by a factor of 10-20. Scatchard plots indicate that, in large part, this difference is attributable to differences in the affinity of each receptor for its ligand. In competition-inhibition studies with unlabeled IGF-1, the half-maximal inhibition of ^{125}I-IGF-1 binding occurred at 0.08 nM. Unlabeled insulin was approximately 400 times less effective in inhibiting IGF-1 binding. It was also found that the IGF-1 receptor exhibits a kinase activity that autophosphorylates the receptor's beta subunit in a concentration and time dependent manner. Interestingly, however, at equal levels of IGF-1 and insulin binding, the IGF-1 receptor autophosphorylation response is markedly weaker than the autophosphorylation seen with the insulin receptor. In addition to an autophosphorylation response, IGF-1 receptors also exhibit kinase activity towards the retinal G-protein, transducin. The incorporation of ^{32}P into transducin was concentration and time dependent and the alpha-GDP form of transducin was a more effective substrate than was the alpha-GTP form. IGF-1 receptors purified from retina rod-outer segments exhibit a tyrosine-specific kinase activity and incorporate ^{32}P into poly (glu, tyr) 4:1 in a concentration (half maximum = 0.25 nM) and time dependent manner. SDS-PAGE analysis of retinal crude membranes crosslinked to ^{125}I-IGF-1 and then treated with neuraminidase, revealed the existence of two differentially glycosylated IGF-1 receptor alpha-subunit subpopulations. Specifically, it was found that neuraminidase increased the mobility of subunits in the upper half of the alpha-subunit radiographic band while smaller receptors, in the lower half of the radiographic band, were relatively unaffected. Further work will be required to determine the function of IGF-1 receptors in retinal physiology.

284.9 **INSULIN-LIKE GROWTH FACTOR-II (IGF-II) BINDING SITES IN THE RAT BRAIN: LOCALIZATION BY QUANTITATIVE AUTORADIOGRAPHY.** **D.G. Baskin, N.J. Bohannon*, M.G. King*, and R.G. Rosenfeld*. University of Washington and Veterans Administration Medical Center, Division of Endocrinology/Metabolism, Seattle, WA 98108, and Dept. of Pediatrics, Stanford University, Stanford, CA 94305**

Receptors for IGF-II, a growth promoting peptide (MW ca. 7500), which is made in the liver and has insulin-like structure and biological activity, have been identified in brain membrane preparations. This finding has raised interest in the hypothesis that IGF-II may influence the functions and development of the CNS. The precise locations were IGF-II acts within the CNS are largely unknown, however. We approached this problem by identifying brain IGF-II binding sites in situ with quantitative autoradiography. Slide-mounted cryostat sections (20 um) of brain were immersed in a solution containing 0.1 nM [125-I]-IGF-II, which was mixed with 100 nM [Thr-59]-IGF-I (Amgen) to block binding of the labeled IGF-II to brain IGF-I receptors. After incubation for 2 hrs at 22C, the sections were rinsed at 0C, dried, and placed in contact with LKB Ultrofilm for 5 days. Relative concentrations of bound iodoIGF-II within labeled regions were measured by video densitometry of the autoradiographic images, using the Drexel DUMAS/BRAIN computer/software system for quantitative autoradiography. Visual examination of the autoradiographic images showed that binding sites for iodoIGF-II were highly concentrated in discrete loci. The locations of major iodoIGF-II binding densities delineated well known anatomical landmarks, particularly certain neuronal laminae and nuclei. Highest binding (69-85 dpm/sq mm) was present in the dentate gyrus and Ca1, Ca2, Ca3 and Ca4 regions of the hippocampus, in the supraotic nucleus, choroid plexus, olfactory pyriform cortex, mitral cell layer of olfactory bulb, and habenula. Moderate binding (50-68 dpm/sq mm) was present in the subfornical organ, caudate-putamen, lateral hypothalamus, ventromedial hypothalamus, hypothalamic paraventricular nucleus, red nucleus, median eminence, pontine nuclei, external plexiform and inner granule cell layers of the olfactory bulb, and suprachiasmatic nucleus. Low binding (<49 dpm/sq mm) was present in the thalamus, superior colliculus, medial geniculate, and arcuate nucleus, as well as anterior and posterior pituitary glands. Binding was similar to background levels when iodoIGF-II was mixed with unlabeled IGF-II (from Dr. R. Humbel), rat IGF-II (MSA), or antibodies against the rat IGF-II receptor. The data are consistent with the conclusion that binding sites with characteristics of IGF-II receptors are associated with cells in some (but not all) brain regions containing high densitites of neuronal cell bodies. Many of these regions are characterized by pyramidal-type cell bodies, which suggest that IGF-II binding sites are associated with axosomatic synapses. These results suggest that cells which are sensitive to and regulated by IGF-II are found within specific, highly localized neural pathways and neuroendocrine centers of the brain.

284.10 CHARACTERIZATION AND DISTRIBUTION OF BINDING BY ANTIBODIES TO RAT INSULIN-LIKE GROWTH FACTOR-II (TYPE II) RECEPTOR IN CNS AND OTHER TISSUES. I. Ocrant*, K.L. Valentino, H. Pham*, R.G. Rosenfeld*, R.L. Hintz*, and D.M. Wilson*. Depts. of Pediatrics and Psychiatry, Stanford Univ. School of Medicine, Stanford, CA 94305.

Insulin-like growth factors (IGFs) I and II are peptides homologous to insulin and mitogenic for a variety of mammalian cells. Important in somatic growth and probably important in differentiation, both types of IGFs and their receptors are found in the CNS from fetal through adult life. A description of the distribution of IGF-II receptors at the organ and cellular level was undertaken in order to further an understanding of the possible role of this peptide in the CNS.

A rabbit antiserum was raised by primary immunization with lectin affinity purified receptors from a rat cell line (18,54-SF) rich in type II receptors, followed by booster immunizations with rat IGF-II affinity purified receptors from the same cell line. A monoclonal antibody was produced by immunization of mice with the latter preparation. The specificities of these antibodies were demonstrated by their ability to immunoprecipitate rat type II receptors, by similar patterns of immunostaining in sections of brain and other tissues, and by inhibition of immunostaining by homologous ligand. The polyclonal antiserum was further characterized by its ability to specifically block the binding of IGF-II and by Western blot.

Adult rats were perfused with fixative. Brains and other tissues were removed, frozen, and sectioned. Antibodies were applied and then detected with rhodamine or fluorescein conjugated second antibodies. Type II receptors were localized primarily in ependymal cells, choroid plexus, and mesenchymal cells surrounding small and large blood vessels in adult rat brain sections. Likewise, immunostaining of rat muscle, kidney, and liver disclosed primarily mesenchymal staining. Studies in fetal tissues are in progress.

When immunostaining was performed on 18,54-SF cells and B104 rat neuroblastoma cells, the type II receptors were primarily localized to the plasma membrane and also in the Golgi apparatus following permeabilization with Triton X-100.

Primary, dispersed, adult rat brain cell cultures were established which included many viable neuronal cells at day 14 of culture. Immunohistochemical localization of type II receptors was confined to nonneuronal cells. Cells which were positively stained showed the same pattern of cellular localization as 18,54-SF and B104 cells.

We conclude that type II (IGF-II) receptors are present in significant amounts in the CNS, and are primarily localized to nonneuronal cells. This provides important information for future research into the possible actions of this peptide in the CNS and other tissues.

284.11 FUNCTIONAL ANGIOTENSIN RECEPTORS INDUCED IN XENOPUS OOCYTES BY INJECTED mRNA. L.J. Greenfield, Jr., K.R. Lynch* and J.T. Hackett. Neuroscience Program and Depts. of Physiology and Pharmacology, Univ. of Virginia School of Medicine, Charlottesville, Va. 22908.

The Xenopus oocyte can synthesize and insert foreign receptors and ion channels into its membrane when injected with exogenous messenger RNA. Oocytes injected with poly $(A)^+$ RNA from mouse liver, cow adrenal medulla, rat kidney or rat brain synthesize functional angiotensin receptors, detected by ^{125}I-Angiotensin II (I-AII) binding or voltage clamp electrophysiology. RNA was isolated by guanidinium thiocyanate/cesium chloride centrifugation and purified by oligo-dT cellulose chromatography. Intact oocytes injected with 20-30 ng of mRNA were incubated 48 hrs later for 2.5 hrs in 10^5 cpm/oocyte carrier-free I-AII (2200 Ci/mmol), competing peptides, and ^{14}C sucrose to monitor internalization of medium. Cells were then washed and counted individually for ^{125}I and ^{14}C. Mouse liver mRNA induced 305±26 cpm bound/oocyte (n=11), compared to 15±4 cpm/oocyte (n=9) for vehicle-injected cells. Incubation with 10^{-6} M Sar^1Ile^8AII reduced binding to 56±10 cpm/oocyte. Bovine adrenal medulla mRNA gave maximal binding of 176±15 cpm/oocyte (n=9). IA-II binding was blocked by 10^{-8} M AII and by AI, AIII and saralasin (10^{-6} M), but not by unrelated peptides. Mouse liver mRNA also induced expression of the mouse H_2D^d major histocompatibility antigen, detected by iodinated antibody, which confirms the expression of foreign membrane proteins. Oocytes injected with mRNA from mouse liver, rat kidney, brainstem or diencephalon and voltage clamped to -70 mV responded to superfused human AII (1 to 100 nM) with a fluctuating inward current. Cells injected with vehicle or mRNA from caudate nucleus or cerebellum did not respond to AII (1 uM). The magnitude of the currents was highly variable between cells, ranging from 10 to several hundred nA. The reversal potential (determined by intersection of I/V curves obtained by ramp voltage commands given before and during the AII response) was -21.8 ± 3.7 mV (n=5), consistent with the chloride equilibrium potential. Slope conductance increased from 888±89 nS to 2480±580 nS, or over 300%. The shape of the response was also variable; after an initial delay of 30 to 90 seconds, a large inward current "spike" lasting 5 to 15 seconds was often observed, followed by oscillations of smaller amplitude at about 0.3 Hz. In some cells, a smooth inward current was seen; the reversal potential of this response was similar to that of fluctuating currents. Reapplication of AII often evoked no response, even one hour or more after initial application. The inward Cl^- current is similar to that evoked by acetylcholine, glutamate, and 5-HT on endogenous or mRNA-induced receptors, and may involve the same ion channels and second messengers. Localization of brain A-II receptor mRNA to brainstem and diencephalon suggests that these responses may represent neuronal A-II receptors. (NIH HL33513 & NSF BNS840629)

284.12 ^{125}I-ANGIOTENSIN III BINDING IN THE RAT BRAINSTEM. R.C. Speth, T. Balestreri*, J. Erickson and J.W. Harding. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

Angiotensin III, the des asp^1 heptapeptide fragment of angiotensin II (Ang II), is an active metabolite of Ang II. In the brain it has been shown to cause dipsogenic and pressor responses with a potency similar to that of Ang II. Administered iontophoretically into the brain, Ang III is a more potent excitant of neuronal cell firing than Ang II (Harding and Felix, Brain Res. In press). We are using in vitro receptor autoradiography to investigate the binding of radioiodinated Ang III. Rat brains were frozen sectioned at 10-20 µm, thaw mounted to subbed slides, and stored at -20°C. Sections were thawed and preincubated for 30 min at 22°C in a medium containing 150 mM NaCl, 10 mM $MgCl_2$, 5 mM EGTA, 5 mM dithiothreitol, 5 µM bacitracin, 5 µM puromycin, aprotinin 0.2 U/ml, 50 mM $NaPO_4$, pH 7.1, and 0.1% bovine albumin. Sections were next incubated for 40 min at 22°C in the same medium containing 0.7 nM ^{125}I-Ang III. Adjacent sections were incubated in the presence of 0.7 nM ^{125}I-Ang III plus 1 µM Ang II. Sections were then rinsed in water and buffer and quickly dried under a stream of hot air. For comparison, additional brainstem sections were incubated with ^{125}I-Ang II (0.6 nM, 60 min at 22°C) and ^{125}I-Sar^1,Ile^8Ang II (0.3 nM, 120 min at 22°C) in the presence and absence of 1 µM Ang II. Sections were apposed to x-ray film to visualize radioligand binding. Incubation medium was subsequently analyzed for metabolism of the radioligands by the brain sections using HPLC. The incubation medium virtually abolished metabolism of the radioiodinated angiotensins by sections of rat brainstem. Deletion of bacitracin, puromycin, or aprotinin from the incubation medium revealed metabolism of ^{125}I-Ang III but did not affect metabolism of ^{125}I-Sar^1, Ile^8Ang II. Examination of autoradiograms from the brainstem indicated high specific binding of ^{125}I-Ang II and ^{125}I-Sar^1,Ile^8Ang II to the solitary tract nucleus, dorsal vagal motor nucleus, spinal trigeminal nucleus, locus coeruleus, and inferior olivary nucleus. In contrast, ^{125}I-Ang III binding was observed only in the inferior olivary nucleus and locus coeruleus. This disparity suggests that Ang III may not act at all of the same sites in the brain as Ang II and that there is a heterogeneity of brain Ang II receptors. Since Ang III causes pressor and dipsogenic responses similar to Ang II when administered intraventricularly, determination of the specific binding sites for ^{125}I-Ang III in the brain may identify the brain areas mediating the pressor and dipsogenic responses to Ang II in the brain. Grant support NIH NS21305 and HL32063 and AHA 831145.

284.13 PURIFICATION OF PITUITARY CRF RECEPTORS. Erica Nishimura*, Nils Billestrup*, Marilyn Perrin* and Wylie Vale. The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA 92037.

Corticotropin releasing factor (CRF), the primary hypothalamic neurohormone involved in the regulation of pituitary ACTH secretion, initiates its effects by binding to specific cell surface receptors. As a means of eventually understanding the molecular basis of CRF action, pituitary CRF receptors were solubilized and purified by affinity chromatography to apparent homogeneity.

The zwitterionic detergent CHAPS was used to solubilize functional CRF receptors from bovine anterior pituitary membranes. The radioligand [Nle^{21}, ^{125}I-Tyr]-ovine CRF (^{125}I-oCRF) was employed to measure specific soluble CRF binding sites. The apparent Kd of the solubilized form of the receptor (100 nM) was greater than that measured for membrane bound CRF receptors (1 nM). This decrease in affinity following solubilization has been observed for other cyclase coupled peptide hormone receptors and has been attributed to the possible disassociation of regulatory proteins from the receptor during detergent extraction. The solubilized material was incubated 17 hr at 4° C with wheat germ agglutinin (WGA)-agarose, then washed with 12 column volumes of 50 mM Tris-HCl, pH 7.4 buffer. The solubilized receptor was retained on the WGA-agarose column and could be eluted with 0.3 M N-acetylglucosamine, resulting in an approximate 4-fold increase in specific activity. This material was applied to CRF-agarose which was prepared by conjugating [$Nle^{21,38}$,Arg^{36}]-rat CRF to Affi-gel 10 (Bio-Rad). Following overnight incubation at 4° C the gel was washed with 10 column volumes of Tris buffer and the CRF receptor was eluted with 0.5 N acetic acid, pH 5.0 containing 0.5 mM CHAPS. Overall, a 2,500-5,000 fold purification was achieved with a 6-12% recovery in activity.

SDS gel electrophoresis of the affinity purified receptor, examined by silver staining, revealed a single protein of apparent Mr = 70,000. This is in agreement with the relative molecular weight of the CRF receptor identified by cross-linking of ^{125}I-oCRF to bovine anterior pituitary membranes (Nishimura et al., submitted).

285.1 RETINOTECTAL W-CELL PLASTICITY: EXPERIMENTALLY INDUCED RETINAL PROJECTIONS TO AUDITORY THALAMUS IN FERRETS. A.W. Roe*, P.E. Garraghty, and M. Sur. (SPON: R.D.G. McKay). Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

In ferrets in which visual cortex and superior colliculus have been ablated and auditory thalamus deafferented at birth, an aberrant visual pathway is produced that in the adult mediates visual input from the retina to the auditory thalamus and, in turn, to auditory cortex (Sur and Garraghty, Soc. Neurosci. Abstr. 12:592, '86; cf. Schneider, Brain Beh. Evol. 8:73, '73; Frost, J. Comp. Neurol. 203:227, '81). We have now tested the hypothesis that the retino-auditory thalamus projections are mediated by a "W-cell" pathway that normally projects to the superior colliculus.

Newborn ferret pups underwent the following surgery: the superior colliculus was ablated unilaterally and the ipsilateral brachium of the inferior colliculus was cut to deafferent the auditory thalamus (in particular, the medial geniculate nucleus, MGN) and thus provide alternative target space for retinal afferents. After these animals had matured, HRP-WGA injections were made into the eye contralateral to the lesioned hemisphere. In addition to the normal retinal-recipient zones in thalamus, we found label in the dorsal, ventral, and medial divisions of the MGN, as well as the lateral division of the posterior nuclear complex (PO_2) and the lateral posterior nucleus (LP) of the thalamus. This projection was sparsely and nonuniformly distributed across these targets, appearing in clumps. Physiologically, the retino-MGN pathway exhibited W-like properties: cells were poorly driven visually, had responses that waxed and waned, and had long latencies to chiasm stimulation.

To examine the retinal source of these projections, we injected HRP into: 1) the thalamus of normal adult animals, 2) the superficial superior colliculus of normal adults, and 3) the thalamus of neonatally operated animals. Whereas retinal ganglion cells back-filled from thalamus of normal animals included those of large (>350 um^2), medium (200-350 um^2), and small (<200 um^2) soma size, those projecting to superficial superior colliculus were only of small soma size. Importantly, thalamic injections in the operated animals revealed a greater percentage of small sized back-filled retinal cells than that resulting from thalamic injections in normal animals. The presence of additional small retinal ganglion cells projecting to the thalamus in our operated animals suggests that cells normally projecting to superior colliculus have rerouted their axons to visual thalamus (LP) and auditory thalamus (MGN and PO_2).

285.2 TRAJECTORIES AND BRANCHING PATTERNS OF OPTIC TRACT AXONS THAT PROJECT TRANSIENTLY TO SOMATOSENSORY THALAMUS IN THE NEONATAL HAMSTER. R.B. Langdon, J.M. Freeman, and D.O. Frost. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Retinofugal axons project transiently to the thalamic somatosensory (ventrobasal, VB) nucleus from the day of birth (PO) to the third postnatal day (P3) in hamsters (Frost, 1984, J. Comp. Neurol. 230:576). The region of VB receiving this projection is contiguous with the overlying dorsal lateral geniculate nucleus (LGd). In rodents, retinofugal axons pass through the thalamus to the mesencephalon in the superficial optic tract (SOT) as a sheet that covers the LGd, and in the internal optic tract (IOT) that courses parallel to the SOT in fascicles distributed through the thickness of the LGd. In adult hamsters, SOT axons send collaterals to the thalamus, whereas IOT axons do not (Schneider & Jhaveri, 1983, Neurosci. Abst. 9:809). In this study, we examined, on PO, P1, P2 and P4, the trajectories and branching patterns of individual SOT and IOT axons. We concentrated on axons that projected transiently to VB. Golgi-like axonal filling was achieved in vitro by lodging pellets of HRP in the optic tract just ventral to the LGd. After incubation, brains were fixed, sectioned, reacted with DAB/Co/Ni, osmicated, and plastic-embedded.

SOT and IOT axons were consistently labeled anterogradely and retrogradely for ca. 2 mm from the injection sites. Prior to P4, collaterals of SOT axons were confined to the outer half of LGd. In contrast, neonatal IOT axons sent long, unbranched, radially oriented collaterals through the LGd into VB. The distribution of these collaterals was congruent with that of retino-VB projections labeled by intraocular HRP injection; like the intraocularly labeled projections, they disappeared between P2 and P4 (Frost, ibid). Starting on P4, the collaterals of SOT axons extended deeper into LGd and elaborated their terminal arbors.

The development of retinofugal axons is viewed as occurring in 3 distinct stages: (1) elongation of the main axon trunk; (2) extension of collaterals into target nuclei; and (3) elaboration of terminal arbors (Jhaveri, Edwards & Schneider, 1983, Anat. Rec. 205:225A; Frost, ibid.). The present data show that the retino-VB projection is due to exuberance in stage (2), namely, transient extension of thalamic collaterals by IOT axons.

This work was supported by grants EY03465, NS22807, and NS07224 from the NIH and 5-417 from the March of Dimes.

285.3 SYNAPSE FORMATION BY OPTIC TRACT AXONS THAT PROJECT TRANSIENTLY TO SOMATOSENSORY AND AUDITORY NUCLEI IN THE NEONATAL HAMSTER. J.M. Freeman and D.O. Frost. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Retinofugal axons project transiently to multiple non-visual nuclei in the neonatal hamster including the thalamic somatosensory (ventrobasal, VB) nucleus and the ventro-caudal part of the midbrain auditory nucleus, the inferior colliculus (IC; a small retinal projection to dorsal IC persists permanently; Frost, J. Comp. Neurol., 230:576, 1984). The transient retino-VB and retino-IC projections are prominent during the first few days of life, but absent after days P3 and P8, respectively (PO = day of birth). In order to understand the mechanisms controlling the stabilization/elimination of immature neural connections, we have investigated whether the transient axons form synapses before withdrawing.

Retinal projections were labeled at various ages from PO to P8 by anterograde transport of intraocularly injected HRP. 100um sections were cut parasagittally in the midbrain and coronally in the thalamus. HRP was demonstrated using the Hanker-Yates technique with Co/Ni intensification. Following the HRP reaction, sections were embedded in plastic for electron microscopy (EM).

The transient projection to IC was visible in the 100um sections as one or more clearly defined fascicles which coursed superficially around the convexity of IC and sometimes extended almost to its ventral extremity. Selected 100 um sections were re-sectioned at 8um so that the most distal portion of the projection could be isolated and thin sectioned. Using this technique, we identified by EM many labeled axon trunks, growth cones and structures that appeared to be presynaptic elements making contacts satisfying the criteria for synapses (presence of pre- and post-synaptic membrane thickenings and clear vesicles concentrated in the presynaptic profile).

The transient projections to VB were diffuse, not fasciculated. By EM, labeled profiles were scarce and so far only one has been seen that makes contacts meeting the criteria for synapses. The scarcity of such profiles reflects a sampling problem due to their diffuse distribution in VB. A similar sampling problem also occurs in the thalamic visual (lateral geniculate) nucleus. We have begun to use an in vitro labeling technique that allows the isolation of single, HRP-filled axons in VB and should increase our yield of labeled elements making synapses.

These data demonstrate that transient retino-IC- (and probably retino-VB) axons make synapses before they withdraw. Thus, activity-dependent mechanisms may be responsible for the elimination of these axons.

285.4 VISUAL RESPONSES OF SOMATOSENSORY CORTEX NEURONS IN HAMSTERS WITH STABILIZED RETINAL PROJECTIONS TO SOMATOSENSORY THALAMUS. C. Metin* and D.O. Frost. Institut des Neurosciences, Université Pierre et Marie Curie, Paris, France. Section of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

Ablation of the superior colliculus and dorsal lateral geniculate nucleus (LGd) and partial deafferentation of the thalamic somatosensory (ventrobasal, VB) nucleus in newborn hamsters, permanently stabilize the normally transient, neonatal retino-VB projection. We have found visually evoked multi-unit responses in the first and second somatosensory cortices (SI and SII, respectively) of operated- but not of normal, adult hamsters. Here, we quantitatively compare the visual response properties of single neurons in SI and SII of operated hamsters and in primary visual cortex (area 17) of normal animals.

Adult hamsters were anesthetized with urethane and paralysed. In normal hamsters, area 17 neurons had receptive fields (RFs) with areas of ca. $90°^2$. 60% of the neurons were "asymmetric" - they responded best to stimuli moving in one or both directions along a specific axis; 25% of the neurons were "symmetric" - they responded equally to all directions of stimulus movement. The cells were heterogeneous in their velocity preferences (range 8-180°/sec). 40% of the neurons were orientation tuned. All orientations and movement directions were represented. Symmetric cells were usually ON-center, OFF-center or ON/OFF, while asymmetric ones were simple or complex. Mean response latency was ca. 200 msec. Neurons were recorded at all cortical depths. Most visual neurons in SI and SII of operated hamsters had RF's with 2 response areas separated by 20-40°, each covering ca. $100°^2$. 25% of the neurons were asymmetric; 50% were symmetric. The neurons generally preferred rapidly moving stimuli (range 10-200°/sec; 60% of cells preferred 50-200°/sec). All movement directions were represented. Orientation preference, when present, was weak. Among neurons that responded to stationary stimuli, ON/OFF responses predominated. Mean response latency was ca. 200 msec. 50% of visually responsive neurons were recorded near the layer III/IV border. 25% of visually responsive neurons also responded to somatosensory stimulation.

Thus, visually responsive neurons in SI and SII of operated hamsters have many essential features of neurons in area 17 of normal hamsters. Our results suggest two hypotheses that are not mutually exclusive: 1) thalamic or cortical structures that normally process information of different modalities perform similar transformations on their inputs so that they can process information from other modalities; 2) the functional differentiation of specific sensory structures depends on their afferents. Supported by grants EY03465 & NS22807 from the NIH, 5-417 from the March of Dimes and UA1199 from the CNRS.

285.5 VISUAL CORTEX RECEIVING AN ABERRANT SOMATOSENSORY INPUT MAINTAINS NORMALLY TRANSIENT PYRAMIDAL TRACT AXONS. Dennis D.M. O'Leary and Brent B. Stanfield, McDonnell Center for Studies of Higher Brain Function, Dept of Neurosurgery, Washington Univ. Sch. of Med., St. Louis, MO 63110, and NIMH, Poolesville, MD 20837.

During the first two postnatal weeks neurons in the rat occipital (visual) cortex transiently extend axons through the pyramidal tract (PT). We have investigated factors that may be involved in the selective elimination of these PT axons which occurs during the third week. We first examined the effect of removing permanent targets of the occipital PT neurons (which we previously identified as the superior colliculus - SC, and basilar pontine nuclei - BPN) on the elimination of occipital PT axons. At birth we removed the cerebellum (which resulted in the degeneration of the BPN) and the SC bilaterally. On P34 we injected the pyramidal decussation (PD) with lul of 2% Fast Blue (FB). The animals were perfused on P40. Even in the complete absence of the SC and BPN, few if any FB labeled neurons are seen in the occipital cortex. Thus events occurring in the definitive targets of the early occipital PT neurons do not appear to precipitate the normal loss of their PT axon collateral.

However, in a second series of rats in which we removed at birth a large part of right rostral cortex, neurons in right occipital cortex could be labeled by FB injected into the PD on P34. Both the number and the tangential distribution of occipital PT neurons are increased in rats that, in addition to the cortical lesion, were bilaterally enucleated at birth. In similarly lesioned rats, we find an aberrant medial lemniscal projection to the right dorsal lateral geniculate nucleus (dLGN). In these additional experiments we injected bilaterally on P34 0.2 ul of 2.5% WGA-HRP/10% HRP in the lower medulla of normal rats, rats with a right rostral cortical lesion, and bilaterally enucleated rats with a right rostral cortical lesion. One day later, the rats were perfused and their brains processed by the TMB protocol. No label is present in the dLGN of the normal rats, but in the lesioned rats labeled fibers can be followed into the right dLGN where they ramify. In rats with only a cortical lesion the label in the dLGN is largely confined to its more ventral and lateral parts, while in the enucleated and cortical lesioned rats the amount of dLGN label is greater and is spread over much of the nucleus. These differences in the aberrant medial lemniscal projection to the dLGN appear to correlate with the number and distribution of occipital PT neurons. Our results indicate that the transient occipital PT axons can be maintained. Further, they suggest that the input relayed through the thalamus influences which subcortical projections initially extended by the visual cortex will be retained. Supported by NIH Grants EY70205 and NS18506.

285.6 THE DEVELOPMENT OF TRANSITORY AUDITORY-TO-VISUAL CORTEX PROJECTIONS IN THE CAT. G.M. Innocenti, P. Berbel* and P. Melzer*, Institute of Anatomy, University of Lausanne, CH-1005 Lausanne.

In newborn kittens, visual areas 17 and 18 receive intra- and inter-hemispheric projections not only from other visual areas but also from auditory areas, including A1 and A2, in both hemispheres. Projections from auditory areas originate from supragranular layers 2 and 3, and much less densely from 5 and 6 (Innocenti and Clarke, Dev. Brain Res., 14:143, 1984). The postnatal fate of this projection has now been studied in i) normal kittens of different ages (2, 7.5, 8, 14, 14.5, 22, 30, 40 days) and 3 adults; ii) 2 adult cats which had been binocularly enucleated at birth; iii) 5 kittens of different ages (11, 14, 18, 27, 41 days) and 7 adult cats which all received injections of the "axon sparing" excitotoxin ibotenic acid (ibo; 1-2 µl; 30 µg/µl) in their visual areas 17 and 18 on postnatal days 2 or 3. The two latter experiments were meant to investigate, respectively, the role of the retina and of the target cortex in the development of auditory-to-visual projections. Connections were traced retrogradely (fast blue, diamidino yellow, rhodamine latex beads, WGA-HRP) from areas 17-18 or anterogradely (WGA-HRP) from A1-A2. In addition, in selected cases, ibo-injected cortex was characterized by Nissl and Golgi staining, cytochrome oxidase histochemistry, glial fibrillary acidic protein immuno-histochemistry, electron microscopy, (^{14}C)-2-deoxy-D-glucose autoradiography and single-unit recordings.

Normally, the auditory-to-visual projections have almost completely disappeared in the adult; a few layer 5 and 6 neurons can nevertheless be labeled in ipsi- and contralateral A1 and A2, especially after large injections involving together areas 17, 18 and 19. Transitory axons are eliminated by day 30, apparently without having ever entered the visual areas to any significant extent. Bilateral enucleation at birth does not prevent the loss of the projection from the supragranular layers, but possibly a few more neurons remain in the infragranular layers. In contrast, neonatally ibo-injected areas 17 and 18 maintain the juvenile intra- and inter-hemispheric projections from supra- and infragranular layers of A1-A2. What causes this abnormal stabilization is unclear. Ibo-injected visual areas have lost their deep layers and show cytoarchitectonic changes similar to those found in microgyria, a congenital malformation of human neocortex; nevertheless they retain several normal connections and functional properties. The juvenile, exuberant projection from medial area 17 (Innocenti et al., Neurosci. Lett., 4:237, 1977) to the ibo-injected cortex is eliminated as normally. Axons from auditory cortex, however, have access to the "microgyric" cortex, and form terminal arbors and probably synapses in it.

285.7 IDENTIFICATION OF LATERAL GENICULATE CELLS TRANSIENTLY PROJECTING TO THE POSTEROMEDIAL LATERAL SUPRASYLVIAN AREA (PMLS) IN KITTENS. L.L. Bruce[1] and B.E. Stein[2]. Dept. Rehab. Med.[1] and Physiol.[2], Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Lateral geniculate cells in laminae A, A1, and C of the newborn kitten have connections with PMLS that begin retracting at about the time of eyelid opening. The retraction is nearly completed by 2 months postnatal (Bruce, L.L. and Stein, B.E., Soc. Neurosci. Abstr., 12:438, 1986). However, cells in laminae C1-3, where only W-cells are found, retain their connections with PMLS into adulthood. Although X- and Y-cells are located solely in the laminae that have transient connections with PMLS, it was not clear whether only X-, only Y-, or both X- and Y-cells have transient connections with PMLS. Since geniculate X-, Y-, and W-cells have different average somal sizes, the distribution of somal sizes can be used to evaluate the cell types involved in the transient projection.

In each kitten, an injection of fast blue (a long-lasting retrogradely transported dye) was made in PMLS at 6-7 days postnatal, prior to the onset of retraction. At 4 weeks of age, a second injection of horseradish peroxidase was made in striate cortex (area 17) that labeled X-, Y-, and W-cells in all geniculate laminae. The next day, the kittens were perfused with saline followed by 3% paraformaldehyde in citrate buffer and the tissue was processed for the HRP reaction. Fast blue- and HRP-labeled cells in each geniculate lamina were traced using a drawing tube. Somal areas were measured using a digital graphics tablet interfaced to a computer.

The distribution of the sizes of PMLS-projecting cells in laminae A and A1 was almost identical to the distribution of geniculate cells in the same laminae that project to area 17. Thus the transient geniculo-PMLS projection appears to be derived from both X- and Y-cells. Within the C complex, the size distribution of PMLS-projecting cells includes a population that is smaller than those in the population projecting to area 17. This suggests that within the C complex there may be a population of cells with very small somata that project to PMLS but not to area 17.

These data indicate that X-, Y-, and W-cells project to PMLS for a short period following birth. During maturation, X- and Y-cells, but not W-cells, lose their axon collaterals with PMLS. The reasons why X- and Y-cells are at a competitive disadvantage for maintaining connections with PMLS are not yet clear.

Supported by NIH grant EY06502.

285.8 CELLULAR CONSTITUENTS OF THE INTERMEDIATE ZONE DURING PRENATAL DEVELOPMENT OF THE CEREBRAL CORTEX. A. Ghosh and C.J. Shatz. Dept. Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

During the development of the mammalian cerebral cortex the white matter- called the intermediate zone (IZ) at these early ages- is a complex region that contains radial glia and migrating neurons en route from the ventricular zone (VZ) to the cortical plate (CP) (Rakic, J. Comp. Neurol. 145:61, 1972), as well as waiting thalamocortical axons that will eventually grow into the CP. A special transient type of neuron, the subplate neuron, is also present (Chun et al, Nature 325:617, 1987). To learn more about the organization of the IZ, and the morphology of the waiting axons, we made localized injections of HRP within the IZ between embryonic day 45 (E45) and E62 during the development of the cat's visual cortex (gestation is 65 days).

At each age studied, HRP injections at several radial distances from the VZ were made into the IZ of 2mm thick parasagittal slices through the telencephalon that were removed and maintained in vitro for 5 hrs. All injections labeled radial glia and migrating neurons. However, the labeling of other cellular elements was a function of the depth of the injection. Injections just below the CP always labeled a small group of subplate neurons immediately surrounding the injection site. In contrast, deeper injections labeled rather smooth, radially aligned processes that ended in terminal arbors well above the injection site, frequently within the vicinity of the subplate cells. With increasing age, many of these arbors were located progressively closer to the CP, and by E57, some of them were present in future cortical layer 6. While some of these processes could be arborizing radial glial cells (Schmechel & Rakic, Anat. Embryol. 156:115, 1979), we think it more likely that many are the waiting thalamocortical axons by virtue of their axon-like appearance, their location and their presence within the CP by E57- a time when transneuronal autoradiographic labeling experiments indicate that the geniculocortical afferents begin their ingrowth into the CP (Shatz & Luskin, J. Neurosci. 6: 3655, 1986). Moreover, in order to label these arborizing processes, the injection site had to be close to the optic radiations, as verified by transneuronal autoradiography in conjunction with in vitro HRP labeling.

These observations indicate that within the IZ different cellular populations are distributed at different depths. Further, if the arborizing processes are indeed the thalamocortical axons, then during the waiting period axons need not end in simple growth cones but rather can elaborate terminal arborizations in locations distant from their final destinations. In that case, these axons may participate in complex interactions, perhaps with the subplate cells which are known to receive synaptic contacts at these ages. Supported by NIH grants EY02858 to CJS and MH17047 to AG.

285.9 **PATTERNS OF CYTOCHROME OXIDASE ACTIVITY AND ACETYLCHOLINESTERASE STAINING IN THE VISUAL CORTEX OF THE DEVELOPING FERRET.**

Jean D. Peduzzi. Dept. of Physiol. Optics, School of Optometry, University of Alabama at Birmingham, Birmingham, AL 35294.

Previous studies from our laboratory (Jackson, Peduzzi and Hickey, 1984; Jackson and Hickey, 1986) have defined the birthdates and time-course of migration for neurons destined to reside in each of the layers of the ferret's visual cortex. Just as the location of neurons born on a given day changes during development, the pattern of cytochrome oxidase activity in the developing visual cortex differs markedly from the pattern observed in the visual cortex of the adult ferret. At postnatal day 10 (P10), the only intense cytochrome oxidase activity is present at the most superficial part of the cortical plate. Cells located at the top of the cortical plate at P10 are found in layer IV of the adult animal. At P15, the only intense cytochrome oxidase activity is again located at the top of the cortical plate. However, the cells located in this region at P15 ultimately reside in layers II and III of the adult visual cortex. At P24, there is some cytochrome oxidase activity at the uppermost part of layer II (a region containing immature neurons). At this age, there is also an intense band of cytochrome oxidase activity in layer IV which is characteristic of the adult primary visual cortex. The difference in the patterns of cytochrome oxidase activity in the visual cortex of the developing and mature animals may reflect the increased metabolic activity of neurons during their rapid differentiation at the uppermost part of the cortical plate.

The pattern of acetylcholinesterase (AChE) histochemical staining in the ferret visual cortex also varies at different times in development. AChE staining at P7 reveals a region containing fewer reactive fibers (compared to surrounding regions) at the caudal pole of the cortex. At P10, the cortical plate lacks staining except for a few fibers crossing perpendicular to the pial surface. Light staining is present above and below the cortical plate. The pattern at P15 is similar to that seen in the P10 animal, with the exception that the staining is generally more intense, with the greatest density of reactive fibers being in layer V. By P24, all the cortical layers are stained except for layer IV; i.e., the general pattern found in the adult primary visual cortex. Although the AChE pattern changes during development, it provides a convenient method to identify the extent of the primary visual cortex.

Further studies are needed to determine if there is a correlation between the arrival of the geniculocortical fibers and the changing patterns of cytochrome oxidase activity and AChE histochemical staining in the primary visual cortex during development.

Supported by EY01338 and EY03039.

285.10 **DEVELOPMENT OF LAMINAR AND COLUMNAR PATTERNS OF CYTOCHROME OXIDASE ACTIVITY IN GALAGO VISUAL CORTEX.**

G.J. Condo, S.L. Florence, and V.A. Casagrande, Departments of Cell Biology and Psychology, Vanderbilt University School of Medicine, Nashville, TN 37232.

The distribution of cytochrome oxidase (CO) staining is a useful marker for identification of functional modules within the primate visual cortex. In the prosimian primate galago previous reports have shown that in striate cortex, zones which receive input from Y-like, X-like, and W-like LGN layers stain darkly with CO, i.e. cortical layers IVα, IVβ, and blobs in III. We were interested in determining the appearance of this pattern during development when the galago visual system is known to be most susceptible to visual experience. CO-staining patterns were examined in area 17 in 55 galagos, *Galago crassicaudatus* (GC) and *Galago senegalensis* (GS). CO-stained sections from flattened cortices, and parasagittally or coronally sectioned cases were compared to adjacent Nissl and fiber stained sections. Our results confirm that in adults the darkest CO-staining occurs in the LGN recipient zones. In addition, there is also evidence of periodic staining in layer IVα, faint periodic staining in the upper 2/3 of layer VI, and staining of some large pyramidal cells in layer V. The periodicity of CO staining in layers IVα and VI is aligned with the CO blobs in layers II/III. The frequency of CO-blobs per mm^2 in GC is on average 2.6 in cortex representing central vision and 2.9 in cortex representing peripheral vision. By contrast, area 17 in GS is smaller, with 4.4 and 5.3 blobs per mm^2 in central and peripheral visual field representations, respectively. At birth (P0) in both species, the CO pattern is similar to that of the adult with the exception that blobs in layers II/III are lighter staining, blobs in layer VI are more distinct, the number of highly reactive pyramidal cells per unit area in layer V is greater, and layer IV in some cases appears to have three sublaminae. As in adults, at P0 there are more blobs per mm^2 in layers III and IV in cortex representing peripheral vision than in cortex representing central vision. From P0 to adulthood the only changes that occur (other than possible changes in blob frequency) are that blobs in layers II/III become more heavily stained, the frequency and intensity of CO-reactive pyramidal cells in layer V declines, and the blobs in layer VI become very faint. In GC the supragranular layers appear adult-like by 6 weeks and the infragranular layers appear adult-like by 12 weeks. Our results show that the galago is born with basically the same CO pattern seen in an adult; the main difference is a shift in staining emphasis from the infragranular to the supragranular layers. In addition our results suggest some interesting relationships. First, since magnocellular LGN cells terminate within layer IVα, the light/dark periodicity (which roughly matches that of a L/R ocular dominance column pair) must mean that the Y-like LGN pathway from the two eyes does not drive cortex equivalently. Likewise the CO periodicity in layer IV suggests that feedback from layer VI to the LGN may be dominated by one eye. Second, concerning the immature cortex, it is noteworthy that the size of LGN axonal arbors innervating layer IV at P0 is larger relative to the total area of striate cortex than in the adult, indicating that the forces which organize the frequency distribution of the blobs may not be related directly to LGN input.

Supported by NIH EY01778 to VAC and EY05770 to GJC.

285.11 **POSTNATAL DEVELOPMENT OF INTRINSIC AXONAL ARBORS OF PYRAMIDAL NEURONS IN CAT STRIATE CORTEX.**

L.C. Katz & T.N. Wiesel. Lab. of Neurobiology, Rockefeller Univ., 1230 York Ave., N.Y. NY 10021.

Within striate cortex, distinct patterns of axonal collaterals provide defined avenues for communication within layers (horizontal connections) and between layers (vertical connections). Pyramidal cells in layers 2/3, for example, project vertically and horizontally within layers 2/3 and to layer 5, but lack appreciable collaterals within layer 4. Nothing is known about how this laminar specificity arises. We therefore examined the development of this intrinsic circuit, from postnatal day (PND) 5 to PND 110, using intracellular fluorescent dye injections in brain slices.

At the youngest ages, laminar specificity was even more precise than in the adult. Until PND 12, no sprouts, spines, or collaterals were present in layer 4. Although rudimentary, both layer 3 and layer 5 collaterals were present, and of equivalant lengths, suggesting that they emerged from the parent axon in rough synchrony. From PND 14-28 about half the cells had one or two small spine-like processes (< 10 μm long) in layer 4. At PND 50-110, in contrast, the axons of many layer 2/3 cells had numerous spine-like processes, and 2-4 collaterals, sometimes 100 μm long and branched, within layer 4, which are also seen in adult cats. Therefore the laminar specificity of this connection results from highly precise initial outgrowth, not removal of inappropriate branches.

Within layer 2/3, axon arbor development appeared conservative. At PND 5, 80% of cells had collaterals, an average of 3.5 per cell. No processes emerged within 50 μm of the soma. The cell's collaterals emerged closely spaced, suggesting that certain regions of the main axon are specialized to support collateral outgrowth. By PND 7 each cell averaged 4.5 collaterals: this number remained constant through PND 110. Thus a cell's complement of collaterals appears specified early, prior to extensive collateral outgrowth. Cells strengthen their vertical and horizontal connections by repeated branching of existing collaterals, not by growth of new ones: at PND 5, few collaterals branched, by PND 13, over 40% branched, and by PND 20, 75%. Long horizontal collaterals within layer 2/3 were observed by PND 13 in about half the filled cells. Some travelled over 1 mm, but without further branching. Clustered horizontal connections within layer 2/3 only emerged at about PND 50. In contrast, by PND 20, the vertical axonal arbor of many cells was already well-developed, with collaterals branching repeatedly near the cell's apical dendrites. This implies that vertical intralaminar connections develop considerably before distant horizontal connections.

Supported by the L.P. Markey Charitable Trust and EY05253.

285.12 **DEVELOPMENT OF LAMINA SPECIFIC CORTICAL CONNECTIONS.**

T.A. Coogan* and A. Burkhalter (SPON: G.W. Harding). Dept. of Neurosurgery, Washington University School of Medicine, St. Louis, MO 63110.

Previously we have shown using retrograde tracing of the connection between area 17 and 18a in the developing rat cortex that primary visual cortical neurons in lower layers are labeled before cells in upper layers. To identify the laminar targets of area 17 neurons in area 18a and compare their termination patterns during development we used anterograde tracing with Phaseolus vulgaris leucoagglutinin (PHA-L) in neonatal and adult Long Evans rats.

PHA-L was injected into area 17 of neonatal rats at postnatal day 5 (P5) and into adult animals. After 2-7 days survival, animals were perfused, the brains sectioned and the lectin visualized immunocytochemically.

The laminar pattern of connections in adult animals has been investigated by concentrating injections in either the superficial or deep layers. In adult animals deeper cortical layers of area 17, (layers 4, 5 and 6), project to layers 1-6 in area 18a. Superficial layers (layers 1, 2/3), in contrast, have their terminals limited to superficial layers.

Fibers labeled after an injection on postnatal day 5 (P5) and visualized after a 2 day survival, appear immature. Growth cones are seen on many fibers. These intracortical fibers do not have abundant varicosities nor do they show dense ramifications in target areas, features typical of cortical fibers in adult animals.

The injections in neonatal animals involved all cortical layers of area 17, but fibers in area 18a are only seen in layers 6, 5, and 1. Occasionally fibers are seen in the still differentiating superficial layers, but these fibers do not extend outside of area 17.

The absence of fibers in the superficial layers at P7 leads us to two related hypotheses. The first is that the ability of cortical neurons to receive synapses is expressed in a sequence which is determined, like the gradient of axon outgrowth, by the sequence of generation of cortical cells. The second takes note of the fact that the earliest innervated layers, layers 6, 5, and 1, are exactly those layers which are not innervated in the adult by fibers from superficial layers. We suggest that the early arriving fibers, from early generated cells, inhibit fibers from superficial layers from terminating in layers 6, 5, and 1, by a competitive process.

286.1 NICOTINIC ACETYLCHOLINE RECEPTORS REGULATE CHLORIDE CHANNELS IN CULTURED NEURONS FROM THE CHICK EMBRYO CEREBRUM. M.H. Jalilian Tehrani and E.M. Barnes, Jr. Depts. of Biochem. and Physiol. and Mol. Biophys., Baylor Col. of Med., Houston, TX 77030.

The expression in vitro of neurotransmission systems by neuronal cultures provides preparations which are amenable to biochemical and biophysical investigations. We have shown previously that cultured neurons from the chick embryo cerebrum contain all of the GABAergic synaptic elements with properties similar to those in vivo. We report here that these cultures also express high levels of cholinergic synaptic elements.

Cultured neurons permeabilized with Triton X-100 contained choline acetyltransferase activity (7.0 ± 1.8 nmol/hr•mg protein) at levels which are 76% those of the adult brain. Acetylcholine esterase was also found at high levels (134 ± 5 nmol/min•mg) representing 106% of the activity in the chicken cerebrum. Specific binding of [^{3}H]-N-methylscopolamine (NMS) and [^{3}H]nicotine to membranes was used to assay muscarinic and nicotinic receptors, respectively. The Kd value for [^{3}H]NMS binding was 0.25 ± 0.05 nM, similar to the value (0.17 ± 0.08 nM) for chicken cerebrum; whereas the Bmax value for cultures (210 ± 50 fmol/mg) represented 37% of the receptor density of adult tissue). Likewise, neurons bound [^{3}H]nicotine with a Kd = 15 ± 1 nM which was comparable to the cerebrum (Kd = 25 ± 2 nM); the nicotinic receptor density (29 ± 2 fmol/mg) was 58% of that found for the adult tissue. These findings confirm the preponderance of muscarinic receptors over nicotinic receptors in the vertebrate brain. The culture system may also prove useful in investigating the physiological functions of central ACh receptors.

Without exogenous ligands, cerebral neurons possess a persistent ^{36}Cl ion permeability. Less than 20% of this ^{36}Cl uptake is inhibited by bicuculline, strychnine, stilbene sulfonates, loop diuretics, or by omission of K or Na from the medium. However, 60% of this ^{36}Cl flux was blocked by 100 μM carbachol or nicotine, but not by 100 μM muscarine. The chloride channel blocker t-butylbicyclophosphorothionate at a 10 μM concentration also inhibited over 50% of the ^{36}Cl flux. The effect of nicotine and carbachol was reversed by the nicotinic antagonists, hexamethonium (10 μM) and d-tubocurarine (50 μM), but 10 μM scopolamine was ineffective. These results suggest a novel coupling between nicotinic receptors and Cl channels in the vertebrate brain.

Supported by grants AM 17436 and NS 11535 from NIH.

286.2 EFFECT OF BASAL FOREBRAIN INJECTION OF CARBACHOL ON ACETYLCHOLINE (ACH) TURNOVER AND 8-ARM RADIAL MAZE PERFORMANCE. A. Sullivan,* K.L. Hambrecht,* L.G. Farley*, B.G. Lyeth and S.E. Robinson, (SPON: D.A. Brase) Department of Pharmacology and Toxicology, Medical College of Virginia, Richmond, VA 23298

Intrastriatal injection of soman (14.85 nmol) elevates the concentration of ACh in the striatum without significantly affecting the content of ACh in other brain regions. However, ACh turnover, as measured by a mass fragmentographic technique, is decreased in the parietal cortex following such treatment. It appears that the effect of intrastriatal soman on cortical ACh turnover results from stimulation of basal forebrain cholinergic cell bodies by elevated ACh produced in the striatum, as ACh turnover was significantly reduced in the parietal cortex after unilateral injection of carbachol (5nmol, 1 μl) in the basal forebrain through stereotaxically-implanted chronic guide cannulas (AP + 6.06, L 2.4 and V-1.6, according to the atlas of Konig and Klippel). This area has been identified as the source of cholinergic innervation of the parietal cortex (Bigl et al., Brain Res. Bull. 8: 727, 1982). The turnover rate of ACh was reduced by 46% in the ipsilateral cortex and by 29% in the contralateral cortex, but was not affected in the striatum 20 min after the carbachol injection.

In order to determine if this reduction in ACh turnover had behavioral relevance, the effect of bilateral injection of carbachol was studied on performance in the 8-arm radial maze, which has been used to measure short-term, or working, memory. Sixteen male Sprague-Dawley rats (beginning at 150g) were maintained at 85% of their free-feeding weight. Rats were adapted to the maze and trained to a criterion of one or fewer working memory errors per trial. Rats were tested each weekday and the trials were restricted to the rats entering each of the 8 arms or a maximum of 10 min. Rats not reaching criterion after 25 sessions were removed from the study. Bilateral guide cannulas aimed at the basal forebrain were implanted. On the third day after surgery, rats were again performing at criterion. Injection of artificial CSF did not significantly affect performance in the radial maze. However, bilateral injection of carbachol significantly slowed performance in the radial maze (9.8 ± 0.2 min versus 6.0 ± 0.9 min run time) and, in most cases, prevented the rats from entering all the arms. With the exception of one subject, the animals did not appear to exhibit impaired movement. Additional studies must be performed to determine if the disruption of radial maze performance involves cognitive or motor deficits. However, it must be pointed out that intrastriatal injection of soman at doses that inhibit cortical ACh turnover does not affect locomotor behavior (Lynch et al., Pharmacol. Biochem. Behav. 24: 941, 1986).

286.3 CIRCULATING CHOLINE LEVELS DO NOT REFLECT THE ABILITY OF CENTRAL CHOLINERGIC NEURONS TO SYNTHESIZE AND RELEASE ACETYLCHOLINE. L.Wecker, G. Cawley* and S. Rothermel*, Louisiana State Univ. Medical Center, New Orleans, LA 70112.

Whether or not chronic alterations in circulating levels of choline alter the availability of precursor with consequent changes in acetylcholine (ACh) synthesis is a question of fundamental importance to both basic scientists and clinicians. Thus, the objective of these studies was to determine the effects of alterations in the dietary availability of choline on serum choline levels and on the synthesis and release of ACh in striata. Rats were maintained on either choline deficient (0% choline chloride), control (0.2% choline chloride), or choline supplemented (2.0% choline chloride) diets for 30-40 days. Serum levels of choline in rats fed the control diet were 15 uM and choline deficiency reduced levels by 20%, whereas supplementation increased levels by 52%. The total choline pool in the circulation, which is composed primarily of lipid esters, was 1.4 mM in the control animals, and was not altered by either deficiency or supplementation. To ascertain the effects of the diets on ACh turnover, striatal slices (0.4mm) were incubated in choline-free buffer, and the synthesis and release of neurotransmitter were measured. The initial tissue content of ACh in slices from the control group was 3.5 nmoles/mg pt, and values did not differ among dietary groups. The amount of ACh synthesized was 1.4 nmoles/mg pt/60 min for control samples and ACh was released in a linear fashion at a rate of 6.8 pmoles/mg pt/min. ACh synthesis and release from tissue from supplemented rats did not differ from controls and was 1.2 nmoles/mg pt/60 min and 6.9 pmoles/mg pt/min, respectively. In contrast, ACh synthesis and release from slices from deficient rats were not as vigorous as in the control group; release proceeded at a rate of only 46% and synthesis was 77% of control values. To determine whether this difference reflected alterations in the availability of precursor for ACh synthesis, the concentration and release of choline from the slices were determined. The initial tissue content of choline in slices from the control group was 4.4 nmoles/mg pt, and values did not differ among dietary groups. Choline was released linearly from slices in the control group at a rate of 18 pmoles/mg pt/min. Slices from the deficient group exhibited a 20% reduction in choline release, whereas release from striata in the supplemented rats increased by 51%. Results indicate that dietary choline supplementation does not alter ACh turnover in brain, despite an increase in precursor availability. In contrast, choline deficiency limits available precursor and depresses ACh turnover. (Supported by NIMH-33443.)

286.4 CONTROL OF ACETYLCHOLINE SYNTHESIS AND SECRETION BY LA-N-2 HUMAN NEUROBLASTOMA CELLS IN CULTURE. U.I. Richardson*, J.K. Blusztajn*, M. Liscovitch*, M. Irwin*, and R.J. Wurtman (SPON: M. Karnovsky) Dept. of Brain & Cognitive Sciences, MIT, Cambridge, MA 01239.

The LA-N-2 strain of human neuroblastoma cells has been shown to contain large amounts of acetylcholine (ACh). We have investigated the rates of ACh synthesis and release in LA-N-2 cells in order to characterize them as a potential model of cholinergic neurons. When grown in a serum-containing medium the cells do not extend many neurites. In the absence of serum most cells develop neurites that can reach a length of 0.1 mm. Electron microscopic examination reveals cytoskeletal structures in these processes. The cells elaborate an extensive Golgi apparatus whose vesicles may contain ACh.

ACh content of the cells (determined by a radioenzymatic assay) varies with extracellular choline concentration in a saturable fashion, reaching a maximum of approximately 1 nmol/mg protein. Radiolabeled choline is taken up by the cells [and then converted to ACh or phosphocholine (PCh) as determined by purification from cell extracts by high performance liquid chromatography] in a saturable manner which is described by a single rectangular hyperbola. Hemicholinium-3 (HC-3)(0.1 mM) inhibits this uptake as shown in the table:

	Km (μM)		Vmax (pmol/mg protein/5 min)	
	control	HC-3	control	HC-3
Choline	35.5±1.8	53.4±10.9	821.3±14.5	730.2±44.3
Acetylcholine	28.4±2.1	62.0± 2.1	623.8± 8.6	394.0±62.0
Phosphocholine	7.9±1.7	66.7±15.0	106.8± 6.2	73.7± 7.3

Turnover rates of ACh and PCh (half-lives of 4 and 25 hours, respectively) were determined by pulse-chase experiments with [^{3}H]choline. Most of the radioactivity lost from the ACh pool was recovered in the medium, suggesting that ACh turnover is primarily associated with its release. The radioactivity lost from the PCh pool was quantitatively recovered in the form of phosphatidylcholine (PtdCho) suggesting that the PCh is protected from intracellular hydrolysis and is used as precursor of PtdCho.

The cells release ACh spontaneously and this release is enhanced upon depolarization with potassium or veratridine (the latter effect is blocked by tetrodotoxin), or by a muscarinic agonist, carbachol. LA-N-2 cells contain acetylcholinesterase and release this enzyme into the medium upon depolarization with potassium in a calcium-dependent manner.

Taken together the data demonstrate that LA-N-2 cells exhibit properties of differentiated cholinergic neurons and promise to be a useful in vitro model for studies of ACh synthesis and release.

286.5 **CHOLINERGIC - GABAERGIC RECIPROCAL SYNAPTIC INTERCONNECTION IN THE RAT SEPTAL AREA AND ITS HIPPOCAMPO-SEPTAL AFFERENTS: EM DOUBLE IMMUNOSTAINING COMBINED WITH DEGENERATION.** C.Leranth and M.Frotscher Yale University, School of Med. Section of Neuroanatomy and Dept. of OB/GYN, New Haven, CT. 06510 and (M.F.) Dept. of Anatomy, Johann Wolfgang Goethe Univ. Frankfurt a.M. F.R.G.

The cholinergic innervation of rat hippocampus pyramidal, Golgi identified granule cells, and using EM double immunostaining (EMDI), the cholinergic innervation of dentate hilar area GABAergic and somatostatin immunoreactive inter- and commissural neurons has been reported in our laboratory (Frotscher and Leranth, 1985, 1986; Leranth and Frotscher, 1987). In recent studies we analyzed the synaptic interconnections of these septo-hippocampal cholinergic neurons with GABAergic neurons and hippocampo-septal afferents in the rat septal area.

Preembedding EMDI using immunoperoxidase and avidinated colloidal gold as two contrasting electron dense immunolabels revealed cholinergic innervation of septal GABAergic neurons and GABAergic innervation of septal cholinergic neurons. The combination of fimbria-fornix transection with immunostaining for GAD demonstrated that degenerated hippocampal afferents to the septum terminate on GABAergic and non-GABAergic septal neurons. In contrast, following the same operation and immunostaining for ChAT, synaptic connections between degenerated hippocampal afferents and septal cholinergic neurons were not found.

These observations led us to the conclusion that septal projective cholinergic neurons receive inputs from GABAergic neurons, while septal GABAergic neurons are innervated by both cholinergic and hippocampal afferents. However, the question still arises whether the same septal GABAergic neurons are targets of both hippocampal and cholinergic inputs.

286.6 Tonically active nucleus basalis neurons in the awake monkey project to cerebral cortex. Russell T. Richardson and Mahlon R. DeLong, Depts. of Neurology and Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD 21205.

Neurons within the nucleus basalis of Meynert (NBM) in awake monkeys have previously been described as having a characteristic tonic discharge pattern (DeLong, J. Neurophysiol. 34:414, 1971). Neurons displaying this discharge pattern have the same anatomical distribution as the cortically projecting cholinergic neurons of the NBM in that they are consistently found ventral to the globus pallidus and within the medullary laminae. We now confirm that at least some of these spontaneously active neurons project to cerebral cortex.

Three pairs of stainless steel stimulating electrodes were implanted near the cingulum bundle of a male rhesus monkey. The cingulum bundle contains numerous axons of NBM cells that project to cortex (Kitt et. al., Brain Res. 406:192, 1987). Therefore, antidromic activation of an NBM neuron from the cingulum bundle would indicate that the neuron projects to the cortex. Neurons were considered to be antidromically activated if the driven action potentials had a constant latency, followed paired pulse stimulation of 200 Hz, and collided with orthodromic action potentials. Stimulation pulses were 300 msec square waves up to 3 mA.

To date, seven tonically firing NBM neurons have been antidromically activated in the awake monkey. Spontaneous discharge rates ranged from 7 to 18 Hz (mean: 12 Hz), and the coefficients of variation of the interspike interval ranged from 46 to 78% (mean 61%). The duration of the initial negativity of the action potential (200-10KHz filtering) ranged from 240 to 320 usec (mean: 264 usec). The discharge rates, interspike interval variances, and spike durations of these antidromically driven cells are similar to those of tonically active NBM neurons recorded previously (Mitchell et. al., Exp. Brain Res., in press).

The activity of three of the seven neurons was recorded while the monkey performed a go/no-go task as described previously (Richardson & DeLong, Soc. Neurosci. Abstr. 12:356, 1986). One cell did not respond, and two cells had significant ($p < .01$) changes in firing only in the choice phase of the task, with no differences between responses on go trials and no-go trials. In the earlier study of 82 NBM neurons, the most common response occurred in the choice phase of the go/no-go task, with no significant response differences between go and no-go trials in 89% of the cases. Thus, despite the small number of antidromically driven neurons, their activity in this task was comparable to that of other tonically discharging NBM neurons.

These findings indicate that the previously characterized population of tonically active NBM neurons project to cerebral cortex.

286.7 CARBACHOL CONJUGATED MICROSPHERES: A NEW PHARMACOLOGICALLY ACTIVE RETROGRADE PROBE FOR MAPPING BEHAVIORALLY EFFECTIVE DRUG INJECTION SITES IN THE MAMMALIAN BRAIN. J. Quattrochi, H.A. Baghdoyan, R. Madison, T. Hensch*, and J.A. Hobson. Laboratory of Neurophysiology, Harvard Medical School, Boston, MA 02115.

Microinjection of cholinergic agonists into the dorsolateral pontine tegmentum has been shown to elicit desynchronized (D) sleep signs and a D sleep-like behavioral state in adult cats. However, a consistent methodological problem underlying the injection of pharmacological agents in these studies is the extent of diffusion from the injection site. Also, it is impossible to know from such experiments which cholinergic neurons project to the injection site. In order to restrict diffusion and retrogradely label neurons which project to a more precisely defined anatomic site in the cat brainstem, we now report the conjugation of the cholinergic agonist, carbachol, to fluorescent latex microspheres.

Carbachol was covalently linked to rhodamine fluorescent microspheres. Pharmacological effectiveness was assessed by scoring polygraphic recordings of behavioral state after carbachol microspheres in 250 nl saline were administered through chronically implanted guide tubes stereotaxically aimed at the anterior dorsolateral pontine reticular formation. All injections were unilateral into the same site and consisted of the conjugate reaction solution extensively dialyzed without microspheres, carbachol alone (4 microgram dose), or carbachol microspheres. Measures of behavioral state include latency to onset of the first D episode (D latency) and percentage of the total recording time (4 hours) spent in D sleep (D percentage).

D latency after administration of carbachol microspheres was 9.2 min compared with 4.2 min after carbachol alone and 108.2±48.5 min in control conjugate dialysis solution and baseline recordings. D percentage was similar between carbachol microspheres (61%) and carbachol alone (62%) compared to 4.3±1.2% in controls. D percentage was markedly greater during the first two hours (75% and 68.1%) for carbachol microspheres than for carbachol (50.7% each hour). However, by the fourth hour D percentage was greater with carbachol (74.3%) compared with carbachol microspheres (21.5%).

This micropharmacologic application of fluorescent microspheres now facilitates the precise in vivo characterization of cholinergic sleep-generating neurons with a specificity unattainable with present methodology.

Supported by grant MH13923 and a grant from the Whitaker Foundation.

286.8 BRAIN BINDING SITES FOR THE ACETYLCHOLINE UPTAKE BLOCKER AH5183: PHARMACOLOGY AND EFFECTS OF LESIONS. M. R. Marien+, D. McHugh* and C. A. Altar. +Douglas Hospital Research Center, 6875 Lasalle Blvd., Verdun, Canada, and Neuroscience/Cardiovascular Res., Pharmaceuticals Div., CIBA-GEIGY Corp., Summit, NJ, 07901, USA.

AH5183 is a noncompetitive inhibitor of high-affinity acetylcholine transport into cholinergic vesicles. Using quantitative autoradiography, we have shown that [3H]AH5183 binds specifically, saturably and with high affinity to sites in rat brain which are located in cholinergic nerve terminal regions (Marien, Parsons and Altar, PNAS 84:876, 1987). The present study investigated the pharmacology and the cholinergic terminal localization of the [3H]AH5183 binding site. The binding of [3H]AH5183 (kindly supplied by Dr. S. Parsons) to 20 um-thick brain sections of male Sprague-Dawley rats (Tac:SD) was performed and analyzed by quantitative autoradiography as previously described (Marien et al, 1987; Altar et al, J. Neurosci. Meth. 10:173, 1984).

[3H]AH5183 binding was not displaced by 10 µM concentrations of hemicholinium-3 or by cholinergic, adrenergic, dopaminergic, GABAergic, glutamatergic, sigma, phencyclidine, or calcium channel receptor ligands. Of 60 compounds tested, the active displacers of [3H]AH5183 binding were (IC50, nM): quinacrine (3600), ketanserin (500), decahydro-3-(4-phenyl-1-piperidinyl)-2-naphthalenol (100), haloperidol (43), and 3-(4-phenyl-1-piperidinyl-2-hydroxyaminotetralin (14).

Cholinergic afferents to the neocortex or hippocampus were unilaterally lesioned 14 days before sacrifice by injection of 150 nmoles of quinolinic acid into the nucleus basalis magnocellularis or by transection of the fimbria. Respective reductions of choline acetyltransferase activity in the frontal cortex (-52%) or hippocampus (-80%) were accompanied by decreases in the Bmax (but not the Kd) values of [3H]AH5183 binding in the frontal cortex (-29%, $n = 6$, $p < 0.01$) and hippocampus (-25%, $n = 10$, $p < 0.001$).

These findings further demonstrate the unique pharmacology of the [3H]AH5183 recognition site in brain, and indicate a presynaptic localization for a proportion of these sites on neocortical and hippocampal cholinergic afferents.

286.9 A SINGLE RNA SPECIES INJECTED IN XENOPUS OOCYTE DIRECTS THE SYNTHESIS OF ACTIVE CHOLINE ACETYLTRANSFERASE. R.E. McCaman, L. Carbini*, V. Maines* and P.M. Salvaterra. Div. Neurosciences, Beckman Research Institute/City of Hope, Duarte, CA 91010.

We have recently isolated and characterized a cDNA clone containing a 728 amino acid coding sequence for Drosophila choline acetyltransferase (ChAT; EC 2.3.1.6) (Itoh et. al., PNAS 83:4081, 1986). In this study we have tested the ability of this clone to produce active enzyme. We have sub-cloned the lambda gt11 insert of the Drosophila ChAT cDNA into the pGEM2 plasmid (Promega Biotech Inc.) that allows us to synthesize in vitro a single species of complementary RNA (cRNA).

Stage 5 oocytes from Xenopus laevis were microinjected with 25-50 nl of diethylpyrocarbonate-treated water containing approximately .02-50 ng of capped ChAT RNA in the sense orientation. Control oocytes were injected with either an equal volume of water or 50 nl of water containing antisense RNA. Control and experimental oocytes were assayed for ChAT activity and endogenous levels of acetylcholine (ACh) and choline.

The measured levels of ChAT activity in several different experiments range from 40 to 1300 pmole/min/oocyte. The level of ChAT activity observed in control oocytes was below the level of detection (i.e. <1 pmole/min/oocyte. RNA injected oocytes also showed a high level of endogenous ACh (up to 350 pmole/oocyte). Control oocytes produced no detectable (i.e. <.5 pmole/oocyte) endogenous ACh. The steady state level of choline was reduced during synthesis of ACh. Analyses using the Western blot technique showed that the extracts from Xenopus injected with sense RNA contained a single 75 kd polypeptide recognized by anti bodies to the Drosophila ChAT fusion protein produced by the cDNA clone. The size of this polypeptide agrees well with the major polypeptide recognized by these same antibodies in SDS homogenate of fresh Drosophila heads. No immunoreactive proteins were produced by control oocytes.

We conclude from these results that enzymatically active ChAT protein is produced by oocytes injected with the ChAT cRNA. In addition, the protein is very similar, if not identical to the major form of ChAT present in Drosophila.

Supported in part by a grant from NINCDS.

286.10 MOLECULAR FORMS OF ACETYLCHOLINESTERASE FROM ADULT LAMPREY BRAIN AND AMMOCOETE SKELETAL MUSCLE. Leo Pezzementi, Hugh C. Nickson,* Robert C. Dunn,* and Ronald J. Bradley. Birmingham-Southern College and University of Alabama at Birmingham, Birmingham, Al.

Lampreys belong to the most primitive class of vertebrates, the Agnatha. To learn more about the evolution of acetylcholinesterase (AChE) in the vertebrates, we studied the cholinesterase activity from the brain of the adult lamprey and from the skeletal muscle of the larval form, the ammocoete. We found that the brain enzyme is true AChE and that 98% of it is present in the G_4 globular form. Only 1% of the AChE was found distributed among the asymmetric forms, A_4, A_8, and A_{12}; an additional 1% of the activity could not be extracted. The identity of the asymmetric forms was confirmed by collagenase digestion. These data demonstrate that asymmetric AChE is present in the brains of organisms representing all classes of vertebrates. However, our results raise questions about a proposed phylogenetic relationship concerning vertebrate brain AChE.

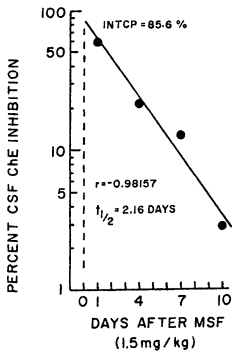
The ammocoete is a relatively non-motile filter-feeder, which, in terms of anatomy and behavior, superficially resembles the cephalochordate amphioxus. Although the molecular forms of AChE from amphioxus are not known, urochordates and echinoderms possess only globular esterase. In addition to providing insights into the evolution of AChE, a study of esterase in the ammocoete could provide information about developmental changes in the enzyme. We found that cholinesterase activity of the ammocoete is also due to AChE and that 85% of the esterase is present in globular enzyme. The predominant globular from detected was G_4. In contrast to skeletal muscle from spawning adult lamprey, considerable amounts of G_1 and G_2 were also observed. Additionally, approximately 5% of the esterase was found distributed among the asymmetric forms A_4, A_8, and A_{12}. Ten percent of the esterase could not be extracted. Thus, AChE from ammocoete skeletal muscle is qualitatively similar to adult enzyme since both exist in globular and asymmetric forms; however, at the same time, the larval enzyme is quantitatively different in its complement of globular forms. Since G_1 and G_2 are probably precurors of G_4, the lack of the smaller globular forms in muscle from spawning adult may be related to the deteriorating condition of the spawning lamprey. This research was supported by a Cottrell College Science Grant From Research Corporation to L. P.

286.11 METHANESULFONYL FLUORIDE: AN ACTIVE CNS CHOLINESTERASE INHIBITOR IN PRIMATES. D.E. Moss, P.Z. Manderscheid, R. Palacios*, and R.G. Perez*. Lab. of Psychobiochemistry, Dept. of Psychology, Univ. of Texas at El Paso, El Paso, TX 79968.

Methanesulfonyl fluoride (MSF) can produce up to 90% inhibition of rat brain ChE with less than 35% inhibition of peripheral enzyme measured in smooth muscle, skeletal muscle and heart (Moss et al., 1985). Because MSF, a CNS selective ChE inhibitor with low general toxicity, may be therapetically valuable in dementia in Alzheimer's disease or other CNS diseases, it was important to determine if MSF would produce similar effects in primates.

M. fasicularis were injected i.m. with increasing doses of MSF in sterile peanut oil until a dose of 1.0 mg/kg was used for 11 injections given 3 times per week and then a dose of 1.5 mg/kg was maintained for 12 injections given 2 times per week. At the end of this treatment, RBC AChE was inhibited over 80% while plasma BChE was inhibited about 30%. Cortical biopsies taken 2 or 3 days after the last injection showed that treated monkeys were inhibited 80% relative to controls. At no time during treatment did any monkey show toxic effects as shown by blood chemistry, behavior, or loss of weight or vigor.

At least six months after the completion of the previous experiment, inhibition of CSF ChE by MSF was studied. In this experiment, a single injection of 1.5 mg/kg MSF produced 85% inhibition of CSF ChE which also showed a half-time for the recovery of enzyme activity of 2.16 days. A single injection of 3.0 mg/kg produced virtually 100% inhibition. This dose produced a general malaise but no toxic or respiratory crisis.



Because of the remarkably low toxicity associated with CNS ChE inhibition produced by MSF, it appears that the extreme toxicity of other ChE inhibitors may not be due entirely to inhibition of ChE in the CNS but may also involve other mechanisms of toxicity. MSF may be safe and efficacous in human therapeutics.

287.1 PHENCYCLIDINE RECEPTOR LIGANDS ATTENUATE CORTICAL NEURONAL INJURY FOLLOWING HYPOXIA OR N-METHYL-D-ASPARTATE EXPOSURE. M.P. Goldberg, V. Visekul* and D.W. Choi. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

The dissociative anesthetic phencyclidine (PCP) and the sigma opiate SKF 10,047 (SKF) have been reported to antagonize neuroexcitation at N-methyl-D-aspartate (NMDA) receptors. We investigated the possibility that these and related compounds might systematically reduce the cortical neuronal injury produced either by hypoxia, or by toxic exposure to NMDA.

Cultures of dissociated mouse neocortical neurons and glia were exposed to a hypoxic atmosphere of 5% CO_2 / 95% N_2 at 37° for 10 hr. 24 hr later, control (untreated) cultures showed widespread neuronal damage and substantial efflux of lactate dehydrogenase (LDH) to the bathing medium. In contrast, addition of the following compounds at 100 µM to the exposure medium (during and after hypoxia) led to preservation of neuronal morphology and marked reduction of LDH efflux: PCP, ketamine, (+)-SKF, (-)-SKF, (±)-pentazocine (PENT), dextrorphan, and levorphanol. Quantitative concentration-response studies showed half-maximal reduction (ED_{50}) of LDH release in the range of 1 µM PCP, 10 µM (+)-SKF, and 30 µM PENT.

In separate experiments, these drugs were tested for ability to attenuate the neurotoxicity induced by direct application of NMDA itself. Cultures were exposed to 500 µM NMDA for 5 min, either alone, or in the presence of an added antagonist drug, before being returned to normal medium and assessed 1 d later. In this paradigm, each of the compounds listed above at 100 µM yielded substantial reduction of NMDA neurotoxicity. Quantitative concentration-protection studies with PCP, (+)-SKF, and PENT showed ED_{50} values in the range of 3 µM PCP, 10 µM (+)-SKF, and 30 µM PENT.

The observed potency order for reduction of both NMDA- and hypoxia-mediated cortical neuronal injury (PCP > SKF > PENT) corresponds to that previously reported by Olney et al. (Neurosci Lett 68: 29) for antagonizing acute NMDA excitotoxicity in the chick retina. This order also corresponds to that obtained in binding studies of the phencyclidine receptor site, and differs from that alternatively expected at the high-affinity SKF / sigma receptor site (Largent et al., J Pharm Exp Ther 238: 739), thus favoring the notion that the former is the site associated with the NMDA receptor channel. In addition, the close correlation between the pharmacology of hypoxic neuronal injury and NMDA neurotoxicity observed here provides additional evidence that these two processes are related.

287.2 METHADONE SELECTIVELY AND NON-STEREOSPECIFICALLY ATTENUATES N-METHYL-D-ASPARTATE RECEPTOR-MEDIATED NEUROTOXICITY: A GENERALIZABLE PROPERTY OF OPIOIDS? D.W. Choi and V. Viseskul*. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

N-methyl-D-aspartate (NMDA) receptor-mediated toxicity may participate in the pathogenesis of neuronal cell loss in several acute and chronic neurological diseases. We have recently shown that the opioid agonist levorphanol and the opioid antagonist naloxone, both can selectively antagonize NMDA neurotoxicity in cortical cultures. The present experiments further explored the ability of methadone and other opioid compounds to antagonize excitatory amino acid neurotoxicity.

Exposure of murine neocortical cell cultures to a 5 min pulse of 500 µM NMDA resulted by the following day in widespread neuronal disintegration and a substantial efflux of lactate dehydrogenase (LDH) to the bathing medium. Addition of 10 µM - 1 mM (±)-methadone to the NMDA exposure solution produced a concentration-dependent reduction (ED_{50} about 100 µM) in both the morphological evidence of neuronal cell damage, and the efflux of LDH, with near complete blockade at higher concentrations. In contrast, 1 mM (±)-methadone produced little attenuation of quisqualate neurotoxicity (500 µM for 5 mins). 30 - 100 µM (±)-methadone also markedly attenuated the neurotoxicity of the endogenous NMDA agonist, quinolinate (1 mM for 20 - 24 h) without affecting the neurotoxicity of kainate (100 µM for 20 - 24 h).

The potent opioid isomer (-)-methadone, and the weak opioid enantiomer (+)-methadone, appeared grossly equipotent (and similar to the racemate) at blocking the neurotoxicity of NMDA. Other experiments showed that high (200 µM - 10 mM) concentrations of morphine itself (and somewhat lower concentrations of (+)-morphine), as well as 1 - 3 mM concentrations of codeine, meperidine, fentanyl, and nalorphine, also produced some attenuation of NMDA-induced neurotoxicity.

Thus methadone and several other opioids exhibit novel antagonist activity against NMDA receptor-mediated neurotoxicity in vitro. In the four cases where stereospecificity was tested, this activity was found to an equal or greater degree in the non-opioid dextrorotatory enantiomers [(+)-methadone, dextrorphan, (+)-naloxone, and (+)-morphine], suggesting that the neuron-protective effect is not mediated by conventional opiate receptors. Many opioids are clinically available and cross the blood-brain barrier easily. The more potent members of this class of drugs - and perhaps especially their enantiomers, which would offer reduced opiate receptor-related side effects - may have potential as clinical therapeutic agents.

287.3 GLUTAMATE NEUROTOXICITY AND ASTROCYTE SWELLING: LACK OF INVOLVEMENT OF NMDA RECEPTOR. P. H. Chan, L. Chu*, A. Yu* and S. Chen* (SPON: R. Fishman). Department of Neurology, Brain Edema Research Center, University of California, San Francisco, CA 94143

Excitatory neurotransmitter L-glutamic acid (GLU) and its agonists N-methyl-D-aspartate (NMDA) have been implicated in selective vulnerability and neuronal death following ischemia, hypoglycemia and epileptic seizures. NMDA receptor antagonists have been shown to reduce the ischemia or hypoglycemia-induced neuronal death of hippocampus in vivo. Furthermore, these NMDA receptor antagonists also reduce the GLU-induced swelling and death in neuronal cell culture in vitro. We have reported previously that GLU and its agonists including homocysteic acid, kainic acid, aspartic acid and NMDA caused significant cellular swelling and cation changes in brain slices (Chan et al, J Neurochem 33:1309, 1979). However, the role of GLU and the NMDA antagonists on glial cell swelling and injury was not delineated in those studies. We now study the excitotoxic mechanisms of glial swelling using intact cerebral cortical astrocytes of newborn rats. The intracellular water space (IWS) (measured by 3-O-methyl [^{14}C]-D-glucose) was increased (control = 3.4 + 0.2 ul/mg protein) by GLU (1 mM) by 175%, 213% at 1 hour and 4 hours respectively and was returned to baseline at 24 hours. The GLU-induced IWS changes were dose-dependent. Among the GLU agonists, homocysteic acid at equal molar concentration exhibited similar potency in inducing astrocytic swelling (214%), followed by L-aspartate (ASP) (160%) and quisqualate (152%), whereas NMDA, kainate and quinolinate were not effective. Unlike GLU and ASP, both homocysteic acid and quisqualate caused a persistant increase in IWS of astrocytes with prolonged incubation time (e.g. 24 hours). DL-2-amino 5-phosphonovaleric acid (APV) and 2-amino-7-phosphonoheptanoic acid (APH), antagonists of NMDA-preferred receptor, and kynurenic acid, a non-specific GLU receptor antagonist at a concentration of 1 mM were not effective in inducing cellular swelling of astrocytes. Furthermore, pretreatment with APV, APH, or kynurenic acid failed to reduce the GLU-induced astrocytic swelling. These data indicate that GLU may exert its excitotoxic effects on astrocytic swelling through mechanisms other than those mediated by NMDA receptor. Supported by NS-14543.

287.4 ISCHEMIC BRAIN DAMAGE IS REDUCED BY SYSTEMIC ADMINISTRATION OF THE N-METHYL-D-ASPARTATE (NMDA) ANTAGONIST, MK-801. C. Park*, D.G. Nehls*, E. Ozyurt*, D.I. Graham*, J. McCulloch. Wellcome Surgical Institute, University of Glasgow, Glasgow, G61 1QH, Scotland.

Previous studies have indicated that N-methyl-D-aspartate (NMDA) receptor antagonists are capable of reducing the amount of damage caused by cerebral ischemia when administered by direct intraparenchymal injection (Simon et al., Science, 226:850, 1984). MK-801 is a new potent non-competitive NMDA antagonist which readily penetrates into the CNS (Wong, E.H.F., et al., Proc. Natl. Acad. Sci. USA, 83:7104, 1986). We have studied the protective effects of this agent in models of permanent focal cerebral ischemia in cats and rats.

Animals underwent microsurgical occlusion of the middle cerebral artery (MCA) under general anesthesia. In cats, saline or MK-801 (5 mg/kg i.v.) was given 30 minutes prior to occlusion or 2 hours after occlusion. In rats, saline or MK-801 (0.5 mg/kg i.v.) was given 30 minutes prior to or 30 minutes after occlusion. Anesthesia was maintained for 3 hours (rats) or 6 hours (cats) at which time the animals were sacrificed and the brains perfusion fixed. Ischemic area was determined at multiple coronal planes and the volume of the area showing early ischemic cell change was computed.

In cats, with pre-treatment, MK-801 significantly reduced the volume of the hemisphere with early ischemic cell change from 3231 ± 394 mm^3 (control) to 1602 ± 445 mm^3 (MK-801) ($P<0.01$). The protective effect occurred predominantly in the cortex where the ischemic volume was decreased by 57% ($P<0.01$), whereas there was no significant reduction in ischemic volume in the caudate nucleus. In rats pretreated with MK-801, the volume of the hemisphere showing early ischemic cell change was reduced by 38% ($P<0.005$). Throughout all the levels of sections, there was a consistent decrease in ischemic volume suggesting that protection occurred throughout the ischemic area and was not limited to the ischemic penumbra. This contrasts with the effects of nimodipine in the same model in which protection was limited to the ischemic penumbra.

MK-801 is extremely effective in reducing the amount of ischemic damage in a model of focal ischemia using pre-treatment. The results of pre-treatment will be compared to those of treatment with MK-801 administered after MCA occlusion.

287.5 COMPARATIVE EFFICACY OF VARIOUS AGENTS IN PREVENTING GLUTAMATE-INDUCED OR ISCHEMIC NEURONAL DEGENERATION IN CHICK RETINA. J.W. Olney, M.T. Price, J. Labruyere*, E. Silverman*, M. Mueller*. Department of Psychiatry, Washington University Medical School, St. Louis, MO 63110.

Recent evidence suggests that certain neurodegenerative conditions, including anoxic-ischemic brain damage, may be mediated by the neurotoxic (excitotoxic) action of excitatory amino acid (EAA) transmitters. Glutamate (Glu), the most abundant EAA in the CNS, is released in toxic concentrations under ischemic conditions and is presumed to be the endogenous pathogen primarily responsible for ischemia-induced neuronal degeneration. Three subtypes of Glu receptors are thought to mediate excitotoxic events, each being named after an agonist to which it is differentially sensitive--N-methyl aspartate (NMA), quisqualate (Quis), kainate (KA). Recent evidence suggests that NMA-specific antagonists may be effective in vivo as neuroprotective agents in ischemia. It should be noted, however, that this evidence pertains exclusively to CA-1 hippocampal neurons which may be unique in having an exceedingly high ratio of NMA to non-NMA receptors. Neurons having a larger complement of non-NMA receptors might be less well protected by NMA antagonists since Glu, a mixed EAA agonist that acts at all EAA receptor subtypes, is not prevented by NMA antagonists from activating non-NMA receptors.

To explore this issue we have comparatively evaluated in the ex vivo chick embryo retina the ability of various EAA antagonists to protect against the neurotoxic actions of prototypic EAA agonists (NMA, KA, Quis or Glu) with their ability to protect retinal neurons against ischemia (oxygen-glucose deprivation). We found NMA antagonists quite potent in blocking NMA neurotoxicity but weak in blocking KA, Quis, Glu or ischemic damage. Of all agents tested, the most effective in blocking ischemic degeneration was the thiobarbiturate, Thiamylal, which behaves in the retina as a broad spectrum antagonist that blocks NMA as well as KA, Quis and Glu toxicity.

Our findings support the interpretation that endogenous Glu mediates ischemic neuronal degeneration in the chick retina and that many retinal neurons have non-NMA receptors where Glu exerts excitotoxic action in the presence of NMA receptor blockade. Since many CNS neurons may have a substantial complement of non-NMA as well as NMA receptors, NMA antagonists may not adequately protect such neurons against anoxic-ischemic degeneration. Whether broad spectrum EAA antagonists such as thiamylal might be more effective warrants evaluation. Supported by RSA MH38894 (JWO) and a grant from the Washington Univ/Monsanto Biomedical Res Fund.

287.6 A DELAYED EXCITOTOXIC MECHANISM MEDIATES THE DEGENERATION OF RAT STRIATAL NEURONES CAUSED BY N-METHYL-D-ASPARTATE AND QUINOLINATE. A.C. Foster, R. Gill* and G.N. Woodruff*. Merck Sharp and Dohme Research Labs., Terlings Park, Eastwick Road, Harlow, Essex, U.K.

Intra-cerebral injection of excitotoxins has been used extensively to produce neuronal lesions and provide animal models of human neurodegenerative disorders. However, the degree to which such acute neurotoxicity experiments can mimic chronic neurodegenerative events has been questioned. Using the selective, non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 (Wong et al, PNAS 83: 7104, 1986), we now provide evidence that the degeneration of rat striatal neurones caused by local injection of NMDA receptor agonists is mediated by a delayed mechanism more akin to a chronic degenerative event than was previously suspected.

Male Sprague-Dawley rats (250-350g) were anaesthetised with equithesin and stereotaxic injection of quinolinate (QUIN, 200nmol), NMDA (200nmol) or kainate (5nmol) in 1µl of phosphate-buffered saline made into the right striatum over a period of 2 min. Animals were injected with a single dose of 10mg/kg MK-801 (i.p.) at various times and killed 7 days following excitotoxin injection, their striata dissected and neuronal degeneration assessed by measuring cholineacetyl transferase (CAT) and glutamate decarboxylase (GAD) activities.

We have previously reported that neuronal degeneration caused by NMDA or quinolinate was prevented by 10mg/kg MK-801 when the drug was administered i.p. 1 hour prior to excitotoxin injection (Foster et al, Br. J. Pharmac. Proc. Suppl. 89 87OP, 1986 and 90 7P, 1987). As shown below, the degeneration of striatal neurones caused by NMDA or QUIN was also prevented by MK-801 given i.p. up to 5 hours after excitotoxin injection. The protection of cholinergic neurones was virtually complete when MK-801 was administered at 1 and 2 hours and still significant at 5 hours. GABAergic neurones were partially protected at 1 and 2 hours.

% decrease of enzyme activity (mean ± SEM, N = 3-10 per group)

Excitotoxin		Untreated controls	10mg/kg MK-801 given at times after excitotoxin 1h	2h	5h	24h
QUIN	CAT:	78.7 ± 4.5	0.8 ± 0.5**	4.6 ± 2.2**	41.8 ± 6.8**	67.9 ± 12.9
200nmol	GAD:	84.2 ± 2.6	23.0 ± 4.0**	42.2 ± 5.0**	79.4 ± 1.9	70.5 ± 12.1
NMDA	CAT:	52.6 ± 9.0	5.7 ± 2.2**	2.9 ± 1.6**	9.3 ± 2.4**	47.9 ± 11.1
200nmol	GAD:	59.4 ± 6.9	15.4 ± 4.1**	33.9 ± 15.0*	51.9 ± 4.0	65.5 ± 9.0

* P < 0.05, ** P < 0.01 Dunnett's Multiple Range Test

In contrast, MK-801 (10mg/kg, i.p.) administered 2 hours following intra-striatal injection of kainate (5nmol) was unable to prevent reductions in striatal CAT and GAD activities induced by this excitotoxin.

The ability of MK-801 to prevent the local neurotoxicity caused by NMDA agonists when administered after their injection indicates that these excitotoxic effects are mediated by a delayed mechanism which requires activation of NMDA receptors. Delayed degenerative events are characteristic of certain types of ischaemic-induced neuropathology (Kirino, Brain Res. 239: 57, 1982) and may be a reflection of neurotoxic sequalae resulting from an overstimulation of NMDA receptors.

287.7 DIFFERENTIAL SPARING OF NADPH-DIAPHORASE NEURONS IN QUINOLINIC LESIONED RAT AND PRIMATE STRIATUM

Joseph B. Martin, Neil W. Kowall, Robert J. Ferrante, P. Ben Cipolloni and M. Flint Beal
Neurology Service, Mass. General Hospital and Harvard Medical School and Depts. Anat. and Neurol. Boston University School of Medicine, Boston, MA

Quinolinic acid is an endogenous excitotoxin present in human brain that reproduces the neurochemical profile of Huntington's disease when injected into rat neostriatum. In the present study we have made lesions with quinolinic acid in both rat and primate striatum to further evaluate the neuronal selectivity of the lesions. A dose of either 120 or 240 nmol of quinolinic acid or 10 nmol of kainic acid was injected into the anterior rat striatum over 2 minutes. Similarly lesions were made in 3 rhesus monkeys by injecting either 240 nmol in 1 µl or 360 nmol in 1.5 µl. These lesions were made at 5 anterior-posterior levels in both the caudate and putamen. Both rats and monkeys were sacrificed two weeks after the lesions. Sections were stained for NADPH-diaphorase (NADPH-d) and cresyl violet. Some rats were pretreated with diisopropyl fluorophosphate and later double stained for both acetylcholinesterase (AChE) and NADPH-d. In both species there was a lesion core in which there was almost total neuronal loss and dense gliosis. Within these areas there were no preserved NADPH-d neurons. To evaluate possible selective neuronal sparing, both NADPH-d and Nissl stained neurons were counted within the transition zone (TZ) bordering the lesion core. This zone is characterized by partial neuronal depletion and moderate gliosis. Control cell counts were made in identical regions in the contralateral unlesioned striatum. The total number of Nissl stained neurons was depleted 50% within the TZ, as compared to the control side. In rats, the percent of NADPH-d neurons was significantly increased in the TZ as compared to the control side (control: 3.5%, lesion: 8.0%). In rhesus monkeys, the percent of NADPH-d neurons was also significantly increased from 1.7% to 3.4%. In contrast to these findings, kainic acid lesions in rats resulted in a significant reduction of NADPH-d neurons (control: 2.2%, lesion: 0.9%), in a region in which there was 28% total neuronal depletion. In the AChE/NADPH-d stained quinolinic rat lesions, all NADPH-d and AChE neurons were counted throughout the striatum in tissue sections at 200 um intervals. AChE neurons could often be seen and were relatively preserved in the core of the lesion, as compared to NADPH-d neurons. At more posterior levels, 2 mm from the center of the lesion, sparing of NADPH-d neurons relative to AChE was seen. These findings indicate that NADPH-d neurons are spared relative to Nissl stained neurons in quinolinic acid lesions in both rat and monkey.

287.8 SYSTEMIC APPROACHES TO PREVENTING QUINOLINIC ACID NEUROTOXICITY IN RAT STRIATUM

M. Flint Beal, Neil Kowall, Kenton Swartz and Joseph B. Martin
Neurology Service, Mass. General Hospital, Boston, MA 02114

If quinolinic acid or another endogenous excitotoxin is involved in the pathogenesis of Huntington's disease (HD), then a systemic therapy capable of blocking its neurotoxicity might be useful therapeutically in HD in an attempt to halt the disease process. In the present study we have examined the ability of a wide variety of compounds to modify quinolinic acid neurotoxicity in rat striatum. Compounds were administered intraperitoneally 30 minutes before stereotactically injecting 240 nmol of quinolinic acid into the anterior striatum. One week after the injections the animals were sacrificed and the lesioned and contralateral striatum were dissected. The ability of agents to block neurotoxicity was assessed by comparison both with saline injected controls and with the contralateral side. The extent of the lesions was measured biochemically with determinations of substance P, GABA, somatostatin and neuropeptide Y. Histologic examination of lesions was also made. The free radical blockers vitamin C, vitamin E and beta-carotene had no beneficial effect and buthionine sulfoxine, a glutathione depleter, also had no detrimental effect. Allopurinol has been shown to ameliorate ischemic damage felt to be associated with free radical formation. Neither pretreatment with 50 nor 100 mg/kg had any beneficial effect. Nimodipine is a blocker of voltage-dependent calcium channels. Since increased calcium concentrations have been implicated in excitotoxin mediated neuronal death we examined the effects of this compound. Pretreatment at doses of 2.0, 4.0, or 10.0 mg/kg had no beneficial effect.

The effects of quinolinic acid are known to be blocked by co-injection with N-methyl-D-aspartate blockers APV and APH. Neither of these compounds administered systemically at a dose of 50 mg/kg had a beneficial effect. Baclofen has been reported to block release of glutamate. Pretreatment with 10 mg/kg did not modify toxicity. Recently Iversen and colleagues have reported that MK-801 is a systemically effective N-methyl-D-aspartate blocker. A dose of 1.0 mg/kg had no effect however there was partial protection at 2.0 mg/kg which showed a dose-response to complete protection at a dose of 4.0 mg/kg. These data therefore show that MK-801 can prevent neuronal toxicity in the quinolinic acid model of HD.

Supported by NS 16367. Dr. Iversen of Merck, Sharp and Dohme generously provided MK-801.

287.9 **STUDIES OF EFFECTS OF CHRONIC LOW-LEVEL QUINOLINIC ACID EXPOSURE IN ORGANOTYPIC CULTURES OF THE RAT CORTICOSTRIATAL SYSTEM.** W.O. Whetsell, Jr. and Robert Schwarcz. (SPON: M.D. Johnson) Vanderbilt University School of Medicine, Nashville, TN and Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, MD.

The endogenous amino acid, quinolinic acid (QUIN), has been shown to produce specific post-synaptic neurodegenerative changes in rat CNS tissue both in vivo and in vitro. This excitatory amino acid ("excitotoxin") has received increasing investigative attention as an endogenous agent which may produce a slowly-developing specific neurodegeneration in certain neurological disorders. For that reason, we have begun to examine the effects of chronic administration of low levels of QUIN in CNS tissues which have been shown to undergo acute neurodegenerative changes after exposure to relatively high levels of QUIN. Organotypic cultures of rat corticostriatal system, which have been of particular value in examining the QUIN effect (Whetsell and Schwarcz, J. Neural Transm., Suppl. 19:53, 1983), were used in these experiments. Cultures of rat cerebral cortex (CX), caudate nucleus (CA) or combination cortex-caudate (CXCA) cultures, all more than 21 days in vitro, were exposed to 100 nM QUIN in feeding medium for up to six weeks; control feeding medium contained 34 nM QUIN, a concentration which is similar to that seen in human CSF. QUIN concentrations were measured radioenzymatically by the method of Foster et al. (Anal. Biochem. 158:98, 1986). Sequential light microscopic evaluation of QUIN-exposed cultures showed no detectable alterations in the living state (compared to controls) until the fourth weeks of exposure. At that time, QUIN-exposed cultures exhibited some increased density; by six weeks exposure, some cultures showed scattered small vacuoles like those seen acutely after incubation with 1 mM QUIN. In several cases, cultures continued to deteriorate so that they detached from their carrying coverslips by six weeks exposure to QUIN. Ultrastructural evaluation demonstrated that there was no alteration in cultures exposed to control feeding medium for up to six weeks. CA cultures exposed to 100 nM QUIN for six weeks also showed no ultrastructural change. CX and CXCA cultures exposed to 100 nM QUIN exhibited scattered isolated post-synaptic swelling of apparently asymmetrical synapses or occasional swelling of dendrites at 15 days of QUIN incubation. By six weeks of QUIN treatment, such cultures had undergone severe degenerative changes indistinguishable from changes observed after 24 to 36 hours exposure to 1 mM QUIN. Results of this study indicate that in this tissue culture model chronic low-level QUIN can induce a slowly evolving neurodegenerative change; the change appears to be dependent upon normal corticostriatal synaptogenesis.

(Supported by USPHS grant NS20509.)

287.10 **N-METHYL-D-ASPARTATE RECEPTOR ANTAGONIST MK-801 IMPROVES OUTCOME FOLLOWING EXPERIMENTAL SPINAL CORD INJURY IN RATS.** A. I. Faden and R. P. Simon. Department of Neurology, Univ. of California, San Francisco, and Center for Neural Injury, Veterans Administration Medical Center, San Francisco, CA 94121.

It has recently been shown that a selective N-methyl-D-aspartate (NMDA) receptor blocker — 2-amino-7-phosphonoheptanoic acid (2-APH) — can protect central nervous system neurons from ischemia or hypoglycemia. However, 2-APH does not readily cross the blood-brain-barrier and therefore it has been administered by direct parenchymal injection. MK-801 [(+)-5-methyl-10,11-dihydro-5H-dibenzo[a,d]cyclohepten-5,10-imine maleate] is a selective, non-competitive, centrally active NMDA receptor antagonist, which may require activation of NMDA receptors for its action. We examined the possibility that NMDA receptors, which are present in the spinal cord, may mediate certain of the secondary pathophysiological consequences of traumatic spinal cord injury by evaluating the effects of MK-801 on outcome following traumatic spinal cord injury in rats. Animals were anesthetized with pentobarbital (60 mg/kg, i.p.). Following laminectomy, trauma was produced at the T-10 spinal segment utilizing the Allen method, in which a 10 g weight was dropped 5 cm through a guide tube onto an impounder plate resting on exposed dura mater. Animals (n = 30) were randomly assigned to treatment with MK-801 (1 mg/kg) or equal volume saline, administered as a slow intravenous injection at 15 min posttrauma. Animals were evaluated neurologically utilizing both behavioral measures (Tarlov scale) and angle board performance by an individual unaware of treatment group. Rats treated with MK-801 showed significantly improved neurological recovery at 4 weeks posttrauma as evidenced by both motor scores ($p < 0.05$) and angle board scores ($p < 0.01$). Eight of fifteen MK-801-treated animals regained walking ability as compared to three of fifteen controls. These results are consistent with the hypothesis that excitatory amino acids, through actions at NMDA receptors, contribute to the pathophysiology of traumatic spinal cord injury. The data suggest that selective NMDA receptor antagonists may be beneficial in the treatment of spinal cord injury.

287.11 EFFECTS OF MK801, AN NMDA RECEPTOR ANTAGONIST, ON KAINATE INDUCED SEIZURES IN RATS. G.G. Smith*, G.T. Golden, P.F. Reyes*, R.G. Fariello (SPON: C.P. Bianchi). Research & Neurology, VAMC, Coatesville, PA and Neurology & Pharmacology, Thomas Jefferson University, Philadelphia, PA

The systemic administration of kainic acid (KA), a rigid glutamate analog, induces seizures and neuronal damage through several mechanisms some of which involve activation of the NMDA receptor. Therefore we have studied the effects of MK801 pretreatment on the limbic status epilepticus induced by KA in rats. Male Wistar/Furth albino rats had electrodes implanted under anesthesia in the hippocampus and cortical leads for chronic EEG recordings. Ten days after recovery various groups (n=10) received MK801, up to 10 mg/kg alone, KA (10 mg/kg ip) alone or 30 min after 0.1, 1 and 10 mg/kg MK801. The behavior and EEG were monitored for the subsequent 250 min. The number of subclinical (only EEG) and electroclinical seizures, number of wet dog shake (WDS) episodes, the time of onset of seizures and the total percent of time spent in ictal episodes were recorded and compared in the various groups. MK801 alone did not cause seizures but at 1 and 10 mg/kg reduced and abolished, respectively, all spontaneous motor activity. MK801 potentiated, in a dose dependent manner, KA EEG epileptogenicity. Behavioral seizures were increased only in the 0.1 mg/kg group but were abolished in the 1 and 10 mg groups. WDS were reduced in a dose dependent fashion by MK801. Rats in the MK801 groups spent more time and entered earlier in EEG seizure activity. The electrophysiological results will be compared to histological data assessing presence and severity of neuronal damage in the various experimental groups. (Supported by Veterans Administration.)

287.12 THE EFFECTS OF N-METHYL-D-ASPARTATE (NMDA) RECEPTOR BLOCKADE UPON LOCAL CEREBRAL GLUCOSE UTILISATION AND LOCAL CEREBRAL BLOOD FLOW. D.G. Nehls*, C. Park*, and J. McCulloch. (SPON: S.E. Blackshaw). Wellcome Surgical Institute, University of Glasgow, Glasgow, G61 1QH, Scotland.

N-methyl-D-aspartate (NMDA) receptors are involved in excitatory (glutamate) neurotransmission and have been implicated in a wide range of neurological diseases including cerebral ischemic damage and chronic degenerative disorders (Meldrum, B., Clinical Science, 68:113, 1985). MK-801 is a potent NMDA antagonist which readily crosses the blood-brain barrier (Wong, E.H.F. , et al., Proc. Natl. Acad. Sci. USA, 83:7104, 1986). We have examined the functional consequences of NMDA receptor blockade using deoxyglucose autoradiography, and have also studied the concurrent alterations of local cerebral blood flow.

The effects of NMDA blockade upon local cerebral glucose utilisation (LCGU) and local cerebral blood flow (LCBF) were examined in 41 discrete neuroanatomic loci. After insertion of femoral vessel cannulae, Sprague-Dawley rats were allowed to recover from anesthesia for two hours, and received either saline or MK-801 (0.5 mg/kg i.v.) prior to determination of LCBF of LCGU by quantitative autoradiography.

Glucose Use. MK-801 administration produced significant increases in LCGU in limbic circuits. This was especially marked in the posterior entorhinal cortex (+137%) and posterior cingulate cortex (+62%), and in the hippocampus. There was a significant depression of cortical metabolism in the auditory, sensory-motor and frontal cortices (-34%). LCGU remained relatively constant in the thalamus, with the exception of the anterior thalamic nucleus (+63%). LCGU in the cerebellum and brainstem was minimally altered with MK-801.

Cerebral blood flow. In the majority of regions, LCBF was not significantly altered. However, it was markedly and significantly increased in the limbic system and in the visual cortex, mediodorsal thalamus, caudate nucleus, dorsal septal nucleus and nucleus accumbens. LCBF was significantly lowered in the cerebellum.

There was evidence of LCBF:LCGU uncoupling as increases in LCGU occurrerd in specific areas (superficial layers of the cortex and the molecular layer of the hippocampus), whereas LCBF was increased diffusely throughout the posterior cortex and hippocampus.

NMDA receptor blockade has a profound effect upon LCBF and LCGU throughout the brain, but especially in the limbic system where NMDA receptors are plentiful. Such large and widespread effects on metabolism and blood flow will be of importance as NMDA antagonists are used with increasing frequency for the treatment of neurologic disorders.

288.1 **STUDIES ON DESCENDING PATHWAYS MEDIATING PRESSOR RESPONSES PRODUCED BY CENTRAL ADMINISTRATION OF ANGIOTENSIN II (ANG II) HYPERTONIC SODIUM CHLORIDE (HS) AND CARBACHOL (CARB).** H. Ohta and M. J. Brody. (SPON. R.L. Dundore). Dept. of Pharmacol., Cardiovasc. Ctr., Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

The pressor response produced by cerebroventricular (i.c.v.) administration of ANG II involves midline structures along the lamina terminalis. Receptor regions in the circumventricular organs send projections to the median preoptic nucleus which in turn is the source of two descending pathways. Our previous studies demonstrated that the pathway descending medially through anterior hypothalamus, ventromedial hypothalamus and periaqueductal gray is necessary for the central pressor actions produced by ANG II. The descending pathways necessary for the pressor actions of HS and CARB have not been determined. The purpose of the present study was to determine whether the medial projections or lateral projections descending through medial forebrain bundle (MFB) region are involved differentially in the pressor responses to the 3 agents. Studies were conducted on conscious unrestrained rats instrumented for continuous recording of arterial pressure (AP) and heart rate (HR). The agents were administered through an i.c.v. cannula. Microinjections of lidocaine (LIDO) (200 nl, 2%) were used to reversibly interrupt neuronal transmission. The pressor responses produced by ANG II (100 ng) 1 M HS (5 µl) and CARB (50 ng) were reduced by the injection of LIDO bilaterally in the region of paraventricular nucleus (PVN). Responses to ANG II and HS were affected to a greater extent than those produced by CARB. Little effect was produced by single injection of LIDO into the midline region just above the PVN. The responses to the 3 pressor agents were not affected on the average by LIDO injected bilaterally into lateral aspects of MFB, however of 8 rats tested, no effect was produced by MFB injection of LIDO in 5 rats whereas the responses to HS were reversibly attenuated in 3 rats without any change in response to ANG II or CARB. LIDO injected into the medial structures had no effect on baseline HR or AP however in contrast the bilateral injections into lateral MFB produced a marked increase in HR (86 bpm) and a lesser increase in AP (14 mmHg). These results suggest: 1) pressor responses produced by 3 different agents appear to depend upon pathways descending medially in the region of the third ventricle; 2) the effects of interrupting these midline descending projections appear to be partially differential in that responses to CARB are affected less than those of ANG II and HS; 3) lateral projections through MFB play a less significant role in mediating the responses to the pressor agents; 4) projections through lateral MFB appear to be involved in tonic inhibition of primarily HR and secondarily AP since their neuronal interruption in the conscious state produces marked changes in these cardiovascular parameters. (Supp. by HLB-14388.)

288.2 ALTERNATIVE MECHANISM FOR ATTENUATED ANGIOTENSIN II AND NOREPINEPHRINE PRESSOR RESPONSES IN AV3V LESIONED DOGS. A.F. Tramposch, O.U. Lopes,* C.M. Ferrario, C.L. Chernicky. The Research Institute, The Cleveland Clinic Foundation, Cleveland Ohio 44106.

To determine the role of preoptic hypothalamic structures in the pressor response to intravenous (IV) infusion of angiotensin II (Ang II), the anteroventral third ventricle (AV3V) region was lesioned in 11 dogs using a bayonet shaped microknife (Marson et al. Hypertension 7: I-80, 1985). The lesion denervated the organum vasculosum of the lamina terminalis, nucleus medianus and the medial preoptic nucleus. 2-3 days after denervation dogs displayed adipsia associated with hypernatremia (175 ± 2 mEq/L) and increases in osmolality (352 ± 5 mOsm/kg) and angiotensin II immunoreactivity (Ang II-ir) (124 ± 26 pg/ml). In contrast, plasma levels of arginine vasopressin (AVP) were reduced from (4 ± 2 pg/ml to 0.1 ± 0.1 pg/ml). AV3V lesion did not produce any significant change in baseline mean arterial pressure (MAP) (99 ± 4 mmH Hg) whereas heart rate increased (131 ± 8 beats/min). These changes were accompanied by a significant ($p < 0.05$) decrease in the peak change in MAP produced by IV Ang II infusions at rates of 4 and 20 ng/kg/min. The slope of the Ang II dose response curve decreased from 1.4 to 0.6 (mm Hg/(ng/kg/min)). Four lesioned dogs in which vascular reactivity was tested showed significant ($p < 0.05$) decreases in the pressor responses to IV norepinephrine (NE) at doses of 5, 10, and 20 µg. The slope of the NE dose response curve decreased from 3.1 to 1.8 (mm Hg/µg). Nine AV3V lesioned dogs treated with desmopressin acetate (DDAVP) for 1-3 days, normalized plasma sodium levels and Ang II-ir in conjunction with a restoration of the pressor responsiveness to IV Ang II. Pressor responsiveness to NE remained depressed after teatment with DDAVP. These data suggest that a decrease in vascular reactivity associated with increases in plasma sodium and Ang II-ir may be a cause of the attenuated pressor response to IV infusion of Ang II and NE in AV3V lesioned dogs. These data raises a question about the interpretation of previous studies which suggested an exclusive, direct, central effect of Ang II on AV3V structures. (Supported in part by NIH Grant HL-6835).

288.3 GLUTAMATE-SENSITIVE NEURONS IN CIRCUMVENTRICULAR ORGANS SUPPORT HYPERTENSION IN SPONTANEOUSLY HYPERTENSIVE RAT (SHR). D.K. Hartle. Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322

High concentrations of L-glutamate (G) produce receptor-mediated neurotoxicity thought to be subsequent to unregulated influx of Ca++ during sustained excitation of ion-channel linked G receptors. These exist within the CNS, but not in the peripheral autonomic nervous system. G can be administered s.c. to achieve plasma levels high enough to kill G-sensitive neurons in regions of the brain not protected by the blood-brain-barrier (the circumventricular organs, CVOs). Of these, only area postrema and the subfornical organ sustain a significant number of cell deaths after 9mg/g G, s.c., but not with control injections of hypertonic saline. Parenteral G treatment (9mg/g, s.c.) produced a permanent lowering of BP in the SHR, but did not lower BP in normotensive rats. The depressor effect was accounted for by a reduction in total peripheral resistance. G treatment in the adolescent SHR prevented the expression of hypertension in the adult period. A non-specific G antagonist, GDEE (glutamate diethyl ester), was found to protect the SHR from the BP lowering effect of G toxcity when it was infused at the rate of 3.3 mg/min for 30 min, starting 10 min prior to the s.c. G injection. GDEE infused alone produced significant bradycardia (-65 BPM) in normotensive rats that was rapidly reversible by muscarinic blockade with atropine. Bradycardia was reversed totally within 1 hr after discontinuation of the GDEE infusion. Bilateral cervical vagotomy blocked bradycardia during GDEE infusions, indicating a probable central site of GDEE action. Because GDEE produces tachycardia when injected behind blood brain barrier in certain brainstem cardiovascular regions, these negative chronotropic effects of GDEE may be via modulation of neurons outside the blood-brain barrier. Both CVOs damaged by G treatments obviously contain G receptors. GDEE may protect blood pressure in the SHR and produce reversible bradycardia in the normotensive rat by occupying some of these CVO receptors. These experiments also suggest that G receptors exist on CVO neurons that are required to support SHR hypertension. EURF,AHA-GA Affil, and NIH-HLBI 1 RO1 HL37705-01.

288.4 CARDIOVASCULAR EFFECTS OF ELECTRICAL AND CHEMICAL STIMULATION OF THE AMYGDALA OF ANESTHETIZED AND CONSCIOUS RATS. A.J. Gelsema*, D.J. McKitrick*, and F.R. Calaresu. Dept. of Physiology, University of Western Ontario, London (Ont), Canada N6A 5C1.

It has been shown in anesthetized rats that electrical stimulation of sites located in the central, medial and basolateral nuclei of the amygdala results in changes in arterial pressure (AP) and heart rate (HR). To dissociate the effects of electrical stimulation on neuronal cell bodies and fibers, in 18 artificially ventilated, paralyzed, urethane anesthetized rats we compared the effect on AP and HR of electrical stimulation (90-150 µA) of 92 histologically verified sites in and around these 3 nuclei with the effect of microinjections of DL-homocysteate (DLH, 0.15 M, 50-100 nl) into the same sites. Electrical stimulation resulted in depressor responses in most sites (89%), whereas chemical stimulation produced significantly fewer (25%) depressor responses. Changes in AP were accompanied by variable changes in HR. In an additional series of 17 rats comparison of the responses to electrical stimulation and injections of a more concentrated solution of DLH (1.0 M) into 70 amygdaloid sites showed that electrical stimulation elicited depressor responses in 83% of the sites and chemical stimulation resulted in depressor responses in only 16% of the sites. Finally, to study the effect of chemical and electrical stimulation without the influence of anesthetics, 9 rats were instrumented for electrical and chemical stimulation and recording of AP and HR in the conscious state. Electrical stimulation (50-250 µA) in the area of the central and basolateral nuclei in these rats resulted in an increase in AP in 6, in a decrease in 2 and in a biphasic response in one rat. Restlessness and exploratory behavior accompanied these cardiovascular responses. Injections of 50 to 200 nl amounts of a 1.0 M solution of DLH into the same sites never elicited behavioral or cardiovascular changes. These results suggest that either the cardiovascular effects of electrical stimulation in the amygdala are mainly due to activation of fibers or that chemical and electrical stimulation activate different neuronal elements in the same anatomical site.

288.5 CHANGES IN REGIONAL HEXOKINASE ACTIVITY IN THE BRAIN OF DOCA-SALT HYPERTENSIVE RATS. W.E. Turton* and J. Ciriello. (SPON: J.A. Kiernan). Department of Physiology, University of Western Ontario, London, Ontario, Canada N6A 5C1.

It has been demonstrated that treatment of unilaterally nephrectomized (Nx) rats with deoxycorticosterone acetate (DOCA) results in elevated arterial pressure (AP). While the role of the kidney in this experimental model of hypertension has been much discussed, little is known about the associations of the brain with the hypertensive process. In the present study, those regions of the brain whose metabolic activity was altered after DOCA-salt treatment were functionally mapped using hexokinase (HK) histochemistry, which reflects the rate of glucose utilization in the brain. After recording AP (tail cuff) and heart rate (HR) for a control period of 4 days, rats were either Nx unilaterally or sham-Nx. After recording AP and HR for 10 days, the Nx rats were then subjected to daily injections of either 2.5 mg DOCA suspended in 0.2 ml peanut oil or 0.2 ml peanut oil. All animals were allowed to drink 1% saline ad libitum. AP and HR were recorded for an additional 18 days, at which point the rats were anesthetized with sodium pentobarbital and perfused transcardially with saline. The brains were removed and quickly frozen, sectioned (20μm) on a cryostat and mounted on glass slides. Transverse sections extending from the rostral aspect of the septum to the spinomedullary junction were processed for HK histochemistry as described previously (Acta.Histochem.28:286,1967). Changes in HK activity were assessed by densitometric measurements of areas containing HK reaction product. The AP of DOCA-salt treated rats was significantly elevated compared to the oil injected and sham-Nx control animals (146 ± 2 mmHg, 119 ± 4 mmHg and 114 ± 3 mmHg, respectively), while HR was significantly reduced in these animals compared to the oil injected and sham-Nx control groups (375 ± 11 bpm, 432 ± 8 bpm and 419 ± 7 bpm, respectively). Significant increases in HK activity were observed in the median preoptic nucleus, bed nucleus of the stria terminalis, subfornical organ, magnocellular and parvocellular components of the paraventricular nucleus of the hypothalamus, supraoptic nucleus, nucleus ambiguus, rostral (C_1 region) and caudal (A_1 region) of the ventrolateral medulla, intermediate portion of the nucleus of the solitary tract and dorsal motor nucleus of the vagus, and caudal dorsal vagal complex (A_2 region) of the DOCA- salt treated animals compared to both groups of control animals. These data have shown that DOCA-salt treatment alters the activity of central structures previously implicated in the regulation of AP and body fluid balance and suggest that these structures are associated with the hypertensive process.

288.6 INVOLVEMENT OF CENTRAL NERVOUS SYSTEM OXYTOCIN (OX), VASOPRESSIN (VP), OR ANGIOTENSION II (AII) SYSTEMS IN THE CARDIOVASCULAR RESPONSES TO ACUTE STRESS IN RATS. M.F. Callahan, S.L. Eskridge*, and K.A. Gruber*. Wake Forest University Medical Center, Winston-Salem, NC 27103.

Lesions of the anteroventral third ventricle (AV3V) region of the forebrain disrupt the tachycardia response to footshock stress. We have shown that a similar effect is produced when the V_1 vasopressin receptor antagonist ($(CH_2)_5$Tyr(ME)AVP) is administered into the fourth ventricle of the hindbrain, suggesting that central Vp systems participate in the sympathetic nervous system response to stress. The current studies explored the role of central peptidergic control of the cardiovascular responses by utilizing animals with lesions of the paraventricular nucleus (PVN), animals genetically deficient in Vp synthesis, i.e., Brattleboro rats, and antagonism of central AII receptors.

Male Sprague-Dawley (S-D) rats received anodal electrolytic lesions (1.0 mA, 20 sec) of the PVN. Two weeks later, the rats received a right carotid artery catheter. One day later, mean arterial prsesure (MAP) and heart rate (HR) were determined in the home cage and upon transfer, immediately and 5 min post-footshock. The stress consisted of 5 min of intermittent footshock (1.0 mA, 0.5 sec every 5 sec). Brattleboro and Long-Evans control rats received chronic arterial and venous catheters and were maintained in metabolic cages. Approximately 2 weeks after surgery, these animals were also subjected to the stress protocol. An additional group of male S-D rats received a lateral cerebral ventricle cannulae followed one week later by carotid artery catheterization. Approximately 2 weeks later, these rats were subjected to 2 stress sessions, one following an i.c.v. infusion of balanced Earle's solution, and one following i.c.v. [Sar^{1}Ile^8]-Angiotensin II infusion (SarIle, 20 ug/18 ul/10 min).

Lesion of the PVN had no effect on baseline CV values, but attenuated the immediate post-footshock tachycardia (HR +74±25 in controls and +20±12 bpm in rats with the PVN destroyed bilaterally). A group of animals with less than 50% of the PVN destroyed showed a tachycardic response (93±6bpm). In the second study, Brattleboro rats and Long-Evans controls showed similar increases in HR (130±13 vs 147±12 bpm, respectively). Finally, infusion of SarIle had no effect on either the resting CV parameters or the stress response. These results suggest that while the PVN plays a role in CV stress responses, neither central Vp nor AII systems are involved. Since previous studies showed that lesions of the AV3V region interfere not only with VP but also Ox secretion, that the Vp antagonist also blocks Ox receptors, and that Ox cell bodies are also located in the PVN, the current studies would suggest that the central Ox system may be prepotent in mediating the CV responses to stress. 288.7 MU-OPIOID RECEPTORS, THYROTROPIN RELEASING HORMONE AND GLUTAMATE IN THE PREOPTIC AREA MODULATE DISTINCT HEMODYNAMIC FUNCTIONS IN THE RAT.

A-L Sirén and G. Feuerstein, Department of Neurology, USUHS, Bethesda, Maryland

Electrical stimulation of the median preoptic nucleus (POM) of the rat is known to induce a distinct cardiovascular response ("defense reaction") which features increases in mean arterial pressure, cardiac output and heart rate as well as hindquarter skeletal muscle vasodilation and renal and gastrointestinal vasoconstriction. The present studies aimed to investigate the role of thyrotropin releasing hormone (TRH) and the mu-opioid agonist [D-Ala^2,Me-Phe^4, Gly-ol^5] Enkephalin (DAGO) in mediating these responses. TRH and DAGO were microinjected into the POM of both conscious and anesthetized rats while monitoring selected organ blood flow and efferent sympathetic nerve activity. In conscious rats (n = 20) prepared chronically with Doppler flow probes around the lower abdominal aorta (mainly hindquarter skeletal muscle blood flow), renal (R) and mesenteric (M) arteries TRH microinjected into the POM (2.4-24 nmol/500nl) increased blood pressure, heart rate and hindquarter (HQ) vascular resistance (VR). The RBF and MBF significantly decreased (M > R) due to an increase in RVR and MVR respectively. The maximum changes in hemodynamic variables were reached within 1 min after the TRH injections and the effects subsided within 5 min. DAGO (0.1 -10nmol/500nl) in the POM induced pressor and bradycardiac/tachycardiac effects which were accompanied with HQ vasodilation and M and R vasoconstriction. The effects of DAGO, however, became apparent 2-5 min after the injection and subsided within 30 - 60 min. Injections of glutamate (0.1 - 100nmol/500nl) induced variable effects on the hemodynamic variables. In some rats a slight hypotensive effect with no significant changes in regional BF were observed, while in some rats pressor, HQ vasodilator and M and R vasoconstrictor responses followed glutamate injections. However, high doses of glutamate (100nmol/500nl) were always required to induce the similar pattern of hemodynamic changes than with picomole doses of TRH. In anesthetized rats (n = 12) TRH and DAGO also markedly increased renal and splanchnic sympathetic nerve activity. In summary, microinjections of TRH or DAGO into the POM increased blood pressure, induced HQ vasodilation and R and M vasoconstriction in the conscious rat. In anesthetized rats an increase in efferent sympathetic nerve activity was found after placement of these peptides into POM. Though the TRH and mu-opioid connections from the POM to other cardiovascular brain nuclei and to spinal cord remain to be evaluated, the present results might suggest that both TRH and mu-opioid receptors have a role in the hypothalamic regulation of peripheral organ flow by modulating the sympathetic outflow.

288.8 LESIONS OF THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS ALTERS THE DEVELOPMENT OF TWO-KIDNEY, ONE-CLIP RENAL HYPERTENSION IN THE RAT. T.X. Zhang* and J. Ciriello. (SPON: D.L. Jones). Dept. of Physiology, University of Western Ontario, London, Canada N6A 5C1.

We have previously shown that the paraventricular nucleus of the hypothalamus (PVH) is involved in the development and maintenance of neurogenic hypertension resulting from aortic baroreceptor denervation and in the development of spontaneous hypertension in the rat. In the present study the contribution of PVH neurons to the development of the elevated arterial pressure (AP) in the renin-dependent two-kidney, one-clip (2K1C) model of renal hypertension was investigated in the rat. After recording AP (tail cuff) for a control period of one week the rats were randomly assigned to two groups: one group was subjected to bilateral electrolytic lesions of the PVH region and the other to sham-PVH lesions. Animals in these two groups were later randomly assigned to two additional groups: in one group a 0.2 mm diameter clip was placed on the left renal artery and in the other group the artery was exposed but a clip was not placed on it. PVH lesions did not alter significantly AP from control levels. On the other hand, AP in the sham-PVH lesioned-2K1C rats was significantly elevated (154 ± 5 and 166 ± 6 mmHg at 7 and 14 days after placement of the renal artery clip, respectively) compared to the other three groups. In addition, AP was significantly elevated (136 ± 4 mmHg) in the PVH lesioned-2K1C animals on day 14 compared to sham-PVH lesioned sham-clip (125 ± 3 mmHg) and PVH lesioned-sham-clip (118 ± 5 mmHg) animals, but not on day 7 after the placement of the renal artery clip. These data demonstrate that PVH neurons are involved in the development and full expression of the elevated AP in the 2K1C model of renal hypertension and that these changes in AP are dependent on the integrity of this hypothalamic structure.

288.9 CONTRIBUTION OF NEURONS IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS TO THE PRESSOR RESPONSE ELICITED BY ACTIVATION OF AFFERENT RENAL NERVES. J. Ciriello and M.M. Caverson. Department of Physiology, University of Western Ontario, London, Canada N6A 5C1.

Afferent renal nerves (ARN) are known to contain sensory fibers that carry information from mechanoreceptors and chemoreceptors located in the kidney to the central nervous system. Recently, activation of ARN has been shown to: 1) alter the firing frequency of neurons in the paraventricular nucleus (PVH), 2) elicit a pressor response which is abolished by ganglionic blockade and administration of a vasopressin (AVP) antagonist, and 3) result in an increase in circulating levels of plasma AVP. These data suggest that ARN may influence arterial pressure (AP) by altering the discharge of AVP magnocellular neurosecretory neurons in the PVH. Therefore, two series of experiments were done to determine the contribution of PVH magnocellular neurons to the pressor response elicited by stimulation of ARN. In the first series, electrical stimulation (10 s train, 2 ms pulse duration, 40 Hz, 500 μA) of ARN in chloralose anesthetized, paralyzed and artificially ventilated, sinoaortic and vagal denervated cats elicited a pressor response that consisted of two components: a primary (1°) component (+45.6 ± 8.4 mmHg) that was time-locked to the stimulus and a secondary (2°) component (+43.4 ± 11 mmHg) that outlasted the 10 s stimulation period by 2-3 min. Reversible blockade of PVH neurons induced by bilateral injections of procaine hydrochloride or bilateral electrolytic lesions of the PVH resulted in a 43% and 68% attenuation of the 1° and 2° components, respectively, of the ARN pressor response. On the other hand, injections of 0.9% saline into the PVH or electrolytic lesions of hypothalamic regions anterior, dorsal or ventral to the PVH did not alter the ARN pressor response.

In the second series, following transpharyngeal exposure of the ventral surface of the hypothalamus and hypophysis, extracellular recordings were obtained from 86 single units in the PVH identified by antidromic invasion from the neurohypophysis in chloralose anesthetized, paralyzed and artificially ventilated cats. Of the 86 antidromic units, 17 (20%) were excited by stimulation of ARN. The latencies of the orthodromic response to stimulation of ARN ranged from 70 to 325 ms. The anatomical location of these responsive cells overlapped with that of AVP immunoreactive cells in the PVH. These data suggest that PVH neurons are components of long-loop reflex pathways involved in the integration of afferent inputs from the kidney and which function in the control of AP and AVP release.

288.10 CARDIOVASCULAR REGULATION IN THE EARLY PHASE OF STRESS-INDUCED HYPERTENSION IN THE BORDERLINE HYPERTENSIVE RAT (BHR). B.J. Sanders, S. Knardahl*, and A.K. Johnson. Departments of Psychology and Pharmacology and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

The BHR is the first generation offspring of WKY x SHR and has been shown to become hypertensive when chronically exposed to a shock-shock conflict paradigm (Lawler et al. Hypertension, 3:406-505, 1981). Analysis of the time course of development of this hypertension reveals at least three distinct stages. During the early phase blood pressure has not begun to rise, the middle phase is characterized by a significant increase in pressure, and the full expression of permanent hypertension is observed in the late phase. The underlying mechanisms involved in each of these stages remain unclear. The purpose of the present study, therefore, was to compare cardiovascular responses to ganglionic blockade and central administration of hypertonic cerebrospinal fluid (CSF) in BHR during the early phase of stress-induced hypertension with age matched control animals. After 3 weeks of exposure to the conflict paradigm animals were instrumented with femoral arterial catheters and lateral ventricular cannulae. Following recovery, mean arterial pressure (MAP) and heart rate (HR) were measured in their home cages and plasma samples were taken for norepinephrine (NE) and epinephrine (E) analysis. Also, depressor responses to hexemethonium (30 mg/kg, i.a.) and pressor responses to 4 ul injections of hypertonic CSF (.64, 1.0, 1.9 uEq/L) were determined. The data reveal that after 3 weeks of conflict stress there were no differences between stressed and control animals with respect to MAP (133 vs 134 mmHg), HR (327 vs 350 bpm), NE (253 vs 215 pg/ml), and E (244 vs 201 pg/ml). However, there was a significantly ($p < .05$) greater fall in MAP to ganglionic blockade in stressed animals compared with controls (-56 vs -39 mmHg). Finally, although there were significant elevations in MAP to all doses of hypertonic CSF, stressed and control BHR responded similarly to each dose. These data suggest that during the early phase of stress-induced hypertension, when blood pressure has not yet increased, the sympathetic nervous system contribution to vascular tone is exaggerated in stressed BHR compared to controls.

288.11 BETA-2 ADRENOCEPTORS INFLUENCE THE CARDIOVASCULAR RESPONSES TO AN ACUTE STRESSOR IN THE BORDERLINE HYPERTENSIVE RAT. R. F. Kirby, R. Fisher, C. H. Woodworth, and A. K. Johnson, Depts. of Psychology and Pharmacology and the Cardiovascular Center, University of Iowa.

We have previously demonstrated that rats of varying genetic predispositions to develop hypertension have minimal increases in blood pressure immediately following the cessation of an acute footshock episode that produces large increases in heart rate and plasma catecholamines. The ability to maintain pressure near resting levels following footshock stress appears to depend upon specific changes in regional blood flow; including a vasodilation in the hindlimb vasculature. Evidence from many studies indicates that this vasodilation may be mediated by adrenal epinephrine acting on beta-2 adrenoceptors located in the hindlinb vasculature. In the present study, the cardiovascular responses to transfer to a novel environment and intermittent footshock stress were compared following beta-2 antagonism or vehicle treatment in Wistar-Kyoto (WKY) or borderline hypertensive rats (BHR). All animals were raised in our laboratory and BHR were the F1 generation offspring of WKY females and spontaneously hypertensive males. At 20 weeks of age, catheters were implanted into the right common carotid artery for determination of mean arterial pressure (MAP, mmHg) and heart rate (HR, beats/min) and the administration of drugs. Resting home cage HR was comparable between WKY and BHR, while MAP was elevated in BHR. The increase above resting levels following transfer and footshock for WKY and BHR animals are presented below.

	Transfer		0' Post FS		5' Post FS	
	HR	MAP	HR	MAP	HR	MAP
WKY-Veh	56±17	8±4	99±21	13±3	43±11	3±3
WKY-ICI	34±17	17±4	91±12	15±3	51±8	7±4
BHR-Veh	120±10	12±4	217±7	15±6	157±12	13±4
BHR-ICI	6±11	37±5	78±13	26±2	56±13	24±3

data are means ± SEM; n= 6 to 12 animals per group.

The HR increase in vehicle-pretreated BHR was greater than that of the WKY following stress. However, MAP responses were fairly comparable. Pretreatment with the selective beta-2 antagonist ICI118.551 (1mg/kg i.a.) attenuated the HR increase and exaggerated the MAP response to the stressors in the BHR but did not affect the WKY response. In the present findings, it is unknown to what extent the greater MAP response of the BHR-ICI animals influenced the HR response. These data indicate that beta-2 adrenoceptors may help to offset a large pressor response to stress in BHR and point to the need for examining regional blood flow changes of animals susceptible to the development of hypertension in response to environmental challenges.

288.12 EFFECTS OF BASAL FOREBRAIN LESIONS AND CHOLINOMIMETICS ON CEREBRAL CORTICAL MICROVASCULAR PERFUSION (CCMP) IN RAT: CONTINUOUS MEASUREMENT BY LASER-DOPPLER FLOWMETRY. A.M. May* and S.P. Arnerić (SPON: Wm. H. Cline, Jr.), Department of Pharmacology, Southern IL University School of Medicine, Springfield, IL 62708

Alzheimer's disease (AD) is characterized by decreased cholinergic innervation of the cerebral cortex and decreased cerebral blood flow (CBF) (J. Cereb. Blood Flow Metab. 5:S131-S144, 1985). Since acetylcholine dilates blood vessels in brain and, thus, would increase CBF, it is possible that the decrease in CBF occurring with AD is the result of a decreased cortical cholinergic innervation arising from the basal forebrain (BF). This study sought to determine in rat whether: 1) ibotenic acid (IBO) lesions of the BF, a procedure that decreases the cortical cholinergic innervation, mimics the reductions in CCMP found in AD; and 2) physostigmine (PHYSO), a cholinomimetic which effectively improves the memory defects of AD, may act to locally increase CCMP. IBO (5 μg/0.5 μl) was microinjected unilaterally into the BF of male rats under halothane anesthesia and vehicle contralaterally. Twenty-one days later rats were evaluated for concurrent changes in CCMP, biochemical alteration in cortical enzymes and histological confirmation of the lesion site. Rats were anesthetized (chloralose), paralyzed, artificially ventilated and arterial blood gasses controlled. A craniotomy was performed over the parietal cortex (PCx) and occipital cortex (OCx). CCMP was measured continuously with laser-doppler flowmetry. Drugs were delivered intravenously (i.v.) or microinjected intracortically (ict.) through a glass micropipette (70 μm, o.d.; 100-400 nl) positioned 0.7 mm beneath the surface probe (0.8 mm, o.d.). In unoperated rats resting CCMP did not differ between right and left sides ($p > 0.05$; N=7). In contrast, IBO lesions of the BF decreased CCMP in the PCx by 26±7% ($p < 0.05$; N =6) without affecting CCMP in contralateral or adjacent OCx. Choline acetyltransferase activity was correspondingly decreased within the lesioned PCx by 55±5%; ($p < 0.05$, N=6), while intrinsic cortical neurons containing glutamic acid decarboxylase were unaffected. Dose-dependent (0.2-0.8 nmol, ict.; N=3-8; $p < 0.05$) increases in CCMP occurred with PHYSO (up to +148%), carbachol (+232%) and papaverine (+325%); vehicle was without effect (+12%); arterial pressure was unchanged. Similarly, CCMP was maximally increased (+181%) 3 min after i.v. PHYSO (0.154 μmol/ kg), remaining elevated 10-15 min. Atropine (0.8 nmol, ict.) prevented the increase in CCMP by i.v. PHYSO without affecting the accompanying hypertension. Conclusions: 1) IBO lesions of the BF selectively decrease CCMP and cortical cholinergic innervation similar to that reported in patients with AD; 2) Local and systemic administration of cholinomimetics increase CCMP via a local muscarinic cholinergic mechanism which operates independent of changes in arterial pressure or dilation of large resistance vessels (Supported by SIU Sch. of Med.).

289.1 EFFECTS OF IRON DEFICIENCY AND BRAIN LESIONS ON THE MOTOR ACTIVITY AND BODY T° CIRCADIAN CYCLES IN RATS. S. Yehuda and M. B. H. Youdim*. Dept. of Psychol., Bar-Ilan Univ., Ramat-Gan, and Rappaport Fam. Inst. Med. Sci., Technion, Haifa, Israel.

Iron deficiency is the most prevalent nutritional disorder in man. Rats made nutritionally iron-deficient (ID) have significantly lower brain iron (40-60%) and dopamine D2 receptor number (Bmax) (50%) (Ben Shachar et al., J. Neurochem., 45:999, 1975). On the behavioral level, the ID rats exhibit a clear deficit in learning (Yehuda et al., Pharmacol. Biochem. Behav., 25:141-144, 1986), and reversal of motor activity and body temperature circadian cycles (Youdim et al., Eur. J. Pharmacol., 74:295-301, 1981).

The effects of selective brain lesions on the circadian cycles of motor activity and body T° were studied in intact, pinealectomized, hypophysectomized, and area postrema-lesioned rats.

	No lesion		Pinealec-tomized		Hypophysec-tomized		Area Postrema X	
Diet	Control	ID	Control	ID	Control	ID	Control	ID
Colonic T°								
Peak	24:00	09:00	03:00	09:00	24:00	24:00	24:00	12:00
Trough	12:00	03:00	12:00	24:00	12:00	12:00	09:00	03:00
Motor Activity								
Peak	03:00	09:00	03:00	03:00	03:00	09:00	24:00	09:00
Trough	09:00	03:00	09:00	09:00	09:00	03:00	06:00	24:00

The results showed that among ID intact rats both circadian cycles were reversed. ID pinealectomized rats showed body T° reversed cycle but not motor activity, while ID hypophysectomized rats behaved in an opposite manner; their motor activity cycle (but not the body T° cycle) was reversed. Area postrema-lesioned rats exhibited shifted phase cycles, and ID AP-lesioned rats also exhibited shifted phase reversal cycles. These results may explain the neuropharmacological basis of ID effects.

289.2 **OLFACTORY BULBECTOMY MODEL OF DEPRESSION: EJACULATORY AND CIRCADIAN DYSFUNCTION AND THEIR RESPONSE TO ANTIDEPRESSANT TREATMENT** A.R. LUMIA*[1], F.J. SALCHLI*[1], E.L. AYERS*[1], M.Y. McGINNIS*[2], B.S. McEWEN[3], M.H. TEICHER*[4] (SPON: J.W. GERST)

1: Dept. of Psychology, Skidmore College, Saratoga Springs, NY, 12866. 2:Mount Sinai Medical School, CUNY, New York, NY, 10021. 3: The Rockefeller University, New York, NY, 10021. 4:Mailman Research Center, McLean Hospital, Belmont, MA, 02178.

The bilateral olfactory bulbectomized rat (**OBX**)has been proposed as an animal model of depression and as a screen for antidepressant drugs(Jesberger,et. al., Behav. Neurosci. 100:2,1986).OBX abolishes sexual behavior (Lumia et.al, Brain Research, 404,1987) and disrupts activity (Jesberger,et. al., Behav. Neurosci. 100:2,1986); symptoms indicative of depression. .We hypothesized that OBX would (1) eliminate ejaculation and disrupt normal daily activity patterns, (2) that treatment with a known anti-depressant drug would normalize the **OBX** induced ejacualtory and circadian activity deficits. This study examined the effect of amitriptylene (**AMI**) (5mg./kg/BW) effectiveness in normalizing the **OBX** induced copulatory deficit and daily running wheel activity rhythms. Male Sprauge-Dawley rats were maintained individually under a 12:12 reverse light/dark cycle in standard running wheels interfaced with a real time computerized data collection system. Sexually experienced animals were either **OBX** or sham operated and tested for copulation prior to and following surgery and following either 14 days of **AMI** or control vehicle administration. All animal activity was recorded for four consecutive days from a subset of 13 animals prior to and following surgery and after treatment with **AMI** or saline. For each animal the total number of revolutions in the dark and light phase was recorded and a D/L ratio computed.

Results show that significantly fewer OBX ejaculated (**p=.02**). **AMI** increased the number of OBX males that achieved ejaculation (**OBX/saline = 40%:OBX/AMI = 77%**).In contrast, sham operates treated with **AMI** showed a temporary decreased ejaculatory potential (**p=.02**). For running wheel activity **OBX** significantly increased activity in the light phase and **AMI** normalized this abberant circadian pattern. An ANOVA indicated that surgery was significant at **p<.02** and the surgery/drug interaction at **p<.005**. Chronobiological analysis' are currently underway to further delineate the mechanisms underlying these changes in activity patterns The results of this study indicate that **OBX** may serve as a model for the vegetative symptoms of unipolar major depression. (This work was supported by grants from the FREED FOUNDATION and SKIDMORE COLLEGE to A.R.L.)

289.3 IN VIVO ELECTROPHYSIOLOGICAL EVIDENCE IN THE RAT BRAIN SUGGESTING AN INTERACTION BETWEEN IMIPRAMINE BINDING SITES AND TERMINAL 5-HT AUTORECEPTORS. P. Blier, Y. Chaput* and C. de Montigny. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Canada H3C 3J7.

Autoreceptors on 5-HT terminals modulate the release of 5-HT into the synaptic cleft. [^{3}H]Imipramine, and more specifically [^{3}H]citalopram and [^{3}H]paroxetine, bind to a site associated with the 5-HT reuptake pump on the same terminals. We have shown that long-term treatment with the antidepressant 5-HT reuptake blocker citalopram decreases the function of the terminal 5-HT autoreceptor (Naunyn-Schmiedeberg's Arch. Pharmacol., 333: 342, 1986). The present study was undertaken to determine whether increased synaptic availability of 5-HT or activation of the [^{3}H]imipramine binding sites is responsible for this modification.

Male Sprague-Dawley rats were treated with the 5-HT reuptake blocker fluoxetine (10 mg/kg/day, i.p.) for 14 days, the MAO-A inhibitor clorgyline (1 mg/kg/day, s.c.) for 21 days, or saline. Extracellular recordings were obtained from CA_3 dorsal hippocampus pyramidal neurons under chloral hydrate anesthesia. The effectiveness of the electrical stimulation of the ascending 5-HT pathway at the level of the ventromedial tegmentum in depressing the firing activity of these neurons was determined from computer-generated peristimulus time histograms. The function of the terminal 5-HT autoreceptors was assessed by comparing the effectiveness of the stimulation prior to, and immediately following, methiothepin (1 mg/kg, i.v.), a terminal 5-HT autoreceptor antagonist, and by determining the ratio (S2/S1) of effectiveness 0.8 Hz (S1) and 5 Hz (S2) stimulations.

Long-term administration of both fluoxetine and clorgyline increased the efficacy of the stimulation of the 5-HT pathway. However, the enhancing effect of the terminal 5-HT autoreceptor antagonist methiothepin was reduced in the fluoxetine but not in the clorgyline group. The reduction of the function of the terminal 5-HT autoreceptor by fluoxetine was further evidenced by the decreased ratio of effectiveness of the 0.8 and 5 Hz stimulations. To verify that the reuptake blockade per se could not account for the increased synaptic efficacy of 5-HT projections following long-term fluoxetine, the drug was administered acutely to naive rats (5 mg/kg, i.v.). It did not increase the efficacy of the stimulation of the 5-HT pathway.

Two conclusions are drawn from these results: 1) the increased efficacy of 5-HT synaptic transmission by long-term treatment with antidepressant 5-HT reuptake blockers is not directly due to 5-HT reuptake blockade, but rather to a reduced function of the terminal 5-HT autoreceptor; 2) the latter phenomenon cannot be ascribed to an increased availability of 5-HT in the synaptic cleft as it was not produced by long-term clorgyline treatment. Hence, these results suggest that the desensitization of terminal 5-HT autoreceptors might result from the long-term activation of the [^{3}H] imipramine binding sites.

289.4 TRACAZOLATE INCREASES PUNISHED RESPONDING IN A GELLER-SEIFTER CONFLICT TEST WITH INCREMENTAL SHOCK. J.L. Howard and G.T. Pollard. Dept. of Pharmacology, Burroughs Wellcome Co., Research Triangle Park, NC 27709.

Standard anxiolytics such as benzodiazepines increase lever-pressing that has been suppressed by electric shock (Geller, I. and Seifter, J., Psychopharmacologia, 1:482, 1960). The atypical putative anxiolytic tracazolate has been reported not to increase punished lever-pressing significantly in rat at doses up to 40 mg/kg p.o., although it did significantly increase punished drinking in the Vogel test at 10 and 20 mg/kg p.o. (Patel, J.B. and Malick, J.B., Eur. J. Pharm., 78:323, 1982). We tested chlordiazepoxide 5-40 mg/kg p.o. and tracazolate 20-320 mg/kg p.o. in a modified Geller-Seifter procedure with incremental shock (Pollard, G.T. and Howard, J.L., Psychopharmacology, 62:117, 1979). Both compounds significantly increased punished lever-pressing; tracazolate's effect occurred clearly only at doses higher than those previously tested. We also explored tracazolate's possible mechanism of action at the benzodiazepine-GABA-chloride ionophore complex. We attempted to replicate in our procedure the finding that the benzodiazepine receptor blocker RO15-1788 had no effect on tracazolate's anti-conflict action in the punished drinking test (Patel, J.B. et al., Eur. J. Pharm., 86:295, 1983); and we tested the interactive effect of a GABA transaminase inhibitor to determine whether it would potentiate tracazolate's anti-conflict action as aminooxyacetic acid (AOAA) did in the case of diazepam (McCloskey, T.C., et al., Fed. Proc., 46:1302, 1987).

289.5 DISCRIMINATION BETWEEN NALTREXONE AND SALINE IN SQUIRREL MONKEYS RESPONDING UNDER A FIXED-RATIO SCHEDULE OF STIMULUS-SHOCK TERMINATION. C.P. France* and W.H. Morse* (SPON: J. Maggio). Laboratory of Psychobiology, Harvard Medical School, Boston, MA 02115.

The discriminative stimulus effects of naltrexone were studied in squirrel monkeys discriminating between saline and 3.2 mg/kg of naltrexone while responding under a fixed-ratio (FR) 5 schedule of stimulus-shock termination. Monkeys received an i.m. injection (saline or drug) during the first min of a 10-min timeout (TO) that preceded the session. During the session electric shocks were scheduled to be delivered every 5 sec in the presence of a stimulus light. Five consecutive lever presses on the injection-appropriate lever terminated the shock-associated stimulus for 50 sec. Failure to complete the response requirement within 5 sec resulted in the delivery of brief electric shock to the tail. Responses on the injection-inappropriate lever reset the FR requirement on the injection-appropriate lever. Test sessions were identical to training sessions except that 5 consecutive responses on either lever terminated the shock schedule. Squirrel monkeys discriminated reliably between injections of naltrexone and saline after approximately 200 training sessions. Naltrexone occasioned responding on the drug lever in a dose-related manner and monkeys generalized completely to naltrexone (i.e., >90% responding on the naltrexone lever) at doses of 1.0-3.2 mg/kg. Smaller doses of naltrexone occasioned responding predominantly on the saline lever and larger doses occasioned responding predominantly on the drug lever. Up to a dose of 10.0 mg/kg of naltrexone the latency to terminate the shock-associated stimulus was not different between drug and saline sessions. Among other drugs that were studied, only those with opioid antagonistic actions (e.g., nalorphine) substituted completely for the naltrexone discriminative stimulus. Drug discrimination with naltrexone in squirrel monkeys is of special interest because this species shows a pronounced super-sensitivity to some effects of opioid antagonists.

289.6 MOTIVATIONAL PROPERTIES OF OPIOIDS: EVIDENCE THAT TOLERANCE DEVELOPS TO THEIR REINFORCING AND AVERSIVE EFFECTS.
T.S. Shippenberg*, M. Emmett-Oglesby+ and A. Herz*. Dept. of Neuropharmacology, Max-Planck-Institut für Psychiatrie, D-8033 Planegg-Martinsried, F.R.G. and +Dept. of Pharmacology, Tx. College of Osteopathic Medicine, Fort Worth, Tx., U.S.A.

The motivational properties of opioids are well documented. μ-Receptor agonists function as positive reinforcers, producing euphoria whereas κ-agonists induce aversive motivational states. It is not at all clear, however, whether tolerance develops to either of these effects. This study employed a place preference conditioning procedure to characterize the motivational properties of μ- and κ-agonists and determine whether prior, non-contingent exposure to an opioid modifies their reinforcing and/or aversive effects. Male S/D rats received sc injections of the μ-agonist, morphine (10.0-20.0 mg/kg/day), the κ-agonist, U-69593 (0.64 mg/kg/day) or vehicle for 4 days prior to place conditioning. They were then exposed to 1 distinct environment following injections of the conditioning drug and to a different environment following vehicle injections. After 4 such sessions, place preference was assessed by allowing uninjected rats access to both places and measuring time spent in each. Morphine at doses of 1.0 mg/kg and higher produced a marked preference for the drug-paired place in vehicle treated rats. In contrast, U-69593 (0.16-0.64 mg/kg) produced dose-related place aversions. Administration of morphine prior to conditioning resulted in a 3-fold shift to the right of the morphine dose-response curve. Significant preferences were only observed at doses of 10.0 mg/kg and higher. Chronic morphine treatment did not modify the reinforcing effects of another drug of abuse, amphetamine or the aversive properties produced by a κ-agonist. Chronic U-69593 treatment eliminated the aversive effect associated with its acute administration. This treatment did not, however, attenuate the reinforcing effects of morphine. These data demonstrate that tolerance develops to the reinforcing and aversive properties of opioids and that this effect occurs in non-opioid dependent subjects. Furthermore, they suggest that tolerance to the euphorigenic or positive reinforcing effects of opioids may be a critical factor underlying chronic opioid abuse.

289.7 ETHANOL ENHANCES THE NICOTINE-INDUCED BEHAVIORAL DESENSITIZATION TO NICOTINE IN LONG-SLEEP AND SHORT-SLEEP MICE. C.M. de Fiebre* and A.C. Collins Inst. for Behav. Genetics, University of Colorado, Boulder, CO 80309.

Long-Sleep (LS) and Short-Sleep (SS) mice, which have been selectively bred for differential sensitivity to ethanol (EtOH) anesthesia, also differ in sensitivity to nicotine. The greater sensitivity of the LS mouse line is not due to differential metabolism or distribution of the drug. Therefore these mice differ in sensitivity to nicotine because of differential CNS sensitivity. However, these two mouse lines do not differ in receptor numbers as measured by the binding of nicotine and α-bungarotoxin. Pretreatment with nicotine (2mg/kg) causes a decreased sensitivity to nicotine-induced seizures in these mice. This decreased sensitivity, a behavioral desensitization, could be due to desensitization of nicotinic receptors. Alcohols have been found to stabilize the nicotinic receptors from electroplaques in the high affinity (desensitized) state (Young, A.P. & Sigman, D.S., Mol. Pharmacol., 20:498, 1981). If the behavioral desensitization displayed by LS and SS mice is due to desensitization of nicotinic receptors, co-pretreatment with nicotine and alcohols should result in an enhancement of this phenomenon. LS and SS mice were pretreated with nicotine (2 mg/kg) and EtOH (0.25 and 1.5 g/kg for the LS and SS, respectively) 30 min prior to challenge with seizure-producing doses of nicotine. EtOH doses which did not display anticonvulsant properties were used in this experiment. In SS mice, EtOH co-pretreatment greatly enhanced the behavioral desensitization produced by nicotine pretreatment alone. No enhancement was seen in the LS mice probably due to the low dose of EtOH given to the LS mice and the relatively long pretreatment time. Therefore, animals of both selected lines were pretreated with nicotine (2 mg/kg) and EtOH (0.75 g/kg) 15 min prior to nicotine challenge. In LS mice, this pretreatment greatly enhanced the behavioral desensitization seen with nicotine alone. Furthermore, pretreatment with this dose of EtOH alone did not produce a significant change in nicotine-induced seizure-sensitivity in LS mice. SS mice co-pretreated with this dose of EtOH showed an enhanced behavioral desensitization, although this enhancement was not as great as that seen at the higher EtOH dose. This enhancement produced by EtOH is consistent with a stabilization of nicotinic receptors in a desensitized state. Perhaps the LS and SS mice differ in sensitivity to nicotine due to differences in the ratio of desensitized to sensitized receptors in non-pretreated animals.

289.8 THE CONDITIONED SUPPRESSION OF DRINKING (CSD) PARADIGM: A POTENTIAL "ANIMAL MODEL" FOR THE STUDY OF PANIC DISORDER? David J. Fontana and Randall L. Commissaris (SPON: Ernest L. Abel). Department of Pharmaceutical Sciences, College of Pharmacy & AHP, Wayne State Univ., Detroit, MI 48202.

Although numerous animal procedures have been employed as "model" behaviors for the study of generalized anxiety and agents effective in the treatment of generalized anxiety, an analogous "behavioral model" for the study of Panic Disorder (PD) does not exist. In the present study, the effects of imipramine and desipramine were examined in a potential "animal model" for the study of PD, the Conditioned Suppression of Drinking (CSD) paradigm. In daily ten-minute sessions, water-deprived rats were trained to drink from a tube which was occasionally electrified (0.5mA). Electrification was signalled by a tone. Within 2-3 weeks, control (i.e., non-drug) CSD behavior had stabilized (approximately 20 shocks/session and 10-15 ml water/session) and drug testing was begun. Imipramine was administered both in an acute (3.5 - 20 mg/kg; 10-minute pre-treatment) and a chronic (2.5 mg/kg, i.p., twice daily for 5 weeks) regimen; desipramine was also administered in a chronic (5.0 mg/kg, i.p., twice daily for 5 weeks) regimen. Acute administration of imipramine failed to produce a selective effect on this conflict behavior, decreasing both the number of shocks received and water intake (unpunished responding) in a dose-dependent manner relative to saline controls. In contrast, chronic administration of either imipramine or desipramine resulted in a gradual and selective increase in the number of shocks received in CSD sessions over the course of several weeks of testing. This time-dependent increase in punished responding in the CSD observed during chronic imipramine or desipramine treatments parallels the time-dependent reduction in the frequency and severity of panic attacks in PD patients receiving chronic tricyclic anti-depressants. Thus, the CSD paradigm might serve as an "animal model" for the study of PD and potential anti-panic agents.

289.9 ASYMMETRIC PURINERGIC RESPONSES TO DOPAMINE RECEPTOR ACTIVATION IN THE LESIONED RAT: NEUROCHEMICAL AND BEHAVIORAL CORRELATIONS. D.M.Togasaki[1,2], T.S.Brannan*[3], L.K.H.Leung*[2], J.G.Young[2,4] and P.J.Knott[1,2,5]. Departments of Neurobiology[1], Psychiatry[2], Neurology[3], Pediatrics[4] and Pharmacology[5]. The Mount Sinai School of Medicine, New York, N.Y. 10029, U.S.A.

Striatal extracellular fluid (ECF) concentrations of uric acid (UA) can be monitored with linear sweep voltammetry at carbon paste electrodes (Mueller,K.J. et al Brain Res. 335: 231, 1985). We also find that L-DOPA induced turning behavior in the unilaterally lesioned rat correlates with increased striatal UA production.

Male Sprague-Dawley rats (200-225g), unilaterally lesioned with 6-OHDA were tested 6-8 days later with apomorphine (0.25mg/kg). Rats exhibiting clear circling were implanted bilaterally with carbon paste working electrodes for chronic voltammetric recording 3-4 days after the apomorphine screen. 3 days following implantation they were injected with L-DOPA (25mg/kg i.p.). Semi-differentiated linear sweep voltammograms (from -430 to +900mV at 10mV/s using a BAS DCV5 voltammetry controller) were obtained at 10 minute intervals concurrently with videorecordings of circling behavior. In other studies, bilateral striatal microdialysis probes similar to those previously described (Clemens,J.A. and Phebus,L.A. Life Sci., 35: 671, 1984) were used to monitor ECF L-DOPA and dopamine metabolite concentrations in response to L-DOPA (50mg/kg i.p.) in similarly lesioned apomorphine-screened anesthetized rats.

Voltammetric Peak 2 (uric acid) also increased in both lesioned and intact striata but the change was larger on the lesioned side. Moreover, the difference in the increase of UA signal (lesioned minus unlesioned) correlated strikingly with the net turning behavior away from the lesioned side which had occurred 10min previously. In separate studies uricase microinfusion close to the voltammetric electrode abolished the L-DOPA induced increase of Peak 2 and also this peak was increased following infusion of the dopaminergic agonist, apomorphine. Using microdialysis, ECF L-DOPA changes were similar in both lesioned and intact striata and that DOPAC and HVA changes were much larger in the unlesioned striata. Changes of L-DOPA, the dopamine metabolites or 5-HIAA measured in striatal dialysates by HPLC-EC could not account for the differential response of peak 2 in the lesioned and unlesioned striata measured by voltammetry. This coupled with other studies from our laboratory continue to confirm that peak 2 is largely due to UA. The correlation of striatal UA production with a behavioral change suggests that UA may reflect functional neuronal events related to dopamine receptor interaction rather than tissue damage or other consequences of the invasive technique.

289.10 CAFFEINE ELEVATES THRESHOLD FOR INTRACRANIAL ELECTRICAL BRAIN STIMULATION IN THE RAT: TOLERANCE AND WITHDRAWAL. G.K. Mumford*[1], D.B. Neill*[2] and S.G. Holtzman*[1] (SPON: W.T. Frazier). Depts. of Pharmacology[1] and Psychology[2], Emory University, Atlanta, GA 30322.

Many behavioral stimulants, such as d-amphetamine, decrease the reinforcement threshold for intracranial self-stimulation (ICSS). Caffeine is a behavioral stimulant and the most widely consumed behaviorally-active compound in the world. Its effect on ICSS has not been well characterized. In this study we used an autotitration procedure to examine the effects of both acute and chronic caffeine administration on rate of responding and threshold for ICSS.

Adult male rats were trained to press one of two levers for an electrical stimulus delivered via electrodes stereotaxically implanted in the medial forebrain bundle of the lateral hypothalamus. Pressing the first lever delivered a 150 msec train of current and was recorded as a response. Every fifth response decreased the current intensity by a "step" of 3 μA. Pressing the second lever reset the current intensity to a preset maximum starting value, which was set individually such that each rat typically allowed the current to drop 10-12 steps before resetting In this way a characteristic reinforcement threshold (in μA) was established for each animal. Rats were overtrained in this procedure in daily 15 minute sessions before drug testing began.

Caffeine (1.0-56 mg/kg IP) administered 30 min prior to a session produced a significant dose-dependent elevation of reinforcement threshold (ie, earlier resetting), with response rate affected only at the highest dose (40% decrease; n=13). In contrast, d-amphetamine (0.75 mg/kg IP) significantly lowered reinforcement threshold in these subjects, with no effect upon response rate. Other rats (n=9) were allowed 10-min of access every 6 hr to drinking bottles containing either water (baseline condition) or a caffeine solution (1.0 mg/ml) as their sole fluid source for 10 consecutive days. Caffeine intake averaged 72 mg/kg/day. Animals were tested in the autotitration procedure at the same time each day, 5 hr after a period of access to their drinking bottles. After one day of caffeine intake, mean reinforcement thresholds were elevated significantly, with no corresponding change in response rate. Tolerance developed rapidly to this effect: thresholds returned to baseline (precaffeine) on day 2 and remained stable until the caffeine solution was replaced with drug-free tap water on day 10. Both reinforcement thresholds and response rates were decreased 24 hr later, and returned to baseline levels gradually, over 3-5 days. These changes are consistent with a drug withdrawal phenomenon. (Supported in part by Grants DA03413 and MH37340 and by RSA DA00008.)

289.11 THE SENSITIVITY OF CONDITIONED TASTE AVERSIONS AS A BEHAVIORAL BASELINE TO ASSESS THE DISCRIMINATIVE STIMULUS PROPERTIES OF NALOXONE. M. Kautz*, R. Jeffreys*, S. McBride*, S. Pournaghash*, M. Schwartz*, T. Titley*, A. Wachsman*, J.P. Mastropaolo and A.L. Riley (SPON: G. Gelanutsos). Psychopharmacology Lab, The American University, Washington, D.C. 20016.

Drug discrimination learning is a powerful tool for the in vivo assessment of the mechanism of drug action and has served as a technique for the classification of drugs on the basis of the "subjective state" they produce. Although discriminative control of behavior has been produced by a wide range of drug stimuli, there are differences in the rate of acquisition and degree of control obtained with various drugs. Naloxone hydrochloride, for example, produces only weak discriminative control, and even here, only at extremely high doses (e.g., 25 mg/kg).

Recently, the conditioned taste aversion procedure has been demonstrated to be a viable behavioral baseline to examine control by drug states (Mastropaolo, J.P., Moskowitz, K.H., Dacanay, R.J., & Riley, A.L., Neurosci. Abstr., 12:912, 1986). Specifically, following the injection of phencyclidine (PCP) rats were given a pairing of a saccharin taste and the emetic LiCl. Following an injection of distilled water (i.e., the absence of PCP), these same rats were given saccharin alone. After only three conditioning trials, the presence or absence of PCP controlled the avoidance or acceptance of saccharin. Since such rapid control by PCP is in contrast to that seen in more traditional operant assessments of discriminative control by drugs, it may be that the conditioned taste aversion design is more sensitive to control by drug states.

To test further the sensitivity of this paradigm, the present study examined the ability of naloxone to serve as a discriminative cue within the conditioned taste aversion design. Specifically, groups of water-deprived rats were injected with either .1, .3, 1 or 3 mg/kg naloxone 10 min prior to receiving 20-min access to saccharin. Immediately following saccharin consumption, all rats were injected with the toxin LiCl. This procedure was repeated every fourth day for 10 conditioning trials. On intervening days, subjects were injected with distilled water prior to receiving a non-poisoned presentation of saccharin.

Animals learned to avoid saccharin after six conditioning trials, with the degree of the aversion directly related to the dose of naloxone. Only at the lowest dose administered (i.e., .1 mg/kg) was there no evidence of stimulus control. These data suggest that the conditioned taste aversion paradigm may be useful as a sensitive behavioral baseline for the assessment of drug discrimination.

289.12 MOTOR ABNORMALITIES EVOKED BY CO-TRANSMITTERS: ANALYSIS OF TRH AND 5-HT SYNDROMES. A. Dailey* and M.R. Pranzatelli. (SPON: T.A. Pedley). Dept. of Neurology, Div. of Pediatric Neurology, College of Physicians and Surgeons of Columbia Univ., N.Y., NY 10032.

The motor abnormalities evoked by the co-transmitters thyrotrophin-releasing hormone (TRH) and serotonin (5-HT) offer a unique opportunity to study the functional significance of anatomic co-localization to the pharmacology of motor systems. The relationship of the two behavioral syndromes has not been previously studied using putative selective ligands at 5-HT receptor subtypes. Both the degradation-stabilized TRH analog MK-771 (in naive rats) and 5-hydroxytryptophan (5-HTP) (in rats with 5,7-dihydroxytryptamine DHT lesions) evoked forepaw tapping, Straub tail, hindlimb abduction, lateral head weaving, and shaking behavior. Sniffing and rearing were features of the MK-771 but not the 5-HT syndrome. Axial myoclonic jerks were evident in the 5-HT- but not the MK-771-evoked syndrome. MK-771 induced two types of shaking behavior: head shakes and wet-dog shakes (WDS). Neither independently was dose-related, unlike total shaking behaviors. MK-771-induced shaking behavior was pharmacologically dissociated from other MK-771-evoked motor behaviors. Both a 5-HT-1A agonist (8-OH-DPAT) and antagonist (isapirone) blocked WDS, but these drugs and putative 5-HT-1B (RU 24969) and 5-HT-2 (DOI) agonists and the 5-HT antagonists methysergide (nonselective), ritanserin (5-HT-2 selective), and l-propranolol (5-HT-1 selective) did not block other behavioral effects of MK-771. Each 5-HT agonist added its characteristic features to the MK-771 syndrome, such as hyperactivity (RU 24969) and lateral head weaving with reduction of rearing (8-OH-DPAT). 5-HTP reduced the threshold dose for MK-771-induced hyperthermia. Except for an antitremor effect, the putative 5-HT-1 antagonists isapirone and l-propranolol did not have similar effects, suggesting different sites of action. DHT-treated rats were behaviorally supersensitive to 10 mg/kg MK-771 as indicated by a significantly shortened latency of onset of WDS and greater frequency of abnormal forepaw movements. The same rats were also supersensitive to 50 mg/kg 5-HTP to a significantly greater degree. MK-771 did not evoke new behaviors in rats with DHT lesions. These data suggest behavioral relatedness of the TRH and 5-HT motor syndromes, but distinctive pharmacologic features and presumed mechanisms of action, despite the relation of TRH and 5-HT as co-transmitters. The pharmacologic dissociation of WDS and other behaviors suggests different regional loci or effector pathways. Further studies of the relation of the two syndromes await the availability of TRH antagonists.

290.1 ENVIRONMENTAL AND ENDOGENOUS CONTROL OF FEEDING AND PERCH HOPPING RHYTHMICITY IN THE HOUSE SPARROW. C.C. Chabot* and M.Menaker (SPON: D.J.Hudson). Institute of Neuroscience, University of Oregon, Eugene, Oregon. 97403.

The perch hopping activity of several avian passerine species can be rendered arrhythmic by removal of the pineal gland (P-X) or by exposure to constant light (LL). The pineal hormone melatonin also has effects on perch hopping rhythms of birds. While P-X always abolishes perch hopping rhythmicity in house sparrows, it often leaves the perch hopping activity of starlings rhythmic. In those individual starlings whose perch hopping rhythmicity is abolished by P-X or LL, feeding activity measured concurrently from the same bird remains rhythmic (Gwinner, unpublished; Ganshirt et al., 1983). One of several interpretations of this result is that the two behaviors are controlled by different clock systems. To test this idea we asked whether rhythmic feeding activity of the house sparrow persists under conditions which abolish locomotor rhythmicity.

Records of locomotor activity and feeding behavior were obtained concurrently from individual sparrows treated in several different ways: intact sparrows exposed to light/dark cycles, constant darkness and constant light of several intensities; P-X sparrows in constant darkness; and sparrows implanted with melatonin filled silastic capsules held in constant darkness.

The results are clear: Rhythms of feeding behavior are present in a light/dark cycle and persist in constant darkness with the same period as perch hopping rhythms; P-X consistently abolishes both feeding and perch hopping rhythms; implantation of melatonin filled silastic capsules leads to arrhythmicity in both behaviors; and exposure to LL affects both the feeding and perch hopping activity patterns in near identical fashion.

These results suggest that, at least in the house sparrow, feeding and perch hopping rhythms are under the influence of the same circadian control system of which the pineal gland is an integral part.

290.2 MATERNAL-FETAL COMMUNICATION OF DAYLENGTH: DEFINITION OF THE CRITICAL PERIOD FOR RECEPTION OF THE PRENATAL SIGNAL. D.R. Weaver, J.T. Keohan*, and S.M. Reppert. Children's Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Recent studies show that an animals's prior photoperiodic history influences its response to a subsequent photoperiodic treatment. Photoperiodic history begins during the prenatal period in montane voles and Djungarian hamsters, as the prenatal light-dark cycle is perceived by the fetus and influences reproductive development in these species (Biol Reprod 1984, 31: 499; Biol Reprod 1986, 34:664). Production of melatonin from the maternal pineal gland is involved in communication of daylength to the fetus in Djungarian hamsters. By varying the nightly duration of melatonin infusion into pinealectomized (PNX) dams during pregnancy, we showed that the duration of melatonin secretion is the signal communicating daylength to the fetus (Endocrinology 1986, 119: 2861). In the present study, we administered melatonin to PNX Djungarian hamsters (Phodopus sungorus) during restricted periods of gestation to delineate when maternal-fetal communication of daylength occurs.

First, we established that infusions of melatonin (50 ng delivered over 10 hr per night) to PNX dams for the last 4 to 7 nights of gestation consistently stimulate reproductive development in pups reared in 14L:10D (14L) postnatally. The offspring of melatonin-infused PNX dams reared in 14L had paired testes weights on day 34 approximately seven times greater than pups of uninfused PNX dams reared in 14L (420 vs. 60 mg, respectively).

To determine when during gestation this effect of melatonin is maximal, we restricted the period of infusion to a single night. Regardless of when the infusion was delivered, one night of infusion was ineffective in stimulating postnatal reproductive maturation. Two consecutive nights of melatonin infusion did stimulate testicular weight of the male offspring, however. By varying the timing of infusion relative to the time of birth, we have identified an apparent critical period 2 to 5 days before birth during which melatonin infusions are most effective in stimulating postnatal testicular growth of the male offspring. Even the peak response to two infusions was less than the response to 4 or more consecutive infusions, e.g., the response appears to be graded. This, along with the ineffectiveness of the single-night infusions, suggests that the prenatal daylength signal must be repeated, reinforcing itself over several days, in order to be effective. Interestingly, infusions delivered the last 2 nights of gestation were relatively ineffective in stimulating postnatal reproductive development. The decline in response to infusions delivered at the end of pregnancy may indicate that there is a programmed neural insensitivity to melatonin during the late prenatal and early postnatal periods. Supported by HD14427.

290.3 EFFECTS OF MELATONIN ON SUPRACHIASMATIC NUCLEUS METABOLISM IN RATS. M.H. Roberts, V.M. Cassone and R.Y. Moore, Depts. of Neurology and Neurobiology and Behavior, SUNY-Stony Brook, Stony Brook, NY 11794

The suprachiasmatic nucleus (SCN) is a central pacemaker in the rodent circadian system. In non-mammalian vertebrates the pineal gland also plays a prominent role in circadian organization. While pinealectomy in some birds results in arrhythmicity, pinealectomy in rodents has little effect on behavioral rhythms. Despite the lack of effect of pinealectomy, recent studies indicate that daily injection of the pineal hormone, melatonin, can entrain circadian rhythms of locomotor activity in rats if administered at CT 12. This effect depends upon the SCN. In an attempt to determine the physiology of melatonin's effects, we addressed two issues in the current study; the effect of melatonin on metabolic activity and protein synthesis in the SCN.

In the first study we measured the effect of melatonin injection at CT10 and CT14 on 2-deoxyglucose (2DG) uptake in the SCN of blind and intact rats. The effect of melatonin (1mg/kg in 1% ethanol: saline) was compared to the effect of ethanol:saline alone. Fifteen minutes following drug injection animals were injected with 150uCi/kg of 14C-2DG. Forty-five minutes later, animals were sacrificed, brains removed and processed for autoradiography. Densitometric analysis indicates that deoxyglucose uptake is inhibited at CT10 by melatonin treatment ($p<0.01$). The results, summarized below, are expressed as deoxyglucose uptake in pM/g/hr $\pm$ SD (n=3 in each group).

		DEOXYGLUCOSE UPTAKE	
TIME	ANIMAL	SALINE	MELATONIN
CT10	intact	395.0 $\pm$ 98.7 *	290.1 $\pm$ 21.5
CT10	blind	386.3 $\pm$ 43.1 *	279.5 $\pm$ 18.0
CT14	intact	293.8 $\pm$ 5.7	288.4 $\pm$ 24.6
CT14	blind	289.6 $\pm$ 7.6	271.4 $\pm$ 17.8

To determine the effect of melatonin on protein synthesis, 6 rats were cannulated in the lateral ventricle, five days prior to being injected with melatonin (n=3) or ethanol:saline at CT 10. Fifteen minutes later animals were intraventricularly injected with 1.4mCi of 35S-methionine. Two hours later animals were sacrificed, brains removed, and the SCN was dissected and homogenized in SDS buffer. Ethanol:saline treated rats showed an SCN specific activity of 18598 $\pm$ 1666 DPM/ug protein, which was decreased to 8095 $\pm$ 3580 DPM/ug by melatonin. These values are equivalent to values obtained mid-day and mid-night in an initial pilot study (17686 D; 7996 N).

These results indicate that the SCN may be a target for melatonin's effects on the rodent circadian system. Furthermore, the effect of melatonin on protein synthesis, although preliminary, may provide a basis for using this hormone as a probe to dissect the biochemical mechanism of circadian rhythm generation in the SCN. 290.4 LUZINDOLE (N-0774) ANTAGONIZED THE MELATONIN-INDUCED INHIBITION OF ^{3}H-DOPAMINE RELEASE FROM RABBIT RETINA. M. L. Dubocovich. Dept., Pharmacol., Northwestern Univ. Med. Sch. Chicago, IL 60611.

Melatonin, at picomolar concentrations, inhibits the calcium-dependent release of ^{3}H-dopamine from the rabbit retina, through activation of a site possessing pharmacological characteristics of a receptor (Dubocovich, M.L., J. Pharmacol. Exp. Ther., 234: 395, 1985). We demonstrate here that the indole compound luzindole (N-0774) antagonizes the melatonin-induced inhibition of ^{3}H-dopamine release from rabbit retina. Albino rabbits maintained on a 10/14 hour dark/light cycle were killed in the middle of the dark cycle. Retinas were labeled in vitro with ^{3}H-dopamine. Calcium-dependent release of ^{3}H-dopamine was elicited by field stimulation at 3 Hz (2 min, 2 msec., 20 mA) twice in each experiment. The percent of total tissue radioactivity release above basal during the first period of stimulation (S_1) was 2.31 $\pm$ 0.13 % (n=14), and the ratio S_2/S_1 was 0.98 $\pm$ 0.05 (n=14). Melatonin (IC_{50}=40 pM), and the melatonin receptor agonists 6-chloromelatonin (IC_{50}=40 pM) and 6,7-dichloro-2-methylmelatonin (IC_{50}=10 pM) inhibited in a concentration-dependent manner the calcium-dependent release of ^{3}H-dopamine when added alone before the second period of stimulation (S_2). Maximal inhibitory effects (75-80 %) by the melatonin receptor agonists were obtained at a concentration of 1 nM. Luzindole did not modify the calcium-dependent release of ^{3}H-dopamine when added alone before S_2 (S_2/S_1 ratio: 0.78 $\pm$ 0.08, n=4; 1.00 $\pm$ 0.01, n=3; and 0.93 $\pm$ 0.11, n=4 for 0.1, 1 and 10 uM luzindole, respectively). Luzindole (0.1-10 uM) shifted the concentration-effect curves of the melatonin receptor agonists to the right without changing their maximal inhibitory effects. The equilibrium dissociation constant (K_B) for luzindole calculated from the Schild regression using melatonin as agonist was 20 nM. The equilibrium dissociation constant for luzindole determined using 6-chloromelatonin was 22 nM and using 6,7-di-chloro-methylmelatonin was 16 nM. Taken together these results suggest a) that there is a competitive relationship between the melatonin antagonist luzindole and the agonist melatonin, and b) that the three melatonin receptor agonists used in these experiments activate the same presynaptic melatonin receptor to mediate inhibition of ^{3}H-dopamine release as the calculated K_B values for luzindole were identical. Luzindole, expected to mimic the effects of light, may help to understand the role of melatonin in photoperiodic regulation of behavioral and physiological processes in vertebrates. Supported by Nelson Research and NIH RR 05470.

290.5 EFFECT OF THE MELATONIN RECEPTOR ANTAGONIST LUZINDOLE (N-0774) IN THE MOUSE BEHAVIOURAL DESPAIR TEST. E. Mogilnicka* and M.L. Dubocovich. (SPON: D.N. Krause). Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL. 60611.

The pineal hormone melatonin has been implicated in the regulation of behavioral and physiological processes such as circadian rhythms in birds, reproduction in rodents, and as recently reported seasonal affective disorders in humans (Lewy et al., Science 235: 352, 1987). Understanding of the role of melatonin in these processes has been hampered by the lack of a melatonin receptor antagonists. The availability of luzindole, a selective melatonin receptor antagonist (Dubocovich, M.L., Neurosc. Abs., 1987) led us to investigate the role of endogenous melatonin in the mouse behavioral despair test which is used to screen for antidepressant activity (Porsolt et al., Arch. Int. Pharmacodyn. Ther., 229: 327, 1977). This test measures the reduction of immobilitity during forced swimming. Experiments were conducted at noon and at midnight in albino ND/4 and C3H/HeN mice kept on a 14/10 hour light/dark cycle (8 mice per group). In C3H/HeN mice pineal melatonin levels are higher during the dark period (Hotz, M.M., Behavior Genetics 15: 595, 1985). In C3H/HeN mice the duration of immobility at midnight (68.4 $\pm$ 2.29 sec) was significantly longer than at noon (47.7 $\pm$ 3.4 sec, $p < 0.001$) while in ND/4 mice the duration of immobility was identical at both times (midnight: 88.1 $\pm$ 5.9 sec). The tricyclic antidepressant desipramine (30 mg/kg, i.p.) significantly reduced the duration of immobility both in the C3H/HeN mice (noon: 12.5 $\pm$ 3.3 sec; midnight: 5.2 $\pm$ 2.1 sec) and in the ND/4 mice (noon: 38.2 $\pm$ 5.1 sec; midnight: 44.7 $\pm$ 12.4 sec). In the C3H/NeH mice luzindole (10 mg/kg) 60 min after i.p. administration, significantly reduced the duration of immobility at noon (28.2 $\pm$ 6.9 sec) and at midnight (16.1 $\pm$ 5.2 sec). This effect was more pronounced at midnight. Luzindole did not affect the duration of immobility in the ND/4 mice either at noon (57.4 $\pm$ 8.9) or midnight (72.4 $\pm$ 4.9). Melatonin (30 mg/kg, i.p.) did not affect the duration of immobility in C3H/NeH mice, but completly abolished the effect of luzindole (10 mg/kg). In C3H/NeH mice kept in constant light during 1 week, which pressumably abolished the night increase in pineal melatonin, the duration of immobility measured at midnight was reduced (38.3 $\pm$ 7.9 sec) to values obtained in controls at noon. The light treatment abolished the effect of luzindole (10 mg/kg) at midnight (49.9 $\pm$ 10 sec). Taken together these data suggest that endogenous melatonin plays a role in the C3H/NeH mice behavioral despair test, but not in the ND/4 mice. We suggest that the melatonin receptor antagonist luzindole may have a potential therapeutic value in the treatment of chronobiologic mood disorders. Supported by Nelson Research and NIH RR 05470.

290.6 CIRCADIAN RHYTHMS IN ALZHEIMER'S DISEASE. J.W. Renfrew*, C. May*, L. Tamarkin*, R.P. Friedland and S.I. Rapoport (SPON: Q. Smith). Lab. of Neuroscience, Nat. Inst. on Aging, National Institutes of Health, Bethesda, MD 20892.

Patients with Alzheimer's disease (AD) often develop sleep disturbances and nocturnal wandering over the course of their illness. Previous animal studies have indicated that the suprachiasmatic nucleus of the hypothalamus may regulate circadian rhythms. This nucleus may be affected in AD.

To further study wandering in AD, we sought to characterize the circadian rhythms of plasma melatonin and physical activity in a group of 6 patients with probable AD (mean age 71.5 yr, range 54 to 89 yr) and 6 healthy, age-matched control subjects (mean age 73 yr, range 55 to 91 yr). The AD patients were moderately to severely demented and they were all living at home. All subjects were in good physical health and were medication-free at the time of study. Pairs of an AD patient and a control subject were admitted to the NIH Clinical Center for 5 days, including a 2-day acclimation period and were maintained on a set daily routine and a caffeine-free diet. An indwelling intravenous catheter was placed in one arm of each subject to obtain blood samples hourly, for 48 consecutive hours. Each subject also wore a patient activity monitor (PAM) on the other arm to monitor activity continuously over the same period. The behaviors of each subject (awake, resting, or sleeping) for each hour of the study were observed and recorded. An average 24-hr day was constructed from the data accumulated on the third and fourth day for each subject.

The circadian patterns of plasma melatonin differed significantly between the AD patient and control groups (analysis of variance; $F=2.43$, $df=23$, $p<0.05$); the nocturnal rise in plasma melatonin appeared much less prominent in the AD patients. The oldest subjects were found to have the lowest levels of plasma melatonin, in agreement with previous studies. The 2 AD patients who exhibited the most night-time wandering during the study were found by PAM to have the greatest nocturnal activity, and only modest nocturnal elevations in plasma melatonin. All subjects demonstrated significant diurnal variations in activity; however, the mean activity of the AD patients exceeded those of the control subjects in 21 of 24 hours. Thus, regulation of circadian rhythms may be abnormal in AD, possibly due to hypothalamic dysfunction. We suggest that the PAM may be useful in determining abnormal patterns of activity, and in assessing the efficacy of therapies for ameliorating these behaviors.

290.7 ENTRAINMENT AND DEVELOPMENT OF TOLERANCE OF THE MAMMALIAN CIRCADIAN CLOCK TO DAILY INJECTIONS OF TRIAZOLAM. F.W. Turek, J.-J. Vanderhaeghen and O. Van Reeth*. Lab. of Neuropathology & Neuropeptides Research, Free Univ. of Brussels, Belgium and Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60201.

The recent discovery that a single injection of the short-acting benzodiazepine, triazolam (Tz), can induce pronounced phase shifts in a master circadian pacemaker in hamsters, raises the possibility that repeated daily injections of Tz might be able to entrain a central circadian clock. To test this hypothesis, the circadian rhythm of wheel-running behavior was monitored in blind hamsters injected intraperitoneally with 2.5 mg of Tz (N=8) or vehicle (V,N=10) every day for five days and then every other day for 20 days. The first injection occured 3-6 hrs before the onset of activity and subsequent injections occurred at the same real clock time. Injections of V had no effect on the rhythm. While the first 2-3 injections of Tz induced pronounced advances in the activity rhythm (mean advance= 252$\pm$53 min.), subsequent injections had no effect. In a second study, six blind hamsters were injected every day for 25 days with 2.5 mg of Tz. The first few injections induced a pronounced advance in the activity rhythm (mean advance= 193$\pm$52 min.), but after 3-5 days, the injections had no effect.

In a third study, blind hamsters were injected intraperitoneally with 0.1 mg of Tz (N=10) or V (N=9) every day for 49 days; thereafter, the animals were left undisturbed for an additional 15 days. The timing of the daily injections followed the same pattern as in the first two studies. While injections of V did not induce any clear change in the activity rhythm, the first few injections of Tz induced a pronounced advance of the rhythm in 9 of the 10 animals that averaged 262$\pm$41 minutes. In these 9 animals, daily injections of Tz entrained the activity rhythm for about the first 15 days, and then the activity rhythm of all the animals began to free-run with a period less than 24 hrs. During the last 10 days of injections, the mean period of the activity rhythm for the Tz-treated animals (23.91$\pm$0.02 hrs) was significantly less ($p< 0.001$) than that observed in V-injected animals (24.26$\pm$0.03 hrs). Importantly, this difference in period persisted throughout the 15-days following termination of the injections.

These results indicate that it is possible to entrain a circadian clock for at least a limited time period with daily injections of triazolam. However, the clock becomes tolerant to the phase shifting effects of triazolam and the time course for the development of this tolerance is dose dependent. Furthermore, it is possible to induce major changes in the period of the circadian clock with daily injections of triazolam, and these changes persist for at least 15 days even after the termination of drug treatment. Treatment with a short-acting benzodiazepine can have pronounced and long-term effects on the mammalian circadian clock system.

290.8 TRIAZOLAM FACILITATES REENTRAINEMNT OF CIRCADIAN CLOCK FOLLOWING AN 8-HOUR ADVANCE OR DELAY IN THE LIGHT DARK CYCLE. O. Van Reeth*, J.J. Vanderhaeghen and F.W. Turek (SPON: B. Menco). Lab. of Neuropathology and Neuropeptides Research, Free Univ. of Brussels, Belgium and Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60201.

A single injection of the short acting benzodiazepine triazolam (Tz) can induce permanent and pronounced phase shifts in the circadian rhythm of locomotor activity of hamsters free running either in constant darkness or in constant light. The magnitude and the direction of these phase shifts are dependent on the time when Tz is administrated relative to the onset of locomotor activity. These results suggest that it might be possible to alter the time it takes for the biological clock to resynchronize to a new light schedule after a shift in the light dark cycle.

To test this hypothesis, male golden hamsters housed in individual running wheel cages and maintained on a LD 14/10 cycle were submitted to an 8 hour advance in the LD cycle. On the first or the second day after the light shift, they received a single intraperitoneal injection of vehicle(V) or 2.5 mg Tz 6-7 hours prior to the expected onset of locomotor activity. In the vehicle treated animals, the transient period (i.e. until the onset of activity again occured near the time of lights off) lasted an average of 8.1 days (N=16). The mean transient period was significantly reduced ($p<0.01$) in animals injected with Tz on either the first (3.75 days, N=8) or the second (5.5 days, N=10) day after the shift. Animals injected with Tz on day one reentrained significantly faster ($p<0.05$) than those injected on day two.

In another study, hamsters on a LD 14/10 cycle were submitted to an 8 hour delay in the LD cycle and received an injection of Tz or V 5-6 hours after the expected onset of the activity rhythm on the first day following the shift in the light cycle. The animals received two supplementary injections of Tz or V 24 and 48 hours after the first injection. The transient period necessary before the onset of locomotor activity was again within 30 min of the new LD cycle was 16.9$\pm$1.5 days in the animals treated with V (N=10) and 8.4$\pm$0.7 days (N=10) in the animals treated with Tz ($P<0.001$).

These findings demonstrate that triazolam can markedly reduce the time it takes for a biological clock of the hamster to be resynchronized after a phase advance or a phase delay in the LD cycle. This raises the possibility that, if triazolam can also induce phase shifts in human circadian rhythms, it might be possible to designate appropriate drug therapies for situations in which human circadian rhythms are desynchronized from the external environement, such as occurs during jet lag and shift work.

290.9 TRIAZOLAM ACCELERATES THE ADAPTATION OF THE CIRCADIAN RHYTHM OF CORTISOL TO AN 8-HOUR DELAY OF THE SLEEP-WAKE CYCLE IN MAN. E. Van Cauter*, A. Van Onderbergen*, D. Bosson* and G. Copinschi* (SPON: J. Joy). School of Medicine, Free University of Brussels, B-1070 Belgium and Dept. of Medicine, The University of Chicago, Illinois 60637.

It has recently been shown that triazolam, a short-acting benzodiazepine, can induce phase shifts of the circadian clock of hamsters. The magnitude and direction of these phase shifts depend on the time of drug administration. These findings prompted us to determine whether triazolam, a widely used hypnotic, would accelerate in man the adaptation of the 24-h periodicity of cortisol secretion following an abrupt shift of the sleep-wake cycle.

Six normal male volunteers, aged 21-30 yrs, were studied once with triazolam and once with placebo, in random order. The two studies were spaced 2 months apart. In each study, the 24-h profile of plasma cortisol was obtained at 20-min intervals under basal conditions, as well as 1, 3 and 5 days after an 8-h delay of the usual sleep-wake cycle. This delay was obtained by sleep deprivation from 23:00 to 07:00 on the first day. These conditions mimicked in the laboratory the shift in the sleep-wake cycle experienced in the course of a westward transatlantic flight crossing 8 time zones. A bedtime schedule of 07:00 to 15:00 was enforced for 5 consecutive 24-h periods. The entire study was preceded by 3 nights of habituation to the study unit. Triazolam (0.5mg) or placebo was given at 04:00 on the first shifted night and at 07:00 on the following nights. Best-fit patterns, based on the periodogram method, were calculated for each individual 24-h cortisol profile. Melatonin levels will also be measured on each plasma sample collected in the course of this investigation. The assay is currently under progress and the results will be analyzed and reported in a similar fashion as described here for cortisol.

Adaptation of the 24-hour cortisol profile to the 8-hour delay in the sleep-wake cycle involved an overall alteration of the complex waveshape of the cortisol rhythm. Therefore, the timing of the acrophase and of the nadir, the cortisol level at the acrophase, the total duration of the quiescent period (QP), the fragmentation of the QP and the time corresponding to the end of the QP were determined for each profile and these 6 parameters were combined to calculate a global adaptation index (GAI) to the time shift. On days 1 and 3, the GAI was significantly higher ($p<0.05$) following treatment with triazolam than after treatment with placebo indicating that the administration of triazolam had facilitated the rate of reentrainment of the cortisol rhythm to the 8-hour delay in the sleep-wake cycle. These results suggest that short-acting benzodiazepines may be useful in the treatment of conditions associated with abnormal circadian synchronization, such as occurs during "jet lag" and in shift-workers.

290.10 PHASE RESPONSE CHARACTERISTICS OF FEEDING SCHEDULES IN RATS. G.J. Coleman and R. Francis. (Spon: G.A. Bell) Department of Psychology, La Trobe University, Bundoora, Vic., 3083., Australia.

There is much evidence for a circadian oscillator in the rat which is distinct from the SCN (supra-chiasmatic nuclei) based, light-dark (LD) entrained oscillator (Boulos, Z., Rosenwasser, A. & Terman, M., Behavioural Brain Research, 1:36-65, 1980).

Recently, we have found that the Australian marsupial Sminthopsis macroura froggatti exhibits pronounced phase-shifts in free-running activity rhythms following 3 days of food deprivation (Coleman, G., O'Reilly, H. & Armstrong, S. (Neuroscience Abstracts, 15:816, 1985). It is not known what the mechanism for this phase-shift is nor is it known whether the phase shift is SCN mediated. A close inspection of previously published data from our laboratories (Clarke, J. & Coleman, G., Physiology & Behavior, 36:105-113, 1986) indicates that laboratory rats may also show such phase-shifts in activity rhythms following 3 days of food deprivation. In an unpublished study, we have found that a prior meal-feeding schedule is not necessary for deprivation-induced phase shifts to occur in Sminthopsis macroura froggatti. It remains to be determined whether the time of day at which food is presented followng deprivation has an effect on the induced phase-shift.

Our published data suggest that the phase shift in activity following deprivation occurs on the day at which food is reinstated. Thus the availability of food may serve as the stimulus for the phase shift. This is supported by the data from meal-feeding experiments where a daily presentation of a 2-hour meal could produce a daily phase shift in the meal-associated oscillator thereby producing entrainment as reflected in anticipatory activity.

Two experiments were conducted. In the first, Long Evans rats aged 29 days were maintained on 12:12 cycle LD for 15 days, then placed in constant dark (DD) for 36 days. During DD, rats were deprived of food for 3 days on two occasions. Following reinstatement of food at various times of day, no phase shifts were observed. Rats were then placed in constant light (LL) of 30-40 lux. When a 3-day deprivation was followed by food reinstatement, phase shifts were observed.

In a second experiment, Long Evans rats aged 95 days were placed in a 12:12 LD cycle for 15 days, then LL of 10 lux was introduced. After 15 days LL, all rats were deprived of food for 3 days and food was reinstated at different times of the day, 4 hours apart. Phase shifts in activity were observed, and a phase response curve (PRC) was constructed. This curve was characterized by considerable between-rat variability, and a much longer phase delay component than phase advance.

It was concluded that deprivation induced phase-shifts in Long Evans rats can only occur in LL and that the PRC of food reinstatement is less stable than that for light.

REGENERATION II

291.1 WHITE MATTER ASTROCYTES. DO THEY PRODUCE A NON-PERMISSIVE SUBSTRATE FOR AXONAL GROWTH. A. Bignami, D. Dahl, V. Gilad and G. Gilad. Veterans Administration Medical Center and Harvard Medical School, Boston, MA.

Most observations concerning failure of regeneration in the CNS could be readily explained if myelinated white matter rather than the glial scar constituted an impenetrable barrier for axonal growth: (i) Abortive regeneration in spinal cord tracts following transection. (ii) Extensive axonal sprouting and synaptic reorganization in adult spinal cord and cerebral gray matter following partial deafferentation. (iii) Growth of CNS axons into peripheral nerve graft through glial scars at the brain graft interface. (iv) Inability of regenerating posterior spinal roots to penetrate into spinal cord white matter. (v) Extensive regeneration in two non-myelinated CNS tracts (olfactory nerve and hypothalamohypophysial tract).

If myelinated white matter is in fact an impenetrable barrier for axonal growth, the following characteristics should be expected for the hypothetical repellent: (i) White matter specificity. (ii) Extracellular or cell surface localization. (iii) Late appearance in ontogeny as axons continue to grow until relatively late in development (e.g. cortico-spinal axons only reach the lumbar spinal cord on post-natal day 9 in the rat).

Brain specific hyaluronectin (BHN), the main component of hyaluronectin, a glycoprotein fraction isolated by Delpech and Havalent from human brain by affinity chromatography on hyaluronate-Sepharose (J. Neurochem. 36:855, 1981), appears to fulfill these criteria: (i) White matter specificity; within spinal cord white matter, immunocytochemically localized BHN forms a fine mesh surrounding individual myelinated axons paralleling the distribution of astrocytes as revealed by GFAP localization (Bignami and Dahl, PNAS 83:3518, 1986; J. Neurocytol. 15:671, 1986). (ii) Extracellular or cell surface localization; all hyaluronate-binding proteins so far reported in the literature are either extracellular or cell surface proteins. (iii) Late appearance in ontogeny; BHN first appears in white matter after the onset of myelination.

Experiments conducted in tissue culture are compatible with this hypothesis. Cells dissociated from fetal rat spinal cord or postnatal rat cerebellum were seeded on coverslips coated with polylysine on one half and with a hyaluronectin preparation on the other. Poor cell attachment was observed and neurite outgrowth was blocked on hyaluronectin. Neurites, which grew abundantly on the polylysine substrate, did not extend to the hyaluronectin coated surface. Thus, if BHN fills the space between myelinated fibers, it would effectively prevent axonal growth. Supported by N.I.H. grant NS 13034 and by the Veterans Administration.

291.2 PROTEINS OF RAT CNS WHITE MATTER AND OF MYELIN FORMING OLIGODENDROCYTES ARE POTENT INHIBITORS OF NEURITE OUTGROWTH AND OF CELL LOCOMOTION. P. Caroni* and M. E. Schwab. Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland.

Extensive neurite outgrowth is not found in differentiated CNS tissue of higher vertebrates. Lacking favorable substrates, trophic factors or presence of inhibitors are possible underlying mechanisms.

Primary cultures of dissociated rat optic nerve contain cells which are strictly avoided by growing neurites as well as by migrating fibroblasts. Such cells are identified as myelin forming oligodendrocytes, as they are $GalC^+$, mAb $A_2B_5^-$, mAB O_4^+, and myelin basic protein positive. Myelin fractions from rat spinal cord adsorbed to PLYS-coated culture dishes represent a highly non-permissive substrate for neurite outgrowth for sensory and sympathetic neurons in presence of NGF, and for neuroblastoma cells stimulated with dibutyryl cAMP. Likewise, spreading of a number of cells, including 3T3-fibroblasts was inhibited. Non-permissivity is not found in PNS myelin fractions nor in cell membrane fractions from other tissues and is completely abolished by mild proteolysis. Non-permissive substrate components can be extracted with detergent and reconstituted in highly active form in artificial lipid vesicles. Active vesicles are formed from SDS-PAGE separated proteins of about 250kD and 30kD. Spreading-inhibiting proteins are effective in amounts lower than 10 ng/cm^2 of culture dish. High yields of active proteins are recovered from inhibitory oligodendrocyte-containing cultures, but not from Schwann cell cultures nor from a number of tissues including liver, kidney, and skeletal muscle. Addition of 250kD proteins to permissive liver or PNS myelin protein in ratios of up to 1/100 and subsequent reconstitution results in inhibitory mixed liposomes. Monoclonal antibody against 250kD inhibitor protein weakly but specifically stains the surface of myelin-forming oligodendrocytes in culture. Antibody adsorbtion partially neutralizes inhibition of cultured oligodendrocytes and of CNS myelin. Inhibitor protein is insoluble in the absence of detergent and is not a highly negatively charged proteoglycan. We hypothesize that such inhibitors might effectively prevent neurites from growing along "mature" CNS fiber tracts.

291.3 TISSUE CULTURE STUDIES INDICATE THAT MYELINATION BY OLIGODENDROCYTES OBTAINED FROM ADULT TISSUE IS SUPPRESSED BY ASTROCYTES. C.L. Rosen, P.M. Wood* and R.P. Bunge, Depts. Biol. and Anatomy/Neurobiol., Washington University, St. Louis, MO 63110.

Whereas remyelination is known to occur in the central nervous system (CNS), the degree of remyelination varies after different demyelinating injuries. Because the tissue response to demyelinating injury in the CNS often involves astrocytes (AS) as well as oligodendrocytes (OL), the role of the AS in fostering or inhibiting remyelination has been debated. The influence of AS on OL function was assessed by comparing OL proliferation and myelination in cultures of neurons and added purified adult OL (N+OL) with and without added purified type I AS (N+OL+AS). Pure neuronal cultures were prepared from embryonic rat dorsal root ganglia (Wood and Williams, Dev. Brain Res. 12:225, 1984). OL (immunostained for galactocerebroside) were purified by fluorodeoxyuridine treatment of crude glial cultures prepared from adult rat spinal cord and contained fewer than 2% AS (immunostained for glial fibrillary acidic protein). AS were purified from postnatal rat cerebral cortex (Noble et al., J. Neurosci. 4:1892, 1983). After preparation of the neuronal cultures, they were seeded with 10^5 purified OL; 1-2 weeks later AS were added to some of those N+OL cultures. After an additional 4-5 wks the cultures were stained with Sudan black and the number of OL and the amount of myelination determined by light microscopy.

Extensive OL proliferation and myelination was observed in control N + OL cultures which contained at most a few 100 AS. Very few OL and essentially no myelination was seen in N+OL+AS cultures which contained a monolayer of confluent AS. To determine if this inhibition of ODC function was mediated by cell contact or by soluble factors, OL proliferation and myelination were studied in N+OL cultures fed with type I AS conditioned medium treated to restore original nutrient levels (ACM). In addition, OL function in dialyzed ACM and boiled ACM was assessed. The results showed that factors in ACM effectively blocked OL proliferation and myelination. In dialyzed ACM the number of OL was nearly the same as in controls but myelination was only slightly improved. In boiled ACM the number of OL remained low and only a little myelin was seen. These results suggest that type I AS release at least 2 factors which can affect OL functions: one with a MW of $< 10{,}000$ which blocks OL proliferation, and another with a MW of $> 10{,}000$, which is heat stable, and blocks myelination. In this culture system type I AS suppress OL function; because this suppression appears to be mediated by a soluble agent it may be possible to isolate and identify the responsible factor(s). (Supported by RG1118 from the National Multiple Sclerosis Society.)

291.4 PREFERENTIAL REINNERVATION OF MOTOR NERVES BY REGENERATING MOTOR AXONS. T.M.Brushart.Dept. of Orthopaedics, Johns Hopkins Hospital, Baltimore, Maryland 21205.

Regeneration of axons into inappropriate Schwann cell tubes may adversely affect the outcome of peripheral nerve suture. However, the degree to which motor axons reinnervate sensory Schwann cell tubes, and vice versa, has not been determined. These experiments quantify the sensory and motor neurons regenerating across a proximal nerve suture into terminal sensory and motor branches. The rat femoral nerve was cut and sutured proximally where sensory and motor axons intermingle. Horseradish peroxidase (HRP) was then applied distally to the sensory or motor branch to identify reinnervating neurons.

Four experimental groups each contained 20 female Sprague-Dawley rats: adult (12-14 wks, 250 gms), juvenile (3 wks, 50 gm), adult rotation, and juvenile rotation. In adult and juvenile groups both proximal femoral nerves were severed, precisely realigned, and sutured, while in the rotation groups the distal stumps were rotated 90° before suturing. Eight weeks were allowed for regeneration. HRP was then applied to one sensory branch and the opposite motor branch. Animals were perfused with fixative 48° later and the lumbar spinal cords and dorsal root ganglia were sectioned at 80u and processed with tetramethyl benzidine to demonstrate HRP within neurons. Labeled cells were counted by an observer unaware of which branch had received HRP, and the counts were subjected to paired T test analysis. Control experiments determined the number of sensory and motoneurons innervating the femoral nerve in normal animals and the number and total axoplasmic area of myelinated axons in the sensory and motor branches.

More motoneurons were labeled from the motor branch than from the sensory branch in all groups; the difference was significant for juvenile ($p = .0002$) and juvenile rotation ($p = .029$) animals. Sensory neuron labeling was significantly greater from the sensory branch in all groups ($p = .016$). The motor findings suggest a specific interaction between regenerating motor axons and Schwann cell tubes leading to the motor branch. The sensory findings could be a random response to the greater number of myelinated axons in the sensory branch, and are thus more difficult to interpret.

Preferential motor reinnervation was significant in juvenile animals but not in adults. The superior results of nerve suture in children, previously attributed to age-related central reorganization, may therefore also reflect peripheral factors. Definition of the precise mechanism of preferential motor reinnervation and its augumentation, especially in adults, could improve the prognosis of injury to nerves containing both sensory and motor axons.

291.5 TEMPORAL CHARACTERIZATION OF FUNCTIONAL RECOVERY IN MICE AFTER SCIATIC NERVE REPAIR WITH BIORESORBABLE GUIDES. M. Tang*, Psychology Dept., Rutgers Univ., New Brunswick, NJ 08903, R. Madison & R. Sidman, Neurosci. Dept., Harvard Med. School, Boston, MA 02215, F. Mares* & R. Tang*. Polymer Lab., Corp. Tech., Allied-Signal Inc., Morristown, NJ 07960.

The objective of repairing damaged nerves is to restore function to the affected parts. Except for EMG data, there is sparse information on recovery of function following reconnection of peripheral axons. We now report an attempt to characterize temporally the recovery of sensory motor functions following sciatic nerve repair with bioresorbable polymer nerve guides (Guides 0A1 and 0B1, Allied-Signal Inc.).

24 adult, male C57BL/6J mice were trained to walk on a revolving plane (motor function). Latency to withdraw from a 104^{o}F stimulus was also determined for both hind limbs (sensory function). After training, the sciatic nerve was exposed and transected at mid-thigh. The two stumps were sutured into 0A1 or 0B1 bioresorbable nerve guides (N=8 ea.) to yield a final gap distance of 4mm. Solid guides were used for the remaining 8 mice to prevent regeneration (negative control).

Motor functions were severely affected (40-60%) in all animals at 3 weeks post-surgery. Performance of the 0A1-guide mice recovered fully to pre-surgical levels by the 12th week. Animals with the 0B1 guide recovered to only 80%, even by week 24. Slight improvement was noted in the negative controls, probably due to practice effects. Correlation (r) between motor function and the # of myelinated axons in the regenerated nerve cable revealed S-shaped functions for both repaired groups. Sensory functions recovered steadily throughout the 24-week period to a mean of 85 and 94%, but negative controls, although showing insignificant sensory improvements initially, achieved similar levels of recovery by week 24. For all groups, zero-order r's were obtained between the degree of sensory recovery and the number of myelinated axons.

These data suggest that 1) sensory recovery is independent of regeneration and probably reflects collateral innervation, 2) regenerated nerves support motor function, the degree of recovery dependent on the type of guide and 3) a critical number of regenerated axons is needed before motor function recovers.

291.6 IDENTIFICATION AND CHARACTERIZATION OF cDNA CLONES TO GENES ASSOCIATED WITH PERIPHERAL NERVOUS SYSTEM REGENERATION. H.D. Shine, A.W. Sandrock, W.D. Matthew and L. Villa-Komaroff. Depts. of Neuropath. and Neurobiol., Harvard Med. School and Dept. of Neurosci., Children's Hospital, Boston, MA 02115.

Axons of the peripheral nervous system (PNS) readily regenerate after injury in response to molecules in the PNS environment. While well characterized molecules such as laminin may play important roles, evidence suggests that the regenerative capacity of the PNS is mediated by molecules not yet defined. We have used a combination of hybridoma and molecular biological technologies in an effort to identify and characterize novel regeneration-associated molecules.

To identify molecules resident in the regenerating PNS that may support axonal regeneration a panel of monoclonal antibodies was raised to molecules differentially expressed during regeneration. Mice were tolerized by immunizations with a crude preparation of normal rat peripheral nerve concurrent with injections of the anti-mitotic agent, cyclophosphamide. The mice were then re-immunized with a crude membrane preparation of peripheral nerve that had been cut 4 to 7 days before removal and their spleen cells fused with myeloma cells to produce hybridomas. One antibody, designated RN3B3, localized to Schwann cell basal lamina and blocked axonal growth in a bioassay (Matthew and Sandrock, Neurosci. Abstr. 11:1254, 1985).

To characterize the RN3B3 antigen we used the antibody to identify cDNA clones in an expression library that should contain its message sequence. The cDNA library was created in the bacteriophage lambda gtll to mRNA isolated from developing (1 day-old) rabbit peripheral nerve. The use of the lambda gtll system permits identification of clones of interest by immunochemical means in addition to standard DNA-DNA hybridization methods. Rabbit neo-natal nerve was used to insure that enough tissue was available for efficient mRNA isolation. We reasoned that genes expressed during nerve regeneration would be expressed during development. Immunocytochemical analysis demonstrated that RN3B3 stained neo-natal sciatic nerve. Twenty-two clones were identified via immunochemical screening of approximately 500,000 recombinant bacteriophage. Single-strand probes generated from the sequences recognize message in peripheral nerve and in other tissues shown to immuno-stain with RN3B3. Their sequences are not homologous to sequences presently in the GenBank data base suggesting that they represent novel proteins.

291.7 A TUBULAR PROSTHESIS FOR NERVE REPAIR: EFFECTS OF BASEMENT MEMBRANE MATERIALS, LAMININ, AND POROSITY. R. Madison. Departments of Neuropathology and Neuroscience, Harvard Medical School, Childrens Hospital, Boston, Ma. 02115.

Since Bunger's initial report in 1891, entubulation repair has been used to repair severed peripheral nerves. Although many different materials have been used to fabricate such prostheses, none have yielded completely satisfactory results. The current study used nerve conduits fabricated from collagen materials and assessed the effects of porosity, and laminin alone or in conjuction with other basement membrane components. Purified laminin was obtained from human placenta. Laminin in conjunction with other basement membrane components (Matrigel, Collaborative Research) was a generous gift of Drs. Kleinman and Martin, NIH.

Thirty-two adult C57BL/6J male mice, four in each of eight groups, received sciatic nerve transections and entubulation repair as detailed previously (Madison et. al., Exp. Neurol., 95:378-390, 1987). Collagen based nerve conduits were fabricated by American Biomaterials Corporation, Plainsboro, N.J. (see also abstract by Shu-Tung Li). Four weeks following entubulation repair animals were perfused with fixatives, the nerve conduit dissected out, and processed for plastic embedding. Semi-thin sections were cut at mid-tube level, stained with toluidine blue, and the number of myelinated axons was determined with a computer assisted microscope. The number of myelinated axons for each group (mean ± std. dev.) is given in brackets following the description of the particular nerve conduit.

All nerve conduits consisted of Type I collagen and/or the following: 1)collagen alone with small pores, (see abstract by Shu-Tung Li) [861±462]; 2)#1 plus purified laminin protein 1:1 (W/W) [1358±454]; 3)#1 plus purified laminin protein 7:1 [1319±96]; 4)#1 plus Matrigel 2:1 (W/W) [1022±506]; 5)#1 plus Matrigel 1:1 [1511±172]; 6)#1 plus Matrigel 1:5 [1505±146]; 7)collagen alone with large pores [3963±1990]; 8)control unoperated mice [3851±196].

The results suggest that increasing concentrations of Matrigel added to Type I collagen nerve conduits or increasing their porosity increases the number of myelinated axons regenerating across the transection site. Analysis of variance and Student-Neuman Keuls comparisons shows only the large porous conduit group to be significantly different from the others. Retrtograde labeling studies are in progress to determine if this increase in the number of myelinated axons represents a greater number of primary motor and sensory neurons that are able to send an axon through the nerve conduit. Supported by NIH grant NS22404.

291.8 Porous Collagen Nerve Conduits for Nerve Regeneration: In Vitro Characterization Studies. Shu-Tung Li (SPON: M.E. Frank) American Biomaterials Corporation, Plainsboro, NJ. 08536

It is well recognized that the functional recovery of an injured nerve depends on the cellular environment. In order to facilitate nerve regeneration, collagen-based tubular guiding conduits were developed. This study was specifically designed to test the effect of the membrane permeability of the guiding conduit on nerve regeneration. I report here the results of in vitro characterization studies of the conduits. The results of in vivo performance of these conduits will be presented in the following paper by Dr. Roger Madison.

Tubular nerve conduits with different pore sizes were fabricated from purified bovine tendon collagen. In order to eliminate material related variations, collagen prepared from the same batch was used to fabricate both types of conduits. Surface and cross-sectional morphology were examined by scanning electron microscopy (SEM). The permeability of the membrane to glucose (MW=180) and to bovine serum albumin (BSA) (MW=68,000) was measured as follows: The collagen conduits of various diameters were filled with a .25%(w/v) glucose or a 1% BSA solution in 0.9%NaCl. The ends of the conduits were ligated and the conduits were then incubated in 15-20 ml of the same solution in the absence of the molecules of interest. The diffusion of glucose and BSA across the membrane was measured spectrophotometrically. Anthrone was used as a reagent for glucose and Coomassie Brilliant Blue G-250 was used as a dye reagent for BSA.

SEM of the small pore conduit showed a uniform structure throughout the cross-section of the conduit membrane. SEM of the large pore conduit showed a two-layered structure, a thin inner layer with tightly packed collagen fibers and an outer layer of open structure. The lumen surface of the small pore conduits had a typical film-like morphology. The lumen surface of the large pore conduits consisted of bundles of collagen fibers intermingled in a multi-layered mesh structure. The results of permeability studies showed that both types of conduits were permeable to glucose. The equilibrium concentration was reached in one hour and six hours for the large pore and small pore conduit, respectively. However, only the large pore conduit was permeable to BSA. Approximately 50% of the BSA diffused across the large pore conduit in 24 hours, whereas none of the BSA diffused across the small pore conduit.

The selective permeability of the conduit membrane to molecules of a defined size provides an experimental tool to investigate the effect of the local cellular environment on nerve regeneration in a systematic, quantitative and mechanistic manner.

291.9 D.C. ELECTRICAL FIELDS DO NOT INFLUENCE MOTOR RECOVERY FOLLOWING RAT TIBIAL NERVE TRANSECTION. J.M. Kerns and J.A Gramm . Department of Anatomy, Rush Medical College, Chicago, IL 60612

Our previous studies have shown that D.C. electrical fields promote the early stages of nerve regeneration following sciatic neurectomy. In the present study, we sectioned only the tibial nerve branch on both sides in eight adult rats to prevent toe-chewing. The nerves were anastomosed with 10-0 sutures. The treatment side received a battery implant delivering 10 uA to the lesion site with the cathode distal, while the contralateral control side had a neutral implant. The twitch tension of the digital flexors was monitored at weekly intervals and compared to preoperative values. At 77 dpo the battery was removed and both distal tibial branches were dipped in HRP for 1 hr, with a 72 hr period prior to perfusion fixation. The lumbosacral spinal cord was removed and sectioned (50 um) for TMB incubation and motoneuron cell counts. At no time during the recovery period was there a side difference in the twitch tension amplitude. The relative index of recovery at 77 dpo was 0.66 (0.05) and 0.61 (0.03) for the treated and untreated sides respectively. This corresponds to a mean ratio of 1.10 (t=0.96). At 80 dpo the mean number of labeled motoneurons was 1372 (68) on the treatment side and 1306 (33) on the no-treatment side. Again, the ratio between sides of 1.06 was not significantly different (t=0.9). The results from these two analytical methods had a correlation coefficient of 0.60. We conclude that the motor recovery in a single nerve fascicle which is transected and conventionally repaired, is not enhanced by the application of a continuous D.C. electrical field at the delivered dose. These and other experimental models and methods are being investigated further. Supported by NIH grant NS 19769 and BRSG S07 RR05477.

291.10 NERVE REGENERATION CHANGES WITH FILTERS OF DIFFERENT PORE SIZE. C.B. Jenq, L.L. Jenq* and R.E. Coggeshall Marine Biomed. Inst. and Depts. Anat. & Neurosci. and Physiol. & Biophys., Univ. Tex. Med. Br., Galveston, TX 77550.

An experimental reason for placing stumps of a transected nerve in an impermeable tube is that substances derived from the nerve stumps are pooled and separated from cells and soluble substances in the body in general. Our previous work showed that regeneration was improved when the impermeable tube was made permeable by cutting macroscopic holes in its side. To begin exploring the reasons for the improvements, we covered the holes in the perforated tubes with filters of 2 different pore sizes, 5.0 µm and 1.2 µm, and quantitated the regenerated axons in the present study. The results shown in the following table are myelinated (MY) and unmyelinated (UN) axon counts from rat nerves at 8 weeks after the sciatic nerves were transected and the stumps separated with an 8mm gap.

(SCIATIC: sciatic nerve. SURAL: sural nerve. NMG: medial gastrocnemius nerve)

In the paradigm with the 5.0 µm pore size, cells from the connective tissue space invaded through the millipore filter and mingled with the regenerated nerve in the tube, whereas with the 1.2 µm pore size, no cells were found in the filter. These findings suggest that cells from the general connective tissue should be considered when designing experimental procedures to maximize the regeneration potential of regenerating axons. (Supported by Muscular Dystrophy Association, NIH grants NS17039, NS11255, and the Florence and Marie Hall Endowment).

291.11 PREPARATION OF ACELLULAR NERVE FOR GRAFTING BY COCULTURE WITH MACROPHAGES. A.K. Gulati*, A. M. Behzadian* and T.R. Swift* (SPON: M.J. Mulroy). Departments of Anatomy and Neurology, Medical College of Georgia, Augusta, GA 30912.

It has been proposed that a suitable graft material for peripheral nerve gap repair be composed of basal lamina tubes lying parallel to one another. Earlier methods used in preparing such grafts have included various chemical and mechanical treatments. The present study describes an in vitro method to prepare acellular basal lamina nerves by coculturing them with macrophages. Inbred Fischer rats were used and under chloral hydrate anesthesia the sciatic nerve was cut to allow in situ degeneration. Six to eight weeks later the degenerated tibial and peroneal nerves were removed and cut into 1 cm pieces. Some of these nerves were repeatedly frozen in liquid nitrogen and thawed and then placed individually in culture dishes with RPMI medium supplemented with 20% fetal bovine serum. Five million peritoneal macrophages obtained from another Fischer rat also were included in each dish. The remaining nerves were not frozen and thawed but placed in culture as above for comparison. Nerves for each group were removed after 1,3,5,7 and 12 days in culture for light and electron microscopic analysis. Schwann and perineurial cells in forzen and thawed nerves disintegrated and their cellular debris absorbed by the cocultured macrophages. By 7 days in culture these nerves were completely devoid of cellular elements. However, basal lamina of Schwann cell and perineurium persisted as hollow tubes as determined by laminin antibody staining and electron microscopy. Presence of well organized collagen fibrils was also observed in the endoneurium and perineurium. Analysis of cultured nerves which were not frozen and thawed revealed presence of many Schwann cells, arranged in columns, as well as perineurial cells. Presence of basal lamina and collagen fibers was also observed in the endoneurium and perineurium of unfrozen nerves. These results show that nerves devoid of any cellular structures but composed of basal lamina and connective tissue can be prepared after in vitro coculture with macrophages. Nerves prepared by this in vitro method may serve as suitable graft material for peripheral nerve gap repair.

291.12 CONDUCTION PROPERTIES OF NERVE FIBERS REGENERATED ACROSS GAP BRIDGED BY BIODEGRADABLE POLYMER MATRIX I.V. Yannas,* C. Krarup,* A. Chang,* T.V. Norregaard,* N.T. Zervas, and R. Sethi.* Fibers and Polymers Lab., Mass. Inst. Technology, Cambridge MA 02139, Division of Neurology, Brigham and Women's Hospital, Boston MA 02115 and Division of Neurosurgery, Mass. General Hospital, Boston MA 02114.

An electrophysiological procedure has been used to monitor the extent of physiological recovery of rat sciatic nerve which was cut, generating a 10-mm gap. The gap was grafted with a silicone tube filled with a highly porous, biodegradable collagen-glycosaminoglycan (CG) polymer. A previous study showed that regeneration of a morphologically adequate nerve occurred across a 15-mm gap in silicone tubes which contained CG polymer but not in empty tubes (Yannas, I.V., Orgill, D.P., Silver, J., Norregaard, T.V., Zervas, N.T. and Schoene, W.C., Trans. Soc. Biomaterials 8:146, 1985). Maximal electrical stimulus pulses, 0.1 ms in duration were delivered to the regenerating nerve at the sciatic notch near the hip and at the tibial branch near the ankle. The recording electrode (concentric needle electrode, TECA CF-25) was placed in the plantar muscles. Action potentials were photographed from an oscilloscope. We followed the restoration of conduction in longitudinal studies in a group of 7 rats which were grafted with a silicone tube filled with CG polymer. These rats were grafted contralaterally with empty silicone tubes (controls). No response was registered in the first measurement, performed 3 wks after surgery. The first response was recorded with filled tubes at about 11 wks. Only one of the empty tubes showed evidence of regeneration, about 14 wks after surgery. When a response was first recorded the distal motor latency was 2-3 times longer than normal, the conduction velocity across the gap was less than 40% normal and the amplitude of these early responses averaged less than 5% normal. In subsequent measurements the distal motor latency gradually recovered to near normal, the conduction velocity to near 60% normal and the amplitude recovered to about 20% normal. Even after 25 weeks of follow up only one of the 7 empty tubes showed evidence of regeneration. We conclude that the procedure described adequately monitors the restoration of conduction in the sciatic nerve. These results extend earlier morphological findings on the ability of certain CG polymers to support regeneration of sciatic nerve across a long gap.

VISUAL CORTEX V

292.1 **FLATTENING VISUAL CORTEX AT IMAGE RESOLUTION: QUANTITATIVE COMPUTER RECONSTRUCTION OF THE MACAQUE OCULAR DOMINANCE COLUMN PATTERN** *E.L. Schwartz, A. Shaw* and D. Weinshall** Computational Neuro. Lab. NYU Med. Ctr. 550 1st Ave NY NY 10016 and Courant Inst. of Math. Sciences.

We have previously described an algorithm designed to flatten cortex with minimal distortion or error [1]. This algorithm operates on a three dimensional polyhedral model of the surface of cortex, composed of perhaps several thousand small triangles. This level of detail is sufficient to provide a good approximation to the surface geometry of a cortical structure. However, the level of detail of a polyhedral model (e.g. roughly .5 mm^2) is not sufficient to represent details such as the columnar pattern of V1.

In the present work, we describe an algorithm for constructing an image resolution flattening of Macaque visual cortex. We illustrate this algorithm with a specimen of (Macaque) striate cortex, stained for cytochrome oxidase following enucleation of one eye. The cytochrome oxidase data from coronal sections cut at 40 μ clearly indicated the ocular dominance column pattern. The design goal was to reconstruct this pattern, at the full 40 μ resolution of the digitized sections, in three dimensions. A polyhedral model of striate cortex was then constructed from these data and it was numerically flattened. This yielded a planar model of the cortex, for which the median distance error was 5%. Next, a three dimensional model of layer IV of the stained cortex was constructed. This procedure required the construction of the full three dimensional cortical model at image resolution, and then the use of a "brain peeler" or digital tangential microtome, to "peel" lamina of the model cortex until layer IV was isolated as a thin (40μ) three dimensional section. A computer graphic of a "peel" representing much of the occipital pole will be demonstrated. Finally, the 3D "brain peel", which is a digital image of stained layer IV of cortex, was image mapped into the flattened two dimensional model of the cortex. The result of these steps was a two dimensional image of the ocular dominance column pattern of striate cortex, at 40μ resolution, with 5% metric error. The cortical representation of the optic disk, as well as full details of the columnar pattern, are clearly produced.

This work represents the completion of a system of computer aided neuro-anatomy, which is adequate to manipulate cortical specimens on the scale of an entire occipital pole, at a level of detail sufficient to resolve functional architecture, in both three dimensions and two dimensions. This work allows questions related to the metric structure of visual cortical areas (e.g. topography, columnar geometry, etc.) to be studied with full quantitative rigor.

292.2 **A NEW METHOD FOR MEASURING THE VISUOTOPIC MAP FUNCTION OF STRIATE CORTEX:VALIDATION WITH MACAQUE DATA AND POSSIBLE EXTENSION TO MEASUREMENT OF THE HUMAN MAP** *D. Weinshall * and E. L. Schwartz(SPON:E. Flamm)* Computational Neuro. Lab. NYU Med. Ctr. 550 1st Ave NY NY 10016 and Courant Inst. of Math. Sciences.

The observation and measurement of the visuotopic map of primate visual cortex is a classical experimental activity. A number of psychophysical (e.g. vernier acuity, visual acuity, Panum's area, stereo acuity, motion thresholds) and anatomical (e.g. retinal cell densities) measurements bear at least a qualitative relationship to the presumed curve of cortical magnification. However, there is no accurate and direct method for estimating human magnification factor; and even for the case of monkeys, where microelectrode and 2DG experiments have been performed, there is still uncertainty in this area. What is the correct functional form for the primate map? What is the variance of this estimate across a population?

In order to address these issues, we have constructed [1] a computer generated planar approximation to the surface of Macaque striate cortex (median flattening error = 5%). This eliminates errors associated with cortical surface curvature. We then implemented a numerical algorithm which generates the unique isotropic map from the retinal hemisphere to the surface of the cortex, constrained by a single interior point (e.g. the representation of the optic disk) and a direction at this point. We used this algorithm to analyze three different hemispheres (one from our lab, computer flattened; and two from previously published data from other labs). The same analysis was used in each case, which was based on the assumption that the striate map is isotropic (i.e. conformal: this means that magnification factor does not depend *locally* on direction). Although the assumption that Macaque V1 is locally isotropic is the basis of this analysis, this is an assumption which is supported, at least approximately, by several recent experimental studies [2]. We further support this conclusion by showing that the variance and range of map parameters generated by our numerical/anatomical method is comparable to those between existing microelectrode studies. In other words, given as data a flattened V1 and a single topographic location (and direction) within it, we are able to numerically estimate cortical magnification about as well as other existing methods.

Since our numerical-anatomical method is similar in its results to current micro-electrode measurements of V1 topography, it should be possible to apply this method to human visual cortex, and to obtain an estimate of the human map function with a precision which is comparable to current measurements of magnification factor in monkeys.

[1]E. Schwartz and B. Merker. IEEE Comp. Graph. and App. 6:36-44 (1986)
[2]A particular conformal map, based on the complex logarithm, has been stated to be a good approximation to the V1 map in a number of recent experiments: Dow et al, J. Neurosci. 5:890-902; Van Essen et al, Vis. Res. 24:429-448; Tootel et al, Science 227:1066.

292.3 EMERGENCE OF CYTOARCHITECTONIC DIFFERENCES BETWEEN AREAS 17 AND 18 IN THE DEVELOPING RHESUS MONKEY.

R.W. Williams, K. Ryder*, and P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

There are striking differences in laminar patterns of neurons in areas 17 and 18 of primate neocortex. In addition to qualitative differences between these visual areas, it has been reported that the number of neurons in 30-μm-wide columns of cortex is about 2.5 times greater in area 17 than in area 18 of adult monkeys (Rockel et al., Brain **103**:221, 1980). We have used computer-aided methods to study the emergence of cytoarchitectonic differentiation of these two areas in developing rhesus monkeys, and have tested the possible contributions of neuron death and differential expansion of cells and neuropil in the development of this marked cortical heterogeneity.

Comparisons of neuron number and density were made in areas 17 and 18 of twelve monkeys ranging in age from embryonic day E80 to birth (E165), in 4 neonates, and in 10 adults. Particular care was made to quantify sites on single sections in which curvature of occipital cortex was minimal. Sites were generally 1 to 2 mm on either side of the 17-18 border. Video-enhanced differential interference contrast microscopy, in combination with a video-overlay system, was used to get accurate counts of Nissl-stained neurons. Series of adjacent fields, 30-μm wide, extending through the full thickness of cortex were counted and summed.

We found that at maturity the number of neurons per radial probe is on average 1.5 times greater (range from 1.3 to 2.2) in area 17 than in area 18 of ten adult monkeys. Variation in the ratio of neurons per radial unit is substantial. No relation was evident between the ratio and the retinotopic locale that we examined. The higher values in area 17 are mainly due to the greater density of neurons in the supragranular layers II and III, and to a lesser degree to a greater density of neurons in sublaminae of layers IV and VI. As early as E85 the boundary separating 17 and 18 can be recognized in Nissl-stained tissue, nearly two weeks before the last neurons destined for layers II and III have been generated (Rakic, Science **183**:425, 1974). At this age there is a clear distinction between layers V and VI in areas 17 and 18. Nonetheless, counts between E85 and E99 revealed no consistent difference in the number of cells per radial unit in 17 and 18 (n=4). Ratios ranged from 0.9 to 1.1. In contrast, in prenatal animals between E118 and birth (n=5), the 17-18 ratio was only slightly less than the adult average (1.4 vs 1.5). The ratios appear to change most rapidly over a period of less than 1 month—from E100 to E120. This change is associated with the breaking up of the undifferentiated cortical plate into layer IV and its sublaminae, with the emergence of the supragranular layers, and with expansion of the deep cortical layers. The quantitative changes between areas 17 and 18 are not due to the selective elimination of neurons in area 18 since cell death is insignificant prior to E118 in both areas. Furthermore, the incidence of cell death is somewhat greater in area 17 than in area 18 in cases examined at E118 and E128, and is largely limited to supragranular layers.

The emergence of cytoarchitectonic differences between areas 17 and 18 correlates well with the ingrowth of thalamic fibers into the cortical plate (Rakic, Nature **261**:467, 1976) and with the emergence of the mature pattern of cellular lamination. The results indicate that the quantitative difference between area 17 and area 18 is due principally to a differential increase in neuropil that causes greater horizontal (areal) expansion of area 18 than of area 17 between E100 and E120.

292.4 DISTRIBUTION, DENSITY AND ULTRASTRUCTURE OF SYNAPSES IN THE VISUAL CORTEX IN MONKEYS DEVOID OF RETINAL INPUT FROM EARLY EMBRYONIC STAGES.

J.-P. Bourgeois and P. Rakic, Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven, CT 06510.

Early bilateral enucleation in rhesus monkey embryos markedly reduces the number of geniculocortical axons and surface area of the striate cortex, but has little effect on its thickness, cytoarchitectonic layering pattern (Rakic and Williams, Abstr. Soc. Neurosci., '86), or on the laminar distribution of several neurotransmitter receptors (Rakic et al., Abstr. Soc. Neurosci., '87). Here, we examine the effect of this procedure on synaptoarchitecture of the striate cortex.

Binocular enucleation was performed at embyonic (E) days E67 and E59, prior to the growth of geniculocortical fibers into the developing cortical plate (Rakic, '76, Nature, 261:467). Fetuses were returned to the uterus, delivered at term (E165) and sacrificed at 3 months and 3 years, respectively. In experimental animals and in age-matched controls, 3 to 6 vertical probes were prepared. Each probe consisted of about 100 overlapping electron micrographs spanning the thickness of the cortex in the posterior bank of the calcarine fissure. All synapses were counted and classified according to our standard protocol (Bourgeois and Rakic, Abstr. Soc. Neurosci., '83). In agreement with the previous study, the striate cortex had normal thickness, and a normal complement of layers and sublayers. The mean density of synaptic contacts per unit of neuropil across all cortical layers in the striate cortex of the two operated animals was similar to that in their corresponding age-matched controls (ca. 30 contacts per 100um^2 of neuropil). The proportions of synaptic contacts on dendritic spines (ca. 75%) and shafts (ca. 25%) were unchanged in all cortical layers of enucleated animals, except in layer IVC of the 3 year-old operated animal, where these proportions were reversed. The proportion of symmetric versus asymmetric synapses and their mean length was within the normal range of variability. The normal range of density, size and proportion of synapses in area 17 of early enucleates came as a surprise given that the number of geniculate neurons which project to the striate cortex was drastically reduced and that they never received any information from the retina. However, the results are in harmony with findings of similar synaptic densities recorded in functionally and anatomically distinct cytoarchitectonic areas that receive different types and amounts of thalamic input (Rakic et al., Science, '86, 232:232). Our observations indicate that the density of synaptic contacts per unit of neuropil may develop to a certain optimal level in the cortex, regardless of the number or type of thalamocortical connections and their functional properties. Supported by EY02593 and Program Project NS22807.

292.5 INNERVATION OF MONKEY STRIATE CORTEX BY PHYSIOLOGICALLY IDENTIFIED AND HRP-FILLED THALAMOCORTICAL AFFERENTS

T.F.Freund[1,2], K.A.C.Martin[2], I.Soltész[1,2], P.Somogyi[1,2] and D.Whitteridge[2] (SPON: Z.Henderson) [1]1st Dept. Anatomy, Semmelweis University, Budapest, Hungary, and [2]MRC Anatomical Neuropharmacology Unit, Dept. Pharamcology, Oxford, U.K.

Single thalamocortical axons were recorded in the white matter or layer VI of the monkey striate cortex, and visualized by intraaxonal injection of HRP. Two axons were characterized - on the basis of their response to visual stimuli - as originating from magnocellular (MA) and two from parvocellular (PA) LGN neurons. Camera lucida or computer-assisted three dimensional reconstruction of the axons revealed that the MA axons had extensive arbors in layer IVCα, forming 2-3 distinct clumps at 200-400μm intervals, each being 400-800μm in diameter, elongated in the anteroposterior direction. The PA afferents terminated in layer IVCβ. One of them had two 150-200μm diameter clumps with approximately 200μm interval, the other had a single arbor of 200μm diameter. Collaterals to layer VI from both types of afferents were very sparse. The MA axons had at least twice as many boutons as the PA axons. Electron microscopy of 272 (115 MA, 157 PA) boutons of these axons revealed that all gave at least one synapse in case of both axons. The maximum number of synaptic contacts made by a single bouton was 5. The average number of synapses per bouton was found to be higher for the MA afferent (2.03) than for the PA axon (1.79). Most postsynaptic elements were tested for GABA in immunoreactivity by a postembedding immunogold procedure.

MA afferents				PA afferents			
Total	Somata	D.shafts	Spines	Total	Somata	D.shafts	Spines
229	3(1.3)	108(47.2)	118(51.5)	224	7(3.1)	74(33.0)	143(68.9)
				GABA(+)			
8.1%	100%	14.4%	0%	8.5%	100%	16.4%	0%

Numbers in table refer to number of synapses, those in brackets are percentages of total. Numbers in lower line indicate percentages of targets immunoreactive for GABA.

Both types of axon contacted a much higher percentage of dendritic shafts than X and Y axons in the cat (Freund et al., J.comp.Neurol.242:263-274, 1985). A large number of the target dendrites contained lamellar bodies (an organelle similar to the spine apparatus in structure) near the site of the thalamic synapse. These showed the ultrastructural characteristics of spiny dendrites, and were invariably negative for GABA. The higher number of boutons of the MA axons together with a greater proportion of synapses/bouton means that the MA input to the striate cortex is magnified relative to the PA input.

292.6 LOCAL CIRCUIT NEURONS IN LAYERS 5B AND 6 OF MONKEY STRIATE VISUAL CORTEX.

J.S. Lund, M.J. Hawken* and A.J. Parker*. Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA 15261 and *Department of Physiology, Oxford University, Oxford, England OX13PT.

Using Golgi Rapid impregnations of infant monkey striate cortex, a study has been made of the organization of local circuit (LC) neurons in layers 5B and 6. These neurons have smooth or sparsely spined dendrites in the adult and the great majority contain the inhibitory neurotransmitter GABA; they comprise 15-25% of the neuron population in the cerebral cortex. The LC neurons of layers 5B and 6 differ from each other in their axon projections to the more superficial layers; LC neurons with dendrites restricted to layer 5B make axon projections to layers 2 and 3A, while LC neurons lying in layer 6 project to 5A, 4C, 4A and 3B. These LC axon projections parallel the different recurrent axon projections of pyramidal neurons in layers 5B and 6. Some varieties of LC neuron have axons and dendrites that pass between layers 5B and 6 suggesting inhibitory interaction occurs between the layers. Several varieties of the layer 5B LC neurons send axon trunks into the white matter, raising the possibility that inhibitory neurons may make efferent projections from this layer.

The diverse axon characteristics of LC neurons in layers 5B and 6 suggest the presence of a wide variety of these neurons in the deep layers. In lamina 5B 'chandelier' neurons are found with dendrites and characteristic axon arbors (targeting pyramidal neuron initial axon segments) restricted to layer 5B and the 5B-6 border. The junctional region of layers 5B and 6 seems to be a specialized region with 'basket' LC neurons lying within it with horizontally oriented dendrites and large diameter stout axon trunks running long distances within this border region emitting vertical terminal collaterals at intervals. These 'basket' neurons resemble similar neurons found in upper lamina 4Cα whose axons spread laterally in layers 4B and 4A; these neurons may form part of the substrate for direction selective responses which characterize layer 6 and the upper 4Cα-4B-4A region. Also in upper layer 6 and the 5B-6 border zone lie the cell bodies of the largest pyramidal neurons of striate cortex, whose axons innervate the motion sensitive cortical area MT and project to the superior colliculus. The somata of these giant pyramidal neurons are encased in true 'basket' arrays of terminal boutons arising from the axon trunks of a distinct population of 'basket neurons' lying in layer 6 with dendritic characteristics in common with 'chandelier' neurons.

292.7 THE TWO TYPES OF IPSPs IN NEOCORTEX HAVE VERY DIFFERENT EFFECTS ON REPETITIVE FIRING OF PYRAMIDAL CELLS. L.R. Silva and B.W. Connors. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Two types of IPSP may be evoked onto pyramidal cells of the neocortex: 1) $IPSP_1$ is fast, Cl^--dependent, high conductance, and $GABA_A$-mediated; 2) $IPSP_2$ is prolonged, K^+-dependent, low conductance and possibly $GABA_B$-mediated. We have examined how each of these IPSPs modifies the input/output properties of cortical neurons. Coronal slices of rat somatosensory cortex and cat primary visual cortex were prepared and maintained in vitro. Intracellular recordings were made from pyramidal neurons in layers II-III. Intracellular current pulses (> 200 msec) of varying amplitudes were applied to generate repetitive action potentials.

Firing frequency of pyramidal neurons shows strong accomodation. The frequency vs. current (f/I) function for the first interspike interval was initially very steep (mean of 492 Hz/nA), but fell abruptly to a secondary slope of 87 nA a few tenths of a nA above action potential threshold. The f/I function for steady-state firing yielded a single, nearly linear slope across the entire current range, with a mean of 31 Hz/nA. GABA, focally applied to the recorded cell, strongly activates $GABA_A$ receptors. Small GABA applications caused a profound increase in threshold (the current intensity needed to evoke a single spike) and the moderate applications completely eliminated single or repetitive spikes at currents up to 3 nA. Similarly, during $IPSP_1$ the threshold for one spike was greatly increased, and repetitive spikes were abolished. $IPSP_1$ completely suppressed steady state firing at all currents tested.

Baclofen specifically activated $GABA_B$ receptors and mimicked $IPSP_2$. In baclofen, thresholds were somewhat increased, and the primary slope of the initial f/I was shifted to the right by a mean of 0.26 nA. In addition, the steepness of this slope was increased to a mean of 792 Hz/nA. At high current intensities, the firing rate for the initial spikes in a train was actually slightly higher in the presence of baclofen than in its absence. In contrast, steady-state firing was slightly depressed at all currents. $IPSP_2$ effects were similar to those of baclofen.

We conclude that the two types of IPSP have very different functions in the neocortex: $IPSP_1$ profoundly depresses firing during both phasic and tonic stimuli. In contrast, the effects of $IPSP_2$ are more subtle; thresholds for phasic and tonic firing are increased, but the sensitivity of initial firing rates is increased within a low and narrow current range. In addition, $IPSP_1$ provides precise temporal control of firing, whereas $IPSP_2$ exerts a more protracted modulation. Supported by the NSF, NIH and the Klingenstein Fund.

292.8 SEROTONERGIC SYNAPSES IN MONKEY PRIMARY VISUAL CORTEX. A.D. de Lima*, F.E. Bloom and J.H. Morrison (Spon: W. Young) Division of Preclinical Neurosciences and Endocrinology. Research Institute of Scripps Clinic, La Jolla, CA 92037.

Efferent fibers from the serotonergic raphe nuclei are known to reach the entire neocortex where they presumably release serotonin. The macaque neocortex receives a very dense serotonergic innervation, which reaches its highest density in layer IV of primary sensory regions such as primary visual cortex. We studied the morphology and distribution of serotonergic fibers and synapses in the primary visual cortex of adult cynomolgus monkeys using an antibody against serotonin and the avidin-biotin method. In addition we quantified the laminar distribution of labeled varicosities by light microscopy using computer assisted counting programs (EMMA; W.G. Young et al., Neurosci. Abstr., 1985). In accordance with previous studies in this species, we observed that although serotonin immunoreactive fibers were labeled in all cortical layers, at least three bands with higher density of innervation could be readily recognized at low magnifications. The most dorsal band, also the widest (approx. 0.6 mm), was coincident with layers IIIB to IVC-alpha. A second band, fairly thin (approx. 0.1 mm), was coincident with sublamina VA. Ventrally, layer VIB formed a third dense band of innervation (approx. 0.3 mm thick). Among these regions, fibers and varicosities were most numerous in sublayers IVB and IVC-alpha ($3870/mm^2$). The lowest number of varicosities was in layer I ($685/mm^2$). At the electron microscopic level, synaptic contacts were observed through the entire thickness of area 17, with higher frequency in layer IV. The labeled synaptic varicosites (mean diameter = 545 nm) were packed with synaptic vesicles and formed type I synaptic complexes (mean length = 242 nm) presenting conspicuous post-synaptic densities. Dendritic shafts were the most common post-synaptic target of the labeled synapses. Among these post-synaptic dendrites, which were characteristically of small diameter (mean = 355 nm), profiles with ultrastructural features of both spiny and smooth dendrites were observed. The small diameter of most of the post-synaptic dendrites and the absence of axosomatic synapses indicates that distal dendrites are preferentially contacted by serotonergic varicosities. In conclusion, while direct identification of the postsynaptic neurons will be required for complete characterization of this circuitry, these data suggest that serotonergic interactions in visual cortex are directed more towards the distal dendrites of granular and subgranular neurons than to targets in the supragranular layers.

292.9 THE IN VITRO VISUAL CORTICAL SLICE IN RODENT AS A MODEL SYSTEM FOR STUDYING CORTICAL MICROCIRCUITRY, REVEALED BY CURRENT SOURCE DENSITY ANALYSIS (CSD). G. Vaknin, T.J. Teyler. Dept. of Neurobiolgy, N.E. Ohio Univ. Col. of Med., Rootstown, OH 44272.

Some of the advantages of the in vitro cortical slice in studying cortical microcircuitry are stability and reproducibility of the evoked response, the precision in which one can place the recording and stimulating electrodes and the ability to change the media surrounding the tissue. One of the limitations of the visual cortical slice is the discreteness in stimulating the white matter. The following study is an attempt to overcome this limitation. We have used Current Source Density (CSD) analysis to study neocortical microcircuitry in 400um thick coronal and saggital slice of rat and mouse visual cortex. A 60um diam. microbipolar stimulating electrode was positioned in the white matter (dorsally in coronal slice, ventrally in saggital slice) or in the gray matter (every 200um from surface to white matter). A laminar field potential profile was recorded in area OCl perpendicular to white matter (spacing of 100um in rat and 50um in mouse) , from which 2nd nearest neighbor one dimensional CSDs were calculated. In coronal slices recordings were made on-line (perpendicular to stimulation site) and off-line (200, 400um lateral; 200, 400, 600um medial). In saggital slices the same procedure was used in the rostral-caudal axis. In the experiment in which gray matter was stimulated the recordings were made 300-400um off-line (lateral) in both coronal and saggital slices.

The CSD analysis revealed the following pattern of activity: A) coronal slice white matter stimulation, recording off-line 200 to 400um.,(medially),: the earliest sinks in layer IV are seen in some cases. The sinks in layer III with the corresponding sources above are prominent and seen in every profile. Sinks in layer I and II are not seen in most cases. The infragranular layers are characterized by massive sinks in layer VI drawing its current from above. Recording laterally reveals only the infragranular activity. B) saggital slice, white matter stimulation, recording off-line 250 to 350um., (caudally),: the supragranular layers are characterized by massive sinks in layers I and II with corresponding sources in layers III and IV. The infragranular layers are characterized by a large sink in layer V which draws its current from layer VI. Recording more caudally or rostrally results in diminished infragranular activity, the supragranular activity is still prominent but smaller. C) gray matter stimulation and recording: in both coronal and saggital slices, stimulation in layers I/II reveals sinks in layers I/II. As the stimulating electrode is lowered to layer IV/V additional sinks appear at corresponding depths. Below layer IV/V, additional sinks are seen, but supragranular sinks decrease.

(Supported by NIH #DA03755, ONR #86k0664 & EPA #CR813394)

292.10 THE DISTRIBUTION AND CELLULAR LOCALISATION OF MUSCARINIC ACETYLCHOLINE RECEPTOR SUBTYPES IN THE DEVELOPING CAT STRIATE CORTEX. Glen T. Prusky, Christopher Shaw*, and Max S. Cynader. Departments of Psychology and Physiology and Biophysics, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The selective affinity of the muscarinic acetylcholine receptor (mAChR) antagonist pirenzepine (PZ) for the M_1-mAChR, and the mAChR agonist oxotremorine-M (OXO-M) for the M_2-mAChR have been demonstrated in membrane receptor binding experiments. In this study we investigate the binding site characteristics, laminar distribution and cellular localisation of M_1 and M_2-mAChR during development of the cat striate cortex using $[^3H]$PZ and $[^3H]$OXO-M as selective ligands with in vitro receptor autoradiography.

$[^3H]$PZ (M_1) binding sites are primarily localised in the superficial and deep cortical layers of adult cat striate cortex (layers 1-3 and 5-6) with the most dense labelling in layer I and a distinct band in layer V. $[^3H]$OXO-M (M_2) binding sites also avoid the middle cortical layers, but labelling with this ligand is most prominent in layers V and VI with less pronounced binding in layers I and II.

Surgical isolation of a portion of striate cortex in adult animals does not reduce $[^3H]$PZ or $[^3H]$OXO-M binding in the deafferented cortex, but neuron-specific excitotoxic lesions of striate cortex with quinolinic acid abolish both populations of mAChR. This shows that neither M_1 nor M_2-mAChR are located on neuronal afferents terminating within striate cortex, but rather that they are associated with intrinsic cortical neurons.

Immediately following birth, M_1-mAChR are specifically localised in cortical layer IV. The number of M_1-mAChR increases in this and other layers, achieving a homogeneous distribution across all cortical layers by postnatal day 30. Between days 30 and 50 this distribution alters and the adult pattern of binding develops with dense labelling in the superficial and deep cortical layers, while layer IV contains relatively few M_1-mAChR. M_2-mAChR are also localised in layer IV at birth, but layer VI is also densely labelled at this time. The M_2 receptors continue to increase in number in layers IV and VI and are still concentrated in these layers until day 60. Thereafter, the receptors redistribute and achieve their adult pattern by day 90. Thus, although both M_1 and M_2-mAChR populations reverse their specific laminar distribution during the critical period for visual development, the time-course of this redistribution is several weeks later for M_2-mAChR than for M_1-mAChR.

The differential time-course of redistribution of these two classes of mAChR may be relevant to the mechanisms of critical period plasticity in kitten visual cortex.

292.11 CELLULAR LOCALIZATION OF RECEPTOR POPULATIONS IN CAT VISUAL CORTEX USING QUINOLINIC ACID LESIONS C. Shaw*, G. Prusky, F. Van Huizen* and M. Cynader (SPON: R. Brown) Department of Psychology, Dalhousie University, Halifax, N.S., Canada, B3H 4J1

We have previously described the laminar and areal distributions of a number of neurotransmitter receptors in cat visual cortex (Shaw et al., Brain Res. Bull., 16:661, 1986). We now extend our localization of these receptors to the cellular level by using quinolinic acid (QA), an excitotoxin which selectively destroys neurons and their processes, while sparing glia as well as axons and axon terminals originating outside the lesion zone (Schwarcz et al., Science, 219:316, 1983).

A series of 1 μl QA injections (300 nmol/μl saline, pH. 7.4) were made in the visual cortex of adult cats using a Hamilton microsyringe. Injections were made so as to distribute the 1 μl QA to all cortical laminae. Animals were sacrificed 4 - 14 days after QA injections and the visual cortex processed for electron microscopy (EM) or in vitro receptor autoradiography. QA damage was found in all cortical laminae although the areal extent of damage appeared greatest in layer VI. EM at 4 and 14 days revealed a general and severe loss of neurons and the presence of cellular 'debris' in the affected zone. Axon terminals (which made no synaptic contacts), fibers of passage and glia were noted in approximately normal proportions as compared to unlesioned zones. After 14 days survival some proliferation of astrocytes was noted.

In vitro autoradiography in the lesion zone revealed a drastic decrease in the following receptors: the various putative subtypes of muscarinic acetylcholine (ACh) (labelled with ^{3}H-QNB, ^{3}H-NMS, ^{3}H-pirenzepine, ^{3}H-oxotremorine-M), A_1-adenosine (^{3}H-CHA), cholecystokinin (^{3}H-CCK-5), NMDA/quisqualate/kainate (^{3}H-glutamate, ^{3}H-AMPA, ^{3}H-kainate) $GABA_B$ (^{3}H-baclofen) and in the voltage-sensitive calcium channel binding site (^{3}H-PN-200). In contrast, nicotinic ACh (^{3}H-nicotine), $GABA_A$ (^{3}H-muscimol) and benzodiazepine (^{3}H-FNZ) receptors were either unaffected or increased in number 4 days after QA injections. At 14 days however, $GABA_A$ and benzodiazepine receptor densities were reduced.

The receptors which disappear 4 days after QA injections presumably represent those located on neurons or neuronal processes. Those receptors which survive must reside on axon terminals, fibers of passage, cellular debris and/or glia. The loss of certain receptors at 14 days ($GABA_A$ and benzodiazepine) may suggest a secondary and more selective loss after QA of the cellular elements with which these receptors are associated.

The present results extend our description of receptor loci to the cellular level and provide a more comprehensive view of cortical 'chemical circuitry'.

292.12 DIFFERENCES IN THE RICHNESS OF THE ENVIRONMENT INDUCE CHANGES IN THE RECEPTIVE FIELD PROPERTIES OF CAT VISUAL CORTEX NEURONS. C. Beaulieu and M. Cynader. Dept. of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada. B3H 4J1.

In a recent study on the cat visual cortex, it was demonstrated that the size and the number of synaptic contacts associated with flat vesicles (FS synapses) are affected by the richness of the animal's environment during development (Beaulieu and Colonnier Soc. Neurosci. Abs. 11: 226, 1985). Since the vast majority of FS synapses are GABAergic (Somogyi and Hodgson, J. Histochem. Cytochem. 33: 249, 1985) and many of the properties of visual cortex neurons are GABA dependent, it has been suggested that these morphological synaptic changes induced by the richness of the environment correlate with differences in cortical receptive field properties. In the present study, this has been verified by recording the action potentials of area 17 cells in two groups of cats raised either in isolation (impoverished condition, IC) or in a colony (enriched condition, EC).

To date, 152 cells have been recorded in EC and IC cats. Quantitative estimations have been made of spontaneous activity and of orientation and direction selectivities. Responses were quantified using a PDP/11 computer.

Spontaneous activity is not significantly affected by the richness of the environment. However, orientation tuning is not as sharp in IC animals (mean half width at half height is equal to 51^o) as in EC cats (32^o). Moreover, the decrease in the cellular responsivity at 90^o from the preferred orientation is not as pronounced in IC cats. At the orthogonal orientation, only 70% of the impoverished cells show activity decreases of at least half of their maximal response while this proportion reaches 99% in enriched cats. In addition, modest diminutions in the proportion of direction-selective cortical cells are found in IC animals. It appears however, that this selectivity is less affected by the richness of the environment than the width of the orientation tuning.

These physiological differences support the hypothesis of a structure-function relationship between FS synapses and the receptive field properties of the visual neurons. (Supported by MRC and NSERC Canadian grants to M.C. and by FRSQ postdoctoral fellowship to C.B.)

292.13 RECOVERY OF CYTOCHROME OXIDASE ACTIVITY IN THE ADULT MACAQUE VISUAL SYSTEM AFTER TERMINATION OF IMPULSE BLOCKAGE DUE TO TETRODOTOXIN: (SPON: L.K. Vaughn). E.W. Carroll* and M. Wong-Riley. Depts. Basic Sci., Marquette U. Sch. of Dent., and Anat. & Cell. Biol., Med. Coll. of Wis., Milwaukee, WI 53233.

Previously, we have shown that the blockage of impulse transmission with intravitreal injections of tetrodotoxin (TTX) led to significant yet reversible changes in cytochrome oxidase (C.O.) activity in the adult cat visual system (Wong-Riley & Riley, '83), and the effects of TTX in the monkey visual system (Wong-Riley & Carroll; '83,'84). The present investigation sought to examine the morphological basis of recovery in C.O. activity in the macaque striate cortex by following the time course and quantifying the areal recovery in the metabolically active laminae II-III "puffs". Nine adult monkeys (M. mulatta) were monocularly injected with 19ug TTX in 10 ul D.W. every 3-4 days for 1wk, 2wks and 4wks. Recovery times were: 6wks for 1wk TTX; 4wks, 5wks and 9wks after 2wks of TTX; and 4wks for 4wks TTX. Animals were perfused and tissues reacted for cytochrome oxidase histochemistry as in our previous studies. Serial tracings were made of the puffs, and areal measurements (N=100/animal) made using a digitizing pad. Results were contrasted with normal and saline injected controls and TTX treated animals. Retinae and dorsal lateral geniculates (dLGN) of recovery (R) animals were compared with corresponding TTX_2 treated animals. In controls, average puff area was 50,176 um^2 (saline controls=49,277 um^2). Retinae of all recovery animals were similiar to controls; however, with only 4wks recovery, slightly diminished C.O. activity was still evident in the inner plexiform layer of the retina, dLGN and lamina IVC. With additional recovery time, little if any differences were detected in the retina, dLGN and cortex. After 1wk of TTX_2 the average size of "affected" puffs had decreased to 36,965 um^2 (26% decrease). 1wkTTX/6wksR: average area of "recovered" puffs had increased to 47,496 um^2 (95% of control). With 2wks TTX, affected puffs averaged 33,337 um^2 (34% decrease). 2wksTTX/4wksR: average area of TTX recovered puffs was 45,528 um^2 (92% control). 2wksTTX/ 5wks and 9wksR: as ocular dominance columns were not visible, areas represent an average of recovered and unaffected puffs. After 5wks and 9wksR, puffs averaged 50,914 um^2 and 53,054 um^2 respectively (comparable to controls). 4wksTTX/4wksR: average area of recovered puffs was 45,528 um^2 (92% control) while unaffected puffs averaged 51,615 um^2. These results indicate that, given sufficient time for recovery from intravitreal TTX injections, and based on morphological criteria, there is complete recovery of the C.O. activity in the puffs after retinal impulse blockage. (Supported by NIH EY05439; MWR).

292.14 EFFECT OF MONOCULAR LID-SUTURE, ENUCLEATION AND RETINAL IMPULSE BLOCKAGE ON THE VOLUME OF CYTOCHROME OXIDASE-RICH PUFFS IN THE ADULT MACAQUE STRIATE CORTEX. T.C. Trusk and M.T.T. Wong-Riley, Dept. of Anatomy and Cellular Biology, Medical College of Wisconsin, Milwaukee, WI, 53226.

Monocular enucleation and retinal impulse blockage with tetrodotoxin (TTX) have been shown to selectively decrease the cross-sectional area of cytochrome oxidase (C.O.)-rich puffs within laminae II and III of macaque striate cortex (Horton, 1984; Wong-Riley & Carroll, 1984). The affected puffs lie in exact register with lightly-stained bands in layer IVC, where afferent input from the deprived eye predominates. The effect of prolonged lid-suture on C.O. staining patterns in the adult is less clear. In this study, we compared the volumes of supragranular C.O.-rich puffs from the primary visual cortex of adult *Macaca fascicularis* that had been monocularly deprived by either 2 weeks of enucleation (ME), 2 weeks of retinal impulse blockage (intravitreal injections of 19 ug TTX in 10 uL water every 3-4 days), or lid-suture for periods ranging from 1 to 2.5 years. The volume of C.O.-reactive tissue within puffs was obtained from three-dimensional reconstructions of striate cortex sectioned tangentially and processed for C.O. histochemistry. Consistent with previous findings, puffs in all visually deprived monkeys were arranged in alternating rows of large, dark- and small, lightly-stained puffs. The center-to-center spacing of puffs both within and between rows was consistent indicating little evidence of tissue shrinkage. The volume of C.O.-reactive tissue within control puffs from large, darkly-reactive rows was similar in all visually deprived monkeys (0.0112, 0.0122, and 0.0124 mm^3 in ME, TTX and lid-sutured macaques, respectively). The volume of treatment puffs from small,lightly reactive rows decreased by nearly 50% in ME- (0.0068 mm^3) and TTX-treated animals (0.0063 mm^3), and was reduced by 25% in lid-sutured monkeys (0.0088 mm^3). Preliminary results indicate that these reductions in volume result from less reaction product in peripheral regions of the treatment puffs. In lamina IVC, light- and darkly-reactive bands in register with treatment and control puff rows were evident in ME- and TTX-treated monkeys. In contrast, C.O. staining in layer IVC of lid-sutured monkeys was heavy and homogeneous throughout. It is worth noting that this result is not consistent with the observation of lamina IVC banding in younger macaques lid-sutured for shorter periods (Hendry and Jones, 1986; Horton, 1984). These results suggest that the mature macaque visual cortex responds differentially to these forms of visual deprivation. The effects of long term lid-suture in adult macaques are more prominent in supragranular striate cortex, reflecting a special type of functional deprivation in the fully-developed visual system. [Supported by NIH EY07016 (TCT) and EY05439 (MWR).]

292.15 THE EFFECT OF 2-AMINO-4-PHOSPHONOBUTYRATE (APB) ON INDUCED CONTRAST PERCEPTION IN MONKEYS. R.P. Dolan and P.H. Schiller. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA. 02139.

The phenomenon of induced contrast perception, whereby the perceived brightness of a stimulus is dependent on the surrounding intensity, is well documented in humans. The present studies were designed to determine the role of background in the perception of induced contrast in the monkey. The contribution of the ON channel in this phenomenon was assessed by selective blockade with APB.

An adult rhesus monkey was trained to discriminate the lighter or darker of two stimuli. Trials were initiated when the monkey fixated a small centrally placed black square, after which two stimuli would appear to the left and right of fixation. The background was either homogeneous or graded in intensity from left to right. One of the two stimuli was varied in intensity and the two stimuli were considered to be equal in perceived brightness when the choice between them became random. After characterization of the animal's performance, an intravitreal injection of APB was made under halothane anaesthesia and the monkey was tested with the other eye patched.

The results show that the apparent brightness of the stimuli prior to application of APB depended primarily on the difference in intensity between each stimulus and the immediate background rather than on the absolute intensity of the stimuli. Thus in diagram A below the two stimuli would be perceived as equally dark whereas in B the stimulus on the right would be perceived as much darker. Following APB administration performance on the light stimuli decreased markedly. Performance on the dark stimuli showed only a minor deficit, and as before the injection, the animal's perception depended on the difference between the stimuli and the background and not on absolute intensity.

These findings show that for dark stimuli induced contrast perception does not depend on the ON channel, suggesting that the center-surround mechanisms assumed to be involved are created independently within each of the two channels.

292.16 COLUMNAR ORGANIZATION OF VISUAL CORTEX IN DOLPHIN BRAIN. P. J. Morgane, M. S. Jacobs and I. I. Glezer. Worcester Foundation for Expt. Biology, Shrewsbury, Mass. 01545, Dept. Pathology, NYU Dental Center, New York, N.Y. 10010, Dept. Anatomy, City University of New York Medical School, New York, N.Y. 10031.

We have used computer assisted image analysis techniques to study the visual cortical areas in the dolphin brain which have been mapped physiologically by the Russian workers (Supin et al., 1978). By use of cytoarchitectural analyses we identified two types of cortex in the visual areas of the lateral gyrus: (1) heterolaminar cortex corresponding to areas in and bordering the entolateral sulcus from which primary type visual evoked responses were obtained and (2) homolaminar cortex corresponding to areas lateral and medial to the entolateral sulcus from which secondary type visual evoked responses were obtained. Using computer assisted morphometric methods we demonstrated for the first time in the dolphin cortex a columnar type of organization with both major and minor columns being found in both types of cortex. Our determinations of the columnar organization of dolphin visual cortex relates to the cytoarchitectonic structure of columns and these should not at this stage be considered equivalent to physiological columnar organization as quantified by immunofluorescence and other techniques. In our studies comparative analyses were done between dolphin, human and bat visual cortices. In dolphins the major columns averaged 168 μ in diameter while in human striate cortex these cytoarchitectonic columns measured 105 μ in diameter indicating that we are measuring only a component of the larger physiological column which average 600-1000 μ in the human. The small architectonic columns average 20 μ diameter in the dolphin versus 15 μ in human striate cortex. The frequency of small columns per mm of cortex in dolphin is approximately one-half the value for the human whereas the frequency of the major columns is about two-thirds the human value. The diameter of the minor columns in bat brain is larger than these columns in human area 17 but smaller than in both types of dolphin visual cortex. The major columns in visual cortex of the bat are intermediate in size between human and dolphin. These studies indicate, even in models of the so-called "initial" brain organization represented by the bat and dolphin that the same fundamental vertical organization of cortical cellular elements prevails. The radial cytoarchitectonic columns revealed in the dolphin appear to be components of larger columns such as the dominance columns in human visual cortex which reach approximately 1 mm in diameter. Further studies are in progress to more precisely establish the boundaries of the major and minor columns in both types of visual cortex we have identified in the dolphin. Additionally, it is important to examine the organization of columns in a brain such as in dolphins where the primary afferent input is to layer I rather than layer IV. (Supported by NSF Grant 85-45732 and NIH Grant HD 06364).

292.17 SPECIFIC FEATURES OF BLOOD-BRAIN BARRIER ULTRASTRUCTURE IN DIFFERENT REGIONS OF THE DOLPHIN BRAIN(Stenella coeruleoalba). Glezer I.I., Morgane P.J. and M.S. Jacobs. CUNY Med. School, New York, NY 10031, Osborn Laboratories of Marine Sciences of New York Aquarium. New York Zoological Society, Brooklyn, NY 11224, Worcester Foundation for Exp. Biology, Shrewsbury, MA 01545.

The ultrastructural characteristics of endothelial and perivascular glial cells were investigated in the visual cortex of the lateral gyrus, head of the caudate nucleus of the striatum and in the cerebellar cortex of the anterior cerebellar lobe(vermis) of the dolphin brain(Stenella coeruleoalba). It was found thatall three areas sampled for transmission electron microscopy have some specific features of the ultrastructure of the blood-brain interface. Thus, only in the cortex did we find both tight and adhesive junctions present in the endothelium and in the pericapillary glial belt. Also, the endothelial junctions are longest in the neocortical capillaries and artereioles as compared to these in striatum and cerebellum. In the caudate nucleus the endothelial junctions are much shorter and represented by both tight and adhesive types, whereas pericapillary glio-glial junctions are represented only by adhesive types(zonulae and maculae adherentes). In the cerebellar cortex endothelial junctions have the same characteristics as in the striatum. However, pericapillary glio-glial junctions there differe significantly from these in cortex and striatum and show an elaborate system of gap junctions. The tight and adhesive types of juctions between pericapillary glial cells are not found in the cerebellar cortex of the dolphin. Thus, in bothtelencephalic regions(cerebral neocortex and striatum) of the dolphin brain the blood-brain interface is characterized by the presence of double barrier(endothelial and glial), whereas in the metencephalon(cerebellum) there is only endothelial barrier. Our data might be tentatively interpreted as an evidence of higher specialization of the blood-brain barrier in the telencephalic structures of the dolphin brain as compared withstructures of the brain stem. This specialization might be related to the total aquatic adaptation of the dolphins evolved in the ecological niche which demands deep diving and fast surfacing for biological success of these aquatic mammals.

292.18 COLUMNAR MULTIPLICATION/MODIFICATION HYPOTHESIS: RELATION TO NEOCORTICAL EVOLUTION IN CETACEA. Jacobs M.S., Glezer I.I. and P.J. Morgane. CUNY Med. School, New York, NY 10031, Osborn Laboratories of Marine Sciences of New York Aquarium. New York Zoological Society, Brooklyn, NY 11224, Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Columnar organization of the neocortex has been found in all investigated terrestrial mammals(Mountcastle, 1957, 1979). Comparing columnar organization of the dolphin neocortex with that of terrestrial mammals, we can tentatively speculate that in neocortical phylogenesis two main processes have taken place: 1) Multiplication of the columns, that eventually may have resulted in an expansion of the neocortex, and 2) structural modification of the columns that may be associated to differentiation of the neocortex into areas and subareas. The different emphasis on either multiplication or modification of the columns may have resulted in the presence of four modes of neocortical evolution and subsequently in the presence of four types of neocortical organization in extant mammals.

Thus, in the mode which we define as conservative and present in basal Insectivora and Chiroptera both multiplication and modification of the archetypal columns have been minimal and neocortex retained main features of the so-called "initial" brain. In the mode that is defined as progressive-conservative and that may be found in the lower species of most mammalian orders, modification of the columns has taken place mainly, while multiplication has been moderate. These have resulted in the appearance of small and medium-sized neocortices with well-differentiated areal and subareal divisions. In the mode that is defined by us as progressive and present in higher species of most mammalian orders, both modification and multiplication of the columns appear to have been most intensive and resulted in the development of the large neocortices with extremely differentiated areas and subareas. In the fourth mode which we define as conservative-progressive, found only in extant Cetacea, modification of the archetypal columns appear to be minimal; whereas, multiplication of these columns has been extreme resulting in the development of a highly expanded neocortex characterized by many conservative features. A comparison of whales with the most progressive types of terrestrial mammals shows that from an "initial" brain line, there have evolved two quantitatively large brain lines with absolutely different qualitative characteristics of neocortex.

292.19 ORGANIZATION OF THE GENICULOCORTICAL PROJECTION IN TURTLES. K.A. Mulligan and P.S. Ulinski. Dept. Anatomy, University of Chicago, Chicago, IL 60637.

Visual cortex in turtles is located in a cortical area known as D2 (Heller and Ulinski, '87) and contains cells responsive to small, moving stimuli anywhere in visual space (Mazurskaya, '73). These cells differ from those in the primary visual cortex of mammals which respond to stimuli in restricted areas of visual space. Their wide-field receptive fields make it likely they are involved in analyzing stimuli moving throughout visual space. Thus, this and the following abstract deal with the mechanisms through which turtle cortical neurons receive information from all points in visual space.

Cells in the dorsal lateral geniculate complex have restricted visual receptive fields (Boiko, '80) and project to visual cortex through the lateral forebrain bundle. Geniculocortical axons were labeled in an *in vitro* wholebrain preparation by iontophoretic or pressure injections of horseradish peroxidase into the lateral forebrain bundle as it passes beneath the floor of the lateral ventricle. Cortical wholemounts were maintained in oxygenated turtle Ringer's solution for up to twelve hours and then flattened, fixed and reacted using diaminobenzidine as the chromagen. Labeled axons could be traced in relatively straight or gently curved trajectories from all along the cortex's ventrolateral edge for up to 2 mm through both the lateral (pallial thickening) and medial parts of visual cortex. Individual axons are fine, unbranched and bear fusiform varicosities along their entire lengths. Detailed analysis of twenty-four well-labeled axons shows varicosities are small (mean $\pm$ S.D. of long diameter = 1.4 $\pm$ 0.9 um) and spaced irregularly at intervals ranging from less than 10 um to greater than 70 um (mean $\pm$ S.D. = 16 $\pm$ 17 um). Single axons display small variations in the number of varicosities per 100 um segment, but there is no consistent variation as a function of distance along the axon.

The results show that the geniculocortical projection in turtles is organized in a point-to-line fashion. Each geniculate cell projects via an unbranched, varicose axon to a line of cortical cells throughout the medio-lateral extent of the visual cortex. All of the cortical cells along the line should, thus, share the restricted receptive field of that geniculate neuron.

The next abstract continues the analysis by considering the relationship between neurons at a given cortical locus and neurons in the dorsal lateral geniculate complex.

292.20 REPRESENTATION OF VISUAL SPACE IN THE VISUAL CORTEX OF TURTLES. P.S. Ulinski and K.A. Mulligan. Dept. of Anatomy, University of Chicago, Chicago IL 60637

The study reported in the preceding abstract demonstrates that neurons in the dorsal lateral geniculate complex of turtles project to the visual cortex via a point-to-line projection. Since the geniculate complex contains a point-to-point representation of the retinal surface (with the nasotemporal axis of the retina represented along the rostrocaudal axis of the geniculate), the point-to-line nature of the geniculocortical map raises the issue of how visual space is represented in turtle visual cortex.

This question was addressed using the retrograde transport of horseradish peroxidase *in vivo* to determine the spatial relation between neurons in the geniculate complex and the visual cortex. Turtles received iontophoretic injections of horseradish peroxidase in restricted loci within the visual cortex. After survival times of seven days, visual cortex was reconstructed from transverse serial sections to accurately plot the center of each injection site, and the distribution of retrogradely labeled neurons was plotted in the ipsilateral geniculate complex. Injections near the rostral pole of visual cortex label neurons near the caudal pole of the geniculate complex. Injections at progressively more caudal loci label neurons at progressively more rostral loci in the geniculate complex. Injections near both the medial and lateral edges of the visual cortex label neurons along a dorsoventral band in the geniculate complex.

Thus, there is a systematic representation of the horizontal meridian of visual space along the rostrocaudal axis of the visual cortex. However, the point-to-line character of the geniculocortical projection effects a collapse of each vertical meridian such that cortical cells receiving information about stimluli at any given horizontal eccentricity will receive convergent information from all points along that vertical meridian. Since physiological studies show that each cortical neuron is also responsive to stimuli at all points along the horizontal meridian, there must be intracortical projections that effect a subsequent collapse of the horizontal meridian. We suspect that this two-step construction of wide-field receptive fields allows turtle cortical neurons to respond preferentially to visual stimuli that appear successively at two disjunct horizontal eccentricities within visual space.

292.21 THE DISTRIBUTIONS OF SUBSTANCE P-LIKE AND CHOLECYSTOKININ-LIKE IMMUNOREACTIVITY WITHIN THE VISUAL WULST IN PIGEONS. T. Shimizu, H.J. Karten and K.T. Keyser*. Dept. of Neurosciences, School of Medicine, M-008, Univ. of California, San Diego, La Jolla, CA 92093.

The visual wulst of birds is a laminated dorsomedial telencephalic elevation with many similarities to mammalian visual cortex. The major laminar components of the wulst, from dorsal surface inward, include the hyperstriatum accessorium (HA), the nucleus intercalatus hyperstriatum accessorium (IHA), the hyperstriatum intercalatus superior (HIS), the lamina frontalis suprema (LFM), the hyperstriatum dorsale (HD) and the lamina frontalis superior (LFS). Thalamic efferents terminate in HD and IHA. Efferents from the wulst to the tectum arise from HA.

Immunohistochemical techniques were used to examine the distributions of substance P-like immunoreactivity (SP-LI) and cholecystokinin octapeptide-like immunoreactivity (CCK8-LI) within the visual wulst in pigeons (*Columba livia*).

Neurons containing SP-LI were found in HA, the most superficial layer of the wulst. SP-LI neurons were also observed at the dorsolateral edge along the wulst, and the medial portion of the hyperstriatum ventrale dorsoventrale (HVdv). Fibers and terminals containing SP-LI were also found within the above areas. A large number of intensely immunoreactive terminals and fibers were observed in the areas located mediodorsal and lateral to HD, the deepest layer within the wulst. The ventral portion ("core") of HD was only lightly stained and contained fine SP-positive fibers. In addition to the visual wulst, the area parahippocampalis (APH) and hippocampus (HP), medial to HA, contain numerous neurons and fibers that show intense SP-LI.

Using *in situ* hybridization, we localized mRNA for preprotachykinins, precursors for substance P and substance K, in APH and the dorsolateral region of HA. The distributions of probe-labelled cells closely matched the results of the immunohistochemical study.

Intense CCK8-LI was found within neurons and fibers in HIS and HD. The hyperstriatum ventrale (HV), which is ventral to HD, also contains large numbers of diffusely distributed CCK8-LI neurons and fibers. A high density of the staining was observed in HD, LFS and along the anterior margin of HVdv. In addition, CCK8-LI was found in APH, HP and the medial portion of HV.

The diversity of transmitters/peptides within the visual wulst indicates that the constituent layers are biochemically, as well as cytoarchitectonically distinct.

292.22 PATTERN ONSET EVOKED POTENTIALS FROM STRIATE AND EXTRASTRIATE CORTEX. BW van Dijk and H Spekreijse. dept. of Visual Systems Analysis, the Netherlands Ophthalmic Research Institute, POBox 12141, 1100AC, Amsterdam, the Netherlands.

We have introduced a technique to find physiologically meaningful components in visually evoked potentials recorded with large electrode arrays attached to the occipital scalp (Maier et al., Vision Res., 27:165, 1987). This technique is employed on the pattern onset visually evoked potential to study the properties of the components attributed to different cortical areas. The stimuli used were checkerboard patterns that appeared and disappeared abruptly in a 300/500 ms duty cycle. The parameters of interest were element size, contrast and ocular input. Spatially filtered checkerboard patterns were also employed. Results indicate the presence of an acuity mechanism underlying the activity from the striate cortex. This mechanism responds to very small pattern elements, is monocular and the responses from this mechanism hardly depend on contrast. The activity from extra-striate cortex is from a contrast mechanism; it shows spatial frequency tuning, its responses saturate at relatively high contrast values and it receives binocular input.

293.1 PROXIMAL RETINAL CONTRIBUTIONS TO THE DARK-ADAPTED ERG IN THE CAT: A K^+-MÜLLER CELL MODEL. L. J. Frishman* and R. H. Steinberg (SPON: J. A. Fox) Depts. of Ophthalmology and Physiology, UCSF, San Francisco, CA 94143

At intensities above 5 log q deg^{-2} s^{-1}, the electroretinogram (ERG) comes from distal retina and consists of an initial negative-going a-wave followed by two positive components: PII (b-wave and dc component) and the c-wave. However, at near threshold intensities (3.0-3.5 log q deg^{-2} s^{-1}) the dark-adapted ERG obtained with 4 s flashes shows three clear negative components: a fast negative response at stimulus onset, a slow negative response that increases in amplitude for about 2 seconds, and a negative-going off response that come from proximal retina.

The fast negative response was previously shown to derive from the scotopic threshold response (STR), a negative-going proximal retinal response that inverts distally. It saturates about 2.5 log units below rod saturation and is distinct from the higher threshold PII in distal retina (Sieving, Frishman, and Steinberg, 1986).

The slow negative response, like the STR, also depends on threshold activity of proximal retina. Negative-going responses at 2-4 s after stimulus onset were maximal in proximal retina. Responses inverted in mid-retina, and were positive distally. The distal positive potential was not slow PIII since subretinal $[K^+]_o$, measured with K^+-selective microelectrodes, did not decrease at these low intensities. Nor was it a photoreceptor potential since intravitreal injections of APB (0.5-1mM vitreal conc.) blocked the entire negative dark-adapted ERG, including the off response. The later response resulted from a merging of the slow negative response and the rapid offset of PII.

The data support a K^+-Müller cell model for the negative responses. Light-evoked increases in K^+ were largest and fastest in proximal retina, and they followed the dynamic range of the negative responses. Intravitreal injections of Ba^{++} (≈3 mM), a K^+ conductance blocker, blocked the negative responses in the ERG and proximal retina. PII enlarged intraretinally, and dominated the ERG.

Inversion of the STR and slow negative response in distal retina suggests that current flow in the cat Müller cell is dominated at low intensities by a distally oriented current loop rather than by a proximally oriented loop toward the highly conductive vitreal endfoot, as described for frog (e.g. Newman and Odette, 1984). Domination by the distal loop appeared to increase over the time-course of the slow negative response, perhaps because sustained release of K^+ in proximal retina decreased the proximal loop by reducing the K^+ concentration gradient across the Müller cell's vitreal endfoot.

293.2 **EFFECTS OF COBALT AND LOW CALCIUM ON LIGHT-EVOKED $[K^+]_o$ CHANGES IN THE SUBRETINAL SPACE AND ON THE CHICK DC ELECTRORETINOGRAM.** R.P. Gallemore* and R.H. Steinberg. Depts. of Physiology and Ophthalmology, University of California, San Francisco, 94143.

While using Co^{2+} and low Ca^{2+} to suppress Ca^{2+}-dependent synaptic transmission in a preparation of chick retina-pigment epithelium-choroid, we observed significant effects on the potentials of the DC electroretinogram (DC ERG). Both Co^{2+} (2-3 mM) and low Ca^{2+} (0.18 mM, ten fold decrease) increased the amplitude of the two responses of the DC ERG that result from the light-evoked $[K^+]_o$ decrease in the subretinal space: the c-wave and the fast-oscillation trough (FOT). Monitoring of subretinal $[K^+]_o$ with K^+-selective microelectrodes showed that Co^{2+} and low Ca^{2+} increased the amplitude of the light-evoked $[K^+]_o$ decrease, and this can account for the observed increase in the c-wave and FOT. With maintained illumination there was also an increase in the rate of $[K^+]_o$ reaccumulation, which follows the $[K^+]_o$ decrease, and at light-offset the overshoot of $[K^+]_o$ was also increased. These results are consistent with Co^{2+} and low Ca^{2+} increasing the photoreceptors' dark current and, thereby, increasing both the photoreceptors' Na^+/K^+ pump rate and the photoresponse.

Strikingly, both Co^{2+} and low Ca^{2+} also increased the amplitude of the DC ERG light peak significantly, and shortened its time to peak. The light peak is a slow positive potential that originates from the retinal pigment epithelium as a basal membrane depolarization in response to a substance believed to be produced by the photoreceptors. The light peak is not thought to be caused by $[K+]_o$ changes in the subretinal space. Since the light-peak amplitude increases with a purported increase in the photoreceptors' dark current, these results provide support for a photoreceptoral origin for the light-peak substance. The increase in the light-peak amplitude suggests that the amount of light-peak substance produced by the photoreceptors could be a function of the photoresponse and/or the rate of the Na^+/K^+ pump.

293.3 **MÜLLER CELL INVOLVEMENT IN ELECTRORETINOGRAM GENERATION AND pH REGULATION IN THE VERTEBRATE RETINA.** R. Wen* and B. Oakley II, NBB Program and Depts. of ECE and Biophysics, Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801.

We recorded light-evoked changes in Müller (glial) cell membrane voltage (V_m) and in $[K^+]_o$, as well as the electroretinogram (ERG), in the isolated retina of the toad, Bufo marinus. Our measurements of the V_m and ERG waveforms (latency, amplitude, and time course) provide strong support of the hypotheses that the ERG b-wave and slow PIII components are produced by a rapid depolarization and a slow hyperpolarization, respectively, of the Müller cell membrane. The Müller cell hyperpolarization seems to be produced by a light-evoked decrease in $[K^+]_o$, which, in turn, is produced by the rod photoreceptors.

Switching pH buffer systems between phosphate and bicarbonate produced dramatic changes in both the ERG and the light-evoked responses of Müller cells. In phosphate-buffered solutions (nominally HCO_3^--free), both the b-wave and the Müller cell depolarization were severely attenuated, and the response waveforms were dominated by the slow PIII component and the membrane hyperpolarization. Conversely, in bicarbonate-buffered solutions, both slow PIII and the Müller cell hyperpolarization were attenuated, and the response waveforms were dominated by the b-wave and the membrane depolarization. These observed effects appear to be due to changing intracellular HCO_3^- and/or pH in Müller cells. Acetazolamide inhibits carbonic anhydrase, which is located in Müller cells, and produces effects similar to increasing HCO_3^-. SITS produces effects similar to reducing HCO_3^-, most likely by blocking a Cl^-/HCO_3^- exchanger in the Müller cell membrane. The effects of increasing HCO_3^- may be due to blocking a specific K^+-conductance in Müller cells, since similar effects also were produced by superfusion with Cs^+, and Müller cell input resistance increased upon switching from phosphate-buffered solution to bicarbonate-buffered solution.

Aerobic glycolysis in rod photoreceptors produces lactic acid, and we suggest that the Müller cells may provide a mechanism to remove the resulting H^+, and thereby prevent changes in extracellular pH. Based on our results, it seems that protons enter the Müller cells down their electrochemical gradient, and that HCO_3^- enters via a Cl^-/HCO_3^- exchanger. Within the Müller cells, these ions form carbonic acid, which then is dehydrated by carbonic anhydrase to form CO_2 and H_2O. Therefore, we suggest that the Müller cells provide a mechanism to buffer changes in retinal pH. Supported by NIH grant EY04364.

293.4 THE EFFECT OF ACETAZOLAMIDE ON THE ERG b-WAVE OF THE SKATE. S.H. Hensley*, P.J. Linser* and J.L. Cohen. (SPON: R. Grubbs). Wright State University Biomedical Sciences Ph.D. Program, Dayton, Ohio 45435, Mount Desert Island Biological Laboratory, Salsbury Cove, Maine 04672 and C.V. Whitney Marine Laboratory, St. Augustine, Florida 32086.

Work in our laboratory using monoclonal and polyclonal antibodies has demonstrated the presence of the enzyme carbonic anhydrase II in Muller cells in the retina of the skate, Raja oscellata. Carbonic anhydrase catalyzes the hydration of carbon dioxide, a reaction which is important in the regulation of intracellular pH. Since the Muller cells are thought to be the site of origin of the b-wave of the ERG, we examined the effect of acetazolamide, a potent inhibitor of carbonic anhydrase activity, on the b-wave of the electroretinogram of the skate.

Pieces of eyecup were incubated consecutively in each of the following solutions; (1) normal elasmobranch saline, (2) elasmobranch saline containing 500 uM acetazolamide, (3) normal elasmobranch saline. The ERG was recorded after each step. Acetazolamide decreased the b-wave amplitude by approximately 50% compared to control responses over a five log unit intensity range. The effect of acetazolmide was reversible, as the b-wave amplitude increased following washout in normal elasmobranch saline. To test if acetazolamide was acting on the photoreceptors, pieces of eyecup were incubated in aspartate to isolate the receptor potential (RP). Acetazolamide had no effect on the RP compared to the control response.

The results of this study indicate that inhibition of carbonic anhydrase activity affects the normal function of the Muller cells, resulting in a decrease in the amplitude of the b-wave. The data support the functional importance of the Muller cell in the generation of the b-wave. (Supported by a fellowship from the Lucille P. Markey Trust to J.L.C.)

293.5 **DIFFERENTIAL EFFECTS OF NEUROTENSIN ON RABBIT ERG OSCILLATORY POTENTIALS.** P. Olivier and F.B. Jolicoeur
Departments of Ophthalmology and Psychiatry , University of Sherbrooke, Québec, Canada, J1H 5N4.

The presence of neurotensin (NT) in the retina of a variety of animal species has been reported(Brecha et al.Neurosci. 6:1329, 1981). Although the physiological significance of retinal NT remains to be ascertained, we have shown recently that NT markedly decreased both A and B wave amplitudes without affecting implicit response times. (F.B.Jolicoeur and P.Olivier: Neurosci. Abstr.12: 640,1986). In order to further characterize the actions of NT on retinal responses to photic stimulation, the effects of various doses of NT on oscillatory potentials (OP) were examined.

Experiments were performed using adult pigmented rabbits, curarized, maintained under pentobarbital anesthesia and ventilated through a tracheostomy. Pupils were maximally dilated with cyclopentolate and neosynephrine drops. Animals were dark adapted for 60 min and baseline ERG recordings of four distinct OPs (1 to 4) were first obtained. Different groups of animals (n= 6) were then injected intravitreally in one eye with either 0.9 % NaCl, 0.1, 1.0 or 10.0 µg NT. Another group of animals received 10 µg of the generally inactive analogue [Ala ^{11}]- NT . For each animal, the fellow eye received a 0.9 percent NaCl solution. Volume of injections was 0.1 ml. ERG recordings were then performed at 15, 30, 60, 90, 120 and 150 min following injections.

Results revealed significant dose related reductions in OP 1 amplitudes which first appeared at 90 min and were still present at 150 min following NT administration. None of the NT doses significantly altered OP 2 amplitudes. Interestingly, OP 3 amplitudes were significantly enhanced with all doses of the peptide. These increases were first detected at 15 min and progressed throughout the experiment. On the other hand, OP 4 amplitudes were significantly decreased at 60 min following administration of the largest dose of NT. The implicit response times of each oscillatory potential were not affected by NT. Finally, the administration of 10 µg of the analog [Ala ^{11}]-NT did not affect the amplitudes nor the implicit response times of oscillatory potentials, indicating that the observed effects with NT can not be attributed to non-specific effects of intravitreal administration of a tridecapeptide.

Together, the present results demonstrate that NT has highly selective modulatory effects on retinal responses to photic stimulation. Furthermore, the differential effects of NT point to different mechanisms generating individual oscillatory potentials.

293.6 **THE EXCITOTOXINS KAINIC ACID AND IBOTENIC ACID HAVE DIFFERENT EFFECTS ON GANGLION CELL ACTIVITY AND ELECTRORETINOGRAM (ERG) IN THE CAT RETINA.** A. W. Przybyszewski*, N. Sucher*, M. Hagner*, and O.-J. Grüsser. (SPON: J. J. Kulikowski). Dept. of Physiology, Freie Universität, Arnimallee 22, 1 Berlin 33, Germany-West.

In anaesthetized cats (35 mg/kg pentobarbital initial dosis, 3-6 mg/h pentobarbital infusion) corneal ERG and single unit activity from optic tract fibres were recorded before and up to six hours after intravitreous injections of kainic acid (KA) (1 mg/eye) or ibotenic acid (IBO) (0.5-1 mg/eye). The effects of these excitotoxins were compared with those of D- and L-2-amino-4-phosphonobutyrate (APB) and the quinolinic acid analog cis-2,3-piperidine dicarboxylic acid (PDA) *(Soc. Neurosci. Abstr., 12: 959, 1986).*

1) KA led to a change in the ERG commencing about 5 minutes after injection: b-wave amplitude decreased and its latency increased (also relative to the latency of the a-wave) with time. After 6 hours only a very small b-wave was evoked with high stimulus luminance. Concomitantly the slope of the b-wave intensity function decreased, while the a-wave became more prominent and the slope of its intensity function increased. Off-center ganglion cell activity (postinhibitory activation) showed a considerable decrease in the response to 10 ms flashes, while the flash-induced initial inhibition was not impaired and increased relative to the flash-induced excitation during the first hour after the KA injection.

2) In contrast to KA, ibotenic acid did not affect the ERG significantly, but did reduce the flash-induced postinhibitory activation and the spontaneous activity of off-center ganglion cells. The flash-induced activation in on- and off-center ganglion cells disappeared about 60-90 minutes after injection of IBO. This excitotoxin is believed to be metabolized into muscimol, a hypothetic GABA-agonist. In comparable doses, however, muscimol changed neither the ERG nor single unit activity.

3) The flash responses were transformed into power spectra (PS) and the frequency range between 6 and 200 Hz was analysed in detail. The excitotoxins changed the shape and maximum frequency of the PS and reduced the stability of PS sampled for successive flash responses.

4) In conclusion it seems that KA has direct and/or indirect effects on the neural activity in both the distal and proximal retina. Off-excitation was more sensitive than on-excitation and on-inhibition. IBO seems to interact primarily with receptors in the proximal retina and to have no effect on on-bipolar cells. The influence of these excitotoxins on the retinal network activity differs therefore from that of L-APB, which blocks the signal transmission through on-bipolar cells and D-APB, which seems to have a gliotoxic action on Müller-cells. PDA-effects on ganglion cell activity were reversible within about one hour and the ERG b-wave was only slightly diminished.

The work was supported in part by a grant of the Deutsche Forschungsgemeinschaft (Gr 161).

293.7 **Morphine attenuates rod and cone components of the human electroretinogram.** M.J. Jaffe , R. Rittmaster , R.J. Wyatt. Neuropsychiatry Branch, St. Elizabeth's Hospital (NIMH) and Developmental Endocrinology Branch (NIH).

Retinal opioid binding-sites have been found in the guinea pig, cow, monkey and human. Cells with enkephalin-like immuno-reactivity have been found in: i) the inner margin of the inner nuclear layer and, ii) several laminae of the inner plexiform layer. Despite the growing knowledge of opioid neuro-anatomy, however, their function within the retina is largely unknown. A probe that can be used to assess the functional effects of different neuroactive drugs on the retina of humans is the electroretinogram (ERG), a flash-evoked, mass electrical response.

In our study, six normal males with a mean age of 22.8 years (±s.d. 2.3) gave informed consent to have their ERG measured before and after the i.m. administration of 10 mg morphine. All subjects in all groups agreed to abstain from caffeine and tobacco. For all groups, eligibility criteria included for both eyes a best corrected visual acuity of 20/20 or better, normal confrontation visual fields, intraocular pressure, slit lamp and fundus examination. The ERG recordings were obtained using a ganzfeld stimul-ation system and bipolar Burian-Allen contact lens electrode. Isolation of the rod and cone components of the ERG and the oscillatory potentials have been previously described. The effects of morphine on the ERG were evaluated with an analysis of variance.

Morphine has a general attenuating effect upon the ERG signals mediated by both rod and cone processes of the human retina. Across the flash intensities tested, morphine resulted in a mean attenuation in rod b-wave amplitude of 11% ($p<0.01$) and a mean delay of 4% in its latency ($p<0.0001$).

Responsivity of cone mechanisms was also attenuated by morphine. Under conditions of dark-adaptation, the latency of the cone a-wave was delayed by 3% ($p<0.01$) across the intensities tested. An attenuating effect of morphine on photoreceptors of humans is corroborated by a similar delay of 5% ($p<0.001$) on the light-adapted cone a-wave. Morphines's attenuating effect on cone processing is further supported by the 8% delay ($p<0.01$) of the 'blue cone' b-wave across the intensities tested. The oscillatory potentials (OPs), believed to represent feedback circuits within the retina, are delayed by morphine. The latency of each of the first 3 oscillatory potentials is increased by 2% ($p<0.01$ for OP1 and $p<0.0001$ for OP2 and OP3) across the intensities tested.

Our ERG results suggest that systemically administered morphine does cross the blood-retina barrier and reduces the gain of the retina's responsivity to light flashes. Possible interactions with the dopamine D-2 autoreceptor will be discussed.

293.8 **EFFECTS OF SYSTEMIC AND INTRAOCULAR ADMINISTRATION OF MESCALINE ON FLASH EVOKED POTENTIALS IN THE INTACT, AWAKE RAT.** J.T. Eells and D.M. Wilkison. Dept. of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226

Mescaline is a phenethylamine hallucinogen capable of eliciting profound perceptual distortion including visual hallucinations. We have previously reported a reduction in the primary component of the flash evoked potential (FEP) by mescaline. This report details further investigations of the mechanism and possible sites of action of mescaline in the visual system.

Hooded Long Evans rats were anesthetized with pentobarbital and indwelling epidural screw electrodes were stereotaxically implanted over the right and left visual cortices at points 7 mm posterior to bregma and 4 mm lateral to the midline. Ground and reference electrodes were placed 2 mm anterior and 2 mm lateral to bregma. Following a one-week recovery period recording sessions were initiated. FEPS were recorded in response to 10 µsec flashes at a rate of 0.4 Hz. Mescaline was administered intraperitoneally (20 mg/kg) or intraocularly (1 µl of a 400 mg/ml solution under anesthesia). Input/output curves at 3 luminescence intensities were established prior to drug administration and at defined intervals thereafter. The averaged FEP consisted of a primary (P20-N30) component and a secondary (P50-N70-P100) component.

Mescaline significantly attenuated the amplitude of the primary (P20-N30) component of the FEP at all three stimulus intensities. This effect was maximal 60 min after drug administration. Intraocular injection of mescaline produced a similar degree of inhibition with a maximal effect observed 20 min after drug administration. To determine if the mydriatic actions of mescaline contributed to the observed reduction in FEP; the effects of atropine and phenylephrine, alone and in combination with mescaline, on the FEP were examined. Atropine (1%ophthalmic solution), atropine, methyl nitrate (0.1 mg/kg,ip) and phenylephrine (2.5%ophthalmic solution) had no effect alone on the FEP. However, both atropine and atropine methyl nitrate antagonized the effect of mescaline on the FEP. Phenylephrine did not.

These data suggest that mescaline increases the threshold and slope of the visual response to flash in the rat. The magnitude and the specificity of the effects of mescaline on the P20-N30 primary response suggest that the drug produces deficits in conduction through the retino-geniculato-cortical system. Furthermore, these effects may be mediated by an action of mescaline at the level of the retina which may be modulated by cholinergic systems. Supported by NIDA, R01 DA 03785.

293.9 INFLUENCE OF GABACULINE TREATMENT ON GABA IMMUNOREACTIVITY IN RAT RETINA. M.H. Makman*, J.F. Cubells and S.U. Walkley (SPON: N.S. Sharpless). Depts. of Neuroscience, Biochemistry and Molecular Pharmacology, Albert Einstein Col. of Med., Bronx, NY 10461

In the mammalian retina γ-aminobutyric acid (GABA) appears to be synthesized exclusively in a subset of amacrine cells. However, many other retinal neurons and also Muller cells can accumulate GABA and degrade GABA by the action of GABA-transaminase (GABA-T). Gabaculine (gbc) is an enzyme-activated irreversible inhibitor of GABA-T. We recently demonstrated that subcutaneous (s.c.) injection into rats of gbc produces a progressive and long-lasting inhibition of GABA-T as well as a progressive and sustained increase in the level of GABA in the retina (Cubells et al., J. Pharm. Exp. Therap., 238:508 (1986); Brain Res., in press). We report here the influence of gbc treatment on the amount and localization of GABA in rat retina as visualized by GABA immunocytochemistry.

Long-Evans rats were treated with 10 mg/kg gbc (s.c.) for 2 or 8 hours. Posterior orbits were sectioned for peroxidase immunocytochemistry with a highly specific GABA antibody. Immunocytochemical controls were performed on sections incubated in normal serum. Sections were examined under the light microscope for peroxidase reaction product.

In the control retinas GABA immunoreactivity (GABA-IR) was detected most prominantly in cell bodies fairly regularly spaced in the inner aspect of the inner nuclear layer (INL). Also there was a prominant network of GABA-IR in the inner plexform layer (IPL). Some GABA-IR was evident in the ganglion cell layer (GCL). However GABA-IR was almost totally absent from the outer nuclear layer (ONL). After treatment with gbc for 2 hrs GABA-IR in the retina was markedly increased overall, with an additional increase from 2 to 8 hrs. Distribution of GABA-IR in retinas of the gbc-treated animals was strikingly different from the controls. Following gbc treatment the number of cell bodies exhibiting intense GABA-IR was markedly increased. Numerous processes containing GABA-IR were now evident coursing through the ONL. In addition considerable GABA-IR now appeared to be in processes coursing vertically across layers. GABA-IR was also increased at the inner aspect of the GCL.

Thus, gbc-treatment causes a major change both in the distribution and amount of endogenous GABA within the retina. The qualitative changes are highly suggestive of a major accumulation of GABA in Muller cells, in turn permitting exposure to GABA of certain neurons that normally have little or no access to GABA. Hence, gbc treatment would qualitatively as well as quantitatively alter GABAergic function in retina. These considerations may also apply to GABAergic function in brain following GABA-T inhibition, e.g., when GABA-T inhibitors are used in man for treatment of epilepsy.

293.10 THE EFFECTS OF APB ON RETINAL SYNTHESIS AND RELEASE OF GABA: EVIDENCE THAT ON-CHANNEL BIPOLAR CELL ACTIVITY INFLUENCES RETINAL GABAERGIC TRANSMISSION. J.F. Cubells, C. Ndubuka* and M.H.Makman*. Depts. of Biochemistry, Neuroscience and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY 10461

Subcutaneous (s.c.) administration of gabaculine (gbc), an irreversible inhibitor of GABA-transaminase, produces a linear increase in retinal GABA for up to 4 hours post-injection (Cubells et al., Brain Res., in press). We report here the effect of light on the post-gbc synthesis of retinal GABA in vivo, as well as the effects of 2-amino-4-phosphonobutyrate (APB) on retinal GABA synthesis in vivo and on release of newly synthesized 3H-GABA from retinal synaptosomes in vitro. APB is a glutamate receptor agonist previously found to selectively block the light response of on-channel bipolar cells.

Rats were given 10 mg/kg gbc s.c.; 15 min afterwards they were placed in a completely darkened room, held under ambient laboratory lighting, or were ether-anaesthetized and given 3 nmoles of APB intraocularly (i.o.) in one eye and 3 ul of 0.9% NaCl in the other. Rats given i.o. injections were then placed in darkness or held under ambient light. Rats were killed 1.25 hrs after gbc injection and retinal GABA measured. For in vitro experiments, rat retinal synaptosomes were preincubated with 3H-glutamate, aliquots of resuspended washed synaptosomes incubated in the presence of APB or other agents and the 3H-GABA released into the medium then determined.

Retinal GABA levels were higher in rats held in the light than in those placed in darkness after s.c. gbc (62.9 ± 1.7 vs 54.4 ± 1.9 nmol/retina). Initial (pre-gbc) GABA levels were the same in light and dark (approximately 23 nmol/retina). In gbc-treated rats held in the light, the GABA level in retinae from APB-injected eyes was diminished compared to that from saline-injected eyes (49.6 ± 1.8 nmol/retina vs 57.8 ± 1.1 nmol/retina). In contrast, when gbc-treated rats were placed into darkness, GABA levels were not different in retinae from APB vs saline-injected eyes (47.4 ± 1.0 vs 47.6 ± 1.8 nmol/retina). In vitro, APB exerted a small stimulatory effect on synaptosomal GABA release: Release of newly synthesized 3H-GABA was 3.4% in the presence of 1.0 mM APB, compared to 2.9% for the control, 7.6% with 0.01 mM kainate and 7.7% with 1.0 mM glutamate. The in vitro results further suggest that APB inhibition of GABA synthesis in vivo is not due to a direct action of APB on GABA-synthesizing amacrine cells.

It is concluded that retinal GABA synthesis is stimulated by light. Furthermore, this stimulation may be indirect and specifically caused by activity of on-channel bipolar cells. Hence APB is inhibitory in the light but not in the dark when on-bipolars are already hyperpolarized by endogenous transmitter. (T32 GM7288)

293.11 QUANTITATIVE ANALYSIS OF THE DISTRIBUTION OF GAD- AND GABA-LIKE IMMUNOREACTIVITY WITHIN THE TURTLE RETINA: A DOUBLE-LABEL STUDY. W.D. Eldred and L. Hurd, Dept of Biology, Boston University, Boston, MA, 02215

This double-label study details the coexistence of GABA and GAD in subpopulations of retinal cells in the turtle, Pseudemys scripta elegans. Sections were treated with antisera directed against GAD and GABA. The fluorescent markers FITC and TRITC, conjugated to appropriate secondary antibodies, were used to distinguish the two different primary antibodies.

GAD immunoreactivity was seen in cell bodies in the inner and outer regions of the inner nuclear layer (INL), and in processes within the inner plexiform layer (IPL) and outer plexiform layer (OPL). GABA immunoreactivity was seen in cell bodies in the inner and outer regions of the INL and within the ganglion cell layer (GCL), and in processes in the OPL and IPL. The intracellular labeling of these antibodies apparently differed in that the GABA antibody labeled the entire somata of the cells while the GAD antibody was concentrated only in the cytoplasm and not the nucleus.

Both GABA and GAD positive neurons gave rise to processes which arborized in the IPL, although they were observed to have different stratification patterns. We quantified the labeling of the cells near the inner border of the INL, and used a scanning densitometer (SD) to quantify the stratification patterns of the labeling within the IPL. The SD peaks have been described on the basis of their relative position within a normalized IPL sample, where L0 would represent the INL/IPL border and L100 the IPL/GCL border. Analysis of GAD labeling yielded seven distinct bands, with peaks centered at positions L8, L18, L28, L42, L57, L74, and L88. GABA yielded five bands, centered at positions L14, L26, L63, L79, and L90. Four of the five GABA bands were statistically identical to corresponding GAD bands, with the fifth GABA band, at L14, being the exception. GABA antibody failed to label bands at positions corresponding to the GAD bands at L8 and L42.

Cell counts of labeled cell bodies at the IPL/INL border have shown a 67% correspondence between the labeling seen with GABA and GAD antibodies, with more GABA than GAD positive cells. At least two anatomically distinct cell types have been observed which ramify in characteristically different lamina: one in the proximal bands and one in the distal bands. Our research indicated, that in the turtle retina the GABA and GAD antisera we used produced labeling which was significantly different in the INL and IPL. This research supported by EY04785 to WDE.

293.12 DOPAMINERGIC AND INDOLEAMINE ACCUMULATING AMACRINE CELLS BOTH EXPRESS GABA-LIKE IMMUNOREACTIVITY IN CAT RETINA. H. Wässle and M.H. Chun*, Max-Planck-Institut für Hirnforschung, Deutschordenstr. 46, D-6000 Frankfurt 71, W. Germany

In the cat retina immunoreactivity for TH (tyrosine hydroxylase) revealed a population of amacrine cells with large cell bodies and a preferred stratification close to the inner nuclear layer (Oyster et al., 1985, PNAS 82, 6335-6339). They occur at a very low density (0.1% of all amacrine cells) and seem to be a cell type common to all mammalian retinae.

GABA-like immunoreactivity was found in approximately 30% of all amacrine cells. Consecutive 1 µm thick semithin sections were incubated in antisera to either TH or GABA. In 3 out of 4 TH-like immunoreactive amacrine cells there was also GABA-immunoreactivity present. Hence it is quite likely that the majority of dopaminergic amacrine cells of the cat retina express GABA-like immunoreactivity.

Uptake of 5-HT (5-hydroxytryptamine) following injection of 20 µg into the vitreous, labelled approximately 10% of all amacrine cells and at least two morphologically different types could be discerned (Wässle et al., 1987, J. Neurosci.). Following 5-HT uptake, consecutive 1 µm thick semithin sections were incubated in antisera to either 5-HT or GABA. 91% of all 5-HT accumulating amacrine cells expressed GABA-like immunoreactivity. Since in the cat retina endogeneous 5-HT could not be found by immunocytochemistry, one has to consider the possibility that some GABAergic amacrine cells take up indoleamines.

In rabbit retina uptake of 5-HT following injection into the vitreous labelled approximately 6% of all amacrine cells. When consecutive semithin sections were incubated with antisera to either 5-HT or GABA, 75-80% of all 5-HT accumulating amacrine cells expressed GABA-like immunoreactivity. This confirms a similar study by Osborne and Beaton (1986, Brain Res. 382, 158-162) and makes it likely that both serotonin-accumulating amacrine types of rabbit retina (Vaney, 1986, Science 233, 444-446; Sandell & Masland, 1986, J. Neurosci. 6, 3331-3347) express GABA-like immunoreactivity.

293.13 CHOLINERGIC AMACRINE CELLS OF THE RABBIT RETINA EXPRESS GABA- AND GAD-LIKE IMMUNOREACTIVITY. N. Brecha, D. Johnson, L. Peichl*, H. Wässle. Departments of Anatomy and Medicine, UCLA School of Medicine, Los Angeles, CA 90024, Max Planck Institute für Hirnforschung, Frankfurt, West Germany.

In the rabbit retina, several histochemically defined cell populations have been identified, including those containing peptides, dopamine, acetylcholine and GABA. Cholinergic amacrine and displaced amacrine cells have been described and these cells selectively accumulate the fluorescent dye 4,6 diamidino-2-phenylindole (DAPI). GABAergic amacrine and displaced amacrine cells have also been identified. The present studies have examined the distribution and co-existence of the cholinergic and GABAergic cell populations.

Normal, optic nerve sectioned and intraocularly DAPI-treated retinas, some pretreated with colchicine, were fixed in a paraformaldehyde and glutaraldehyde solution and subsequently processed by immunohistochemical methods using antibodies to GABA, glutamic acid decarboxylase (GAD) and choline acetyltransferase (CAT). Double label studies demonstrated that all DAPI accumulating cells in the ganglion cell layer (GCL) and prominently labeled DAPI accumulating cells in the inner nuclear layer (INL) contained either GABA or GAD immunoreactivity. In the GCL, GABA or GAD immunoreactive cells which did not accumulate DAPI were also identified and in mid-peripheral retina, these cells make up 10-20% of the total GABA immunoreactive cell population. These cells were characterized by medium to large size somata. In optic nerve sectioned retinas, there was no apparent loss in the number of DAPI accumulating or small size GABA immunoreactive cells. Quantitative studies of the GCL from whole mounted retinas demonstrated that displaced amacrine, GABA and CAT cell populations have a parallel distribution across the retina. GABA and CAT immunoreactive cell density is highest in central retina over the visual streak (GABA, 1150 cells/sq mm; CAT, 850 cells/sq mm) and lower in mid-peripheral (GABA, 400 cells/sq mm; CAT, 350 cells/sq mm) and peripheral retina (GABA, 270 cells/sq mm; CAT, 250 cells/sq mm). CAT immunoreactive and the majority of GABA immunoreactive cells have an identical appearance characterized by a round, small cell body and both of these immunoreactive cell populations have similar spacing in all retinal regions. In summary, these studies demonstrate that cholinergic amacrine cells form a subpopulation of the GABAergic amacrine cell population in the rabbit retina.

We wish to thank Drs. Streit, Oertel and Epstein for antibodies to GABA, GAD and CAT, respectively. Supported by EY 04067 and a Sloan Fellowship to NB and the Max Planck Institute.

293.14 SYNAPTIC ORGANIZATION OF CHOLINERGIC AMACRINE CELLS IN THE RABBIT RETINA. T. Millar* and I.G. Morgan. Centre for Visual Sciences and Research School of Biological Sciences, Australian National University, GPO Box 475, Canberra City, ACT 2601, Australia.

Cholinergic amacrine cells were detected by immunohistochemistry in the rabbit retina using an antiserum prepared against affinity-purified chicken choline acetyltransferase (Johnson, C.D. and Epstein, M.L. J. Neurochem. 46: 968, 1986). At the light microscope level, immunoreactive cell bodies were detected in the inner nuclear layer and the ganglion cell layer, and there were two immunoreactive synaptic layers in the inner plexiform layer. These corresponded well to the putative cholinergic amacrine cells detected in the rabbit retina by localizing sites of acetylcholine synthesis (Masland, R.H. and Mills, J.W. J. Cell Biol. 83: 159, 1979), as starburst cells in Golgi studies (Famiglietti, E.V. Brain Research 261: 138, 1983), by selective neurofibrillar staining (Vaney, D.I., Peichl, L. and Boycott, B.B. J. comp. Neurol 199: 373, 1981) and by DAPI-labelling (Masland, R.H., Mills, J.W. and Hayden, S.A. Proc. R. Soc. 223: 79, 1984. At the electron microscope level, immunoreactivity was associated with processes in the inner plexiform layer which formed clusters within the dense synaptic bands observed at the light microscope level. The processes were derived from amacrine cells since they formed conventional synapses onto processes of ganglion cells and non-immunoreactive amacrine cells. Inputs to the cholinergic processes were observed from bipolar cells, but no input was observed from non-immunoreactive amacrine cells. A feature of the synaptic organization of the cholinergic cells was the occurrence of synapses between immunoreactive profiles within the clusters - a feature also observed in the chicken and goldfish retinas. These features need to be taken into account in models of how the cholinergic amacrine cells are involved in generating directional selectivity at the ganglion cell level.

293.15 INTRAOCULAR ADMINISTRATION OF ETHYLCHOLINE MUSTARD AZIRIDINIUM ION (AF64A): EFFECTS ON CHOLINERGIC AMACRINE CELLS OF THE RABBIT RETINA. A.W. Spira[1], T. Razniewska[1], R. Goldade[1], and I.G. Morgan[2]. [1]Dept. of Anatomy and Lions' Sight Centre, The University of Calgary, Calgary, Alberta, T2N 4N1; [2]Dept. of Behavioural Biology, Australian National U., Canberra, ACT 2601, Australia.

The introduction of the choline analog ethylcholine mustard aziridinium ion, AF64A, (ECMA) into the central nervous system has a profound effect on several important properties of cholinergic neurones (Rylett, B.J. and Calhoun, E.H., J. Neurochem., 34:713, 1980; Fisher, A. et al., J. Pharmacol. Exp. Ther. 222:140, 1982). The retina, with its readily accessible and richly endowed set of well-characterized cholinergic neurones, constitutes a favourable model for investigation of the structural, functional and developmental effects of this neurotoxin. Recent studies of the effect of ECMA on cholinergic neurones in the chick retina (Millar, T.J., et al., J. Neurosci. 7:343, 1987) have demonstrated a loss of acetylcholinesterase and of choline acetyltransferase-like immunoreactivity (ChAT-IR) from the mirror-symmetrical amacrine cells of the inner nuclear (INL) and ganglion cell layers (GCL), and from their processes in the inner plexiform layer (IPL). We have now investigated the effect of intraocular injections of ECMA in anesthetized albino New Zealand rabbits to determine whether the effects on mammalian cholinergic retinal neurones are comparable to those of the chick. Retinas were examined one or four weeks after administration of ECMA on two successive days at a dosage of 30nmoles/10ul injected volume of saline or 10% dimethylsulfoxide (DMSO). Acetylcholine (ACh) levels were assayed by hplc with electrochemical detection (Potter, P.E. et al., J. Neurochem. 41:188, 1983). Tissues were processed for histology and for localization of ChAT-IR in sections and whole-mounts. The primary anti-ChAT serum used was that developed by Johnson and Epstein (J. Neurochem. 46:968, 1986). ECMA (30nmoles) produced a retinal lesion which caused minimal, histological changes, while effecting a sharp reduction in both assayable acetylcholine and ChAT-immunoreactivities. Reduction of ACh by ECMA/saline, as compared to opposite vehicle injected eyes, was 40% at one week post-injection and was sustained at that level at four weeks. ECMA/DMSO resulted in a sustained 25% loss. Histologic alterations were limited to transient changes in photoreceptor outer segments. ChAT-IR was considerably reduced in the half retina adjacent to the injection site. Viewed in both sectioned and intact whole-mounts, it was deficient in the cholinergic INL cells and in the corresponding sublamina 'a' of the IPL. Amacrine cells within the GCL, in contrast, were much less affected at this dosage, retaining ChAT-IR in perikarya and their processes in sublamina 'b' of the IPL. The lesion induced by ECMA appears to be long lasting; it differs from that produced in the chick in primarily involving one of the two symmetrical classes of amacrine cells. It may therefore prove useful in studies of the functional characteristics of rabbit cholinergic cells.

293.16 THE MECHANISM OF DIRECTION SELECTIVITY IN RABBIT RETINAL GANGLION CELLS

F.R. Amthor[1], N.M. Grzywacz[2] and L.A. Mistler[2]*
[1]Dept. of Psychology, Univ. of Alabama at Birmingham 35294
[2]Center for Biological Information Processing, M.I.T., Cambridge, MA

The computational mechanism of On-Off direction selective (DS) rabbit retinal ganglion cells was investigated by comparing their responses to low contrast drifting gratings with the predictions of three basic types of theoretical models: (1) correlation-type second order models such as those proposed for direction selectivity in the fly (Poggio and Reichardt, 1973), which have recently been applied to human psychophysical results (van Santen and Sperling, 1984), (2) threshold models that discriminate the different maximum amplitudes of intracellularly summed responses to preferred vs. null direction stimuli (Grzywacz and Koch, 1987), and (3) a rectified correlation model proposed to take into account segregated On and Off pathways in the retina (Grzywacz and Koch, 1987). Biophysically plausible implementations of these theoretical models that predict different DS cell responses to low contrast drifting gratings may be made in some detail for On-Off DS ganglion cells in rabbit retina because key electrotonic and morphological parameters have been previously defined by intracellular recording and staining (Amthor et al., 1984).

Our experimental results show that DS cell responses to drifting sinusoidal gratings cannot be accounted for by a pure second order (correlation-type) mechanism; Fourier analysis of PST histogram responses to single sine wave gratings reveals significant power at higher than second order harmonics at contrasts as low as 1%, where direction selectivity is still significant. Extant biophysical and morphological data suggest that this may be due to rectifications associated with the segregation of On and Off pathways.

Thresholds are unlikely to be the nonlinearity underlying the DS mechanism because responses to drifting phase locked multiple sinusoidal gratings are not better than the sum of the responses to the isolated components, despite the fact that the summated waveform of two gratings should at some points be more superthreshold than the individual components. The threshold model is also inadequate to explain our finding that in cells which have sufficient maintained firing, statistically significant direction selectivity can exist at very low contrasts that is invariant to the phase angle between pairs of gratings, although phase angle strongly effects the maximum total amplitude of the summated gratings.

The model in which rectified inputs interact by a multiplicative correlation mechanism seems to be most consistent with our results.

293.17 **SYNAPTIC DRUGS INJECTED INTO THE VITREOUS AFFECT THE RETINAL CONTROL OF TURTLE EYE MOVEMENTS.** M. Ariel. Departments of Behavioral Neuroscience and Psychiatry, and Center for Neuroscience, University of Pittsburgh. Pittsburgh, PA 15260.

The analysis of receptive field properties of Directionally Sensitive (DS) retinal ganglion cells during synaptic drug application has shown that similar drugs have similar effects across species. For example, retinal application of the GABA antagonist picrotoxin enables DS cells to respond equally to stimulus movement in all directions, for both rabbit and turtle. GABA antagonism thus blocks DS processing in the vertebrate retina. This conclusion was useful in the interpretation of the effects of intravitreal picrotoxin on eye movement control in the cat, reported last year at this meeting. Similar experiments have now been repeated for turtle and extended to other drugs which are being studied in this laboratory during in vitro recording DS retinal ganglion cells.

Following subcutaneous injections of lidocaine at cranial pressure points, a turtle, Pseudemys Scripta, was placed in a plexiglass box with its head fixed at the center of sets of horizontal and vertical Helmholtz coils. A contact lens search coil was placed on the anesthetized cornea of either eye to measure eye position. Following control records of spontaneous and optokinetic eye movements under various stimulus conditions, intravitreal injections of 20 uL were made through a 30 gauge needle with a Hamilton syringe. Within 30 minutes, the contact lens was replaced on the eye and its movements were recorded while the stimulus conditions were repeated.

As with the cat and rabbit, intravitreal injection of 3.3 mM picrotoxin resulted in a spontaneous nystagmus by that eye with a temporal-to-nasal slow phase. Another selective GABA antagonist, bicuculline, has a very similar effect, and has been found to be effective at concentration in the syringe as low as 34 uM. Assuming a substantial dilution of the injection within the vitreous and retina, these drug induced eye movements are a sensitive indicator of the functioning of DS cells.

For both GABA antagonists, recovery is observed by the day after injection. Similar to rabbit and cats (without visual cortex), the effect of these GABA antagonists was potent enough to block light evoke movements in response to nasal-to-temporal monocular stimulation. However, unlike those mammals, each eye of the turtle may move independently. Thus, during monocular drug application, only the injected eye is affected, whereas the other (unyoked) occluded eye serves as a simultaneous control.

Neostigmine, an acetylcholinesterase inhibitor, increased eye movements at low doses and yet blocked them at high doses. Amino-Phosphono-Butyrate (5.4 mM), which block ON cells in other vertebrate retinas, also blocks visually evoked nystagmus in turtle. These results support the view that drugs which effect DS retinal ganglion cells also modulate pathways involved in subcortical reflexive eye movements. **(Supported by NIH grant EY0578).**

293.18 THE ON CHANNEL IS NECESSARY FOR OPTOKINETIC NYSTAGMUS AT HIGH SPATIO-TEMPORAL FREQUENCIES IN GOLDFISH. P.J. DeMarco*, J.D. Nussdorf*, D.A. Brockman* and M.K. Powers. Dept. of Psychology, Vanderbilt University, Nashville, TN, 37240.

The vertebrate visual system can be subdivided into ON and OFF channels, but differences in function between these channels remain obscure. We assessed the behavioral consequences of blocking ON channel activity with 2-amino-4-phosphonobutyric acid (APB) by measuring the optokinetic nystagmus reflex (OKN) of the goldfish (Carassius auratus). APB was injected bilaterally into the eyes of fish to yield vitreal concentrations of 10, 100, 500, or 1000 uM; controls received saline carrier solution. Two square wave gratings (0.039 & 0.19 cycles/degree visual angle) and a homogeneous field served as stimuli. OKN response was assessed by counting the number of saccadic eye movements over 3-5, 30 sec trials for each stimulus condition. OKN was measured for approximately two weeks following APB treatment. A dose response function revealed that deficits in OKN occurred for animals that received high doses of APB and were exposed to the high spatial frequency stimulus. Fish receiving 1000 uM APB showed a significant decrease in OKN response to the high spatial frequency on post-injection days 0 and 1, and were fully recovered by post-injection day 3. In this experiment, stimuli were rotated about the animals at a constant speed of 72 deg/sec. This translates to temporal frequencies of 2.8 cycles/sec for the low spatial frequency grating and 14 cycles/sec for the high spatial frequency grating. When stimulus gratings were counterbalanced for temporal frequency, disruption in OKN was only apparent for the high spatial frequency rotating at high temporal frequency. These results imply that when high spatial frequencies are presented at high temporal frequencies, blocking the ON channel significantly decreases OKN response. We conclude that: 1) high concentrations of APB disrupt the processing of high spatiotemporal information by the visuomotor system and, 2) the disruption is transient, lasting no longer than 4 days. For the goldfish, processing by the ON channel is necessary to maintain the OKN reflex at high spatiotemporal frequencies. Supported by NIH grant EY03352, BRSG SO7-RR07201 and the Department of Psychology Honors Fund.

293.19 SPATIOTEMPORAL CHARACTERISTICS OF THE RETINAL GANGLION CELLS OF THE FROG. M.L.Mallon* and E.Micheli-Tzanakou. Department of Biomedical Engineering, Rutgers University College of Engineering, Piscataway, New Jersey 08855

In this study the latencies of the spatial components of the ganglion cell Receptive Fields (RFs) are examined for information pertaining to neural pathways in the retina for each of those spatial components.

Multiunit extracellular recordings were performed on ganglion cell fibers terminating in the superficial layers of the optic tecta of medium size grass frogs (Rana Pipiens). The units were separated using an amplitude discrimination method and the RFs were mapped using semi-automated scanning techniques. The response matrix produced is smoothed and linearly transformed into our intensity matrix which is further analyzed by a clustering method[1] to separate the RF into its spatial components. These spatial components which approximate the center, surround and outer surround are then used as stimuli and the latencies in addition to responses are collected for each cluster.

Data were collected for 33 recording sites for a total of 86 neurons. The data show a strong anticorrelation between the magnitudes of responses and the latencies. A weighted increase in latency from center to surround to outer surround of the RF was observed. A simple neural network is proposed for each of the spatial components that fits the experimental data.

293.20 MODELS OF MOVEMENT SENSITIVITY IN TYPE-2 GANGLION CELLS OF FROG RETINA. J. L. Teeters* (SPON: M.A. Arbib). Dept. of Computer Science, University of Southern Calif., Los Angeles, CA 90089-0782

Most ganglion cells in frog retina are movement sensitive. Their response (firing rate) is porpotional to the velocity of the stimulus raised to a constant exponent, $R = k * V^c$. Simulation done by others indicate that models consisting of a differentiation of bipolar cell signals, followed by rectification and spatial summation onto the ganglion cell can explain this velocity dependency. (See O.J. Grusser, U. Grusser-Cornehis, In Frog Neurobiology, R. Llinas & W. Precht. eds, Springer-Verlag 1976, Page 396 for review.)

We use computer simulation to examine the functional validity of these models from two standpoint: The stability of the models in response to parameter changes, and their ability to account for response properties other then velocity dependence. Our current emphasis is the type 2 ganglion cell. The velocity response of the model seems to be very stable to parameter changes. Halving or doubling most time constants does not significantly degrade the behavior. However other response properties (such as response to moving stimuli under stroboscopic illunimation, the response to stationary stimuli being enhanced by previous movement, local adaptation, and erasability) are not accounted for. Extensions to the basic model to encompass these other phenomena are being made. The goal is the development of single model which simultaneously accounts for many response properties. Research supported in part by the NIH under grant 7 R01 NS24926-01 from National Institute of Neurological and Communicative Disorders and Stroke and by the San Diego Supercomputer Center.

294.1 **PURIFICATION OF RAT RETINAL GANGLION CELLS BY PANNING**
B.E.Silverstein* and L.L.Y.Chun* (SPON: V.Tran). Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Studies of neurons and their interactions with other cell types often require pure neuronal cell populations. Previous methods of enrichment for ganglion cells from whole-retina dissociates include density gradient centrifugation (Beale *et al.*, 1983; Sarthy *et al.*, 1983) and use of a fluorescence activated cell sorter (Armson and Bennett, 1983). These procedures are time consuming and yield at best a cell population containing 75% retinal ganglion cells (RGCs).

Isolation of a highly pure (>98%) population of RGCs from a whole-retina cell suspension was effected by the technique of antibody-mediated plate adhesion ("panning") developed by Wysocki and Sato (1978). Plastic petri dishes are prepared by sequential incubation with affinity purified anti-mouse immunoglobulin and then with mouse monoclonal supernatant containing antibody directed against the Thy1.1 antigen. Retinas are dissected *in situ* from P8 rats, dissociated using the proteolytic enzyme papain (Lam, 1972; Bader *et al.*, 1978; Huettner and Baughman, 1986), and triturated. The resulting suspension of single cells is incubated on the panning plates. After removal of the non-adherent cells, the plates are gently washed. The adherent cells are then dislodged by pipetting medium against the plate, yielding a suspension of purified Thy1.1-positive cells.

Samples from the suspensions of whole-retina cells, non-adherent cells, and putative purified RGCs were labeled with anti-Thy1.1 antibody and analyzed with flow cytometry. The whole-retina cell suspension contained 0.35% Thy1.1-positive cells, corresponding to 135,000 Thy1.1-positive cells/retina. The non-adherent and RGC suspensions had 0.14% and 98% Thy1.1-positive cells, respectively. Thus, there was a 280 fold enrichment of Thy1.1-positive cells. The final yield of RGCs was 80,000 cells/retina or 60% of all Thy 1.1-positive cells in the whole-retina dissociate.

Because the retina contains macrophages, which might adhere to the panning plate nonspecifically, as well as other Thy1.1-positive cells, the purity of the RGC population is being studied immunohistochemically. Antibodies directed against GFAP, vimentin, lymphocytes, and macrophages are being used to probe the RGC population for contaminating cell types. However, virtually all cells label with antisera directed against neuron specific enolase and neurofilaments.

This simple, inexpensive, panning procedure rapidly yields a large number of highly pure RGCs. Retinal dissociates from six rats may be prepared and panned in under five hours, yielding 10^6 RGCs.

294.2 **MAb 2-54: AN ANTIBODY THAT BINDS TO A 38 KDa SYNAPTIC VESICLE PROTEIN IN THE RETINA.**
V. Gaur*, D. Possin*, W. Eldred and P.V. Sarthy (SPON: K. Chan). Depts. Ophthalmology and Physiology & Biophysics, University of Washington, Seattle, WA 98195, and Dept. of Biology, Boston University, Boston, MA 02215.

During a search for monoclonal antibodies that bind to specific cell types in the rat retina, we have obtained an antibody, 2-54, that binds only to the two synaptic layers in the retina. MAb 2-54 showed broad species cross-reactivity and labeled retinas from human, monkey, cow, rat, mouse, Xenopus, turtle, goldfish, and Anolis. In certain retinas, a difference in the staining of the two plexiform layers was noted. For example, in the mouse retina, the IPL was strongly stained while the OPL was barely stained, whereas with Anolis the reverse was true. A closer examination of the OPL staining in the monkey retina suggested labeling of both rod and cone terminals.

Ultrastructural localization was carried out using an avidin/biotin-peroxidase pre-embedding technique. The antibody was found to label presynaptic terminals in the plexiform layer and the reaction product was associated with synaptic vesicles. In the turtle retina the amacrine terminals were particularly strongly labeled.

The distribution of the antigen was also investigated in other areas of the nervous system as well as in other organs. Cryostat sections of rat spinal cord, cerebellum, cerebrum, hippocampus, adrenal gland, kidney, and diaphragm were screened. In most brain areas, 2-54 gave a punctate staining in regions containing nerve terminals while the white matter was negative. In the cerebellum, immunoreactivity was seen as small dots in the molecular layer and as large, irregular patches in the granule cell layer. In the spinal cord, staining was once again restricted to nerve terminals. There was no staining of the adrenal gland, kidney, and diaphragm.

Double-diffusion assays showed that MAb 2-54 was an IgG_3. Western blotting of rat retinal homogenates suggested that the antibody binds to a 38 KDa protein. Its ultrastructural localization to vesicles, broad cross-reactivity, and M_r of the antigen indicated that the antibody may be directed against a previously characterized synaptic vesicle protein, Synaptophysin. Comparative Western blotting studies using a commercially available (Boeringer Mannheim) MAb to bovine Synaptophysin showed that the antigens recognized by the two antibodies co-migrated. Further biochemical studies are underway to determine whether 2-54 is directed against Synaptophysin. Nevertheless, the tissue distribution of 2-54 staining is different from that reported for Synaptophysin MAbs, and therefore suggests binding to a new epitope on the Synaptophysin molecule. Developmental studies show that the pattern of binding of 2-54 and that of another synaptic vesicle antibody, SV48, are different in the rat retina. (Supported by EY03664 and EY01730)

294.3 **LOCALIZATION OF GABA RECEPTORS ON PHOTORECEPTOR SYNAPTIC TERMINALS IN GOLDFISH AND CHICKEN RETINAS BY IMMUNOCYTOCHEMISTRY.**
S. Yazulla, K.M. Studholme*, J. Vitorica* and A.L. DeBlas. Dept. Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

A large body of physiological and pharmacological evidence indicates that GABA is a feedback transmitter from a class of horizontal cells to cone photoreceptors in the retinas of nonmammals. However, GABA receptors have not yet been demonstrated on photoreceptors by morphological techniques. We have used a mouse monoclonal antibody (mAb)62-3G1 to GABA receptors in the retinas of chicken and goldfish at the light microscopical level. The mAb 62-3G1 was produced by immunizing BALB/c mice with the $GABA_A$/benzodiazepine receptor complex that had been purified by affinity chromatography on immobilized Ro7-1986/1. The mAb 62-3G1 immunoprecipitated the receptor complex and reacted in immunoblots with the 57,000 Mr peptide which is the [^{3}H]muscimol binding subunit of the receptor complex (Vitorica, Park and DeBlas, Eur. J. Pharmacol., in press). Cryostrat sections were incubated in mAb and processed by a standard indirect PAP method. In both species, GABA receptor immunoreactivity (GABAr-IR) was distributed in a laminar pattern throughout the inner plexiform layer (IPL), similar to that previously shown for GABA-IR and GAD-IR. However, in the outer plexiform layer (OPL) GABAr-IR was restricted to the synaptic terminals of photoreceptors, unlike GABA-IR and GAD-IR which are localized to horizontal cells. Photoreceptor inner segments, nuclei and outer segments were not labeled by GABAr-IR. In chicken, there were two layers of labeled synaptic terminals in the OPL. We could not determine if only cone terminals or if both rod and cone terminals were labeled by GABAr-IR. In goldfish retina, cone synaptic terminals were intensely labeled by GABAr-IR. Rod terminals appeared to be unlabeled or much reduced in label. Cones, unlike rods, are thought to receive GABAergic inhibition from horizontal cells in nonmammalian retinas. The absence of GABAr-IR labeling of horizontal cells suggests that this mAb labels GABA synaptic receptors rather than high affinity GABA transporters in the outer retina of chicken and goldfish. This is the first morphological evidence for synaptic GABA receptors located on cone photoreceptor synaptic terminals.

294.4 **MONOCLONAL ANTIBODIES TO RABBIT RETINAL PHOTORECEPTORS OR MÜLLER CELLS.**
W. H. Tsai[1], J. N. Hokoc*[2], A. P. Mariani*[2] and M. Nirenberg[1]. [1]Laboratory of Biochemical Genetics, NHLBI and [2]Laboratory of Neurophysiology, NINCDS. National Institutes of Health, Bethesda, MD 20892.

Retinal tissue from adult New Zealand white rabbits was dispersed by gentle homogenization and crude particulate fractions were injected into the spleens of Balb/c mice. Three days later the spleen cells were harvested and fused with P3X63Ag8.653 mouse myeloma cells. The antibodies synthesized by the 435 hybridoma cell lines produced were screened by immunohistochemistry using radial sections of fixed adult rabbit retina and peroxidase-antiperoxidase and indirect immunofluorescent methods.

The initial screening of antibody specificity revealed 8 monoclonal antibodies that are specific for a single cell type or a layer of the retina; i.e., 3 antibodies are specific for photoreceptor outer segments, 1 for photoreceptor cell soma, 1 for the outer synaptic layer, 2 for Müller cells, and 1 for cell soma in the ganglion cell layer. In addition, 1 antibody is specific for photoreceptor outer segments and photoreceptor cell soma, 1 antibody recognizes photoreceptor outer segments and Müller cells, and 2 antibodies bind to the outer limiting membrane of retina and to cell soma in the ganglion cell layer. Many antibodies also were found that recognize antigens that are distributed in other, more complicated patterns in retina.

294.5 **MONOCLONAL ANTIBODIES THAT RECOGNIZE SUBPOPULATIONS OF CELLS IN THE GANGLION CELL LAYER OF THE CAT'S RETINA.** N. Tumosa, P.D. Spear, L. Kahan*, Dept. of Psychology, Neurosciences Training Program, Dept. of Physiological Chemistry, and Hybridoma Facility, University of Wisconsin, Madison, WI 53706

Physiological studies have shown that there are three relatively distinct functional classes of ganglion cells in the cat's retina. These classes, termed X, Y, and W cells, form the basis of parallel and separate functional outputs from the retina to visual areas of the brain. Morphological studies of the cat's retina also have identified separate classes of ganglion cells based on soma size and dendritic branching patterns. There is good evidence that the largest of these morphological cell types, the alpha cell, corresponds to the physiological Y-cell. The development of a specific marker for alpha/Y cells would be of great assistance in determining their role in vision. To that end, we have attempted to produce a monoclonal antibody specific for alpha/Y cells in the cat's retina.

We first separated cat retinal cells on the basis of soma size. We then injected 2.3 x 10^5 of the largest cells (25-40 um diameter) intrasplenically into a mouse. Several days later the spleen cells were fused with NS-1 mouse myeloma cells. Antibody producing hybridomas were cloned and IgM antibodies were tested for their reaction with the original immunogen of large retinal cells. Antibodies that showed specificity were placed overnight on 25 um cryostat-cut transverse sections of cat's retina. Rinsed tissue was then incubated with peroxidase-labeled goat anti-mouse IgM for 1 hour. Hydrogen peroxide and diaminobenzidine were used to visualize the monoclonal antibody labeled cells.

Many of the monoclonal antibodies reacted with retinal cells; nine were chosen for further analysis. All nine reacted with cell somas in the ganglion cell layer (GCL) and most also reacted with processes that appear to be dendrites. Seven of the antibodies reacted only with cells in the GCL. One of these reacted with a large heterogeneous population of cells; the other six reacted with more homogeneous subpopulations of GCL cells. For instance, one antibody reacted only with very large cells in the GCL whereas others reacted only with smaller cells. Two antibodies reacted with cells in the inner nuclear layer (INL) as well as a subpopulation of cells in the GCL. One of these antibodies reacted with many INL cell somas but labeled no processes. The other reacted with only a few INL cell somas and with processes extending into the inner plexiform layer from both INL and GCL cells. None of the antibodies reacted with elements in any other layer of the retina. Further studies are under way to identify the retinal cell types recognized by each antibody.

294.6 SEROTONIN ANTAGONISTS REDUCE THE EFFICACY OF HORIZONTAL TO GANGLION CELL TRANSMISSION IN THE INNER RETINA OF THE RABBIT. S.C. Mangel, W.J. Brunken and R.F. Miller. Department of Ophthalmology, Washington University School of Medicine, St. Louis, Missouri 63110.

In the rabbit retina, serotonin ($5\text{-}HT_2$) antagonists reduce the spontaneous activity and the on-components of the light-evoked responses of all classes of brisk ganglion cells (Brunken and Daw, 1986). Because the on-surround of off-center cells is affected by these antagonists and because rabbit horizontal cells contribute to the surround of ganglion cells (Mangel and Miller, 1987), we studied whether horizontal cells or the horizontal cell input to ganglion cells is also affected by serotonin antagonists.

In our experiments, LY53857, a $5\text{-}HT_2$ antagonist, was added to the superfused rabbit eyecup, while horizontal and ganglion cells were simultaneously monitored with intracellular and extracellular electrodes, respectively. The light-evoked responses of horizontal-ganglion cell pairs were tested with flashing spots, annuli and slits of light. In some drug applications, sinusoidally-modulated current was injected into a horizontal cell while the extracellular spike activity of a nearby ganglion cell was monitored.

As reported previously, LY53857 (10-80 uM), reduced the spontaneous activity and the on-components of the light responses of ganglion cells. During these effects, the membrane potential and light-evoked responses of horizontal cells remained unchanged, as did the b-wave of the ERG. Later occurring effects on horizontal cells, such as increases in light response amplitude, were also observed. These findings suggest that during the effects of LY53857 on ganglion cells,the serotonin antagonist acts predominantly in the inner retina. Furthermore, a dramatic reduction in the modulation of ganglion cell discharge induced by horizontal cell polarizations during application of the $5\text{-}HT_2$ antagonist was observed. These findings thus suggest that serotonin antagonists can reduce the efficacy of horizontal cell to ganglion cell transmission at an inner retinal site.

Supported by NEI grant ROl EY-05102.

294.7 THE EFFECTS OF GABA AND SEROTONIN ON THE RESPONSE PROPERTIES OF RETINAL HORIZONTAL CELLS OF THE SKATE. J.L. Cohen Dept. of Anatomy, Wright State University School of Medicine and School of Science and Engineering, Dayton, Ohio 45435 and the Mount Desert Island Biological Laboratory, Salsbury Cove, Maine.

The retina of the skate has been shown to possess neurons that contain the neurotransmitters GABA and serotonin (Brunken et al., J. Comp. Neur. 243:1-12, 1986). GABA was found in an interplexiform type cell, while serotonin was located within amacrine cells. We therefore wanted to determine the effect of GABA on the membrane potential, and light-evoked activity of the horizontal cell. We also wanted to determine if serotonin played a role in the activation of the GABAergic interplexiform cells, since it has been found in amacrine cells which may be presynaptic to the GABA-ergic interplexiform cell (Brunken et al., 1986).

Intracellular recordings were made from the superfused eyecup preparation of the skate, Raja oscellata. Horizontal cells were identified by their characteristic response to specific types of light stimuli. They were encountered between 75 and 120 microns below the retinal surface and had resting potentials in the dark between -20mv and -40mv. These cells responded to light with graded hyperpolarizations that increased in amplitude with increasing stimulus diameter. In order to keep the retina in the dark adapted state, stimulus intensities used were approximately one log unit above threshold.

When a 3 minute pulse of 500 uM GABA flowed over the retina, the membrane potential of the cell depolarized approximately 12 mv. As the membrane potential depolarized, the response amplitude of the cell increased. Changes in the waveform of the response was also seen. The response became faster, a transient began to appear in the initial part of the hyperpolarization and the waveform became more complex. As the GABA was washed out with control Ringer's, the membrane potential started to hyperpolarize until it returned to the control resting potential. During this recovery period, the amplitude of the light evoked responses also decreased until it returned to control levels.

Application of 500 uM serotonin to the retina caused a depolarization of the membrane potential approximately 13mv. At the same time there was an increase in the amplitude of the light evoked responses.

Supported by a fellowship from the Lucille P. Markey Trust.

294.8 N-ACETYLASPARTYLGLUTAMATE LOCALIZED BY IMMUNO-ELECTRON MICROSCOPY IN PUTATIVE SYNAPTIC VESICLES IN THE INNER PLEXIFORM LAYER OF THE AMPHIBIAN RETINA. L. C. Williamson* and J. H. Neale (SPON: D. Eagles). Dept. of Biology, Georgetown University, Washington, D.C. 20057.

N-Acetylaspartylglutamate (NAAG) is found specifically and in relatively high concentration in the nervous system. We have reported the use of antisera and affinity purified antibody prepared against NAAG to localize this molecule within specific subpopulations of peripheral and central neurons. In the amphibian retina, NAAG-IR is concentrated in some, but not all, amacrine and bipolar neurons as well as their neurites in the inner plexiform, outer plexiform and inner segmental synaptic layers (Br. Res. 406:397, 1987). In contrast to data we have obtained in the mammalian retina, there is little evidence for NAAG in frog retinal ganglion cells.

In the present study, we have examined the fine structural localization of NAAG-IR within the amphibian inner plexiform layer, a synaptic neuropil containing ganglion cell, amacrine and bipolar neurites. Frogs, Rana pipiens, were fixed by perfusion with carbodiimide and paraformaldehyde. Retinas were removed and postfixed prior to embedding in LR White resin. Ultrathin sections were stained with primary antibody against NAAG and IR was visualized by immunogold labeling. NAAG-IR was observed within some but not all vesicles associated with apparent presynaptic endings in the inner plexiform layer. Only a portion of the vesicles within individual synaptic endings were labeled suggesting the possibility of its co-release with other molecules. Some synapses within the neuropil exhibited no labeled vesicles. At the light microscopic level, NAAG-IR is distributed throughout the cell body and neurites of a subpopulation of amacrine and bipolar cells. Consistent with this result, NAAG-IR was found associated at the ultrastructural level with a number of non-synaptic structures in some inner nuclear layer neurons.

Data on the activation of NMDA receptors by NAAG and on the role of NMDA receptors in amphibian amacrine and bipolar neuron function, together with these ultrastructural results, provide support for the hypothesis that NAAG participates in retinal neurotransmission. Studies of NAAG biosynthesis and release from frog retinal cells in vitro have been initiated. (supported by NIDA grant DA 02297)

294.9 ENKEPHALINS AND DYNORPHINS IN MAMMALIAN RETINA. K.L. Jones* and D.W. Hoffman. Neurochemistry Lab., SIU Sch. of Med., Springfield, IL 62708.

Neuropeptides have been identified in amacrine cells in the retinas of several vertebrate species, where they may serve as neurotransmitters or neuromodulators mediating the action of amacrine cells on the receptive field organization of complex ganglion cells. Several proenkephalin A-derived neuropeptides (the enkephalins), have been identified in the retina of the guinea pig (cavia porcellus), but not in other mammalian retinas, such as the OM strain white rat, despite the fact that opiate receptors have been reported in the rat and other mammalian retinas.

The other neuropeptides which can be endogenous ligands for these opiate receptor binding sites are other enkephalins, or the proenkephalin B-derived peptides (the dynorphins/neoendorphins). Their presence may serve to resolve the discrepancies which currently exist between immunochemical studies of opioid peptides in mammalian retina, and the results of opiate receptor binding studies.

Retinas are removed from anesthetized animals and rapidly sonicated in HPLC buffer, which is composed of 7.5 mM trifluoroacetic acid in 25% acetonitrile. Samples are centrifuged and injected onto a reverse phase column, and eluted with the above HPLC buffer at 0.6 ml/min. Fractions are collected and assayed for peptides by RIA. Preliminary data indicates that although dynorphin B is present in some mammalian retinas, the levels are low and variable. Dynorphin A 1-17 appears to be present in much higher concentrations than dynorphin B. Using combined HPLC-RIA, we have consistently found significant levels of dynorphin A 1-17 in retinas of cat, rabbit, and monkey. This may be the predominant form of the prodynorphin-related peptides in mammalian retina.

Animal	N	Dynorphin A 1-17 (pmol/retina)
Monkey	2	1.48
Rabbit	12	0.81
Cat	6	0.48

294.10 **LOCALIZATION OF MET-ENKEPHALIN-ARG-PHE IN THE VERTEBRATE RETINA.** Y.Y. Thomas Su. Center for Biotechnology, Baylor College of Medicine, 4000 Research Forest Drive, The Woodlands, Texas 77381

It is well established that the structure of proenkephalin A contains four copies of Met-enkephalin (ME) and one copy each of Leu-enkephalin (LE), the heptapeptide ME-Arg-Phe (ME-7) and the octapeptide ME-Arg-Gly-Leu (ME-8). Previous studies from this laboratory have demonstrated the presence, localization, biosynthesis and release of ME in the vertebrate retina. In this communication we report the localization of the heptapeptide ME-7 in the chicken retina.

Isolated eye cups were fixed in buffered (0.1 M phosphate buffer, pH 7.4) 4% paraformaldehyde overnight at 4°C. The retinas were then isolated from the posterior eye cups and cut into small rectangular-shaped pieces. Each piece was embeded in agarose and 75 μm thick transverse sections prepared with a vibratome. The sections were preincubated in 2% normal goat serum in PBS for 2 hours and then incubated in polyclonal anti-ME-7 (1:500 in PBS) overnight at 4°C. The sections were rinsed 3 times for 10 minutes each in PBS and then incubated in a biotinylated goat anti-rabbit IgG (1:200 in PBS) for 2 hours at room temperature. The sections were then rinsed 3 times for 10 minutes each before incubation in the avidin-biotin complex (ABC, 1:100 in PBS) for 2 hours at room temperature. After a 1 hour rinse, the sections were stained with a DAB solution (20 ml PBS, 60 μl H_2O_2, 10 mg diaminobenzidine tetrahydrochloride) for 10 to 20 minutes. The staining reaction was terminated by a 10 minute wash in PBS. The specificity of the immunostaining was determined by incubating retinal sections in antibody which had been preabsorbed with excess ME, LE, ME-Arg, ME-7, ME-8, or β-endorphin (100 μg/ml of antiserum).

An examination of retinal sections revealed that ME-7-like immunoreactivity was localized to a subpopulation amacrine cells in the inner nuclear layer. ME-7 stained pear-shaped cell bodies were situated in the second and third tiers of cells from the border of inner nuclear and inner plexiform layers. These cells sent their processes into sublaminae 1, 3 and 4 of inner plexiform layer. No ME-7 immunostaining was detectable when antibody was preabsorbed with excess ME-Arg or ME-7. However, excess ME, LE, ME-8 or β-endorphin exhibited no effect on ME-7 staining. These observations, therefore, suggested that the immunostaining observed in the tissue is specific for ME-7 and/or ME-Arg.

The distribution of ME-7-like immunoreactivity observed in the present study corresponds quite well with previous reports on the distribution of ME-like immunoreactivity in the avian retina. However, more studies are needed to elucidate their relationships.

Supported by NIH Grant EY03701 and Retina Research Foundation (Houston).

294.11 THE DEVELOPMENT OF CRF-CONTAINING NEURONS IN THE RAT RETINA. D. Zhang and H.H. Yeh, Dept. Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

We have been studying a system of corticotropin releasing factor (CRF)-containing neurons in the rat retina. In the rat retina, CRF has been localized to amacrine cells in the inner nuclear layer and ganglion cells in the ganglion cell layer (Skofitsch and Jabcobowitz, 1984). Recent anatomical evidence from our laboratory, however, suggests the possibility that the majority of CRF-containing cells in the ganglion cell layer may in fact be displaced amacrine cells. To help reveal the identity of CRF-containing neurons, we have examined their developmental profiles as part of our anatomical analysis of the CRF system in the rat retina.

We examined immunohistochemically the development of CRF-containing retinal neurons in Long Evans rats of different ages (embryonic day-20 to postnatal day-19). Beginning with the day of birth, littermates were used for each developmental series; one rat pup from each litter was sacrificed on a selected postnatal day by transcardiac perfusion with ice-cold phosphate buffer under chlorpent anesthesia and then enucleated. The retinas were quickly isolated, prepared as wholemounts, immersed in 4% paraformaldehyde for two hours and stored in cryoprotectant (Watson et al., 1986) so that tissue from a complete developmental series could be processed simultaneously for immunohistochemistry. One wholemount from each rat pup was subsequently embedded in epon to obtain transverse sections.

The first CRF-immunopositive cells were observed by postnatal day-4, when wholemount preparations revealed faintly staining perikarya limited largely to the central (posterior) region of the developing retina. By postnatal day-6, CRF immunoreactivity became more evenly distributed throughout the retina. Transverse sections indicated that, at the earliest detectable time, CRF-immunopositive cells were situated both in the ganglion cell layer and in the innermost aspect of the neuroblastic cell mass destined to become the inner nuclear layer. This is similar to the laminar distribution of CRF-containing cells in the adult rat retina. However, a striking feature in development appears to be shift in the pattern of distribution of these cells. Over the first two postnatal weeks, both the density of CRF-containing cells in the inner nuclear layer and the ratio of cells in the inner nuclear layer to those in the ganglion cell layer decrease. This is consistent with the notion of a perikaryal translocation during development and we postulate that a subpopulation of immature amacrine cells become displaced to the ganglion cell layer. By eye-opening (postnatal day-15), such dynamic developmental changes appear to stabilize and, by postnatal day-19, CRF-containing neurons become morphologically mature.

294.12 SYNAPSES FROM BIPOLAR CELLS ONTO TYROSINE HYDROXYLASE IMMUNOREACTIVE AMACRINE CELLS IN CAT AND RABBIT RETINAS J.N. Hokoc* and A.P. Mariani* (SPON: M.T. Caserta) Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892

Dopaminergic amacrine cells in the vertebrate retina had long been characterized as "interamacrine" as they were only found to be pre- and post-synaptic to other amacrine cells based on uptake studies. Immunohistochemistry with antibodies directed against tyrosine hydroxylase (TH), the rate limiting enzyme in the catecholamine synthetic pathway, revealed synapses from bipolar cell axon terminals to TH-containing neuronal processes at ribbon synapse in the rhesus monkey retina (Hokoc & Mariani, 1987). In fact, these ribbon synapses accounted for the majority of the synaptic input to this transmitter phenotype. This finding provided evidence for a direct, light-mediated pathway from the outer plexiform layer to dopaminergic amacrine cells in the inner plexiform layer and, thus challenged the notion of the dopaminergic amacrine cell type as "interamacrine". In order to determine if the finding of synapses from bipolar cells to dopaminergic amacrine cells could be generalized to other species, we therefore studied the synaptic organization of dopaminergic amacrine cells in the retinas of cat and rabbits with electron microscopy of TH immunoreactivity. In both species, the TH-containing processes possessed small clear vesicles and were presynaptic to nonimmunoreactive amacrine cells. Synapses onto TH-immunoreactive profiles were from bipolar axon terminals at ribbon synapses and from nonimmunoreactive amacrine cells also. These synapses were located in the outermost stratum of the inner plexiform layer. Ribbon synapses onto dopaminergic amacrine cells in retinas of cats and rabbits now demonstrate that the original finding in the primate can be generalized to at least two other species and therefore may be a significant feature in the retinas of many other vertebrates as well.

J.N. Hokoc is on leave from the Federal University of Rio de Janeiro.

294.13 TYROSINE HYDROXYLASE-LIKE IMMUNOREACTIVE AMACRINE CELLS IN THE LARVAL TIGER SALAMANDER RETINA. S.Z. Yang*, C.B. Watt, D.M.K. Lam, and S.M. Wu. Center for Biotechnology, Baylor College of Medicine, The Woodlands, Texas 77381 and Department of Ophthalmology, Baylor College of Medicine, Houston, Texas 77030.

Recently we have initiated studies that systematically examine the structural organization of classical transmitter-specific cell populations in the larval tiger salamander retina (Watt et al., 1987). In the present study, immunocytochemistry was used to examine the organization of tyrosine hydroxylase-like (TH) immunoreactive cells. The antibody to TH was obtained from Eugene Tech and studies were performed using the avidin-biotin method (Vector Laboratories).

Of 728 TH-immunostained cells observed in transverse cryosections obtained from various retinas, 90% were situated in the innermost cell row of the inner nuclear layer and were designated as amacrine cells. Their cell bodies were round- to pyramidal-shaped. The processes of these cells were found to distribute in sublayers 1, 3 and 5 of the inner plexiform layer. The remaining 10% of immunostained cells were found in the ganglion cell layer and were tentatively designated as displaced amacrine cells. Their cell bodies were round- to oval-shaped, and their processes were observed to ramify in sublayers 1, 3, and 5 of the inner plexiform layer.

An examination of whole-mount retinas revealed the size, distribution and density of TH-immunostained cells. TH-amacrine cells ranged from 17 to 19 microns in diameter with the vast majority measuring 18 microns. Displaced TH-amacrine cells were somewhat larger and ranged from 18 to 20 microns in diameter. Both TH-immunostained amacrine and displaced amacrine cells were distributed throughout central and peripheral regions of the retina. The density of TH-amacrine cells was 49±13 cells per mm^2. The density of displaced TH-amacrine cells was not determined in the whole-mount retina, although an examination of transverse sections revealed that they composed 10% of TH-cells. Studies are presently examining the morphology of dendritic fields of TH-immunoreactive amacrine and displaced amacrine cells.

294.14 **GABA-ERGIC GANGLION CELLS IN THE RABBIT RETINA.** **C.B. Watt, B.C. -Y. Yu, D.M.K. Lam, and K.R. Fry.** Center for Biotechnology, Baylor College of Medicine, The Woodlands, Texas 77381.

Previous studies using glutamic acid decarboxylase (GAD) immunocytochemistry and high affinity ^{3}H-GABA uptake autoradiography have suggested the presence of gamma-aminobutyric acid (GABA) in populations of ganglion cells in the rabbit retina. The recent development of an anti-GABA polyclonal antibody has provided an additional tool to investigate the localization of GABA in the central nervous system. We used the GABA antibody in combination with a ganglion cell-specific monoclonal antibody, AB5 (Fry, et al., Brain Research 338:360, 1985), to examine if GABA is present in ganglion cells of the rabbit retina (Yu, et al., Invest. Ophthalmol. Vis. Sci. (Suppl.) 28:349, 1987). These studies revealed that GABA was localized to large, medium and small ganglion cells.

As a continuation of these studies, we have utilized other markers of GABA-ergic activity to further investigate GABA-ergic ganglion cells in the rabbit retina. Both GAD-immunocytochemistry and high-affinity ^{3}H-GABA uptake autoradiography labelled large, medium and small cells which had the appearance of ganglion cells. These techniques also labelled fibers in the nerve fiber layer. Furthermore, ^{3}H-GABA-labelled processes were observed to enter and travel in the optic nerve itself. Subsequent double-label studies utilizing ^{3}H-GABA uptake in combination with the AB5 ganglion cell-specific antibody were performed to definitively identify those ganglion cells which exhibit high affinity uptake of ^{3}H-GABA. These studies revealed that large, medium and small ganglion cells specifically accumulate ^{3}H-GABA. Double-label studies utilizing GAD immunocytochemistry in combination with AB5 immunocytochemistry are presently underway to determine if GAD is present in ganglion cells of the rabbit retina. Future studies are directed towards determining the central projection sites of GABA-ergic ganglion cells.

294.15 RELEASE OF DOPAMINE AND GAMMA-AMINOBUTYRIC ACID FROM THE RETINA FOLLOWING DIISOPROPYLFLUOROPHOSPHATE. A.W. Kirby, A.T. Townsend*, R.G. Stafford*, C.D. Pope* and T.H. Harding*. U.S. Army Aeromedical Research Laboratory, Ft. Rucker, AL 36362.

We previously have demonstrated a preferential loss in the visual evoked response (VER) to low spatial frequency stimulation in cats and rabbits following administration of diisopropylfluorophosphate (DFP), an anticholinesterase agent. Although the most likely mechanism is the prolonged action of acetylcholine (ACh) at cholinergic synapses in the visual pathway, it has become apparent that acetylcholinesterase (AChE) inhibition does not always correlate well with observed changes. This is explained easily if putative neurotransmitters other than ACh are involved following exposure to DFP. Previous neurochemical work from our lab has demonstrated changes in dopamine (DA) and gamma-aminobutyric acid (GABA) both in retina and cortex following administration of DFP. ACh, as well as DA and GABA, has been localized mainly to amacrine cells in the retina. Based upon histochemical localization by others, cholinergic amacrine cells are not in position to alter DA or GABA levels through increased synaptic activity. Therefore, we undertook these experiments to directly investigate release of DA and GABA from the retina.

Seven adult cats and 5 adult rabbits were anesthetized and 50 µCi of ^{3}H-DA or ^{3}H-GABA injected into the vitreous. Following one hour of incubation, the eye was enucleated and the anterior segment and lens removed. The remaining eye cup was rinsed in 54 ml oxygenated Ames buffer for 30 minutes to remove excess label, trimmed to about a 15 mm square (including area centralis), and mounted on a holder. The holder then was transferred through a series of buffer-containing vials, spending 2 minutes in each. DFP was added to 4 vials on the plateau of the release curve. To determine the amount of labeled material released, one ml of buffer from each vial was mixed with 5 ml of scintillation fluid and radioactivity counted with a scintillation counter. Studies thus far have been done without any light modulation.

For the 4 vials containing DFP we observed a biphasic change in release of both DA (4 rabbit eyes; 6 cat eyes) and GABA (6 rabbit eyes; 3 cat eyes). Release was increased consistently in the first vial containing DFP and then decreased. Some experiments were done under conditions to block synaptic transmission during DFP exposure (high Mg^{2+} and low Ca^{2+}). The biphasic change persisted in those experiments (2 rabbit eyes-GABA; 1 cat eye-DA). For one cat eye, 2 mM ACh was substituted for DFP and there was no effect on DA release. Although preliminary, these experiments support the lack of synaptic contact between cholinergic and DA or GABA amacrine cells in cat and rabbit retina. Futhermore, they suggest a direct effect of DFP on neuronal membranes of DA and GABA neurons.

294.16 **IDENTIFICATION OF A DOPAMINE-ACCUMULATING GANGLION CELL TYPE IN THE CAT'S RETINA BY *IN VITRO* FLUORESCENCE.** D.M. Dacey. Dept. of Ophthalmology, Univ. of Washington, Seattle, WA 98195.

Anesthetized cats received intravitreal injections of dopamine and the indoleaminergic transmitter analogue 5,7 dihydroxytryptamine. The eyes were removed after 3-8 hrs and the retinas were dissected in oxygenated Ames medium and mounted flat in a superfusion chamber on the stage of a light microscope. When retinas treated in this way are observed under blue epifluorescence illumination, an intense yellow-green fluorescence is present in distinct subpopulations of neurons in the inner nuclear layer (INL) and ganglion cell layer (GCL), and in their dendrites in the inner plexiform layer (IPL). The complete dendritic morphology of these cells was demonstrated by intracellular injections *in vitro* of lucifer yellow and rhodamine conjugated horseradish peroxidase (HRP). One population of fluorescing neurons corresponds to the dopaminergic amacrine cells shown previously with immunohistochemical and histofluorescence techniques. These cells are located in both the INL and the GCL and give rise to sparsely branched dendrites that narrowly stratify at the outer border of the IPL. Another population of cells is restricted to the ganglion cell layer; they have larger cell bodies and a less intense fluorescence than the dopaminergic amacrines. Intracellular HRP injections into these cells show that they comprise a single morphological type of ganglion cell with the following properties. The spherical cell body ranges in size from about 15 µm near the central area to about 20 µm in the retinal periphery. Dendritic field size increases from 150-200 µm at 0.5 mm from the central area to 500-600 µm in the retinal periphery and is thus about twice the size of a beta cell at any given eccentricity. The axon is medium caliber, about 1 µm in diameter. The dendritic tree is narrowly stratified at the outer border of the IPL (25-30 µm from the cell body when measured *in vitro* after lucifer yellow fills) and shows a characteristic branching pattern marked by gently recurving and meandering dendrites that establish an elliptical field. The dendritic branches do not fill the field uniformly but show a relatively high density and regular spacing in the proximal half of the tree and more sparse, less regular spacing in the distal half. HRP fills of a cluster of adjacent cells show that the distal half of the dendritic field overlaps with its neighbors. In the region of overlap dendrites of neighboring cells interdigitate so that, despite the variation in density across a single field, a constant density and spacing across the plexus of dendrites for the cell population is achieved. As for alpha and beta cells, dendritic field size increases as cell density decreases so that the amount of dendritic overlap also remains constant from center to periphery. Preliminary estimates of cell density based on cell-to-cell spacing suggest that the dopamine-accumuating ganglion cells comprise about 10% of the total ganglion cell population in cats. (Supported by USPHS-NEI grant EY-06098.)

294.17 CATECHOLAMINERGIC GANGLION CELLS IN THE RETINA OF THE PIGEON. K.T. Keyser*, L.R.G. Britto and H.J. Karten. Dept. of Neurosciences, UCSD, La Jolla, CA 92093 and Dept. Physiol. and Biophys., Institute of Biomedical Studies, Sao Paulo State Univ., 05508 Sao Paulo, Brazil.

Tyrosine hydroxylase (TH) converts tyrosine to DOPA and is considered a reliable marker for catecholaminergic neurons. We used a rabbit antiserum directed against tyrosine hydroxylase to investigate the distribution of catecholamines in the retina of the pigeon Columba livia.

Two populations of neurons in the ganglion cell layer (GCL) exhibited TH-like immunoreactivity; a lightly stained type which was not included in this analysis and a more intensely stained type. The heavily stained somata were about 12 um in diameter and, in some sections, could be seen to extend processes into the middle and outer laminae of the inner plexiform layer (IPL). In addition, in many cases the cells gave rise to a single long process which could be followed in the optic fiber layer toward the optic nerve head.

The TH-positive cells in the GCL were present in low density throughout the retina. In the ventral periphery of the retina, there were about 10 TH-positive cells/mm^2. This figure increased to 20-25 cells/mm^2 in an oval central area that included the fovea. There was also a region of higher density (20-22 cells/mm^2) in the central red field. The density decreased in the remainder of the superior nasal and temporal areas to the level found in the ventral periphery.

Multiple injections of rhodamine labelled latex microspheres into the optic tectum resulted in retrograde labelling of a large number of ganglion cells throughout the retina. Many of the TH-positive cells in the GCL also exhibited rhodamine fluorescence. This indicates that these cells project centrally and therefore represent a population of retinal ganglion cells.

Tyrosine hydroxylase immunoreactivity is present in fibers in many areas of the optic tectum including the retinorecipient layers. Some of this may be attributable to central catecholaminergic nuclei. Unilateral enuculation results in little apparent change in the pattern of staining in these areas. This result may be due to both the low numbers of TH-positive ganglion cells and the extensive projections of central catecholaminergic cell groups to the optic tectum. Supported by EY06890 and DAMD 17-86-C-6093/Livingston.

294.18 CHOLINOCEPTIVE NEURONS IN THE RETINA OF THE CHICKEN: AN IMMUNOHISTOCHEMICAL STUDY OF THE NICOTINIC ACETYLCHOLINE RECEPTORS. T.E. Hughes, K.T. Keyser*, P.J. Whiting#*, J.M. Lindstrom#, and H.J. Karten. Dept. of Neurosciences, UCSD, La Jolla, CA 92093 and #Receptor Biology Lab, The Salk Institute for Biological Studies, La Jolla, CA 92138

Choline acetyltransferase (ChAT) antibodies have been used to identify and characterize the presumptive cholinergic neurons in the vertebrate retina. However, the postsynaptic cholinoceptive neurons have been more difficult to identify.

We used monoclonal antibodies directed against the nicotinic acetylcholine receptor (nAChr) of bovine muscle (mAb 210) or chick brain (mAb 270) to investigate the distribution of presumptive cholinoceptive neurons in the retinae of white leghorn chicks. In addition, selected sections were simultaneously labeled with antisera directed against glutamine synthetase (GS) or ChAT to classify the laminar distribution of the labeling of nAChR within the inner plexiform layer (IPL) and its distribution relative to ChAT-like staining, respectively.

The antibodies mAb 210 and 270 stain small to large-sized somata in the ganglion cell layer (GCL) and small to medium-sized cells in the inner half of the inner nuclear layer (INL). They also stain a population of large somata at the INL-IPL border. Labeled dendrites can be followed from the immunoreactive somata into two distinct laminae within the IPL. Double labeling with the GS antiserum reveals that the laminae seen with mAb 210 are centered in laminae 2 and 4. Each of these laminae receive arborizations from the immunoreactive cells in the INL and GCL. However, the relative contributions of the two populations cannot be readily discerned.

Double labeling with the ChAT antiserum reveals that the ChAT distribution within the IPL lies within the broader nAChr stained laminae. No evident co-occurrence of staining of ChAT and nAChR is found in the somata.

These data provide a preliminary identification of at least some of the presumptive cholinoceptive neurons in the chick retina. Since the small and medium-sized cells in the INL are confined to the inner half of the layer, it is probable that the majority of these neurons are amacrine cells. The large somata at the inner margin of the INL resemble the displaced ganglion cells in their morphology and distribution. The majority of the labeled somata in the ganglion cell layer can, on the basis of their size and morphology, be classified as ganglion cells.

294.19 **DISTRIBUTIONS OF CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE ACTIVITIES IN THE RETINAL LAYERS OF THREE AVIAN SPECIES.** L. E. White*, C. D. Ross, and D. A. Godfrey. Dept. of Physiology, Oral Roberts Univ. School of Medicine, Tulsa, OK 74171.

The activities of choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) were assayed in submicrogram samples from retinal layers of avian species using quantitative histochemical techniques. These quantitative data were compared to patterns of staining for ChAT-like immunoreactivity and AChE activity. Red-tailed hawk and road runner were sampled to determine these activities in species of different visually related behaviors. Red and yellow fields of pigeon were sampled to investigate the relationship between the enzymes of acetylcholine metabolism and the gradient of inner plexiform layer (IPL) complexity, increasing from the yellow field to the red. The results are summarized in the table below with enzyme activities expressed as mean ChAT activity (in µmol/kg dry wt/min)/mean AChE activity (in mmol/kg dry wt/min). Most standard errors are less than 15% of the means.

	Red-Tailed Hawk	Pigeon Red Field	Pigeon Yellow Field	Road Runner
OPL	3/163	16/6	4/3	5/3
Inner INL third	3080/72	1362/60	2374/77	547/72
Outer IPL peak	11,033/759	8120/599	9839/616	3000/916
Interpeak minimum	2141/416	557/256	986/399	233/335
Inner IPL peak	7343/687	4143/582	6957/672	1375/768
Ganglion cell layer	3034/166	3362/129	2328/135	917/244

ChAT and AChE activities were concentrated in and near the IPL. Within the IPL, two peaks of ChAT activity were obtained, with the activity of the outer peak exceeding that of the inner. Little ChAT activity was found superficial to the middle of the inner nuclear layer (INL). The distribution of AChE activity corresponded well to that of ChAT activity except in the outer plexiform layer (OPL) and the outer margin of the INL in hawk.

The distributions of enzyme activities suggest that populations of amacrine cells in these avian retinae are cholinergic. In addition to these same cells and presumably cholinoceptive ganglion cells, AChE activity was associated in hawk with a population of horizontal cells that should be unrelated to cholinergic neurotransmission. The quantitative similarities between the activities in red and yellow fields of pigeon indicate that the cholinergic system may not be specifically involved in the increase in IPL complexity across the pigeon retina. The four-fold range of ChAT activity between hawk and road runner suggests important differences in the densities and function of cholinergic elements in these species.

295.1 MULTIMODAL CONVERGENCE OF SENSORY PATHWAYS ON MOTONEURONS OF FLIGHT MUSCLES IN THE FLY (*Calliphora*). K.Hausen* and R. Hengstenberg*. (SPON: C. Wehrhahn). Max-Planck-Institut für biologische Kybernetik, 74 Tübingen, FRG

The flight motor of flies consists of indirect flight muscles, which generate the basic wingbeat pattern during flight, and direct flight muscles, which control the flight course by altering differentially the pitch and beat amplitudes of the wings. The spike-activity in direct flight muscles is phase-coupled to the wing beat-cycle. Visual inputs modulating the activity of the muscles are gated by mechanosensory afferences of the wing-nerve and the halteres, both monitoring the wing-oscillations (Heide,G. in: Nachtigall,W (ed.) Biona-report 2, Fischer, Stuttgart, 1983, pp 35-52).

In order to analyze the neural circuit mediating these interactions, we studied the motoneurons of direct flight muscles and sensory projections in the thoracic ganglion using the cobalt-technique. We employed, in particular, cobalt-infusions of different durations in order to produce selectively first-order stainings, which are due to direct uptake of cobalt into injured neurons, and higher-order stainings of neurons, which are assumed to be caused by cobalt-diffusion through gap junctions from directly stained neurons and which, thus, can demonstrate functional pathways in the nervous system (Strausfeld,N.J. and Bassemir,U., J.Neurocytol., 12:971, 1983).

The motoneurons (Mn) of the direct flight muscles b1, b2, I1, III1, ps1, ps2 were identified and studied light microscopically. All of them show large dendritic domains in the dorsal part of the mesothoracic ganglion and additional dendrites in ventral layers of the ganglion. The axons of Mnb1, Mnb2, and Mn11 project through the anterior dorsal mesothoracic nerve, those of MnIII1 and Mnps1-2 run through the mesothoracic accessory nerve to their target muscles. The dendritic main trunks of Mnb1, Mnb2, and MnIII1 were found to be cobalt-coupled to large interneurons, which constitute a prominent commissure in the dorsal mesothoracic ganglion.

The mechanosensory projections of each haltere form a dense tract in the ipsilateral half of the thoracic ganglion. Prolonged cobalt-infusions into halteres resulted in higher order stainings of axonal bundles and single large interneurons, which terminate in the contralateral parts of the meso- and prothoracic ganglion, in impregnations of the above described neurons of the mesothoracic commissure and in stainings of the Mnb1, Mnb2 and MnIII1.

Impregnations of the wing-nerve revealed terminal arborizations mainly in the mesothoracic ganglion. Second order stainings after wing-nerve infusions did not occur. Dense appositions of wing-nerve terminals and the ventral dendrites of Mnb1 and Mnb2 were, however, frequently observed. Preliminary observations on descending neurons derived from the optic foci of the deutocerebrum and the antennal lobes indicate that these neurons terminate also in close vicinity to the dendrites of the described motoneurons.

The results indicate strongly that the motoneurons of the direct flight muscles are synaptically coupled to interneurons of the dorsal mesothoracic commissure and to different types of sensory interneurons.This suggests that multimodal convergence and gating as described above takes place directly at the dendrites of the motoneurons.

295.2 CHANGES OF THE FLIGHT MOTOR PATTERN DURING PHONOTACTIC STEERING OF THE CRICKET, *TELEOGRYLLUS OCEANICUS*. S. Wang* and R.M. Robertson (SPON: E.G. Gisel). Department of Biology, McGill University, 1205 Ave. Dr. Penfield, Montreal, PQ, H3A 1B1, Canada.

During flight crickets will turn towards conspecific calling songs (positive phonotaxis) and away from ultrasound (negative phonotaxis). Cricket phonotaxis has received a lot of attention in the literature, but how the flight muscles cooperate to achieve steering is still unknown. By making electromyographic (EMG) recordings from the wing muscles of tethered, minimally dissected crickets, *Teleogryllus oceanicus*, we determined the motor pattern during straight flight. Then, by playing either synthesized conspecific calling song (pulses of 5 kHz sound of 30ms duration repeated at 16 pulses/s) or pulses of ultrasound (30 kHz, 30ms duration, 2 pulses/s) to induce steering, we characterized the flight motor pattern underlying steering. Steering was monitored conventionally by observing the movements of the abdomen (the abdomen deflected in the direction of steering).

A photographic analysis of the wing movements showed that during straight flight the extent of elevation of the right and left hindwings was roughly equivalent. However when the cricket turned, the hindwing inside the turn showed a markedly greater elevation than did the hindwing outside the turn. EMG recordings showed that the presentation of sound induced more vigorous flight and a maintained increase in the wingbeat frequency. Also, elevator muscles of the hindwing (118, anterior tergocoxal and 119, posterior tergocoxal) inside a turn increased their level of activity while the same muscles of the hindwing outside a turn showed no change or reduced their level of activity for a few cycles after each sound pulse. The phase of elevator activity within each cycle of depressor activity was altered. Inside a turn the elevator phase decreased indicating that the elevators were active earlier in each cycle. Outside a turn the elevator phase increased but for only a few cycles immediately after each sound pulse. The evidence supports the ideas that steering during flight is accomplished in part by a greater elevation of the hindwing on the inside of a turn relative to that of the hindwing on the outside of a turn, and that this is brought about by an increase in the phase and strength of activity of elevator muscles of the hindwing on the inside of a turn and by a decrease of the same on the outside of a turn.

295.3 EVALUATION OF A HYPOTHESIS FOR THE NEURONAL CONTROL OF JUMPING IN THE LOCUST. I.C. Gynther* and K.G. Pearson (SPON: J. Gillespie). Dept. of Physiology, U. of Alberta, Edmonton, Alberta, CANADA T6G 2H7.

In 1980 Pearson, Heitler and Steeves (J. Neurophysiol., 43:257) presented a hypothesis for explaining the neuronal mechanisms for triggering the jump in the locust, Locusta migratoria. The main features of this hypothesis were 1) the co-contraction phase of the jump is terminated by a burst of activity in a pair of identified interneurons (the M-neurons) which inhibit flexor motoneurons, 2) during the co-contraction phase the excitability of the M-neurons progressively increases due to proprioceptive feedback from hindleg receptors, and 3) burst activity in the M-neurons is generated either by proprioceptive input shifting the membrane potential beyond threshold or by additional excitatory input from the visual or auditory systems summing with the proprioceptive input. This hypothesis was based primarily on the known connectivity of neurons and the responses of the M-neurons to various types of sensory input. Recently we have examined this hypothesis by recording from the M-neurons in behaving animals capable of producing bilateral kicks of the hindlegs (the motor program for these kicks being similar to that for a jump). These recordings have confirmed that the M-neurons are involved in triggering the jump but they have failed to demonstrate other aspects predicted by the original hypothesis.

In support of the proposal that the M-neurons are involved in triggering the jump were the findings that these neurons produce high frequency bursts corresponding to the time of inhibition of flexor activity and that the injection of a brief depolarizing current pulse into an M-neuron could initiate a premature triggering of a kick in one leg. However, suppressing spike activity in an M-neuron by injecting hyperpolarizing currents did not prevent kicks from being triggered. Thus triggering, i.e. flexor inhibition, involves other neurons in addition to the M-neurons.

Findings which were not consistent with the hypothesis of Pearson et al. were that the M-neurons were hyperpolarized during the co-contraction phase and that visual and auditory input during co-contraction failed to trigger kicks. Thus the proposal that M-neuron excitability is increased progressively during co-contraction must be abandoned. The problem of how the M-neurons are excited, thereby helping to terminate co-contraction, remains to be solved.

295.4 DIFFERENT MODES OF INTERNEURONAL ACTIVITY DURING FICTIVE LOCOMOTION IN THE CRAYFISH, PROCAMBARUS CLARKII. A. Chrachri* and F. Clarac, Lab. de Neuro. Comp., 33120 Arcachon, France

Although the thoracic locomotor central generator (LCG) is not rhythmically active when isolated from sensory input, we have shown that application of the muscarinic agonists oxotremorine and pilocarpine induces rhythmic fictive locomotory output in isolated preparations (Neurosci. Lett., in press). We showed this activation results in part from the induction of active regenerative properties in some of the LCG motorneurons (MNs) themselves, and that certain of the MNs have access to the LCG, as current injection into them affects the rhythm's frequency. We have used this pharmacological activation to investigate the cellular and synaptic properties of the locomotory interneurons (INTs).

There are both spiking and nonspiking locomotory INTs; the spiking INTs synapse with fewer MNs than the nonspiking INTs,two types of spiking INTs synapse only with levator and depressor MNs;one type excites levator MNs and inhibits depressor MNs, the other inhibits levator MNs and excites depressor MNs. These INTs presumably reinforce the mutually inhibitory synapses made by these two sets of MNs. However, all spiking INTs that synapse onto promotor or remotor MNs also synapse onto both levator and depressor MNs. These INTs may thus play a limited role in coordinating movements of the two joints. Tonic depolarization of these INTs decreases the intensity of MN bursts, but does not affect cycle frequency. That they are not the rhythmic center of the LCG is further supported in that muscarinic agonists do not induce regenerative membrane properties in them.

All identified nonspiking INTs synapse onto the MNs of both joints, and divide into two classes on the basis of their pattern of synaptic connectivity. One class is appropriate for supporting forward walking (simultaneously exciting levator and promotor and inhibiting depressor and remotor MNs), the other for backward walking (simultaneously exciting levator and remotor MNs, inhibiting depressor and promotor MNs). Current injection into them does not affect pattern frequency, nor do they respond to muscarinic agonists; they are not members of the LCG rhythmic center but instead organize its output into either forward or backward walking.

We tentatively conclude: 1) The motoneurons of the locomotory CG are capable of exhibiting active regenerative membrane properties and have access to its rhythmic center. 2) The locomotory spiking interneurons serve as local coordinating elements in the network, particularly to reinforce the mutual inhibition of MNs innervating antagonistic muscles. 3) The nonspiking interneurons we have identified are appropriate for organizing the motor pattern into backward or forward walking.

295.5 NEURAL MECHANISMS OF REFLEX REVERSAL IN THE CRAYFISH
P.Skorupski* (SPON: D.A.Kuterbach). Dept. of Physiology, University of Bristol, Bristol BS8 1TD, UK.

Experimental work over the last few years in both invertebrates and vertebrates has resulted in changes to the concept of the reflex. Most importantly it is now recognized that the neural circuits underlying reflexes are not hardwired and discrete, but may be substantially modified by centrally generated neural activity. The thoracic CNS of the crayfish maintained in vitro together with a basal limb proprioceptor (the thoracocoxal muscle receptor organ - TCMRO) provides an ideal model system for studying the cellular mechanisms of central reflex modulation.

The isolated thoracic ganglia can produce fictive locomotion, consisting of alternating bursts of activity in promotor motoneurones (MNs) (normally underlying the swing phase in walking) and remotor MNs (normally underlying the stance phase). In the absence of fictive locomotion stretch of the TCMRO elicits a negative feedback promotor stretch reflex mediated by the dynamically sensitive T fibre (one of the two afferent neurones of the TCMRO). During fictive locomotion, however, the reflex effect of the TCMRO reverses in a phase-dependent manner (Skorupski & Sillar, J. Neurophysiol. 55, 689, 1986), so that stretch of the TCMRO during the remotor phase of the rhythm elicits reflex excitation of remotor MNs and inhibition of promotor MNs. Like the promotor stretch reflex recorded in quiescent preparations, this reversed reflex is mediated by the T fibre.

The neural mechanisms underlying the reversal in the sign of reflex transmission from afferent to MN are currently being examined. In principle there are three possible levels at which such modulation could occur: 1) pre-synaptically at the central terminals of afferents, 2) post-synaptically upon interposed interneurones, and 3) post-synaptically upon MNs.

Experiments involving selective intracellular stimulation of the T fibre with simultaneous recording from different categories of post-synaptic neurones indicate that in the crayfish the flow of information from afferent to effector may be modulated at all three levels defined above. Particular attention, however, will be focused on the modulatory role of presynaptic effects on the central terminal of the T fibre.

295.6 Intracellular recordings During Locomotion of Intact Ascaris lumbriciodes.
J.A. Meade* and A.O.W. Stretton (SPON:J. Rand). Neuroscience Training Program,Univ. of Wisconsin - Madison 53706

The question of the control of nematode locomotion has been approached in a variety of ways. Those studying Caenorhabditis elegans have used genetic mutations and laser ablation of specific neurons in order to determine which cells may contribute to or control locomotion (Chalfie et al.,J. Neurosci., 5:4, 1985). Those studying Ascaris have made use of intracellular recordings in dissected preparations to answer the same question.

While results from both directions have been informative, conclusive results are still lacking. Part of the problem is the lack of in vivo experiments. Current studies are being performed on intact Ascaris in an attempt to resolve this question directly.

Intracellular recordings have been made in muscle and motor neurons in intact preparations. The experiments are carried out on an animal which has about 1 cm. dissected in the region just posterior to the pharynx in order to expose the first pair of commissures in the second neural repeating unit. The rest of the animal is free to move. The membrane oscillations seen in dissected pieces of Ascaris do not correlate directly with the locomotory waveform. Instead they seem to occur in bouts which have the same period as that of the body wave as it travels down the animal. It has also been found that mechanical positoning of the portions anterior or posterior to the dissection can change the activity in the dorsal and ventral muscle, suggesting that proprioception may indeed be important.

295.7 OCTOPAMINE INDUCES PROLONGED SPONTANEOUS SWIMMING ACTIVITY IN THE MEDICINAL LEECH, HIRUDO MEDICINALIS.
H. Hashemzadeh and W.O. Friesen, Dept. of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901.

Although spontaneous swimming activity occurs infrequently in preparations of the isolated leech nerve cord, such activity can be induced by adding 0.005-0.1 mM serotonin (5-HT) to the saline bathing the preparation [Willard, A.L., J. Neurosci. 1:936-944, (1981)]. To assess the potential role of other chemical agents for modulation of swimming activity and to analyze the neural mechanisms underlying swim oscillations in the leech, we tested a broad range of substances with leech nerve-cord preparations.

Bath-application of many drugs (transmitters, transmitter precursors, neuromodulators and activators of rhythmic activity in other systems) to leech nerve cords failed to induce swimming activity; namely, cGMP, ACh, NE, dopamine, L-DOPA, D-DOPA, DL-DOPA, histamine, glutamate, kainic acid, kynurenic acid, homosysteic acid, FMRFamide, proctolin, GABA, strychnine, and ethanol. However, bath application of octopamine (OA, 0.001-2 mM), elicited impulse activity in the dorsal posterior (DP) nerves, often as isolated impulse bursts, and promoted spontaneous swimming activity. At low concentrations (0.1 mM), OA induced a few swim episodes with a short latency followed in about 30 min by repeated swim episodes (2-3 per min). Addition of OA at high concentrations (0.1-1.0 mM) quickly induced a series of swimming episodes that continued with little interruption for 2-3 hours. Such spontaneous swimming activity continued when the nerve-cord preparation was reduced to a chain of three segments; moreover, episodes of swim-like bursts (period about 1 s) persisted with diminished regularity in isolated ganglia. The agonists, naphazoline (0.015 mM) and synephrine (0.03-0.3 mM), had effects similar to those observed for OA.

We found that bath application of agents that increase intracellular cAMP levels, including the phosphodiesterase inhibitors, theophylline (2 mM) and IBMX (0.4 mM), and cAMP (0.02-1 mM) and its analogs, 8 Br-cAMP and dibutryl cAMP (0.03-1 mM), reliably mimicked the effects of OA and 5-HT. We propose, therefore, that the induction of spontaneous swimming activity in the leech by OA and 5-HT is mediated by the intracellular accumulation of cyclic AMP. Surprisingly, bath-application of phentolamine (0.08-0.1 mM), an OA antagonist, also mimicked the actions of OA on swimming activity. Supported by NSF grant BNS84-14988.

295.8 TERMINATION OF SWIMMING ACTIVITY BY STIMULATION OF A NEURON IN THE SUBESOPHAGEAL GANGLION OF THE LEECH, HIRUDO MEDICINALIS.
B.A. O'GARA and W. O. FRIESEN, Dept. of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901.

Locomotion in many animals is episodic, implying that control mechanisms exit for both the initiation and termination of the underlying neuronal activity patterns. In the leech, initiation of swimming activity in the isolated nerve cord is controlled in part by trigger neurons, Tr1 and Tr2, which, when transiently stimulated, elicit episodes of swimming oscillations (Brodfuehrer & Friesen, J. Comp. Physiol. A 159:489-502, 1986). Tr1 is the more effective trigger neuron with direct excitatory connections to swim-gating neurons (cells 204 and cells 21/61) that drive the central oscillator circuit for swimming activity. Tr2 appears to have no direct excitatory connections to the swim-gating neurons and moreover provides inhibitory input to many of the neurons of the swim oscillator. We have now found that Tr2 can function to terminate swimming activity in isolated nerve cord preparations (head ganglia through midbody ganglion 18).

When stimulated with brief (0.5 s) depolarizing pulses during an ongoing swim episode, Tr2 acts to delay the onset of the next burst and to reduce slightly the excitation of cells 204 (ibid.). Intense stimulation of Tr2 (3 s train at 50 Hz) terminates swim-related DP (dorsal posterior) nerve bursts and causes a repolarization of cell 204 to the resting level. Stimulation of Tr2 at intermediate intensities causes an interruption of swimming activity for several seconds followed by a gradual depolarization in cell 204 and the resumption of swimming. The onset of both swim termination and cell 204 repolarization follows the onset of Tr2 stimulation with a latency of less than 0.5s. The same stimulus parameters can lead either to swim initiation (when the preparation is quiescent) or to swim termination (during a swim episode), however the latency for swim initiation by Tr2 is about 4 to 9 s compared to about 0.5 s for termination. We propose that Tr2 may have as its primary role the termination of swimming activity in the leech and that swim-initiation by cell Tr2 may be the result of some process of postinhibitory rebound. Supported by NIH grant NS21778.

295.9 NEUROMUSCULAR ARRANGEMENT FOR TWO-SPEED SWIMMING IN A PTEROPOD MOLLUSC. R.A. Satterlie and G.E. Goslow Jr. Dept. of Zoology, Arizona State Univ., Tempe, AZ 85287; Dept. of Biology, Northern Arizona Univ. Flagstaff, AZ 86011.

Forward swimming in the pteropod mollusc Clione limacina features two distinct swimming speeds; slow/hovering and fast. In the former, wing beat frequencies range from 1 to 5 Hz resulting in hovering or slow forward displacement of the animal in the water column. During fast swimming, wing beat frequencies range from 5 to 10 Hz and produce rapid forward movement of the animal, up to 5 body lengths per second.

Two types of histochemically distinct muscle fiber types have been identified in the parapodia of Clione. One type exhibits heavy staining for oxidative enzymes and low myosin-ATPase activity. These fibers show mean peak-twitch times of 73.8 ms and low fatigability, and are thus referred to as slow twitch fatigue-resistant fibers. The second type of fiber shows complementary histochemical staining; low for oxidative enzyme activity and high myosin-ATPase activity. These fibers show peak-twitch times of 20 ms and significant fatigue following three to eight stimuli within the normal range of swimming frequencies (fast twitch fatigue-resistant fibers).

Slow twitch fibers are innervated by a population of small pedal motor neurons (20 - 30 in each pedal ganglion). Cell body diameters range from 15 to 25 μm, and each motor neuron has a restricted innervation field in the ipsilateral parapodium. In contrast, the fast twitch fibers are innervated by two large (cell body diameters - 50-80 μm) pedal motor neurons. One innervates the dorsal swimming musculature and the other the ventral muscles. The innervation field for each cell covers the entire parapodium. Preliminary evidence suggest that the large motor neurons (called general exciters) also innervate some slow twitch fibers, and centrally excite synergistic motor neurons. All neuromuscular contacts are monosynaptic.

During slow swimming, all small motor neurons appear to be active (spiking). The shift from slow to fast swimming involves recruitment of general exciter motor neurons (to spiking mode) and an increase in impulse frequency (per burst) in small motor neurons. The role of pedal interneurons and modulatory inputs to the motor neurons is being investigated.

295.10 CONTROL OF BUCCAL MOTOR PROGRAMS IN *APLYSIA* BY IDENTIFIED NEURONS IN THE CEREBRAL GANGLION. S.C. Rosen*, M.W. Miller*, K. R. Weiss, and I. Kupfermann. Cntr. for Neurobiol. & Behav., Columbia Univ. and New York State Psychiatric Inst., New York, NY 10032.

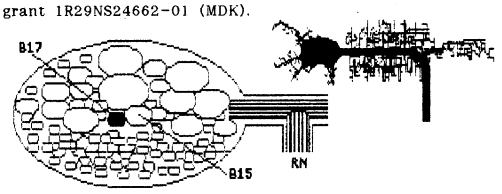
The motoneurons and pattern generator for consummatory phases of feeding behavior, including biting, swallowing, and rejection responses, appear to be located in the buccal ganglion. We have investigated whether specific components of consummatory behavior are controlled by command elements in the cerebral ganglion. Backfills of the cerebral-buccal (C-B) connectives stain approximately 20 cells in each cerebral hemi-ganglion. These include the neuromodulatory, serotonergic, metacerebral cell, 6-8 mechanoafferent (ICBM) neurons that synapse upon major, identified, buccal interneurons B_{4-5} (Rosen et al., *J. Neurophysiol.* 48:271, 1982), and about 12 other neurons, three of which we have now identified. Each of the three: (1) has a characteristic morphology, (2) receives either extensive mechanosensory or chemosensory input, and (3) makes powerful, convergent, synaptic connections to numerous buccal motoneurons and interneurons, including B_{4-5}, via an axon in the C-B connective. Cerebral-Buccal Interneuron 1 (CBI-1), receives monosynaptic EPSPs from primary cerebral mechanoafferent neurons. Firing the CBI-1 produces fast, rapidly decrementing, EPSPs in B_{4-5} and a single, short-latency, coordinated burst pattern involving many buccal cells. Cerebral-Buccal Interneuron 2 (CBI-2) receives excitatory chemosensory inputs from the lips and tentacles. Firing the CBI-2 produces complex, fast and slow, IPSPs and EPSPs in B_{4-5}, and can trigger multiple coordinated bursts from B_{4-5} and other buccal cells. Tonic depolarization of CBI-2 produces repetitive bursting patterns at a rate comparable to that which occurs during normal biting responses. The third interneuron (CBI-3) produces fast and slow IPSPs in B_{4-5} and in excitatory followers of B_{4-5}, but is incapable of producing coordinated buccal bursting. Two hypotheses are suggested by these findings: (1) each interneuron is involved in a separate circuit capable of triggering a different behavioral response, e.g. CBI-1 may trigger defensive withdrawal or rejection and CBI-2 may trigger biting; (2) the coordinated actions of all of three interneurons are necessary for the integration of chemosensory and mechanosensory inputs involved in the initiation of normal feeding.

295.11 IDENTIFICATION OF A BUCCAL NEURON IN *APLYSIA* WHOSE MOTOR OUTPUT CAN BE MODULATED BY SCPb AND 5-HT. M.D. Kirk and M.R. Plummer. Boston University, Dept. of Biology, 2 Cummington St., Boston, MA 02215.

The buccal ganglion of *Aplysia* contains neurons that mediate the patterned motor output underlying consummatory feeding. Several bilaterally paired neurons in this system are identifed and some of them are peptidergic and/or are modulated by peptides. We have identified a neuron unlike those identified previously in that it elicits cyclic patterned motor activity upon maintained depolarization; we have tentatively labelled this neuron B17. The soma of B17 is multipolar and is located on the rostral side of the buccal ganglion lateral to the identified motoneuron B15 (see sketch). The neuron arborizes extensively in the ipsilateral neuropil and in the buccal commissure before sending an axon out the radular nerve (RN).

B17 is normally silent, but bursts during spontaneous cyclic motor activity. It receives direct IPSPs from multifunction neurons B4/B5 and is electrically coupled to the peptidergic retractor motoneuron B15. Suprathreshold depolariztion of B17 can elicit activity in a central pattern generator (CPG) from which it receives synaptic feedback. B17 is electrically coupled to its contralateral homologue and fires in synchrony with it. In cases where cycling is not elicited, maintained depolarization still causes endogenous bursting in B17.

The motor pattern elicited by B17 can be modulated by the peptide SCPb and serotonin. Bath application of these transmitters reversibly altered the interburst intervals and burst durations of the neurons examined. We intend to evaluate more quantitatively the contribution of B17 to the CPG(s) for feeding and how its motor output is modulated by peptide and amine transmitters. Supported by NIH grant 1R29NS24662-01 (MDK).



296.1 CONTRIBUTION OF A CA^{2+} ACTIVATED K^+ CHANNEL TO THE DYNAMICS OF THE MUSCLE SPINDLE. Kruse, M.N. and R.E. Poppele. Laboratory of Neurophysiology, Dept. of Physiology, University of Minnesota. Minneapolis, MN 55455

Reflex tension is developed in phase with a sinusoidally varying muscle stretch. This behavior requires that the phase-lag behavior of muscle contraction be compensated by a (precisely timed) phase-lead in the reflex loop. The appropriate phase-lead occurs in the steps involved in the conversion of muscle stretch into afferent signals by the muscle spindle (Poppele and Terzuolo, Science 159:743,1968). The firing rate of spindles reaches a peak before peak stretch by an amount that depends on the frequency of the stretching sinusoid. The phase advance between 1 Hz and 4 Hz (the mid-frequency dynamics) is adequate compensation for the phase-lag characteristics of a muscle and may represent a "tuning" of the dynamic processes in the spindle which matches the dynamic processes involved in muscle contraction.

We have examined possible mechanisms responsible for the mid-frequency dynamics of the cat muscle spindle. We have shown that they are present when intrafusal muscle fibers are destroyed by mechanical transection or freezing (Kruse and Quick, 1986 Soc. Neurosci. Abst. 12:1084) which suggests that the sensory nerve terminals are responsible for the observed kinetics. This hypothesis was tested by blocking specific ion channels to observe their effect on the mid-frequency dynamics.

Spindles were isolated from cat tenuissimus muscle and their capsule was opened. The spindle's response to sinusoidal stretches of 0.3-4 Hz was recorded both before and after addition of a channel blocker to the bathing solution. TEA and 4-aminopyridine (K^+ channel blockers) and $ZnCl_2$ (a Ca^{2+} channel blocker) were all found to alter the dynamic response in a similar manner. The mid-frequency phase lead and the amplitude dependence on stretch frequency were both reduced. As the K^+ and Ca^{2+} channel blockers had similar effects on the mid-frequency dynamics, it was possible that they were acting via the same mechanism, i.e. a $K^+(Ca^{2+})$ channel. Apamin, a toxin which is specific for $K^+(Ca^{2+})$ channels, had the same effect on the spindle's dynamics as the previous drugs. In addition, the apamin effect was almost completely reversible.

These data support the hypothesis that ion channels in the sensory nerve are in part responsible for the spindle's mid-frequency dynamics, and furthermore specifically implicate a $K^+(Ca^{2+})$ conductance in the mechanism. Thus $K^+(Ca^{2+})$ channels may help "tune" the spindle's stretch response to compensate for muscle dynamics in the stretch reflex. Supported in part by NSF(BNS85-18714).

296.2 MECHANISM AND FUNCTION OF HETEROGENIC INHIBITION BETWEEN ANKLE FLEXORS AND SOLEUS MUSCLE IN THE DECEREBRATE CAT. T. R. Nichols and D. J. Koffler*. Department of Physiology, Emory University School of Medicine, Atlanta, GA 30322.

It was shown previously (Nichols, T. R., Soc. Neurosci. Abstr. 15:213, 1985) that stretching the ankle flexor tibialis anterior (TA) or extensor digitorum longus (EDL) powerfully inhibited the response to stretch of soleus (SOL), and that heterogenic inhibition from SOL to TA (or EDL) was weak or absent. Postsynaptic, reciprocal inhibition is an obvious candidate to mediate the observed heterogenic inhibition, but the asymmetry of the reflex matches the asymmetry of presynaptic inhibition which is powerful from flexor afferents to extensor afferents but not the other way around. The studies reported here were designed to evaluate whether heterogenic inhibition from TA and EDL could be explained by postsynaptic inhibition, or whether a component of the inhibition might be explained by a change in the gain of the stretch reflex as would be expected from presynaptic inhibition. We made use of the technique of delivering mechanical inputs to both tendons of a pair of muscles in premammillary and intercollicular decerebrate cats (Nichols, ibid.). Heterogenic inhibition was evaluated either by stretching TA (or EDL) alone and measuring the change in force in the isometric SOL, or by stretching both flexor and extensor simultaneously and measuring the decrement in the stretch response of SOL. When both experiments were performed at the same initial force, the inhibition observed in the former experiment was usually much smaller than in the latter. This discrepancy was found to be due, however, to a dependence of the inhibition on force rather than to the heterogenic inhibition of autogenic reflex gain. The responses of isometric SOL varied with the amplitude of stretch applied to TA but less than proportionately. The responses to the stretch of TA and EDL together were approximately the sum of the responses to stretch of each flexor individually. Applying equal and opposite length changes of different amplitudes to SOL and to TA (or EDL) as occurs naturally showed that heterogenic inhibition significantly increases the stiffness of SOL even when TA and EDL are inactive. These results suggest that heterogenic inhibition from ankle flexors to SOL can be explained mainly by postsynaptic reciprocal inhibition and that its function is to enhance the mechanical stiffness of the in situ SOL. In support of the proposed mechanism, it was found that heterogenic inhibition was abolished by the intravenous administration of strychnine.

Supported by NS 20855 and the Emory University Research Fund.

296.3 MODULATION OF PRESYNAPTIC INHIBITION BY THE SKIN AND MUSCLE. M. Sabbahi, C.C. Luk*, J.E. Estrella*, and M. Sneath*. Texas Woman's University, School of Physical Therapy, Houston, TX.

Desensitization of the skin with topical anesthesia has been reported to increase the excitability of the H-reflex (Sabbahi & DeLuca, 1982). Desensitization of the muscle (afferents) resulted in similar modulation of the H-reflex (unpublished results). This report discusses the effect of desensitization of skin or muscle on the process of presynaptic inhibition.

Soleus H-reflexes of normal subjects were recorded after electrical stimulation of the posterior tibial nerve with unipolar pulses (1 msec, 0.2 pps at H-max.). The H-reflex was monitored by the M-response. Then an air-driven vibrator (80 Hz) was applied on the Achilles tendon for 60 sec. and the degree of H-reflex inhibition with vibration was calculated and used as a measure for presynaptic inhibition (PI) process (Hagbarth, 1973). Calf skin area was sprayed with topical anesthetic (10% xylocaine) or a placebo. A "phoresor" delivering 4-5 mA of DC for 30 minutes with either 2% Xylocaine with 1:100,00 epinephrine or a placebo was applied to the motor points of the soleus muscle. Previous reports showed that this treatment dose introduces the anesthetic about 2 cm under the treatment electrode. The PI measurements were tested at intervals up to 30 minutes post topical spray or after termination of iontophoresis. The percent change in H-reflex amplitude was averaged and normalized to those before anesthesia and a t-test measured the significance of the difference post-treatment.

Results showed significant inhibition ($p < 0.05$) of the H-reflex 30 min. after anesthetic iontophoresis. As was previously reported the peak-to-peak amplitude of the H-reflex was significantly increased post topical anesthetic. PI was significantly ($p < 0.05$) increased in all subjects after topical or iontophoretic anesthesia. This effect lasted for 30 min. post anesthetic. No measurable changes were recorded post placebo or in the M-response.

These results indicate an increased presynaptic inhibition after desensitization of cutaneous or muscle receptors regardless of the change in the excitability of the α - motoneuron. Cutaneous and muscle receptor afferents may decrease presynaptic inhibition in normal subjects.

296.4 EFFECTS OF CHLORALOSE-URETHANE ANESTHESIA ON RECIPROCAL Ia IPSPs S.-I. Sasaki*, C.S. Yuan*, R.M. Reinking*, A. Taylor and D.G. Stuart. Department of Physiology, University of Arizona Health Science Center, Tucson, AZ 85724.

Previously (J. Neurophysiol., 39: 1375, 1976), we reported that single-axon reciprocal Ia IPSPs in cat motoneurons can be measured by use of spike-triggered averaging (STA). Chloralose-urethane (C-U) anesthesia was used, which we now know has a depressant effect on single-axon recurrent IPSPs (J. Physiol. London, July, 1987, In Press). This and other findings (J. Physiol., London, 218: 495, 1971) suggested that C-U might have a depressant effect on reciprocal Ia IPSPs. We tested for this, by comparing the previous measurements to those obtained from preparations allowed to become unanesthetized following ischemic decapitation (I-D) under halothane anesthesia. In both studies, the reciprocal pathway tested was from Ia afferents in the medial gastrocnemius muscle to motoneurons supplying the extensor digitorum longus and tibialis anterior muscles.

Significantly more ($\chi^2=4.19$, $P<0.05$) single-axon reciprocal Ia IPSPs were recorded in cells from I-D preparations (26/46; 36%) than from C-U preparations (31/105; 23%). Comparisons of selected IPSP characteristics included:

Preparation	Amplitude (uV)	Latency (ms)	Rise-time (ms)	Half-width (ms)
C-U (n=31)	4.9 ± 2.5 (1.5-10.4)	1.8 ± 0.3 (1.2-2.4)	1.4 ± 0.5 (0.6-2.3)	2.8 ± 1.6 (0.9-6.6)
I-D (n=26)	17.5 ± 5.5 (6.4-26.3)	1.7 ± 0.6 (1.0-2.2)	1.8 ± 0.7 (0.9-3.0)	3.9 ± 1.7 (1.6-7.4)

In summary, C-U has as pronounced a depressant effect on the incidence and magnitude of single-axon reciprocal Ia IPSPs as it does on single-axon recurrent IPSPs. This finding invites the possibility of using STA to bring out functional and organizational features of the reciprocal pathway, not readily revealable by other means. (Supported by USPHS grants HL 07249 and NS 07888).

296.5 MONO- AND POLYSYNAPTIC EXCITATORY CONNECTIONS FROM THE GLOSSOPHARYNGEAL AFFERENTS TO THE HYPOGLOSSAL MOTONEURONS IN THE JAPANESE TOAD. T.Matsushima*, M.Satou* and K.Ueda* (SPON:A.Urano) Zool.Inst., Fac. of Sci., Univ. of Tokyo, Tokyo 113, Japan.

Anuran tongue movements are controlled by the visual stimuli for releasing prey-catching behavior ('snapping') and the tactile/gustatory/nociceptive stimuli for eliciting lingual reflexes, including the 'rejection' of unpalatable objects out of the mouth. As a step toward elucidating the neural basis of these movements, we analyzed the neuronal connections from the glossopharyngeal (IX) lingual afferents to the hypoglossal (XII) motoneurons innervating the tongue-protractor and retractor muscles (PMNs and RMNs, respectively), and examined the relationships between these reflex pathways and the polysynaptic excitatory pathways from the optic tectum (Satou,M.et al.,J.Comp.Physiol.A,157:717-737).

Electrical stimuli applied to the ipsilateral IX nerve elicited polysynaptic EPSPs in PMNs and mixed mono- and polysynaptic EPSPs in RMNs. The polysynaptic EPSPs were further spatially facilitated when the optic tectum was simultaneously stimulated. These results suggest that (i) some of the IX afferents have direct connections with RMNs but not with PMNs, and that (ii) some common excitatory interneurons, on which the tectal descending volleys and the IX afferent volleys converge, mediate polysynaptic activation of these motoneurons.

Further double labeling experiments using horseradish peroxidase (HRP) and cobaltic lysine (Co-lys) supported the result (i) of the neurophysiological analyses described above. The IX afferents and their terminals were transganglionically stained with Co-lys, and the XII motoneurons were retrogradely labeled with HRP. The IX axons descending through the fasciculus solitarius (fsol) gave off many terminal branches with beaded appearance in the gray matter ventral and ventrolateral to the fsol. On the other hand, the XII motoneurons had extensive spread of dendritic trees in the lateral, dorsal, medial and contralateral directions. Some of the IX nerve terminals had direct contacts with the dorsal dendrites, the lateral dendrites and the somata of the XII motoneurons, but not with their medial dendrites. These direct contacts mainly occurred in the rostral region of the dorsomedial XII nucleus where RMNs predominates, but not in the caudal region nor in the ventrolateral XII nucleus where PMNs and other XII motoneurons are distributed.

296.6 PERIODONTAL AFFERENTS ALONE DO NOT CAUSE AN ACTIVE JAW-OPENING REFLEX IN THE CAT. A. Taylor, D. Dessem* and O.D. Iyadurai*. Sherrington School of Physiology, UMDS, St. Thomas's Hospital, London SE1 7EH, U.K.

Periodontal mechano-receptors respond to forces applied to the teeth during mastication. They are sensitive and direction specific and have large fast afferents. The part they play in controlling jaw movements must depend primarily on their reflex connexions. They are known to exert a disynaptic inhibition on jaw-closer motoneurones and are commonly thought to excite opener motoneurones. However this may not be the case, because though low-strength electrical stimulation of alveolar nerves readily produces digastric contraction, adequate controls have not been used to ensure that stimulation is restricted to periodontal afferents.

In cats anaesthetised with chloralose the inferior alveolar nerve (IAN) has been stimulated whole or as its separate cutaneous (mental) or periodontal afferent-containing ("tooth") branches. The afferent volley was recorded at the brain-stem entry of the trigeminal nerve, and reflex responses recorded as the emg of temporalis and digastric muscles.

Strong stimulation of IAN caused temporalis inhibition and digastric excitation. Tooth nerve stimulation at just above threshold (T) gave an afferent volley with conduction velocity of 65m/s. Paired stimuli (1.7ms spacing) at 1.25T did not excite digastric, though single stimuli at this strength strongly inhibited temporalis. Full development of the early volley required 1.75T but a slower (Aδ) component appeared at 1.5T at which strength the digastric response occurred. Selective natural stimulation of periodontal afferents by tapping canine teeth inhibited temporalis but failed to excite digastric. Finally, local stimulation of the mesencephalic tract of the trigeminal nerve to excite periodontal afferents (as evidenced by antidromic conduction in tooth nerves but not mental nerves) also caused no jaw-opening reflex (JOR).

Thus we have found no evidence of a contribution of periodontal afferents to the active JOR though they may converge with other afferents on interneurones involved. Consequently, changes in the JOR elicited by IAN stimulation during mastication (Lund, J.P., Drew, T. & Rossignol, S., Brain Behav. Evol., 25; 146, 1984) cannot be taken to indicate changes in periodontal receptor-based reflexes. It remains reasonable to suppose that periodontal afferents can provide negative feedback control of active force applied to the teeth during mastication.

296.7 VARIANCE OF SINGLE-AXON RECURRENT IPSPS: IMPLICATIONS FOR TRANSMISSION IN THE RECURRENT RENSHAW PATHWAY. T.M. Hamm, C.-S. Yuan*, S.-I. Sasaki*, U. Windhorst* and D.G. Stuart. Div. of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013; and Dept. of Physiology, Univ. of Arizona Health Sci. Center, Tucson, AZ 85724.

We have shown recently that stimulation of single motor axons is effective in producing recurrent IPSPs in spinal motoneurons (Hamm et al., J. Physiol. (Lond.), July, 1987, In press). The characteristics of these single-axon recurrent IPSPs permits the analysis of several features of the recurrent Renshaw pathway, such as the distribution of recurrent inhibition between individual motoneurons, as indicated by the magnitude of single-axon recurrent IPSPs (Hamm et al., In press). In addition, the variance of these IPSPs provides additional information about transmission in this circuit, since this characteristic depends not only upon fluctuations in synaptic strength which occur at monosynaptic connections (Jack et al., J. Physiol. (Lond), 321: 65, 1980; Cope and Mendell, J. Neurophysiol., 47: 455, 1981), but also upon the probabilistic discharge of the interposed Renshaw cells. Determinations of the variance of single-axon recurrent IPSPs in motoneurons innervating medial gastrocnemius muscle were made for recordings obtained from cats allowed to become unanesthetized after ischemic decapitation (I.D.). As was found in a preliminary analysis (Hamm et al., Proc. IUPS XXX Congress XVI: 258, 1986), changes in variance associated with single-axon recurrent IPSPs could not be resolved in many instances. This lack of resolvability can be attributed to the small amplitude of the potentials (mean of 46 μV) and the large amount of background synaptic activity in the motoneurons of I.D. preparations. However, the variance of the IPSP could be resolved in some recordings, showing an increase above the level of background synaptic noise during the timecourse of the IPSP. In such instances, the ratio of the standard deviation to the mean amplitude of the recurrent IPSP was in the range of 1.7 to 2.8. Based upon a model of transmission through a disynaptic pathway, ratios of this magnitude suggest that: 1) the combined probability of Renshaw cell discharge and synaptic transmission at each synapse of Renshaw cell and motoneuron in response to motor-axon stimulation is small; 2) the magnitude of IPSPs produced in motoneurons by Renshaw cells is several times that of single-axon recurrent IPSPs (i.e., the amplitude of the former IPSPs should be 100-350 μV).

296.8 PRESYNAPTIC AND POSTSYNAPTIC MECHANISMS CONTROLLING THE GASTROCNEMIUS-SOLEUS MONOSYNAPTIC REFLEXES DURING SCRATCHING. SH DUEMAS* R CUEVA*, J ZAVALA* Spon: William. B. Marks CUIB. Univ. de Colima, Apdo. Postal 199 Colima, Col Mexico & Depto. de Invest., Esc. de Med.,Univ. Autonoma de Chihuahua. Apdo. Postal 1090. Chihuahua, Chih. Mexico.

In decerebrate cats, the phasic gaiting of the monosynaptic reflex (MSR) could be enterly dependent on the excitability of the gastrocnemius-soleus motoneurons (GS-MN) since the excitability of GS group Ia afferent fibers ending in the motor nucleus (MNU) was similar in both phases of the scratch cycle (Baev KV and Kostyuk PG, Neurosci., 6: 205-215, 1981). In this work we studied the MSR and the excitability of group Ia afferent fibers and of the GS-MN in decorticated and in spinalized cats during fictive scratching. A sustained and phasic increase in amplitude of the GS MSR occurred during fictive scratching. Maximal amplituded occurred during activation of GS-MN and minimal amplitud during the flexion (F) phase. There was a sustained increase in excitability in a population of Ia afferent fibers in both decerebrated and spinalized cats. In spinal cats the excitability of group Ia fibers was maximal at the end of the (F) phase and minimal in the third bin of the F-phase. In decorticated cats, the phasic changes in excitability in group Ia ending in the motor nucleus were not observed but antidromic activity (AA) in GS group I afferent fibers occurred during the entire F-phase. Parallel to the episodes of scratching extracellular negative potential shifts (ECP) with a duration of several second were observed in motor nuclei. Phasic potentials with a frequency of 4-6 Hs were superimposed on the ECPs. Intracellular recording of GS-MN showed a depolarization shift in the membrane potential (MPD) related to the GS motoneuron burst activity. A membrane potential hyperpolarization of 1-2 mv occurred between the MPD. Occasionally this MPD changed its frequency of oscillation from 6 Hz to 3 Hz. Sometimes scratch-like activity occurred in the GS nerve at the same time that locomotor-like activity was observed in the tibial anterior nerve.

A primary afferent depolarization (PAD) in GS Ia afferents and a MPD in GS-MN seems to be responsable for the modulation of the GS MSR. The ECPs suggest that this PAD may be potassium mediated. The appearance of different rhythms in antagonist muscular nerves support the hypotesisis of the unit burst generator.

296.9 REVERSIBLE ALTERATIONS OF SPINAL MOTOR OUTPUT IN DECEREBRATE CAT BY BLOCKADE OF TRANSMISSION IN DORSOLATERAL FUNICULI WITH COLD OR LIDOCAINE.
J. S. Carp, R. K. Powers and W. Z. Rymer. Department of Physiology, Northwestern Univ., Chicago, IL 60611.

Several features of partial spinal lesion in humans can be reproduced in dorsolateral funiculi (DLF) lesioned decerebrate cats, including diminished ability to generate force, decreased motoneuron discharge rate, and clasp-knife reactions. This disruption in motor output may result at least in part from a lesion-induced loss of descending modulatory input to spinal neurons. In order to develop a more accessible model of spinal cord injury, we have investigated the possibility that interruption of pathways descending in the DLF using reversible methods can be used to mimic the effects of a surgical lesion.

Cats were decerebrated under halothane/nitrous oxide anesthesia and then allowed to respire room air. Medial gastrocnemius muscle (MG) force, length and EMG were recorded and stored on computer during muscle stretch or manipulation of the contralateral hindlimb to evoke the crossed extensor reflex. Laminectomies were performed at T12 and L5 to allow placement of stimulating and recording electrodes, respectively, for determination of the effects of reversible blockade on a descending volley in the contralateral DLF. Reversible DLF block was instituted at the site of the rostral laminectomy caudal to the stimulating electrode. Cold block was performed by bilateral application of small thermoelectric cooling devices over the DLF. For lidocaine block, a shallow pool was formed with agar to restrict the lidocaine (4%) to this region of the dorsal spinal cord. After recovery from one of these methods of DLF interruption, a surgical lesion of the DLF was performed in some experiments.

During application of either lidocaine or cold block for 20-30 minutes, the amplitude of the descending volley was reduced. Alterations were seen in motor output which were similar to those seen after surgical lesion. Specifically, MG force production was reduced during cold or lidocaine block with respect to that seen at comparable levels of EMG prior to DLF interruption. The power of the MG force spectrum was increased under these conditions. Upon removal of lidocaine or cold block, the effects on MG force-EMG relationships, stretch response and force spectrum showed good recovery. These data suggest that the motor abnormalities induced by surgical lesion can be mimicked by reversible blocking techniques. Experiments are currently being performed to record intracellularly from motoneurons before and during reversible blockade of the DLF to determine if these descending systems modulate motoneuron behavior on a moment-to-moment basis. 296.10 CHANGES IN Ia EPSP SHAPES IN CHRONIC SPINAL CATS ARE NOT EXPLAINED BY CHANGES IN MOTONEURON MEMBRANE PROPERTIES.
S. Hochman*, D. McCrea & B. Gustafsson*, Depts. of Physiology, Univ. of Manitoba, Winnipeg, R3E 0W3, Canada and Univ. of Göteborg, Göteborg, S-400 33, Sweden.

We previously demonstrated that the rise times and half widths of triceps surae composite Ia EPSPs in 6 week spinalized (L1-2) cats were decreased compared to unlesioned controls (Neurosci. Abst 12:186.12, 1986). The present investigation explores the possible contribution of changes in the electrical properties of motoneurons to the demonstrated changes in EPSP shape. Intracellular injection of current pulses was used to determine electrical properties of triceps surae motoneurons. Measurements from each motoneuron in both chronic spinal and unlesioned animals were used to obtain compartmental parameters in a "Rall model" of the motoneuron. For each motoneuron, model "EPSP" rise time and half width were calculated (Gustafsson and Pinter; Neurosci. Lett.51:67- 72, 1984). In addition, composite EPSPs following low threshold electrical stimulation were recorded from these same motoneurons. A 10 compartment model was used and "EPSP conductance" placed in various compartments. The relative distribution of the conductances was -> 0, 0, 0, .15, .35, .35, .15, 0, 0, 0. Mean values for modelled and experimentally measured EPSPs were:

	Rise time (ms)		Half Width (ms)	
	Measured	Modelled	Measured	Modelled
CONTROL	.67	.71	5.30	4.56
SPINAL	.53	.70	3.76	4.32

For unlesioned animals, this distribution produced modelled EPSPs with a similar rise time but somewhat shorter half width than the measured ones. On the other hand, measured EPSPs in chronic spinal animals had considerably faster rise times and faster decays. Moving the above distribution of conductances more proximal (about one compartment), gave modelled EPSPs that more closely approximated those in the chronic spinal animals. It is clear from the present results that changes in EPSPs following chronic spinalization cannot be explained simply on the basis of changes in passive electrical properties of motoneurons. EPSP shape changes are better explained by a change in the distribution of Ia afferent fiber synapses to a more proximal location on the motoneuron.

296.11 DIFFERENTIAL CONTRIBUTIONS OF SOLEUS AND MEDIAL GASTROCNEMIUS TO THE CROSSED EXTENSION REFLEX IN DECEREBRATE CAT.
J.A. McMillan, B.D.Lindsay*, and J.M. McNally*. Dept. of Biology and WAMI Program, Montana State Univ., Bozeman, MT 59717.

An earlier study in this laboratory (Hannon et al., Soc. Neurosci. Abs. 11:700, 1985) demonstrated that vestibular and proprioceptive inputs differentially affect excitability of crossed extension reflex (CER) recorded from rectus femoris (RF) and vastus medialis (VM). RF appears to contribute more to postural reflexes than to dynamic reflexes, suggesting it is "slower" than VM. However, limited anatomical evidence suggests that RF may in fact be "faster" than VM. In the present study we tested the hypothesis that differences between RF and VM are not due to a difference in fast- and slow-twitch units, but rather to the fact that RF is biarticular (strong knee extensor and weak hip flexor) whereas VM is a uniarticular knee extensor.

We recorded CER from two ankle extensors: soleus (SOL) and medial gastrocnemius (MG). SOL is slow and uniarticular. MG is faster and is biarticular (strong ankle extensor and weak knee flexor). Thus, if characteristics of RF reflect its biarticular actions, descending inputs should affect MG and RF similarly. Conversely, if RF does act like a "slow" muscle, then such inputs should affect SOL and RF similarly.

The CER was monitored by recording isometric tension from right SOL and MG in 8 decerebrate cats. Reflexes were evoked by stimulating left sciatic nerve via indwelling electrodes.

The CER from SOL consistently had a lower threshold to stimulation of sciatic nerve than did that from MG. However, threshold for SOL was not appreciably higher when animal was placed on left vs. right body side as is the case for rectus femoris.

Reflexes from both had greater amplitudes when the animal was placed on the right vs. left body side. However, SOL consistently showed a greater sensitivity to body position, much as does RF.

Rotation of chin to right consistently facilitated CER from both SOL and MG. Rotation of chin to left consistently inhibited CER from SOL but had equivocal effects on CER from MG.

In summary, effects of descending inputs on SOL were much more like those on RF than on VM. Neuron pools of SOL and RF share some common integrative substrates which are different in some respects than those impinging on neuron pools of MG and VM. This would suggest that differences between RF and VM are not attributed to the number of joints spanned by each. We propose that, contrary to anatomical evidence, RF is functionally "slower" than is VM.

296.12 DEPRESSION AND FACILITATION OF SPINAL CORD REFLEXES FOLLOWING PHYSOSTIGMINE.
Nagi A. Ibrahim and Barry D. Goldstein. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, Georgia 30912.

Physostigmine is a reversible acetylcholinesterase inhibitor that has been shown to alter the activity of central nervous system cholinergic neurons. The actions of physostigmine on spinal cord reflexes were studied in spinal cord transected cats (C1 section). Supramaximal stimulation of the cut L_7 dorsal root evoked a dorsal root reflex (DRR) in the cut L_6 dorsal root and a monosynaptic reflex (MSR) in the cut L_7 ventral root. Time course experiments revealed that the control DRR tended to increase with time while the control MSR showed little or no change over time. A single injection of physostigmine (0.8 mg/kg, i.v.) depressed the time-dependent increase of the DRR by 20%, 12% and 22% of the control at 5, 60 and 180 min after the injection. However, at higher doses (2 mg/kg, i.v.), physostigmine was found to depress the time-dependent increase of the DRR by 55%, 37% and 61% of the control at similar time intervals following administration. The injection of 0.8 mg/kg physostigmine markedly facilitated the MSR with time. The facilitation of the MSR began shortly after the injection reaching a maximum of 113% above the pre-physostigmine control by 10 min. A slight decrease to 87% above the pre-physostigmine control MSR was observed at 20 min; which was maintained for 3 hr. Conversely, when administered in a dose of 2 mg/kg physostigmine depressed the MSR by 45% of the pre-drug value within the first 5 min of injection. Beyond this period of time, the MSR gradually increased with a maximum value of 165% above the pre-physostigmine control obtained 3 hr after the injection.

Neither atropine nor mecamylamine pretreatment (1 mg/kg, i.v.) prevented significantly the depression of the DRR caused by lower doses of physostigmine. On the other hand, atropine but not mecamylamine markedly antagonized the depressant action of the higher dose of physostigmine on the DRR and reversed the early facilitation of the MSR produced by 0.8 mg/kg physostigmine. The late facilitation observed in the MSR at the lower dose of physostigmine was depressed by both antagonists. At the higher dose of physostigmine (2 mg/kg), mecamylamine but not atropine reversed the early depression of the MSR and blocked the late facilitation. These data suggest that physostigmine modifies the spinal cord reflexes in a dose-dependent manner, probably through muscarinic receptors in the dorsal horn and through both muscarinic and nicotinic receptors in the ventral horn.

297.1 DIFFERENTIAL ROLES OF HIPPOCAMPUS AND CAUDATE NUCLEUS IN MEMORY: SELECTIVE MEDIATION OF "COGNITIVE" AND "ASSOCIATIVE" LEARNING. Mark Packard and Norman M. White, Department of Psychology, McGill University, 1205 Dr. Penfield Ave., Montreal, Quebec, H3A 1B1, Canada.

Learning has been described as the acquisition of associations between stimuli and other stimuli or responses. However it is very difficult to use such a model to explain some instances of learning, and it has therefore been suggested that learning is in fact a much more complicated cognitive process. We tested the hypothesis that the normal brain contains both "associative" and "cognitive" memory substrates in different brain areas.

Animals with bilateral lesions of caudate nucleus or fornix and a control group were tested 2 wk post-operatively on one of two versions of the 8 arm radial maze task. In the standard "cognitive" version, they were habituated to the maze for two days with no food present and then tested daily for 4 days with a food pellet at the end of each arm. The number of errors (revisits) was recorded. In agreement with previous reports, rats with fornix lesions were impaired on this task. The rats with caudate lesions showed no deficit compared to controls.

Different groups of rats with similar lesions were tested on a stimulus-response ("associative") version of the radial maze. Small lights were attached at the entrance to each arm and a tubing system was constructed to permit rapid, unobtrusive rebaiting of the arms. On each of 15 daily trials 4 randomly selected arms were lit and baited. After a rat had visited one of the lit arms it was rebaited. After a second visit to the same arm its light was turned off and no further food was placed there. By visiting each of the 4 lit, baited arms twice animals earned 8 pellets per trial. Rats with caudate lesions were impaired on this task while those with fornix lesions were superior to controls in choice accuracy. Probe trials, run on days 16-19, with only 1 arm lit and baited at a time, showed that the animals had in fact learned to select the lit arms at a level greater than chance, although caudate animals were less accurate than fornix or control rats. Reducing extramaze cues by hanging curtains around the maze significantly improved perfomance of control and fornix animals on this task, however caudate animals were unable to benefit from the removal of these cues and remained significantly impaired.

These results demonstrate a double dissociation of the function of the caudate nucleus and the hippocampus with respect to simple, stimulus-response learning versus more complex, cognitive learning. They are consistent with the hypothesis that neural substrates for both kinds of learning exist in the normal brain: the caudate nucelus is selectively involved in processing associative learning, while the hippocampus selectively mediates cognitive tasks. Ordinarily, the two systems may act synergistically to produce learned behaviors, but the supernormal performance of the fornix animals on the S-R task shows that the two systems can also conflict with each other in some instances.

297.2 RECOVERY OF PERFORMANCE OF SPATIAL NAVIGATION BUT NOT SPATIAL WORKING MEMORY IN WATER MAZE TASKS FOLLOWING ENTORHINAL CORTEX LESIONS. C.R. Goodlett, J.M. Nichols*, R.W. Halloran* and J.R. West, Dept. of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

Entorhinal cortex (ERC) lesions in rats impair spatial navigation (Schenk and Morris, Exp. Brain Res., 58:11, 1985) and spatial working memory processes in appetitive maze tasks (Olton et al., Brain Res., 233:241, 1982). Since the extent of recovery of spatial navigation relative to spatial working memory processes has not been examined using comparable procedures, the effects of ERC lesions were compared in adult male Sprague-Dawley rats given extended testing on the Morris water maze task or on a conditional alternation swim-escape task.

The Morris water maze training required rats to escape from swimming in a water tank by locating a small platform hidden underwater. Eight days of training (56 trials) were given preoperatively, including a probe trial (30 sec with the platform removed). Rats then were given either bilateral ERC lesions or sham surgery and trained postoperatively for 18 (sham) or 25 (lesion) consecutive days, beginning 4 days after surgery, with probe trials interspersed every 4 days. Dependent measures included latencies and path lengths to reach the platform and the percent of time in the target quadrant on the probe trials.

Conditional alternation training used a T-maze that was partially immersed in the water tank. Eight trials were given each day, each consisting of an information run (forced escape with one arm blocked), followed 6 sec later by a choice run (escape ladder in the arm previously blocked). Preoperatively the rats were trained to a performance criterion, and surgery (ERC lesions or sham) was performed on the next day. Postoperative testing began 4 days after surgery and continued for 16 (sham) or 40 (lesion) consecutive days. Horizontal sections stained with cresyl violet were used to confirm the lesions histologically.

The rats trained in the Morris maze learned the spatial navigation problem rapidly (mean latencies < 5 sec in the last 4 days). Sham operations initially resulted in moderate deficits in performance (initial mean latencies $\sim$ 12 sec) that returned to preoperative levels within 5 days. Bilateral ERC lesions severely impaired navigation performance relative to shams (initial mean latencies > 30 sec). However, substantial improvement in performance occurred over days as indicated by all dependent measures, with mean latencies below 9 sec by the 21st postoperative day. In contrast, the ERC lesions reduced performance in the conditional alternation problem to chance, and no improvement in error scores was observed over the 40 days of training. Thus, spatial navigation may be dissociated from spatial working memory on the basis of recovery following ERC lesions. (Supported by NIAAA grant AA06192 to JRW).

297.3 BEHAVIORAL CONSEQUENCES OF N-METHYL ASPARTATE-INDUCED DESTRUCTION OF BASAL FOREBRAIN CHOLINERGIC NEURONS. G.R. Stewart, D.F. Wozniak*, S. Finger* J.W. Olney and C. Cozzari[1]*. Depts. of Psychiatry and Psychology, Washington University, St. Louis, MO 63110, [1]Istituto Di Biologia Cellulare, Rome, Italy.

The basal forebrain cholinergic system (BFCS) is believed to play an important role in cognitive processes, and BFCS dysfunction may be responsible, in part, for cognitive disturbances in Alzheimer's Disease. Several investigators have shown that an excitotoxin lesion destroying BFCS neurons results in significant learning impairment in rats. The excitotoxins used in such studies were either kainate or ibotenate and the primary behavioral focus was on visually guided spatial learning. In the present study a different excitotoxin, N-methyl-D,L-aspartate (NMA), was used to destroy BFCS neurons and behavioral tests included a tactile discrimination (non visual, non spatial) task.

Adult male rats (n=8), injected with NMA bilaterally into the basal forebrain, were tested after a 1 month recovery period. In neurological tests for sensorimotor integrity the rats appeared to be "hyperemotional" but were not otherwise different from unoperated, age-matched controls. When both groups were trained on a rough/smooth tactile discrimination in a T maze the rats with lesions took significantly longer to reach criterion in the acquisition of this task and most did not learn (2 of 8 reached criterion compared to 7 of 8 controls). The same rats were then trained on a radial arm maze to test "working memory". Rats with lesions were significantly impaired in performing this task, but 7 out of 8 reached criterion.

Histological analysis revealed that rats with lesions were largely depleted of neurons immunoreactive for cholineacetyltransferase in peripallidal portions of the BFCS which comprise the rodent homolog to the primate nucleus basalis. There was also a decrease in acetylcholinesterase staining in cerebrocortical terminal fields to which these neurons project.

Our findings support the conclusion that NMA-induced lesions of the BFCS result in the same kind of behavioral deficits associated with other excitotoxin lesions, i.e., deficits in working memory dependent on spatial and visual cues. It is now possible to add that this type of lesion can impair tactile discrimination learning. Because many BFCS neurons destroyed by the excitotoxin projected to the somatosensory cortex, defective somatosensory information processing might have contributed to some of the deficits in the tactile discrimination learning. Supported by RSA MH 38894 (JWO), AG05681 and NS 07057.

297.4 COMPARISON OF BEHAVIORAL EFFECTS OF NUCLEUS BASALIS LESIONS VERSUS SENSORIMOTOR CORTEX ABLATION. D.F. Wozniak*, G.R. Stewart, S. Finger* and J.W. Olney (SPON: B. Hartman). Depts. of Psychiatry and Psychology, Washington University Medical School, St. Louis, MO 63110.

Excitotoxin lesions of the nucleus basalis magnocellularis (NBM) cause deficits in working memory. In addition, we have observed (Stewart et al., this meeting) that rats with such lesions appear hyperemotional (irritable) and are severely impaired in performing a tactile discrimination. Since NBM lesions destroy cholinergic neurons that densely innervate the sensorimotor cortex, the behavioral findings might be explained in terms of an impairment in sensory processing rather than memory. To explore this, we divided rats into 3 groups. In group 1 (n=9), neurons were destroyed by injection of N-methyl-DL-aspartate bilaterally into the NBM; group 2 (n=10) received bilateral ablation (aspiration) of the sensorimotor (SM) cortex; group 3 (n=10) were given sham operations (needle lowered to a point just dorsal to the NBM with no injection). Each group was assessed on a neurological battery to evaluate sensorimotor integrity and on a learning task conducted in a T maze which consisted of a series of five different two-choice tactile discriminations which were graded in difficulty.

The neurological battery revealed that the SM ablated rats showed significantly attenuated tactile hopping and placing responses and, consistent with our prior observation, NBM lesioned rats showed more agitation (irritability) during a reactivity to handling test. Also they spent less time on an elevated perch (platform test), an apparent reflection of hyperemotionality. It should be noted, however, that no significant differences were found among the three groups on 10 other tests of sensorimotor function. In the tactile discrimination test, the NBM lesioned and SM ablated groups did not differ significantly from each other on the series of discriminations but both were significantly impaired compared to the sham operated group.

These findings suggest that the deficit displayed by rats with NBM lesions in the tactile discrimination paradigm might be due, in part, to a loss of NBM fiber inputs to the SM cortex and consequent disruption of SM information processing. Our findings also suggest that NBM lesions may be associated with hyperemotionality, which may additionally confound interpretation of performance in memory/learning tests. Supported by RSA MH 38894 (JWO), AG 05681 and NS 07057.

297.5 THE PREFRONTAL CORTICAL SYSTEM: ALLOCENTRIC VERSUS EGOCENTRIC RESPONDING. M. Rasmussen*, C.A. Barnes and B.L. McNaughton. Behavioral Neuroscience Program, Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Deficits in spatial delayed response tasks have been found after lesions to the prefrontal cortex both in primates (Goldman and Rosvold, 1970) and in rats (Kolb, Nonneman and Singh, 1974). While the deficit appears to be one of spatial memory, it is impossible to know from these studies whether the subjects use an allocentric or an egocentric response strategy.

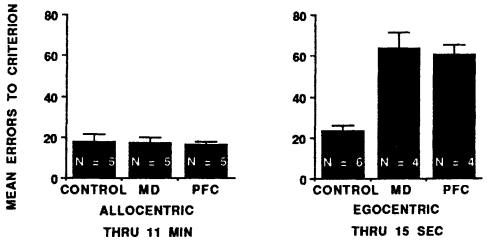
The purpose of the current study is to determine the nature of the spatial memory deficit after injury to the prefrontal cortex and medial dorsal thalamus.

Animals from these two lesion groups were compared with controls on two tests of spatial memory (5 trials per day). The allocentric version, in which the solution depended upon locating alternate places using distal cues, consisted of a cross-maze. Half of the time the Subject must turn in the opposite direction to alternate place and half of the time the direction of the turn is the same on forced and choice trials. The egocentric version requires the Subject to alternate body turns on a Y-maze - half of the time going to a different place on the choice trial and half of the time going to the same place in order to execute the correct turn.

No deficits were found on the allocentric version. All animals were able to meet the test criterion with delays between information and choice trials up to and including 1 minute.

Both prefrontal and medial dorsal thalamic lesions produced severe deficits on the egocentric version relative to controls. Control animals were able to sustain the 1 minute delays while most of the lesioned animals took many more days to master the zero-delay condition and were unable to perform better than chance at the 30 second delay.

Further studies are being conducted to determine whether the deficit is due to inability to remember a previous body turn or inability to select the correct response strategy in the face of damage to the prefrontal system. Supported by AG03376 and NS20331.



297.6 ANTEROGRADE AND RETROGRADE EFFECTS ON PLACE MEMORY AFTER LIMBIC OR DIENCEPHALIC DAMAGE. R. J. Sutherland, K. A. Arnold and A. R. Rodriguez. The University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

Damage to the hippocampal formation (HPC) produces a long lasting behavioural impairment in some memory tasks, particularly those involving conditional associations (e.g., place learning). We address two questions: 1) do subcortical structures connected with the HPC via the fornix differentially contribute to place learning, and 2) are recent and remote place memories differentially affected by damage to the HPC or its subcortical targets?

In Experiment 1 we assessed the effects of damage in several limbic and diencephalic structures on place navigation by rats in the Morris water task. Testing was conducted over ten consecutive days (8 trials per day) and included tests with visible and hidden platforms in a fixed location in the pool. Half of the operated controls and half of the brain damaged rats were trained before surgery, using the same procedures as during testing. All lesions were placed electrolytically, except for HPC damage which was made by multiple, bilateral microinjections of the neurotoxin, colchicine (2.5 µg/0.5 µl saline at 3 sites).

The rats of all lesion groups were able to swim as well as controls to the visible platform. Acquisition of accurate place navigation was achieved by rats with medial septal lesions, incomplete fornix/fimbria transections, and mammillary nuclei, albeit after more trials than controls. Damage to anterior thalamus, medial nucleus accumbens, fornix/fimbria, and HPC prevented acquisition of accurate place navigation. Only complete fornix/fimbria transection or HPC damage abolished preoperatively acquired place navigation.

In Experiment 2 we systematically varied the interval between the end of preoperative place navigation training and colchicine-induced HPC damage (1-12 weeks). Place navigation by all HPC groups was worse than that of their operated control groups during the initial trials of retention testing. However, there was a significant improvement in place navigation performance associated with longer training-surgery intervals. Unlike the other HPC damage groups, by the end of retention testing, the 12-wk group was not significantly different from controls.

The results are consistent with the theory that the HPC, in concert with posterior cortical areas, represents and initially stores conditional associations among events necessary for place memory and over a period of weeks participates in "consolidating" representations stored elsewhere (Sutherland and Rudy, 1987). Relevant subcortical areas only facilitate performance during initial acquisition of information.

297.7 **HIPPOCAMPAL DENERVATION FACILITATES OLFACTORY LEARNING-SET FORMATION AND DOES NOT IMPAIR MEMORY IN A SUCCESSIVE-CUE GO, NO-GO TASK.** T.A. Otto, F. Schottler*, U. Staubli, and G. Lynch. Center for the Neurobiology of Learning and Memory, Univ. of California, Irvine, CA 92717.

In an olfactory discrimination task using simultaneous odor presentation, hippocampal denervation by lesions of the entorhinal cortex produces an 'anterograde amnesia' syndrome in rats which is characterized by unimpaired acquisition of new discriminations (given short intertrial intervals) but deficits in retention of those discriminations when tested 1 hour later (Staubli et al., Proc. Natl. Acad. Sci., 81:5885, 1984). Eichenbaum et al. (Behav. Neurosci., in press) have recently reported that lesions to the fornix either facilitate or impair olfactory learning-set acquisition depending on whether the olfactory cues are presented sequentially or simultaneously, respectively. In the present experiments, we investigated the effects of a more specific hippocampal denervation on two aspects of olfactory learning using sequential odor presentation: 1) the formation of learning sets, and 2) the retention of individual cues.

Ten male Sprague-Dawley rats, 250-280 g, served as subjects. Five received bilateral electrolytic lesions to the entorhinal cortex. The remaining five rats served as sham-lesion controls. During daily odor training sessions, these water-deprived rats were trained to discriminate a single pair of odors which were ejected randomly and successively into the cage by constant-flow air pressure. Nosepoke responses to the arbitrarily-designated 'positive' odor resulted in access to a 0.05 ml water reinforcer; responses to the 'negative' odor went unreinforced. Sessions were terminated when the subject reached a criterion of 18 correct responses in 20 consecutive trials, or at 400 trials maximum. Five such sessions, with session-unique odor pairs, were conducted.

Both groups exhibited olfactory learning set acquisition, evidenced by a marked decrease in the number of trials to criterion across sessions. Hippocampally denervated subjects, however, outperformed their sham-lesioned counterparts in the number of correct responses during the first 20 trials of a session ($p<.05$) and in overall accuracy within a session ($p<.01$). In contrast to the results obtained using simultaneous odor presentation, the experimental animals exhibited no deficit in subsequent tests of retention (reversal). These data are consistent with the notion that the hippocampus is not required for 'procedural' types of memory and suggest that its role in the encoding of specific cues is task, or 'strategy', dependent.

297.8 NORMALIZATION OF HIPPOCAMPAL LESION-INDUCED IMPAIRMENTS BY AN ATYPICAL NEUROLEPTIC. T.L. Steele & L.D. Devenport. Department of Psychology, University of Oklahoma, Norman, OK 73019.

Lesions of the hippocampus produce impairments in many learning tasks, especially those requiring a shift from one behavior to another, as in extinction (1). Similar deficits occur in rats given dopamine (DA) agonists. In both cases, the impairments may be due to stereotypy, increased activity, and decreased exploration (2). Neuroleptics, which block DA receptors, reduce the lesion-induced (3) and drug-induced behaviors (4). Considering that many of the behaviors found in hippocampal-lesioned (HIPP) animals mimic those seen in animals with high levels of DA activity, it is possible that some impairments observed in HIPP animals may not be a direct result of the lesion, but instead are due to increased DA activity. If true, manipulations which suppress DA transmission should normalize performance in HIPP animals. The present experiment tested this assumption by administering an atypical neuroleptic, sulpiride, to sham-operated (SHAM) and HIPP rats.

SHAM and HIPP rats were given daily injections of sulpiride (0, 15, 30, or 60 mg/kg) for 16 consecutive days. On each of these days, rats were placed in a straight alley containing reward and in a second alley (of different color) containing no reward. Animals were given 16 days of extinction (with continued drug administration) in which neither alley contained reward. Running time, exploration, and stereotypy were recorded across sessions.

Sulpiride had little effect on the behavior of SHAM rats, which learned the discrimination readily. HIPP rats receiving saline or low doses of sulpiride ran equally fast in both baited and non-baited alleys. Stereotypy was higher and exploration lower in these rats. However, stereotypy decreased and exploration increased in HIPP rats receiving the higher doses of sulpiride, and these rats were able to acquire the discrimination. During extinctino, sulpiride normalized behavior in HIPP rats, leaving that of SHAM rats unaffected.

The normalization of behavior in HIPP rats implies that hippocampal lesions may be only indirectly responsible for some of their impairments. Since these impairments were corrected by a DA antagonist, it is possible that the hippocampus exerts its effects through the DA system.

297.9 PATHOLOGICAL ALTERATIONS IN THE BASOLATERAL AMYGDALA IN ALZHEIMER'S DISEASE. L.J. Kromer*, B.T. Hyman, G.W. Van Hoesen and A.R. Damasio. Depts. of Anatomy and Neurology, University of Iowa College of Medicine, Iowa City, IA 52242.

The basolateral complex of the amygdala in the human and non-human primate brain accounts for much of the mass of this structure and resembles the cortex in terms of its neural connectivity. For example, it sends projections to the striatum, parts of it receive a sizeable cholinergic input from the nucleus basalis of Meynert and it is interconnected strongly with frontal and temporal cortical areas. Connections with the dorsomedial thalamic nucleus, the nucleus basalis of Meynert, and with the hippocampus and entorhinal cortex, place the basolateral complex of the amygdala in a pivotal position to influence nearly all of the known memory-related neural systems of the forebrain. It is known that the amygdala is targeted for pathology in Alzheimer's disease (AD), but the extent of its involvement has not been delineated or analyzed in terms of its known connectivity. Therefore, we have studied the patterns of pathology in the amygdala of 10 cases of confirmed AD and 5 age-compatible controls using conventional pathological stains such as thionin, Congo red and thioflavin S and immunostaining with the monoclonal antibody Alz-50. Of the four major nuclei that form the basolateral complex, the accessory basal has consistently contained the highest degree of pathological involvement in terms of neuritic plaques and neurofibrillary tangles, and the lateral nucleus, the least. The laterobasal nucleus which receives a powerful cholinergic input typically contains few neuritic plaques, whereas these are found in abundance in the mediobasal nucleus. The heavy pathological involvement of the accessory basal and mediobasal nuclei is of interest, since these nuclei in non-human primates send projections to and receive projections from the subicular and CA1 fields of the hippocampal formation, structures damaged heavily by pathology in AD. Moreover, both nuclei contribute afferents to the dorsomedial thalamic nucleus. Thus, there seems good reason to believe that pathological alterations in the amygdala may contribute to some aspects of the memory impairment that characterizes AD. The selective nature of these changes further highlights the fact that pathological changes in AD target and dissect key structures of the forebrain that contribute to neural systems implicated in memory. 297.10 **EFFECTS OF LESIONS OF THE DORSAL CORTEX AND MEDIAL CORTEX ON THE REVERSAL OF A GO/NO-GO DISCRIMINATION IN TURTLES.** **(Spon. O. B. Ward). W. Grisham* and A. S. Powers. Rosemont College, Rosemont, PA 19010 and Department of Psychology, St. John's University, Jamaica, NY 11439.**

Previous research has shown that turtles with lesions of the dorsal cortex (cd) show a deficit in the reversal of a simultaneous pattern discrimination (Cranney & Powers, 1983). The present experiment examined the effects of cd lesions on the retention and reversal of a go/no-go pattern discrimination. Lesions of the medial cortex (cm) were included as a control.

All turtles were trained on a go/no-go pattern discrimination until the difference in the mean latency to respond to the S+ and S- was at least 50 sec. across 4 consecutive sessions of 20 trials each. After this, the turtles were either given suction ablations aimed at the cd (n=4), electrolytic lesions aimed at the cm (n=5), or were shams (n=6). The turtles were given retention testing to criterion after which the discrimination contingencies were reversed. If the animals failed to respond to either the S+ or S- for at least three consecutive days or if they failed to discriminate between the S+ and S- for many days, they were given remedial training. In remedial training, the turtles were given only S+ trials until they responded with a mean latency of 10 sec. or less for a single session.

As previously reported, lesions of either the cd or the cm did not have any effect on retention (Grisham and Powers, 1985). Nonetheless, brain lesions did produce effects in reversal. A significantly greater proportion of brain-lesioned turtles than shams required remedial training ($p < .05$). The number of days in remedial training required was significantly correlated with bilateral cd damage (Spearman's rho=.49, $p < .05$) but was not correlated with bilateral cm damage (rho=.15, $p > .05$). Apart from the number of days required in remedial training, no other measures showed a difference between lesioned and sham animals.

The results of this experiment suggest that lesions of the cd produce deficits in the reversal of a go/no-go pattern discrimination. The results also suggest that the basis of this deficit is a retardation in the association of excitatory properties with the S+ in cd lesioned animals. This result is consistent with previous results which showed that cd lesioned animals are impaired in the acquisition of a go/no-go discrimination.

297.11 MEDIODORSAL THALAMIC LESIONS IN RATS ALTER REACTIVITY TO ENVIRONMENTAL CUE CHANGES. K. A. Stokes* and P. J. Best. Department of Psychology, University of Virginia, Charlottesville, VA, 22901.

Rats with mediodorsal (MD) thalamic lesions present a number of deficits in learning tasks. MD animals do not perform well on radial maze tasks and have impaired memory for serial position (Stokes and Best, Neurosci. Abstr., 11, 833, 1985; 12, 747, 1986). These deficits imply that MD animals have compromised ability to utilize environmental stimuli to guide behaviour.

The present study examines the effects of electrolytic and ibotenic acid lesions of MD on reactivity to changes in environmental stimuli. The simple behavioural task employed requires the animals merely to move from a start box to a goal box for food reward. Start and goal boxes (each 30 cm long, 15.5 cm wide and 15 cm high) contained one of three sets of visual and tactile cues: 1) white walls and grid floor, 2) black walls and smooth floor or 3) black and white striped walls and carpet floor.

Initially, animals were trained for 5 trials a day in one start box connected to an identical goal box, and for 5 additional trials in a second start box also connected to an identical goal box, until they attained stable latencies to capture the food (40 trials, 4 days). At this point, the goal boxes were changed. For one group, the goal boxes were simply switched. These animals, then, still experienced familiar goal boxes, but in the wrong place. For the other group, both goal boxes were replaced by boxes containing the third set of cues. So, these animals experienced totally novel cues in both goal boxes. The particular cues in each condition were counterbalanced.

Intact animals demonstrate awareness of the goal box switch by arresting, briefly exploring the goal box, and, thus, showing longer latencies to approach the food. They show this reaction not only when the goal box is totally novel, but even when a familiar goal box appears in an inappropriate context. In contrast, MD lesioned animals do not show behavioural arrest and longer latencies when familiar goal boxes are switched. Either they do not pay attention to the goal box cues or they do not recognize their occurrence in an inappropriate or unusual context. However, when goal boxes are changed to novel cues, MD animals do orient to, or "notice", this change. Thus, MD animals can pay attention to environmental cues, but do not process familiar cues in the same way intact animals do, i.e., as specific to particular contexts.

297.12 SPATIAL DELAYED NONMATCHING-TO-SAMPLE AFTER FIMBRIA-FORNIX OR CINGULATE CORTEX LESIONS: A COMPARATIVE STUDY IN RATS AND MONKEYS. A.L.Markowska*, D.S.Olton, E.A.Murray and D. Gaffan. Dept. Psychology, Johns Hopkins Univ.,Baltimore, MD 21218, Lab. Neuropsychology, NIMH, Bethesda, MD 20892, Dept. Expt. Psychology, Univ. Oxford, Oxford, England.

Although experiments with rats and monkeys both provide animal models to examine the brain mechanisms involved in different types of memory, the experimental procedures used for the two species often differ, complicating a direct comparisons of the experimental results. The present experiment tested rats in a spatial delayed nonmatching-to-sample procedure identical to that used by Murray et al for monkeys (Society for Neuroscience Abstract, 1986, p. 976) in order to compare the effect of fornix lesions and cingulate lesions on performance in this task in the two species.

The apparatus was a T maze. Each trial consisted of two runs. During the force run, the entrance to one arm was blocked and the rat entered the other arm to receive food in the box. Following a one-minute interrun interval, the rat had a choice run with both arms open; food was available only in the arm not entered during the previous force run. Four trials were given each day with an intertrial interval of 1 & 1/2 hours. After the rats reached a criterion of 36 correct responses in 40 consecutive trials, they were tested with longer interrun delays (5 mins and 15 mins).

Preoperatively, the rats learned the task more quickly than the monkeys, taking a mean of 70 trials and 11 errors to complete criterion. This rapid acquisition took place in spite of the unusual procedure: only 4 trials per day, a long interrun interval even during initial acquisition, and a long intertrial interval. Postoperatively, control rats continued to choose accurately, and reached criterion in a mean of 46 trials and 4 errors. Both lesions produced a severe impairment of choice accuracy: rats with lesions had a mean choice accuracy of less than 70% after three weeks of testing, and showed no signs of improvement. The magnitude and duration of this impairment was greater for the rats than for the monkeys.

These results demonstrate that when rats and monkeys are tested in similar experimental procedures, lesions of the fimbria-fornix and the cingulate cortex produce similar behavioral impairments. However, the magnitude of the impairment differed in the two species, as did the performance of normal animals. These results provide an important funtional comparison of the behavioral roles of these brain structures, and emphasize the difficulties in obtaining tasks that are equivalent not only in procedure but also in difficulty for two different species.

297.13 CENTRAL BUT NOT BASOLATERAL AMYGDALA MEDIATES MEMORY FOR POSITIVE AFFECTIVE EXPERIENCES. R. D. Walser*, F. P. Kesner, and G. Winzenried*. Department of Psychology, University of Utah, Salt Lake City, Utah 84112.

It has been suggested that the amygdala is involved in mediating memory to the extent that the memory requires the coding of positive affect information. In order to provide support for this idea, rats were trained on a task in which memory for magnitude of reinforcement was tested. It is assumed that memory for magnitude of reinforcement is a function of the activation of affective experiences. To be more specific, rats were first acclimated to a radial arm maze. They then received a single trial per day consisting of a study phase and a test phase. In the study phase, the animals received 1 or 7 pieces (1/4 pieces of Froot Loop cereal) of food on different arms of the maze. After the study phase, the rats were delayed for 10 seconds, 5 or 15 minutes. After the delay during the test phase the animals were allowed to choose between the two arms presented in the study phase. The correct response, leading to an additional Froot Loop reinforcement, was to select the arm in which the animal had received the 7 pieces of food. Animals learned this task to a criterion of 80% or better performance on blocks of 10 trials for each delay within an average of 138 trials. They then received electrolytic lesions of the basolateral or central amygdala. After recovery from surgery animals were tested at each delay. The results indicate that there were no deficits at any delay with basolateral amygdala lesions. In contrast, lesions of the central amygdala produced a marked deficit at the 5 and 15 minute delays, but no deficit at the 10 second delay. Based on the assumption that memory for magnitude of reinforcement is a function of the activation of affective experiences, it is concluded that the central but not basolateral amygdala is involved in the coding of positive affect information.

297.14 REVERSIBLE COLD LESIONS OF THE PARAHIPPOCAMPAL GYRUS RESULT IN DEFICITS ON THE DELAYED MATCH-TO-SAMPLE TASK. George, P.J.[1]*, Horel, J.A.[2], and Cirillo, R.A.[1]*. (SPON: G. Keating) 1. Dept. of Psychology, Syracuse University, Syracuse, NY 13244. 2. Dept. of Anatomy and Cell Biology, SUNY Health Science Center at Syracuse, Syracuse, NY 13210.

In a previous experiment we found that reversible cold lesions of the anterior portion of the inferotemporal gyrus (a. itg.) produced deficits on a delayed match-to-sample (DMS) task, especially at the longer delays (45 seconds). Lesions of posterior itg or any part of the middle temporal gyrus (mtg) did not have any effect on DMS performance at any delay (0-45 seconds). (Horel et al., Society for Neuroscience Abstracts, 15: 324, 1985). This left the question of how a. itg gets its visual input necessary for the DMS task. Martin-Elkins (personal communication) injected horseradish-peroxidase into anterior itg in monkeys and found cells labelled in the posterior parahippocampal gyrus, suggesting that this may be a source of visual input into anterior itg.

In the present experiment, we placed 2 cryodes bilaterally over the mediventral temporal cortex in cynamologous monkeys (Macacca fascicularis). One cryode covered the posterior extent of the posterior parahippocampal gyrus (pg), and one covered the tissue lying lateral to pg, the posterior infertemporal gyrus (p. itg). Both cryodes consisted of 23-ga stainless steel tubing shape to fit over the gyri. Both measured 11 mm long X 5 mm wide and were placed over the dura mater.

Animals were trained preoperatively on a variable DMS task with 0-45 second delays. Stimuli consisted of 560 colored photographs of objects and were presented on rear projection screens that faced the animals who were restrained in chairs. During experimental trials, cooled methanol was pumped through the tubing to bring the temperature of the probes to -5°C; behavioral effects of the lesions were completely reversible within 3 minutes of removing the cold.

Results show a deficit for DMS at the longest delay (45 seconds) with reversible lesions of the pg. Performance on DMS during lesions of p. itg was similar to that of control. The monkeys were also tested on a concurrent visual discriminations. Eight object pairs were presented randomly and in succession and trials-to-criterion were measured under control and the two lesion conditions. Trials-to-criterion during both p. itg and pg lesions were much greater than that of control, suggesting a learning deficit for this task with both cortical lesions. (Supported by NINCDS grant NS 1829-05).

297.15 BEHAVIORAL RESPONSES PARALLEL THE RESPONSES OF HIPPOCAMPAL PLACE CELLS TO ENVIRONMENTAL MANIPULATIONS. J. L. Kubie, R. U. Muller*, S. Davani* and D. Morgenstern*. Depts of Physiol. and Anat. and Cell Biol., S.U.N.Y. Health Sci. Center at Brooklyn, Brooklyn, NY 11203.

The water maze developed by Richard Morris has been of great value in studying the spatial abilities of rats. Moreover, the finding that rats with damaged parts of the hippocampal formation perform poorly in the water maze (Morris & Garrard, *Behav. Br. Res.* 1980) strongly supports the idea that the hippocampus is important in spatial processing, as does the existence of hippocampal place cells (O'Keefe and Nadel, *The Hippocampus as a Cognitive Map*, 1978). Unfortunately, it is extremely difficult to record from or study place cells in the water maze. Our aim was, therefore, to develop a "dry" version of the water maze. This would permit study of place cell activity and a very interesting form of spatial problem solving under similar circumstances, or at the same time.

The dry maze is a 6 ft diameter cylinder. The goal is a sealed food cup buried below 4 inches of wood chips; this replaces the submerged platform of the water maze. The two goals are equivalent in that neither provides stimulus information, so that the location of each can only be efficiently found from spatial relations to distant cues. In the dry maze the major salient cue is a white card that covers 100° of the cylinder wall; other cues are hidden by a circular curtain. Use of the card permits direct comparison with our place cell studies, which employed similar cards. We found that rotating the cue card causes equal rotations of place cell firing fields; halving the size of the cue card causes, at most, rotations of the firing fields, and removing the cue card causes fields to rotate to an unpredictable angular location, but to retain their integrity (Muller & Kubie, *J. Neurosci.* 1987). Our aim was to test the idea that cue manipulations in the dry maze will lead to similar rotations in spatial behavior.

Rats are first permitted to find food on the surface of the wood chips. During formal training, rats start from one of 3 randomly chosen positions. Group 1 rats are subsequently trained to find food buried in a fixed location on each trial. Group 2 rats are trained to find buried food in a different location on each trial. For group 2, each trial is divided into a first half, in which the food location was marked with a dowel, and a second half, in which the food is buried at the same location but is unmarked.

Both groups learned to find the food accurately within thirty trials. Rats took direct paths and usually found the buried food within 15 sec. On trials when no food was buried, rats ran directly to the last rewarded location and dug there, demonstrating the use of spatial cues. On probe trials with food buried randomly with respect to the fixed (group 1) or 1st half of the trial (group 2) locations, rats never found the food, indicating stimuli from the food dishes do not guide the behavior.

When the cue card was rotated and no food was buried, the behavior of rats in both groups was to first dig at a spot consistent with rotation, and then to choose a second spot consistent with no rotation. The results obtained to date demonstrate that the cue card controls spatial behavior in the same way it controls place cell firing. Further studies are needed to determine whether place cell activity and spatial behavior always respond in parallel. The methods described here ought to be of use in a variety of studies on the neurobiology of spatial behavior. (Supported by N.I.H. grant NS20686)

297.16 EFFECTS OF PERINATAL COPPER DEFICIENCY ON RADIAL MAZE PERFORMANCE OF REHABILITATED ADULT RATS. E.S. Halas. USDA, ARS Human Nutrition Research Center, Grand Forks, North Dakota 58202.

Dietary trace elements, including zinc, copper, and iron, have been found to be essential for the proper development of the brain. For example, rehabilitated adult rats who suffered zinc deficiency during gestation and/or lactation were found to have an impaired learning ability and working (short-term) memory. Histological abnormalities were found in the hippocampi of these rats. Interestingly, the hippocampus has the highest concentration of zinc while the locus coeruleus has the highest concentration of copper. Thus, we decided to examine the importance of copper for learning and memory. Starting on the day of conception, and ending on the day of delivery, one group of rat dams was fed a diet containing 1.2 ppm copper; a second group of rats was fed a diet containing 1.7 ppm copper. These two groups were fed a diet containing 0.5 ppm Cu from the day of delivery until the pups were weaned at 23 days of age. A third group of dams was fed a 5.0 ppm Cu diet throughout gestation and lactation. After weaning, all three groups were maintained on the 5.0 ppm Cu diet until they were 120 days old; they were then reduced to 80% of their normal weight and trained on a 17-arm radial maze. There were 8 female rats selected from each of the three groups for a total of 24 rats. Each rat was given 1 trial per day for 25 days. All 17 arms were baited with a single 190 mg food pellet. A trial was terminated when the rat retrieved all 17 pellets or 15 min. had elapsed. The data were analyzed in blocks of 5 trials. During the first 5 trials, no significant differences in percent of correct responses were found among the 3 groups. In the second block, (trials 6-10), the 1.2 ppm group had a significantly lower percent of correct responses than the 1.7 and 5.0 ppm groups. When compared to the other 2 groups, the 1.2 ppm group continued to be significantly inferior in performance during block three (trials 11-15). In the remaining blocks of trials, no significant differences in performance were found among the three groups. No significant differences were found between the 1.7 and 5.00 ppm groups during any of the blocks of trials. These findings suggest that learning was retarded in the 1.2 ppm group but working memory was not impaired. These findings contrasts with those of zinc deficiency, which impaired both learning and working memory. Thus, different trace element deficiencies might injure different structures of the brain resulting in different types of behavioral impairment.

297.17 SEPTO-HIPPOCAMPAL SYSTEM AND PRELIMBIC CORTEX: A NEUROPSYCHOLOGICAL BATTERY ANALYSIS IN THE RAT. G.N.O. BRITO and L.S.O.Brito*. Setor de Neurociencias, Inst. Biom., Univ.Fed.Fluminense, Niteroi, RJ 24210, Brasil.

Research in the neuropsychology of animal memory suggests that lesions in the septo-hippocampal system or medial frontal cortex disrupt working-memory mechanisms but leave intact reference-memory processes. However, most studies use a limited number of behavioral tasks. Also, work on the frontal cortex has usually disregarded the different divisions of the medial frontal area. In the present study, we investigated the functions of the septo-hippocampal system and a specific sector of the medial frontal cortex, the prelimbic area, using a neuropsychological test battery. Procedures for surgery and coordinates for electrolytic lesions in the posterodorsal septum (SEP, N=9), prelimbic cortex (PRE, N=9) and control operations (CON, N=8) were as described in Brito et al (Exp.Brain Res., 46: 52, 1982). After a 3-wk postoperative recovery period, rats were tested in a neuropsychological battery comprised of the following tasks in the order administered: time-spent-eating in a strange box; time-to-emerge from home cage into an open field; activity box; adaptation to a T-maze, continuous alternation, visual discrimination, discrete alternation, and olfactory discrimination all in the same maze; adaptation to a straight runway, response patterning under a single alternation schedule of rewarded and nonrewarded trials, a tactile Go-No Go discrimination, and an approach-avoidance conflict task all in the same runway. SEP and PRE rats were hyperactive compared to CON rats. SEP rats performed the visual, olfactory and tactile discrimination tasks as well as CON rats. However, SEP rats could not perform the T-maze and runway alternation tasks. PRE rats performed as well as CON rats in the T-maze visual and olfactory discrimination tasks. However, PRE rats performed worse than CON rats in the alternation and tactile Go-No Go discrimination tasks. PRE rats performed the alternation tasks better than SEP rats, whereas SEP rats performed the tactile discrimination task better than PRE rats. There were no differences between groups in the performance of the approach-avoidance conflict test. These results support the hypothesis that the septo-hippocampal circuitry and, to a lesser extent, the prelimbic cortex are part of a system involved in working-memory processes.

Supported by grants from CNPq and FINEP.

297.18 CHRONIC ETHANOL CONSUMPTION AND MAMMILLARY BODY LESIONS PRODUCED SIMILAR SPATIAL MEMORY RETRIEVAL DEFICIT IN MICE. D.J. Béracochéa, A.N. Tako and R. Jaffard, Lab. Psychophysiologie, Univ. Bordeaux I, 33405 Talence Cedex.

Prolonged ethanol consumption in mice has been found to result in spatial memory deficits (Béracochéa and Jaffard, Behav. Br. Res.,15:15,198) associated with marked neuronal loss in the median mammillary nucleus (MM)(Lescaudron et al., Neurosc. Lett., 50:151,1984). Other structures generally considered to play a key role in memory processes were also found to exhibit some degree of neuronal loss (see Béracochéa et al., Neurosc. Lett., 73:81, 1987). Consequently the purpose of the present experiment was to determine to what extent, an experimental lesion of the MM alone would produce the same deficit as alcohol treatment. Spontaneous alternation behavior (S.A.) in a T-maze and delayed non matching to sample task in an automated 8-arm radial maze were used. For S.A. two procedures were employed : a sequential and a discrete alternation procedures respectively aimed at evaluating proactive interference (P.I.) and the rate of forgetting.

Results showed that both 6 months of ethanol consumption and experimental MM lesions (electrolytic or cytotoxic) result in an accelerated rate of decay of S.A. (discrete alternation procedure) experimental subjects exhibiting normal S.A. rate at the 5 mn retention interval (R.I.) but reaching chance level performance at 6 hrs as compared to 48 hrs for controls. In the sequential test procedure, both experimental groups exhibited a progressive impairment of performance as the number of trials increased; thus, while their S.A. rate was normal for the 3 first trials of the series, additional trials (4th to 6th) revealed a marked impairment of S.A. as compared to controls. A similar but lesser deficit were observed in the radial maze suggesting that both MM lesioned and alcohol treated mice suffered from an exaggerated vulnerability to P.I. and from an abnormally rapid rate of forgetting.

The second part of the experiment was aimed at testing whether these impairments might result from frequent use of the same material (familiarity). Accordingly, tests were conducted under different conditions varying the intramaze context by placing (ON) or not (OFF: usual test condition) a white cardboard in front of the stem between the two goal arms. Results showed that the deficit observed in both alcohol-treated and MM lesioned animals was totaly alleviated by this change of context, most importantly when it occured on the retention test trial alone.

These results show that both alcohol-treated and MM lesioned animals suffered from a retrieval spatial memory deficit which closely depends on the testing condition and emphasize the key role of mamillary body lesions in this form of alcohol-induced amnesia.

297.19 THE ROLE OF GENDER IN THE BEHAVIORAL EFFECTS OF HIPPOCAMPAL SYMPATHETIC INGROWTH. L. Harrell and D. Parsons*. Dept. of Neurology, VAMC and Univ. Alabama Med. Ctr., Birmingham, AL 35294.

Following cholinergic denervation of the hippocampal formation, peripheral sympathetic nerves originating from the superior cervical ganglia grow into the hippocampus. Multiple studies from our laboratory suggest that hippocampal sympathetic ingrowth (HSI) is functional and can alter behavior. Since gender is known to alter the anatomy of HSI, the present study was performed to assess the effect of this variable on behavioral recovery following HSI.

Sixty-one female and 33 adult male Sprague-Dawley rats were trained on a standard version of the radial 8-arm maze task until they reached a specific learning criterion (visiting 8 baited arms in the first 10 selections over 5 days). Animals from each sex then under 1 of 3 surgical procedures: CON (sham surgeries): MS + Gx (medial septal lesions + ganglionectomy); MS + SGx (MS lesion + sham Gx). Reacquisition of the maze was then assessed.

Twenty-nine female and 17 male rats were excluded from data analysis due to lesion placement or surgical death. Prior to surgery acquisition of the task was significantly faster in male (7.43 $\pm$ .97, (SEM) trials) than female (14.0 $\pm$ 3.4) rats ($p < .01$; ANOVA). No differences were observed by within each gender group. Following surgery male and female rats recovered over-all performance at similar rates. However, marked group differences were observed ($p < .001$; ANOVA). In males, the CON (n=7; 6.0 $\pm$ 6.5) group recovered faster than the MS + Gx (n=5; 19.2 $\pm$ 7.0) group , which recovered faster than the MS + SGx (n=4; 35.7 $\pm$ 7) group ($p < .05$). In females, the CON group (n=12; 12.6 $\pm$ 2.7) recovered faster than the MS + SGx group (n=9; 23.7 $\pm$ 4.5), which inturn recovered faster than the MS + Gx group (n=11; 42.0 $\pm$ 9.1).

The results of this study clearly demonstrate that gender can influence the behavioral effects of HSI. As expected from our previous work, HSI in male rats produced a determintal effect, with slowing of behavioral recovery. In females, however, HSI produced exactly the opposite effect with facilitation of behavior. We believe that this is the first instance in which gender has been shown to alter the behavioral effect of a neuronal reorganization. This work may eventually have important implications in Alzheimer's disease, an illness found in both sexes and associated with cholinergic degeneration and sympathetic ingrowth.

298.1 IDENTIFICATION AND CHARACTERIZATION OF THE OPIATE RECEPTOR IN THE CILIATED PROTOZOAN, TETRAHYMENA. J.B. O'Neill*, B. Zipser*, M.R. Ruff, C.C. Smith, W.J. Higgins and C.B. Pert. Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, ADAMHA, Bethesda, Maryland 20892 and Department of Zoology, University of Maryland, College Park, Maryland 20742.

Tetrahymena, a ciliated protozoan, has a low phylogenetic order, yet is a highly specialized, differentiated organism. It is known to secrete many informational substances, including peptides such as β-endorphin. We wished to investigate the possibility that this organism possesses a functional opiate receptor which might be similar to the well characterized opiate receptor in the rat brain. Binding assays using both living cells and membrane preparations, verified saturable stereospecific, [^{125}I]-β-endorphin binding which was displaceable by various opiates chosen for their specificity for the putative opiate subtypes. SDS-PAGE of a DSS cross-linked receptor-[^{125}I]-β-endorphin complex revealed a pattern of bands which consistently included bands at 110, 58-55, and 29 kD. These bands were all displaceable by the classical antagonist, naloxone, as well as by other opiates thought to be prototypic for various opiate receptor subtypes. Limited proteolysis in SDS-PAGE showed that the 110 kD band could be fragmented into 58-55 and 29 kD bands and that the 58 kD band could generate a 29 kD fragment. The limited digest fragments of the 110, 58-55 doublet and 29 kD bands were remarkably similar to those generated from the rat brain receptor. Analytical isoelectric focusing of digitonin solubilized [^{125}I]-β-endorphin-receptor complexes showed that the isoelectric points from both the rat and Tetrahymena were identical (pI 4.6).

Chemotactic experiments with intact Tetrahymena, demonstrated that these unicellular animals migrated toward a 10^{-9}M β-endorphin gradient. Chemotaxis was blocked by (-) naloxone but not (+) naloxone, suggesting a stereospecific opiate receptor-mediated response. We conclude that Tetrahymena possesses a functional opiate receptor (recognition molecule) similar to the opiate receptor of the rat brain.

298.2 The Effects of FMRFamide on Longitudinal Muscle in the Medicinal Leech. B.J. Norris, J.A. Fiez*, and R.L. Calabrese. Dept. of Biology. Emory Univ. Atlanta, GA 30322

We have previously shown immunocytochemically that a FMRFamide-like peptide is localized in cholinergic motor neurons innervating longitudinal muscle in the medicinal leech. Further, bath applied FMRFamide caused a tonic contraction in longitudinal muscle and occasionally triggered a weak myogenic rhythm (Norris and Calabrese, Neurosci. Abstr. 11:942, 1985). We have gone on to study further the effects of FMRFamide on longitudinal muscle and to characterize the FMRFamide receptors.

Although brief applications of FMRFamide do not potentiate the response of longitudinal muscle to bath applied ACh, we found that extended exposure (30 mins) of longitudinal muscle to FMRFamide potentiates the muscle's response to ACh. This potentiation was manifested as an increase in both the peak tension and the total tension generated with little or no change in the rate of contraction or relaxation. It persisted long after exposure to FMRFamide was terminated. Exposure to FMRFamide also resulted in a potentiation of the response of longitudinal muscle to motor nerve stimulation. The potentiation of the neuromuscular response consisted of little or no increase in the peak tension but a large decline in the rate of relaxation and an increase in the total amount of tension generated. Further experiments will be aimed at determining FMRFamide's effect on the membrane potential of longitudinal muscle and its effect on neuromuscular transmission.

The effects of bath applied FMRFamide analogs on leech longitudinal muscle were compared to those of FMRFamide. The analogs FMRF-OH, RFamide, FMdRFamide and LWMRFA caused no discernible contraction. FLRFamide and YMRFamide caused effects similar to FMRFamide, while Helix FMRFamide-like peptide (pQDPFLRFamide) caused a contraction 2 to 4 times as strong as equimolar concentrations of FMRFamide. The blocked N-terminus of pQDPFLRFamide could protect the molecule from breakdown by proteolytic enzymes, and thus increase its potency. In preliminary experiments, FMRFamide bath applied with protease inhibitors (Trypsin II-T, 1.25 mgs/ml; L-Phenylalanine-L-Alanine 10 mgs/ml; Phenylmethylsulfonyl Fluoride, 1.5 mgs/ml) caused a 3 fold increase in the contraction produced by FMRFamide alone. Further experiments will attempt to characterize the nature of the proteases present and their role in normal peptidergic transmission.

298.3 ELECTROPHYSIOLOGICAL & BIOCHEMICAL EVIDENCE FOR GABA AS A NEUROTRANSMITTER IN HELISOMA TRIVOLVIS. J.E. Richmond, A.G.M. Bulloch and K.D. Lukowiak. Neuroscience Research Group. University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Several aspects of the neural basis of feeding in the pond snail, Helisoma have been described. We have found that the feeding patterned motor activity (PMA) can be modulated by several neurotransmitters including the amino acid, gamma-aminobutyric acid (GABA). GABA has been implicated in synaptic transmission in both vertebrates and invertebrates and is generally considered to be an inhibitory neurotransmitter. This has prompted us to test the hypothesis that GABA may act as a neurotransmitter on some aspect(s) of the rhythm generation which underlies fictive feeding in this snail. Several lines of evidence have been pursued in order to establish a neurotransmitter role for GABA in the CNS and to identify candidate GABAergic neurons.

As reported previously bath application of GABA at concentrations from 5 x 10^{-6}M brings about the onset of PMA in the isolated CNS. Furthermore, iontophoresis of GABA onto key neurons in the buccal ganglia involved in PMA produces both depolarizing and hyperpolarizing responses. Using a GABA antibody, we have mapped candidate GABA neurons in several ganglia of the Helisoma CNS including the buccal ganglia. Almost exclusively these neurons do not have peripheral projections and thus can be considered interneuronal. The specificity of the immunoreactivity was tested by preabsorbing the antibody with a GABA-BSA conjugate. This abolished all staining. HPLC analysis of the CNS using two different analytical systems has confirmed the presence for GABA in the CNS, whereas there is no evidence of GABA in the hemolymph of this snail. In a further investigation in which the CNS was preincubated with ^{3}H glutamate, we were able to demonstrate the incorporation of tritium into the GABA peak which suggests the de novo synthesis of GABA takes place in the CNS of Helisoma.

Taken together this evidence strongly supports the hypothesis that GABA acts as a neurotransmitter in Helisoma. Current experiments are aimed at establishing whether there is a specific uptake mechanism for GABA using autoradiographic techniques and whether GABA is released during excitation of the CNS.

298.4 SIZE AND NUMBER OF SEROTONIN IMMUNOREACTIVE CELLS CHANGE WITH AGE IN ADULTS OF THE SNAIL MELAMPUS. R.H. May, R.L. Ridgway, and S.B. Moffett. Dept. of Zoology, Washington State University, Pullman, WA 99164-4220.

Snails are favored for study by many neurobiologists because of the relative simplicity of their nervous systems, which often contain individually identifiable large cells. The presence of such cells has fostered an assumption that molluscan neurons, while increasing in size via polyploidy, remain constant in number and position during adulthood. We have tested this assumption by determining the size, number, and position of serotonergic cells within the CNS of adult Melampus bidentatus. This pulmonate species is slow-growing and has a long lifespan (> 4 yrs). Shell lengths of reproductive Melampus range from 5-12 mm. An indirect immunofluorescence method, employing a commercial antiserum to serotonin (ImmunoNuclear Corp.), was used to visualize serotonin-containing cells within whole-mounted ganglia of 5, 8, and 10 mm snails. Cell counts and diameters were determined using image analysis (digitizing morphometry: Bioquant II software).

Cells having serotonin-like immunoreactivity (SIR) occurred in 8 of 11 central ganglia of Melampus, the exceptions being the left pleural and paired buccal ganglia. The right pleural ganglion contained only 1-3 SIR cells. Base cell counts (derived from 5 mm snails, n=5) within the other ganglia were as follows: left cerebral, $\bar{X}$=32.4 ± 1.6 (SE); right cerebral, 32.3 ± 3.8; left parietal, 11.8 ± 2.7; right parietal, 29.4 ± 2.7; visceral, 29.2 ± 4.0; left pedal, 74.0 ± 8.5; and right pedal, 89.8 ± 10.6. Comparison of 8 mm animals (n=5) to these baseline values showed significantly ($P < 0.05$) more SIR cells in the right parietal ($\bar{X}$=40.6 ± 2.8 SE) and visceral ($\bar{X}$=34.6 ± 2.7 SE) ganglia, but not in other ganglia. Similar results were obtained when 10 mm (n=5) animals were compared to the baseline values. When values for 10 mm and 8 mm animals were compared only the visceral ganglion ($\bar{X}$=46.5 ± 4.9 SE) showed significantly more SIR cells. The increases in cell number appear to be restricted to clusters of small (8-12 μm diam.) SIR cells. Clusters of larger cells and solitary large SIR cells did not increase in number although anomalies (e.g. duplications) were occasionally seen. All SIR clusters and most solitary large cells showed a significant ($P < 0.05$) increase in average cell diameter with age when 5 mm animals were compared with 8 or 10 mm animals.

We conclude that addition of serotonergic cells can occur into adulthood in Melampus. The data suggest that mitotically competent stem cells or post-mitotic undifferentiated cells exist within the CNS of adults which may contribute to the remarkable ability of this species to replace lost neurons (see Moffett and Austin, J. Comp. Neurol. 207:177-182, 1982). Supported by a Sigma Xi grant to RLR and NIH grant RO1 NS 22896 to SBM.

298.5 SUBSTANCE P-LIKE AND SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE CNS OF THE SNAIL MELAMPUS. R.L. Ridgway and S.B. Moffett, Dept. of Zoology, Washington State Univ., Pullman, WA 99164-4220.

The primitive pulmonate gastropod Melampus bidentatus exhibits a striking ability to regenerate neural tissues in response to injury that can include the replacement of lost neurons (Moffett and Austin, J. Comp. Neurol. 207:177-182, 1982). Our interest is in elucidating the roles played by various neuropeptides and transmitters in Melampus CNS regeneration. Somatostatin-like peptides have recently been shown to induce neuritic outgrowth of axotomized gastropod neurons (Grimm-Jorgenson, Brain Res. 403:121-126, 1987; Bulloch, Brain Res., 1987 (in press)) while substance P and related molecules are known to be potent mitogens in a number of preparations, including the blastema of regenerating flatworms (Salo and Baguna, J. Exp. Zool. 237:129-135, 1986). The present study documents the presence of somatostatin-like and substance P-like molecules in the CNS of Melampus as assayed by whole mount indirect immunofluorescence techniques using commercially prepared antisera (ImmunoNuclear Corp.).

Substance P-like immunoreactive (SP-IR) cells are found in the cerebral, parietal, visceral, and pedal ganglia of Melampus but not in the buccal or pleural ganglia. The SP-IR cells occur in clusters containing 5-30 neurons and are of small to medium size (7-35 μm diam.), the largest being in the right parietal and visceral ganglia. One cluster of smaller SP-IR cells is located within the lateral lobe of each cerebral ganglion. Processes from these cells terminate at an epithelial element within the lobe, the cerebral gland, the lumen of which is also immunoreactive.

Antisera to both somatostatin (SOM) and somatostatin-28 Tyr 4-14 (SOM-28) were employed. As found in the snail Helisoma (Bulloch, see above), only the antiserum to SOM-28 stained neuronal somata; staining by the antiserum to SOM appeared diffuse and non-specific. SOM-28 immunoreactive cells primarily occur in the cerebral ganglia in clusters along the mediodorsal surface. This location corresponds to a group staining light green by Alcian blue/Alcian yellow histochemistry (Ridgway, Comp. Biochem. Physiol., 1987 (in press)). A smaller cluster, including 1-3 cells, occurs in the lateral lobe and, like the SP-IR cells of this region, are associated with the cerebral gland. Substance P-like and somatostatin-28-like immunoreactive neurites are present in virtually all nerves and connectives of Melampus but are especially prevalent in the labial and tentacle nerves. Many of these neurites may be afferent, originating from somata located in peripheral tissues. This study was supported by a Sigma Xi and WSU grants to RLR and by NIH grant R01 NS 22896 to SBM.

298.6 GONADOTROPIC HORMONE-LIKE IMMUNOREACTIVITY IN THE CNS AND THE REPRODUCTIVE TRACTS OF SNAILS AND RATS. J. van Minnen*, R.H.M. Ebberink* and E. Vreugdenhil* (SPON: P.G. Sokolove). Department of Biology, Vrije Universiteit, 1007 MC Amsterdam, The Netherlands

The Caudo-Dorsal Cells (CDC) of the hermaphrodite snail *Lymnaea stagnalis* play a central role in the control of egg laying and associated stereotyped egg-laying behaviour. The CDC produce at least 9 neuropeptides. For 3 of them a function has been demonstrated. One of them is the ovulation hormone (CDCH); calfluxin (CaF1) controls calcium fluxes in the albumen gland and the autotransmitter has an excitatory effect on the CDC. These 3 peptides are all derived from a polyprotein peptide precursor molecule encoded on the CDCH-gene.

With a monoclonal antibody to a synthetic fragment of CDCH (m-aCDCH) and with a c-DNA probe encoding CDCH, the CDC, ectopic CDC, and another type of (small) neurons were labelled in the central nervous system (CNS). Outside the CNS neurons and exocrine epithelial cells reacted with m-aCDCH and the c-DNA probe. Most of the neurons were found in the female part of the reproductive tract. The neurons form numerous immunoreactive fibertracts with varicosities on secretory cells and muscle fibers. Furthermore a few immunoreactive neurons were found in the epithelium of the skin (these are probably sensory neurons). The exocrine cells that reacted with m-aCDCH and the c-DNA probe were only observed in the male part of the reproductive tract. Their secretory material is transferred during a copulation.

The results indicate that there exists a morphological basis for the control of egg-laying and associated behaviour by neurons expressing the CDC-gene(s). Whether the CDCH-like material of the male accessory sex glands has a function as a (pheromone-like?) messenger remains to be established.

In analogy to the situation in *Lymnaea*, we have investigated with immunocytochemistry the male reproductive tracts of rats on the occurrence of gonadotropic hormone-like immunoreactivity. Of the antibodies tried only an antibody to LHRH strongly reacted with most, but not all epithelial cells lining the epididymus, vas deferens, seminal vesicles and coagulation gland. Furthermore, the cells of Leydig showed a weak reaction to the antibody.

298.7 NEUROPEPTIDES IN THE NERVOUS SYSTEM OF THE MARINE SNAIL, BULLA GOULDIANA. J.C. Speh*, M.H. Roberts and R.Y. Moore (SPON: M.F. Bernstein), Depts. of Neurology and Neurobiology and Behavior, SUNY-Stony Brook, Stony Brook, NY 11794.

In this study we report the immunohistochemical identification of several neuropeptides in the central nervous system (CNS) of the marine snail, Bulla gouldiana. The Bulla CNS consists of a series of circumesophageal ganglia which were removed, immersion fixed in Bouin's solution, and imbedded in paraffin. Mounted sections were stained with cresyl violet or prepared for the immunohistochemical visualization of neuropeptides using the Sternberger peroxidase-anti-peroxidase (PAP) technique. Antisera to vasopressin (VP), vasoactive intestinal polypeptide (VIP), met-enkephalin (MENK), luteinizing hormone releasing hormone (LHRH), and cholecystokinin (CCK) were obtained from ImmunoNuclear Corp. Antisera to calcitonin gene related peptide (CGRP) was kindly provided by Dr. N. Brecha, FMRF by E. Weber and synapsin by C. Ouimet. Galanin (GAL) was obtained from Peninsula Labs. All antisera were diluted 1:1000.

The circumesophageal NS of Bulla is comprised of three bilaterally paired ganglia (cerebral:CG, pleural:PLG and pedal:PG) and one unpaired ganglion on the right side (pallial:PAG). VP-like immunoreactivity (VP-LI) is found in a few small cells in the CG and in some larger cells in the PG which also display LHRH-LI. LHRH fibers are found scattered throughout the CNS but are concentrated in the CG. The PAG contains cells that display LHRH-LI and CGRP-LI. In addition to that described above, CGRP-LI also occurs as fiber plexuses in the CG and PLG, and in cells of the PG that also display FMRF-LI. VIP-LI colocalizes with CGRP-LI in some cells of the PAG as well as being present in the neuropil of the CG and PAG. Synapsin containing cells, which also display FMRF-LI, are found in the CG. Some synapsin fibers are present in the neuropil of the CG and PAG. FMRF-LI is the most dense in the Bulla CNS, with cells and fibers found in all ganglia. Some cells in the PG approach 100um in diameter. MENK-LI consists of fibers in the CG and PG and cells in the PG that also contain CCK. CCK-LI is denser than most immunoreactivity, but less so than CGRP or FMRF, with reactive cells and fibers found in all ganglia. GAL-LI appears as a single cell in the CG that also displays CGRP-LI.

In this study we observed cells that contain two or more peptides. Many of these cells are large and identifiable, allowing the possible investigation of the physiology of differential release of colocalized neuroactive substances. In addition, similarities exist between the patterns of immunoreactivity in Bulla and that observed previously in the distantly related pond snail, Lymnaea stagnalis, suggesting that specific neuroanatomical and neurochemical patterns may have been conserved during gastropod evolution. Supported by NIH NS16304.

298.8 REGULATION OF ISOLATED BAG CELL NEURONS OF APLYSIA BY ALPHA-, BETA-, AND GAMMA-BAG CELL PEPTIDES. K.J. Loechner and L.K. Kaczmarek, Depts. of Pharmacology and Physiology, Yale University School of Medicine, New Haven, CT 06510.

Bag cell neurons of Aplysia are a homogeneous group of cells which control egg-laying behavior. Upon electrical stimulation or elevation of cAMP levels, these normally silent neurons generate a discharge during which several neuroactive bag cell peptides (BCPs) are released, including α-, β-, and γ-BCP. We have examined the effects of these peptides on cAMP levels in intact clusters of bag cells, as well as on the delayed voltage-dependent K^+-current (IK(v)) and on action potentials in isolated bag cell neurons.

β-BCP caused an elevation in cAMP levels in intact clusters of bag cell neurons (1uMβ-BCP: 58% increase, $p<.01$; 100uMβ-BCP: 95% increase, $p<.005$). The effect of β-BCP on IK(v) in isolated bag cell neurons was then studied using the whole cell patch-clamp technique. The intracellular solution contained EGTA to eliminate Ca^{++}-dependent K^+-currents. Current was measured during depolarizing steps from a holding potential of -40mv before and after application of peptide (≤10uM). β-BCP caused a decrease in IK(v) (mean decrease=33% ± 7%; n=10). The effect of β-BCP on action potentials in isolated bag cell neurons penetrated with microelectrodes was also examined. Action potentials were evoked with depolarizing pulses before and after application of peptide (≤10uM). β-BCP consistently increased spike amplitude. It is likely that these effects are mediated through the changes in cAMP levels, as similar effects on the delayed outward currents and spike amplitude have previously been described for cAMP analogs and for the adenylate cyclase activator, forskolin.

In contrast to β-BCP, γ-BCP applied to intact clusters resulted in a significant decrease in cAMP levels (1uMγ-BCP: 56% decrease, $p<.005$; 100uMγ-BCP: 49% decrease, $p<.01$). When applied to isolated neurons, γ-BCP (≤10uM) caused a small increase in IK(v) (mean increase= 14 ± 5%; n=6). γ-BCP, however, increased the amplitude of action potentials in the majority of isolated neurons impaled with microelectrodes, suggesting that additional conductances are influenced by this peptide.

Previous work has shown that α-BCP decreased basal and forskolin-stimulated cAMP levels. We have now shown that α-BCP (≤10uM) caused a small increase in IK(v) (mean increase= 16 ± 8%; n=3) in internally dialysed cells. In isolated neurons penetrated with a microelectrode, α-BCP either decreased or had no effect on action potential amplitude. Both of these inhibitory actions of α-BCP are consistent with a decrease in cAMP levels.

In conclusion, it is likely that the actions of these peptides on the neurons from which they are released play a role in setting the threshold and duration of discharges in the bag cell neurons.

298.9 **MYOMODULIN: A POSSIBLE COTRANSMITTER OF THE CHOLINERGIC NEURON L10 OF APLYSIA.** **A. Alevizos, K.R. Weiss, & I. Koester. Center for Neurobiology and Behavior and Departments of Psychiatry and Physiology, and NY State Psychiatric Institute, Columbia University, N.Y., N.Y. 10032**

The L10 neuron of Aplysia californica is a well studied cholinergic cell, having a variety of effects on several identified and non-identified cells of the abdominal ganglion. Kehoe (J. Physiol., 1972) has described some non-cholinergic effects of L10 on cells of the left upper quadrant neurons (cells L1 to L6), R15 and some unidentified cells of the abdominal ganglion. These effects cannot be blocked by acetylcholine blockers and cannot be mimicked by acetylcholine application. We investigated the possibility that some of these actions may be mediated by a peptide cotransmitter.

L10 neurons were labeled with ^{35}S methionine, and the chromatographic properties of radiolabeled peptides were compared to those of neuropeptides that are known to exist in the CNS of Aplysia. One peak of radioactivity coeluted with a recently sequenced Aplysia neuropeptide (Cropper et al, PNAS in press), myomodulin, through three steps of sequential reverse phase high pressure liquid chromatography in which 3 different counterions were used (TFA, HFBA and TEA acetate). This result provides strong evidence that L10 contains myomodulin, a candidate cotransmitter for the cholinergic neuron L10.

We studied the effects of the synthetic peptide on several of the L10 followers. Myomodulin, at concentrations as low as 10^{-7} M produces a long lasting inhibition of some of the RB cells. Similarly, the peptide produces hyperpolarization of some of the LUQ cells and an excitatory effect on unidentified cells of the right lower quadrant of the abdominal ganglion. In addition, bath application of myomodulin reduces the frequency of both spontaneous and evoked Interneuron II bursts by hyperpolarizing cells of the R25 cluster which mediate the bursts, and the R20 cells which modulate burst frequency (Koester, Neurosci. Absts, 1983).

Recently, it has been demonstrated that L10 innervates the renal pore of Aplysia (Koester et al, these abstracts). Thus L10 offers an advantageous model for studying the process of cotransmission both in the CNS and in the periphery.

298.10 CHEMICAL CHARACTERIZATION OF FACTORS RELEASED FROM APLYSIA BODY WALL BY TRAUMATIC STIMULATION. C.-Y. Lin*, J.K Krontiris-Litowitz, B.F. Cooper*, E.T. Walters, and D.J. McAdoo (SPON: W. Weems). Marine Biomed.Inst., U.Texas Med.Branch, Galveston, TX 30322, & Dept.Physiol. U.Texas Med.Sch. Houston, TX 77225.

Intense electrical or mechanical stimulation of isolated body wall of Aplysia releases factors that, if washed out of the stimulated body wall, cause persistent contraction when applied to body wall, cardioacceleration when applied to the heart, and suppression of defensive reflexes when applied to the CNS (Cooper et al., Soc. Neurosci. Abstr. 12:861, 1986; and Krontiris-Litowitz et al., this volume). It seems likely that some of the factors in stimulated body wall wash (SBW) are paracrine and endocrine signals involved in natural responses to traumatic stress. Contractile activity was measured with a strain gauge during perfusion of 0.1-0.5 ml samples through a cannula implanted between the skin and muscle layers of an isolated section of tail body wall. Fractionation of SBW by HPLC in a reverse phase column produced 3 major peaks of activity: one at the beginning of the chromatogram, one at the retention time of the gastropod neuropeptide SCP_B, and one 3 minutes after SCP_B. The first fraction contained a variety of amino acids, including glutamate (ca $5x10^{-6}$M), aspartate (ca 10^{-5}M), and taurine (ca $3x10^{-5}$M). Glutamate and taurine by themselves caused contractions with thresholds between 10^{-5} and 10^{-6}M, indicating that part of the activity in the first fraction is due to amino acids. The neurotransmitters ACh and 5-HT cause relaxation rather than contraction, and thus probably do not contribute to the activity. Dopamine causes strong contractions at concentrations of 10^{-6}-10^{-7}M, but HPLC analysis utilizing electrochemical detection demonstrated that less than $2x10^{-11}$M dopamine is present in SBW, ruling out dopamine as a mediator of SBW-induced contraction. The molluscan neuropeptide FMRFamide causes biphasic responses (brief contraction followed by prolonged relaxation), and thus may contribute to the early phase of SBW-induced contraction, but we have not yet tested for the presence of FMRFamide in SBW. SCP_B causes strong contractions with a threshold of about 10^{-8}M. Because SCP_B has the same retention time as one of the peaks of activity in SBW this peptide is likely to be one of the "trauma factors" released from body wall during noxious stimulation. Contractile activity of SBW has multiple sources, including amino acids, probably SCP_B, and other factors that we have yet to identify. We still need to determine which factors are responsible for an unusual property of SBW (one suggesting a role in wound closure) - its ability to produce maintained, non-desensitizing contractions during prolonged application.

298.11 EFFECTS OF 5,7-DIHYDROXYTRYPTAMINE ON SEROTONIN AND DOPAMINE CONTENTS OF APLYSIA NERVOUS SYSTEM. B. Jahan-Parwar, R.F. Seegal and D.O. Carpenter. Wadsworth Laboratories, NYS Department of Health and School of Public Health, University at Albany, Albany, NY 12201.

The neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) selectively labels serotonin-containing neurons in Aplysia without discernable long-term alteration of the neuronal physiology and total organismic behavior (Jahan-Parwar et al., Soc. Neurosci. Abst., 16:855,1986). This technique has opened avenues for the study of cellular and synaptic organization of the serotonin (5-HT) system and role of 5-HT transmission in mediation and modulation of behavior. As the first step in this study, we have analyzed the time course of 5,7-DHT effects on 5-HT and dopamine (DA) content using high performance liquid chromatography and electrochemical detection. Animals (n=15) were injected with 5,7-DHT creatinine sulfate (10mg/kg) in a 1 ml/kg vehicle solution containing 0.5 mg/ml L-ascorbic acid (as antioxidant) into the hemocoel, and the individual ganglia analyzed for 5-HT, DA and metabolites at days 1, 7 and 21, following injection. Controls (n=6) received vehicle only. The control ganglia contained 5-HT (ng/mg wet weight, mean $\pm$ SE): pedal ganglion, 5-HT = 2.17$\pm$.18, DA = 13.9$\pm$2.4; abdominal ganglion, 5-HT = 1.02$\pm$.09, DA = 7.5$\pm$.9; cerebral ganglion, 5-HT = .47$\pm$.03, DA = 3.57$\pm$.17; buccal ganglion, 5-HT = .41$\pm$.04, DA = 1.78$\pm$.2; pleural ganglion, 5-HT = .02$\pm$.02, DA = .29$\pm$.09. The 5-HT-content of individual ganglia was positively correlated with the number of 5-HT-containing neurons as revealed by the 5,7-DHT labeling and immunohistochemical methods. DA also had a similar distribution in the central ganglia. The 5-HT content of ganglia of 5,7-DHT treated animals was reduced to 90% in day 1, 50% in day 7, and recovered to 110% of the control levels in day 21 following treatment. There was no significant change in the DA content. The recovery of 5-HT content in Aplysia ganglia following treatment with 5,7-DHT contrasts to results obtained in mammalian serotonergic systems. However, the absence of active monoamine oxidase (MAO) in Aplysia (McCaman and Dewhurst, 1972), evidenced in our studies by an absence of MAO catalyzed biogenic amine metabolites (e.g. homovanillic acid or 5-hydroxyindoleacetic acid) in normal or 5,7-DHT treated ganglia, may provide a clue to the species differences in 5,7-DHT neurotoxicity. In mammalian preparations, both 5,6- and 5,7-DHT are readily oxidized by MAO to form reactive intermediates including 5,6 and 5,7-HTAA (Klemm and Baumgarten, 1978), 5,7 dihydroxyindoleacetaldehydes and free radicals. Furthermore, MAO inhibitors prevent the neurotoxic actions of 5,7-DHT. Thus the lack of 5,7-DHT induced 5-HT neurotoxicity in Aplysia may be due to the absence of MAO and hence the formation of reactive intermediate products. (Supported by NSF Grant BNS8313061 to B. J-P)

298.12 CORRELATION OF A SPECIFIC SEROTONIN-INDUCED MEMBRANE CURRENT WITH ^{125}I-LSD BINDING SITES ON IDENTIFIED APLYSIA NEURONS. M.L. Evans, M.J. Kadan, P.R. Hartig, and D.O. Carpenter. Wadsworth Laboratories, NYS Department of Health, School of Public Health, University at Albany, Albany, NY 12201 and School of Hygiene and Public Health, Johns Hopkins University, Baltimore, MD 21205.

The serotonergic ligand ^{125}I-LSD binds to sites in the Aplysia CNS which display regional distribution, pharmacological binding properties, and evidence of coupling to a G-protein consistent with labeling a class of functional serotonin (5-HT) receptors (Kadan and Hartig, Soc. Neurosci. Abstr. 11:994; Neurosci. in press, 1987). These receptors are located primarily within the neuropil, but also on a small subset of neuronal soma. We have identified a pair of upper quadrant neurons on the dorsal surface of the abdominal ganglion which are selectively and specifically labeled by ^{125}I-LSD. These neurons, based on their position, symmetry, and cytological properties, appear to be the functionally symmetrical neurons L1 and R1. In order to study the physiological role of the ^{125}I-LSD-labeled site on these neurons, we compared the electrophysiological and pharmacological properties of their 5-HT-evoked membrane ionic currents with those of neighboring neurons not labeled by ^{125}I-LSD.

Cells L1, L2, L3, L4, L6, and R1 were identified in desheathed ganglia by position, resting membrane potential, action potential firing pattern, synaptic input activity, and the effect of 50 μM acetylcholine (ACh). Voltage clamp currents in response to 50 μM 5-HT provided further criteria for identification. L3 and L6 respond to 5-HT with a slow outward current mediated by an increase in K^+ conductance. L2 and L4 respond to 5-HT with an early, rapidly desensitizating Na^+ conductance increase analogous to the A response described by Gerschenfeld and Paupardin-Tritsch (J. Physiol. 243:427, 1974) followed by a slow, non-desensitizing Ca^{2+} conductance of the type described by Pellmar (Fed. Proc. 40:2631, 1981). L1 and R1 have both components of the L2/L4 5-HT response but interposed between the two is a current due to an increase in Cl^- conductance. The serotonergic antagonists, cyproheptadine and mianserin, which inhibit ^{125}I-LSD binding in vitro, also inhibit the 5-HT evoked Na^+ and Cl^- currents, but have no effect on the K^+ and Ca^{2+} currents. The Na^+ current appears to result from a direct ionotropic effect of 5-HT on membrane conductance. The 5-HT Cl^- current of L1 and R1 has kinetics markedly slower than the rapid Cl^- current induced by ACh in these cells which may further implicate a second messenger involvement consistent with the in vivo evidence of G-protein coupling. We conclude that ^{125}I-LSD specifically labels a population of 5-HT receptors that gate a Cl^- conductance. (Supported by NIH Grant 18435)

298.13 DISTRIBUTION OF THREE MODULATORY TRANSMITTERS WITHIN THE PLEURAL GANGLION OF APLYSIA. L.-T. Lo, J.H. Byrne and L.J. Cleary. Department of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

Activation of neural circuits that modulate the tail withdrawal reflex can alter membrane conductances in sensory neurons in the pleural ganglion. Transmitters, including serotonin (5-HT), FMRFamide and small cardioactive peptide b (SCPb), produce changes similar to those produced by the modulatory circuits. For example, 5-HT and SCPb decrease outward currents, whereas FMRFamide increases them. We used immunoflourescence techniques to examine the distribution of these transmitters within the cluster of pleural sensory neurons.

The somata of most sensory neurons are enveloped by fibers with prominent varicosities that contain 5-HT-like immunoreactivity (IR). Immunopositive fibers are more abundant near somata that lie close to the neuropil, but a particularly dense plexus of 5-HT-like IR surrounds a few isolated somata. These fibers are extrinsic to the pleural ganglion, for we found no serotonergic cell bodies there.

FMRFamide-like IR is distributed within the cluster of sensory neurons in a pattern similar to that of 5-HT, although there are fewer processes. FMRFamide-like IR is also located close to the neuropil and densely envelops a few selected sensory neurons. On the other hand, some FMRFamide-like IR is intrinsic to the ganglion, for many somata within the ganglion are immunopositive. Among these are several smaller cells adjacent to the cluster of sensory neurons. We have found interneurons in this region that hyperpolarize sensory neurons.

SCPb has pharmacological effects on sensory neurons similar to those of 5-HT, but has a different distribution within the pleural ganglion. No SCPb-like IR is found around any cell bodies, although it does penetrate diffusely through the neuropil. Only one or two somata within the pleural ganglion contain SCPb-like IR.

The proximity of varicosities containing 5-HT- and FMRFamide-like IR to somata of sensory neurons suggests that these transmitters have multiple functions. In addition to short-term effects on membrane conductances, they may also have long-term effects on metabolic processes that are confined to the somata. For example, 5-HT is capable of inducing persistent cellular changes requiring protein synthesis (Montarolo et al, 1986). The lack of axosomatic contacts by fibers containing SCPb does not rule out a role for this transmitter, however, since the fibers may contact sensory neurons within the neuropil.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION II

299.1 **Cholecystokinin Attenuates Dopamine-Mediated Glucose Utilization Changes in Selected Brain Areas After Nucleus Accumbens Injection**

S.K. Kuo*, C.A. Tamminga, K. Tanimoto, J.N. Crawley, T.N. Chase
ETB, NINCDS, NIH, Bethesda, MD 20892; MPRC, Department of Psychiatry, University of Maryland, Baltimore, MD 21228

Several lines of evidence now indicate that cholecystokinin octapeptide (CCK-8) coexists with dopamine (DA) in some DA-containing mesencephalic neurons projecting to the nucleus accumbens (NA), amygdala, olfactory tubercles, and frontal cortex. Moreover, biochemical and electrophysiologic studies suggest interactions between CCK-8 and DA in these terminal areas. While the behavioral actions of DA system activation are well described, consequences of CCK-8 system perturbation are less firmly established. But, it has been shown that CCK-8, microinfused into the NA where CCK/DA neurons terminate, potentiates DA-induced hyperlocomotion and apomorphine-induced steretypy (Crawley, J Neurosci 5: 1972, 1985). The experiments reported here explore the neural pathway mediating the DA effect on locomotor behavior and the nature of the CCK-8 potentiation of this effect. To study this, we injected dopamine (20 g in 0.2 l), CCK-8 (10 ng in 0.2 l), dopamine + CCK-8 (above doses), or saline (0.2 l) bilaterally into the caudal medial NA in 20 male albino rats with chronically implanted guide canulae. Glucose utilization was measured in 54 different brain areas using quantitative 2-deoxyglucose (2DG) autoradiography, as previously described (Tamminga, Eur J Pharm, in Press). Results are expressed in moles glucose/100 gm brain tissue/min. Statistical analysis was done with analysis of variance and student's t test and Duncan test; results of principle component analysis will be reported.

Results show no effect of CCK-8 alone on local cerebral glucose utilization (LCGU) in the brain areas analyzed. Dopamine alone decreased LCGU in several areas related to motor function and sensory processing, including the superior olive, periaquaductal grey, medial geniculate, and auditory cortex; moreover, in all areas where suggestive changes occurred, the LCGU was reduced by DA alone. CCK-8 attenuated the effects of DA on LCGU changes in several brain areas, including the caudate nucleus, globus pallidus, subthalamic nucleus, lateral preoptic area, and the superficial and deep layers of superior colliculus. Multivariate analytic techniques may indicate key interactions between different motor areas responsible for behavioral potentiation.

299.2 LITHIUM AND PHORBOL ESTERS INCREASE RELEASE OF CHOLECYSTOKININ FROM BRAIN SLICES INCUBATED IN VITRO. L.R. Allard*, K. Gysling*, and M.C. Beinfeld* (SPON: N.A. Connors). Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Previous studies in our laboratory have focused on identifying factors which regulate cholecystokinin (CCK) release from slices of rat caudato-putamen (cp) incubated in vitro, with CCK release elicited by potassium stimulation. Several lines of evidence suggested that the release is under predominantly negative control by an unknown substance (which we call "X") which is released along with CCK by a calcium-dependent mechanism. Further studies (described in adjacent poster) provide evidence that excitatory amino acids are potent inhibitors of CCK release. Studies described here were performed to determine whether the products of inositol phospholipid turnover might mediate the inhibitory action of substance X.

Lithium is known to interrupt the phosphoinositol cycle by inhibiting myo-inositol-1-phosphatase. Phorbol esters mimic the action of diacylglycerol (a product of inositol phospholipid turnover) and activate protein kinase C directly. Phorbols also have a negative "feedback" action which uncouples or desensitizes agonist receptors and can block inositol phospholipid turnover in the presence of agonists (Leeb-Lundberg et al., Proc. Natl. Acad. Sci. USA 82:5651, 1985).

Incubation of slices of cp and frontal cortex with lithium (10 mM) for 40 minutes prior to potassium stimulation elevated CCK release by about a factor of 2 relative to controls. Incubation of slices of cp, frontal cortex, and hippocampus with the active phorbols phorbol 12-13-dibutyrate and phorbol 12-myristate-13 acetate at 10^{-7} or 10^{-6}M for 15 minutes induced a 2 to 3 fold elevation of CCK release in the presence of either 40 or 60 mM potassium. The inactive 4 α-phorbol did not alter CCK release. The stimulatory effect of these compounds required preincubation.

The enhancement of CCK release by an agent which inhibits inositol phospholipid turnover (lithium) and by an agent which mimics the action of diacylglycerol (phorbols) can be best explained by proposing that the effect of phorbols on CCK release is related to their ability to inhibit inositol phospholipid turnover. These results suggest that the release of CCK in some brain regions is under inhibitory control by a substance or substances which use inositol phospholipid turnover as its mediator. The identity of these putative endogenous inhibitory substance(s) and their relationship to phosphoinositol turnover is still under investigation.

This work supported in part by NIH grant NS18667 and RR05388 (to St. Louis University).

299.3 CHOLECYSTOKININ RELEASE FROM SLICES OF RAT CAUDATO-PUTAMEN INDUCED BY POTASSIUM IS INHIBITED BY EXCITATORY AMINO ACIDS. J.M. Stone*, L.R. Allard*, and M.C. Beinfeld* (SPON: M.H. Cooper). Department of Pharmacology, St. Louis Univ. Med. Sch., St. Louis, MO 63104.

Previously this laboratory has shown that the release of cholecystokinin (CCK) from rat caudato-putamen (cp) slices is under strong inhibitory control by a substance (or substances) which we call "X" released from cp and cerebral cortical slices by potassium in a Ca^{++}-dependent manner. Further studies on the chemical nature of "X" have indicated that it is likely to be a small, polar substance not degradable by trypsin.

Cp is known to contain high levels of both excitatory and inhibitory amino acids. The possibility that "X" is an amino acid was investigated. The inhibitory amino acids, glycine (10^{-4} and 10^{-5}M) and GABA (10^{-4} and 10^{-5}M), did not alter CCK release, nor did the GABA agonist, muscimol (10^{-6}M) or the GABA antagonist, picrotoxin (10^{-4}M). However, at concentrations of 10^{-4}M the excitatory amino acids, glutamate and aspartate, and the excitatory dipeptide, N-acetyl-aspartyl-glutamate (NAAG), produced highly significant ($p < .001$) inhibition of CCK release. Percent inhibition of release of CCK as compared to controls ranged from 30% for aspartate, 41% for glutamate and 47% for NAAG. At a concentration of 10^{-5}M aspartate no longer produced a statistically significant inhibition while glutamate and NAAG still produced inhibitions ($p < .02$) of 22% and 16% respectively. The following excitatory amino acid analogs which have been used to define amino acid receptor subtypes had no effect on CCK release at 10^{-4}M: N-methyl-D-aspartic acid (NMDA), quisqualic acid, kainic acid, or ibotenic acid. Glutamate at 10^{-4}M did not inhibit CCK release from cortex or hippocampus.

Recently we have found that D-L-2-amino-4-phosphobutyric acid (APB) at $2x10^{-3}$M reverses the inhibition seen with glutamate at 10^{-4}M, while APB alone had no effect on CCK release. The inhibition of CCK release by these excitatory amino acid analogs does not appear to be mediated by NMDA, quisquate, or kainate-preferring receptors but may be mediated by an APB-sensitive presynaptic side.

The possibility that "X" may be an excitatory amino acid is still under investigation. The observation that glutamate increases phosphoinositol turnover in culture striatal neurons (Slaceczek, et al., Nature 317:717, 1985) and our observation (see adjacent poster) that lithium treatment increases CCK release is consistent with "X" being glutamate. These results suggest a possible mechanism whereby one cortico-striatal excitatory neurotransmitter (glutamate or aspartate) can regulate the activity of another excitatory neurotransmitter (CCK) by modulating its release.

This work supported in part by NIH grants NS18667 (to M.C.B.) and RR05388 (to St. Louis Univ.).

299.4 NUCLEUS BASALIS MAGNOCELLULARIS (nBM) LESIONS INDUCE ABNORMAL CORTICAL LEVELS OF SOMATOSTATIN, NEUROPEPTIDE Y (NPY), CORTICOTROPIN-RELEASING HORMONE (CRH), AND GLUTAMINE.
G.W. Arendash, E.M. Meyer, A.J. Dunn, R. Dawson, and W.J. Millard. Dept. of Biology, Univ. of South Florida, Tampa, FL 33620 and Depts. of Pharmacology, Neuroscience, and Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610.

Senile Dementia of the Alzheimer's type (SDAT) is characterized by marked cholinergic hypofunction in the cerebral cortex, apparently due to loss or dysfunction of cholinergic neurons arising from the nucleus basalis of Meynert (NBM). However, other cortical transmitter systems have also been shown to be affected in SDAT. In this regard, reductions in cortical levels of somatostatin, NPY, and CRH have recently been documented, suggesting involvement of these neuropeptides in the disease process. We have previously found that bilateral lesions of the rat nucleus basalis magnocellular (nBM), which mimic the spontaneous destruction of the NBM-to-cortex cholinergic pathway in SDAT, induce a profound elevation in cortical levels of somatostatin at 10 months after lesioning. The present study investigated the effects of both unilateral and bilateral excitotoxic lesions of the nBM on cortical levels of somatostatin, NPY, CRH, and neuroactive amino acids at several time points.

Adult male Sprague-Dawley rats were given unilateral or bilateral infusions of ibotenic acid (5 ug/1 ul) into the nBM and sacrificed 2, 10, 14, or 20 months later. At both 10 and 14 months following lesions, significant reductions in all presynaptic cholinergic markers were seen in the frontal cortex compared to sham-lesioned controls. In these same lesioned animals, parietal cortex levels of somatostatin, NPY, and CRH were markedly elevated (by 2-3 fold) compared to controls. At 2 months after unilateral nBM lesioning, however, a significant cortical cholinergic hypofunction on the lesion side was associated with reduced cortical levels of somatostatin and NPY, but no effect on cortical CRH, compared to the unlesioned side. Furthermore, the amino acid glutamine (but not aspertate or glutamate) was reduced in frontal cortex and entorhinal cortex at 20 months after bilateral nBM lesioning; a marked cortical cholinergic hypofunction was present at this time point as well.

These results suggest that, in SDAT, a dysfunction of the cortical neuropeptide transmitters somatostatin, NPY, and CRH may be related to a loss or dysfunction of cholinergic innervation to the cortex from the NBM region. The opposite effects of unilateral and bilateral nBM lesions on cortical neuropeptide levels may be related to a lesion-induced loss or dysfunction of corticocortical connections. Several lines of evidence suggest that a breakdown of such corticocortical connections occurs in SDAT.

299.5 **EFFECT OF CYSTEAMINE ADMINISTRATION ON THE IN VIVO BIOSYNTHESIS OF SOMATOSTATIN, OXYTOCIN AND VASOPRESSIN IN RAT HYPOTHALAMUS.** R.P.S. Kwok*, J.L. Cameron, and J.D. Fernstrom. Departments of Psychiatry and Behavioral Neuroscience and the Center for Neuroscience, University of Pittsburgh, Pittsburgh PA 15213.

Cysteamine (CSH) injection causes a rapid (1-4 hr), longlasting (>72 hr) depletion of immunoreactive (IR) somatostatin (SRIF) levels in the rat hypothalamus. IR-Vasopressin (AVP) and IR-oxytocin (OXT) levels are unaffected. We have previously shown that (^{35}S)cysteine incorporation into somatostatin-14 (SRIF-14) and somatostatin-28 (SRIF-28) also falls within 1-4 hr of CSH injection, but is normal 1 wk later (Cameron & Fernstrom, Endocrinology 119:1292,1986). Such results suggest that CSH injection inhibits SRIF biosynthesis, but do not give a complete picture of the role of synthesis inhibition in the prolonged depression of hypothalamic IR-SRIF levels. To gain further insight into the mechanisms by which CSH depletes hypothalamic SRIF, we have performed a more thorough temporal analysis of CSH's effects on the in vivo synthesis and IR levels of SRIF (and AVP and OXT) in the rat hypothalamus.

Male rats received CSH (300 mg/kg, sc) 1,4,6,8,10,12, & 24 hr before the injection of 50 microCi (^{35}S)cysteine into the third ventricle under urethane anesthesia. Four hr later, hypothalami were removed, pooled into groups of 3-4, and immediately homogenized and prepared for HPLC to separate labeled SRIF-14, SRIF-28, OXT and AVP. Other rats received CSH, but not label, and were killed at intervals ranging from ½ to 72 hr later for measurements of IR-SRIF, IR-AVP and IR-OXT in hypothalamus and posterior pituitary.

As previously observed, hypothalamic IR-SRIF levels fell within 2-4 hr to values 50-60% below normal, and remained low for 72 hr (the duration of the IR studies). In contrast, hypothalamic and posterior pituitary IR-AVP and IR-OXT levels remained normal throughout. Label incorporation into HPLC-isolated SRIF-14, SRIF-28 and OXT in hypothalamus was negligible 1 hr after CSH injection, remained low at 4 hr, but was essentially normal 8-10 hr post-CSH administration. In the same animals, label incorporation into AVP was stimulated by CSH injection (a 7-fold increase was noted at 4 hr), but returned to control levels by 8 hr.

The data suggest that SRIF synthesis returns to normal much more rapidly than total endogenous stores. Perhaps the rapid restoration of SRIF synthesis contributes to the longer-term replenishment of peptide stores, though other mechanisms may also (or instead) be responsible. The chemical mechanism(s) by which CSH alters the synthesis rates of these peptides continues to be elusive. However, because AVP labeling is stimulated by CSH injection, it seems unlikely that the drug produces it effects simply by a sulfhydryl-mediated chemical reaction that eliminates all cysteine-containing peptides from hypothalamus.

Supported by the NINCDS (NS20017).

299.6 CHARACTERIZATION OF HYPOTHALAMIC PEPTIDES IN OVERFED AND AD LIBITUM FED RATS BY HIGH PERFORMANCE LIQUID CHROMATOGRAPHY. M. G. Hulsey* and R. J. Martin. Department of Foods and Nutrition, University of Georgia, Athens, Georgia 30602

Sulfated cholecystokinin octapeptide, cholecystokinin tetrapeptide, growth hormone releasing hormone, insulin-like growth factor, somatostatin-14, thyrotropin releasing hormone, and ß-endorphin are thought to be involved in the regulation of food intake. In this study, we attempted to determine if overfeeding would produce changes in the endogenous hypothalamic levels of these (or other) peptides that would be detectable by HPLC.

Nine pairs of Sprague-Dawley rats were housed under a 12 h photoperiod. Initial body weights were 267 ± 2 g and 266 ± 3 g for the control and overfed rats, respectively. A powdered diet was prepared containing (by weight) 60% dextrose, 20% casein, 10% corn oil, 3% cellulose, and 7% AIN vitamin and mineral mix. For the overfed animals, a liquid diet was prepared by mixing four parts of the powdered diet with three parts tap water. Control rats were provided powdered diet ad libitum, and consumed an average of 15 g $daily^{-1}$ Overfed rats were tube-fed meals at 0530, 1330 and 2130 hours daily. The overfed rats were given meals increasing from 5 g to 12.9 g (powder equivalent) over a period of 8 days, and 12.9 g thereafter. After an additional 24 days, body weights were 290 ± 5 g and 501 ± 8 g for the control and overfed rats, respectively.

Animals were sacrificed by decapitation. Hypothalamic sections were immediately dissected on ice, weighed, and frozen on dry ice. Pooled tissues from overfed and ad libitum fed rats were homogenized and extracted with a reverse phase cartridge according to Bennett et al. (Biochem. J. 175:1139-1141). Extracts were chromatographed on a 4.6 mm by 125 mm 5 micron C_{18} column (Whatman Partisphere) using He_2 sparged H_3PO_4 at pH 2.1 with a linear gradient of 0 to 70% (v/v) Acetonitrile over 180 minutes. Detection was by absorbance at 212 nanometers. We obtained several unidentified peaks that had substantially different areas in overfed and control extracts. These peaks of interest do not co-elute with any of the above mentioned peptides. Work in progress will attempt to identify the unknown peaks in extracts from overfed and ad libitum fed rats.

299.7 PARTIAL PURIFICATION OF PEPTIDES WHICH CAUSE CONTRACTION OF APLYSIA MUSCLES. S.L. Knock and D.J. McAdoo. Marine Biomedical Institute and Department of Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, Texas 77550.

The left efferent vein of the marine gastropod, Aplysia, provides an ideal site from which neurons might release messengers into the circulatory system for actions on distant targets. It has been shown that neurons in the abdominal ganglion synthesize and transport peptides from the ganglion down the branchial nerve and store these peptides in terminals within the efferent vein. Substances have been partially purified from the efferent vein and have been tested for their ability to cause contractions of the gastroesophageal artery. These substances are susceptible to proteases, which indicates that they are peptides. Peptides were extracted in acetic acid/acetone and precipitated using excess cold acetone. Precipitates were dissolved in acetic acid/HCl buffer and chromatographed on a Sephadex G50 column. The active peptides eluted with retention volumes that correspond to molecular weights between 2000 and 5500 kilodaltons. The peptides were then separated using reversed phase high performance liquid chromatography. Separations were carried out on both C4 and C8 columns and peptides were eluted using a gradient of 0.1% trifluoroacetic acid (TFA) with acetonitrile as an organic modifier. Two distinct active peptide fractions can be separated by these means, eluting at 19% and 21.5% acetonitrile on the C4 column and 23.5% and 26% on the C8 column. Both peptide fractions cause a series of rhythmic contractions on top of a tonic contraction of the gastroesophageal artery and cause contractions of body wall muscle. These peptide fractions have been shown to elute at distinctly different retentions times from known molluscan cardioactive peptides, Small Cardioactive Peptide b (SCPb) and FMRFamide. SCPa co-elutes with the first active peptide fraction, but does not cause contractions of the gastroesophageal artery.

299.8 COMPARISON OF [^{125}I]AIII AND [^{125}I]AII BINDING TO RAT BRAIN MEMBRANES. R.H. Abhold, J.M. Hanesworth* and J.W. Harding. Dept. Vet. Comp. Anat. Pharmacol. Physiol., Washington State University, Pullman, WA 99164-6520.

Intracerebroventricularly (ICV) applied angiotensin III (AIII) has often been shown to be much less potent than angiotensin II (AII) in stimulating CNS-mediated pressor and dipsogenic responses. In contrast, AII and AIII appear to be equipotent in their ability to competitively displace [^{125}I]AII from CNS binding sites. Conclusions based on competitive displacement studies may be misleading, however, since they do not address the possibility of separate AII and AIII binding sites or activities.

In this study, the binding of [^{125}I]AIII to rat brain membranes was examined and compared to that of [^{125}I]AII. Degradation of each ligand, as monitored by HPLC, was effectively inhibited using fragments of AII and AIII known to have little affinity for angiotensin binding sites. Three classes of [^{125}I]AIII binding sites were observed based on affinity (K_d = 0.13, 1.83, and 10.16 nM) and capacity (B_{max} = 1.30, 18.41, and 67.2 fmol/mg protein, respectively). Two classes of [^{125}I]AII-binding sites of high affinity (K_d = 0.11 and 1.76 nM) and low capacity (B_{max} = 1.03 and 18.86 fmol/mg protein, respectively) were also identified. Cross-displacement studies confirmed that the two highest affinity [^{125}I]AIII-binding sites and the [^{125}I]AII-binding sites were the same. On the other hand, the binding of [^{125}I]AIII to the low affinity [^{125}I]AIII-binding site could not be inhibited with AII. These data imply that previously measured differences in the biological potency of ICV-applied AII and AIII probably do not result from differential binding of these peptides to central angiotensin receptors. It is possible, however, that such differences may result from differential metabolism by tissue angiotensinases.

299.9 SIMILARITIES IN SOLUBILIZED BRAIN AND ADRENAL ANGIOTENSIN RECEPTORS. I. Rogulja and J.W. Harding. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

Previous studies from our laboratory comparing the binding properties of ^{125}I-angiotensin II (AII) and ^{125}I Sar^1,Ile^8-AII (SI-AII) in the rat brain and bovine adrenal cortex consistently indicate a 3-5 times higher number of binding sites for SI-AII as compared with AII. To more rigorously examine the binding properties of these ligands, we chose to use solubilized membrane preparations. ^{125}I-AII, ^{125}I- angiotensin III (AIII) and ^{125}I-SI-AII were bound to angiotensin binding sites from bovine adrenals and/or rat brain solubilized with CHAPS, and chromatographed on a TSK 3000 SW size exclusion column. Multiple binding peaks were detected for each radioligand with similar profiles in brain and adrenals. The elution pattern of bound ^{125}I-SI-AII in both bovine adrenal and rat brain was dramatically different from the patterns seen with ^{125}I-AII and ^{125}I-AIII. Specific ^{125}I-SI-AII binding was detected as 3-5 peaks while ^{125}I-AII and ^{125}I-AIII were found as 2-3 peaks. At least one peak in the adrenals appeared to be common to all these ligands, with selective peaks observable for SI-AII and AIII. Many of the individual peaks could be defined as "specific" based on the ability of cold ligand to displace binding. These results demonstrate that ^{125}I-SI-AII specifically binds to multiple proteins (or different conformations of the same protein) while AII and AIII exhibit binding to a more limited number of sites. The data encourage speculation that the additional binding sites for SI-AII may represent specific aminopeptidases which cannot be visualized with the more labile forms of angiotensin.

299.10 CHARACTERIZATION OF FMRF-NH_2 LIKE MATERIAL IN RAT SPINAL CORD USING ANTIBODIES TO THREE RELATED PEPTIDES IN RADIOIMMUNOASSAY AND HPLC. E.A. Majane and H.-Y.T. Yang. Laboratory of Preclinical Pharmacology, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Two neuropeptides, AGEGLSSPFTSLAAPQRF-NH_2 (A-18-F-NH_2) and FLFQPQRF-NH_2 (F-8-F-NH_2) which were originally detected by FMRF-NH_2 antisera have been isolated from bovine brain, characterized and synthesized. These two peptides can decrease rat tail flick latencies; F-8-F-NH_2 can also attenuate morphine induced analgesia. Using highly sensitive radioimmunoassays (RIAs) developed for F-8-F-NH_2 and A-18-F-NH_2, it has been shown that the highest concentration of these peptides in bovine CNS is found in dorsal spinal cord. A high concentration of F-8-F-NH_2 and A-18-F-NH_2 immunoreactivity (IR) (0.43 and 0.24 pmol/mg protein, respectively) is also found in rat spinal cord. However, HPLC analysis reveals that the rat peptides elute with higher retention times suggesting that they are not identical to the bovine A-18-F-NH_2 and F-8-F-NH_2. Some immunohistochemical studies have shown that FMRF-NH_2-IR and NPY-IR are found in the same neurons in rat CNS suggesting that mammalian FMRF-NH_2-like (LI) and NPY-LI are chemically identical or they are co-localized. In order to clarify this point, we have fractionated rat spinal cord extracts by reverse phase HPLC and radioimmunoassayed each fraction with antisera against the following peptides: FMRF-NH_2, A-18-F-NH_2, F-8-F-NH_2 and NPY (#1 and #2 with differing specificities). Analysis of these fractions with F-8-F-NH_2 antisera detects one major immunoreactive peak (F-8-F-NH_2-LI) eluting with a higher retention time than F-8-F-NH_2 while RIA analysis with A-18-F-NH_2 antisera detects two major peaks. The first peak elutes in the postion of F-8-F-NH_2-LI. Our specificity study indicates that A-18-F-NH_2 antisera cross-reacts considerably with F-8-F-NH_2 thus the first peak is identical to the F-8-F-NH_2-LI. The second peak detected by A-18-F-NH_2 antisera is poorly detected by F-8-F-NH_2 antisera suggesting that this represents rat A-18-F-NH_2-LI. Analysis with FMRF-NH_2 antisera detects at least three immunoreactive peaks; two of these have a much higher affinity for F-8-F-NH_2 and A-18-F-NH_2 antisera. NPY antisera #1 (not C-teriminal directed) detects one main immunoreactive peak eluting in the position of human (rat) NPY, while the C-terminal directed NPY antisera (#2) reveals an additional major cross-reactivity which elutes in the position of A-18-F-NH_2-LI. In conclusion, in rat CNS there are F-8-F-NH_2-LI and A-18-F-NH_2-LI peptides which are distinct from NPY. It is possible that these peptides (FMRF-NH_2-LI) may be detected as NPY-IR immunohistochemically by some NPY antisera.

299.11 THE DISTRIBUTION OF FMRFamide-RELATED PEPTIDES IN THE GASTROPODS. D.A. Price, K.E. Doble*, T.D. Lee*# and M.J. Greenberg. Whitney Lab, Rt. 1, Box 121, St. Augustine, FL 32086. #Div. of Immunol., Beckman Res. Inst. of the City of Hope, 1450 E. Duarte Rd., Duarte, CA 91010.

We have used HPLC, radioimmunoassay and FAB-mass spectroscopy to determine the FMRFamide-like peptides in whole animal extracts of several gastropod species. For two represenative species, Helisoma and Helix, we have compared whole animal extracts to ganglionic extracts, and found no differneces in the peptides present. So we hypothesize that there are no exclusively non-neural members of the FMRFamide family present in molluscs. The number of species we have examined is still small, but a few tentative generalizations about the distribution of these peptides can be made. The tetrapeptide FMRFamide is the predominant representative of its family in most molluscs, but related peptides also occur in some species, especially among the gastropods. First, the tetrapeptide FLRFamide seems to be a ubiquitous minor component, but its ratio to FMRFamide is not constant from species to species. For example, a 1:28 ratio is predicted for the opisthobranch Aplysia based on its FMRFamide precursor, whereas the prosobranch Pomacea has a 1:6 ratio. The shelled opisthobranch, Bulla umbilicata, has a ratio like that of Aplysia, so a low level of FLRFamide may be a general opisthobranch characteristic. The pulmonates have FLRFamide levels more in line with the rest of the phylum, but they contain significant quantities of heptapeptides of the form XDPFLRFamide [where X is Gly (G), Ser (S), pGlu (pQ) or Asn (N)] which are not present in the non-pulmonate members of the phylum. Our earlier work on Helix, Lymnaea and Siphonaria had led us to hypothesize that each pulmonate species has two different heptapeptides, but we now have found that Helix has three different heptapeptides: the pQ, G and S analogs while Helisoma has only the G analog. We had also found that the pQ analog only occurs in stylommatophoran species and the G analog only in basommatophoran ones and had suggested that these were charactersitics of the two suborders. This generalization remains intact.

299.12 **INCREASED THYROTROPIN RELEASING HORMONE [TRH] CATABOLISM IN HUMAN SPINAL CORD OF AMYOTROPHIC LATERAL SCLEROSIS [ALS] PATIENTS IS NOT CAUSED BY INCREASED SPINAL CORD MANGANESE CONTENT**

B.R. Brooks, J.G. Turner, T.M. Schwartz, W.A. Tourtellotte Neurology Service, Wm S. Middleton Memorial VA Hospital and University of Wisconsin ALS Clinical Research Center, Madison, WI 53792, and Wadsworth VA Medical Center, Los Angeles, CA 90073

TRH content in the cervical spinal cord of some ALS patients is decreased [Am J Med Sci 287: 34, 1984; Neurology 36(suppl 1): 139, 1986; Neurology 36: 1218, 1986]. A possible TRH catabolite, histidyl-proline diketopiperazine [HP-DKP], may be increased in the spinal cord of ALS patients [Neurology 36: 1218, 1986]. We have studied by HPLC the catabolism of [^{3}H-pro]-TRH in homogenates of cerebral cortex [CTX], cerebellar cortex [CRB] and cervical, thoracic, and/or lumbar spinal cord [SC]. Autopsy samples were obtained 2-48 hours post mortem in 11 ALS patients and 13 control patients with multiple sclerosis, Huntington's disease, and stroke. TRH degradation is significantly slower in SC [11 $\pm$ 12 fmole/min/mg protein] than in CTX [84 $\pm$ 18] or CRB [85 $\pm$ 14] in 100 mM KPO4 buffer without dithiothreitol [DTT]. Addition of DTT [2 mM] increases only SC TRH catabolism significantly [41 $\pm$ 14 ; $p < 0.05$] with increases of HP-DKP [184 $\pm$ 79 to 876 $\pm$ 193] and HP [22 $\pm$ 34 to 134 $\pm$ 55]. DTT induced TRH catabolism is increased in ALS SC compared with control SC [56 $\pm$ 20; $p < 0.04$]. The proline formed in ALS SC is significantly increased [200 $\pm$ 53 to 321 $\pm$ 58; $p < 0.05$]. Leupeptin, a thiol protease inhibitor, does not inhibit TRH metabolism in control or ALS SC. Manganese is elevated 2X in ALS SC [J Neurol Sci 61: 283, 1983; J Neurol Neurosurg Psychiat 49: 211, 1986]. Addition of Mn to control SC homogenates at 2X and 10X did not lead to increased TRH catabolism. Therefore, [1] SC catabolism of TRH is specifically increased in ALS patients, [2] increased SC catabolism of TRH is not due to a thiol activated protease, [3] in vitro addition of manganese, which is increased in ALS SC and is an activator of some aminopeptidases, does not cause increased TRH catabolism in control SC homogenates.

299.13 ULTRASTRUCTURAL EVIDENCE SUGGESTS VARIATIONS IN BIOSYNTHESIS AND PROCESSING WITHIN LHRH NEURONS AS A FUNCTION OF OVARIECTOMY. J. C. King and G. R. Seiler*. Dept. of Anatomy and Cellular Biology, Tufts Univ. Sch. of Med., Boston MA 02111.

We have reported previously changes in populations of LHRH-immunopositive cell bodies and neurovascular terminals following gonadectomy of rats. The purpose of this study was to investigate the subcellular localization of LHRH within individual perikarya from these populations in ovariectomized female rats. This investigation was directed specifically toward the study of those organelles involved in protein synthesis and processing. The goal was to determine ultrastructural changes in these organelles that might reflect changes in levels of biosynthetic activity. Regions within 50 micrometer Vibratome sections of preoptic-hypothalamus containing LHRH-immunopositive neuronal perikarya [previously used to reconstruct three-dimensional populations, Soc. for Neurosci. 1985 Abs. # 47.1] were removed, mounted on resin cylinders, thin-sectioned and viewed with a JEOL 100 B or Philips CM-10. Electron microscopic studies were restricted to LHRH cells in a mid-line region surrounding the OVLT in the rostral preoptic area. Immunopositive cells identified in toluidine blue stained semi-thin sections were then completely thin-sectioned. One day following ovariectomy, which was performed on metestrus, numerous free polysomes filled the cytoplasm, whereas little rough endoplasmic reticulum [RER] was evident. Six days post-ovariectomy cisternae of RER were abundant and dilated; in close proximity to the RER, were Golgi apparati, which were both numerous and extensive within the cytoplasm. In addition, reaction product was heavily concentrated in the medial saccules or dilated regions of the Golgi complex. By three weeks post-ovariectomy the Golgi lamellae were extensively dilated and the associated vesicles were great in number. These ultrastructural features are consistent with increased synthesis and secretion of LHRH following ovariectomy with increased synthesis of message one day post-ovariectomy, increased processing and secretion six days post-ovariectomy, and reaching a new increased steady state level of biosynthesis and secretion, three weeks after ovariectomy. Few synapses were detected directly contacting LHRH perikarya in these conditions, while synaptic profiles in the surrounding neuropil varied with a suggestion of greater activity one day post-ovariectomy. The synaptic arrangements were often complex with two or more axons contacting a single dendritic profile. These data suggest that the removal of gonadal steroids results in greater biosynthetic activity in LHRH neurons, which may be related to increases in afferent activity in the preoptic area. This work was supported by NSF grant DCB-8702388.

300.1 MK-801 PREVENTS THALAMIC DAMAGE INDUCED BY FOCAL CORTICAL SEIZURES. D.B. Clifford, A. Benz*, J.W. Olney and C.F. Zorumski. Washington University School of Medicine, St. Louis, MO 63110.

Prolonged seizure activity induced by various methods results in brain damage which resembles the excitotoxic type of cytopathology glutamate (Glu) is known to cause. Recently we demonstrated that phencyclidine (PCP) and ketamine, which are non-competitive antagonists of the N-methyl-D-aspartate (NMDA) subtype of Glu receptor, protect against brain damage induced by kainic acid seizures. Here we have explored the ability of MK-801 to protect against thalamic damage induced by sustained seizure activity in the glutamergic corticothalamic tract. MK-801 is an orally active agent that resembles PCP and ketamine in receptor binding and NMDA antagonist properties and is the most powerful anti-excitotoxin known (Price et al, this meeting).

Focal cortical seizures were induced in Sprague Dawley rats by instilling a solution of bicuculline methiodide (2 mM) or pilocarpine (200mM) in an epidural well over the right sensorimotor cortex as previously described (Science 218:177, 1982). Seizure activity was recorded from surface cortical leads. Three hours after induction of seizures the rats were sacrificed by perfusion with aldehyde fixatives and their brains examined for histopathological changes. Experimental rats received MK-801 (1 mg/kg ip) 30 minutes prior to the convulsant; controls received only the convulsant. The convulsant solutions rapidly induced focal status epilepticus in both control and experimental rats which persisted for three hours. Glu-like excitotoxic lesions were consistently present in the thalamus of control rats and consistently absent in MK-801 treated rats. Electrographic seizure activity was recordable from both the cortex and thalamus throughout the 3 hour observation period in both control and experimental rats but it was moderately attenuated in the latter.

We conclude that MK-801 has substantial protective properties against seizure induced brain damage at doses which do not eliminate electrographic seizures. The protection is independent of the chemoconvulsant used to drive focal cortical seizures and presumably is mediated at NMDA receptors where MK-801 is a powerful antagonist. Our findings are consistent with the hypothesis that NMDA receptors are important in the generation of seizure induced brain damage.

300.2 ^{3}H-GLYCOGEN HYDROLYSIS IN THE CEREBRAL CORTEX OF TWO SPONTANEOUSLY EPILEPTIC MOUSE MUTANTS : NORADRENERGIC SUBSENSITIVITY IN THE *TOTTERING* MOUSE AND AGE-DEPENDENT SUPERSENSITIVE RESPONSE TO K^+ IN THE *QUAKING* MOUSE. P.J. Magistretti and P.R. Hof, Dept of Pharmacology, CMU, 1211 - GENEVA 4, Switzerland.

The *tottering* mutant (tg) mouse is characterized by spike-wave discharges accompanied by behavioral absence seizures that resemble petit mal. A cytological abnormality observed in homozygous mutants (tg/tg) is an increase in the number of noradrenergic axons in the terminal fields innervated by the locus coeruleus, including the hippocampus, cerebellum, dorsal lateral geniculate nucleus and neocortex. This increase in axon number is accompanied by enhanced NE levels, up to 200 %, in the corresponding CNS areas. In mouse cerebral cortical slices, NE promotes a ß-adrenergic-mediated hydrolysis of newly synthesized ^{3}H-glycogen in a concentration-dependent manner. In order to assess the sensitivity state of ß-adrenergic receptors chronically exposed to enhanced NE levels, we examined the glycogenolytic effect of NE in the cerebral cortex of tg/tg homozygous, tg/+ heterozygous and +/+ control mice. Our results indicate a shift to the right of the concentration-response curve in tg/tg mice when compared to tg/+, with EC_{50} of approximately 1.7 and 0.6 µM respectively. Comparison with +/+ mice shows an even greater degree of subsensitivity of NE in tg/tg (EC_{50} 1.7 µM in tg/tg vs 0.17 µM in +/+). The decrease in the potency of NE to elicit glycogenolysis is accompanied by a decreased efficacy as the maximal glycogenolytic effect is 52.5 ± 3.1 % of basal levels in tg/tg, 59.6 ± 2 % in tg/+ and 77.6 ± 0.5 % in +/+. These results indicate that a subsensitivity of adrenergic receptors of the ß type, mediating a metabolic action of NE, exists in tg/tg mutants when compared to both tg/+ and +/+ mice. We also examined the glycogenolytic effect of isoproterenol (ISO), a ß-adrenergic agonist which is not actively taken up by noradrenergic terminals. The glycogenolytic response to ISO at 0.1 and 1 µM is also considerably reduced in tg/tg mice when compared to both tg/+ and +/+. These results indicate that the decreased potency and efficacy of NE in promoting glycogenolysis in tg/tg mice is caused by a true subsensitivity of postsynaptic ß-adrenergic receptors. A developmental study has indicated that a considerable degree of sub-sensitivity is already present at post-natal days 1, 3, 7 and 14.

The *quaking* mutant (qk) is characterized by a severe myelin deficiency in the brain due to the impaired differentiation of oligodendrocytes. We have observed a supersensitive response to the glycogenolytic effect of low concentrations of K^+ in cerebral cortical slices prepared from homozygous qk/qk when compared to heterozygous littermates qk/+. Results were (^{3}H-glycogen hydrolysis in % of basal levels ± SEM) : K^+ 6 mM in qk/qk = 35.1 ± 2.2, in qk/+ = 14.1 ± 2.4; K^+ 8 mM in qk/qk = 51.5 ± 1.7, in qk/+ = 30.7 ± 3.2; K^+ 11 mM in qk/qk = 66.9 ± 1.9, in qk/+ = 48.1 ± 2.2. This supersensitive response to K^+ was only observed in mice older than 7 weeks, with differences between qk/qk and qk/+ littermates of 11 % at 8 weeks, 17 % at 15 weeks and 30 % at 30 weeks for 11 mM K^+. No significant differences were observed between qk/+ and control +/+ mice.

300.3 A CHEMICAL & HISTOCHEMICAL ARCHITECTURE OF THE HUMAN EPILEPTIC FOCUS. NS Nadi & AR Wyler*. NINCDS, Bethesda, MD 20892 and Univ Tenn Med Ctr, Memphis, TN 38103.

The chemical parameters in the spiking and non-spiking portions of the human brain have remained largely unknown. Recently we have been able to analyze spiking and non-spiking regions from the human temporal lobe as well as the hippocampus for catecholamines, amino acids, neuropeptides, enzymes and receptors. The brains used in these studies (n=25) were surgically removed under general anesthesia and frozen or fixed within one minute after resection. In each case the non-spiking region was compared to the spiking region from the same patient. The catecholamines were elevated in the spiking region when compared to the non-spiking region: norepinephrine +47.5%, dopamine +58.4% and DOPA +23.5%. Several putative neurotransmitter amino acids were also elevated in the spiking region: glutamate +96.7%, aspartate +209.1%, and glycine +75.6%. GABA, alanine, taurine, and leucine were unchanged in the spiking vs non-spiking regions. Of the neurotransmitter enzymes investigated the spiking cortex contained elevated tyrosine hydroxylase +60.2%, and choline acetyltransferase +57.1%. Glutamate decarboxylase was unchanged. The epileptic cortex had elevated somatostatin +313%, neuropeptide Y +128%, and atrial natriuretic factor +42.7%. The levels of βendorphin, met-enkephalin, cholecystokinin, substance P, and neurotensin were not different in the spiking vs non-spiking region of the cortex. Vasoactive intestinal polypeptide was decreased in the epileptic cortex by 25.7%. Of the receptors measured the spiking region had elevated NMDA receptors +145% but decreased muscarinic receptors -32.5%; βreceptors -51.4%, αreceptors -38.4%. GABA and benzodiazepine receptors were unchanged. The K_d measurements of the receptors showed no change. The hippocampus had glutamate, aspartate, glycine, somatostatin, and neuropeptide Y comparable to the spiking cortex. Since non-spiking hippocampus was not available no comparative studies could be conducted. The increase in somatostatin in the spiking region may have contributed to the excitability of the focus, since this molecule regulates the action of acetylcholine. Glycine by virtue of increasing the potency of glutamate at the NMDA sites may also have contributed to local excitability. The increase in catecholamines may be interpreted as a secondary phenomenon in response to the increased excitability of the region. The histochemical studies in human brain showed a diffuse distribution of tyrosine hydroxylase and a localization of somatostatin to layers II, III, and V. The distribution of neuropeptide Y was similar to that of somatostatin indicating possible colocalization of the peptides. Further histochemical and autoradiographic studies are underway to determine in which regions the increases occur and how these might explain the chemical pathophysiology of seizures.

300.4 OUABAIN BINDING AND ATPASE ACTIVITY IN THE HUMAN EPILEPTIC FOCUS. CL Devlin*, AR Wyler* & NS Nadi, (SPON: RJ Porter). NINCDS, Bethesda, MD 20892, & Univ of Tenn Med Ctr, Memphis, TN 28103.

The role of Na^+-K^+ ATPase in the maintenance of membrane potentials is well established. Several studies in the kindled rat brain as well as other seizure models have been equivocal as to changes in activity of ATPase. Recent studies in brain slices have clearly demonstrated that blocking of Na^+-K^+ ATPase altered the excitability of the membranes. Earlier studies in our laboratory have shown that in the kindled rat brain ouabain binding was significantly decreased (-55%) whereas the Na^+-K^+ ATPase activity was unaltered which implied that there may be fewer molecules of Na^+-K^+ ATPase which may be turning over at a faster rate. The activity of Na^+-K^+ ATPase and the binding of ouabain in 10 spiking and non-spiking foci were removed surgically from the temporal lobe of patients with intractable seizures. The tissues were frozen on dry ice within one minute of resection. Na^+-K^+ ATPase activity and ouabain binding were assayed in the spiking and non-spiking regions of 10 patients. Na^+-K^+ ATPase activity was (mean ± SD) 3.5 ± 0.2 pmol/min/mg protein in the spiking vs 4.0 ± 0.3 pmol/min mg protein in the non-spiking region. Ouabain binding was (mean ± SD) 50.2 ± 15.6 fmol/mg protein in the spiking vs 65.6 ± 10.2 fmol/mg protein in the non-spiking region. Although trends towards a decrease were observed in some patients there was no significant change in the data overall when the data were compared by a student t test or a paired t test. The lack of change in ouabain binding may be interpreted that the decrease in activity of Na^+-K^+ ATPase may be localized to a very small region of the spiking cortex and may not be detectable with the currently available binding and enzyme assay methodologies. Further autoradiographic studies are underway in our laboratory to rule out very localized alterations and will be discussed.

300.5 DECREASED N-METHYL-D-ASPARTATE RECEPTOR DENSITY IN HIPPOCAMPUS OF SEIZURE-SENSITIVE GERBILS. L. Miller*, T.R. Insel, R. Gelhard* and C. Harbaugh*.(SPON: U. Vaidya) Neuroscience Lab, Vet Adm Med Ctr, Wash. D.C. 20422 and Laboratory of Clinical Science, NIMH, Poolesville, MD. 20837.

The Mongolian gerbil, Meriones unguiculatus, is a convenient animal model for investigating neurochemical mechanisms underlying the phenomena of epilepsy. These animals exhibit generalized seizures in response to any unusual stimulus, such as being handled or placed in a novel environment. The seizures vary in severity while the seizure resistant animals can appropriately be used as controls. In the present study we have examined the density of the various glutamate receptor subtypes (N-methyl-D-aspartate, NMDA; Quisqualate, QA; kainate, KA) utilizing this animal model. Our study follows from numerous investigations by others suggesting a possible role of particular glutamate receptor subtypes in the propagation of generalized seizure.

Adult gerbils were screened for seizure susceptibility (SS) and seizure resistance (SR) using a scale of 0-5 to rate the seizures with 5 being the most severe. All animals were examined at least three separate times and only those exhibiting a rank of 4-5 were chosen as SS subjects. Following decapitation gerbil brains were removed and frozen on dry ice. Receptor autoradiography was performed on 15 micron sections of brain tissue. The various glutamate receptor subtypes were analyzed essentially as described by Monaghan et al. (Nature 306: 176, 1984). For the NMDA receptor binding of H(3)-Glutamate was determined in the presence of 5 uM Quisqualic Acid and 100 uM SIIS, for the quisqualate receptor binding of H(3)-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) was determined and for the kainate receptor binding of H(3)-kainic acid was determined. Non-specific binding was determined in the presence of excess quantities of the respective unlabeled ligand. Our results (N=5) are:

Hippocampal Region	% decrease in SS animals		
	NMDA	QA	KA
CA1	17	9	nc
CA3	15	nc	nc
dentate gyrus	16	nc	nc

(nc=no change)

Thus the density of NMDA receptors are significantly decreased in brain tissue from SS gerbils compared to SR controls. Whether the present results for the NMDA receptors represent a generalized pattern throughout the brain or show regional specificity is currently being explored. How these results relate to the seizure susceptibility of these animals will be discussed.

300.6 SUPPRESSION OF CHEMICALLY-INDUCED BEHAVIORAL SEIZURES IN RATS BY A NOVEL SPIDER TOXIN. H. Jackson and T.N. Parks. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT. 84132

Venom from an American grass spider contains at least two toxins that affect calcium currents. The smaller of the two toxins, tentatively designated AG2, has a molecular weight of less than 1000 daltons and seems to suppress calcium currents in an unusually borad spectrum of tissues. Neuronal calcium channels are thought to participate in epileptiform activity by mediating transmitter release and by their probable involvement in the characteristic neuronal bursting associated with seizures. For these reasons, we thought that AG2 might prove to be an effective anticonvulsant when administered peripherally. Male Sprague-Dawley rats (200-300 gm) were injected via the tail vein with one of three widely-used chemical convulsants dissolved in saline: 12 mg/kg kainic acid (KA), 3.6 mg/kg picrotoxin (PIC), or 0.5 mg/kg bicuculline (BIC). Five minutes later, control animals received an additional 0.5 ml intravenous injection of saline or of a gel filtration or high-performance liquid chromatography (HPLC) fraction of the venom known not to have calcium antagonist activity. Experimental animals received 0.5 ml injections of gel filtration or HPLC fractions containing AG2 that have been shown in electrophysiological experiments to have calcium antagonist activity; we estimate this dose to be about 2 μM/kg. For KA treated animals, the incidence of three seizure behaviors was scored for 1 min sampling periods at 5 min intervals for two hours; these behaviors were "wet-dog shakes", forelimb clonus with rearing, and whole-body clonic seizures. Scores on these measures were combined into a seizure index value for each observation period. For PIC and BIC treated animals, the percentage of animals surviving for more than 2 hrs was determined for control and treated goups. AG2 significantly suppresses seizure behavior in KA-treated animals ($p<.001$) and prevents convulsant-induced death in the PIC and BIC treated groups ($p<.005$); these effects are dose-dependent. Venom fractions lacking AG2 have no effect on chemically-induced seizures. Animals treated with convulsants and AG2 appear slightly sedated but retain postural control and responsiveness to external stimuli; they survive indefinitely in apparent good health. The results show that AG2 in low doses can suppress seizures induced by an excitatory amino acid agonist (KA) or two chemically-dissimilar GABA antagonists (PIC and BIC) and suggest that this compound represents a new class of CNS calcium-channel antagonist with potential uses as anticonvulsants.

Supported by USPHS grant NS 17257.

300.7 ALTERATIONS IN BRAIN NEUROTRANSMITTER LEVELS AFFECT SEIZURE SUSCEPTIBILITY IN RAT PUPS. James E. Olson and David Holtzman. Dept Emerg Med, Wright State Univ, Dayton, OH and National Magnet Laboratory, MIT, Cambridge, MA.

Rat pups which receive a unilateral hypoxic-ischemic cerebral insult at 2 days of age are more susceptible than controls to hyperthermia-induced seizures at 10-20 days of age (Olson et al., Epilepsia, 26:360-364, 1985). Since neurotransmitter deficits may contribute to this increased seizure susceptibility, we measured levels of norepinephrine (NE) and acetylcholine (AC) in ten different brain regions of ischemia-damaged and normal animals at 10 days of age.

AC levels were not affected in any brain region by hypoxic-ischemic treatment. Pilot studies suggested that NE levels were decreased in frontal cerebral cortex ipsilateral to the ischemic insult. To investigate the relationship of ischemia-induced damage of specific neurotransmitter systems to increased seizure susceptibility, we measured hyperthermia-induced seizure temperature thresholds (STT) in animals which had been treated with 6-hydroxydopamine (6OHD) or with atropine (AT) to eliminate catecholaminergic neurons or decrease cerebral AC levels, respectively.

Experimental animals were paired by weight with littermates and injected with 0.1 mg 6OHD/gram body weight on the second and third days of life. At 10 days of age, each animal was weighed and the basal body temperature and STT were determined using a rectal thermocouple. Animals in a separate series of litters were treated with 50 ug AT/gram body weight at 10 days of age. Body weights, basal temperatures and STT's were determined 3 hr later.

As shown below, rats treated with 6OHD had lower STT's at 10 days of age compared to control animals ($p<0.05$). The experimental animals also weighed less than controls; however, STT's and body weights were not correlated in control rats. In contrast, rats injected with AT had STT's and body weights which were not different from controls. The mean±SEM basal temperature fell from 35.0±0.2°C in control animals (N=13) to 34.0±0.3°C in AT-injected pups (N=12, $p<0.05$).

These data suggest that a selective decrease in the number or activity of catecholaminergic neurons in ischemia-damaged neonatal rats may increase hyperthermia-induced seizure susceptibility. These results may be important to our understanding of the pathophysiology and sequelae of ischemic brain damage in children.

Agent	STT °C	Basal Temp °C	Weight gm
6OHD	42.6±0.2* (11)	34.8±0.3 (8)	19.0±0.7* (11)
None	43.3±0.2 (9)	35.2±0.4 (8)	21.8±0.6 (9)

300.8 INCREASE IN IBOTENATE-STIMULATED PHOSPHATIDYLINOSITOL HYDROLYSIS IN SLICES OF THE AMYGDALA/PYRIFORM CORTEX AND HIPPOCAMPUS OF RATS BY AMYGDALOID KINDLING. K. Akiyama, N. Yamada*, H. Ujike*, M. Sato† and S. Otsuki*. Dept. of Neuropsychiatry, Okayama University Medical School, Okayama 700, and Dept. of Psychiatry, † Tohoku University School of Medicine, Sendai 980, JAPAN.

Kindling is the process whereby repeated administration of an initially subconvulsive electrical stimulation in the limbic brain areas results in progressive and permanent intensification of electrical discharges culminating in generalized seizure. Although several lines of evidence have indicated that enhancement of neurotransmission of excitatory amino acid (EAA) may underlie induction and maintenance of kindling, neurochemical mechanism of EAA responsible for seizure susceptibility remains to be known. The present study examined ibotenate (IBO)-stimulated phosphoinositide (PI) hydrolysis in slices of the amygdala (AM)/pyriform cortex (PC) and hippocampus (HIPP) of AM kindled rats. Male Sprague Dawley rats were used. A bipolar electrode was stereotaxically implanted into the left AM (coordinate, AP: -0.6, L: 5.2, D: 8.0) under pentobarbital anesthesia. Experimental animals received a kindling stimulus once daily in a 1 sec train of 60 Hz sine waves at a current intensity of 400 μA. Kindling seizure development was assessed using Racine's classification (1975). Daily kindling stimulus was administered to the left AM until a final stage 5 seizure was elicited on 20 consecutive days. Animals with sham operation were used as controls. AM kindled rats and matched controls were decapitated either 24 hours or 7 days after the last AM seizure. PI hydrolysis was measured by accumulation of [^{3}H]inositol 1-phosphate ([^{3}H]IP_1) in the rat brain slices according to the method of Berridge et al.(1982). IBO (10^{-3}M)-stimulated accumulation of [^{3}H]IP_1 increased significantly by 195 % in the AM/PC ($p<0.01$) and by 59 % in the HIPP ($p< 0.05$) of AM kindled rats sacrificed 24 hours after the last seizure. 7 days after the last seizure, a similar magnitude of significant increase (by 171 %, $p<0.05$) was maintained in the AM/PC of AM kindled rats. In contrast, the increase in the HIPP had attenuated to the control level by this time. These results suggest that remarkable and lasting increase in IBO-stimulated PI hydrolysis coupled to EAA receptors in the AM/PC may be associated with development of kindling and long-term maintenance of kindled events.

300.9 **ALTERATIONS IN EXCITATORY AMINO ACID RECEPTORS IN HUMAN TEMPORAL LOBE EPILEPSY.** L.D. Cahan*[1], J.W. Geddes[2], B.H. Choi[3], and C.W. Cotman[2] (SPON: S.K.R. Pixley). Div. of Neurosurgery[1], Depts. of Psychobiology[2] and Pathology[3], University of California, Irvine, CA 92717.

Abnormalities in excitatory amino acid transmitter pathways are proposed to be involved in epilepsy and in the neuronal damage resulting from sustained seizure activity. Vulnerable regions possess a high density of the N-methyl-D-aspartate (NMDA) subclass of glutamate receptors, and NMDA antagonists are effective anticonvulsants in a variety of animal seizure models. Using *in vitro* autoradiography, we have examined the status of the NMDA receptor and of the two additional glutamate receptor subtypes, the kainic acid (KA), and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, in hippocampal sections obtained from surgical resections of temporal lobe epilepsy patients. The results were compared to control tissues obtained at autopsy. Comparable sections were also stained for acetylcholinesterase activity.

The receptor profile in the entorhinal cortex was clearly abnormal, with a striking increase in the density of KA receptors in one patient, and in KA, NMDA, and AMPA receptors in a second patient. Intensification of AChE staining was also apparent. These results would predict hyperactivity of the entorhinal cortex, a prediction supported by the pattern of neuronal loss and the receptor distribution within the hippocampal formation.

In the outer 2/3 of the molecular layer of the dentate gyrus, the terminal zone of the major entorhinal input, excitatory amino acid receptor binding was abolished. Loss of granule cells was also evident. NMDA, AMPA, and KA receptor density was, however, maintained in the inner 1/3 of the molecular layer which receives its input from pyramidal neurons in the hilus. Neuronal and receptor density was also reduced in the hilus and in CA3. In particular, the distinct zone of high density KA receptors and AChE staining in CA3 was absent, replaced by a much broader band of lower intensity. These alterations may reflect plastic changes in the commissural/associational fiber system following the degeneration of granule cells and their axons, the mossy fibers.

Neuronal loss in CA1 was particularly devastating, with almost no pyramidal neurons remaining. This region normally contains a high density of NMDA and AMPA receptors, located postsynaptically on pyramidal cell dendrites. In the epileptic patients, NMDA, AMPA and KA receptors in CA1 were virtually absent. Receptor and neuronal density was, however, maintained in the adjacent prosubiculum. In the subicular region of the parahippocampal gyrus, a wider distribution and increased density of excitatory amino acid receptors was observed. These changes were paralleled by changes in AChE intensity.

These results are consistent with excitotoxic-induced damage but also suggest that the remaining neurons undergo plastic changes which may contribute to the functional propagation of neuronal activity within the epileptic hippocampus.

300.10 PHORBOL ESTER PRODUCES TRANSIENT EPILEPTIFORM ACTIVITY IN HIPPOCAMPAL SLICE. W.A. Wilson and D.V. Lewis V.A. Medical Center and Duke Medical Center, Durham, N.C. 27710

Electrical stimulation of the hippocampal slice induces two different types of plastic change. Moderate tetanic stimulation induces long term potentiation of synaptic transmission or LTP. More intense stimulation with repeated trains induces long term spontaneous epileptiform bursting, a phenomenon termed stimulus train induced bursting or STIB. Recently, activation of protein kinase C by brief application of phorbol esters has been shown to induce LTP in the absence of tetanic stimulation (Malenka et al, Nature, 321:175,1986). Our experiments address the possibility that long term epileptiform bursting could also be induced by phorbol application.

Hippocampal slices (625 uM) were prepared from Sprague-Dawley rats 25-40 days old (100-200 gm), placed in a submersion chamber and perfused with artificial cerebrospinal fluid (ACSF) containing (in mM); NaCl 120, KCl 3.3, CaC12 1.8, Mg SO4 1.2, NaHCO3 25, NaH2PO4 1.23 and dextrose 10 at pH 7.4. 4B phorbol -12, 13-diacetate (PDAc) was added to the ACSF. Field potentials were recorded in the s. pyramidale and radiatum of CA3b. Monopolar stimuli (0.1 msec, 5 -10V) were delivered to s. radiatum of CA3a.

After determining that the amplitudes of the fields were stable, perfusion with 2 uM PDAc was begun. After 5-6 min in PDAc, the amplitude of the field potentials (both orthodromic population spike and slow wave) in s. pyramidale was doubled or tripled. After 7-10 min spontaneous bursting began in CA3. Bursts had the typical appearance of multiple population spikes riding on a long positive slow wave and occurred at rates of 0.1 to 0.5 Hz. In some slices, there were transient episodes where the bursts became more rapid and complex resembling electrographic seizures. Washing the slices after 15-20 min exposure to PDAc resulted in a gradual (10-20 min) disappearance of the bursting. However, the increased amplitude of the field potentials persisted for hours and was stable indicating LTP had occurred.

These results suggest that, in CA3, PDAc can induce epileptiform bursting as well as persistent LTP. However, under appropriate conditions the bursting is reversible, whereas the potentiation is not. Perhaps the mechanisms underlying STIB involve more than transient activation of protein kinase C.

300.11 ALL-OR-NONE ELECTROGRAPHIC SEIZURES IN THE RAT HIPPOCAMPAL SLICE IN PHYSIOLOGICAL MAGNESIUM MEDIUM: INDUCTION AND TRIGGERING BY STIMULUS TRAINS. W.W. Anderson, H.S. Swartzwelder and W.A. Wilson, V.A. Med. Ctr. and Duke Univ. Med. Ctr. Durham NC 27705.

Previous studies have shown that spontaneous electrographic seizures (EGSs) can occur in the hippocampal slice for several hours in Mg-free artificial cerebrospinal fluid (0-Mg ACSF) containing the GABAb agonist baclofen (Anderson et al. Brain Res. 398:215 1986; Swartzwelder et al. Brain Res. 1987). We report here that similar all-or-none EGSs can be triggered by stimulus trains in ACSF containing normal Mg (with or without baclofen) following induction by several stimulus trains or exposure to 0-Mg ACSF.

Hippocampal slices (625 uM) were obtained from male Sprague-Dawley rats (25-35 days old). Extracellular recording and stimulation were performed from s. pyramidale and s. radiatum of CA3, respectively. Normal ACSF included (in mM) 0.9 Mg and 1.3 Ca. Rat CSF contains 0.88 mM Mg (Chutkow and Meyers, Neurology 18:963).

When slices were not producing spontaneous EGSs in 0-Mg ACSF + 2-5 uM baclofen, EGSs could be triggered by either a single pulse or a weak stimulus train (2 s, 3-10 pulses). Stronger stimulus trains (2 s, 120 pulses) triggered virtually identical EGSs.

When Mg was raised to 0.6, 0.9 or 1.2 mM (with or without baclofen) following exposure to 0-Mg ACSF, stimulus trains could still trigger EGSs, and their durations were independent of the suprathreshold stimulus intensity. However, the EGSs were shorter (25 versus 50 s), and more (17-56) pulses/train were required for triggering. Thresholds were also shown by varying train duration.

Alternatively, after slices had been stimulated by 10 or more trains (2 s, 60 Hz; once every 10 min) in normal ACSF + 2-5 uM baclofen, stimulus trains (above a threshold 17-29 pulses/train) triggered similar all-or-none EGSs. The EGSs increased after each of the first few stimulus trains, indicating that EGS induction occurred as a result of the trains. Five of 10 slices from 10 animals produced unambiguous all-or-none EGSs in 0.9-1.2 mM Mg following induction by stimulus trains, 0-Mg ACSF, or stimulus trains followed by 0-Mg ACSF.

In contrast, when slices from older rats (50-75 days old) were stimulated as during STIB (Stasheff et al. Brain Res. 344:296 1985) (2 s, 60 Hz trains once every 5 min, in 1.2 Mg/1.8 Ca, no baclofen, and with spontaneous bursting), the afterdischarge duration was not all-or-none but was sigmoidally related to stimulus intensity.

The induction, stimulus threshold, and all-or-none nature of EGSs are phenomenologically similar to the induction and triggering of seizures in whole animals during kindling. The existence of a post-stimulus all-or-none EGS also suggests that the EGS cannot simply be produced by a long duration EPSP, but implies the involvement of one or more regenerative mechanisms. Supported by the VA and NIH grant NS-17771.

300.12 MK-801 AND PCP PROTECT AGAINST ISCHEMIC NEURONAL DEGENERATION IN THE GERBIL HIPPOCAMPUS. J.J. Lawrence*, T.A. Fuller and J.W. Olney (SPON: M.S. Shahid Salles). Dept. of Psychiatry, Washington University School of Medicine, St. Louis, Mo. 63110.

Recent evidence suggests that certain neurodegenerative conditions, including anoxic-ischemic brain damage, may be mediated by the neurotoxic (excitotoxic) action of excitatory amino acid (EAA) transmitters. The N-methyl-D-aspartate (NMA) subtype of EAA receptor, the most abundant EAA receptor in brain, is thought to play a major role in such degenerative processes. Phencyclidine (PCP) and MK-801, which have similar receptor binding and NMA antagonist properties (Wong et al., PNAS, 83, 7104, 1986), are of potential interest as neuroprotective agents as they freely penetrate blood brain barriers and, by in vitro tests, are the most powerful (MK-801 > PCP) antagonists of NMA neurotoxicity known (Price et al., this meeting). Foster et al., (Br J Pharm 90, 9p, 1987) recently found that MK-801 (1-10 mg/kg ip) protects against the delayed degeneration of hippocampal CA1 neurons induced by 5 min of forebrain ischemia in the gerbil. Using both PCP and MK-801, we have tested the reproducibility of these findings.

Young adult gerbils (50-60 gm) were either untreated or given PCP or MK-801 in various doses ip 15 min prior to 7.5 min bilateral occlusion of the carotid arteries (in our hands, it required 7.5 min to consistently produce delayed degeneration of CA1 hippocampal pyramids). Four days following the ischemic episode, the gerbils were sacrificed by perfusion fixation under anesthesia and the brains processed for light and electron microscopy. Of 16 control animals that received no pretreatment, all had moderate-to-severe CA1 pyramidal cell loss which was bilateral but often non-symmetrical with regard to severity. In gerbils pretreated with MK-801 at 10 mg/kg (n = 6), total protection against CA1 hippocampal loss was evident in 50% and partial protection was achieved in the remainder (damage less severe and restricted to one side). A similar protective effect was provided by MK-801 at 1 mg/kg (n=6), with 50% having no damage and 50% having damage of reduced severity. At 0.1 mg/kg, MK-801 exerted no appreciable protective effect. Findings were less clearly interpretable with PCP in that 3 of 6 animals treated at 10 mg/kg escaped brain damage but the other 50% were severely damaged bilaterally, as were 4 of 4 gerbils treated with 5 mg/kg PCP.

These preliminary findings are generally confirmatory of the observations of Foster et al. We obtained a definite protective effect with MK-801 in the 1-10 mg/kg dose range which is not quite as dramatic as they reported, but we were dealing with a more prolonged ischemic insult. Supported by RSA MH 38894 (JWO) and Washington Univ/Monsanto Biomed Res Fund. MK-801 was generously supplied by Merck, Sharp and Dohme.

300.13 ALTERATION OF A1 ADENOSINE RECEPTOR DENSITY FOLLOWING TRANSIENT FOREBRAIN ISCHEMIA AND FIMBRIA/FORNIX LESIONS.

G.A. Block*, A.M. Buchan* and W.A. Pulsinelli (SPON:D. Levy) Cornell University Medical College, New York, NY 10021

Ischemic injury to CA1 pyramidal neurons is attenuated by A1 adenosine receptor agonist treatment (Block,G. and Pulsinelli,W.A., J. Cereb. Blood Flow Metab. ,in press) and fimbria/fornix lesioning (Buchan,A.M. and Pulsinelli,W.A.,Soc. Neurosci. Abs,submitted) and may be related to alterations in A1 adenosine receptors (Lee,K. et al.,Brain Res. 380:155,1986). To test the hypothesis that changes in A1 receptors contribute to selective neuronal loss, striatal and hippocampal ^{3}H-cyclohexyladenosine receptor density and affinity were measured in striatal and hippocampal membrane fractions of: 1)control, 2)unilateral fimbria/fornix lesioned, and 3) 2 and 6 hr. postischemic rats following 30 min. of transient forebrain ischemia.

A1 RECEPTOR DENSITY

	CONTROL	POST-ISCHEMIA 2 HR	POST-ISCHEMIA 6 HR
HIPPOCAMPUS	283±36(7)	219*±10(5)	243*±16(5)
STRIATUM	186±41(6)	110*±23(6)	139*±17(6)

(All values in fmoles/mg protein)
*p<0.005 vs. control (ANOVA with Scheffe comparison)

Transient ischemia resulted in a significant reduction in A1 receptor density but not affinity (data not shown). Fimbria/fornix lesioning of septal input to the hippocampus significantly increased ipsilateral receptor density [lesioned side 354±65 (3) vs. contralateral side 223±39 (3) ,p<0.02 (paired t-test)].

Thus,decreased A1 receptor density may explain post-ischemic neuronal hyperexcitability and death. Attenuation of CA1 pyramidal cell death by fimbria/fornix lesioning in part be due to possible heterologous increase in A1 receptors in the hippocampus.

300.14 THE GLUTAMATE(GLU) ANTAGONIST MK-801 BLOCKS HYPOXIC-ISCHEMIC(HI) BRAIN NECROSIS IN IMMATURE RATS.

J McDonald*, F Silverstein*, D Cardona* MV Johnston (SPON: C. D'Amato). Neuroscience Lab., University of Michigan, Ann Arbor, MI 48104

We found that MK-801, a noncompetetive blocker of excitatory amino acid responses mediated by NMDA receptors, protects the immature brain from necrosis caused by hypoxia-ischemia. In 7 d.o. rat pups anesthesized with ether, the right carotid artery was ligated. 2 hrs later, they were placed in 8% oxygen, 92% nitrogen for 3 hrs. Pups received I.P. injection of MK-801(1 mg/kg) or diluent before &/or mid-way in hypoxia. Examination of diluent treated pups 5 days later showed reduction in mass of the HI cerebral hemisphere compared with the opposite side with prominent neuronal loss in hippocampus(HIP), cortex & basal ganglia. Two injections of MK-801, just before & midway during hypoxia reduced the disparity in hemisphere weights(untreated, -11±3%, N=19 vs. treated, -2±1%,N=24 P<.007). A single dose before hypoxia(N=10) or in mid hypoxia(N=5) was similarly effective. MK-801 reduced the incidence of moderate to severe hemisphere necrosis(>10% reduction) from 58% in the diluent group(N=19) to 20% in groups given a single injection(N=10). Protocols with 2 injections(N=9) or 1 dose midway through hypoxia(N=5) eliminated severe injury. The drug preserved regions in the HI hemispheres which were grossly destroyed in untreated pups. In contrast to MK-801, I.C.V. injection of the GLU receptor antagonists APH & kynurenic acid either failed to protect or worsened neuronal injury in the model. The neuroprotective effects of MK-801 may be related to blockade of effects of GLU receptors expressed in the neonatal brain(Greenamyre et al, J Neurosci 7:1022). Using in vitro autoradiography, we identified distinct patterns of quisqualate & NMDA preferring binding sites for ^{3}H-glutamate in vulnerable regions. ^{3}H-TCP binding to the PCP/NMDA cation channel complex blocked by MK-801(Maragos et al, Eur J Pharm 123:173), corresponded to areas of NMDA receptor binding in cortex, HIP & striatum. Furthermore, MK-801 blocked the prominent destructive effects of NMDA(25 nmoles) injected directly into the striatum at this age. The results support the hypothesis that GLU release mediates HI neuronal destruction in the neonatal brain by activating receptor operated cation channels.

300.15 SELECTIVE SPARING OF NADPH-DIAPHORASE REACTIVE NEURONS IN NEONATAL HYPOXIC-ISCHEMIC INJURY.

R.P. Simon, D.M. Ferriero, T.K. McIntosh and S.M. Sagar. Department of Neurology, San Francisco General Hospital, and Department of Neurology, University of California, San Francisco, CA 94143.

In murine cortical cell cultures exposed to the endogenous excitatory neurotoxin quinolinate (an N-methyl-D-aspartate [NMDA] agonist), there is striking preservation of a subpopulation of neurons containing the enzyme NADPH-diaphorase (NADPH-d). In rats, ischemia of the forebrain produces lesions of selectively vulnerable hippocampal pyramidal cells which can be blocked by focal microinfusion of 2-amino-7-phosphonoheptanoic acid, an antagonist at the NMDA receptor. Since excitatory amino acid transmitters, acting through the NMDA receptor, seem to be implicated in neuronal death from ischemia, we hypothesized that NADPH-d reactive neurons should be selectively spared in neonatal hypoxic-ischemia (HIE).

In the neonatal Levine model of HIE, the left carotid artery is ligated in 7 day old rat pups and animals are then subjected to a hypoxic (8% O_2, 92% N_2) atmosphere for 2 hours. This injury results in a marked loss of cortical and striatal neurons on the affected side of the brain. We have previously shown histochemically that, despite this loss, there is selective sparing of the NADPH-d reactive neurons. We now report biochemical data supporting the sparing of NADPH-d reactive neurons. Concentrations of somatostatin (SLI) and neuropeptide (NPY), two peptides which co-localize with NADPH-d in cortical and striatal neurons, were measured by RIA after 10 days survival. Dynorphin (dyn) and leucine-enkephalin (leu-enk) concentrations were determined as biochemical markers of non-NADPH-d reactive neurons. In the cortex and striatum, there was no difference in SLI and NPY concentrations between ischemic and contralateral sides. In the ischemic cortex, dyn and leu-enk decreased to 12% and 34%, respectively, of concentrations found in contralateral hemisphere. There was no change in dyn or leu-enk concentrations between ischemic and contralateral striatum.

These results show that, in the damaged cortex of HIE rat pups, there is selective sparing of a class of neurons containing SLI, NPY and NADPH-d. Cell death is documented by the loss of cortical neurons containing leu-enk and dyn. The mechanism of the cell death may be through excitatory transmitters acting at the NMDA receptor; the NADPH-d reactive neurons appear to be resistant to such damage.

301.1 SIMULTANEOUS DETECTION OF LHRH, LH AND FSH IN THE CASTRATED MALE RAT USING PUSH-PULL PERFUSION OF THE ANTERIOR PITUITARY COUPLED WITH CONTINUOUS EXCHANGE TRANSFUSION. R.L. Pickle,* V.D. Ramirez and H.F. Urbanski (SPON: S. Balagura). Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801 and Neuroscience Division, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Push-pull perfusion (PPP) has earned the reputation of being a useful technique for the in vivo determination of the release rate of neurochemicals in several species. The recent application of the push-pull cannula (PPC) to the anterior pituitary (AP) has proven to be a valuable innovation for the examination of neuroendocrine control of the hypophysis. Previous studies using PPP to examine neuroendocrine control of gonadotrophin secretion were limited to placement of the PPC in the hypothalamus. Moreover, complications associated with sequential bleeding for a protracted period of time restricted these investigations to the use of larger animals. In an attempt to circumvent these limitations the current study combines PPP of the AP with exchange transfusion blood sampling, facilitating the simultaneous measurement of LHRH and gonadotrophin levels in the rat. Young adult male rats (90 days of age) were stereotaxically implanted with a PPC (24ga) in the AP and orchidectomized 7-10 d prior to sampling. One day prior to sampling the animals were fitted with indwelling jugular and femoral catheters. On the day of sampling the stylette of the outter cannula assembly was replaced with an inner cannula assembly (33ga). The AP was perfused with modified KRP (pH 7.4) containing 0.1mM bacitracin at a flow rate of 20 ul/min for 5-7 hrs. Continuous 10-min perfusate fractions were collected for subsequent LHRH assay. At least 15 min prior to the start of the blood sampling period the jugular and femoral catheters were flushed with heparinized saline and connected to the sampling and replacement tubing respectively. Continuous 5-min blood samples were withdrawn from the jugular vein at a rate of 30 ul/min using a peristaltic pump. A second channel of the same pump continuously infused a blood replacement mixture into the femoral vein, thereby maintaining a relatively constant blood volume. The samples were centrifuged and the plasmas stored until assayed for LH and FSH. Results were analyzed using the Pulsar program by Merriam & Wachter. The means of the release rate, frequency and amplitude of LHRH pulses were: 0.243 pg/min; 47 min; and 3.80 pg respectively (n=4). Of a total of 28 LHRH pulses observed 21% were not associated with a significantly detectable gonadotrophin pulse. However, of the 23 LH pulses observed, 78% were temporally associated with a LHRH pulse and of 9 FSH pulses observed, 88% exhibited this temporal relationship. These findings suggest that LHRH appears to orchestrate the pulsatile secretion of not only LH but also FSH, giving further support for the idea that LHRH is in fact, GnRH.

301.2 STUDIES OF THE ROLE OF THE NMDA RECEPTOR IN THE REGULATION OF HYPOTHALAMIC GONADOTROPIN RELEASING HORMONE RELEASE IN THE RAT M. Arslan*, C. R. Pohl*, and T. M. Plant (SPON: F. J. Huff). Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261

When administered in subtoxic doses, the neuroexcitatory amino acid analog, N-methyl-DL-aspartic acid (NMA), acutely stimulates the release of luteinizing hormone (LH) in rodents and primates by driving a suprapituitary mechanism (Shainker, B.A. and Cicero, T.J., Brain Res., 184:425, 1980; Gay, V.L. and Plant, T.M. Endocrinology, in press, 1987). Neuroinhibitory amino acids, GABA and taurine, have been shown to be effective in blocking the NMA-induced LH release, but have been regarded as nonspecific antagonists since they exert their action at loci other than those of the NMA receptors (Olney, J.W. and Price, M.T., Brain Res. Bull., 5 Suppl. 2:361, 1980). Recent electrophysiological studies indicate that 2-amino-5-phosphonopentanoic acid (AP5) is a potent and specific antagonist of the NMA receptor (Olverman, H.J. et al., Nature, 307:460, 1984). In the present investigation, the antagonistic effect of AP5 on NMA-evoked GnRH release from hypothalamic neurons of the rat was examined indirectly by monitoring moment-to-moment changes in circulating LH concentrations.

Adult male Sprague-Dawley rats weighing between 250-300 g were used in the study. The animals were implanted with an indwelling cardiac catheter via the right internal jugular vein for withdrawal of sequential blood samples and drug infusion. Blood samples were collected at -5, 0,5,10,15,25, and 35 min relative to drug or vehicle (V) administration at 0 min. Plasma LH was estimated by RIA using NIH-LH-RP-2 as the standard. The animals received AP5+NMA, V+NMA, or V alone. AP5 (30 mg/kg BW) was injected 1 min prior to the administration of NMA (15 mg/kg BW). Following NMA injection, mean plasma LH concentrations rose from <0.3 to 1.4 ng/ml at 5 min, and reached a peak of ≈2.0 ng/ml at 10 min. The gonadotropin concentrations then declined and fell to levels of <0.4 ng/ml at 35 min post-injection. Treatment with AP5 prior to NMA administration completely blocked the LH releasing action of the neuroexcitatory amino acid. In AP5+NMA treated animals, the plasma LH concentrations were indistinguishable from the vehicle treated controls. These data indicate that AP5 is an effective and potent antagonist of NMA-dependent LH release in the adult male rat and apparently lacks the weak agonistic effect described for α-aminoadipate (αAA), which also specifically antagonizes the LH releasing action of NMA (Olney, J.W. and Price, M.T., Brain Res. Bull., 5 Suppl. 2:361, 1980). Whether AP5 can by itself alter the drive of the neuroregulatory system responsible for gonadotropin secretion, is yet to be determined.

This study was supported by NIH grants HD 08610 and HD 13254.

301.3 QUANTITATIVE HYBRIDIZATION HISTOCHEMISTRY FOR LHRH mRNA IN ORGANOTYPIC CULTURES. S. Wray, T. Zoeller[1] and H. Gainer, NINCDS and [1]NIMH, Bethesda,MD 20892.

We have developed an *in vitro* organotypic culturing system in which LHRH neurons express their peptide hormone and maintain an organization reminiscent of that seen *in vivo* (Wray et al., Soc.Neuroscience Abstr., 12,1177,1986). Using this technique, we have found that the number of immunoreactive LHRH neurons in cultured sections containing the OVLT (with or without the anterior pituitary (AP)) significantly decreases in the presence of estradiol (E_2 ,10^{-7}M) for 18-21 days (Wray et al., in prep). This effect is not seen in cultured sections containing LHRH neurons from areas rostral to, or caudal to, the OVLT. A decrease in immunoreactive cells could represent either an increase in peptide turnover or release and/or a decrease in peptide synthesis. To address this question, *in situ* hybridization on cultured sections was performed.

400 μm diencephalon sections from 4 day old rats were plated on coverslips with or without a section of the AP. Half of the coverslips received E_2 (10^{-7}M) in their media. The cultures were maintained at 36° for 17-20 days and then fixed in 4% paraformaldehyde/0.2% picric acid in 0.1M sodium cacodylate buffer (pH 7.2) for 20 min. The sections were rinsed in phosphate buffered saline, treated with acetic anhydride, dehydrated in alcohol, and delipidated in chloroform. After rehydration, the sections were air dried.The coverslips were attached, culture side up, to glass slides with at least one untreated and one treated culture/slide. Cultures were hybridized overnight at 37° with an ^{35}S-labeled 48-base oligonucleotide probe complementary to the mRNA region encoding LHRH. Following post-hybridization washes, the slides were dried and dipped in diluted Kodak NTB-3 emulsion and exposed for 2-3 weeks. Cellular levels of LHRH mRNA were estimated by measuring optical density of individual labeled cells using an image analysis system. Several cultures taken from the level of the OVLT contained over 100 labeled cells. To date, 1176 labeled cells from 27 cultures have been analyzed. The distribution and total number of labeled cells resembled that seen in cultures stained by immunocytochemistry. We are currently examining whether the addition of the AP, and/or E_2 differentially affected the mRNA level of LHRH cells in the rostral diencephalon, at the level of the OVLT or within the caudal diencephalon.

301.4 MODULATION OF HYPOTHALAMIC LUTEINIZING HORMONE-RELEASING HORMONE SECRETION BY ATRIOPEPTIN IN VITRO. B.T. Miller* and T.J. Collins* (SPON: T.J. Cicero). Dept. of Anatomy & Neurosciences, University of Texas Medical Branch, Galveston, TX 77550.

A recently discovered, major hormonal system - the atriopeptin system - has been shown to be intimately involved in the regulation of water balance, electrolyte balance and systemic blood pressure. New experimental evidence indicates that atriopeptins, which are present in large amounts in cardiac tissue, are also produced in the brain. Immunopositive atriopeptin neurons have been identified in the rat hypothalamus, and fibers containing atriopeptin-like peptides are present in the external zone of the median eminance. Moreover, there is some evidence that hypothalamic atriopeptins might be involved in the control of pituitary hormone secretion, either directly, or by acting as neuromodulators in the hypothalamus. We have found that the presence of micromolar amounts of atriopeptin II (APIII) appears to enhance the secretion of luteinizing hormone-releasing hormone (LHRH) during in vitro incubations of rat or mouse hypothalamic tissue fragments.

Bissected medial basal hypothalami from either Sprague-Dawley-derived adult male rats or C57CL/6 adult male mice were individually incubated in a Kreb's-Ringer's-HEPES medium containing concentrations of APIII ranging from 0 micromolar to 10 micromolar. Matched incubations with neocortical tissue served as controls. The LHRH secreted by the tissues into the media was measured by RIA. Significant increases in the release of LHRH were observed at concentrations as low as 1 micromolar APIII. The APIII-associated increases were completely suppressed in calcium-free media which contained 1 mM EGTA, a calcium chelator. These results suggest that hypothalamic atriopeptin might be involved in the modulation of LHRH secretion in the rat and mouse. Whether hypothalamic atriopeptin exerts only stimulatory effects on LHRH secretion is currently unclear, however since earlier reports suggest that atriopeptins suppress the in vivo secretion of luteinizing hormone from the pituitary.

301.5 A MAPPING OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH) NEUROTERMINALS WITH THE PUSH-PULL PERFUSION METHOD IN THE RHESUS MONKEY. M. Gearing* and E. Terasawa. Neuroscience Training Prog. and Wisconsin Reg. Primate Res. Ctr., Univ. of Wisc., Madison, WI 53715.

Previously, we have reported a method for the measurement of *in vivo* LHRH release in conscious monkeys using a push-pull cannula inserted into the stalk-median eminence (S-ME). Our method offers great flexibility and accuracy in positioning the cannula tip, and allows multiple experiments with different cannula locations in the S-ME of a single animal. In the present study, we investigated the relationship between sampling location and LHRH release in 34 experiments performed in 14 ovariectomized female rhesus monkeys. Prior to perfusion, a cranial pedestal was fixed to the skull and a push-pull cannula was inserted into the S-ME through the pedestal. Based on X-ray ventriculography, the ventral edge of the infundibular recess of the third ventricle, at the midline level, was designated as the zero reference point. None of the cannula tip placements were in the third ventricle. Modified Krebs-Ringer phosphate buffer solution was infused through the push cannula and perfusate collected in 10-minute fractions through the pull cannula by identically calibrated pumps at a rate of 20 μl/min for 10-18 hr. LHRH was measured by radioimmunoassay. 1) Within an individual animal in which multiple experiments were conducted with different cannula placements, LHRH pulse frequency was consistent, while LHRH pulse amplitude and mean LHRH release varied considerably with cannula location. 2) Cannula tip placements bilaterally within 1 mm of the midline resulted in higher mean LHRH release (3.7±0.9 pg/ml) than more lateral (1-2 mm) placements (1.7±0.5 pg/ml). 3) When cannula tip placements were within 1 mm of the midline, highest mean LHRH release (10.8±1.5 pg/ml) was obtained at the ventral margin of the median eminence, between the zero reference point and 1.5 mm caudal to it, where the zona externa is located; 4) mean LHRH release was lower (3.1±0.9 pg/ml) when the cannula tip was located in the region between the zona externa and the base of the third ventricle, dorsal to the area described in 3; 5) rostral placements, in the area between the optic chiasm and the zero reference point, resulted in low mean LHRH release (1.3±0.2 pg/ml), as did placements in the area 1.5-2.5 mm caudal to the infundibular recess (1.2±0.9 pg/ml). These physiological results parallel the anatomical distribution of LHRH-immunoreactive fibers (Silverman, et.al., *J. Comp. Neurol., 211*:309, 1982). Therefore, our push-pull perfusion method is reliable and useful for the *in vivo* measurement of LHRH, as well as other neuropeptides and/or neurotransmitters. (Supported by NIH Grants RR00167, HD11355 and HD15433.)

301.6 DEGRADATION OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH) BY HYPOTHALAMIC AND ANTERIOR PITUITARY MEMBRANES AND BY INTACT PITUITARY AtT20 CELLS IS INITIATED BY CLEAVAGE OF THE TYR^5-GLY^6 BOND BY ENDOPEPTIDASE-24.15. C.J. Molineaux, C. Michaud* and M. Orlowski*. Dept. of Pharmacology, Mount Sinai Sch. of Med. of the City Univ. of New York, New York, N.Y. 10029

Degradation of LHRH within the hypothalamus and/or the anterior lobe (AL) of the pituitary may play a significant neuroendocrine role in modulating the release of luteinizing hormone (LH) and follicular stimulating hormone (FSH). LHRH (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2) was incubated with a particulate fraction of homogenates prepared from rat hypothalamus and from pituitary AL, as well as both membrane preparations and intact cells of the pituitary tumor line AtT20. Products of enzymatic degradation were separated by HPLC and were identified by amino acid analysis. Incubation with hypothalamic fractions yielded two main peptides, pGlu-His-Trp-Ser-Tyr and pGlu-His-Trp, indicating cleavage of the Tyr-Gly and Trp-Ser bonds. Incubation with pituitary fractions under conditions in which 50-80% of the peptide was degraded, yielded only pGlu-His-Trp. No degradation products of the C-terminal part of the peptide were isolated, indicating rapid degradation by the action of aminopeptidases. Incubation of pituitary fractions with LHRH in the presence of captopril, an inhibitor of angiotensin converting enzyme (ACE) led to an accumulation of pGlu-His-Trp-Ser-Tyr and pGlu-His-Trp-Ser-Tyr-Gly, indicating that in the absence of captopril these peptides are rapidly degraded by the action of ACE. Incubation of pituitary fractions in the presence of N-[1(RS)-carboxy-3-phenylpropyl]-Ala-Ala-Phe-pAB (cFP-AAF-pAB), a specific inhibitor of endopeptidase-24.15 synthesized in our laboratory, prevented the formation of any of the above peptides and greatly decreased the degradation of LHRH, indicating that formation of these products is dependent on the presence of endopeptidase-24.15 activity. Incubation of pituitary fractions with LHRH in the presence N-[1(RS)-carboxy-2-phenylethyl]-Phe-pAB, an inhibitor of endopeptidase-24.11 ("enkephalinase"), did not prevent formation of pGlu-His-Trp. Incubation of LHRH with intact AtT20 cells in monolayer culture led to the formation of pGlu-His-Trp. Formation of this peptide and LHRH degradation were completely prevented in the presence of cFP-AAF-pAB. Incubation with captopril alone led to the formation of pGlu-His-Trp-Ser-Tyr. These data are consistent with the conclusion that the primary and quantitatively dominating reaction in degradation of LHRH is cleavage of the Tyr-Gly bond by the action of endopeptidase-24.15, a zinc-metalloendopeptidase previously identified and isolated in this laboratory [Orlowski, M., Michaud, C. and Chu, T. Eur. J. Biochem. 135: 81-88 (1983)]. A minor cleavage in pituitary membrane preparations involves the Gly-Leu bond, apparently catalyzed by endopeptidase-24.11. 301.7 **SUPPRESSION OF IN-VITRO "BASAL" GONADOTROPIN SECRETION BY GnRH ANTAGONIST: DIFFERENTIAL EFFECTS ON METESTROUS AND PROESTROUS RAT PITUITARIES.** **E.S. Hiatt* and N.B. Schwartz*.** (SPON: L.H. Pinto). Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

We have reported a sex-specific change in in-vitro basal gonadotropin secretion rate (BSR; release in the absence of exogenous GnRH) by anterior pituitary fragments 2 and 6 days after gonadectomy (Hiatt and Schwartz, Biol. Reprod. 34:Abst. 212, 1986). In females, BSR of LH and FSH increases in parallel with serum values, while in males BSR is significantly reduced despite elevated serum levels. These findings led us to test the dependence of in-vitro BSR on prior exposure to GnRH in vivo. We chose to compare two estrous cycle stages, proestrus (PRO), when BSR and GnRH receptor levels are high, and metestrus (MET), when levels are low. Rats were given a single s.c. injection (100 ug/.25ml corn oil) of a potent GnRH antagonist (ANTAG; WY 45760; [AcB(2)D-Nal^1-4-F-D-Phe^2-D-Trp^3-D-Arg^6-LHRH] or oil either 12h or 1h prior to sacrifice at 0800h on PRO or MET. Pituitaries were cut into eighths and perifused for 8h using the Endotronics ACUSYST^{TM} perifusion system. For the first 4h, half of the glands from oil-injected rats were given Med 199 containing 1 uM ANTAG; the remainder received Med 199 alone. Starting at 5h all chambers received hourly 15-min pulses of 1 uM GnRH. Perifusates were assayed for LH and FSH by RIA. In PRO rats ANTAG injection lowered LH BSR to 50% and FSH to 70% of oil-treated controls regardless of time of injection. ANTAG administered in vitro suppressed LH BSR to 30% and FSH to 55% of controls. In contrast, in MET rats BSR of LH and FSH are 20% and 70% of control PRO rat values and were unaffected by ANTAG treatment either in vivo or in vitro. In PRO pituitaries LH and FSH responses to the first GnRH pulse were blunted by ANTAG in vivo but subsequent pulses were unaffected; MET responses were not different from controls. In-vitro ANTAG suppressed GnRH-stimulated release to 10-20% of controls at both cycle stages. The lower effectiveness of ANTAG in suppressing FSH has not been shown previously in vitro, but is consistent with in vivo studies in this lab (Grady et al., Neuroendocrinol. 40:246, 1985). Our findings suggest that pituitary fragments, in which cell-cell contact is maintained in culture, retain an appreciable amount of endogenous GnRH that stimulates "basal" gonadotropin secretion. The relative ineffectiveness of the ANTAG in lowering BSR in MET compared to PRO pituitary fragments suggests that there is less GnRH present, as predicted by lower GnRH release and pituitary receptor levels in MET rats. Thus, for questions concerning physiological regulation of gonadotropin secretion, the use of pituitary fragments may be more appropriate than more widely used dispersed cell preparations. 301.8 INTERMITTENT PULSES OF SEROTONIN ELICIT BIPHASIC EFFECTS ON THE IN VITRO RELEASE OF LHRH IN THE OVARIECTOMIZED-ESTRADIOL-TREATED RAT. D. C. Meyer. Dept. of Physiology, Eastern Virginia School of Medicine, Norfolk, VA 23501.

The neurotransmitter serotonin(5-HT) has well known effects on the release of luteinizing hormone (LH) which may also be estrogen dependent. An in vitro superfusion system was used to assess the potential role of serotonin in modulating the release of luteinizing hormone releasing hormone (LHRH) from the mediobasal-suprachiasmatic-preoptic area (MBH-POA-SCN) in the ovariectomized (OVX) E_2 implanted rat model of LH release. Regularly cycling female Holtzman strain rats, maintained on a photoperiod of 01^{00}-15^{00} H. light were OVX, and silastic capsules containing estradiol-17 beta (150 ug/ml) or sesame oil implanted s.c. Two days later the rats were killed at 10^{00} H and the MBH-POA-SCN isolated. Tissue was superfused in vitro with Krebs Ringer Phosphate buffer (KRP) for 2 hours followed by 3 hours of KRP with intermittent infusion of 5-HT at increasing concentrations: 1 x 10^{-10} M (1st hour); 1 x 10^{-8} M (2nd hour); 1 x 10^{-6} M (3rd hour). Superfusate was collected every 10 min. for the entire 5 hour incubation period and LHRH measured by RIA with the following results(Mean ± S.E.):

Treatment	LHRH (pg/10min)	Period (min)
OVX Control	1.2±0.3	34.8±4.2
OVX 5-HT	0.8±0.2 *	45.6±4.9 *
OVX E_2 Control	1.5±0.3	38.0±3.8
OVX E_2 5-HT	1.9±0.2	30.8±2.7 *

* P = .05 vs. control (paired T test)

These results suggest that the combined effect of all doses of 5-HT have a marked effect on LHRH output and period (frequency), significantly decreasing LHRH output and increasing the period in the OVX model. In contrast in OVX rats given estradiol, 5-HT increased output and significantly decreased the period of LHRH release. This indicates that the effect of 5-HT in modulating LHRH release may be related to the estradiol level in the rat and could serve as one mechanism to coordinate the release of LHRH with photoperiodic and steroid cues. This work was supported by HD 20535 to DCM.

301.9 SEX DIFFERENCE IN THE EFFECT OF MATING ON THE PULSATILE SECRETION OF LUTEINIZING HORMONE IN THE FERRET. R.S. Carroll, M.S. Erskine and M.J. Baum . Dept of Biology, Boston University, Boston, MA 02215.

Unlike males of many other mammalian species, male ferrets retain the capacity to exhibit receptive components of feminine mating behavior in response to treatment with estradiol (E2). The present study was conducted to see whether male ferrets also retain the capacity to exhibit surges in the secretion of luteinizing hormone (LH) after mating which are comparable to the coitus-induced LH surges needed to induce ovulation in estrous females. Female ferrets which were either gonadally intact and in estrus, or gonadectomized and maintained on a 'pulsed' regimen of daily E2 injections (5 ug/kg/2x/day) exhibited a large surge in plasma LH, characterized by an elevation in mean LH levels and an increase in the number of LH pulses, after receipt of an intromission from a stud male. By contrast, no such surge in LH secretion occurred in males which achieved an intromission with a female, regardless of whether they were gonadally intact and in breeding condition, or gonadectomized and given the same 'pulsed' estrogen regimen as that given to the females. In fact, gonadally intact breeding males which achieved an intromission had significantly fewer LH pulses 1-5 h later than unmated males bled serially over the same time period. This decrease in LH pulse frequency was followed by a significant rise in mean plasma levels of androgen 5-12 h later. This sexually dimorphic LH response to intromission probably does not reflect a sex difference in pituitary responsiveness to the endogenous release of gonadotropin releasing hormone (GnRH) because gonadectomized E2-treated male and female ferrets showed equivalent LH responses to the intravenous administration of several doses (2,4,8,16 ug/kg) of GnRH (Carroll et al., Biol. Reprod. 34:112, 1986). Ferrets' sexually dimorphic LH responses to intromission probably reflect a sex difference in the processing of somatosensory inputs from the genitalia or in the neural control of GnRH release into the hypophyseal portal vessels. (This work was supported by HD21094, RCDA MH000392 to MJB and MH09259 to RSC).

301.10 LUTEINIZING HORMONE (LH) SUPPRESSION IN MALE RATS EXPOSED TO A MINIMAL HORMONAL STIMULUS OF TESTOSTERONE, ESTRADIOL OR DIHYDROTESTOSTERONE. M.Y. McGinnis*, M.C. Mirth* and R.M. Dreifuss* (SPON: J.E. Shriver). Dept. of Anatomy, Mt. Sinai Sch. Med., CUNY, New York, NY 10029.

Exogenous testosterone (T) treatment suppresses LH release in castrate male rats. However, estradiol (E_2) and dihydrotestosterone (DHT), two major metabolites of T, have been shown to suppress LH levels to an even greater extent than T. In the present study, Silastic capsules were devised to provide constant serum levels of T, E_2 and DHT in the physiological range for male rats. The ability of these minimal hormonal stimuli to suppress LH, and the time course of LH suppression following capsule insertion were investigated.

Adult, male, Long-Evans rats were castrated 3-4 weeks prior to blood sampling. In the first experiment, castrates received subdermal implants of either two 10mm T-filled silastic capsules, one 5mm 10% E_2 capsule (diluted with cholesterol), one 5 mm DHT capsule, one 10% E_2 capsule plus one 5mm DHT capsule or blank (Bk) capsules. After 14 days of hormone exposure, trunk blood was collected. Results showed that all steroid treatments significantly suppressed LH release. Lowest LH levels were found in rats receiving 10% E_2, DHT or 10% E_2 plus DHT.

In a second experiment, the time course of LH suppression was determined. Open flank pouches were pre-formed the day before blood sampling. Animals were bled at hourly intervals from the tail vein. After the first hourly sample, silastic capsules as described above (T,10% E_2, DHT or Bk) were placed into the flank pouches (without anesthesia), and sampling continued for up to 7 h. Results confirm previous studies showing that LH suppression requires 4-6 h of T exposure. In contrast, LH levels were suppressed within 2-3 h after exposure to 10% E_2 or DHT.

To examine the effects of these hormones on pulsatile LH release, a third experiment was conducted. Castrate males received open flank pouches and indwelling catheters placed in the common carotid artery. The following day blood samples were taken every 6 min. After the first hour of sampling, capsules (T,10% E_2, DHT or Bk) were inserted into the pouches of awake, freely-moving rats and sampling continued for up to 7 h. All three hormone treatments suppressed LH pulses; 10% E_2 was most effective, DHT was intermediate and T was less effective. Blank capsules had no effect on pulsatile LH secretion.

Our results indicate that even when a minimal hormonal stimulus is used, both E_2 and DHT suppress LH more rapidly and to a greater extent than T. It is suggested that major differences in androgenic regulation of copulatory behavior and gonadotropin regulation may exist in male rats.

301.11 CORRELATION OF RAT PITUITARY PROLACTIN mRNA AND HORMONE CONTENT WITH SERUM LEVELS DURING THE ESTROGEN INDUCED SURGE. A.J. Carrillo, Z.D. Sharp* and L.V. DePaolo. Dept. of Cellular & Structural Biology and Physiology, The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284

The model of the serum Prl surge generated in the ovariectomized rat following estradiol benzoate (EB) treatment was used to study the relationship between prolactin (Prl) release and biosynthesis. Adult ovariectomized rats were injected (s.c.) with 7ug of EB or vehicle at noon of day 0. Three days later (day 3) the rats were decapitated every 4 h over a 24 h period (beginning at 0800 h) for determination of serum and pituitary Prl and growth hormone (GH) levels by RIA. In addition, Prl and GH mRNA content was determined using dot blot hybridization with cDNAs.

Administration of EB resulted in a significant rise in serum Prl levels at 1200, 1600 and 2000 h on day 3 when compared to controls. In addition, EB treatment elicited a marked increase in pituitary prolactin levels at all time periods examined except during and after the Prl surge (1600, 2000, and 2400 h) when there was a significant reduction in stored pituitary Prl. Pituitary Prl mRNA content in the EB-treated group was significantly elevated (4 to 6 fold) over control levels throughout the study. Furthermore, Prl mRNA levels in EB-treated rats were significantly higher at 2000 and 2400 h than at other time periods. In contrast to its effects on Prl, EB treatment had a slight inhibitory effect on pituitary content of GH at 2000 and 2400 h when compared to controls; otherwise this steroid had no effect on serum GH levels and pituitary content of GH mRNA. Interestingly, serum GH levels and pituitary GH mRNA content in both treatment and control groups exhibited a circadian periodicity with peak values occurring during the lights-on hours.

These data show that estrogen has a continuous stimulatory effect on pituitary content of Prl and its corresponding mRNA in the rat for at least 3 days after injection. Thus, maintenance of elevated Prl mRNA levels may be necessary for the occurrence of Prl surges. Furthermore, the finding that serum Prl was elevated only at certain times (1200-2000 h) while Prl mRNA content was increased at all times in the EB treated rats suggests a differential regulation between hormone release and biosynthesis.

301.12 EFFECTS OF HYPERPROLACTINEMIA ON LH SECRETION FOLLOWING ELECTRO-CHEMICAL STIMULATION OF THE MEDIAL PREOPTIC AREA. C. Shu* and M. Selmanoff (SPON: D. Ruchkin). Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

Chronic hyperprolactinemia is known to decrease LH secretion perhaps by causing decreased secretion of LHRH. We have utilized the 7315a prolactin-secreting pituitary tumor to induce a hyperprolactinemic state sufficient to suppress the postcastration LH rise. We then stimulated LHRH cell bodies in the medial preoptic area (MPOA) to see if the evoked LH secretory profile was different in hyperprolactinemic compared with age-matched controls.

Intact, female Buffalo rats (Harlan Sprague Dawley, Inc.) were innoculated with a suspension of minced tumor tissue. Tissue to initiate our tumor line was kindly provided by Dr. Robert M. MacLeod. Two to three weeks later the tumors had become palpable and rats were ovariectomized (Day 1). On Day 7 rats were implanted sc with estradiol-containing Silastic capsules which maintain levels of circulating estradiol of about 15pg/ml. This concentration of estradiol exerts a negative feedback effect and induces daily LH surges similar to those seen on proestrous afternoon. On Day 8 rats were implanted with an indwelling right atrial catheter. On Day 9 rats were anesthetized with ketamine/acepromazine before the critical period (11am-1pm) such that the afternoon LH surge was blocked. In a stereotaxic apparatus, a bilateral, electrochemical stimulus was applied to the MPOA (100μA, 60sec) and the rats sequentially bled at 0,15,30,45,60,90,120 and 180min thereafter. Cardiac perfusion of the brain was performed with sequential 20ml volumes of 0.9% saline, potassium ferrocyanide and 10% neutral buffered formalin. Cryostat sections of the brain revealed that the blue reaction product extended from the diagonal band of Broca to the caudal extent of the medial preoptic nucleus. At the time of stimulation the tumor volume was about $60cm^3$ (range = $50-80cm^3$).

LH values at time 0 were suppressed in tumor-bearing rats (99 ± 11ng/ml LH-RP-1) compared with controls (343 ± 11ng/ml). Significant suppression was also seen in rats not receiving estradiol (241 ± 35 vs 520 ± 95ng/ml respectively). Electrochemical stimulation resulted in a significant LH increase at 15min with peak levels attained 90min poststimulation. With the exception of the 0 time values, the LH profile of hyperprolactinemic and control rats did not differ.

These results demonstrate that the chronic hyperprolactinemia produced by the 7315a tumor suppresses postcastration LH secretion in the presence and absence of estradiol. Upon stimulation of the LHRH neurons, the LH response is not modified by this hyperprolactinemic state.

301.13 Effects of Testosterone, Dihydrotestosterone, and Estrogen on Luteinizing Hormone Secretion in Castrated Male Ferrets. Y.P. Tang* and C.L. Sisk (SPON: G.B. Ellis), Neuroscience Program and Department of Psychology, Michigan State University, E. Lansing, MI 48824-1117.

The biological activity of testosterone often depends on the conversion of testosterone within the target cell to an androgenic or estrogenic metabolite. We have previously demonstrated that testosterone exerts negative feedback effects on luteinizing hormone (LH) secretion in male ferrets. Castration results in an increase in LH secretion; testosterone replacement prevents this castration response. The purpose of this study was to compare the relative ability of testosterone (T), dihydrotestosterone (DHT) and estrogen (E) to suppress LH secretion in castrated ferrets.

Adult male ferrets housed under 18 hr of light/day were castrated. Two weeks after castration, the ferrets were divided into 3 groups which over the next five weeks received subcutaneous Silastic capsules containing either T, DHT, or E. Five different doses of the steroid capsules (one dose each week) were administered. T- and DHT-treated ferrets received 1, 2.5, 5, 10, and 15 mm capsule length/100 g body weight; E-treated ferrets received 0.1, 0.25, 0.5, 1, and 1.5 mm capsule length/100 g body weight. Blood samples were collected via heart puncture from lightly anesthetized ferrets immediately before castration, two weeks after castration, and after each week of treatment with the five doses of steroid. Plasma LH concentrations were measured by radioimmunoassay.

Castration resulted in a rise in plasma LH from 0.09 ng/ml before castration to 0.47 ng/ml two weeks after castration. Postcastration LH levels were not different among the groups before steroid treatment began. Plasma LH concentrations were significantly reduced in castrated ferrets by all doses of DHT and E; mean LH levels were nearly undetectable at the four highest doses of these two steroids. In contrast, the lowest dose of T was completely ineffective in suppressing LH, and the next higher dose resulted in only a partial reduction in plasma LH concentrations. These results demonstrate that relatively low doses of DHT (1 mm/100 g body b.w.) and E (0.1 mm/100 g b.w.) inhibit LH secretion, but that T suppresses LH release only at higher doses ($\geq$ 2.5 mm/100 g b.w.). This experiment indicates that E is more effective than DHT, and that DHT is more effective than T, in inhibiting LH secretion in castrated ferrets. This suggests that in intact ferrets, steroid negative feedback on LH secretion may be mediated by the conversion of testosterone to DHT and E within hypothalamic and/or pituitary cells. Supported by HD-21588.

301.14 The Effects of Gonadal Steroids on Vasoactive Intestinal Peptide (VIP) Concentrations in the Hypothalamus of Male and Female Rats. P.N. Riskind, S.M. Gabriel and J.I. Koenig, Neurology Service, Mass General Hospital, and Harvard Medical School, Boston, MA 02114

VIP potently stimulates prolactin (PRL) secretion from *in vitro* cultured pituitary glands. Furthermore, immunoneutralization studies have demonstrated a role for VIP during suckling- and 5-HT- induced PRL secretion. These findings, combined with the high concentrations of VIP in the rat hypothalamus and hypophysial portal blood suggest that VIP may be of importance in regulating the secretion of PRL in this species. Gonadal steroids such as estrogen have profound stimulatory effects upon the concentrations of PRL found in the pituitary and blood of the rat. Therefore, we have sought to determine the involvement of hypothalamic VIP as a mediator of these gonadal steroid effects. Sixty-day-old male and female Sprague-Dawley rats received either bilateral gonadectomies or sham operations under ether anesthesia. Two weeks later, the animals received Silastic capsule implants containing estradiol 17-beta (E2), testosterone (T) or cholesterol (Chol). Animals were sacrificed 12 to 15 days after initiation of the steroid or control treatment. Antisera to VIP were generated in rabbits, using porcine VIP conjugated to key limpet hemocyanin. The assay sensitivity was less than 2 pg VIP/tube. Rat hypothalamic extracts displaced radiolabeled VIP binding to the antibody in a manner parallel to the standard curve. The antibody did not crossreact with porcine PHI or members of the secretin peptide family. Sephadex G-50 chromatography and HPLC of rat hypothalamic extracts revealed single peaks of VIP immunoreactivity which coeluted with VIP standard. Hypothalamic VIP concentrations of male rats were unaffected by castration or gonadal steroid treatments, in agreement with a previous report. However, hypothalamic VIP concentrations were higher in female rats than in male rats (Dl females 237 $\pm$ 8 pg VIP/mg protein, proestrus 213 $\pm$ 22 pg VIP/mg protein vs intact males 157 $\pm$ 13 pg VIP/mg protein). Ovariectomized rats had somewhat lower hypothalamic VIP concentrations (193 $\pm$ 12 pg VIP/mg protein) than either group of intact females, but none of the steroid treatments restored VIP concentrations to ovarian-intact levels. These results indicate that the more dynamic PRL secretory activity of female rats than male rats may be related to higher hypothalamic VIP concentrations in females. Our results also suggest that, in addition to estrogen, other ovarian factors such as progesterone may play a role in maintaining hypothalamic VIP concentrations. Supported by AM 26252.

301.15 APPLICATION OF A CHEMICAL REDOX SYSTEM FOR DELIVERY OF DRUGS TO THE BRAIN: ETHINYL ESTRADIOL. M.E. Brewster,* K. S. Estes and N. Bodor.* Pharmatec, Inc., Alachua, FL 32615 and Ctr. for Drug Design and Delivery, College of Pharmacy, Univ. of Florida, Gainesville, FL 32610.

A redox-based chemical delivery system (CDS), analogous to the $NAD^+ \rightleftarrows NADH$ coenzyme system recently was developed and shown capable of brain-directed delivery of several drugs. Application of the CDS to estradiol (E_2) resulted in sustained LH inhibition in castrate rats and prostate and seminal vessicle weight decrease in male rats which could not be attributed to circulating E_2 levels. This action was far more pronounced than equimolar treatment with estradiol valerate (EV) or E_2 alone (Life Sci. 40:1327-1334, 1987). The CDS was applied to ethinyl estradiol (EE) in an attempt to improve the stability and activity of the estrogen carrier. Distribution studies in rats verified brain directed delivery of EE. Brain concentrations of the oxidized EE carrier complex were sustained with $t_{\frac{1}{2}}$ approximately 2½ days after i.v. administration of CDS-EE while blood levels rapidly fell. Free EE brain levels were similarly sustained after CDS-EE. Levels of EE were not detectable 3 h following treatment with equimolar doses of uncoupled EE. To monitor the duration of central estrogen action, LH was measured in ovariectamized rats. Rats were treated i.v. with 1.0, 0.3, 0.1 or 0.03 mg/kg CDS-EE or vehicle. Twelve days later, serum LH was dampened 67%, 53%, 44% and 14% compared to controls and by day 18 decreased 76%, 46%, 16% and increased 2% in these respective groups. Only the highest dose group had significantly decreased serum LH on day 25. When body weight gain in these rats was monitored, significant and dose-related decreases were observed in rats treated with 0.1 mg/kg or higher doses. Significant decreases were maintained through the 25 day duration of the study. Intact female rats had a similar dose related decrease in body weight gain following a single i.v. dose. Significant decreases were maintained for 27, 12 and 3 days following treatment with 3.0, 1.0 and 0.3 mg/kg, respectively. Uterine weights did not show significant dose-related change. These data showing dose and time relationship of sustained drug action are consistent with the brain directed CDS. The marked effects on body weight gain support a centrally mediated action of E_2 in regulating weight gain in female rats. These pharmacokinetic and pharmacodynamic data indicate a 3- to 5-fold increased potency compared with similar studies of the CDS for estradiol. This increased activity may be attributed to increased brain drug delivery and/or related to the potency of hydrolyzed free EE.

301.16 CHANGES IN PROLACTIN FOLLOWING ACUTE VS CHRONIC ESTROGENIC STIMULI. G.E. Resch* and K. Fair* (SPON: J. Voogt). Div. of Structural and Systems Biol., Univ. Mo. - Kansas City, Kansas City, MO 64110.

Estrogenic action targeted on the brain modulates the function of neuroendocrine systems. Estrogen analogs have been useful tools in understanding estrogenic action. This report describes plasma prolactin (Prl) responses elicited during chronic and acute administration of estradiol (E2) and an estrogenic analog (F2) *in vivo*.

Initial experiments using daily drug injections in oil showed the expected Prl rise to E2. The rise in Prl under F2 stimulation was 50% below that for E2. The marked responsiveness of the CNS to F2 in these data is similar to that of endogenous estrogens.

Subsequently, acute experiments were conducted using intra-arterial bolus injections. These experiments were designed, in part, to study the time course of the Prl response. Serial blood sampling for Prl assay was taken with volume replacement to minimize total blood volume loss. Capillary tube hematocrits were used as an index of sampling stress, previously shown to elevate Prl.

Data show that F2 elicited a rise and fall in Prl levels, which mirrors that for E2. However, the onset of E2-elicited Prl was 30 min. earlier than for F2 and showed a graded increase over time to the peak value. The F2-elicited Prl values were smaller and less consistent in the early phases and reached peak values at the same time as for E2.

In another experiment, pituitary and uterine weights (organ/body weight ratios) showed a preferential increase to E2 vs F2 in pituitary, but not in uterine weight over the time course of the experiments. These data indicate a potent central (pituitary) effect compared to the uterine response.

Comparisons of these data, *in vivo*, with previous *in vitro* pituitary results indicate a slower onset and smaller rise in Prl to intra-arterially administered agents than was seen *in vitro*. Similarly, F2 elicited responses had longer latencies but were comparable to those elicited by E2. The study of estrogenic actions using F2 may facilitate a more detailed understanding of how the brain, as a target of endogenous humoral agents, regulates Prl release.

302.1 ISOLATION OF CDNA CLONES FROM RAT HIPPOCAMPUS RESPONSIVE TO GLUCOCORTICOIDS. J.N. Masters, N.R. Nichols and C.E. Finch. Andrus Gerontology Center, Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191

We have recently characterized the effects of corticosterone (CORT) on steady-state RNA levels in various brain regions of the male rat by 2-D gel electrophoresis of in vitro translation products (Nichols et al., 1986, Soc. Neuroscience Abstract 188.14, p691). In all regions examined, three translation products were increased (35, 33 and 20 kdalton polypeptides) and one product decreased (50 kdalton) in response to administered CORT. Furthermore, the 35, 33 and 20 kdalton products were increased in response to stress (Nichols et al., this vol.).

In order to further characterize these products and possibly increase our sensitivity in identifying other RNAs that change in response to CORT, we screened a rat hippocampal cDNA library in lambda gt10 by differential hybridization using cDNA derived from adrenalectomized (ADX) and ADX+CORT treated (3d) animals. From approximately 20,000 recombinants screened, 25 showed a differential response with the primary screen. Following the secondary screen, 7 clones were further characterized by binding purified phage DNA to nylon membranes in a slot blot apparatus and hybridizing duplicate blots with the ADX or ADX+CORT cDNA probes. Four of the seven clones were confirmed to respond to CORT; clones 1-1, 5-5 and 11-3 were increased 2-3 fold and clone 2-2 increased about 10 fold.

Total RNAs isolated from the hippocampus from three separate animal experiments(3 day treatment) were fractionated on a formaldehyde-agarose gel, transferred to a nylon membrane and probed with the insert of clone 2-2. An RNA of about 3.7kb was found to hybridize and showed a 10-fold response between ADX and ADX+CORT RNA. Another clone which did not change in response to CORT was used as a control in a duplicate blot.

Since the 35, 33 and 20 kdalton in vitro translation products show large increases to administered CORT, we speculate that clone 2-2 may represent one of these peptides. Hybrid arrested or selected translation will be used to confirm this hypothesis. Additionally, clones 1-1, 5-5 and 11-3 may represent RNAs which we did not detect in the original in vitro translation experiments which will need to be confirmed with other experiments.

302.2 VIBRATORY STRESS ELLICITS RAPID GLUCOCORTICOID RESPONSES IN RAT HIPPOCAMPAL RNA. N.R. Nichols, A.S. Khan* L.K. Maedo* J.N. Masters and C.E. Finch. Andrus Gerontology Center, Dept. of Biological Sciences, Univ. of Southern Calif., Los Angeles, CA 90089-0191.

Rapid effects of glucocorticoids on rat hippocampus include stimulation of cellular metabolism, behavioral changes, and neuroendocrine regulation. Previously, we described select increases in three poly(A)-containing RNAs, coding for 35, 33, and 20 kdalton polypeptides, in response to administered corticosterone (CORT) in rat hippocampus, and also cortex, striatum, cerebellum and hypothalamus (Nichols et al., 1986, Soc. Neurosci. Abstract 188.14, p.691). We postulated that similar responses of large magnitude (5- to 50-fold) in different brain regions might represent a new class of stress responses in rodent brain. We now show that rapid increases within 2 hr of CORT treatment are seen for these RNAs. Moreover, similar increases are induced by the physiological stress of shaking for 2 hr in a cage mounted on a Dubnoff metabolic shaker. Hippocampal RNA responses in three groups of male Fisher 344 rats (intact, intact + stress, and adrenalectomized + stress) were compared by in vitro translation of isolated total RNA and subsequent 2-dimensional gel electrophoresis and fluorography. Translation products were quantitated on 10 d film exposures by computerized videodensitometry and densities were normalized between fluorographs with reference to unchanging spots (0.8- to 1.2-fold). Responses are expressed as fold-change with respect to intact and adrenalectomized (ADX) control values:

POLYPEPTIDE M_r	INTACT + STRESS / INTACT	INTACT + STRESS / ADX + STRESS	2 HR CORT / ADX
35 kdalton	5-fold	6-fold	12-fold
33 kdalton	1	14	20
20 kdalton	3	4	6

All three responses exhibited glucocorticoid specificity (RU 28362 $\geq$ CORT >> aldosterone > dihydrotestosterone = ADX control; e.g. 35 kdalton polypeptide fold-changes with respect to ADX control were 21, 13, 2, 1 and 1, respectively). These responses represent specific gene products which are being differentially regulated by elevated glucocorticoid levels and vibratory stress, and may be important in neuronal/glial functions governing behavioral and neuroendocrine events in the physiological adaptation to stress. Their relation to the well-known heat-shock/stress responses remains to be established.

302.3 REGULATION OF GLUCOCORTICOID RECEPTOR MESSENGER RNA CONCENTRATIONS IN RAT BRAIN REGIONS.
N. Barden & A. Peiffer. Ontogénèse et Génétique Moléculaire, Le Centre Hospitalier de l'Université Laval, Quebec G1V 4G2, Canada.

We have studied the regulation of glucocorticoid receptor (GR) mRNA concentrations in two brain regions: the hippocampus, which has a particularly high GR content, and the hypothalamus, an important neuroendocrine integration site for the control of stress hormone secretion. Past studies have shown that both adrenal and gonadal steroids differentially influence glucocorticoid binding site concentrations depending upon the brain region. To determine if these changes are also exerted on GR mRNA concentrations, we have used a Northern blot assay to quantify GR mRNA. Total RNA was extracted from hypothalamus or hippocampus by a guanidium isothiocyante method and purified by centrifugation on CsCl density gradients followed by phenol/chloroform extraction. Northern blots were hybridized with [^{32}P]-labelled Riboprobe corresponding to a 2.2 Kb fragment of GR mRNA and quantified by densitometry. GR mRNA levels were expressed in relation to the ß-actin mRNA concentration of the same sample. Autoradiographic results indicated that the GR mRNA found in both hippocampus and hypothalamus migrated in the same 6.5-7Kb region as did GR mRNA isolated from liver or pituitary gland. The concentration of GR mRNA in hippocampus was approximately 70% greater than it was in the hypothalamus. We recently reported that ovariectomy increases and that estrogens suppress GR mRNA concentrations in rat pituitary gland. GR mRNA concentrations were also increased in the brain of bilaterally ovariectomized female rats 12 days after surgery. However, this effect was significantly greater in the hypothalamus than it was in the hippocampus. In contrast, the GR mRNA concentration of hippocampal tissue showed a greater decrease in response to exogenous corticosterone than did hypothalamic GR mRNA levels. The hypothalamic GR mRNA concentration of ovariectomized-adrenalectomized animals was greater than that of either ovariectomized only or adrenalectomized only animals. It remains to be determined by *in situ* hybridization whether or not these actions of adrenal and gonadal steroids are exerted on the same hypothalamic cell populations.

302.4 GLUCOCORTICOID RECEPTOR GENE EXPRESSION IN RAT PITUITARY GLAND INTERMEDIATE LOBE.
A. Peiffer & N. Barden. Ontogénèse et Génétique Moléculaire, Le Centre Hospitalier de l'Université Laval, Québec, Qc, G1V 4G2, Canada.

We have recently reported that estrogens influence glucocorticoid receptor (GR) mRNA concentrations in rat pituitary anterior lobe. The presence of GR mRNA and its regulation by estrogens was subsequently investigated in the rat pituitary intermediate lobe using Northern blot and *in situ* hybridization techniques. Female rats (250 g) which had been bilaterally ovariectomized under light ether anaesthesia were (at different times after surgery) perfused with 4% paraformaldehyde, pH 7.4 (for the *in situ* hybridization studies) or decapitated. Total RNA was isolated from intermediate lobe tissue by the guanidium isothiocyanate method and purified by centrifugation on CsCl gradients followed by phenol/chloroform extraction. Autoradiographic results of Northern blots hybridized with [^{32}P]-labelled Riboprobe corresponding to to a 2.2 Kb fragment of GR mRNA showed that GR mRNA concentrations are barely detectable or undetectable in normal animals. These findings concord with the lack of immunodetectable GR in the pituitary gland intermediate lobe of intact animals. In ovariectomized rats, however, a strong hybridization signal was given by the presence of a 6.5-7Kb GR mRNA. This GR mRNA species was identical, on Northern blots, to that found in liver and anterior pituitary gland. The effect of ovariectomy on intermediate lobe GR mRNA, which was detected at 12 days and was further increased at 4 weeks post-operatively, was reversed by administration of near-physiological doses of 17-ß-estradiol. *In situ* hybridization experiments on 10 µm frozen pituitary sections affixed to poly-L-lysine-coated slides were done in order to confirm the findings of the Northern blot studies. Slides were incubated with a [^{3}H]-labelled cRNA probe diluted in hybridization buffer (50% formamide, 10% dextran sulfate, 3x SSC,1x Denhardt's, 100 µg denatured salmon sperm DNA, 100 µg yeast tRNA) at a concentration of 3.0 x 10^6 cpm/ml,then washed, dried and coated with film emulsion. The results of these studies confirm our observations made in the Northern blot studies on the effect of ovariectomy on GR mRNA concentrations in rat pituitary intermediate lobe. It remains to be determined whether or not the GR mRNA induced by ovariectomy is translated into a functional receptor protein.

302.5 GLUCOCORTICOID REGULATION OF PREPROENKEPHALIN mRNA LEVEL IN RAT STRIATUM. H.M.Chao*, M.Blum[1], J.L.Roberts[1] and B.S.McEwen. Lab. of Neuroendocrinology, Rockefeller University, N.Y., N.Y. 10021 and [1]Dept. of Neurobiology, Mt. Sinai School of Medicine, N.Y., N.Y. 10029

In order to investigate the regulation of preproenkephalin mRNA in rat brain, we have applied a sensitive assay for determining mRNA levels. This assay employs a radioactively labeled antisense riboprobe derived from the rat brain preproenkephalin cDNA of S.Sabol. This riboprobe is hybridized in solution to total RNA from brain tissue and subsequently treated with RNAse T2, in a modification of the SP6 quantitative nuclease protection assay (Zinn, K., et al, Cell 34:865, 1983). Using this assay we determined that the relative abundance of preproenkephalin mRNA in total RNA from five specific brain regions was as follows: striatum >> hypothalamus, pons-medulla > cerebellum > hippocampus. In Northern analyses, this riboprobe hybridizes to a single mRNA species of approximately 1.5 kb, in these five brain regions.

Previous studies have shown that preproenkephalin gene expression can be regulated by hormones. Administration of dexamethasone results in an increase in immunoreactive enkephalin levels in rat striatum (Rossier, J., et al, Life Sci.25:2105, 1979). Moreover, in vitro experiments have indicated that glucocorticoid treatment can result in an increase in preproenkephalin mRNA levels (Yoshikawa, K. and S.L.Sabol, BBRC 139:1, 1986). Using the RNAse T2 protection assay , we compared the levels of striatal preproenkephalin mRNA in adrenalectomized (ADX) rats with those of ADX rats injected s.c. with corticosterone (40 mg/kg per day for 5 days). The animals treated with corticosterone showed an approximately 2-fold higher level of preproenkephalin mRNA than the ADX animals injected with vehicle. Parallel measurements of actin mRNA showed no such increase in actin gene expression with corticosterone treatment. Preproenkephalin mRNA levels in the other brain regions investigated (where the basal levels of expression are significantly lower than in striatum) seemed largely unaffected by the corticosterone treatment. Studies are currently in progress to determine whether stress will mimic the effects of glucocorticoids on the level of preproenkephalin mRNA in the striatum. (Supported by NS07080.)

302.6 ROLE OF THE PITUITARY-ADRENOCORTICAL AXIS IN THE CONTROL OF TYROSINE HYDROXYLASE (TH), PHENYLETHANOLAMINE-N-METHYL TRANSFERASE (PNMT) AND PROENKEPHALIN (pEK) mRNA AND ENKEPHALIN LEVELS IN THE SYMPATHOADRENAL SYSTEM. O.H. Viveros, P. Lee, R.J. Rigual*, J.-S. Hong, M.K. Stachowiak*. Laboratory of Behavioral and Neurological Toxicology, NIEHS, NIH , P.O. Box 12233, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

pEK A derived peptides are colocalized with catecholamines (CA) in adrenal medulla and sympathetic ganglia. During stress enkephalins are released together with CA and produce unique physiological effects. Recently we began to investigate the mechanisms which control hormonal output from the sympathoadrenal system. We have shown that the adaptation of adrenomedullary cells to enhanced transmitter release involves increased mRNA levels, synthesis and postranslational processing of CA enzymes and pEK. The purpose of this study was to examine roles of the pituitary-adrenocortical axis in the control of these processes in the rat adrenal medulla (AM) and superior cervical ganglia (SCG). Male Fisher rats were hypophysectomized (HPX) or sham-operated (SO) at the age of 8 weeks and were supplemented with 5% sucrose and saline. Two weeks later animals received injections of saline or dexamethasone (DEX, 1 mg/kg, i.p.) for 5 days, and were decapitated 12 hours after last injection. Total RNA and protein content decreased by 25-50% after hypophysectomy and were not restored by DEX. The relative abundance of specific mRNAs (units/mg total RNA) was estimated by dot blot hybridization and northern analysis using cloned TH, PNMT, pEK cDNA probes. The abundance of adrenomedullary PNMT mRNA decreased in HPX by 50%. DEX injections reversed these changes completely, but did not affect PNMT mRNA levels in SO. TH mRNA abundance in AM and SCG was not altered in HPX, but it was increased after DEX treatment (30-50% increase in both SO and HPX animals). pEK mRNA levels in SCG and AM were decreased after hypophysectomy by 16 and 27%, and responded to DEX treatment only in HPX (60-80% increase). To assess posible changes in enkephalin precursor processing both cryptic (CM - after trypsin and carboxypeptidase B digestions) and native (NM - without enzyme digestions)[Met-5]-enkephalin-like immunoreactivity was measured. In AM specific content of CM and NM (pmoles/mg protein) increased by 25% and 100% after hypophysectomy suggesting an enhanced processing of precursor peptides. This increase in NM/CM ratio was not affected by DEX. In SCG, hypophsectomy produced 35% decrease in NM/CM ratio, which was reversed by DEX. In conclusion, the relative abundances of TH, PNMT, and pEK mRNAs are differentially controlled by the pituitary-adrenocortical axis. This control is mediated by glucocorticoid receptors which also stimulate synthesis (AM) and processing (SCG) of enkephalins. In addition, the pituitary-adrenocortical axis exerts an inhibitory influence on the processing of adrenomedullary enkephalins by glucocorticoid independent mechanisms.

302.7 ROLE OF THE SPLANCHNIC NERVE ACTIVITY IN THE CONTROL OF TYROSINE HYDROXYLASE (TH), PHENYLETHANOLAMINE-N-METHYL TRANSFERASE (PNMT) AND PROENKEPHALIN (pEK) mRNA LEVELS IN THE RAT ADRENAL MEDULLA. J.-S. Hong, L. Thai*, R.J. Rigual*, O.H., Viveros, M.K. Stachowiak*, Laboratory of Behavioral and Neurological Toxicology, NIEHS, NIH, P.O. Box 12233, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

The effects of splanchnic nerve (SPN) stimulation on the levels of TH, PNMT, and pEK mRNA were investigated in the rat adrenal medulla. Male Fisher rats were anesthetized with chloral hydrate (320 mg/kg i.p.). Both adrenal glands were decentralized by transecting branches of SPN just below ganglia. Distal portion of the left transected nerve was stimulated at either 15 or 5 HZ, with 1 msec, 40 Volt pulses for 1 hour. Subsequently rats were sutured and allowed to recover from anesthesia and killed at different time intervals. TH, PNMT, and pEK mRNA levels were estimated by RNA-dot blot hybridization and northern analysis. Two to four hours after nerve transection, TH and pEK mRNA levels were increased by 30-60% in the decentralized side when compared to the nonoperated controls. Stimulation of SPN at 15 Hz resulted in additional increases. Increase in TH mRNA was found already 1 hour after the end of stimulation and the changes in pEK mRNA occurred 1 hour later: both increases achieved maximal levels (50-80%) 3 hours following the end of stimulation. In contrast, relative abundances of PNMT mRNA in denervated and stimulated glands were not changed. In another experiment, SPN branches were stimulated at 5 Hz. Two hours later TH, PNMT, and pEK mRNA levels in the stimulated gland were 21-35% lower than those of the nonstimulated side. To study possible mechanisms underlying the above-mentioned changes, rats were injected with atropine alone (1 mg/kg i.p.) or in combination with chlorisondamine (10 mg/kg i.p.) 10 min before anesthesia and at the end of 1 hour SPN stimulation. Atropine alone did not alter the effect of stimulation on mRNA levels. Combined treatment with both antagonists did not prevent the increases in mRNA levels in denervated adrenal medulla. However, such treatment completely reversed 15 Hz induced increases in mRNA levels of TH and pEK. In fact, decreases of mRNA levels (30-40%) compared to non-stimulated side were found. In contrast, 5 Hz stimulation-induced decreases in mRNA levels of TH, PNMT and pEK were not affected by atropine in combination with chlorisondamine. In conclusion, depending on stimulation frequency, SPN exerts both stimulatory and inhibitory effects on the expression of TH and pEK mRNA, but only an inhibitory effect on the expression of PNMT mRNA was observed. Stimulatory effects are mediated through nicotinic mechanisms, however, mechanisms underlying inhibitory effects remain unclear.

302.8 **DIFFERENTIAL REGULATION OF THE mRNAs FOR THE CATECHOLAMINE ENZYMES TYROSINE HYDROXYLASE AND PHENYLETHANOLAMINE N-METHYLTRANSFERASE IN BOVINE CHROMAFFIN CELLS.** *M.J. Evinger, J.M. Carroll, S.E. Hyman, H.M. Goodman*, and T.H. Joh.* Lab. of Molec. Neurobiol., Cornell Univ. Med. Coll., New York, NY 10021 and Dept. Mol. Biol., Mass. Gen. Hosp., Boston, MA 02114

Tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT) are the enzymes responsible for synthesis of the catecholamine (CA) neurotransmitters dopamine and epinephrine, respectively. Because adrenergic cells of the brainstem and adrenal medulla express TH and PNMT, both coordinate and differential control of the genes for these two CA biosynthetic enzymes may be analyzed concurrently in these tissues. This study compares the transcriptional regulation of TH and PNMT mRNAs in response to major regulatory effectors of CA production in the adrenal gland. Specifically, hormonal and neural modulation of the steady state levels of TH and PNMT mRNAs have been analyzed in response to treatment with glucocorticoid hormones, to increased levels of cAMP and to depolarization with potassium.

Bovine adrenal medullae were dissociated by treatment with collagenase, fractionated by centrifugation on Percoll density gradients, and plated at a density of 3×10^5 cells/ cm^2 in DMEM:F12 (1:1) medium containing 10% fetal calf serum (FCS). Following treatment with a specific effector, cells were lysed with NP-40 (0.5%) and SDS (0.2%) and total RNAs, isolated by extraction with phenol and chloroform, were fractionated on agarose-formaldehyde gels. Northern blot analyses permitted the detection and quantitation of specific CA mRNAs by hybridization with either bovine TH cDNA (700 b.p. Kpn-Pst I fragment) or PNMT cDNA (1100 b.p.).

Glucocorticoids are required for maintenance of PNMT activity *in vivo* in the rat adrenal gland. We have previously demonstrated that both the rate of transcription and the steady-state levels of adrenal PNMT mRNA increase following treatment with dexamethasone in hypophysectomized rats. In the present studies, bovine adrenal chromaffin cells were established *in vitro* for 2 days in the presence of 10% FCS before replacement with serum-free or glucocorticoid-depleted media. Cultures were maintained for 3-5 days prior to treatment with 10 μM dexamethasone. In serum-free medium, PNMT mRNA increased significantly within 24 hr of treatment with dexamethasone. Moreover, an increase in PNMT mRNA was detectable within 5 hr of addition of exogenous hormone to cells in glucocorticoid-depleted medium. These results indicate that glucocorticoids exert a direct influence on production of bovine adrenal PNMT mRNA and that the effect observed *in vitro* is analogous to that observed in rat adrenal cells *in vivo*.

Synthesis of PNMT mRNA, however, responds differently to certain effectors which stimulate production of other CA enzyme mRNAs. Specifically, TH and PNMT mRNAs respond differently to forskolin, an activator of adenylate cyclase. In the presence of the phosphodiesterase inhibitor isobutylmethylxanthine, 1 and 10 μM forskolin produces a rapid and marked increase in TH mRNA, while the level of PNMT mRNA remains the same as that seen in control cultures. Therefore unlike TH mRNA, accumulation of PNMT mRNA is not stimulated by increased concentrations of the second messenger cAMP. Furthermore, depolarization of chromaffin cells by 50 mM K^+ in the presence of 5 mM Ca^{2+} results in an increase of TH mRNA although comparable changes were not observed for PNMT mRNA.

These studies suggest that modulation of CA mRNA levels constitutes one major means for exerting coordinate and differential regulation on the genes in the CA biosynthetic pathway. Moreover, these results indicate that bovine adrenal chromaffin cells *in vitro* provide an excellent system for investigating molecular mechanisms of CA gene transcriptional regulation.

(Supported by NIMH grant MH 24285 and Hoechst AG to MGH.)

302.9 THE REGULATION OF TYROSINE HYDROXYLASE EXPRESSION IN THE PERIPHERAL NERVOUS SYSTEM OF THE RAT. D.R. Studelska*, R. Soriano*, M.I. Johnson and K.L. O'Malley (SPON: S. Brimijoin). Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Tyrosine hydroxylase (TH) is the initial and rate-limiting enzyme necessary for catecholamine biosynthesis in adrenergic neurons. The intracellular and transsynaptic regulation of its activity has been studied for many years. Now that the rat TH gene has been cloned, the study of the genetic regulation of TH production at the level of mRNA production is feasible. The present studies employed the technique of in situ hybridization.

Neurons were dissociated from embryonic superior cervical ganglia (SCG) and explanted on collagen-coated coverslips in serum-supplemented media containing fluorodeoxyuridine to destroy nonneuronal cells. The cultured neurons were then transferred to N2, a defined medium. The cells were then subjected to various treatments such as exposure to drugs thought to perturb TH expression, i.e., dexamethasone. Following treatment, cells were rinsed, fixed and stored in ETOH.

Anti-sense RNA probes were made from portions of a full length rat TH cDNA inserted in the Bluescript plasmid vector. Cells were rinsed and prehybridized at 42°C. The radiolabeled probe was then applied at a concentration of 1.2×10^6 DPM/ml in the same buffer for an overnight incubation at 42°c. The next day the cells were treated with RNase A and then washed at 42°C to remove unhybridized probe. The cells were then airdried, coated with Kodak NTB2 nuclear track emulsion, and kept in a light tight box for an exposure of one week before the grains were developed.

Dexamethasone increased TH mRNA production, however, the expression of TH message in the explanted cells was quite variable. This variability may reflect the heterogeneity of the SCG neurons, which innervate diverse tissues, and which are known to be quite different in their neuropeptide content. Since similar experiments in sectioned adult ganglia did not demonstrate as much variability, it is possible the variable expression in the cultured cells was due to maturational differences. TH message is also expressed in the cholinergic neurons of nodose ganglia, which are of placodal rather than neural crest origin. The comparison of the regulation of the TH gene in these anatomically contiguous, but embryologically distant neurons may provide insights into the regulatory mechanisms of genes that are integral to the function of neuronal transmission.

302.10 FLUPHENAZINE-N-MUSTARD (FNM)-INDUCED CHANGES IN LEVELS OF mRNAs FOR PREPROTACHYKININ (PPT) AND TYROSINE HYDROXYLASE (TH) IN THE STRIATUM AND SUBSTANTIA NIGRA (SN) OF THE MOUSE AS DETECTED BY IN SITU HYBRIDIZATION CYTOCHEMISTRY (ISHC). L.T. Weiss (1), N. Mahy (2)*, and M.-F. Chesselet (1), Depts. of Pharmacology, The Medical College of Pennsylvania (1) and University of Pennsylvania (2), Philadelphia, PA.

Chronic alteration of dopaminergic neurotransmission in the striatum and SN occurs in Parkinson's disease and with chronic neuroleptic treatment. In this study, we sought to determine whether blockade of dopaminergic receptors modifies the expression of specific genes in striatal and nigral neurons. Male Swiss Webster mice were injected 2 times, 8 hours apart, for 2 consecutive days with a dose of FNM (4 um/kg), which irreversibly blocks D_2 but not D_1 dopaminergic receptors. The mice were sacrificed the following day. The right striata were dissected out and used for HPLC analysis. The left side of the brains were frozen, cut on a cryostat and processed for ISHC using ^{35}S-labelled RNA probes with emulsion autoradiography (1). Levels of hybridized mRNAs were compared by visual and computer-assisted grain analysis. Probes complementary to mRNA for PPT (H.U. Affolter) coding for substance P and K, for TH (D. Chikaraishi) and glutamic acid decarboxylase (GAD; A.J. Tobin) were used. In FNM-treated mice, a decrease in labelling for PPT mRNA was observed in the striatum and for TH mRNA in the SN pars compacta. The specificity of these changes was assessed by the lack of modification of GAD mRNA levels in pallidal neurons of the same animals. The decrease in PPT mRNA in striatal neurons of FNM-treated mice confirms that interruption of dopaminergic transmission in the striatum decreases tachykinin gene expression and suggests an involvement of D_2 dopaminergic receptors in this effect. The decrease in TH mRNA in nigral neurons of FNM treated mice contrasted with a two-fold increase in the striatal turnover of dopamine (DA), measured as the ratio of the levels of the DA metabolite DOPAC to DA. This suggests that a compensatory decrease in TH gene expression occurs when dopaminergic nigrostriatal neurons are activated by sustained blockade of D_2 dopaminergic receptors. These results provide evidence that changes in specific gene expression measured in single cells by ISHC of specific mRNA's can be induced by short term blockade of striatal and nigral dopaminergic receptors and suggest that such changes can be involved in the adaptation of striatal and nigral neurons to changes in dopaminergic transmission.

302.11 INCREASED STRIATAL PREPROENKEPHALIN mRNA INDUCED BY HALOPERIDOL DECANOATE. M.R. Emmett*, P.L. Wood and B. Petrack, Neuroscience Research, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, New Jersey, 07901.

Haloperidol, injected daily into rats for 2-3 weeks, increased preproenkephalin mRNA in striatum but not in other brain regions (Tang et al, Proc. Natl. Acad. Sci., 80: 3841, 1983). The authors suggest that the antipsychotic action of haloperidol might result from its ability to increase striatal enkephalin levels. Recently, haloperidol decanoate, a pro-drug, has been used as a long-acting neuroleptic in schizophrenic patients. In the present study, we tested the possibility that two injections of haloperidol decanoate during a 3-week period might be as effective as daily injections of the parent drug in elevating preproenkephalin mRNA levels in rat striatum.

Four groups of Sprague-Dawley rats were injected according to the following schedule.

1. Haloperidol, 1 mg/kg, subcutaneously (s.c.), daily for 21 days.
2. s.c.-Control, saline, 0.2 ml, s.c., daily for 21 days.
3. Haloperidol decanoate, 20 mg/kg, intramuscularly (i.m.), Day 1 and Day 11.
4. i.m.-Control, saline, Day 1 and Day 11.

On Day 21, the rats were killed by decapitation. Brain regions were dissected, immediately frozen in liquid nitrogen and stored at -70°C. Liver was taken as a negative control.

Total RNA was extracted from the tissues and quantitated via both northern blot and slot blot analyses. The preproenkephalin mRNA was hybridized with a 911 base-pair fragment from pRPE-2/SP64, a plasmid containing the cDNA for rat preproenkephalin. The probe was labeled with ^{32}P-CTP, using a random priming procedure. Preproenkephalin cRNA, synthesized via a riboprobe system, was used as a positive control.

The probe identified an mRNA in striatum and hypothalamus (from all groups) of approximately 1400 bases, whereas no hybridization was observed with liver RNA. The amount of preproenkephalin mRNA in striatum from haloperidol and haloperidol decanoate treated rats was approximately triple that in striatum from the two groups of saline controls. Haloperidol decanoate also mimicked the parent drug in increasing preproenkephalin mRNA in slot blot analyses. In contrast, neither drug affected preproenkephalin mRNA levels in hypothalamus.

These studies demonstrate that haloperidol decanoate functions as a long-acting haloperidol in selectively elevating striatal preproenkephalin mRNA, consistent with its action as a pro-drug antipsychotic agent.

302.12 POST-MORTEM STABILITY OF PREPROENKEPHALIN mRNA IN RAT BRAIN. M.M. GARCIA* AND R.E. HARLAN. (Spon: C.H. Norris) Departments of Pharmacology and Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

The measurement of mRNA levels in brain tissue is becoming an increasingly important technique for the neuroscientist. As the use of such methods becomes more common, the influence of exogenous factors such as anesthesia on RNA levels and the stability of RNA in unfixed post-mortem tissue become matters of interest. The latter problem is especially of interest to those working with human tissue.

In order to study these questions, we killed 6 groups of rats (3-4 rats per group) by decapitation. The brains were removed from the skulls and frozen on dry ice at 0 min, 15 min, 1 hr, 4 hr or 8 hr after decapitation. One groups of animals at 0 min was anesthetized with pentobarbital prior to decapitation. Except for the zero-time group, in which brains were removed immediately, the brains were left in situ in the skulls at room temperature until removal for freezing. The brains were stored at -80°C until use. Total RNA was extracted from each brain using the guanidinium isothiocyanate-cesium chloride method, and the RNA content determined spectrophotometrically. One and 0.5 µg of RNA from each sample was dotted in duplicate onto nitrocellulose with vacuum filtration. The filter was air-dried and baked at 80°C under vacuum for 2 hr. The RNA on the filter was hybridized to a ^{32}P-labeled cDNA complementary to rat preproenkephalin (PPE) mRNA (gift of R. Howells). Hybrids were detected autoradiographically and quantitated with a scanning densitometer.

Analysis of these results showed no significant difference in PPE mRNA levels between the untreated rats and those treated with pentobarbital. There were also no significant differences between the 0 min values and those in the 15 min, 1 hr, 4 hr, or 8 hr groups. In addition, RNA from each sample was electrophoresed on a 1% agarose gel and stained with ethidium bromide. There was no detectable degradation of the 28S and 18S ribosomal RNA bands even 8 hours post-mortem.

These results suggest that PPE mRNA is stable in post-mortem, unfixed brain tissue for at least 8 hours. This should be of considerable interest and importance to those working with human models, while the additional finding that pentobarbital anethesia does not effect PPE mRNA levels should be of interest to those using animal models for the study of gene expression in the brain. Supported by NS24148

302.13 COMBINED IN SITU HYBRIDIZATION AND IMMUNOHISTOCHEMISTRY FOR CCK AND TYROSINE HYDROXYLASE IN RAT VENTRAL MIDBRAIN. K. Seroogy[1], M. Schalling[1], S. Brene*[1], A. Dagerlind*[1], S.Y. Chai*[1], H. Persson*[2], J. Dixon[3], D. Filer*[4], M. Goldstein[4], J. Walsh*[5] and T. Hökfelt*[1]. [1]Department of Histology, Karolinska Institutet, Stockholm, Sweden, [2]Department of Medical Genetics, Uppsala University, Uppsala, Sweden, [3]Department of Biochemistry, Purdue University, West Lafayette, IN, USA, [4]New York University, Medical Center, New York, NY, USA, [5]CURE, VA Medical Center-Wadsworth, Los Angeles, CA, USA.

As further analysis of dopamine/cholecystokinin (CCK) coexistence within neurons of the ventral midbrain at both the mRNA and post-translational product levels, we have combined the techniques of in situ hybridization and immunohistochemistry on the same tissue section. Normal and colchicine-treated rat brains (either unfixed or paraformaldehyde-fixed) were cut in a cryostat at 14 µm and sections through the ventral mesencephalon were thaw-mounted onto glass slides. Sections were initially processed for hybridization histochemistry using either cDNA probes for CCK and tyrosine hydroxylase (TH) (the biosynthetic enzyme for dopamine) labelled with $\alpha(^{35}S)$-dNTP's by nick-translation or, alternatively, synthetic oligonucleotide probes for both CCK (48 bp) and TH (48 bp) labelled on the 3' end with $\alpha(^{35}S)$-dATP using terminal deoxynucleotidyl transferase. Hybridization was conducted at 42°C for 16-18 h using $1\text{-}2\times10^6$ cpm per slide. Following X-ray film autoradiography, the sections were then processed for the simultaneous immunohistochemical detection of CCK and TH using a double-label immunofluorescence method and photographed. Finally, the slides were dipped in nuclear track emulsion, exposed and processed autoradiographically for cellular localization of CCK and TH mRNA.

Neurons throughout the substantia nigra (A9), ventral tegmental area (A10) and several midline nuclei were found to contain CCK or TH mRNA. The results obtained with either type of probe were the same. Both CCK and TH immunoreactivity were detected within TH or CCK mRNA-labelled perikarya, respectively. We are currently analyzing the effects of several neuroleptics on CCK and TH mRNA levels in ventral midbrain neurons. In additon, the distributions of CCK and TH mRNA-containing somata are being examined in the ventral mesencephalon of other species, including cat.

302.14 IN SITU HYBRIDIZATION HISTOCHEMISTRY OF TYROSINE HYDROXYLASE mRNA IN RAT BRAIN. Frank Baldino, Jr.*, Ariel Deutch, Robert H. Roth, Rudolph G. Krause, II*, and Michael E. Lewis. Medical Products Department, E. I. du Pont de Nemours, Wilmington DE and Department of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT.

Tyrosine hydroxylase is the rate-limiting enzyme in catecholamine biosynthesis in the CNS. Recently we have developed a synthetic oligonucleotide probe to resolve transcripts coding for this enzyme within individual neurons. Here we report the distribution and relative abundance of TH messenger RNA throughout the midbrain and brainstem regions of the rat CNS.

In situ hybridization and the appropriate controls were performed according to our previously published methods. A 30 base oligodeoxynucleotide probe, complementary to the 3' exon coding region of rat tyrosine hydroxylase mRNA, was used to detect transcripts coding for the rat TH precursor. Probes were radiolabeled on the 3' end using [^{35}S]dATP with terminal transferase according to our previously published procedures. Alternate 15 m sections were processed for immunohistochemistry using the avidin-biotin method with antibodies directed against the C-terminus of tyrosine hydroxylase. Hybridization signal was detected with emulsion autoradiography.

Localization of mRNA was characterized by an extremely dense accumulation of silver grains in the neuronal cytoplasm with little or no label over the nucleus. There was a marked concordance in the distribution of hybridization signal and TH-immunoreactive neurons. Labeled neurons were observed in the substantia nigra pars compacta, ventral tegmental area, locus coereleus, ventral lateral medulla, nucleus tractus solitarius, subcoereleus and arcuate nucleus. Destruction of the A8 neurons with 6-OHDA resulted in a loss of hybridization signal associated with these neurons. Thus, single cell resolution of this relatively rare transcript, coupled with immunodetection of TH, should provide the basis for further studes on the regulation of TH expression in the CNS.

302.15 COMPUTER-AIDED ANALYSIS OF CELLULAR RESOLUTION IN SITU HYBRIDIZATION HISTOCHEMISTRY IN BRAIN. W. T. Rogers*, J. S. Schwaber and M. E. Lewis, Engineering and Medical Products Departments, E. I. du Pont de Nemours & Co., Inc., Wilmington, DE 19898 (SPON: M.D. Dibner)

We describe here a method for relative quantitation of mRNA levels with single neuron resolution. Following processing for in situ hybridization histochemistry, tissue sections are emulsion-dipped, exposed, and developed. The method relies first on locating autoradiographically-labeled cells by dark-field microscopic visualization of silver grains over counterstained neuronal profiles by a computer-aided method of "flying-field mapping" (Rogers et al., Applied Optics, '87). Each location is then stored in a digital database with an accuracy of 1 micron. Once a schematic map of the tissue section and of labeled neurons has been created, the stage is automatically driven to the location of each mapped neuron. Computer-based image analysis of sequentially located, high resolution, small fields containing individual cell images is then performed. Each cell image is digitized and subjected to a dynamically determined video threshold. We establish that the number of pixels above threshold is proportional to the number of silver grains by calibration against manually counted grains in a representative sampling of labeled cells. A sampling of background fields is also digitized and the average grain count subtracted from each cell's grain count. Maps of cell distributions are then constructed, with cell marks color coded for relative mRNA levels. These maps yield information heretofor unavailable on regional distribution of quantitative cellular expression of specific mRNA in brain. This method should greatly facilitate the analysis of changes in gene expression during development and following various physiological and pharmacological manipulations.

302.16 *IN SITU* HYBRIDIZATION FOR TYROSINE HYDROXYLASE: HYPOTHALAMIC DISTRIBUTION AND SEXUAL DIMORPHISM WITHIN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS. R.B. Simerly and L.W. Swanson. Howard Hughes Medical Institute and The Salk Institute, La Jolla, CA 92037.

It is generally accepted that the hypothalamus contains 5 major dopaminergic cell groups which extend from rostral parts of the A14 and A15 groups, to the caudal A13, A12, and A11 cell groups. We have examined the distribution of cells within the hypothalamus that express mRNA encoding tyrosine hydroxylase (TH), the rate limiting enzyme for catecholamine biosynthesis, by applying *in situ* hybridization histochemistry in the rat brain with ^{35}S labeled cRNA probes (~10^7 cpm/ml). SP6 polymerase was used to transcribe antisense riboprobes from the 280 b.p. insert that was subcloned into the SP65 vector system by Drs. E. Lewis and D. Chikaraishi (see Lewis et al., J. Biol. Chem. 258:14632, '83) who generously provided this template for the present study. TH-mRNA containing cells were found in the region of each hypothalamic dopaminergic cell group with distributions that were virtually identical to those of TH-immunoreactive cells. Hypothalamic nuclei that contained heavily labeled cells include the anteroventral periventricular nucleus, suprachiasmatic preoptic nucleus, the preoptic and anterior parts of the periventricular nucleus, the paraventricular and arcuate nuclei, as well as the zona incerta, posterior hypothalamic area, and perifornical region of the lateral hypothalamus.

Of particular interest is the population of dopaminergic cells within the anteroventral periventricular nucleus (AVPv). As compared to males, the AVPv in female rats contains over 3 times as many dopaminergic cells, and this sexual dimorphism appears to be dependant on the perinatal levels of gonadal steroids (see Simerly et al., Neuroendocrinol., 40:501, '85). In order to evaluate the possibility of a similar sexual dimorphism in the number of cells that express TH mRNA we prepared 2 adjacent 1-in-3 series of 20µm thick sections through the AVPv of male and female Sprague-Dawley rats and processed one of the series for *in situ* hybridization histochemistry. The adjacent series of sections was processed for immunohistochemistry by using an antiserum against TH that was provided by Dr. T. Joh. Consistent with our earlier findings, over 3 times as many TH-immunoreactive cells were found within the AVPv of female rats as were found in males. In addition, a comparable sexual dimorphism was found for cells that express TH mRNA. No sexual differences were detected for either the number of TH-immunoreactive, or TH mRNA containing cells located within the ventrally adjacent suprachiasmatic preoptic nucleus.

These findings suggest that perinatal gonadal steroids specify the number of cells within the AVPv that express TH in detectable amounts by determining the number of cells that are capable of expressing sufficient quantities of TH message, as opposed to a sex-specific alteration in the post-translational processing of the enzyme.

302.17 TRANSNEURONAL REGULATION OF TYROSINE HYDROXYLASE mRNA EXPRESSION IN THE RODENT MAIN OLFACTORY BULB. M. E. Ehrlich, T.H. Joh, F.L. Margolis, and H. Baker. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021 and Roche Inst. Mol. Biol., Nutley, NJ 07110.

Peripheral deafferentation of the main olfactory bulb produced by destruction of olfactory sensory neurons results in profound alterations in a population of juxtaglomerular dopamine neurons. In surgically deafferented rats and three weeks following chemical deafferentation (intranasal irrigation with 0.17M $ZnSO_4$) in mice, activity and immunoreactivity of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis, were reduced to 10-20% of control levels. Several lines of evidence indicated that these dopamine neurons do not die. For example, in rat, the activity and immunoreactivity of aromatic amino acid decarboxylase, the second enzyme in dopamine biosynthesis, are only minimally decreased. In this study, we investigated the molecular mechanisms underlying the alteration in expression of the dopamine phenotype. Poly A^+ mRNA was isolated from control and chemically deafferented CD-1 mice, and the relative amounts of TH-like mRNA was determined by Northern blot analysis. The probe was a 400 bp nick-translated Eco RI - Kpn fragment of a rat TH cDNA. Hybridization to equal amounts of control mouse adrenal and olfactory bulb A^+ mRNA yielded a single band, of approximately the same intensity, at 1.9 Kb, the same size as that reported for rat adrenal and brain TH mRNA. Densitometric analysis of hybridization intensity to equal amounts of A^+ mRNA from control and chemically deafferented mouse olfactory bulb revealed an 85% decrease in hybridization. Therefore, a change in the stable amount of TH mRNA easily accounts for the loss in detectable TH protein. Further experiments are required to determine whether the alteration in TH mRNA levels may be attributed to a lower rate of TH gene transcription, or increased mRNA degradation. In addition, we demonstrated that olfactory marker protein mRNA, as previously reported (PNAS 84: 1704-1708, 1987), is present in olfactory bulb and interestingly, also decreased markedly following deafferentation. We conclude that transneuronal regulation of TH gene expression significantly affects TH activity and immunoreactivity in the rodent main olfactory bulb.

302.18 **TYROSINE HYDROXYLASE IN THE YOUNG AND AGED MOUSE BRAIN - HYBRIDIZATION HISTOCHEMISTRY AND IMMUNOCYTOCHEMISTRY.** B.K. Gupta*[1], M. Gupta[1], M.H. Stoler*[2], L.H. Fossom[3], and A.W. Tank[3] (SPON: S. Demeter). Departments of Neurobiology and Anatomy[1], Pathology[2], and Pharmacology[3], U of R Sch. Med., Rochester, NY 14642.

Tyrosine hydroxylase (TH) is the rate-limiting enzyme in the biosynthesis of catecholamines. Immunohistochemical studies have demonstrated the presence of TH-positive dopaminergic neurons in substantia nigra (SN) and the ventral tegmental area (VTA). It has been reported previously that the activity of TH in the striatum decreases in aged rats compared with their younger counterparts. The present study was undertaken to investigate if this decrease is due to: (a) altered TH levels in the neurons of SN, (b) altered expression for TH mRNA in the dopaminergic neurons of SN, or (c) a decrease in the number of TH-positive neurons, and if such a decrease also may be present in the VTA of aged mice compared with the young adults. Male C57BL/6 young adult (2-3 months old) and aged (24 months old) mice were divided into four groups. Fresh pieces of substantia nigra and the ventral tegmental area were dissected out from one group of animals, frozen, and processed to detect TH levels. A second group was perfused intracardially with 4% paraformaldehyde. The brains were removed, 10μm thick sections were cut through the SN and VTA, and processed for in situ hybridization using ^{3}H-RNA probe complementary to TH mRNA. ^{3}H-labeled sense probe was used as negative control. Alternate sections were stained immunocytochemically for TH. Brains from similarly perfused third group were removed, 40μm thick serial sections were cut through SN and VTA and processed for TH immunocytochemistry. Fresh tissue samples were taken from a fourth group and TH mRNA levels were measured from SN and VTA using dot-blot and Northern blot analysis. In both SN and the VTA, silver grains were observed over dopaminergic cells that were positive immunocytochemically for TH in the alternate sections. Although the number of cells expressing TH mRNA using in situ hybridization in SN and the VTA were similar in both the young and aged mice, we are further investigating if the expression of TH per cell in the two age groups varies. Results of these studies will be presented.

302PO MOLECULAR AND GENETIC ANALYSIS OF A GENE SELECTIVELY TRANSCRIBED IN PRIMARY NEURAL CULTURES OF *DROSOPHILA MELANOGASTER*. E.K. Neumann*, A. Furst*, and A.P. Mahowald*. (SPON: J. Kriegler) Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio 44106.

We have previously described the isolation of a genomic clone containing a gene whose transcript is selectively expressed in embryonic neural cultures of *Drosophila*. The gene maps to the 23A region of the second chromosome near the Decapentaplegic complex. A 2.3 kb transcript appears at low levels in early embryos and increases at 14 hrs of embryogenesis. This is approximately the time we observe a five-fold increase of the transcript in the neural cultures. In addition, a 1.3 kb transcript, whose spatial and temporal pattern of expression is distinct from the 2.3 kb transcript, is transcribed nearby and in the opposite direction.

Initial results of strand-specific *in situ* hybridization experiments with cultured cells and embryonic sections reveal a localization of the transcript to neural cells and the salivary gland. Cultured cells show labelling only in a subset of neurons in some differentiated neural clusters and not to any other cell types. Hybridization with the opposite strand results in labelling of non-neural cell types and not neural clusters.

Three genetic deficiencies uncovering this region have allowed us to screen a set of 27 lethal mutations obtained from W. Gelbart, which are potential candidates for this gene. Nine of these mutants belong to one complementation group. Four out of the nine show lethal neural defects in embryos as visualized by anti-HRP. Northern, Southern, and *in situ* hybridization analyses of the mutants are now underway to determine a correlation between the mutants and the gene.

303.1 SACCADIC REACTIONS TO DOUBLE-STEP STIMULI: THE INFLUENCE OF MOVEMENT AMENDMENT DIRECTION. G.K. Kerr* and R.J. Lockwood*. (SPON: S. Dunlop). Neuromuscular Lab., Dept. of Human Movement Studies, Univ. of Western Australia, Nedlands 6009, Australia.

The response of the saccadic control system to continuing (C) or reversing (R) a previously initiated saccade was assessed by means of double-step stimuli. Six subjects practised an initial 15 degree horizontal saccade to a central 0.12 degree target on day 1. On two subsequent days a 10 degree C or R amendment of the initial saccade was required. Initial saccades were triggered by a pulse step of the start target and for movement amendments by a second target step at one of eight different inter-stimulus intervals on 57% of trials. Eye movements were recorded by EOG with head movements being restricted by a rigid head and chin support.

Plots of initial movement amplitudes and inter-response intervals as a function of the amount of shared processing time (TO) of the two stimuli revealed two phases of movement amendment. When TO was less than 105ms (SD=18.85) the initial saccade was lengthened (C) or shortened (R) prior to producing a second saccade. This appeared to be accomplished by modulation of the peak velocity. As TO decreased from 105ms the time taken to produce a second saccade increased to reach a peak at almost zero overlap (TO= -1.29ms, SD=8.77). This rate of increase was greater for R than C amendments ($t(5)=3.759$, $p=.0132$).

The results support a continuous parallel processing model of visual afferent information (Becker and Jurgens, Vis. Res. 19:967-983, 1979). An initial refractory period, during which a second saccade cannot be generated, results from a prior modification of the initial saccade. This period is analagous to a duty cycle of action, reported for ballistically initiated arm movements, which must be completed before a second response can occur (Terzuolo et al., Brain Res. 58:217-222, 1973). Subsequent delays are dependent on the direction of the amendment and indicate that the initial patterns of neural and muscular discharge may be the limiting factors.

303.2 SACCADES TO TARGETS IN VISUAL FIELDS CONTRALATERAL TO OCCIPITAL LOBECTOMIES A.D.Epstein*, R.J.Tusa, S.E.Gordon*, and N.R.Miller* (SPON: R.S.Fisher). Departments of Neurology and Ophthalmology, Johns Hopkins University, Baltimore, Maryland 21205-2191.

Previous studies suggest that patients with occipital lobe strokes have the ability to make accurate saccades to targets in the opposite, "blind" visual field. Several objections have been raised to these studies: 1)possibility of residual striate cortex, 2)scatter of target light into the intact field, 3)failure to stabilize the head, and 4)lack of eye movement recordings.

We tested three patients with complete homonymous hemianopias produced by 6, 7.5, and 10 cm occipital lobectomies performed 14, 8, and 10 years before entry. Each target was presented unpredictably 10-60° away from the previous target in the horizontal meridian, and was generated by either 3 fL light-emitting diodes (LED) or 1000 fL He-Ne laser spots. The patient had to fixate the target light before being presented with a new one. Each patient performed 700-900 trials. The head was stabilized with a bite bar, and eye movements were recorded by electro-oculography.

With LED targets there was a weak correlation of the amplitude of the first saccade and target step size into the blind field. The mean value of all first saccade amplitudes to 20, 40, and 60° target steps from all positions is shown in line A of the table. This trend disappeared when the amplitudes of the first saccade initiated from only one orbital position were analyzed (line B). This suggests that these were target-searching saccades whose amplitudes were affected by the orbital position from which the saccade started. With laser targets the amplitude of the first saccade in one patient correlated with target step size even for saccades initiated from the same orbital position (line C). This patient had the smallest lesion and was age 9 at operation, whereas the others were 14 and 25.

These findings suggest that some occipital lobectomy patients have the ability to make reasonably accurate saccades to targets presented in their blind fields. This ability may depend on high stimulus intensity, minimal lesion size, and minimal age at operation.

Target step size ->		20°	40°	60°
Amplitude of first saccade	A	12.8	16.5	17.1
	B	17.3	21.9	17.1
	C	17.5	23.9	44.3

303.3 **SACCADIC EYE MOVEMENTS WITHOUT VISUAL FEEDBACK: MEMORY-LINKED SENSORIMOTOR SPATIAL TRANSFORMATION.** J.W.Gnadt, R.M.Bracewell*, R.A.Andersen. The Salk Institute, La Jolla, CA 92037

Three rhesus and 5 human subjects were trained to make saccade-like movements to remembered target locations defined by visual targets. Experiments were performed in a dark room. Because no visual feedback was available during the delay between target presentation and eye movement, nor during the eye movement itself, the task afforded a behavioral measure of memory-linked spatial sensorimotor transformation. Eye movements were measured using the scleral search coil technique. Compared to control saccades made to visible targets, saccades to remembered target locations were grossly spatially distorted (upwards saccades hypermetric, downward saccades hypometric), often had markedly curved trajectories, had reduced velocities, and were more variable. The precise form of the distortion was idiosyncratic. Subjects received different degrees of feedback of targeting accuracy: For monkey M02, the target came back on after the eye movement. Monkeys M13 and M88 were rewarded for successfully completing the movements with a spatial accuracy of ± 10 deg. or ± 20 deg., respectively; no visual feedback was presented. The distortion was smallest for monkey M02 (mean vertical error = +2.0 deg., $p<.01$; mean horizontal error = +0.7 deg., NS), intermediate for monkey M13 (vertical = +5.8 deg., $p<.01$; horizontal = +1.7 deg., $p<.01$), and largest for monkey M88 (vertical = +8.7 deg., $p<.01$; horizontal = +3.5 deg., $p<.01$). Humans received no feedback during trials. For humans, the mean errors were +2.2 deg. vertical ($p<.01$), and +2.0 horizontal ($p<.01$). There were significant nonlinear interactions between direction and length of eye movements for the 2 monkeys and 2 humans tested. Although most movements had an upward component of error, each direction of movement had a unique direction and magnitude of error. Main sequence analysis revealed that movements to remembered targets had slower velocities than corresponding movements to visible targets. The error accumulated rapidly for the first 500 ms of response delay with little additional accumulation. The addition of visual cues improved performance significantly in the one monkey and one human tested: The spatial accuracy and movement dynamics improved slightly in a dimly lit room and substantially when a random dot pattern was superimposed on the viewing screen. Analysis of equivalent eye movements originating from different orbital positions demonstrated similar, though statistically different, patterns of distortion in each of 2 monkeys and 2 humans tested. The similarities demonstrated that the distortions were oculocentric (i.e. retinotopic or related to movement vector) and not to a tendency to look towards a specific orbital or spatial position. The differences, however, suggested that the trajectories of movement were not the only factors involved in the distortions.

303.4 EYE MOVEMENTS EVOKED FROM SITES BETWEEN THE FRONTAL AND SUPPLEMENTARY EYE FIELDS. A. R. Mitz and M. Godschalk. Laboratory of Neurophysiology, National Institute of Mental Health, Bethesda, MD 20892.

Two eye fields have been identified in the monkey frontal lobe with the aid of low current (under 50 μA) microstimulation: the frontal eye field (FEF) in the rostral bank of the arcuate sulcus, within area 8 (Bruce et al., J. Neurophysiol. 54:714, 1985) and the supplementary eye field (SEF), on the medial aspect of area 6, slightly rostral to the FEF (Schlag and Schlag-Rey, J. Neurophysiol. 57:179, 1987). By using a modified microstimulation technique (Mitz and Wise, J. Neurosci., 7:1010, 1987) we have found a continuous representation of eye movements from the FEF to the SEF.

A recording chamber was implanted over areas 6 and 8 in each of 2 rhesus monkeys. Current pulses of up to 65 μA were delivered through glass-coated platinum-irridium electrodes every 200 μm in depth along 150 tracks in each monkey. The stimulation electrodes had tip exposures of 1000 μm^2, 5 to 10 times greater than typically used for microstimulation. Constant current, biphasic (negative-positive, 0.2 ms each phase) pulses were delivered at 330 pulses/s in trains of 31 pulses. Eye movements were watched by two observers in both monkeys and, in the second monkey, recorded by infrared oculometry.

Due to the effectiveness of the unique electrode and long stimulus trains, the boundaries of the FEF and of the SEF were not distinct. Including the FEF and SEF, conjugate eye movements were evoked from a 3-6 mm wide cortical strip, 21 mm in mediolateral extent. Movement thresholds were usually below 40 μA, but only occasionally below 15 μA outside area 8. Stimulation at sites in medial area 8 and adjacent area 6 evoked either conjugate eye movements, orofacial movements, or both. Eye movements evoked from this general region were typical for FEF stimulation sites, i.e. repeated stimuli delivered at a given site evoked conjugate eye movements of a fixed direction and angular displacement. More medially, evoked movements were more like some described for stimulation in the SEF, i.e. conjugate saccades towards a single final (contralateral) eye position. The direction, displacement and reliability of each saccade depended upon the initial eye position. In addition, saccades seemed to be less reliably evoked if the animal was visually fixating or tracking an object in space. Saccades were more reliably evoked if the initial eye position was in the ipsilateral hemifield.

From these results we infer that there is a continuum of eye movement representation from the FEF to the SEF, and possibly a gradual functional transition between these two areas.

303.5 FUNCTIONAL AND ANATOMICAL RELATIONS OF CENTRAL THALAMUS AND CORTICAL OCULOMOTOR AREAS. M. Schlag-Rey, I.M. Jeffers, S. Sampogna, and J. Schlag. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024-1763.

The central thalamus (intralaminar and paralaminar complex = IMLc) is known to carry oculomotor-related signals. Connections of the IMLc with the major cortical areas controlling the gaze - frontal eye field (FEF), supplementary eye field (SEF), inferior parietal lobule (IPL) - have been demonstrated but which signals are transmitted through which projections is unknown. The purpose of this study was to clarify our understanding of the cortico-thalamic network concerned with eye movements by using a combined physiological and anatomical approach.

In 4 trained Macaca nemestrina implanted with eye coils the IMLc was probed with microstimulation (20 to 40 cathodal pulses, 0.2 ms duration, 250 Hz, 10-80 μA). A consistent topographical organization was observed: goal-directed saccades were evoked caudally and laterally, fixed-vector saccades rostrally and medially. Following the systematic mapping of the IMLc by microstimulation in one hemisphere, a small injection of tracer (WGA-HRP or Bisbenzimide) was placed in SEF or FEF, in the same or opposite hemisphere. Control injections were placed in SMA or area 4 (2 additional monkeys).

WGA-HRP injected at a focal SEF site yielding goal-directed saccades labeled the caudal IMLc near or at the site where similar goal-directed saccades had been evoked. This result parallels our previous finding that units encoding eye position are more frequently encountered in the caudal part of the IMLc than in the rostral one. Label from SEF sites yielding small, fixed-vector saccades was found in more anterior and medial parts of IMLc but not at its most rostral level.

A small injection in the FEF region known to produce small saccades (confirmed by the labeling of the anterior superior colliculus) produced discrete labels in the mediodorsal and intralaminar nuclei, partially overlapping the region labeled by SEF. Some thalamic sites (particularly ventral ones) yielding small saccades (<5°) at low threshold (20 μA) were not labeled by either FEF or SEF injections.

In contrast with SEF and FEF results, injections placed in area 4 and SMA failed to label the oculomotor IMLc. Compared at the same antero-posterior levels, small injections of FEF, SEF, SMA and area 4 labeled distinct thalamic zones organized from the most medial (FEF) to the most lateral (area 4). (Supported by USPHS grants EY02305, EY05879 and NS07898).

303.6 *VISUAL NEURONS IN THE SUPERIOR TEMPORAL SULCUS (STS) OF BEHAVING MACAQUE MONKEYS CAN DISCRIMINATE PASSIVE AND SELF-INDUCED RETINAL SLIP.* *R.G. Erickson*, P. Thier* and W. Koehler*. (Spon: M.Slaughter). Department of Neurology, University of Tübingen, 7400 Tübingen W. Germany.*

The ability to maintain a constant spatial reference requires discrimination between externally and self-induced retinal slip.

*To test the hypothesis that this discrimination is reflected in the response profiles of directionally selective cortical visual neurons, the activity of single units in the motion sensitive visual areas of the STS was recorded and their responses to passive and self-induced retinal slip were compared. The cells recorded so far appear to fall into two broad categories: 1) Large field (LF) directional cells (eg 40*40deg or larger) on the anterior bank that respond to passive movement of any size stimulus (up to 90*90deg) in the preferred direction, and at least some of which respond even to rotation of a fullfield optokinetic drum. Despite the lack of evidence for inhibitory surrounds, none of the LF cells tested responded to the same visual movement occurring as a consequence of active eye movements. 2) Small field (SF) directional neurons (eg 5*5deg or smaller, less than 10deg eccentricity) on the posterior bank, a portion of which responded only to passive visual stimulation and not to stimulus movement generated by active eye movements. Some of these cells did not respond to large patterns and may have silent inhibitory surrounds. Other SF neurons responded identically to both active and passive stimulation.*

Our results clearly show that many neurons in the STS can discriminate self-induced and passively generated retinal slip. There are two mechanisms that could account for this ability. One is the reception of an efference copy signal (Holst, von and Mittelstaedt, Naturwissenschaften 37,1950). The recent finding of motion sensitive cells with antagonistic silent inhibitory surrounds, however, has led to the suggestion that purely visual mechanisms could also cancel the effect of self-induced retinal slip (Allman et al., Ann. Rev. Neurosci. 8, 1985), thereby mimicing the effect of an efference copy. Although the responses of SF neurons could be accounted for by visual mechanisms, the response properties of LF neurons leave open the possibility that they receive a true efference copy signal.

303.7 INTERACTION OF VISUALLY GUIDED SACCADES WITH SACCADES INDUCED BY ELECTRICAL STIMULATION OF POSTERIOR PARIETAL CORTEX. D.D.Kurylo* (SPON: A.A.Skavenski). Psychology Department, Northeastern University, Boston, MA 02115.

This was an extension of my prior work which demonstrated that saccades can be elicited by micro-electrical stimulation of two discrete zones of posterior parietal cortex (PPC). The extension involved exploring the way in which these electrically induced saccades interact with normal visually guided saccades. Electrical stimulation was made to sites within PPC of two alert nemestrina monkeys while they performed saccadic eye movements to follow a target which was stepped to an eccentric position. Onset time of electrical stimulation was varied to occur before, during, or after the onset of eccentric visual targets. Stimuli were arranged to yield saccades in orthogonal directions. There was a competition between the two types of saccades which prevented their simultaneous production. When electrical stimulation started anytime during the latency period of the visual saccade, that saccade was aborted and only the electrical saccade appeared. Vector summation of the two saccades was never seen. With sufficient temporal separation of the two stimuli, both saccades occurred separated by a latency of no less than 170 msec. Visually guided saccades remained accurate even when the visual target went off before either saccade started. These interactions of electrical stimulation and visually guided saccades suggest that the execusion of these two types of saccades are mutually exclusive, probably due to the utilization of common elements during their programming.

303.8 DOES MICROSTIMULATION GENERATE THE TRAJECTORY OR SPECIFY THE GOAL OF FIXED-VECTOR SACCADES? J. Schlag and M. Schlag-Rey. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024-1763.

Electrical stimulation (250 Hz) was performed at several sites of the monkey's forebrain which produced fixed vector saccades when the eyes were steady at stimulation onset. Twelve sites were studied in the central thalamus, 4 in the arcuate frontal eye field, and 11 in the supplementary eye field. Latencies ranged from 60 to 120 ms, threshold current from 10 to 100 μA. When the same stimulus trains were applied during or immediately after a spontaneous eye movement, the saccade trajectory was considerably modified in all cases: the eyes were driven from wherever they happened to be after the spontaneous movement to the destination where the fixed-vector saccade would have brought them, had no spontaneous movement occurred. Thus, the transformed trajectory of the evoked saccade compensated for the preceding spontaneous deviation of the eyes. This consistently occurred if the stimulation started within 10 to 150 ms from the onset of the spontaneous saccade. At 150 to ~ 200 ms intervals, the saccade course became less predictable. After ~ 200 ms, evoked saccades recovered their fixed-vector characteristics: they moved the eyes for a fixed distance in a fixed direction from the position after the spontaneous saccade.

This finding has several implications: 1) It suggests that the "fixed-vector" saccades studied were directed toward a goal defined with respect to an eye position sampled before the spontaneous movement. Our hypothesis is that the electrical stimulation evoked a retinotopic goal (such as the retinotopic representation of a target) whose spatial coordinates were then computed at a further stage to calculate the appropriate saccadic vector. 2) The signal of eye position which serves as reference to locate the goal must be internally delayed to compensate for the long time taken for transmission and processing of visual input signals.

Evoked goal-directed saccades (converging toward a point in space) were not modified in their course when coming on the trail of a spontaneous eye movement. Theoretically, fixed-vector saccades due to the elicitation of a motor error signal should not be altered either. If this is confirmed, the present paradigm may be valuable for testing whether a given brain site processes a visual error or a motor error signal. (Supported by USPHS grants EY02305 and EY05879).

303.9 LATERAL HEAD AND BODY MOVEMENTS DUE TO ELECTRICAL STIMULATION OF FIVE SEPARATE AXON BUNDLES. E.J. Tehovnik, J.S. Yeomans and K. Buckenham*, Dept. of Psychology, Univ. Toronto, Toronto, Canada M5S 1A1.

Lateral eye, head, and circling movements are evoked by electrical stimulation in many brain regions from the frontal cortex to the pons. These movements are due to activation of at least five separate axon bundles in rats. Videotapes showing circling movements in each of these bundles have been analyzed and are available. Within each bundle, similar behaviors and refractory period distributions are observed. Collision-like effects are observed within each bundle when stimulating two points concurrently, which defines the trajectory of these axons, and allows estimation of the distribution of conduction velocities (e.g., Yeomans & Linney, 1985). Collision-like effects have never been seen when stimulating between different bundles.

The most reliable lateral movements occur in the uncrossed tegmentobulbar bundle near the midline anywhere from rostral midbrain tegmentum to caudal pons. No habituation to maintained stimulation occurs. The conduction velocities range from 2 to 20 m/sec. Less reliable circling occurs in superior colliculus, because two bundles producing opposite movements originate in the tectum. The crossed tectoreticulospinal bundle produces contraversive circling and dominates in most sites (Sahibzada et al., 1986; Ellard & Goodale, 1986). The uncrossed tectopontine bundle produces ipsiversive turning which is less smooth and more "cringing". Ipsiversive circling is observed when the crossed axons are cut. The conduction velocities of these tectal axons are slightly slower than the tegmentobulbar axons.

Over 90% collision has been obtained between substantia nigra and internal capsule (Tehovnik & Yeomans, 1986). Habituation to maintained stimulation occurs in 30-90 sec. The conduction velocities (0.9 to 4.4 m/sec) and trajectories are similar to striatonigral axons, although too fast to be nigrostriatal dopamine axons. The only lateral movement sites producing collision with anteromedial cortex are in the rostral striatum, suggesting that the corticostriate path also produces circling. The responses are very unreliable, require high currents, and often seizures are seen. Habituation occurs within 10 sec.

We propose that lateral eye, head and body movements are due to activation of corticostriate, striatonigral, tectopontine, tectoreticulospinal or tegmentobulbuar bundles.

303.10 MULTIMODAL INTERACTIONS IN SUPERIOR COLLICULUS: INDEPENDENT EFFECTS ON ON-, OFF-, AND PREMOTOR RESPONSES OF INDIVIDUAL CELLS. Carol K. Peck and Franklin S. Wartman III. School of Optometry, University of Missouri-St. Louis, St. Louis, MO 63121.

Most neurons in the intermediate and deep layers of the superior colliculus respond to both the onset and offset of visual targets through their receptive field. Moreover, visual, auditory and somatosensory inputs converge on single cells in these laminae, and their simultaneous presentation can markedly enhance or depress the activity of a given neuron. The present study shows that individual cells often show selective enhancement of their on-, off- and premotor responses.

Multimodal (visual/auditory) cells were identified in extracellular recordings from 3 chronically-prepared, alert, trained cats. The head was free to move in the horizontal plane (up to ± 45 deg.). Horizontal and vertical components of gaze (eye position in space) were measured with a scleral search coil technique. Horizontal head position was measured with a low-torque linear potentiometer, and horizontal eye position (in the head) was calculated from these signals. Cells were tested while the cat performed a delayed saccade task. Gaze saccades (with head free) and eye saccades (with head fixed) were made toward, or close to, the center of the cell's movement field. Response latency, duration, mean impulse and number of impulses per trial were measured. Single-modality and combined-modality trials were interleaved.

Forty-five cells were studied, and complete data sets (on-, off- and movement-related) were collected from 25 of these. In a significant number of cells (11/25) for which complete data sets were collected, presentation of multimodal (visual/auditory) stimuli had differential effects upon the on-, off-, and movement-related responses of individual collicular neurons. Multimodal depression was generally greatest in the on-responses of cells showing long-latency tonic responses to the onset of a target in either modality. Such cells typically discharged phasically in response to the offset of a target in either modality and exhibited little, if any, multimodal enhancement (or depression) of the off-response. Movement-related discharges were often more vigorous with visual-auditory targets than with either modality alone.

These data suggest that, in some collicular neurons, neither the presence nor the sign (enhancement or depression) of multimodal sensory interactions permit simple predictions of the effects of multimodal targets on that cell's premotor responses during controlled orienting behavior. Supported by USPHS grant NS-21238 and by the Weldon Spring fund of the University of Missouri.

303.11 **THE EFFECT OF FRONTAL EYE FIELD AND SUPERIOR COLLICULUS LESIONS ON THE SACCADIC AND PURSUIT EYE MOVEMENT INITIATION.** P.H. Schiller, N.K. Logothetis. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA

In humans and monkeys smooth-pursuit eye movements (EM) can be generated with considerably shorter latencies than can saccadic EM. This fact is one of several observations suggesting that the pursuit and saccadic systems are controlled by different neural mechanisms. Ablation studies have shown that the latency of saccadic EM in monkeys is increased following superior colliculus (SC) but not frontal eye field (FEF) lesions; FEF lesions on the other hand produce deficits in predictive pursuit EM, suggesting that this area may be involved both in saccadic and pursuit EM generation. In order to further examine this question the effect of FEF and SC lesions were examined on the latency of pursuit and on saccadic EM initiation.

Monkeys were trained to fixate a target. After a variable delay the target was turned off and reappeared several degrees to the left or to the right while performing a ramp movement at various velocities. The animal's task was to saccade to the moving target. Accomplishment of the task was rewarded with drops of apple juice. Because of the shorter latency of pursuit initiation, pursuit movement began prior to the saccade to the moving target (usually within 80 to 100 ms in our situation) and then continued after target acquisition suggesting that the pursuit system can use pre-saccade image velocity information from peripheral retina to set the pre and post-saccadic pursuit velocity whenever a ramp movement is initiated in the periphery. The effects of FEF and SC lesions were determined on the performance of this task.

Our results showed increased saccadic latencies following SC lesions and changes in the metrics of saccades following FEF lesion. The pursuit performance of the animal was unaffected by either lesion. Both computation of the pre-saccadic velocity and saccade size through this velocity information were unaffected.

303.12 SACCADE-RELATED BURST CELLS IN THE SUPERIOR COLLICULUS: RELATIONSHIP OF ACTIVITY WITH SACCADIC VELOCITY. W.H. Rohrer*, J.M. White*, and D.L. Sparks. Department of Physiology and Biophysics, University of Alabama at Birmingham, Birmingham, AL 35294.

Reversible inactivation of the superior colliculus (SC) produces dramatic alterations in the direction, amplitude and velocity of visually-guided saccades (Hikosaka & Wurtz, 1986). However, cells related to saccadic velocity have not been reported in the primate SC. The saccade-related burst cells of the SC generate a high frequency discharge beginning 18-20 msec before saccade onset. This saccade-related burst encodes the direction and amplitude of a saccade by the location of the active neuronal population, not by the frequency or other characteristics of the burst (Sparks & Mays, 1980). Sparks and Mays failed to find a relationship between saccadic velocity and the parameters of the burst (Sparks & Mays, unpublished observations) but they studied only visually-guided movements which have a narrow range of velocities for equal amplitude movements. The range of saccadic velocities can be extended by requiring saccades to the remembered location of a target as well as saccades to a continuously present target. We used these tasks to re-examine the burst characteristics of saccade-related cells in the SC preceding saccades covering a wide range of velocities.

Rhesus monkeys, with implanted scleral search coils, were trained to perform two behavioral tasks: one requiring a saccade to a continuously present visual target (visually-guided saccade), the other requiring a saccade to the location of a briefly flashed target (remembered saccade). Extracellular recordings were made from single units in the deep layers of the superior colliculus during visually guided and remembered saccades.

We selected remembered and visually-guided saccades matched for direction and amplitude (within 1 °). The velocity of remembered saccades was lower and their duration lengthened relative to visually-guided saccades. The mean spike rate and peak frequency (for the interval beginning 30 msec before saccade onset and ending 20 msec after saccade onset) of most saccade-related cells were positively correlated with the peak velocity of the saccade. Some cells which burst for visually-guided saccades did not burst at all during remembered saccades. Only a few cells fired as vigorously before remembered as before visually-guided saccades.

These results (and those of Berthoz et al., 1986 for the cat) suggest that in addition to encoding the amplitude and direction of saccades by location of cell activity within the topographic map, the superior colliculus can influence saccadic velocity. Variations in saccadic velocity may reflect changes in both the size and level of activity of the active population of collicular burst neurons. (Supported by NIH EY05486 and EY01189).

303.13 **SACCADE ENDPOINT SCATTER AND PROPERTIES OF THE COLLICULAR MOTOR MAP.** J.A.M. Van Gisbergen* and A.J. Van Opstal*, (SPON: C. Gielen). Dept. Med. Phys. Biophys., Univ. of Nijmegen, 6525 EZ Nijmegen, The Netherlands

According to Deubel (1987), human visually-elicited saccades have relatively more scatter in amplitude (R) than in direction (Φ). We have found that this holds also for saccades obtained by collicular electrical stimulation in the rhesus monkey. To explore how collicular mechanisms may cause saccade precision to be different along the R and Φ dimensions, we have made simulations with a slightly extended version of a recent model for the role of collicular ensemble coding in the saccadic system (Van Gisbergen et al., Neuroscience, 1987). This model has an anisotropic logarithmic mapping from the retina onto the motor colliculus whereby the target creates a dome-shaped motor activity profile. The four parameters specifying the mapping and the spatial extent of the motor activity were estimated earlier by Ottes et al., (Vision Res., 26: 857-873, 1986) from electrophysiological data. The efferent section of the model specifies how neural activity in the motor map is translated into a normometric movement. To account for saccade endpoint scatter, the location of maximum motor activity has a small trial-to-trial variability around the mean position. This noisy variation in the afferent mapping of the model is characterized by a Gaussian distribution (standard deviation: s mm) which is translation invariant when target position is changed.

Simulations show how saccade endpoint scatter depends upon the properties of the model: 1) The nonhomogeneity of the logarithmic afferent mapping causes endpoint scatter to increase with saccade amplitude; 2) The amount of R vs Φ scatter depends upon the degree of anisotropy in the afferent mapping.

We have measured R- and Φ-scatter of visually-elicited saccades (2<R<50 deg) in three human subjects with the scleral coil technique. The results confirm Deubel's finding and can only be matched by the model if the collicular magnification factor for Φ exceeds magnification for the R dimension. The amount of R-scatter in the data was roughly proportional to R but, unlike in the model, showed a tendency to saturate at very large amplitudes (R = 50 deg). When expressed in collicular dimensions the saccade endpoint scatter appears to be quite small (s = 50 μm) compared with the width of the dome shaped motor activity profile and the size of the collicular map which are both in the order of millimeters. Consequently, if the collicular motor map is indeed anisotropically organized, a small amount of scatter in the location of recruited motor activity would already be sufficient to explain our saccade-scatter data.

303.14 HOW TO COMPUTE EYE POSITION QUATERNIONS. D. Tweed* and T. Vilis. Depts. of Physiology and Ophthalmology. University of Western Ontario, London, Ontario, Canada N6A 5C1.

We have argued elsewhere[1] that quaternions, which express rotations in terms of axes and amplitudes, are the most convenient and meaningful representation of eye position in three dimensions. One advantage is that quaternions are more symmetric than other representations. For example, the Fick system defines horizontal position with respect to a head-fixed axis and torsion with respect to an eye-fixed axis. If experiments show that these two components behave differently, it may not be clear how much of the difference is due to their dissimilar definitions. With quaternions all components are defined using a single rotation axis.

In this poster we describe how to compute eye position quaternions and angular velocity vectors from the outputs of two search coils on one eye in two magnetic fields; the coils need not be orthogonal, nor need their locations on the eye be known. We describe three data processing programs. The first computes eye position quaternions and velocities. The second finds primary position using the quaternions for several gaze directions. The third transforms the eye position quaternions so they are expressed relative to primary position (i.e. so that primary position is represented by the quaternion 1) and moves the quaternions and velocity vectors into a coordinate system where Listing's plane is the yz plane. The method's accuracy is chiefly limited by non-uniformity of the magnetic fields; within 45° of centre, we can compute rotation amplitudes to within about 1° and axes to within 2°. In some cases the data processing can be simplified without an excessive loss of accuracy: if the two search coils are orthogonal and the eye is within 20° of centre, then three coil signals, appropriately scaled but with no other processing, give the vector of the eye position quaternion with an error of less than 11%; and differentiating the signals yields a reasonable estimate of eye velocity. Other coil arrangements or larger eccentricities would increase the error.

Velocity plots computed by the three programs show that the axes of human and monkey saccades tilt out of Listing's plane as predicted by a feedback model[1] in which motor error is the quotient of desired and actual eye position. The axes show that the saccadic eye velocity signal has three degrees of freedom, and hence that the two pools of nonhorizontal short lead burst neurons function independently for saccades.

303.15 VOLUNTARY, VESTIBULAR-CONTINGENT SACCADES TO JUST VIEWED EARTH-FIXED TARGETS FOLLOWING HEAD MOVEMENT IN DARKNESS. J. Bloomberg*, G. Melvill Jones and B. Segal. Aerospace Med. Res. Unit, Dept. of Physiol., McGill Univ., Montréal, Québec, Canada H3G 1Y6

To foveate a target with head fixed, the superior colliculus appears to utilize a retinal error (retinotopic) signal together with an internal signal representing eye position re head (craniotopic) to specify ocular saccade direction and amplitude (e.g. Mays & Sparks, J. Neurophysiol. 43:207, 1980). However, when the head is free to move, saccade generation requires the addition of a head movement signal to operate in a spatiotopic frame of reference. The present study investigates whether a vestibular response to head rotation could suffice to generate volitional saccades to a just-viewed earth-fixed target.

Human subjects sat on a servo-controlled rotating chair, with head fixed to it by a dental bite. First, a central earth-fixed target was visually fixated. Fixation was then transferred to a low intensity (LED) head-fixed target just under the first. The subject was then passively rotated in darkness to the right or left through one of five randomly chosen amplitudes (5°-30°), while suppressing the vestibulo-ocular reflex by fixation on the head-fixed target. After cessation of head rotation and while still in the dark, a voluntary saccade was made to the remembered earth-fixed target. Finally, in the light, the actual earth-fixed target was re-foveated to record the oculomotor error. For 9 subjects, angular amplitude was controlled by varying the duration of turn (0.1-0.6s) at constant velocity (40°/s). For 4 subjects, velocity was varied (20°/s-80°/s) with constant duration of turn (0.35s). Accuracy of saccades to the just viewed target was quantified by saccadic gain calculated as the amplitude of the saccade in the dark divided by the ideal amplitude to have attained the target (i.e. unity gain = perfect target acquisition). All subjects consistently made appropriately-sized saccades towards the earth-fixed target, in the dark, independent of whether the controlled variable was duration or velocity. Mean saccadic gain in variable duration tests was 1.01 ± 0.016 (SE), n = 533, and in variable velocity tests was 1.00 ± 0.014, n = 218.

Since the saccade was generated in darkness and eye movements were suppressed during head rotation, it is inferred that the relevant input to the saccadic system most probably derived from a memory of the preceding vestibular response to head rotation. Hence we conclude that a remembered vestibular-contingent input to the saccadic system can suffice for the generation of appropriate volitional saccades within a spatiotopic frame of reference. More generally the vestibular-contingent signal could provide the necessary input for spatiotopic saccadic gaze control during head movement (Guitton et al. J. Neurophysiol. 52: 1030, 1984).

303.16 **SPATIAL PROPERTIES OF SIGNALS CARRIED BY SECOND ORDER VESTIBULOOCULAR RELAY NEURONS IN THE CAT.** B. W. Peterson, W. Graf and J. F. Baker, Dept. of Physiology, Northwestern Univ. Med. School, CHI, IL 60611 and Rockefeller Univ., NY, NY, 10021.

We have continued experiments to determine at what levels in the 3-neuron vestibulooocular reflex arc the sensorimotor transformation from vestibular to extraocular muscle coordinates is implemented. Activity of second-order vestibular neurons, identified by their monosynaptic response to electrical stimulation of the labyrinth, was recorded intra-axonally using micropipettes filled with horseradish peroxidase (HRP) dissolved in KCl-Tris buffer solution. Responses to natural vestibular stimulation were recorded during 0.5 Hz rotations in the horizontal plane and in 4-20 vertical planes. Selected neurons were stained intracellularly with HRP for single cell morphology which established their projections to oculomotor nuclei.

To date we have recorded from 50 second order vestibulooocular neurons (2VONs) recorded in the medial longitudinal fasciculus between abducens and trochlear nuclei. Neurons were classified according to whether they were activated from the labyrinth ipsi- or contralateral to the recording site and according to the canal from which they received their strongest input. Sixteen 2VONs received their primary input from the ipsi- or contralateral anterior canal (AC). Eight non-convergent AC neurons responded maximally to rotation in a plane within 10° of the AC plane while 4 AC neurons received sufficient convergent input from the orthogonal vertical canals to shift their plane of maximum response more than 10° from the AC plane. These shifts were symmetrical about the AC plane so that the population average was within 5° of that plane. Of 23 ipsi- and contralateral posterior canal (PC) neurons, 7 were non-convergent while 11 received sufficient convergent input from the orthogonal vertical canals to shift their plane of maximum response more than 10° from the PC plane. The shift was almost always towards the roll plane so that the population average was 3.5° from the activation plane of the oblique eye muscles. The rotational responses of 4 AC and 10 PC neurons indicated that they received convergent input from the horizontal canals. However, when responses were averaged, these horizontal responses tended to cancel leaving little net population response to horizontal rotation. We also encountered 11 ascending axons of second order neurons activated primarily from the horizontal canals. Six of these received significant input from the vertical canals but the mean population response was within 4° of the horizontal canal plane.

While some of the neuronal populations are still small, the data show that multiple canal convergence upon 2VONs can shift the response of vertical canal neurons into the plane of the oblique eye muscles. We conclude that this convergence is one mechanism for generating the appropriate spatial response of these muscles. Interestingly, we have never found an AC or PC neuron whose response was shifted far enough to align with the plane of vertical rectus muscles. Motoneurons of these muscles often receive convergent input from second order neurons of all 4 vertical canals. Thus their spatial properties may depend upon the bilateral divergent projections of second-order AC and PC neurons.

303.17 RESPONSE PROPERTIES OF HEAD-AND-EYE-VELOCITY CELLS IN THE NUCLEUS PREPOSITUS HYPOGLOSSI AND THE MEDIAL VESTIBULAR NUCLEUS OF THE BEHAVING MONKEY. J.L. McFarland and A.F. Fuchs. Regional Primate Research Center and Department of Physiology & Biophysics, University of Washington, Seattle, WA 98115.

The vestibulo-ocular reflex (VOR) stabilizes images of stationary objects on the retina as the head moves. When the head rotates, the VOR generates compensatory eye movements which rotate the eyes in the opposite direction. In order to stabilize the image of an object that is moving with the head this reflex must be suppressed.

The VOR is served by a three neuron arc that includes the eighth nerve, vestibular nuclei interneurons and the extraocular motor neurons. At least one interneuron, the TVP cell, continues to be deeply modulated with head velocity even when the monkey suppresses the VOR to hold the eye fixed in the head. It has been suggested that the unwanted head velocity signal from TVP cells is cancelled at the motoneuron. We have recorded from cells in the medulla which might serve such a role.

Some single units in the medial vestibular nucleus (MVN) and the nucleus prepositus hypoglossi (NPH) discharge during horizontal head rotation and smooth pursuit eye movements in the same direction. They discharge approximately in phase with head velocity during suppression of the VOR and in phase with eye velocity during smooth pursuit. The sensitivities to head and pursuit velocity are nearly equal. Two thirds of the cells increased rates for movements toward the recording site (i.e. Type 1 for head rotation), while the remainder were Type 2. During the VOR in the light these cells manifest little, if any, modulation. They resemble, therefore, the "gaze velocity" cells of the flocculus and Y-group. In addition, to head and eye velocity sensitivity, many of these cells (60%) also increased their steady firing rate for eye position (static position coefficients averaged 1.9 spikes/second/degree). About half of the cells exhibited a burst of spikes during saccades in their "on" direction. These horizontal head-and-eye-velocity cells usually operated at slower rates than most other oculomotor-related neurons.

Medullary head-and-eye-velocity cells were recorded in areas that project to the ipsilateral and contralateral abducens nucleus. They also carry head and eye velocity signals that are appropriate to cancel the VOR and to participate in the control of voluntary eye movements. Therefore, we suggest that these head- and-eye-velocity cells project to the abducens nucleus where they provide signals that help modulate the VOR.

303.18 VESTIBULAR NUCLEUS SIGNALS AFTER INACTIVATION OF "EYE VELOCITY STORAGE" BY BILATERAL VESTIBULAR NEURECTOMY IN PRIMATES. W.Waespe*, U.Schwarz. Dept of Neurology, University Hospital Zurich,CH-8091 Zurich,Switzerland (WW); NIH, Bethesda (US)

The existence of an "eye velocity storage" element has been postulated in the Vestibulo-ocular reflex (VOR) to account for the dynamically "slow" changes in the eye velocity of OKN, and the occurrence of OKAN. Activity changes of some vestibular nuclei neurons have similar dynamics during OKN and OKAN as activity of the "storage" element. Bilateral vestibular neurectomy (BVN) permanently abolishes VOR, OKAN and the "slow" component of OKN. As primary vestibular neurons do not mediate visual or eye velocity signals the effects of BVN on OKN and OKAN are puzzling. It was suggested that BVN inactivates not only primary but also secondary vestibular neurons.

To test this hypothesis we recorded several months after BVN the activity of all neurons encountered in the vestibular nuclei during spontaneous eye movements, OKN, SP (smooth pursuit) and suppression of OKN in trained monkeys.

The results are in agreement with the idea that BVN interrupts the process of "eye velocity storage" at the level of the vestibular nuclei. The recordings, however, failed to identify which neurons are inactivated by BVN. The number and classes of recorded neurons seem to be similar to those in normal monkey. Many neurons were found which behaved -save the absent labyrinthine response- during spontaneous eye movements and SP exactly as "tonic (position) -vestibular-pause ("TVP" or "PVP") cells and vestibular-plus-position (vI/eII) cells in normal monkey. During OKN, these cells were also modulated in relation to eye velocity but sensitivity was substantially smaller than in normal monkey. All other neurons, some of which probably corresponded to "pure-vestibular" or "vestibular-plus-saccade" neurons,known to be activated during OKN in normal monkey, failed to do so after BVN.

We conclude that probably only a few vestibular nuclei neurons are functionally inactivated by BVN which disrupts the process of "eye velocity storage". Their number is obviously too small to be detectable by the method of cell sampling. We can exclude, however, that a particular class of functionally defined vestibular nuclei neurons are inactivated by BVN.

303.19 A BRAIN STEM SITE OF PLASTICITY IN THE VESTIBULO-OCULAR REFLEX IN MONKEYS. S.G. Lisberger and T.A. Pavelko, Department of Physiology and Division of Neurobiology, University of California, San Francisco, CA, 94143.

The vestibulo-ocular reflex (VOR) generates smooth eye movements that are equal to and opposite head movement, even in total darkness. As a result, the retinal images from the stationary surroundings remain stable during head turns in the light. If retinal image stability is disrupted persistently during head turns, the VOR undergoes long-term adaptive plasticity. In the lab, we induce large increases or decreases in the gain of the VOR (eye velocity divided by head velocity) by fitting monkeys with magnifying or miniaturizing spectacles.

We now report that the site of synaptic changes underlying VOR plasticity is in vestibular inputs to flocculus target neurons (FTNs). FTNs are inhibited at latencies of 1.0 to 1.9 msec by single shock stimulation of the flocculus. They are located in the medial vestibular nucleus. The majority discharge in relation to contralaterally directed eye movement during steady fixation, smooth pursuit and the VOR. When VOR gain is normal, the relationship between FTN firing rate and eye velocity is the same during smooth pursuit with the head fixed as during the VOR in the dark. Thus, the firing of each FTN during pursuit is an absolute against which the firing rate during the VOR can be compared in monkeys with altered VOR gains. After adaptive changes in the VOR, FTNs show dramatic changes in firing. 1) During the VOR in the dark, they express changes that exceed the magnitude of the change in the VOR. When VOR gain is low, for example, many FTNs show increased firing for an *ipsilaterally* directed VOR. In normal monkeys, FTNs show increased firing for a contralaterally directed VOR. This neural exaggeration of the behavioral change is expected in the modified pathways to overcome the effects of other, parallel VOR pathways that are not modified. 2) During tracking of a target that moves exactly with a sinusoidal head rotation, FTNs also show changes in firing. After decreases in VOR gain, for example, the firing rate of FTNs becomes modulated out-of-phase with their excitatory input from the ipsilateral vestibular nerve. Normally, FTNs show little or no modulation of firing rate in this stimulus condition.

Previous work showed that the change in FTN firing probably is not inherited from changes in the firing of afferents to FTNs. Second-order vestibular neurons, which presumably project to FTNs, do not show changes in firing in adapted monkeys. Purkinje cells in the flocculus *do* show changes in firing in adapted monkeys, but the direction of the changes is opposite that which would either account for the behavior of FTNs in adapted monkeys or cause the observed changes in the VOR. This suggests that the site of plasticity is across a synapse onto FTNs from either 1) floccular Purkinje cells or 2) brain stem vestibular neurons. We have excluded the possibility of changes across the inhibitory synapse from Purkinje cells onto FTNs, since stimulation of the flocculus evokes an eye movement that is not modified in relation to changes in the gain of the VOR.

We conclude that plasticity of the VOR is mediated by changes in the synaptic efficacy of brain stem vestibular inputs to flocculus target neurons. Previous work argues that there may also be synaptic changes in the flocculus, but these cannot be the primary modification that causes plasticity in VOR gain. Rather, the changes in the flocculus attempt to miminize the modulation of Purkinje cell simple spike firing during the adapted VOR. (Supported by NIH grant EY03878).

303.20 MULTIDIMENSIONAL GEOMETRIES INTRINSIC TO COGNITIVE CNS HYPERSPACES, AND THEIR METAORGANIZATION BY A SENSORIMOTOR APPARATUS. ***A.J. Pellionisz,*** Department of Physiology & Biophysics, New York University Medical Center, New York, NY 10016

Tensor Network Theory of the CNS is built on the axiom that the CNS expresses physical invariants of the external world in coordinates intrinsic to the organism. In such *general* frames dual geometrical representations are possible by assigning to invariants both sensory (covariant) and motor (contravariant) vectors. Neither, however, fully characterizes the invariant; one passively measures it without yielding a knowledge how to generate it, the other can produce it but not necessarily with appropriate metrical properties. Understanding the link between the two representations is all the more important, since in a sensorimotor system they are connected via a neuronal network, whose role will then be revealed.

Indeed, the general question how the sensory is related to the motor realm is a central problem in *experimental neuroscience* (which yields anatomical and physiological knowledge of the transfer), in *brain theory* (which mathematizes of its understanding) and in the *neurocomputer & neurobotics* fields (which utilize this understanding by physically implemented means). In neuroscience it is known that for a representation of the external world (for its *cognitive model)* such as obtained by *vision,* employing solely a sensory apparatus is not sufficient (the retina goes blind if our eye cannot move around). *An interaction of sensory and motor expressions is necessary for a geometrical model of invariants in the CNS.*

Neuronal networks that are required for moving the eye according to the retinal image (either by saccadic, or smooth pursuit manner) are known at least partially. Also, it is evident that the retina, the sup.colliculus, pontine saccadic bursters (etc; even the visual cortex) and finally the eye muscles all utilize various vectorial coordinate systems intrinsic to these structurofunctional units. In terms of tensor network theory, the connection between the sensory and motor domain is the metric tensor that transforms covariant descriptive vectorial representations into contravariant constructive vectorial expressions. Mathematically, if this link between dual representations is established, *all geometrical features of a multi-dimensional CNS hyperspace are comprised in such metric tensor.* This is why both experimental research (of how the structure and function of arrays of neurons in existing networks implement metric properties of body geometries) and theoretical neurophysics (revealing mathematical features of CNS hyperspaces) are expected to focus on physical and functional brain geometries.

For the visuo-oculomotor system, both the physical geometrical properties of the muscles, and the matching functional geometry that is necessary to coordinate the action of the overcomplete muscles are well explored. Tensorial models of how sensory and motor metrics can evolve in an interaction with the physical geometry of a respective sensory or motor apparatus have been elaborated for the vestibulo-collic, retino-collic, retino-ocular and vestibulo-ocular neuronal arc. It was also postulated by the Metaorganization-principle, however, that once a dual sensorimotor representation emerges, a hierarchical representation of the function of the total circuit can be obtained, which comprises an internal cognitive geometrical model of the interrelation of sensory and motor expressions; called (in this case) *vision.* A model of how neuronal networks of the tectum and visual cortex may implement such a cognitive space, invoked by the primary retino-ocular arc, will be presented. — Support: NS22999 & NS13742

304.1 GABA INHIBITION AT THE PERIARCUATE CORTEX OF THE RHESUS MONKEY AND THE VISUAL DISCRIMINATION REVERSAL TASK WITH GO/NO-GO PERFORMANCES. K. Kubota, A. Mikami and T. Oishi*. Dept. of Neurophysiology, Primate Res. Inst., Kyoto Univ., Inuyama, Aichi, Japan, 484.

To examine roles of GABAergic inhibitory interneurons of the monkey periarcuate cortex in the control of behavior, a GABA antagonist,Bicuculline,was injected locally into the cortical depths of left periarcuate cortex of one rhesus monkey, while the monkey was performing a visual discrimination reversal task with GO/NO-GO performances with right hand (symmetrically reinforced, correction method). Yellow circle presented on the display was erased by monkey's lever press. After a fixed WAITing period,CUE(red or green spot) appeared for 1 s, and was followed again by yellow circle. The monkey continued to press the lever for more than 1.2 s, if the CUE was green(NO-GO RESPONSE). He released the lever within 1.2 s, if the CUE was red(GO RESPONSE). Correct responses were rewarded. Whenever the monkey responded correctly for succesive 11 trials, the task was reversed, that is, associations of two colors and two responses were changed.

After a single injection of Bicuculline methiodide (SIGMA) dissolved in physiological saline (5-15 ug, 5 ug/1uL;10 uL syringe, ITO. Type MS-10;injection speed, 1 uL/min), the monkey made more errors in NO-GO RESPONSE period with decrease or no changes of number of errors in GO RESPONSE period. The monkey tended to release the lever in WAITing and CUE periods. Occurrences of task reversals decreased. Correct performance rate decreased by 5-10% from preceding control level of 70-90%. The effect started about 20 min after the injection and continued for 40-60 min. Performance rate returned to the control, stayed at the same level,or gradually went down until the monkey discontinued the task. In the extreme case, 10ug injection induced muscle contractions in fore-and upper-limbs for 1 hr and performance rate went down to 15%.

Thus, Bicuculline made the monkey difficult to continue to press the lever during the task. It is speculated that neurons of the contralateral periarcuate cortex, specifically active in NO-GO RESPONSE period, are of GABA inhibitory and give inhibitory influences to neurons with facilitatory influence which leads to the lever relsease movement.

304.2 SPATIAL DISCRIMINATION PROPERTIES OF PREFRONTAL CORTICAL NEURONS OF MONKEYS PERFORMING A DELAYED ALTERNATION TASK. S. Carlson*, H. Tanila*, K. Jokelainen*, H. Hämäläinen and A. Pertovaara.

Department of Physiology, University of Helsinki, Finland.(SPON:ENA)

Spatially discriminative delay related neurons have been studied earlier in the prefrontal cortex of monkeys (Niki, H. Brain Res 68: 197, 1974). The function of some of such neurons has been shown to be dependent on the spatial relations of the choice keys. In the present work dorsolateral prefrontal cortical neurons were studied in monkeys performing a delayed alternation task in which the choice pads in the panel were to the right or left or up and down from the central pad. Two monkeys were trained to hold the central pad for 1-5s. This delay period was indicated by a visual cue above the pad. At the end of the delay period the hold cue went off and a pair of visual cues above a pair of choice pads was illuminated to indicate that the monkey could release the central pad and touch either of the choice pads. Alternating touching of the choice pads after the hold period resulted in a juice reward. Errenous touching was not rewarded. The monkey was first instructed to perform the task to the right for 15-20 trials then to the left and finally in the upward direction. The monkey had also been trained to perform the task according to auditory cues. After a neuron had been recorded during the first three modes of the task (right/left/up) the visual cues were turned off and the auditory cues on and the neuron was again recorded in the different modes of the task. Hand movements were monitored with EMG and eye movements with EOG.
Preliminary analysis of the task related neurons showed response specific and reward related neurons. Both spatially discriminative and nondiscriminative delay related neurons were recorded. The responses of some spatially discriminative neurons were diminished by the occurrence of mistakes in the performance of the monkeys. Most of the delay related spatially discriminative neurons were not dependent on the relative position of the choise pads to each other.The preliminary analysis indicated , however, that the delay related spatially discriminative neurons included units which code the relative position of the choice pads (left/right/up and down). The activity of these neurons was neither dependent on the direction of the impending hand movement nor on the modality of the cue (auditory/visual).

304.3 INVESTIGATION OF THE ROLES OF DORSOMEDIAL AND VENTROLATERAL PREMOTOR REGIONS AND THE FRONTAL EYE FIELDS IN VISUALLY GUIDED MOVEMENTS. J.D. Schall, S.E. Mann and P.H. Schiller Dept. Brain and Cognitive Science, M.I.T., Cambridge, MA 02139

Frontal cortex contains a number of regions which are involved in the generation of visually guided movements. The purpose of this investigation was to determine if the dorsomedial frontal cortex (DMFC), the post-arcuate premotor region (PM) and the frontal eye fields (FEF) could be distinguished on the basis of neuronal activity recorded during performance of visually guided movements. We also investigated whether the DMFC accesses the oculomotor nuclei through the superior colliculus or FEF.

Four rhesus monkeys were trained to perform visually guided eye and arm movements. In each region we found examples of neurons which responded in relation to all elements of the task. Many cells discharged following the appearance of the visual target. Some of these neurons responded transiently; others discharged until the cue for movement, and others fired until the saccade. Such visually responsive cells were most common in the FEF and DMFC and less common in PM. Cells which discharged before saccades were common in the FEF and DMFC, and cells which fired before arm movements were found in DMFC and PM. These movement related neurons were most active before goal-directed movements and less active before spontaneous movements. We found many other neurons in each of these regions which exhibited clearly modulated activity during the task but were less closely linked to the individual elements of the task.

It has been demonstrated in this laboratory that the FEF and superior colliculus have independent access to the oculomotor nuclei. To ascertain whether the DMFC influences the oculomotor nuclei through the FEF or the superior colliculus, unilateral lesions of both of these structures were performed in one monkey. Microstimulation of DMFC elicited saccades following ablation of either the FEF or the superior colliculus. Moreover, stimulation of the DMFC ipsilateral to the ablated FEF at sites which initially evoked contralateral saccades now elicited ipsilateral saccades.

These results indicate that each of these regions contain neuronal activity which may provide a substrate for the generation of visually guided movements and that DMFC accesses the oculomotor nuclei independent of the FEF or superior colliculus. 304.4 MOVEMENT FIELDS OF NEURONS IN THE PREMOTOR CORTEX OF THE PRIMATE. S.-K. Park, J.-J. Wang*, J.H. Kim and T.J. Ebner. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455.

This study evaluated the representation of horizontal, two dimensional movements in the premotor cortex of the primate, emphasizing the characteristics of the movement fields of these cells. Starting from a central start zone two Rhesus monkeys were required to move to one of 30 randomly presented target zones displayed on a computer controlled, horizontally positioned video screen using a draftsman's arm style manipulandum. A cursor was projected on the video screen and provided real time visual update of the animal's position. The task required placing the cursor within the start and target boxes. Target zones were arranged in five sets of equally spaced targets (60°) around a central start zone, each set at a different distance. Chronic unit recording techniques were used to record the activity of 198 premotor cortical neurons before and during this task. In addition to recording the position of the hand (manipulandum position) and features of trajectory kinematics in the horizontal plane, chronic EMG electrodes were used to monitor shoulder and forearm EMG activity. Horizontal and vertical eye movements were monitored using an infrared oculometer. Three dimensional plots of the cells firing rate above background for the discharge prior to (premovement component) and after the onset of movement (movement component) were constructed. Premotor cortical cells which increased their discharge prior to or during the task showed a preferential modulation for a specific region (direction and amplitude) of horizontal extrapersonal space in which the movement was made. Although the extent of the movement field could be large, the discharge was clearly restricted to a region of the horizontal work space. Also the movement fields exhibited a distinct center where the discharge was maximal. In most cells both the premovement and movement components increased over the same region of horizontal space. In a few cells the importance of the starting position was evaluated. In this group of cells the modulation was dependent on the movement origin. These preliminary observations on the characteristics of the movement fields of premotor cortical neurons raise the intriguing possibility that aspects of extrapersonal space are represented in these cells discharge. 304.5 FRONTAL CORTEX: NEURONAL ACTIVITY PRECEDING DIRECTIONAL AND NON-DIRECTIONAL CUES. E. Vaadia* and S.P. Wise, Lab. Neurophysiology, NIMH, Bethesda MD 20892

The activity of 429 frontal cortex neurons of a rhesus monkey was recorded before and during forelimb reaching in two tasks, presented in blocks of 20 trials each. In both tasks, we studied firing-rate modulation during the period between trial initiation (when the monkey touched the central of three keys) and the onset of a visuospatial timing cue. The monkey was required to begin its forelimb movement to either the left or right target key within 2 s of cue onset, but not before 1 s had elapsed. In one task, the cue (a "directional cue") provided information about the timing and direction of limb movement that would be rewarded on that trial. In the other task, the cue (a "nondirectional cue") provided only timing information; the direction of limb movement that would be rewarded was inversely related to the number of prior consecutive movements in a given direction.

Of 252 task-related neurons, 75 showed pre-cue activity. Pre-cue activity could begin from soon after trial initiation to >3 s later. From trial to trial, the change in pre-cue activity began at a highly variable time before the cue and the firing rate was less consistent than other neural activity patterns observed in this area. However, the offset time of the pre-cue activity was, in most cases, highly consistent and time-locked to the cue-onset.

Leftward vs. rightward movements. No units showed significant differences in pre-cue activity dependent on the direction of limb movement on the forthcoming or previous trial. Thus, the data do not support the hypothesis that pre-cue activity reflects the preparation for a specific limb movement, i.e., motor set.

Directional vs. nondirectional cues. Most (64/75) units with pre-cue activity showed no clear activity differences between the two tasks. Thus, these data do not support the notion that pre-cue activity reflects aspects that distinguished the two tasks: (a) the possibility of using movement, reward or stimulus information from the previous trials to make a choice on the next trial, (b) the predictability of reward, or (c) attention to the instructional content of the cue. We therefore hypothesize that most pre-cue activity reflects or contributes to the main aspect common to the two tasks: the animal's attention to the timing of the cue.

For those few (11/75) cells that differed in pre-cue activity between the two tasks, on the basis of additional testing and analysis we can argue against the above points a (pre-cue activity was greater during directional-cue trials) and b (changing the reward probability in directional-cue trials did not affect pre-cue activity). It therefore remains possible that this pre-cue activity reflects or contributes to attention toward the instructional information transmitted by the cue, as well as to its timing.

304.6 NEURONAL ACTIVITY BEFORE HINDLIMB AND FORELIMB MOVEMENT IN PREMOTOR CORTEX OF RHESUS MONKEYS. K. Kurata and S.P. Wise, Laboratory of Neurophysiology, NIMH, Bethesda, MD 20892

We recorded single-unit activity in the premotor cortex (PM) of two rhesus monkeys in order to study movement- or set-related activity associated with hindlimb or forelimb movement. Each monkey was trained to either press a key by flexion of the right hand or to lift a pedal by dorsiflexion of the right foot. The monkeys' leg and arm were loosely fixed to restrict large movements to the distal limbs. In the task, after a 1 s intertrial interval, either a yellow or a green light emitting diode (LED) was illuminated as an instruction stimulus. When the yellow LED was illuminated, a foot movement was required, and when the green LED was illuminated, a hand movement was required. The monkeys then had to withhold movement for a randomized delay period of 1.5-3.6 s, after which a red LED was illuminated as a trigger stimulus (TS). After the TS, the monkeys had to make the appropriate movement within 800 ms to receive a juice reward.

EMG analysis showed that while the monkeys were performing the task there was no consistent change in muscle activity during the delay period and that changes in muscle activity were limited to the appropriate limb on each trial. Out of 572 task-related neurons recorded in the left PM of the two monkeys, 149 neurons showed set-related activity, defined as significant increases or decreases in discharge rate throughout most of the delay period, and 299 neurons showed movement-related activity, defined as significant changes in discharge rate starting ≤300 ms before the onset of movement.

	Number of PM Neurons		
Activity	Hand only	Foot only	Mixed
Set-related	57	62	30
Movement-related	112	114	73

In both monkeys, foot set- and movement-related neurons were concentrated near the superior precentral sulcus, and hand set- and movement-related neurons were located lateral to the "foot" neurons. The distribution of mixed (foot and hand) set- and movement-related neurons overlapped with the location of "hand" and "foot" neurons.

The results show that most PM neurons contribute to the preparation for and execution of specific limb movements rather than movement per se. Further, the differential distribution of neurons with activity related to hindlimb vs. forelimb movement support previous indications* that PM is topographically organized.

304.7 THE EFFECTS OF COOLING MIDLINE CEREBRAL CORTEX, INCLUDING THE SUPPLEMENTARY MOTOR AREA, ON MOVEMENT-RELATED NEURONAL RESPONSES IN AREA 4 OF CONSCIOUS MONKEYS. E. M. Schmidt, R. Porter and J. S. McIntosh. NIH, NINCDS, LNLC, Bethesda, MD 20892 (EMS and JSM) and The John Curtin School of Med. Res. Canberra, Australia 2601 (RP).

The supplementary motor area (SMA) has been shown to play a role in the performance of movements by a variety of techniques including neurophysiological recordings, intracortical microstimulation, and cerebral blood flow studies. The hypothesis that SMA may influence the responsiveness of area 4 neurons to kinesthetic stimuli (Wiesendanger, et al. '73) has received support from the observation that conditioning stimulation in SMA modifies the latency and/or magnitude of responses of area 4 cells that were produced by passive arm displacements (Hummelsheim, et al. '86). To further test this hypothesis, the movement and perturbation-related responses of area 4 cells were examined before, during and after SMA cooling.

A Rhesus monkey was trained to flex and extend the wrist in response to movement of a visual target on a video monitor. The monkey's hand was held in a molded form coupled to a torque motor which produced a simulated spring load. The monkey was required to match a wrist-movement coupled cursor to a target for a period of at least one second to receive a reward. Halfway through the random duration hold period, a 50 ms torque pulse was applied to perturb the wrist in either the flexion or extension direction.

After training, the following items were implanted under pentobarbital anesthesia and aseptic conditions: 1) six bipolar EMG leads in the right forearm muscles; 2) a recording chamber over the arm area of the contralateral precentral motor cortex; 3) a cooling chamber placed within the sagittal fissure overlying the territory of SMA; and 4) a head restraint device.

The only effect observed on wrist movements when the chamber was cooled to 10°C, and cortex on both sides of the midline was cooled below 25°C, was a possible reduction in their spontaneity. The animal could perform the task with the same speed as before cooling, and the accuracy of positioning and holding the target was unimpaired. No tremor or drift away from the intended displacement was observed. Thus far, the activities of 39 task-related area 4 neurons have been analysed for periods before, during and after bilateral SMA cooling. Eleven of these neurons exhibited a torque pulse response but showed no qualitative difference in the response during cooling.

Under the test conditions employed, we found no evidence that SMA modulates sensory responses of area 4 neurons. This absence of an effect of short term, reversible disturbance of function of SMA, contrasts with the apparent long term modulation of long-latency stretch reflexes which follows unilateral SMA lesions in man (Dick et al. '87).

304.8 ROSTROCAUDAL TOPOGRAPHY IN THE CORTICO-CORTICAL CONNECTIONS OF MEDIAL AGRANULAR CORTEX IN RATS. Gregory S. Goodwin*, Roger L. Reep and James V. Corwin* SPON: (Richard D. Johnson). Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610; and Department of Psychology, University of New Orleans-Lakefront, New Orleans, LA 70148.

Medial agranular cortex (AGm) is a component of rodent sensorimotor cortex which appears to be a frontal eyefield and may also function as a supplementary motor area. In addition, unilateral lesions of AGm result in neglect to visual, auditory and somatic sensory stimuli presented in the contralateral hemispace. Previous studies have indicated rostrocaudal differences in AGm with respect to various aspects of these functions. In order to delineate the cortico-cortical circuitry which may participate in these functions, we have investigated the topography of cortical afferents to AGm using 3% aqueous Fluorogold (FG) as a retrograde tracer, delivered in focal injections (0.02-0.10ul) through a 33g Hamilton syringe or glass micropipettes with tip diameters of 20-30um. When FG injections were made in AGm at levels rostral to the genu of the corpus callosum, large numbers of labeled cells were seen bilaterally in ventrolateral orbital cortex. In the caudal part of ipsilateral somatic sensory cortex, extensive labeling is present as fairly continuous sheets of cells in layers III and V, extending from the lateral margin of AGm down to the rhinal fissure. Visual cortex contains moderate to heavy labeling arranged as intermittent clusters of labeled cells in layers III and V. FG-positive cells were also found in the retrosplenial, perirhinal and entorhinal areas, primarily ipsilaterally.

As injections are centered in progressively more caudal portions of AGm, the orbital cortex labeling shifts medially such that only the medial orbital area contains FG-positive cells in cases with injections in far caudal AGm. In somatic sensory cortex there is a steady decline in the number of labeled cells as injections are located more caudally in AGm. This is expressed as a breakup of the continuous pattern of FG-positive cells into clusters of cells which become increasingly more separated from each other. Eventually, with injections in very caudal AGm, only two clusters remain: one just lateral to AGm and another just dorsal to the rhinal fissure. In visual cortex the already intermittent pattern is progressively extended such that fewer clusters are seen with more caudal AGm injections. Labeling in the perirhinal and entorhinal areas becomes gradually sparser with more caudally placed injections, without showing any clustering effects. One region which shows increased labeling with more caudal AGm injections is the dorsal taenia tecta immediately rostral to the genu of the corpus callosum.

These findings illustrate a rostrocaudal topography in the cortical connections of AGm, and indicate possible anatomical substrates by which certain functional differences throughout AGm may be expressed.

Supported by the University of Florida Division of Sponsored Research and the Maxwell Fund.

304.9 CIRCULAR ORGANIZATION OF CONNECTIONS LINKING MIDBRAIN AREAS, SECTORS OF THE MEDIODORSAL THALAMUS, AND PREFRONTAL AREAS IN THE RAT. T. W. Deacon, A. Sokoloff, and D. Wecht. Biological Anthropology, Harvard Univ., Cambridge, MA 02138.

Numerous studies have noted that the dorsal medial (areas Cg1, Cg3, and F2 of Zilles) and the rhinal sulcal divisions (areas AIv and AId) of the prefrontal cortex in the rat brain are distinguished by non-overlapping projections from different subsectors of the mediodorsal nucleus (MD) of the thalamus. In order to determine if this topographic distinction is maintained with respect to mesencephalic connections as well, we have investigated connections from prefrontal areas to midbrain and tectal areas and from these mesencephalic areas to MD using both autoradiographic (tritiated proline and leucine) and enzymatic (WGA-HRP) tracers. The present report focuses on the interconnections between these structures.

Tracers injected into the dorsomedial prefrontal area (DMPFC) label cells and/or axon terminals (depending on the tracer employed) in the dorsal and lateral sector of MD, and label axon terminals in the intermediate and deep layers of the superior colliculus, the dorsolateral sector of the central gray area, and the deep mesencephalic nucleus. Tracers injected into the sulcal prefrontal area (RSPFC) label cells and/or axon terminals in the medial sector of MD, and label axon terminals in the deep mesencephalic nucleus and the adjacent ventrolateral sector of the central gray. Tracer injections into the far rostral pole of the cortex that include medial, sulcal, and orbital sectors of the prefrontal area label cells and/or axon terminals in the ventral sector of MD, and label axon terminals in the deep gray layer of the superior colliculus and the adjacent tegmental area medial to the brachium of the inferior colliculus. Tracer injections centered in the intermediate and deep layers of the superior colliculus label axon terminals in the dorsal and lateral sector of MD and cells in layer V of DMPFC. Tracer injections centered deep to the superior colliculus within the dorsal tegmental area label axon terminals in the ventral sector of MD and cell bodies in layer V of both DMPFC and RSPFC near the frontal pole. Tracer injections centered within the deep mesencephalic nucleus label axon terminals in the posterior medial sector of MD and cells in layer V of RSPFC. These results suggest that the connections linking areas of the midbrain, MD thalamus, and prefrontal cortex are organized into at least three spatially segregated circuits that each exhibit a circular topology.

304.10 CORTICAL PROJECTIONS OF THE ROSTRAL INTRALAMINAR NUCLEI. G.J. Royce, S. Bromley*, C. Gracco* and R.M. Beckstead. Dept. Anatomy, Univ. of Wisconsin, Madison, WI 53706 and Dept. Anatomy & Cell Biology, Med. Univ. of South Carolina, Charleston, SC 29425.

The organization of the projections from the rostral intralaminar thalamic nuclei to the cerebral cortex was examined in the cat by autoradiography after deposits of ^{3}H-amino acids into the central lateral (CL), paracentral (Pc), central medial (CeM), and para-stria medullaris (paraSM) nuclei.

Following injections into the CL nucleus, label was found on the lateral side within the presylvian (PrS) sulcus, throughout most of the suprasylvian (Ss) gyrus, including the adjacent lateral and suprasylvian sulci, and in the posterior corner of the ectosylvian gyrus. Also on the medial side, label was present in the orbitofrontal (Of), precentral agranular (Prag), anterior limbic (La), retrosplenial (Rs), and postsubicular (Ps) areas. Label was also present throughout the cingulate (Cg) gyrus and on both banks of the splenial (Sp) sulcus, as well as on both banks of the cruciate (Cru) sulcus (areas 4 and 6).

Projections from the Pc nucleus were similar to the CL projections, in that on the lateral side label was found within the PrS sulcus, Ss gyrus and adjacent lateral and Ss sulci, and posterior ectosylvian gyrus. Also on the medial side, label was present in the Of, Prag, La, Rs, and Ps areas, within the cruciate and splenial sulci, and in portions of the lateral gyrus that were clearly within area 17.

Injections of the CeM nucleus which also included the rhomboid nucleus were followed by labeling in the PrS, but in contrast to the CL and Pc projections, the Ss gyrus was labeled only in its posterior part. However, the CeM clearly, if sparsely, projects to the posterior lateral gyrus, part of area 17, both laterally and medially. In addition, medially, CeM projects to the rostral cortex (Of, Prag, La, Cru sulcus, and rostral cingulate gyrus), but largely spares the more posterior limbic areas.

The paraSM nucleus, which had been included previously with the lateral posterior (LP) nucleus, was shown to differ from the rest of LP by projecting to the striatum (Beckstead, '84). The paraSM nucleus projects only to the presylvian sulcus and orbitofrontal cortex laterally, but on the medial side has an extensive input which is very similar to the CL and Pc projections, i.e., label is present in the Of, Prag, La, Rs, and Ps areas, in the cruciate and splenial sulci and in the posterior lateral gyrus (area 17).

The laminar distribution of label was as follows: the CL, Pc and paraSM nuclei projected primarily to layers I and III, whereas the CeM input was found in layers I and VI. Also, the CL projection had a patchy appearance in the posterior limbic field.

Supported by NIH grant NS13453 and NSF grant BNS85-04438.

304.11 TOPOGRAPHICAL DISTRIBUTION OF CELLS OF ORIGIN OF THALAMIC EFFERENTS TO POSTERIOR PARIETAL CORTEX IN RHESUS MONKEY. Jeremy D. Schmahmann* and Deepak N. Pandya. Departments of Anatomy and Neurology, Boston University School of Medicine, Boston, MA 02118, and E.N.R.M. Veterans Hospital, Bedford, MA 01730.

A previous WGA-HRP study demonstrated that certain thalamic nuclei project to the superior parietal lobule (SPL) and inferior parietal lobule (IPL) in rhesus monkey (Schmahmann and Pandya 1986). The patterns of thalamic afferents were different for each architectonic area of the SPL and IPL, however some thalamic nuclei were seen to project to more than one area. In order to define the precise topography within individual thalamic nuclei of the cells projecting to different subregions within the posterior parietal cortex, the present study was undertaken using fluorescent retrograde tracers. After sectioning the corpus callosum, fast blue, rhodamine latex microspheres and diamidino yellow were placed in three rostral to caudal sites in the SPL (areas PE and PEc) and IPL (areas PFG, PG, and Opt of Pandya and Seltzer 1982) in the left and right hemispheres respectively.

The SPL receives projections predominantly from the LP and PO nuclei, whereas the IPL afferents are mainly from PM, with a lesser input from LP. Unique to caudal IPL, area Opt, is strong input from LD and the anterior nuclei, AV and AM. Pulvinar oralis sends projections only to the most rostral region of IPL. Both SPL and IPL receive light but consistent projections from VL, VPL, the lateral part of MD, and the intralaminar nuclei (Pcn, CL, CM).

Within nuclei projecting to both SPL and IPL, and most notably in LP, more lateral portions project to SPL, more medial portions to IPL. In the regions of LP and PM that have connections with the posterior parietal cortex, thalamic neurons projecting to the rostral parietal lobe are located in ventral positions, whereas those projecting to the caudal parietal lobe are situated more dorsally. Thalamic neurons projecting to the mid-parietal lobe occupy an intermediate position. Within individual nuclei there is only minimal overlap of neurons projecting to the different subregions of the SPL and IPL. No double-labelled neurons were observed projecting to the IPL, and only occasional double-labelled neurons were found in LP following injections of rostral and middle regions of SPL.

Thus there is topographic specificity in the medio-lateral and dorso-ventral dimensions within individual thalamic nuclei of neurons projecting to the posterior parietal cortex.

Supported in part by NIH grants T32 NS07152 and 16841, and the E.N.R.M. Veterans Hospital, Bedford, MA.

304.12 SPATIAL RELATIONSHIPS OF CALLOSAL AND ASSOCIATION NEURONS IN FRONTAL AND PARIETAL CORTICES OF MONKEYS. P.B. Johnson*, A. Angelucci*, R. M. Ziparo*, M. Bentivoglio, D. Minciacchi* and R. Caminiti. Institute of Physiology, Univ. of Rome and Institute of Neurology, Catholic Univ., Rome, Italy.

The spatial relationships of callosal and association neurons of frontal and parietal cortical areas were studied with a double-labelling strategy. Fast blue and nuclear yellow were injected at appropriate time intervals in the left frontal (areas 4 and 6) and right posterior parietal (area 5) cortices, respectively, of two Macaca fascicularis. This allowed the study of the following retrogradely labelled cells: in the frontal lobe, callosal cells projecting to the contralateral frontal lobe and association neurons projecting to ipsilateral area 5; in the parietal lobe, callosal cells projecting to contralateral area 5 and association cells projecting to the frontal lobe. In all cortices studied, the distribution of callosal and association neurons was uneven. They were found in layers II, III, V and VI, although the former predominated in the lower part of layer III while the latter were more numerous in the upper part of the same layer. Spectral and coherency analyses were used to study the distribution of the labelled cells in the tangential cortical domain. The spectral analysis describes the periodic variations in cell number contained in these distributions, here examined along the anteroposterior cortical axis. The coherency analysis expresses, for a given range of periodicities, the amount of linear relationship between two distributions. The spectral analysis showed that the predominant feature of the tangential arrangement of callosal and association cells in both frontal and parietal areas consisted of periodicities in their number with peak-to-peak distances of more than 4 mm. In reconstructed 2-dimensional flattened images of the cortex these periodicities were observed in the form of bands with various shapes and orientations. Further, the spectrum contained additional periodicities with peak-to-peak distances of 1-3 mm, which would correspond to a more minute and local arrangement of labelled neurons in groups of 500-1500 µm width. These latter periodicities were not the main component of the spectrum. In our case the coherency study provided a quantitative description of the degree of similarity between callosal and association distributions in the cortical space, together with their phase relationships. This analysis showed a high degree of similarity between supra and infragranular distributions of the same cell population. However, the coherency showed varying degrees of similarity and phase between callosal and association neurons of frontal versus parietal cortex. These results indicate that the cells of origin of callosal and association connections in both frontal and parietal areas are independently distributed in the cortical space. However, when the periodic content of their distributions is considered, a common principle underlies their spatial organization.

304.13 DOPAMINERGIC PROJECTIONS TO PREFRONTAL AND PARIETAL CORTICAL REGIONS IN MONKEY (MACACA FASCICULARIS). D.A. Lewis, S.L. Foote, M. Goldstein, J.H. Morrison. Res. Inst. of Scripps Clin., La Jolla, CA 92037 and NYU Med. Cen., New York, NY.

Using an antiserum directed against tyrosine hydroxylase (TH), which appears to selectively label dopaminergic (DA) fibers in monkey neocortex (J. Neurosci. 7:279, 1987), we characterized the distribution of labeled fibers in the prefrontal and parietal regions of Old World cynomolgus monkeys (Macaca fascicularis). The density of TH-IR fibers exhibited substantial heterogeneity, both across and within cortical cytoarchitectonic regions. In prefrontal cortex, fiber density was greatest in area 9; within this region, the medial surface had a greater density of labeled processes than the dorsal surface. Numerous TH-IR fibers were also present in area 24 (anterior cingulate), where fiber density was greater in the supracallosal than in the pregenual or infracallosal portions. Adjacent area 25 on the medial surface had a lower and more homogeneous density of labeled fibers. An intermediate density of TH-IR fibers was present on the orbital surface. The density of labeled fibers was lowest in areas 46 and 10. Within area 46, fiber density was greatest on the dorsal surface, decreased in both banks of the principal sulcus and was lowest in the fundus of this sulcus. In parietal cortex, the density of TH-IR fibers was markedly diminished in the posterior bank of the central sulcus compared to the adjacent motor regions. Fiber density increased substantially in both lateral and caudal directions such that area 7 had a greater density of labeled fibers than area 5. Some posterior cingulate areas also contained a high density of TH-IR fibers. The laminar pattern of fiber distribution in a given area of cortex was systematically related to the overall fiber density of that area. For example, in the lightly innervated area 46, labeled fibers were present primarily in layer I and in layers V-VI, whereas in the densely innervated area 9, TH-IR fibers were present in all layers.

The presence of DA projections to parietal cortex was confirmed by the injection of fast blue, a retrogradely transported dye, into area 7 in 2 monkeys. In both animals, fast blue-positive, TH-IR neurons were identified in the ipsilateral substantia nigra-ventral tegmental area (SN-VTA). Fast blue-positive neurons without TH-IR were also found in the SN-VTA.

Thus, in addition to possessing a number of other common anatomical features, monkey prefrontal and parietal regions also both receive DA projections which exhibit substantial inter- and intraregional differences in fiber density and/or laminar distribution. These findings suggest that the influence of DA on the function of association areas of monkey neocortex may be both widespread and regionally specific. 304.14 **INTERDIGITATION OF CALLOSAL AND METABOLIC COLUMNS IN PRIMATE PREFRONTAL CORTEX: A DOUBLE LABEL HRP AND 2DG STUDY.** A.S. Clark, H.R. Friedman, M.L. Schwartz, and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Major classes of cortical input to the prefrontal association cortex display a modular organization; following injection of different anterograde tracers into the cortex of the principal sulcus (PS) of one hemisphere and the posterior parietal cortex of the opposite hemisphere, terminals form an alternating pattern of ipsilateral and contralateral columns (Goldman-Rakic and Schwartz, Science 216:755, 1982). Columnar properties of organization also hold true for other aspects of cortical information processing. Functional activity, as revealed in 2DG metabolic labeling, is not uniformly distributed throughout the prefrontal cortex, but forms columns of high metabolic activity alternating with equivalent areas of low metabolic activity (Goldman-Rakic, Trends Neurosci. 7(11): 419, 1984). This raises the possibility that the columnar pattern of metabolic activity may be related to the patterns of specific afferent connections in association cortex. Combining the ^{14}C-2DG metabolic labeling method with HRP histochemistry, we report the relationship between two aspects of columnar organization of the cerebral cortex in the monkey; anatomical columns of callosal origin and functional metabolic columns.

WGA-HRP was injected into the posterior third of the PS which projects contralaterally via callosal fibers to the prefrontal cortex (PFC) of the opposite hemisphere. Two days after the HRP injection, the monkey received a single i.v. injection of ^{14}C-2DG (100 μCi/kg), followed by a 45 min. period during which he sat quietly in a primate chair. An overdose of sodium pentobarbital was administered, the animal was perfused with mixed aldehydes and the brain was dissected into tissue blocks to be quick frozen in isopentane cooled in dry ice.

Tissue blocks from the PFC contralateral to the injected PS were cryostat sectioned in the coronal plane at a thickness of 20-30μ. Adjacent sections were (1) histochemically reacted with TMB to reveal the distribution of anterograde and retrograde HRP labeling or, (2) apposed to x-ray film for 6-7 days to visualize the pattern of 2DG metabolic labeling. Additional sections were stained with cresyl violet. Camera lucida drawings of HRP terminal label were superimposed onto photographic prints of 2DG images taken from adjacent tissue sections to examine the relationship of the different labeled territories.

HRP callosal columns with widths ranging from 0.5-1.0mm and 2DG columns of high metabolic activity having similar widths were present in the dorsal and ventral banks of the PS as well as the areas bordering them, and were particularly demarcated in the dorsal bank. In this region, callosal columns were interdigitated with columns of high metabolic activity. The apposition of some adjacent columns was striking; the borders of HRP columns abutted columns of high metabolic activity with no overlap between them. Other regions of the PS appeared to have more complex labeling relationships: in some regions, areas of high metabolic activity and callosal label were in precise register and in other regions the relationship was less clear. We are currently conducting studies to clarify the role of technical, anatomical and behavioral variables to the generation of these relationships.

304.15 CONNECTIONS OF THE PULVINAR AND ADJACENT THALAMIC NUCLEI WITH THE PRIMARY MOTOR AND PREMOTOR CORTEX IN MACAQUE MONKEYS. G.P. Standage and G.S. Doetsch. Depts. of Anatomy, Surgery (Neurosurgery), and Physiology and Endocrinology, Medical College of Georgia, Augusta, GA 30912.

Possible interconnections of the pulvinar and adjoining thalamic nuclei with motor areas of the cerebral cortex were examined using the HRP method. Single injections (.01 ul) of wheat germ conjugated HRP were made into the anterior portion of the pulvinar, involving both the medial (pul m.) and oral (pul o.) pulvinar subdivisions. Single or multiple adjacent injections of HRP (.025 ul each) were made into the primary motor and premotor cortex, two in cortical area 4 and two in cortical area 6.

Following injections into the pulvinar, HRP labeled cells were found in areas 4 and 6, primarily confined to layer V. Additional labeling was found in areas 8, 45, and 46 of the frontal lobe and areas 5, 7, and the medial surface of the parietal lobe. Labeled cells were typically found in clusters of three to six neurons separated by regions devoid of labeled cells.

A cortical injection into the hand region of area 4 resulted in labeled cells and axon terminals located primarily within the ventral and anterior parts of pul m. and in the ventral part of pul o. Labeled cells and axon terminals formed a single band oriented from dorsomedial to ventrolateral within each of the two subdivisions of the pulvinar. In addition, labeling was present in the border region between the caudal ventroposterior lateral nucleus (VPLc) and the lateral posterior nucleus (LP).

Cortical injections into area 6 produced labeling within pul m. and pul o., and less consistently within the lateral subdivision of the pulvinar (pul l.). An injection near the midline, anterior to the foot region of area 4, produced labeling of cells located dorsally within all three subdivisions of the pulvinar. Conversely, an injection placed laterally in area 6, anterior to the hand region of area 4, resulted in labeled cells located ventrally in pul m. and pul o., but produced no labeling in pul l. Labeled cells and terminals formed two bands oriented from dorsomedial to ventrolateral within the two subdivisions. Additional labeling was found within VPLc and LP.

These preliminary data suggest that the pulvinar complex is reciprocally connected with the primary motor and premotor cortex. The interconnections appear to be differentially distributed, at least those of pul m. and pul o. The connections of the pulvinar with areas 4 and 6--together with those of areas 5 and 7--may play an important role in the control of intentional movements of the upper limbs and eyes (see Acuna et al. Exp. Br. Research:52,411-422,'83).

304.16 THE PRIMATE MEDIAL PULVINAR (MP) AND ITS CONNECTIONS WITH THE FRONTAL LOBES AND OTHER CORTICAL AREAS. M. Giguere and P.S. Goldman-Rakic. Sec. Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Recently it has become clear that the prefrontal cortex (PFC) in primates receives a major thalamic innervation from the medial pulvinar nucleus (MP) in addition to its well known projection from the mediodorsal nucleus. To elucidate the regional and laminar distribution of MP connections with the cerebral cortex, WGA-HRP or tritiated aminoacids were injected in various portions of MP in six rhesus monkeys. Sections were examined for HRP-positive cells and terminals under bright and dark field illumination. Every other section was charted and the results reconstructed on standard diagrams in each case.

Following injections restricted to the lateral part of MP, labeling was observed most densely in the principal sulcus, the lateral orbital cortex and inferior convexity, while injections placed more medially in MP labeled medial areas of the frontal lobe more intensely. This topography corresponds precisely to that obtained following HRP injections in PFC (Goldman-Rakic and Porrino,J.C.N.242:535,1985). As described for the mediodorsal connection with the PFC (Giguere and Goldman-Rakic, Neurosc. Abst.11:671, 1985), the cortical cells of origin of MP afferents are located in layer VI, with occasional cells labeled in superficial layer V, whereas the MP terminals are located in the middle layers III and IV and form a disjunctive pattern of bands throughout the labeled areas of the PFC. No labeled terminals are found in layer I. The density of labeled terminals often surpassed that of labeled cells in some parts of the PFC.

In addition to its prefrontal connections, MP projects to an extensive network of ipsilateral association areas. In agreement with other studies, the superior temporal sulcus, the granular and dysgranular parts of the insular cortex, the lateral and medial posterior parietal cortex, the posterior cingulate, the retrosplenial area as well as the parahippocampal gyrus are all extensively and reciprocally connected with the medial pulvinar. The distribution of labeled cells and terminals in these areas corresponds to that observed in prefrontal cortex, though no disparity in density of labeled cells and terminals was noticed. Recent studies in this laboratory have demonstrated that the principal sulcus is reciprocally connected with all of the areas that receive MP afferents (Selemon and Goldman-Rakic, Neurosc. Abst. 11: 323). It therefore appears that the medial pulvinar, which is particularly prominent in primates, is in position to recruit or activate an entire distributed neural system dedicated to a common function. 304.17 MULTIMODAL EFFERENT PROJECTIONS FROM THE POSTERIOR CINGULATE CORTEX IN THE RHESUS MONKEY. C.L. Barnes and D.N. Pandya. Bedford Veterans Hospital, Bedford, MA 01730 and Depts. of Anatomy and Neurology, Boston Univ. Sch. of Med., Boston, MA 02118.

In recent years, several multimodal areas have been identified in the frontal lobe, parietotemporal area and the parahippocampal gyrus. These multimodal areas have been proposed from the anatomical and physiological demonstration as recipient areas of converging efferents from parasensory association areas of the somatosensory, auditory and visual modalities. In the present study, we have observed that specific regions of the caudal cingulate gyrus (area 23 and retrosplenial cortex, area 29) seem to project to specific parts of the parasensory association areas in the parietal lobe, superior temporal gyrus and inferotemporal region.

In eleven rhesus monkeys, Fluorescent Retrograde Dyes (FRT-Rhodamine labeled latex microspheres, Diamidino Yellow, Fast Blue) were injected in different subdivisions of the parietal lobe (somatosensory), superior temporal gyrus (auditory) and inferotemporal region (visual) in a single animal. The resulting differentially labeled neurons were traced in the hemispheres. We observed an overlapping pattern of retrogradely labeled cell bodies in areas 23 and 29 following FRT injections confined to areas Opt and caudal PG of the inferior parietal lobule, areas paAlt and Ts3 of the superior temporal gyrus and areas TF and TL (Rosene and Pandya, Soc. Neurosci. Abstr., 1983) of the posterior parahippocampal gyrus. In contrast, FRT injections restricted to the surrounding areas POa and rostral PG of the inferior parietal lobule, areas Ts1 and Ts2 of the superior temporal gyrus, and areas TE2 and TE3 of the lateral inferotemporal region did not produce labeled neurons in these parts of cingulate cortex. The labeled neurons in the cingulate region were found in layers III and V-VI. Despite the overlapping pattern of retrogradely labeled neurons, only few double labeled neurons were identified in the deep layers of these regions, especially following injections of areas Opt and TF. Thus, these posterior cingulate areas send projections to those areas known to subserve the peripheral vision, audition, and highly integrated somatosensation.

Multimodal areas have been identified in the superior temporal sulcus and the frontal lobe as well as the paralimbic areas of parahippocampal gyrus based on the convergence of afferent connections. However, the multimodal nature of the posterior cingulate and retrosplenial cortices is based on their efferent connections. These findings indicate that specific parasensory association areas are influenced by a common limbic source. (Supported in part by ENRM VA Hospital, Bedford, MA and Grant 16841 to DNP)

304.18 PROJECTIONS TO A TONOTOPICALLY-ORGANIZED VOCAL MOTOR REGION OF ANTERIOR CINGULATE CORTEX IN THE MUSTACHED BAT. W.E. O'Neill, D.M. Gooler and R.D. Frisina, Dept. of Physiology, Univ. of Rochester Sch. of Med. and Dent., Rochester, NY 14642.

The mustached bat emits multiharmonic biosonar signals consisting of a long constant frequency (CF) component followed by a terminal frequency modulation. Relative motion between the bat and its surroundings induces a Doppler-shift in the echo frequency, which the bat compensates by adjusting the frequency of its emitted sonar pulses. Doppler-shift compensation stabilizes the echo frequency at the frequency to which the bat's inner ear is sharply tuned. This permits the resolution of small frequency and amplitude modulations in the echo caused by the wing movements of insect targets.

We have previously discovered that microstimulation in the anterior cingulate cortex (ACg) elicits biosonar cries rostrally, and audible social vocalizations caudally. Moreover, the region from which sonar cries can be elicited is tonotopically organized, so that the dominant 2nd harmonic of the elicited pulses increases systematically from 58 to about 61 kHz along a rostrocaudal axis. Thus, unlike the other vocal control regions previously studied in bats, this area contains a neural substrate for the control of vocal frequencies emitted during Doppler-shift compensation. In an effort to determine the pathways by which echo frequency information reaches the ACg, we have studied the connections to this region after focal injections of HRP. Ipsilaterally we found retrogradely labeled cell bodies in layers II and III of the dorso-rostral auditory cortex, in a location likely to contain neurons sensitive to harmonic combinations (CF/CF neurons) discovered in previous studies (Suga et al., Science 203:270-274, 1979). Additionally, a very small number of labeled cells are consistently found in the dorsal division of the medial geniculate body of the thalamus. Other non-auditory regions of thalamus showed many more retrogradely labeled cells. These included cell groups in the medial and lateral parts of the medial lateral nucleus, and cells scattered throughout the ventral anterior nucleus, both of which are components of thalamic motor systems. Contralaterally, labeled cells were found in layers II/III of both the ACg and prefrontal/frontal cortex dorsal and lateral to ACg. These are directly adjacent and rostral to the injected site in ACg. These cortical projections may provide auditory information indirectly to ACg, since previous studies have shown connections to frontal cortex from auditory cortex (Kobler et al, Soc. Neurosci. Abstr. 9:956, 1983).

In conclusion, direct and indirect pathways exist which may provide the auditory feedback necessary in ACg for control of vocal frequency for Doppler-shift compensation. Supported by PHS-NINCDS grant no. 1 RO1 NS21268 to WEO.

304.19 POSTNATAL MATURATION OF HUMAN FRONTAL CORTEX:NEW CYTOARCHITECTONIC CRITERIA. I.Kostović, M.Judaš+ and N.Bogdanović+, Sect. of Neuroanatomy Dept.of Anatomy, Medical Faculty, Univ.of Zagreb, Yugoslavia.

Classical cytoarchitectonic studies have described postnatal development of human cerebral cortex as a sequence of progressive maturational events.The aim of this study was to develop new approach using criteria for evaluation of regressive histogenetic events,modular cell arrangements and establishment of cortical projections.The following criteria were applied:(1) for regressive events:a) disappearance of transient fetal layers (sobplate zone) and cells,b) resolution of granular layer (IV) and disappearance of six-layered pattern,(2) for modular and tangential rearrangements: cell clustering and radial columnation,(3) for progressive differentiation: standard criteria (laminar and cytological maturation, decrease in cell-packing density).This parameters were tested on selected frontal areas (agranular-premotor,dysgranular-intermediate and granular-prepolar) by analyzing serial Nissl-stained celloidin sections prepared from postmortem frontal lobe of 11 children ranging between neonatal period to 14 years (y.).In the newborn all frontal non-central areas appear very immature when compared on the basis of regressive (1) and modular (2) criteria.In addition, boundaries between areas are poorly defined.Thus,prominent granular layer (IV),fetal subplate layer and clusters of layer V pyramidal (3-6) neurons are present throughout frontal cortex.This indicates rather uniform development across the entire frontal lobe.However, based on the progressive criteria (3) premotor area appear to be more mature then prepolar cortex or Broca area.Period between 3-9 months is characterized by gradual emergence of pyramidal cell clusters in layer III,rearrangements in vertical alignement and disappearance of fetal layers.At age of 3 y. frontal agranular (premotor) cortex shows relative maturity due to the disappearance of granularity (criterion-c-1),dispersion of small cell clusters (c-2) and cytoarchitectonic differentiation (c-3).In contrast, frontal granular (prepolar) cortex and Broca area show signs of protracted development:abundance of fetal cells in deep cortex, presence of layer IV (c-1) and immature appearance of layer III (c-3).Between 11-14 y. additional change was observed:Appearance of deep staining among the large layer III pyramidal cells which tended to be distributed in a spatially periodic pattern which is different from small cluster system.This study demonstrated validity of regressive and modular cytoarchitectonic criteria as complements to the "standard" criteria.The following conclusions are drown based on this approach:During infancy there exists a rather synchronous development of all frontal areas.Pyramidal cell cluster formation reflects growth of cortical efferents.The cytoarchitectonic organization of the frontal granular cortex continues to develop during childhood and puberty.

305.1 NEURONAL ACTIVITIES OF THALAMO-CORTICAL AND HIPPOCAMPAL SYSTEMS DURING AUDITORY WORKING MEMORY PROCESSING IN THE RAT. Y. Sakurai. Dept. of Psychology, Toyama Med. & Pharmaceu. Univ., Sugitani, Toyama 930-01, JAPAN.

Certain aspects of memory involve thalamo-cortical function. Unit activity in the prefrontal cortex (PFC) and dorsomedial thalamus (DMT) was related to working memory for response (Sakurai & Sugimoto, Behav. Brain Res., 17:213, 1985; 20:295, 1986). Many previous studies have shown relationships between hippocampus (HPC) and several types of memory. The present study was designed to examine the unit activity of the thalamo-cortical (PFC and DMT) and the hippocampal (CA1, CA3, DG) systems during a task for auditory working memory, about which little has been known as compared to visual and spatial memory. The task was an auditory version of continuous nonmatching-to-sample (CNM) task, originally introduced by Pontecorvo (Animal Learn. & Behav., 11:356, 1983). At the start of each trial, a tone (8 kHz or 1 kHz) was presented and continued for 10 sec. One second after the onset of the tone, the guillotine door opened and the response-panel was available for 3 sec. During a nonmatch trial (NM), the stimulus was different than that during the preceding trial and a panelpress (Go) provided food reward. During a match (M) trial, the stimulus was the same as that during the preceding trial and a Go response turned on a buzzer. With this training schedule, the optimal strategy for the rat was a Go response on NM trials and a No-Go response (not pressing the panel) on M trials. The intertrial interval was 3 sec which functions as a delay period. Following completion of the training, the rat was anesthetized and nichrome wires (25μ) for single unit recording were chronically implanted stereotaxically into the PFC, DMT, CA1, CA3, and DG. The wires were connected to a 60-wire plastic plug, and the whole assembly was fixed with dental cement to the skull. Five days after surgery, the rat was retrained in the CNM task and each unit was recorded during performance of the task. Unit activity was analyzed in three temporal periods of the task: the last 3 sec of the tone in one trial, the first 1 sec of the tone during the next trial, and the 3 sec of delay period between them. During these three periods, six types of frequency histograms classified the activity by stimulus (high tone or low tone), responses (Go or No-Go) and outcomes of the responses (correct or error). By this analysis, each unit could be judged to be related to the auditory perception, the motor control, or the working memory processing. The ratios of each type of units in the PFC, DMT, CA1, CA3, and DG are currently under investigation. Comparison among those structures in relation to the auditory working memory processing will be discussed.

305.2 MEMORY DEFICIT IN PASSIVE-AVOIDANCE LEARNING IN BULBECTOMIZED LONG-EVANS HOODED RATS. B.M. Thorne and J. Rowles*. Miss. State Univ., Miss. State, MS 39762.

Complete olfactory bulb removal in rats typically results in increased muricide, increased activity, hyperirritability to handling, and a deficit in passive-avoidance (P-A) learning. Because bulbectomized rats are usually hyperactive, it is possible that the P-A deficit stems from an inability to withhold a response rather than from a lack of memory. To compare the memory loss hypothesis with the hyperactivity hypothesis of the P-A learning deficit, we employed a modified P-A apparatus which permitted an alternative to behavioral inhibition.

The modified P-A apparatus consisted of an illuminated common platform connected to two discriminably different chambers. Rats were given 6 acquisition trials in which entry into each of the dark chambers was alternated. On the last trial, each subject received a 3-sec, 1 ma footshock. Twenty-four hours later, all animals were tested on retention of the footshock by being placed on the platform with access permitted to both chambers. A correct response on the postshock trial was defined as either failing to leave the platform within 5 min or choosing the chamber in which shock had not been presented during acquisition.

In agreement with most previous studies, bulbectomy resulted in significant weight loss in the males, increased irritability in both sexes relative to the controls, elevated muricidal behavior in the males, and increased open-field activity in both sexes. On the P-A task, bulbectomy decreased response latencies on 4 of the 6 acquisition trials. In addition, control animals showed clear evidence for habituation to the platform, i.e., increasing response latencies across trials. Bulbectomized rats showed no evidence for habituation. On the postshock trial, 25 of 26 operated control rats stayed on the platform, while this was true for only 6 of 30 bulbectomized animals. According to the definition, all of the control animals made the correct response, while 9 of 30 OB rats made an incorrect response. The difference was significant indicating a memory defect in bulbectomized rats on the P-A task.

305.3 AN ATTENTIONAL-ASSOCIATIVE NETWORK THAT SIMULATES THE TOPOGRAPHY OF THE NICTITATING MEMBRANE RESPONSE, HIPPOCAMPAL AND SEPTAL NEURONAL FIRING, AND THE EFFECTS OF HIPPOCAMPAL LESIONS AND STIMULATION, DURING CLASSICAL CONDITIONING. Nestor A. Schmajuk. Center for Adaptive Systems. Boston University. Boston, MA 02215.

The present study introduces a real-time version of the Pearce-Hall (1980) model that is capable of associations among conditioned stimuli (CS), and incorporates performance rules that convert learning variables into topography of the rabbit nictitating membrane (NM) response and associated neural firing.

By assuming that hippocampal lesions (HL) and hippocampal stimulation (HS) affect computations of attentional variables, the model is able to simulate HL and HS effects on many classical conditioning paradigms. In the normal case, associability of CS_i when presented with event k is given by: $\alpha_i^k = |\lambda^k - B^k|$, where B^k is the aggregate prediction of event k made upon all CSs present at a given moment, and λ^k represents the intensity of event k. In the HL case, associability is given by $\alpha_i^{US} = |\lambda^{US} - V_i^{US}|$, where V_i^k is the net associative value between CS_i and event k. Computer simulations for the HL case were carried out for the following protocols: acquisition under different interstimulus intervals (ISI), conditioned inhibition, extinction under different ISIs, latent inhibition, blocking, overshadowing, discrimination reversal, and sensory preconditioning. Regarding HS, the present study assumes that α^{US} increases when HS is applied.

Neural activity in the hippocampus was simulated by assuming that hippocampal neurons code the instantaneous magnitude of B^{US}. Neural activity in the medial septum was simulated by assuming that septal neurons code the instantaneous magnitude of $\Sigma_j \alpha_j$, i.e., by the sum of CS and US associabilities. Simulations of CA1 hippocampal unit activity during acquisition and extinction, and medial septum unit activity during acquisition of conditioning, are presented.

Although some discrepancies between simulation results and relevant literature were noted, the network proved capable of simulating a large portion of the experimental data.

305.4 LOCAL AND GLOBAL FEATURE EXTRACTION USING COHESIVE AND DISCONNECTED TEMPLATES WITH MACHINE VISION CROSS-CORRELATION PROGRAMS. R. B. Glassman. Dept. of Psychology, Lake Forest College, Lake Forest, IL 60045.

Vision may be a result not only of a hierarchical building of local perceptual "bricks" at low levels of the visual system into larger perceptual "houses" at higher levels of the brain; rather parallel processing of local and global information may take place beginning at the lowest levels of connections from retina to cortex (Hughes, H. C. & Sprague, J. M., Exp. Brain Res., 61:332-354, 1986). While primarily serial-processing computers can simulate such processes only in a slow, roundabout way, they can help in evaluating the logic of hypotheses about image processing.

Two programs, written using the convolution function of the IRI P256 vision machine with array processor, were used to run cross-correlations, normalized for local brightness, between a template comprising pixels representing a small piece of an object-image, and every translational position in a scene in which the same object appeared. Two-dimensional correlogram plots represented the degree of match as brightness, at each pixel position. In one program all pixels were contiguous within a rectangular border ("cohesive template") while the other program permitted an arbitrary spatial distribution of small patches of pixels ("disconnected template"). With the latter program, it was possible more precisely to iconically define a feature in terms of the critical information about form and gray level, while excluding irrelevant information.

A higher degree of selectivity was achieved with disconnected templates. In the special case of a simple, high-contrast object, good recognition occurred over a distance factor of two ("perceptual size constancy"), but more conceptual and empirical work is needed to more generally determine the conditions under which the disconnected template technique helps or hinders feature extraction.

Some of the correlograms have a visually intriguing three-dimensional quality or an embroidery-like quality; these seem to be the result of redundancies within template and scene. Beauty may or may not be truth, but perhaps these effects can be used to facilitate the search for a match in a computer pattern recognition process. This would be so if the effects can function as filters or amplifications of relevant information, or as guides in a second stage of the search process. If evolution has made such a discovery, perhaps these effects are analogous to some aspects of organismic visual processing.

(Work carried out at Oak Ridge National Laboratory, Center for Engineering Systems Advanced Research.)

305.5 **FACILITATION OF LEARNING, ENHANCEMENT OF MEMORY, AND PROTECTION AGAINST AMNESIA BY A BENZODIAZEPINE ANTAGONIST IN MICE.** H. Lal, P. Bhakthavatsalam*, and M.J. Forster. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

Benzodiazepines are known to impair learning and memory performance. The present investigation provides evidence that a benzodiazepine antagonist, Ro 15-1788, facilitates learning and memory in mice. In one experiment, 3-month-old HSD:(ICR)BR mice were injected i.p. with either saline or Ro 15-1788 (40 mg/kg i.p.), 10 min prior to acquisition of a discriminated escape habit. Acquisition consisted of training trials on which the mice were required to enter the correct goal arm of a T-maze to escape footshock. Training was discontinued when a correct arm choice had occurred on three consecutive trials, and retention was measured 2-weeks later by determining the number of trials required to reverse the T-maze habit. When compared to saline-treated controls, Ro 15-1788-treated mice required significantly **fewer trials for acquisition of the T-maze habit**, but significantly **more trials for its reversal** during retention. This finding suggested that Ro 15-1788 had facilitated both learning and memory for the T-maze choice discrimination. In a second experiment, Ro 15-1788 was tested for its ability to protect against amnesia induced by scopolamine in a step-through, passive-avoidance paradigm. Separate groups of mice were injected with either Ro 15-1788 (40 mg/kg) or saline, 20 min prior to a passive avoidance acquisition trial in which entry from the light to the dark chamber of a 2-compartment apparatus was followed by a 5-sec, 2.0 mA footshock. Scopolamine (0.64 mg/kg) or saline was injected 10 min prior to the acquisition trial, and retention was measured by the latency to enter the dark chamber during a 24-h retention test. Mice receiving only scopolamine prior to training showed poorer retention (shorter step-through latencies) when compared with control mice receiving only saline. Ro 15-1788 pre-treated mice trained under scopolamine showed latencies comparable to those of the control group, suggesting that Ro 15-1788 pre-treatment had afforded **protection against scopolamine-induced amnesia.** The enhancement of learning and memory performance by Ro 15-1788 suggests that endogenous ligands for benzodiazepine receptors exert a negative modulatory influence upon brain processes involved in cognitive performance. Those processes involved appear to include the cholinergic system, as Ro 15-1788 afforded protection against memory disruption produced through muscarinic receptor blockade.

Supported by NIH-NIA grant R23-AG06182 (M.J.F.) and NIH-BRSG award S07 RR05879 (T.C.O.M) .

305.6 **HABITUATION AND STIMULUS-SPECIFIC NEURONAL RESPONSES RECORDED FROM THE AMYGDALA OF THE MONKEY**
F.A.W. Wilson & E.T. Rolls. Dept. of Exptl. Psychology, Oxford, U.K.

In order to examine the role of the amygdala in memory function, neuronal activity was recorded in 2 monkeys performing recognition memory and visual discrimination tasks. Typical stimuli were novel and familiar junk objects, familiar foods and faces. In the recognition memory task, lick responses to novel stimuli elicited saline; responses to familiar stimuli elicited fruit juice. Stimuli presented as familiar were shown after 0,2,4,6,8,10,12,14, or 16 other intervening trials. In the visual discrimination task, responses to a circle elicited fruit juice while responses to a square elicited saline. Of 659 neurons recorded, 58% were unresponsive; 35% responded non-specifically; and 2.5% responded differentially in the visual discrimination task. 1.5% responded maximally to novel stimuli, the responses declining with repetition of the stimuli. 'Memory spans' were determined for 5 neurons by plotting responses to familiar stimuli as a function of intervening trials. The magnitude of the differential response decreased with increasing numbers of intervening trials, the memory spans ranging from 2 to 10 trials. The mean latency for the differential responses was 212 ms. Increases in firing rate for familiar stimulus presentations were not observed.

Two groups of selective neurons responded maximally to faces (1.5%), or to foods (1%). The responses of selective neurons were significantly greater to foods or faces than to other stimuli. Selective neurons often responded weakly to ineffective stimuli, but novel stimuli elicited better responses than other ineffective stimuli in certain neurons. Habituation of the selective responses occured in 30% of selective neurons. Recordings sampled the dorsoventral axis of the amygdala, but spared the most anterior, medial and ventral lateral regions. Most responsive neurons were located across the dorsal amygdala, with face-selective neurons located medially in the basal accessory nucleus.

Few task or stimulus-related neurons were observed in this study. This could be due to the specific requirements for activating amygdala neurons and to testing paradigms restricted to the visual modality. However, the activity of the responsive units suggests a contribution by the amygdala to stimulus recognition. The decremental responses indicate a mechanism reflecting the recency of stimulus presentations. The activity of stimulus-selective neurons may encode the presence of highly familiar and emotionally valent stimuli. These results are consistent with a role for the amygdala in behavioral responses to stimuli that are novel, reinforcing and which elicit emotional behavior.

305.7 AREA POSTREMA LESIONS IN RATS ENHANCE NICOTINE-INDUCED CONDITIONED TASTE AVERSIONS. L. Giugno and K.-P. Ossenkopp. Dept. Psychology, University of Western Ontario, London, Ontario, Canada, N6A 5C2.

The area postrema (AP), a circumventricular organ in the fourth ventricle, has been shown to be a chemoreceptor for blood-borne toxins (Borison, Life Sci., 1974, 14, 1807). Several studies have shown that AP is the central chemoreceptive site for injected toxins used to establish conditioned taste aversions (CTA). AP ablation has been shown to abolish CTAs induced by injections of such toxins as LiCl and scopolamine, but levels of amphetamine or motion sickness-induced CTA are not attenuated by these ablations. The present experiment examined the role of AP in nicotine-induced CTA in rats.

Adult male hooded rats were given thermal cautery lesions of AP or sham lesions. Following a 2 week recovery period the animals were adjusted to a 23½ hr/day water deprivation schedule and on the conditioning day all rats were presented with a 0.15% saccharin solution during the normal drinking period. Immediately after this drinking period half of the rats in the lesioned and sham lesioned groups were injected with nicotine (1 mg/kg, i.p.) and the other rats received isotonic saline injections. Starting 3 days after the conditioning trial the animals were given two-bottle choice tests (saccharin vs. water) on 3 consecutive days. Statistical analyses revealed that the rats injected with saline exhibited strong preferences for saccharin. The sham lesioned rats injected with nicotine showed a weak but significant ($p < .05$) CTA to saccharin. The rats with AP lesions and injected with nicotine displayed a significantly ($p < .05$) larger CTA than the sham lesioned rats given nicotine. Thus, AP lesions enhanced the magnitude of the nicotine-induced CTA. In a subsequent test phase all rats were given chocolate metrecal followed by injections of scopolamine hydrochloride (1 mg/kg, i.p.). In a two bottle choice test the AP lesioned rats exhibited significantly ($p < .01$) greater preference for the chocolate taste than the sham lesioned rats. Thus, AP lesions attenuated the magnitude of scopolamine-induced CTA. The present results clearly suggest that nicotine and scopolamine do not act at the same neural site in producing a CTA.

305.8 DEVELOPMENT OF AN ALL-OR-NONE DEPOLARIZING POTENTIAL AFTER BURSTING ACTIVITY IN PIRIFORM CORTEX: A POSSIBLE MODEL FOR THE KINDLING PHENOMENON. W.H. Hoffman* and L.B. Haberly. Neurosci. Training Prog. and Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

Intracellular recordings were obtained from layer II pyramidal cells in slices of rat piriform cortex maintained in vitro. The normal response to stimulation of afferent fibers consists of a single EPSP and Cl^- and K^+ mediated IPSPs (Tseng & Haberly, Neur. Abs. 12:667). Removal of Mg^{++} from the bathing medium resulted in evoked and spontaneous bursting activity; upon return to normal bathing medium the bursting subsided but a second depolarizing potential (2-12mv; 25-125ms duration) developed following the monosynpatic EPSP at a variable latency in all cells examined in 19 slices. This new potential occurred in an all-or-none fashion at low stimulus strengths and could trigger action potential generation. The potential persisted with no apparent decrement for as long as impalements were maintained (up to 10 hr). Its frequency of occurrence was not affected by intracellular current injection, suggesting that it is an EPSP rather than an endogenously mediated potential. It did not appear to result from blockage of inhibitory processes since both Cl^- and K^+ mediated IPSPs were present. Although 10μM APV and 10μM ketamine (NMDA antagonists) blocked bursting in 0 Mg^{++} and the subsequent development of the second depolarizing potential, neither agent at 100μM blocked the second potential once it was established (6 of 6 slices). When bursting activity was induced by 100μM 4-aminopyridine or low (10%) bath Cl rather than 0 Mg^{++}, the second depolarizing potential was also evoked after return to normal medium. While the potential that developed after low Cl^- often disappeared within 1 hour, in 4 of 11 slices it persisted for as long as impalements were maintained (up to 5 hr). The presence of 10-25μM APV or ketamine decreased the intensity of bursting and blocked development of the second potential in 10 of 16 slices, although in 4 of the 6 slices in which the second potential was generated it lasted for the duration of impalements (up to 3 hr). This result suggests that NMDA receptor activation is not required for development of the second potential but does facilitate its development, perhaps as a consequence of the intensification of bursting activity.

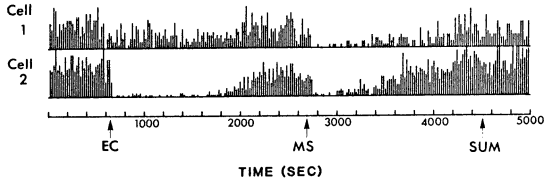
The potential induced by bursting activity in vitro displays a striking resemblance to a second EPSP that appears in pyramidal cells in the piriform cortex of kindled rats in vivo (Sutula & Haberly, Neur. Abs.12:1126). Based on preliminary results obtained by field potential analysis, we postulate that it is mediated by regenerative positive feedback between layer II pyramidal and deep cells following an increase in efficacy of excitatory synapses (see Tseng & Haberly, this vol.). Such a long lasting increase in synaptic efficacy could also have direct relevance to long term memory processes. Supported by NINCDS grant NS19865 to LBH.

305.9 REVERSIBLE INACTIVATION OF HIPPOCAMPAL AFFERENTS SELECTIVELY REDUCES THE SPONTANEOUS DISCHARGE RATE OF DENTATE UNITS. S.J.Y. Mizumori, B. L. McNaughton, C. A. Barnes and K. Fox*. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

This study investigated the consequences of the reversible inactivation of different hippocampal afferents. Exp. 1 assessed the contributions of medial septal (MS), supramammillary (SUM), entorhinal cortical (EC) and contralateral hilar afferents to the activity of units recorded from the hippocampus of anesthetized rats. Exp. 2 examined the relationship between the physiological and mnemonic consequences of selective inactivation of MS or EC in freely behaving rats.

Under Nembutal anesthesia, CA1 complex-spike (CS) cells (N=37) never altered their rate in response to a 0.3-0.5 ul injection of 2% lidocaine (a local anesthetic) into MS, ipsilateral SUM, or ipsilateral EC. In contrast, 45% and 35% of dentate granule cells (N=31) responded to inactivation of MS or EC, respectively, but not SUM, with reduced discharge. A significant increase in granule cell discharge followed injection into the contralateral hilus. Two granule cells that differentially responded to EC, MS and SUM injections are illustrated below. Inactivation of MS and EC, but not SUM, also attenuated firing of some hilar CS cells.

For Exp. 2, rats were implanted with guide cannulae to permit injection of 2% tetracaine (a longer acting anesthetic) and recording "stereotrodes" (McNaughton et al., 1983) for monitoring unit activity while the animals solved a radial maze problem. Five of five CA1 CS cells exhibiting place-specific firing before injection maintained the same specificity in spite of the severe spatial working memory (WM) impairment caused by MS inactivation. In contrast, place fields of four of seven hilar CS cells were silent for the duration of behavioral impairment. Place fields and choice accuracy returned to preinjection levels within about 15 min. Four of five granule cells also showed reduced firing coinciding with the period of behavioral impairment induced by MS inactivation. Ipsilateral EC injection did not affect choice accuracy, yet often resulted in reduced granule cell firing.The main conclusion from these studies to date is that stable place fields can be recorded from CA1 CS cells during the severe spatial WM impairment and large reduction in granule cell activity caused by MS inactivation. Supported by AG05375, AG03376, and NS20331.



305.10 A MULTIPLE REGRESSION ANALYSIS OF BEHAVIORAL CORRELATES OF RAT HIPPOCAMPAL NEURON DISCHARGE. B. Jones Leonard, B.L. McNaughton and C.A. Barnes. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

A number of behavioral variables influence the discharge of hippocampal single units in freely-moving rats. Spatial location is the primary correlate of complex spike (CS) cell discharge, while motion is the primary behavioral correlate of theta cell discharge. However, CS cells also show directional- and velocity-modulated firing (McNaughton et al., Exp. Brain Res., 52:41-49, 1983), and theta cells may exhibit some spatially-selective firing (McNaughton, et al., ibid.; Kubie et al., Soc. Neurosci. Abstr, 11:1231, 1985). Separation of the relative contributions of several variables such as these is a general problem in single unit physiology. For example, in the case of theta cells it has been difficult to distinguish firing correlated with motion from that correlated with spatial location. We have developed an application of multiple regression analysis (MRA) to allow the assessment of the relation of one or several behavioral variables to hippocampal neuron firing while statistically controlling for the effects of other variables.

Single units were recorded from CA1 and the fascia dentata in freely-moving rats. Unit responses and spatial coordinates were collected by a computer while the rat traversed the elevated 8-arm maze. Eight trials of 8-arm traverses were collected and analyzed for each cell. The data for MRA were derived by dividing each arm into 4 space bins. Average neuron firing rates and movement velocities were calculated separately for each bin and radial direction (8 trials x 32 space bins x 2 directions). The 32 spatial locations and 2 directions were represented as binary-valued orthogonal vectors that associated each firing rate with a location, a direction and a velocity. Firing rates were then regressed onto the vectors to obtain the proportion of variance accounted for (Multiple R^2) by spatial location, direction or velocity.

The average R^2 for spatial location for 28 CS cells was 0.261. However, all CS cells showed a significant ($p<.01$) directional component to their spatial firing. When this factor was included, the average R^2 increased to 0.406. In other words, on average 65% of the spatial selectivity was due to the interaction with the directional component. The three-way interaction with space, direction, and velocity increased the R^2 to 0.458. For 12 theta cells 30.4% of the total firing variance was accounted for by a quadratic relationship with velocity. While theta cells showed some spatially selective firing, when the velocity variance was statistically controlled, the individual R^2s for spatial locations and direction were small.

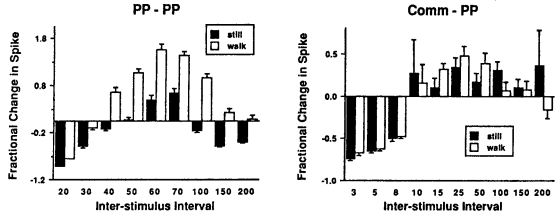
In conclusion, the application of MRA appears to be a useful technique for quantifying behavioral correlations of single unit activity. In the present application it has verified the strong directional component of spatial firing of CS neurons, a component that appears to have been missed in numerous other analyses. Supported by AG-03376 and NS20331.

305.11 EFFECTS OF BEHAVIORAL STATE ON FEEDBACK AND FEEDFORWARD INHIBITION AND FACILITATION IN RAT FASCIA DENTATA. E.J. Green, C.A. Barnes and B.L. McNaughton, Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Prestimulation of the commissural (Comm) or perforant path (PP) afferents shortly prior to stimulation of the PP inhibits the evoked granule cell population spike by activating, respectively, feedforward (Comm-PP) or feedback and feedforward (PP-PP) inhibitory afferents to granule cells. Activation of these pathways at longer latencies can produce an apparent increase in granule cell excitability (spike "facilitation"), the mechanism of which is not well understood. While inhibition and facilitation have been studied in anesthetized preparations, it is not known how they might be altered by the behavioral state of the animal. In these experiments we have evaluated the efficacy of feedback and feedforward inhibition by delivering conditioning shocks to the PP or Comm followed at various intervals by test shocks to the PP while rats were walking slowly on a treadmill or sitting in the same apparatus.

Rats in both behavioral conditions which were given PP prestimulation (PP-PP) exhibited the characteristic pattern of spike inhibition at short intervals and spike facilitation at longer intervals. However, walking rats exhibited a significant right shift in the inhibition/facilitation curve, with markedly smaller amounts of PP-PP inhibition and larger facilitation at some intervals relative to when they were still. These differences could not be accounted for by alterations in the size of the conditioning spike or by the amplitude of the test EPSP. At the stimulus intensities tested thus far, there was no apparent effect of walking on feedforward inhibition produced by commissural prestimulation. There was, however, more spike facilitation at some Comm-PP intervals in walking rats.

These data suggest that the efficacy of inhibitory circuits within the fascia dentata varies with the behavioral state of the animal. Experiments in progress are designed to determine the locus of the behaviorally-dependent alterations within the inhibitory network. Supported by AG05345, AG03376, NS20331.



Examples of PP-PP and Comm-PP interactions as a function of behavioral state for an individual animal.

305.12 BASAL FOREBRAIN GRAFTS INFLUENCE COMPLEX-SPIKE ACTIVITY IN THE HIPPOCAMPUS OF RATS WITH FIMBRIA-FORNIX LESIONS. M.L. Shapiro[1], F.H. Gage[2], and A. Bjorklund[3]. [1]Department of Psychology, Johns Hopkins University, Baltimore, MD, [2]Department of Neurosciences, UCSD, La Jolla, CA, [3]Department of Histology, Lund University, Lund, Sweden.

Complex-spike unit activity from the hippocampus was examined in: (1) normal rats (CON), (2) rats with fimbria-fornix lesions (FF), and (3) rats with fimbria-fornix lesions and intrahippocampal grafts of fetal basal forebrain tissue (GRAFT). The GRAFT rats had previously shown some degree of recovery of spatial memory in the Morris water maze. Single units were recorded while the rats traversed a radial maze during three different types of trials: (1) normal traversal trials, (2) trials in which the maze was covered with cardboard, and (3) trials in which the maze was rotated 90 degrees clockwise. Quantitative analyses of the spatial distribution of activity showed that CON rats had tightly clustered, reliable place-fields that were stable in all trials. In contrast to CON rats, FF rats had more dispersed, less reliable place-fields that were disrupted when the maze was covered or rotated. GRAFT rats had place-fields that were more tightly clustered, more reliable, and more stable when the maze was covered or rotated than the FF rats. Thus, the functioning of hippocampal circuitry was influenced by fetal basal forebrain grafts, and these grafts may have ameliorated the behavioral effects of lesions by restoring, to some degree, critical aspects of neuronal activity in the hippocampus.

305.13 KINDLING OF THE PERFORANT PATH ALTERS DISCRIMINATION-REVERSAL TRAINING OF THE RABBIT NICTITATING MEMBRANE RESPONSE.
G. B. Robinson, D. M-M. Mikula* and T. W. Berger.
Departments of Neurological Surgery, Behavioral Neuroscience and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260

We previously demonstrated that hippocampectomy disrupts reversal learning but not acquisition of the rabbit's nictitating membrane (NM) response to discrimination training (Weikart and Berger, Behav. Brain Res., 1986). In the following study we tested whether similar learning deficits occurred in rabbits with an intact, but neurophysiologically abnormal (i.e. epileptogenic) hippocampus.

Ten male New Zealand White Rabbits were implanted, using electrophysiological control, with stimulation electrodes in the perforant path and a recording electrode in the hippocampal dentate gyrus. Following recovery, 5 rabbits received daily kindling stimulation (2 s, 60 Hz train of 1 ms impulses), at an intensity sufficient to evoke hippocampal epileptiform activity, until 10 class 5 seizures were evoked. The remaining rabbits served as controls. For discrimination training either a tone or a light CS+ was always paired with a corneal airpuff UCS (750 ms ISI), with the other stimulus being the CS- (counterbalanced). A total of 64 CS+ and 64 CS- trials (ITI pseudorandomly varied at 20, 30 or 40 s, averaging 30 s) were given per day (pseudorandom sequence). After reaching a CR rate of >80% to the CS+ and <20% to the CS-, the CS+ and CS- were reversed. Reversal training continued until the same criterion were met, or for a maximum of 28 days.

Kindled animals acquired the initial discrimination significantly ($p<.01$) faster than controls (4.4 vs 13.8 days, respectively). Control animals, however, required significantly ($p<.01$) fewer days (10.0) for reversal learning than the kindled animals (22.2 days), due to the kindled animals continued high response rate to the CS-.

These results demonstrate kindling effects on discrimination-reversal training are more complex than are the effects of hippocampectomy. Although both manipulations disrupt reversal learning, only kindling facilitates acquisition of the initial discrimination. This facilitation may result from a kindling-induced potentiation effect (see Berger, Science, 1984). Kindling also recruits many non-hippocampal structures, a number of which may contribute to either the facilitation or disruption of learning.

305.14 HABITUATION OF THE PYRIFORM CORTEX BURST RESPONSE IN VITRO.
J.R. Plant* and D.C. McIntyre. Dept. of Psychology, Carleton Univ., Ottawa, Ont., Canada K1S 5B6.

Habituation, the gradual decrease in amplitude of a behavioral response to repeated presentation of a specific stimulus, is considered to be the most basic and universal form of learning. The habituated response will recover gradually, however, if the same stimulus is withheld or immediately if a different stimulus is presented.

Due to the complexity of the mammalian central nervous system, investigations of habituation have usually involved more simple nervous systems. The few demonstrations of mammalian CNS habituation have involved the disynaptic fexor reflex in the spinal cord (Thompson, R.F. and Spencer, W.A., Psychol. Rev., 173: 73, 1966) and the monosynaptic population response of the hippocampal dentate gyrus in vitro (Teyler, T.J. and Alger, B.E., Brain Res., 115: 413, 1976). In the present study, we demonstrate habituation of the polysynaptic burst response of the rat pyriform cortex in vitro.

Coronal slices of the amygdala-pyriform cortex were taken from male rats as previously described (McIntyre, D.C. and Wong, R.K.S., J. Neurophysiol., 55: 1295, 1986). Provocation of the burst response, recorded intracellularly from neurons in the layer 3 field of the pyriform cortex, was achieved with a bipolar stimulating electrode positioned in the ventral-lateral amygdala. A monophasic anodal pulse (0.1 ms) was passed between the two electrode tips at an intensity suprathreshold for the all-or-none, polysynaptic excitatory burst event. Although this event was always of the same magnitude when elicited at 0.05 Hz using a constant suprathreshold intensity, it gradually habituated to zero when provoked repeatedly at 0.5 Hz. Subsequently withholding the stimulus resulted in the progressive and full recovery of the event within 60 s. In other experiments, after the response was completely habituated at 0.5 Hz, a polarity reversal of the stimulus on the next pulse (cathodal) resulted in an immediate and full recovery of the original burst response. If the next pulse in the series was reversed again to the original polarity (anodal), the burst event was not observed and appeared to be still fully habituated. This result suggests the habituating process has a stimulus specific nature in these cortical circuits.

In intracellular recordings where stimulation resulted in an antidromic response which was observed immediately antecedent to the burst event, no habituation of the antidromic response was observed, while the burst event exhibited the progressive habituation described above. This result suggests that synaptic mechanisms are required for the realization of habituation in the amygdala-pyriform slice preparation.

305.15 TYPE I AND II THETA-LIKE UNIT ACTIVITY IN STRUCTURES OF THE PAPEZ CIRCUIT DURING DIFFERENTIAL AVOIDANCE CONDITIONING IN RABBITS.
M. Mignard, D. Bentzinger*, N. Bender*, and M. Gabriel.
Dept. of Psychol., Univ. of Illinois, Champaign IL 61820.

Rhythmic bursts of neuronal action potentials exhibiting frequencies (4 - 10 Hz) and behavioral relations similar to the the hippocampal theta rhythm occur in the hippocampal formation during differential avoidance conditioning (Gabriel & Saltwick, Physiol. & Behav., 24:303, 1980). In this task, rabbits learn to avoid a shock unconditional stimulus (US) by stepping in an activity wheel in response to a positive conditional stimulus (CS+, a 1 or 8 kHz .5-sec tone) initiated 5 sec before US onset. They also learn to ignore a negative conditional stimulus, a CS- never followed by the US. Trains of rhythmic 7-8 Hz unit bursts following CS onset were similar to type II "immobility" theta (Kramis et al., Exp. Neurol., 49:58, 1975), whereas bursts attaining 10 Hz just before CR initiation, and continuing at high frequencies (8-10 Hz) during locomotion suggested Type I "movement related" theta. Here we report movement related and/or CS related theta-like bursts of action potentials in the posterior cingulate cortex (Brodmann's Area 29b), the anterior ventral (AV) thalamic nucleus, and the medial mammillary (MM) nucleus. Neither the anterior cingulate cortex (Brodmann's Areas 24 and 32), the medial dorsal thalamic nucleus, nor the anterior dorsal (AD) nucleus exhibit such bursts. The CS related bursts were evident in a majority of the approximately 300 Area 29b records obtained since 1983. A similar high prevalence of this pattern has been noted in the dorsal magnocellular region of the AV nucleus just ventral to the AD nuclear border. In 4 MM nuclear recordings to date, each has exhibited CS related bursts. The cortical and thalamic CS related bursts, like immobility theta, were severely attenuated by systemic atropine (25 & 50 mg/Kg) and scopolamine hydrobromide (1, 2, & 4 mg/Kg), but not by scopolamine methylbromide. Clear phase differences between CS+ and CS- elicited burst trains in conditioned rabbits suggested an informational function for the bursts. We have recorded movement related bursts in Area 29b and in the AV nucleus, but at a substantially reduced prevalence relative to CS related bursts. These results implicate the entire circuit of Papez in theta processes. They also support cingulate cortical involvement in these processes (e.g., Holshiemer, Exp. Brain Res, 47:2, 1982), and they indicate that cingulate cortical theta is not volume conducted from the hippocampus as suggested in recent literature. (supported by NIMH Grant 37915 to M.G.)

305.16 NEURONAL AND BEHAVIORAL CORRELATES OF BILATERAL MAMMILLOTHALAMIC TRACT LESIONS DURING AVOIDANCE LEARNING IN RABBITS.
J. Shenker*, Y. Kubota*, M. Mignard, C. Cuppernell*, D. Swanson*, and M. Gabriel. (Spon: E. Donchin). Dept. Psych., Univ. of IL, Champaign, IL, 61820.

Studies of multi-unit activity (MUA) during discriminative avoidance conditioning in rabbits have established the development of massive training-induced excitatory and discriminative neuronal responses to conditional stimuli in the anteroventral (AV) and mediodorsal (MD) thalamic nuclei (Gabriel et al., Information Processing by the Brain, H. Markowitsch (Ed.), in press, 1987). The AV response survives dorsal subicular or posterior cingulate (Area 29) cortical lesions (Gabriel et al., Exp. Brain Res., in press, 1987), suggesting that subcortical afferents are necessary for its development. A critical AV afferent may be the mammillary bodies (MB), which send diencephalic projections exclusively to the anterior thalamus via the mammillothalamic tract (MTT), and damage to which has been related to memory dysfunction in humans (Mair et al., Brain, 102:749, 1979) and monkeys (Aggleton et al., Exp. Brain Res., 58:190, 1985). Here we evaluate the MB contribution to the AV response via bilateral electrolytic MTT lesions (15-30 s., 1.5 mA.) and MUA neuronal recording during conditioning with rabbits. Microelectrodes (10-40 micron tip) were stereotaxically implanted bilaterally in the AV for MUA recording. Rabbits were trained in a running wheel with pure tones (1 and 8 kHz) as stimuli: a positive conditional stimulus (CS+) predicted a footshock (US), delivered 5 sec. after CS onset, while a negative conditional stimulus (CS-) predicted no US. Post-CS+ wheel locomotion (CR) prevented the US. Bilateral MTT lesions ($N=3$) abolished CR acquisition except for a transient burst of CRs early in training, possibly mediated by an intact MD. Lesions of the adjacent hypothalamus and ventral thalamus had no effect on CR acquisition. MTT lesions also eliminated the training-dependent excitation in the homolateral AV response ($N=6$). However, neuronal CS discrimination in AV persisted: the CS+ response did not change but the CS- response decreased with training. This contrasts with AV responses in controls, wherein a training-induced increased CS+ response exceeds an increased CS- response. Thus the exitatory and discriminative components of the AV response may be separately controlled, with MB input to AV necessary for the former but not the latter. It should now be possible to determine which remaining AV afferent(s) are necessary for CS discrimination.
(Supported by NIMH Grant 37915 to M.G.)

305.17 ANTERIOR CINGULATE CORTICAL IBOTENIC ACID LESIONS ENHANCE CONDITIONING-INDUCED UNIT ACTIVITY IN THE MD THALAMIC NUCLEUS IN RABBITS. M. Gabriel, Y. Kubota*, S. Sparenborg, and K. Straube*. Dept. of Psychol., Univ. Illinois, Champaign, IL 61820

This study is part of a project investigating the neural mediation of discriminative avoidance learning, i.e., learning by rabbits to avoid a shock unconditional stimulus (US) by stepping in a running wheel within 5 sec. after the onset of a .5 sec. tone (a positive conditional stimulus or CS+). Also learned is nonresponse to a negative CS (CS-), a different tone not predictive of shock. Asymptotic performance (conditioned responses [CRs] on >80% of CS+ trials and <8% of CS- trials) occurs after an average of 4-5 daily training sessions, each session consisting of 60 trials with each CS in an irregular order. AV and MD thalamic neurons exhibit massive training-induced discharges to the CSs and lesions in these nuclei blocked acquisition (Gabriel et al., in The Hippocampus., IV:1, 1986). Subicular or posterior cingulate cortical (Area 29) lesions increased CS driven AV thalamic unit activity and subicular lesions also increased CR frequency (Gabriel et al., Exp. Brain. Res., in press, 1986). Area 29 lesions decreased CR frequency because, we propose, AV thalamic output must traverse Area 29 to reach motor structures (e.g., the striatum) for CR output. These results suggested that AV thalamic activity triggers CR output. Also, Area 29 neurons controlled by subicular afferents exert a "limiting" influence on AV thalamic activity in intact animals. Here we test the parallel hypothesis that MD activity is limited by afferents from the anterior cingulate cortex (Area 24). To date, acceptable lesions (>60% cell loss) have been made in 5 rabbits by injecting 5 ug/ul of ibotenic acid (IBO) at six Area 24 sites equally-spaced along the midline in each hemisphere. One ul of IBO per mm of tissue was injected as the cannula was raised from the ventral to the dorsal limits of Area 24. Stainless steel microelectrodes (tip lengths: 10-40 microns) were implanted bilaterally in the MD nucleus for chronic unit recording. MD records were obtained in 4 lesion, 4 saline-injected and 5 noninjected rabbits. In support of the hypothesis, the MD unit response to both CSs was enhanced in lesion rabbits during the sessions of the first behavioral discrimination and criterion attainment ($P<.006$). Activity in the two control groups did not differ. The rabbits with lesions required an average of 8.6 sessions to reach criterion compared to 5.0 sessions in saline injected and incompletely lesioned controls ($P<.08$). We suggest that this learning impairment is due to the elimination of MD driven Area 24 output to striatal motor system targets. (Supported by NIMH Grant 37915 to M.G.)

305.18 AD THALAMIC LESIONS, AV THALAMIC AND CINGULATE CORTICAL NEURONAL ACTIVITY, AND AVIODANCE LEARNING IN RABBITS. Y. Kubota*, J. Shenker*, M. Mignard, D. Bentzinger*, and M. Gabriel. (SPON: P.Johnston). Dept. Psychol., Univ. Illinois, Champaign, IL 61820

The anteroventral (AV) thalamic nucleus develops learning-related discriminative neuronal activity in response to auditory conditional stimuli (CSs) during differential avoidance conditioning in rabbits (Gabriel et al., Science, 208:1050, 1980). The anterodorsal (AD) nucleus exhibits learning-related neuronal changes that are reciprocally related to those in the AV nucleus with respect to the stages of behavioral acquisition (Bice et al., Neurosci. Abstr., 12:517, 1986). In the first training session, AD firing frequency peaked whereas AV and conditioned response (CR) frequency were low. These relations were reversed during the criterial session: AD activity decreased, AV activity was at its peak and many CRs occurred. Also, AD activity increased significantly in response to a novel stimulus. These findings suggest that the AD provides the source of synaptic drive that limits AV activity when unexpected environmental events call for response suppression. It follows that lesions in the AD nucleus should increase AV activity and CR frequency in sessions in which novel training contingencies are experienced.

Bilateral electrolytic or chemical (ibotenic acid) lesions were made in 12 rabbits. Histological examination revealed bilateral damage in the AD nucleus in 4 of these subjects. The remaining subjects had small lesions in the hippocampus or in the cortex. Rabbits were given standard conditioning, followed by extinction (procedures described in adjacent abstract). As predicted the rabbits with AD lesions made significantly more CRs than controls and those with hippocampal or cortical lesions in the first acquisition session and in the first extinction session ($P<.001$). In the first extinction session, the CS-elicited AV activity of rabbits with the AD lesions was greater than that in the control rabbits ($P<.001$). No statistically significant difference was found in the first acquisition session, but there was a trend in the expected direction ($P<.12$). Area 29 activity was enhanced in the same sessions after damage in the AD nucleus ($P<.01$ for both sessions). Increased activity after AD lesions also appeared in Area 24, only in the first acquisition session ($P<.05$). The similarity between these effects and the effects of subicular lesions (Gabriel et al., Exp. Brain Res., in press, 1987) suggests that the subiculum and the AD nucleus cooperate in the limiting of AV activity and behavior in response to unexpected training contingencies. (Supported by NIMH Grant 37915 to M.G.)

NEUROENDOCRINE CONTROLS: OTHER II

306.1 A COMBINED ROLE FOR ESTROGEN AND PROGESTERONE IN THE CYCLING OF OPIATE RECEPTORS IN THE RAT MEDIAL PREOPTIC AREA. M. Hijazi* and R. P. Hammer, Jr. (SPON: H. Gillary). Depts. of Physiology and Anatomy & Reproductive Biology, University of Hawaii School of Medicine, Honolulu, HI 96822.

Opiate receptor distribution in the medial preoptic area (MPOA) is known to be sexually dimorphic and gonadal-steroid dependent. We examined [^{3}H]naloxone binding in autoradiographs of sections containing caudal levels of the MPOA in adult rats. Females were ovariectomized and treated with the following hormonal regimens: 1) acute estrogen (AE) group - subcutaneous injection of 25 ug estradiol benzoate (E) in sesame oil vehicle 2 hrs before decapitation; 2) delayed estrogen (DE) group - subcutaneous injection of 10 ug E at 0 and 24 hrs, followed by decapitation at 72 hrs; 3) estrogen-progesterone (EP) group - subcutaneous injection of 10 ug E at 0 and 24 hrs, 2.5 ug progesterone (P) at 69 hrs, and decapitation at 72 hrs. Males received no surgical or hormonal treatment. Following decapitation, brains were removed, frozen, and sectioned. Sections were incubated for 60 min in 2.5 nM [^{3}H]naloxone in 50 mM Tris (pH 7.4) and 100 nM NaCl at 0°C. These conditions favor binding to the mu-subtype opiate receptor. After incubation, tissue was fixed in paraformaldehyde vapors, defatted in xylene, and apposed to ^{3}H sensitive film in X-ray cassettes. Autoradiographs were analyzed using computer-assisted densitometry and calibrated using autoradiographic standards in units of dpm/mg protein. MPOA [^{3}H]naloxone binding density in males was significantly less ($p<0.01$) than in all hormone-treated female groups. [^{3}H]Naloxone binding in the EP group was significantly greater than in the AE ($p<0.001$) and the DE group ($p<0.01$). MPOA opiate receptor density in the AE and DE groups were not significantly different. Therefore, exposure to P increased MPOA opiate receptor concentration in E-primed females, whereas E alone produced lower MPOA opiate receptor levels. These results confirm earlier studies of MPOA opiate binding during pregnancy (Hammer and Bridges, Brain Res., in press). Further studies using enhanced resolution methods and additional control groups are underway in order to determine the precise neuroanatomical correlate of the gonadal steroid-dependent MPOA opiate receptor region. These data suggest that the cyclical alteration of MPOA opiate receptor density is dependent on the presence of P after sufficient E priming. These gonadal steroid hormones probably act in concert to alter MPOA opiate receptor content. (Supported by UHPHS Awards HD19951, RR08125 and NS01161 to R.P.H.)

306.2 ALPHA-METHYL-PARATYROSINE (αMPT): A TOOL TO EXAMINE THE INTERACTION BETWEEN ESTROGEN, CATECHOLAMINES AND α1 RECEPTORS. M.A. Sortino, N.G. Weiland and P.M. Wise. Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

α MPT is a competitive inhibitor of tyrosine hydroxylase, the rate limiting enzyme in catecholamine biosynthesis. It has been used to block the LH surge which occurs on proestrous afternoon and in several studies relating catecholamine turnover to reproductive function. As estrogen decreases α1-adrenergic receptor densitities in the medial preoptic nucleus, we wanted to determine whether this effect was related to increased norepinephrine (NE) turnover. To assess the relationship between NE and α1 receptor densities, we wished to block the diurnal increase in NE turnover by administering αMPT. It was therefore essential to establish whether αMPT had a direct effect on ^{3}H-Prazosin binding in vitro or in vivo.

In the first experiment slide-mounted, 20 µM thick brain sections were incubated for 30 min with different concentrations of αMPT ($1x10^{-4}$ to $1.28x10^{-2}$ M) in the presence of 2 nM ^{3}H-Prazosin. After 3 subsequent washes, the brain slices were removed with glass fiber filters and counted. αMPT inhibited ^{3}H-Prazosin binding to α1 receptors in a dose-related manner: the first significant inhibition was detected at 400 µM and half maximal inhibition occurred at about 6 mM. Scatchard analysis was performed using ^{3}H-Prazosin in the presence or absence of 3 different concentrations of αMPT. ^{3}H-Prazosin bound to a single class of binding sites with a Kd of 0.6 nM. αMPT exhibited a simple competitive interaction with the ^{3}H-Prazosin binding sites evidenced by a progressive increase in the apparent Kd for ^{3}H-Prazosin in the presence of increasing concentrations of the drug. To establish whether the effect of αMPT on ^{3}H-Prazosin binding is reversible in vitro, brain slices were preincubated with 5 mM αMPT for 30 min, washed and then incubated with ^{3}H-Prazosin for 30 min in the absence of the drug. No inhibition was observed, suggesting that the inhibitory effect of αMPT is fully reversible in vitro. In a final experiment we tested whether αMPT treatment in vivo affected ^{3}H-Prazosin binding in vitro. Rats were treated with αMPT (400 mg/kg, i.p.) and were killed 45 min later. Brains were removed and prepared as described above. α1 receptor densities are unaffected by prior exposure to αMPT in vivo. The data indicate that αMPT inhibits the binding of ^{3}H- Prazosin to α1 receptors in whole brain slices. This effect is reversible and not observed when αMPT is administered in vivo. Therefore αMPT can be used as a tool to inhibit NE activity and study the relationship between catecholamine release and α1 receptor densities. 306.3 IMMUNOCYTOCHEMICAL LOCALIZATION OF PROGESTIN RECEPTORS IN GUINEA PIG BRAIN USING MONOCLONAL ANTIBODIES. J.D. Blaustein, J.C. King and J. Turcotte*. Neuroscience and Behavior Program and Psychology Department, University of Massachusetts, Amherst, MA 01003.

A variety of studies has implicated intracellular neural progestin receptors (PRs) in the mediation of progesterone's effects on sexual behavior in female rodents. Most studies of PRs have used techniques which require binding of radioactively-labeled ligands to the PR. Recently, the feasibility of reliable immunocytochemical detection of PRs in guinea pig brain has been demonstrated (M. Warembourg et al., Brain Research, 384, 121, 1986).

We used monoclonal antibodies directed against either purified chick oviduct PRs or rabbit uterine PRs in an unlabeled immunocytochemical technique. In estradiol-primed ovariectomized guinea pigs (10 ug estradiol benzoate x 3 days), PR-immunoreactive neurons were observed in heaviest concentration in the arcuate nucleus. Other areas of high density are the ventromedial nucleus of the hypothalamus, in particular, the ventrolateral aspect, the periventricular hypothalamus, the periventricular preoptic area, the medial preoptic area and the suprachiasmatic preoptic area. Few PR-positive cells have been detected outside this region. These results are in substantial agreement with previous work using [^{3}H]progesterone autoradiography (S. Sar and W. Stumpf, Science, 183, 1266, 1973).

Confirming a variety of recent reports on the subcellular localization of PRs, immunoreactivity was intranuclear, with little if any reaction product in the soma. No immunoreactivity was seen in ovariectomized animals in the absence of estradiol-priming. Progesterone injection had no effect on the intracellular localization. A single, behaviorally-effective injection of estradiol benzoate (10 ug) 2 days prior to sacrifice was sufficient to induce immunoreactivity, although the intensity was lighter than in animals receiving repeated injections.

A similar pattern of immunoreactivity was seen with monoclonal antibodies to chick or rabbit progestin receptors, although the rabbit antibody resulted in a darker reaction product. In preliminary experiments, we have observed a small degree of colocalization of tyrosine hydroxylase-immunoreactivity (TH) in PR-immunoreactive neurons in the arcuate, but not the periventricular nucleus. In addition, in a limited number of cases, we have observed TH-immunoreactive varicosities closely abutting PR-immunoreactive neurons in the arcuate nucleus.

306.4 CHLORDECONE EFFECTS ON CNS ESTROGEN AND PROGESTERONE RECEPTORS. J. Williams*, K. Eckols*, and L. Uphouse. Department of Biology, Texas Woman's University, Denton, Texas, 76204.

The chlorinated pesticide, chlordecone, mimics estrogen on a variety of parameters, including increased uterine growth, uterine fluid retention and vaginal cornification. In mammalian uterus and chick oviduct, such estrogenicity has been attributed to the pesticide's interaction with the intracellular estradiol receptor. In neural tissue, the similarities between estrogen and chlordecone are less evident. In female rodents, estrogen regulates neuroendocrine function and is essential for the expression of female reproductive behavior. Although chlordecone mimics estradiol's negative feedback on LH (but not FSH) release, it fails to facilitate the LH surge . Similarly, the pesticide fails to mimic estradiol's facilitation of female rat sexual receptivity. Furthermore, chlordecone can attenuate estradiol's effect on both the preovulatory LH surge and sexual receptivity. It is generally assumed that an interaction between estradiol and its intracellular receptor is required to prime the nervous system for an LH surge and for sexual behavior. CNS estrogen receptor replenishment and elevation of the progesterone receptor depend upon estrogen's interaction with its CNS receptor. Consequently, estradiol's effect on CNS steroid receptors is required for progesterone's facilitation of the preovulatory LH surge and sexual receptivity.

In the following studies, chlordecone's interaction with the CNS estradiol receptor and its ability to elevate progesterone receptors were examined in neural and uterine tissues. In both tissues, chlordecone showed evidence of interaction with the intracellular estrogen receptor. The pesticide competed *in vitro* for binding to the receptor and *in vivo*, led to nuclear retention of the estrogen receptor. Chlordecone's potency in competiting for ^{3}H-estradiol binding was relatively low with an IC_{50} about 10^{-4} to 10^{-5}. Nuclear retention duration and time course were also significantly different for chlordecone than for estradiol but there was a definite estrogen receptor elevation in both estradiol and chlordecone treated females.

The apparent estrogenicity of the pesticide at the CNS estrogen receptor was in sharp contrast to its behavior regarding the progesterone receptor. There was no evidence of competition between chlordecone and ^{3}H-R5020 for the progesterone receptor. Female rats receiving chlordecone *in vivo* exhibited levels of CNS progesterone receptors that were identical to control females, while progesterone receptors were significantly elevated by estradiol. The neural effects were clearly distinct from the uterine effects of the pesticide. In uterine tissue, progesterone receptors were significantly elevated by the *in vivo* exposure.

The present results confirm prior suggestions that the similarities between chlordecone and estradiol are more prevalent at peripheral than at neural tissues. It is suggested that the failure of the pesticide to mimic molecular responses to estradiol's interaction with its CNS receptor accounts for the pesticide's failure to reproduce the entire spectrum of neural events characteristic of estrogen.

306.5 ESTROGEN PRIMING AFFECTED MEDIAL AMYGDALA NEURON EXCITABILITY RECORDED INTRACELLULARLY. Mya C. Schiess, Marian Joëls, Patricia Shinnick-Gallagher, UTMB, Dept. of Pharmacology, Galveston, Texas, 77550

The medial nucleus of the rat amygdala (MNA) is a sexually dimorphic structure and a target tissue for estrogen binding. Recently Nabekura et al using an in vitro preparation of the medial amygdala showed that superfusion of 17-beta estradiol had a direct membrane effect, causing a membrane hyperpolarization and a decrease in input resistance (Ri). This effect was thought to be mediated by a decrease in K^+ permeability. In this project, we tested whether estrogen priming (>24 hours) had a long-term or genomic effect on cell activity.

Adult female Spraque-Dawley rats were ovariectomized (OVX) at 10 to 12 weeks. 500 micron coronal slices of the right amygdala including the medial nucleus (-2.3 to -3.3 mm Bregma) were obtained from OVX non-primed (N=20) and OVX estrogen (EB) primed rats (N=24). Estrogen priming involved administration of 100 micrograms of β-estradiol subcutaneously to the nape of the neck 24 hours prior to the experiment. Intracellular recording techniques were employed and discerned that there was no significant difference between the resting membrane potential (RMP) and Ri of the OVX and EB primed cells; OVX RMP=-71 mv/EB RMP=-69 mV, OVX Ri=71 mΩ/EB Ri=68.5Ωm .

Active membrane properties differed significantly between neurons from the OVX non-primed rats and the EB primed rats. Neurons from EB primed rats had prominent voltage dependent depolarizing after potentials (DAP's). Neurons from EB primed rats were spontaneously active with frequent EPSP's (70%), while the OVX non-primed neurons were rarely spontaneous (10%). Intracellular injection of small cathodal pulses of 5 ms and 100 to 300 pA elicited volleys of 3 to 4 spikes (N=22/24), whereas OVX non-primed neurons fired once and then shut off irrespective of the duration or amplitude of current injected (N=20/20). When long cathodal pulses of 500 ms and 100 to 600 pA were passed through the recording electrode 60% of the EB primed neurons did not accommodate, while 95% of the neurons from OVX non-primed rats fired once then shut off.

These results suggest that long-term exposure to estrogen at an estrogen sensitive target tissue such as the MNA increases synaptic activity and enhances neuronal excitability at an intracellular level.

306.6 **PITUITARY-ADRENAL AND THYROID EFFECTS ON THE CONTENT OF MELATONIN IN THE PINEAL GLAND OF THE RAT.** **M. Bauer; R. Poland*; P. Whybrow and A. Frazer, Depart. of Psychiatry, Univ. of Pennsylvania and Vet. Adm. Hospital, Philadelphia, PA, 19104 and Dept. of Psychiatry, Harbor-UCLA Medical Center, Torrance, CA 90509.**

Clinical studies have shown that decreased nocturnal levels of melatonin in serum occur frequently in persons with major depressive disorder. This phenomenon is often accompanied by evidence of increased pituitary-adrenal activity. Similarly, thyroid abnormalities are seen in a subset of depressives. In preclinical studies, both glucocorticoids and thyroid hormones have been shown to alter adrenergic function, which plays an important role in the control of melatonin production. We therefore hypothesized that alterations in the pituitary-adrenal or thyroid axes could alter the nocturnal rise of the content of melatonin in the pineal gland of the rat.

Male Sprague-Dawley rats (200-225 g), housed under a 12:12 light:dark cycle, were used in both experiments. In the first experiment, three groups of rats were treated with once daily s.c. injections of either ACTH(1-24), 10 units; corticosterone, 7.5 mg; or sesame oil vehicle. All injections were given at 1600 hrs and were continued for 9 days. Rats were then sacrificed 2 to 23 hrs after the final injection. Trunk blood was taken for determination of corticosterone in serum. The pineal was removed for measurement of its content of melatonin. Both corticosterone and melatonin were analyzed by radioimmunoassay. Administration of either corticosterone or ACTH caused a significant increase in serum concentrations of corticosterone between 1730-0100 hrs, compared to that measured in controls. Despite this, treated rats did not differ from control rats in either the day- or night-time content of melatonin in the pineal gland.

In the second experiment, animals were obtained 3 days after thyroid-parathyroidectomy (TPx) or sham operation. After 7 days of acclimitization, TPx rats and one group of sham operated animals received for 9 days daily subcutaneous injections of saline (hypothyroid and euthyroid groups, respectively), and one group of sham operated animals received daily injections of 15 ug of triiodothyronine (hyperthyroid group). Both experimental groups showed significant differences from control rats in heart weight-to-body weight ratios, as expected in hypo- and hyperthyroidism. Again, no significant difference was observed in either daytime levels or the nocturnal content of melatonin of the pineal gland in the hypo- or hyperthyroid rats in comparison to that in euthyroid controls.

The results of these two studies indicate that the amplitude of the nocturnal rise of pineal melatonin content is not readily affected by alteration in the pituitary-adrenal or thyroid axes. Alterations in these two neuroendocrine systems may not be responsible for the blunted nocturnal rise in melatonin observed in major depressive disorders. **(Supported by research funds from the Vet. Adm. and USPHS grants MH 29094 and MH 14654).**

306.7 EVIDENCE THAT DARK RELATED CHANGES IN NORADRENERGIC INPUT COULD BE THE ORIGIN OF THE 24 HOUR RHYTHM IN RAT PINEAL BETA-ADRENERGIC RECEPTOR DENSITY. A. Gonzalez-Brito*, R.J. Reiter, D.J. Jones, J.M. Guerrero* and M. Puig-Domingo*. (SPON: T. Mikiten). Dept of Cell. & Struct. Biology and Dept. of Anesthesiology. UTHSCSA, San Antonio, TX 78284-7762.

It has been reported repeatedly that there exists an increase in rat pineal norepinephrine (NE) content and/or turnover during the dark phase; however, studies concerning a 24 h variation in NE release from the sympathetic pineal nerve endings has not been reported. We have recently reported a 24 h variation in rat pineal beta-adrenoreceptor density using a simple procedure that permits measurement of [125I]Iodopindolol ([125I]IPIN) binding to individual pineal glands (Gonzalez-Brito et al, submitted). Since NE interacts with postsynaptics beta-receptors on pinealocytes to regulate the melatonin rhythm, the purpose of the present study was to define the alterations in pineal beta-receptors during the light-dark cycle and to determine if the beta-agonist isoproterenol differentially alters receptor regulation.

Adult male Sprague-Dawley rats maintained in a 14:10 LD cycle (lights on at 0600 h) showed an increase in [125I]IPIN binding sites during the first half of the night which peaked at 0200 h and decreased to lowest values before lights on. We now report that in animals maintained on the same lighting schedule the decrease in [125I]IPIN binding detected late in the dark phase was prevented by moving the animals to light at 0200 h. However, a single subcutaneous (s.c.) injection of isoproterenol (0.5 mg per kg of body weight, dissolved in saline) at 0200 h in light exposed animals induced a decrease in beta-adrenoreceptor density that paralleled and simulated that normally seen in control LD animals at this time. Animals that were kept in light from the onset of the normal dark period (2000 h) exhibited a sustained increase in density of [125I]IPIN binding sites. In these animals a s.c. 0.5 mg/kg isoproterenol injection at 2000 h induced, several hours later, an increase in beta-adrenoreceptor density.

The present results show that both the increase and subsequent decrease in pineal beta-adrenoreceptor density that occurs at night can be modified by changing the lighting environment conditions and can be simulated by the beta-adrenergic agonist isoproterenol. We conclude that the genesis of the 24 h rhythm in pineal beta-adrenoreceptor binding sites previously reported seems to be determined by mechanisms of up and down regulation of the receptors and that such mechanisms are a consequence of photoperiodic induced changes in noradrenergic input to the pineal gland. However, we can not preclude a role for other putative modulating factors.

306.8 POSSIBLE SUPRACHIASMATIC NUCLEUS ---> SPINAL CORD PATHWAYS. J.W. Patrickson, and T.E. Smith*. Department of Anatomy, Schools of Medicine and Dentistry, Loma Linda University, Loma Linda CA 92350.

The secretion of melatonin by the pineal gland is under the control of the circadian rhythm generator, the suprachiasmatic nucleus (SCN) of the hypothalamus. Impulses generated by the SCN ultimately reach the pineal gland via postganglionic sympathetic fibers of the superior cervical ganglia. The objective of this study was to determine the possible SCN - spinal cord pathways. This was accomplished by comparing the efferent projection sites of the SCN (group 1) to those neuronal sites that project to the C8 - T2 segments of the spinal cord (group 2) in Sprague Dawley rats (275 - 325gm). The spinal segments were determined by localizing the distribution of the preganglionics that project to the superior cervical ganglion using the HRP neuron tracing technique.

The efferent projections of SCN were determined by injecting .05µl of 4% WGA-HRP into the nucleus and localizing the anterogradely transported product. Spinal projecting neurons were identified by localizing HRP-positive neurons subsequent to the injection of 0.5µl of 4% WGA-HRP into the spinal cord (C8-T2). Both groups of animals were anesthetized with pentobarbital (50mg/kg). The animals were re-anesthetized and perfused 48hrs post HRP injection, and 30µm frozen sections were made and processed using tetramethylbenzidine as the chromagen.

The sites common to both groups are: the paraventricular nucleus of the hypothalamus (periventricular, dorsal cap, medial parvocellular) and the dorsal hypothalamic area. These sites were also confirmed using double labeling techniques. In addition, spinal projecting neurons were identified within the retrochiasmatic area.

We conclude that these sites represent the most probable pathways by which the SCN relays its circadian generated rhythm to the preganglionic sympathetic neurons of the spinal cord.

306.9 THE EFFECTS OF PINEALECTOMY ON HIGH VOLTAGE CORTICAL ACTIVITY AND AFTERDISCHARGE THRESHOLD AND DURATION FROM THE AMYGDALA IN THE RAT. J.H. Peck, K. Soria, and L.J. Grota. Dept. of Psychology, Ithaca College, Ithaca, NY 14850.

The pineal gland and its hormone melatonin, have been implicated in a variety of disorders including epilepsy, parkinson's disease and seasonal affective disorders. A number of investigators have shown behavioral and EEG effects of pinealectomy. Subsequent injections of pineal concentrate or melatonin have reversed these effects. Our past research has attempted to replicate findings on the pineal's role in epileptic-like abnormal brain EEG. We have used antibody to melatonin and pinealectomy in both acute and chronic preparations without success. This study investigated the role of pinealectomy in afterdischarge production by the amygdala.

Twenty male rats were either pinealectomized or sham operated using a suction technique. One pair of stainless steel bone screws served as cortical electrodes on each hemisphere. Depth electrodes were also implanted in the amygdala and hippocampus contralateral to each other. The rats recovered for one week and EEG was recorded during the light and dark phases of their daily cycle. No efforts were made to prevent the rats from sleeping and hence generating low frequency high voltage outbursts or "sleep spindles". Next, the rats were given an ascending series of constant current shocks from 30 to 1000 microamps, every 5 mins., to the amygdala, during the dark phase of their daily cycle, and afterdischarge was recorded. Only one rat reached a stage 5 seizure and was stopped before reaching the maximum stimulation.

There was significantly more high voltage cortical activity during the day than during the night. But there was no effect of pinealectomy - sham surgery or an interaction. There was a marginal statistical difference in afterdischarge threshold ($.075 > p > .05$), with pinealectomized rats having a lower threshold than shams. There was no significant difference in duration of afterdischarge, but pinealectomized rats had a significantly higher % of trials with amygdala afterdischarge than shams.

These data support the idea that the pineal gland may play a role in some disease states. The role of melatonin should not be taken for granted, however, since most recent evidence indicates that the pineal gland may have direct connections with the brain and hence modify the brain through synaptic connections rather than hormonally.

306.10 NADOLOL OR PROPRANOLOL PREVENTS SHORT PHOTOPERIOD-INDUCED BUT NOT MELATONIN-INDUCED GONADAL REGRESSION IN MALE SYRIAN HAMSTERS. T.H. Champney. Department of Medical Anatomy, Texas A&M University, College Station, TX 77843.

Beta adrenergic control of pineal melatonin (MEL) synthesis is responsible for the nocturnal increase in rat pineal MEL production. Regulation of Syrian hamster MEL synthesis also appears to be regulated by beta adrenergic receptors with a powerful reuptake system. This mechanism prevents pharmacologic stimulation of MEL synthesis unless the reuptake system is blocked or disabled. However, beta adrenergic antagonists are capable of blocking pineal MEL production in Syrian hamsters. The present study examined the ability of two beta adrenergic antagonists, propranolol (PROP) and nadolol (NAD), to block pineal MEL production on a daily basis and, thereby, disrupt the pineal's influence on short photoperiod-induced and MEL-induced gonadal regression. Adult male Syrian hamsters were placed in either long (14L:10D, lights on at 0500h) or short (10L:14D, lights on at 0700h) photoperiods. Short photoperiod (SP) groups consisted of a saline-injected (SAL) group, three PROP-injected groups (500 µg, 250 µg or 125 µg PROP-injected) and a NAD-injected group (250 µg). These hamsters were injected (0.1 ml s.c.) every day for nine weeks at 1630h. Long photoperiod (LP) groups consisted of a SAL group, a PROP group (250 µg), a NAD group (250 µg), a MEL group (25 µg), a PROP + MEL group and a NAD + MEL group. These hamsters were injected (0.1 ml s.c.) every day for nine weeks at 1645h. At the end of the experimental period, the hamsters were killed by decapitation and their testes weights and serum were collected. Serum testosterone was determined by radioimmunoassay kit (Diagnostic Products, Inc.). Both testicular weights and testosterone levels were depressed in SP/SAL, LP/MEL, LP/PROP + MEL and LP/NAD + MEL treated groups ($p<0.001$ vs. LP/SAL). PROP and NAD prevented SP-induced gonadal regression. PROP is a general beta adrenergic antagonist which can cross the blood brain barrier, while NAD is unable to cross the blood brain barrier in appreciable amounts. Therefore, NAD blocks peripheral beta adrenergic receptors without affecting central beta adrenergic function. Since the pineal is located outside of the blood brain barrier, it appears that NAD and PROP are preventing SP-induced gonadal regression by blocking pineal neurotransmission and not by altering central beta adrenergic receptors. Interestingly, PROP and NAD are unable to prevent MEL-induced gonadal regression, even though intact pineal MEL synthesis has been implicated in MEL-induced regression. The present results indicate that the endogenous MEL peak may not be necessary for MEL-induced testicular inhibition. In conclusion, PROP and NAD are capable of preventing SP-induced, pineal mediated gonadal depression, while they are incapable of preventing MEL-induced testicular regression. Supported by NIH grant #RR05814.

306.11 EFFECT OF LIGHT AND ISOPROTERENOL ON THE NOCTURNAL RISE OF TYPE-II THYROXINE 5'-DEIODINASE IN RAT FRONTAL CORTEX. J.M. Guerrero*, M. Puig-Domingo*, R.J. Reiter, A. Gonzalez-Brito* and A. Menendez-Pelaez*. Dept. of Cellular & Structural Biology, UTHSCSA, San Antonio, TX 78284.

We have previously described the existence of a diurnal variation of type-II thyroxine 5'-deiodinase (5'-D) activity in rat frontal cortex. This enzyme exhibits the lowest activity at daytime, increasing progressively after the onset of the dark period with a peak at 0500 h, just prior the lights on. We have also described that maintaining the rats under continuous light enhances the 5'-D activity. We now report, for the first time, the effect of isoproterenol and/or light on rat frontal cortex 5'-D activity. Adult male Sprague-Dawley rats were housed under a 14:10 LD cycle with lights off at 2000 h. A group of animals were injected (s.c.) with a single dose of isoproterenol (0.5 mg/kg in saline) either at 0200 or 0400 h, and 5'-D activity determined at 0400 and 0600 h, respectively. In another experiment, animals were transferred to the light either at 0130 or at 0330 h, then injected with isoproterenol (0200 or 0400 h) and 5'-D activity determined two hours later. 5'-D activity was determined by a radioenzymatic method measuring the release of 125I from [3',5'-125I]T4 and results expressed as fmol 125I released/mg prot/h. As previously described, 5'-D activity increased progressively during the dark period (4.4 ± 0.9 at 0200 h; 7.5 ± 2.2 at 0400 h; 10.1 ± 2.3 at 0600 h). A single injection of isoproterenol at 0200 h elicited an increase of 5'-D activity at0400 h (15.0 ± 2.3; $p<0.01$) but injection at 0400 h was ineffective in increasing the 5'-D activity at 0600 h. When animals were transferred to the light at 0130 h an increase of 5'-D activity was observed both at 0200 h (9.6 ± 3.0; $p<0.05$) and 0400 h (11.9 ± 1.8; $p<0.05$). Similarly, when animals were tranferred to the light at 0300 h, 5'-D activity also increased at 0400 h (23.7 ± 2.8; $p<0.01$); at 0600 the increase was much lower (16.6 ± 2.3; $p<0.05$). A single injection of isoproterenol at 0200 h increased the 5'-D activity at 0400 h (19.6 ± 3.0; $p<0.05$) but the injection at 0400 h had no effect (15.6 ± 2.6). In conclusion, these results confirm that light exposure during the dark period enhances 5'-D activity in rat frontal cortex, being the effect less evident at the end of darkness. Isoproterenol also enhances the 5'-D activity in both control rats and rats transferred to light at night, but only at 0200-0400 h. If the effect of the light is also mediated by an adrenergic input remains to be studied; but it is clear that 5'-D activity is sensitive to both light exposure and isoproterenol only in the middle of the dark period, being insensitive to the same two stimuli just prior the lights on.

Supported by a NSF grant #DCB8410592.

306.12 INTERACTIONS BETWEEN DOPAMINE AND ANGIOTENSIN II IN THE REGULATION OF ALDOSTERONE PRODUCTION. P.Liberini*, C.Missale, M.Memo, M.O.Carruba*, P.F.Spano.(SPON:L.Valzelli) Inst Pharm Exp Ther, School of Medicine Univ of Brescia, Brescia, Italy

Aldosterone (ALD) secretion is subject to both stimulatory and inhibitory control. Angiotensin II (AII) is the primary stimulator of ALD production and an inhibitory role of dopamine (DA) has been recently suggested. On this line, we found that there are both D-1 receptors coupled with stimulation of adenylate cyclase (AC) and D-2 receptors associated with inhibition of AC in rat adrenal glomerulosa.

We now investigated the interactions between DA and AII in the intracellular events leading to ALD production. The intracellular mechanisms by which AII stimulates ALD production appears to involve several molecular events in the plasma membrane of glomerulosa cells including stimulation of polyphosphoinositide turnover. By measuring ALD secretion and cAMP formation in isolated adrenal glomerulosa cells we obtained evidence that AII induced a sustained stimulation of ALD secretion and a rapid and transient increase in cAMP formation. The early effect is an increase in cAMP with a maximum at 10 min with ALD secretion beginning later (at 20 min) and linearly increasing up to 120 min. The pharmacological characterization with AII analogs and AII receptor antagonists is consistent with a role of cAMP in AII steroidogenesis, suggesting a dual messenger function in the action of AII. DA, over the range of 10 nM to 1 uM, inhibited both ALD secretion and cAMP formation induced by submaximal concentrations of AII. DA agonists selectively acting on D-2 receptors such as LY 171555, bromocriptine or dihydroergotoxine, while inactive under basal conditions, were more effective than DA in inhibiting the glomerulosa cell responses to AII. In contrast, the selective D-1 agonist SKF 82526 was virtually inactive. The pharmacological characterization of these effects with DA antagonists is also in line with a role of D-2 receptor inhibiting cAMP formation in the action of DA. As a matter of fact, DA lost its inhibitory effects in rat glomerulosa cells exposed to pertussis toxin (100 ng/ml) for 24 h. In conclusion these data are consistent with a role of cAMP in AII stimulated ALD production and suggest that the inhibitory effect of DA is mediated by inhibition of AII-induced enhancement of cAMP formation through interaction with D-2 receptors.

306.13 SEX DIFFERENCE IN NUCLEAR UPTAKE OF LOW DOSE 3H-CORTICOSTERONE BY LIMBIC STRUCTURES IN RAT. B.B. Turner, E.D. Baker*, and M.S. Ansari*. Dept. of Physiology, College of Medicine, East Tennessee State Univ., Johnson City, TN 37614

We have previously shown that the binding capacity of the hippocampus (HC) for ^{3}H-corticosterone (CORT) is greater in female than male rats, but that binding affinity is less in the female (Kd). The existence of a dual corticoid receptor system has been described in rat brain (Type I, high affinity for CORT; Type II, classical glucocorticoid receptor). We asked whether differences in soluble receptor binding reflect differences in the in vivo uptake of CORT by HC and other limbic structures. We predicted that at low dose the in vivo nuclear uptake of ^{3}H-CORT, reflecting binding to Type I receptors, would be greater in males.

We compared the cell nuclear uptake of a tracer dose of ^{3}H-CORT in several brain regions of male and female rats. In each of ten experiments, two sexually mature, gonadectomized rats were adrenalectomized 12 h before i.v. injection with ^{3}H-CORT (3.5 nmol/kg, 85.8 Ci/mmol). Rats were killed by cardiac perfusion with cold dextran-saline and the following tissues were taken: HC, hypothalamus, cortex, amygdala, pituitary and liver. Purified cell nuclei were prepared by centrifugation of crude pellet through dense sucrose; the radioactivity was then extracted and counted. Samples were assayed for protein and DNA content. The amount of ^{3}H-CORT injected into both sexes was comparable (3.49 nmols/kg for males, and 3.42 for females. Plasma levels of radioactivity at the time of sacrifice were not significantly different (35 pmols/dl for males, and 28 pmols for females). The two tissus showing the highest binding, HC and AMG, also showed a sex difference, with males having greater nuclear uptake: HC, 125 ± 7 vs. 72 ± 4 fmols/mg DNA), $p<0.001$; amygdala, 20 ± 1 vs. 14 ± 2 fmols/ mg DNA $p<0.025$. Nuclear uptake in hypothalamus, cortex, and pituitary was markedly lower; liver nuclear uptake was negligible. A similar pattern of nuclear uptake was obtained when binding was calculated as fmols/mg protein. We suggest that this nuclear uptake represents binding to Type I receptors since nuclear uptake did not occur in the liver (Type II receptors), dosage was extremely low, and high concentrations of Type I receptors have been reported in HC and other limbic structures.

In a separate set of experiments, we determined the binding parameters of ^{3}H-CORT (112 Ci/mmol) to Type I soluble receptors in HC cytosols from male and female rats. Our data indicate that males do not have more Type I receptors in this tissue (68 ± 8 vs. 92 ± 4 fmols/mg protein). However, the dissociation constant (Kd) is considerably lower in cytosols from males as compared to females (0.22 ± 0.01 nM vs. 0.52 ± 0.01 nM, $p<0.01$). This difference in affinity appears sufficient to explain the sex difference in nuclear uptake. Supported by NIH grant NS-22158 to BBT.

306.14 VIP EFFECTS ON ADRENAL STEROIDOGENESIS IN VITRO. L. A. Cunningham* and M. A. Holzwarth. Department of Anatomical Sciences, University of Illinois, Urbana, IL 61801.

The rat adrenal cortex contains a plexus of VIP-immunoreactive nerve fibers which arborize primarily in the capsule and zona glomerulosa region (J. Auton. Nerv. Syst., 11:269). The close apposition of nerve fibers to adrenocortical cells (Cell Tissue Res., 241:139) together with observations of diminished VIP-immunoreactivity following acute stress and increased VIP-immunoreactivity in rats chronically on high dietary potassium suggest that this innervation may be important in the regulation of adrenal function. Therefore, we have tested the effect of VIP on adrenocortical steroidogenesis in normal rat adrenal cortex in vitro.

Capsular portions of rat adrenals which comprise the capsule, zona glomerulosa and a small portion of the zona fasciculata were placed in 200 µl perifusion chambers and continuously perifused with modified Krebs Henseleit buffer containing 0.25% BSA, 0.20% glucose and 3.6 mM K^+, saturated with 95% O_2/5% CO_2 at 37°C (flow rate = 0.3-0.4 ml/minute). Test substances were infused for 20 minutes and five-minute fractions were collected continuously and subsequently assayed for aldosterone and corticosterone content by radioimmunoassay. Mean basal aldosterone and corticosterone secretion rates were approximately 0.1 ± .04 and 1.1 ± 0.23 ng/minute/ adrenal, respectively. ACTH infusion (10^{-12}, 10^{-11}, 10^{-10}, 10^{-9} and 10^{-8}M) increased mean total aldosterone secreted over 50 minutes approximately 1.4, 3, 17, 45 and 60 fold over baseline and increased mean corticosterone 1.3, 2, 4, 9 and 12 fold over baseline (n=4-6 per dose). Angiotensin II infusion (10^{-8}, 10^{-7}, 10^{-6} and 10^{-5}M) stimulated mean aldosterone secretion 1.2, 2, 3 and 8 fold (n=3-6 per dose). VIP infusion (10^{-6}, 10^{-5} and 10^{-4}M) increased mean aldosterone secretion 1.3, 5 and 17 fold over baseline while corticosterone secretion increased 1.9, 4 and 10 fold (n=3-9). Whether the high dose of VIP required to elicit steroidogenesis is the consequence of the perifusion system or a result of low affinity VIP receptors is not known. The structurally related peptide, glucagon (10^{-5} and 10^{-4}M), had no effect on aldosterone secretion which suggests that the effect is specific for VIP. On the other hand, stimulation with $5x10^{-5}$M (Ac-Tyr^1, D-Phe^2)-GRF(1-29)-NH_2, a peptide reported to inhibit VIP binding to high affinity VIP sites in pancreatic tissue (Endocrinology, 116:2653), did not alter basal secretion or VIP-stimulated (10^{-5}M) steroidogenesis. In summary, the presence of VIP-immunoreactive nerve fibers closely associated with adrenocortical cells and the ability of VIP to stimulate steroidogenesis in vitro suggests that this peptide may contribute to the regulation of adrenal steroid secretion in vivo.

306.15 CHARACTERIZATION OF A CORTICOSTERONE-SENSITIVE CYTOSOLIC PHOSPHOPROTEIN FROM RAT HIPPOCAMPUS. L.K. Schlatter* and L.A. Dokas (SPON: H. Waller) Departments of Biochemistry and Neurology, Medical College of Ohio, C.S. 10008, Toledo, OH 43699.

It has been proposed that endogenous glucocorticoids are a cause of cell degeneration in the rat hippocampus as the animal goes through natural aging. Administration of exogenous glucocorticoids can mimic this process, producing first, down-regulation of glucocorticoid receptors in the hippocampus, followed by irreversible cell loss. Phosphorylation of a cytosolic protein band with an apparent molecular weight of 68,000 from the rat hippocampus is increased following subcutaneous injections with 5 mg. of corticosterone at 24 hour intervals. This dosage produces prolonged circulating plasma levels of corticosterone that mimic those observed during stress. The phosphorylation of this protein is also increased in some untreated and sham-treated rats, possibly due to endogenous stress responses in these animals. There are no reproducible phosphorylation changes seen in the crude nuclear, mitochondrial-synaptosomal, or membrane fractions. Using two-dimensional gel electrophoresis, the 68,000 band is split into multiple phosphorylated spots with isoelectric points ranging from 6.6 to 6.2. Phosphorylation of this protein is optimal at pH 6.5. It is not present in the liver cytosolic fraction. The phosphorylation pattern observed with short-term injection (4 hours prior to sacrifice) is similar to that seen in the control animal groups for the longer injection times. However, four hour injections with this same dosage do cause an apparent increase in synthesis of a protein with a molecular weight of approximately 35,000 as indicated by ^{35}S-methionine labeling. No change in ^{35}S-labeling of a protein with a molecular weight of 68,000 is seen. The identity of either protein is at present unknown. However, these changes may be biochemical correlates of a glucocorticoid-induced alteration of hippocampal function. Supported by a grant from the Dorothy VanNess-Thompson Foundation.

306.16 CENTRAL MECHANISMS OF ETHANOL-INDUCED ADRENOCORTICAL RESPONSE IN SELECTIVELY BRED LINES OF MICE. J.M. Zgombick and V.G. Erwin. University of Colorado, School of Pharmacy, Alcohol Research Center, Boulder, Colorado 80309

The stimulatory effects of acute ethanol on the hypothalamo-pituitary-adrenal (HPA) axis were investigated in the selectively bred long-sleep (LS) and short-sleep (SS) mice. Ethanol (0.2-4.5 g/kg ip), CRF (0.1-10 ug iv), and ACTH (0.1-10 ug iv) produced greater dose-dependent elevations in plasma corticosterone (C) in LS than SS mice. However, the differential adrenocortical activation elicited by the peptides was much less pronounced than observed with acute ethanol. Passive immunoneutralization of circulating corticotropin-releasing factor (CRF) completely abolished ethanol-induced elevation in plasma corticosterone in LS mice, suggesting that the response is mediated through an enhanced secretion of hypothalamic CRF. Additionally, these mice were infused intracerebroventricularly (icv) with noradrenergic and cholinergic compounds to ascertain whether these substances modulate the differential adrenocortical response elicited by acute ethanol (2.5 g/kg). Clonidine, an alpha-2 adrenergic agonist, blocked ethanol-induced elevations in plasma C in a dose-dependent manner (1 and 10 ug icv) in LS mice; however, only the 10 ug dose of clonidine effectively antagonized this response in SS mice. Yohimbine (1 ug icv), an alpha-2 adrenergic antagonist, reversed the inhibitory effect of clonidine in ethanol-treated LS and SS mice. Other adrenergic agonists and antagonists were without effect on this stimulatory response. Carbachol (1 ug icv), a nonspecific cholinergic agonist, potentiated ethanol-induced elevation in plasma C in both lines of mice. Cholinergic antagonists did not attenuate ethanol-induced adrenocortical activation. These results suggest that differential adrenocortical response to ethanol exhibited by LS and SS mice (1) is primarily due to differential hypothalamic CRF release, (2) may be mediated through an alpha-2 adrenergic mechanism, and (3) that differences in central noradrenergic systems may account for differential ethanol-induced elevation in plasma C exhibited by LS and SS mice.

306.17 DISTRIBUTION OF A RENIN-RELEASING FACTOR IN RAT BRAIN AND PERIPHERAL TISSUE. J.H. Urban, M.S. Brownfield+ and L.D. Van de Kar. Dept. Pharmacol., Loyola Univ., Maywood, IL 60153 and +Univ. Wis. Sch. Vet. Med., Madison, WI 53706.

We have partially characterized a renin-releasing factor (RRF; Hypertension 9, 1987). The RRF is a peptide with a molecular weight between 5,000-10,000, and is found in both plasma and hypothalamic extracts. Extracts of rat hypothalami produce dose dependent increases in renin release from rat renal cortical slices. The equivalent of the content from one hypothalamus produces a maximal stimulation of renin release in vitro. The present studies were designed to determine the distribution of the RRF in brain and peripheral tissues. To test for the distribution of RRF, rat brains and tissues were dissected, homogenized in boiling water, and then boiled for 20 minutes and centrifuged. The supernatant was added to the kidney slices in a volume that is equal to the content of one hypothalamus. Addition of adrenal extract produced a decrease in renin release from kidney slices. Addition of kidney extract increased the amount of angiotensin I (AI) detected by radioimmunoassay, either by increasing renin release from the slices or by a residual amount of AI that was present within the kidney extract. Extracts of spleen, liver and skeletal muscle did not alter renin release from the kidney slices. A number of brain areas were found to have significant renin releasing activity: cerebellum > medulla oblongata > cerebral cortex > hypothalamus. No significant renin releasing activity was present in the pituitary, pons, thalamus, caudate, hippocampus, midbrain or amygdala. In order to differentiate between RRF contained in cell bodies and RRF in nerve terminals, a group of rats were given intracerebroventricular (icv) injections of colchicine to stop axonal transport of peptides from the cell body. After colchicine treatment, the hypothalamus was the only brain area that exhibited significant renin-releasing activity and this value was increased over the previous (control) value. The renin releasing activity that was previously observed in the cerebral cortex and medulla oblongata was significantly reduced after colchicine treatment. The RRF activity in the cerebellum completely disappeared. These studies suggest that the RRF cell bodies are localized within the hypothalamus and that the renin releasing activity present in other brain areas is likely located in nerve terminals. (Supported in part by the Heart Research Foundation and by Sigma Xi).

306.18 COMPARISON OF ANGIOTENSIN AND ACETYLCHOLINE ON ADRENAL CATECHOLAMINE SECRETION IN DOGS. W.C. Engeland, M.P. Lilly*, P. Miller* and D.S. Gann. Dept. of Surgery, Section of Neurobiology, Brown University/R.I. Hospital, Providence, R.I. 02902

There is evidence that angiotensin (AII) contributes to increased adrenal secretion of epinephrine (E) and norepinephrine (NE) after hemorrhage. AII may act directly on the adrenal or its effect may be centrally mediated. To assess the relative sensitivity of the adrenal medulla to AII compared to that of acetylcholine (ACh) alone, and to coincident presentation of AII and ACh, a preparation was developed for direct arterial injection into the adrenal that permitted measurement of adrenal hormone secretory rates. Also, since circulating AII is a potent stimulus for aldosterone secretion from the adrenal cortex, the effectiveness of AII to stimulate catecholamine secretion was compared to its effectiveness to stimulate aldosterone secretion. Mongrel dogs (n=8) were prepared with catheters in the femoral artery for hemodynamic monitoring, in the lumboadrenal vein for monitoring adrenal blood flow and secretory rates and in the lumboadrenal and phrenicoabdominal arteries for adrenal injections. Forty-eight hours after surgery, dogs were anesthetized with pentobarbital, artificially respired and given supplemental oxygen and iv fluids. Dogs received in random order adrenal injections (200ul) of AII (2, 20 and 200 pmol), of ACh (0.2, 2, 20, 200 nmol), of AII (20 and 200 pmol) with ACh (2 nmol) and of diluent. Adrenal venous samples were collected prior to and at 1, 5 and 10 min after injection with injections separated by 20 min. Catecholamines and aldosterone were measured by HPLC with EC detection and by RIA, respectively. Peak changes in catecholamines (1 min) or in aldosterone (5 min) were analyzed by ANOVA after log transformation to reduce variance. Injection either of ACh or of AII resulted in log dose-dependent increases ($p<0.01$) in E and NE. The range of secretory responses to ACh for E were 98±23 - 2000±379 ng/min and for NE were 25±7 - 408±52 ng/min. The range of secretory responses to AII for E were 111±33- 294±62 ng/min and for NE were 28±8 - 56±16 ng/min. However, AII was 100X as potent as ACh on a molar basis. The secretory responses to 20 and 200 pmol AII was equivalent to those of 2 and 20 nmol ACh, respectively. Neither ACh or AII produced a change in the secretory ratio of E to NE. The responses to AII occurred despite a decrease ($p<0.05$) in adrenal blood flow. No additional hemodynamic effects resulted from AII injection suggesting that the action of AII was restricted to the adrenal gland. When AII was given coincident with ACh, the effect on catecholamine secretion was neither additive nor synergistic; the response to each dose of AII with ACh was equivalent to the response to each dose of AII alone. Injection of AII resulted in a log dose-dependent increase ($p<0.01$) in aldosterone secretion. The range of responses were 5±1 - 26±7 ng/min. However, the minimal dose (2 pmol) of AII that increased ($p<0.05$) aldosterone secretion did not increase E or NE secretion, suggesting that the adrenal cortex is more sensitive to AII than the adrenal medulla. The data show that AII is more potent than ACh as a secretogogue for adrenal catecholamine secretion. However, AII does not augment the catecholamine response to ACh or stimulate catecholamine secretion at a dose that is effective in stimulating adrenocortical secretion. A physiological role for circulating AII in direct activation of adrenomedullary secretion remains to be defined. (Supported in part by NIH grant AM 26381 and GM 27946.

306.19 ANTIBODIES TO CHROMOGRANINS. J. Qian*, R.Y. Xu*, E. Ling*, and R. Hogue Angeletti. Neuropathology, Univ. of Pennsylvania Medical School, Philadelphia, PA 19104-6079.

Specificities of monoclonal antibodies to chromogranins were compared by two dimensional immunoblotting and by immunohistochemical distribution. A polyclonal antibody to the peptide PL26, located near the carboxy terminus of chromogranin A, was used as a standard. Although the function of chromogranin A is not yet known, it appears to be a pan-endocrine marker. It is also found in many neurons, but is not found in exocrine cells. One antibody, 6F2, displayed all of the properties of chromogranin A. Another antibody 3G11, stained with the specificity of chromogranin B. The immunohistochemical distribution of these two proteins was overlapping, but not coextensive. The most unusual antibody was 3C9, which reacted with secretory vesicles in both endocrine and exocrine cells. A final polyclonal antibody to peptide SF24, specific to the carboxy terminal region of the endocrine carboxypeptidase, was also tested. This antibody demonstrated an even wider distribution than antibodies to chromogranin. (NS-22697)

306.20 **REDUCED INSULIN BINDING IN RAT HYPOTHALAMUS AFTER 6-hydroxydopamine (6-OHDA) LESION.** B.J. Wilcox, A.M. Matsumoto*, D.M. Dorsa and D.G. Baskin. Veterans Administration Medical Center and University of Washington, Seattle, WA 98108.

High densities of insulin binding sites have been localized by quantitative autoradiography (QAR) to the arcuate (ARC) nucleus of the hypothalamus. However, the types of cells bearing these binding sites remain unknown. Since biochemical studies on whole hypothalamus suggest that insulin may have a modulatory influence on catecholamine (CA) turnover, we have hypothesized that insulin binding sites may be associated with catecholamine terminals in the ARC nucleus. To test this hypothesis, we measured insulin binding in the ARC by QAR after lesioning catecholamine terminals with 6-OHDA. Male Sprague/Dawley rats were injected stereotaxically with 75 µg (icv) of 6-OHDA. Control rats received only saline vehicle. The animals were sacrificed 7 days after injection. Brains used for biochemical measurement of CA levels were removed, dissected and processed using high performance liquid chromatography with electrochemical detection. Brains from the remaining animals were removed and processed for QAR of insulin binding. Ten micron slide-mounted coronal sections through the hypothalamus were incubated in the presence of 0.1 nM human ^{125}I-insulin for 18 hours at 4°C, rinsed and dried. Non-specific binding was determined by addition of 10 nM unlabeled porcine insulin. The labeled sections were apposed to LKB Ultrofilm for 5 days. Computerized image analysis was used to measure the amount of binding within the ARC and ventromedial (VMN) nuclei, by conversion of optical density of autoradiographic images to radioactivity bound per sq. mm. Treatment with 6-OHDA caused a 65% reduction in NE content in the hypothalamus when compared to saline treated controls (control: 23.6 ± 2.5 ng/mg, n=11; 6-OHDA: 8.25 ± .77 ng/mg, n=12, $p < 0.01$). QAR results from 3 separate experiments show a 20-30% decline in insulin binding in the ARC of the lesioned animals (n=10) when compared to controls ($n=7, p < 0.01$). Data from a typical experiment were: 79 ± 5 dpm/mm^2 vs. 58 ± 7 dpm/mm^2. No change in insulin binding was observed for the VMN. Reduction of insulin binding in the ARC after 6-OHDA lesion supports the hypothesis that insulin binding sites are located pre-synaptically on CA terminals in this area. The results suggest that insulin may modulate neural systems regulated by catecholamines in the ARC.

NEUROTRANSMITTERS: UPTAKE, STORAGE AND SECRETION II

307.1 UPTAKE AND RELEASE OF ENDOGENOUS DOPAMINE FROM RAT STRIATAL SLICES: INTERACTION OF METAPHIT WITH PCP AND NOMIFENSINE. L.P. Dwoskin*, G.A. Gerhardt, C.J. Drebing*, A.E. Jacobson*, R.A. Lessor*, K.C. Rice* and N.R. Zahniser (SPON: L. Gronke). Depts. Pharmacol. and Psychiat., Univ. Co. Hlth. Sci. Ctr., Denver, CO 80262 and NIADDK, Bethesda, MD 20892.

Metaphit is a phencyclidine (PCP) analog which specifically acylates PCP binding sites in vitro (Rafferty et al., FEBS Lett. 181:318, 1985) and antagonizes the behavioral and electrophysiological effects of PCP (Contreras et al., JPET 238:1101, 1986). Also, Metaphit irreversibly inactivates cocaine binding sites in rat striatum (Berger et al., Neuropharm. 25:931, 1986) possibly associated with the dopamine (DA) uptake site. We examined the effect of Metaphit on presynaptic dopaminergic function and its ability to antagonize the effect of PCP and a reversible DA uptake blocker, nomifensine (NOMI). Striatal slices (0.5 mm thick) were incubated for 30 min in Krebs' buffer and for an additional 30 min either in the absence (control) or presence of Metaphit (100 uM). A single control or Metaphit-treated slice was transferred to each chamber and was superfused at 1 ml/min with buffer in the absence or presence of 10 uM PCP or 10 uM NOMI. Doses were chosen based on maximal effects in dose-response curves. After 60 min, one-min samples were collected. Stimulation (1 Hz, 60 pulses) occurred at 62 min. Endogenous DA and dihydroxyphenylacetic acid (DOPAC) in superfusate were measured using HPLC-EC. Ascorbic acid oxidase was added and 50 ul were assayed. The detection limit for both DA and DOPAC was 1 pg/ml/mg tissue. In the absence of drugs, spontaneous outflow of DA and DOPAC were detected (1.4 and 44 pg/ml/mg, respectively) and were increased above basal (2.6 and 290 pg/ml/mg, respectively) over the ten-min period after stimulation (overflow). In control slices, PCP did not change DOPAC or DA outflow. NOMI also did not change the DOPAC outflow, but increased (3.6 pg/ml/mg) DA outflow. PCP and NOMI increased DA overflow (12 and 35 pg/ml/mg, respectively) and decreased DOPAC overflow (64 and 87 pg/ml/mg, respectively). Therefore, PCP appears to act as a DA uptake blocker in this system. Metaphit did not alter DA outflow, but slightly increased DOPAC outflow (56 pg/ml/mg). DA and DOPAC overflow were greatly decreased (0.43 and 12 pg/ml/mg, respectively) by Metaphit. PCP and NOMI did not alter the Metaphit-induced increase in DOPAC outflow. Unexpectedly, the effect of the combinations of Metaphit and PCP or Metaphit and NOMI on DA outflow were greater than the effect of either drugs alone. Metaphit blocked the increase in DA overflow produced by both PCP and NOMI. Therefore, Metaphit may interact with the DA uptake site by acylating a closely associated PCP recognition site. Supported by USPHS NS09199 and AG06434.

307.2 COMPARISON OF THE EFFECTS OF PCP, COCAINE, AMPHETAMINE AND NOMIFENSINE ON ELECTRICALLY-EVOKED ENDOGENOUS DOPAMINE RELEASE AND RE-UPTAKE FROM RAT STRIATAL SLICES. C.C. WILCOX*, L.P. DWOSKIN*, G.A. GERHARDT, N.R. ZAHNISER (SPON: M. Luttges). Depts. Pharmacol. and Psychiat. Univ. Co. Hlth. Sci. Ctr., DENVER, CO 80262

Phencyclidine (PCP) may act to block the re-uptake of dopamine (DA) and/or stimulate the release of DA. The effect of PCP on dopaminergic function was compared to that of cocaine and nomifensine (uptake blockers) and to amphetamine (presumed releaser).

Endogenous DA and dihydroxyphenylacetic acid (DOPAC) were measured in the superfusate from rat striatal slices using HPLC-EC. Each chamber contained a single (0.5 mm thick) slice superfused at 1 ml/min with Kreb's buffer containing a single dose (.01-100 uM) of drug. After 60 min of superfusion, 12 one-min samples were collected. The slices were stimulated (60 pulses, 1Hz) at 62 min. Ascorbic acid oxidase was added to each sample and 50 ul were assayed. The limit of detection was 1 pg/ml/mg tissue. In superfusate from control samples (absence of drug) DA and DOPAC were detected (1.4 and 35 pg/ml/mg, respectively) prior to stimulation (outflow) and were increased to 5.0 and 190 pg/ml/mg, respectively, upon electrical stimulation (overflow). Only high doses of cocaine (10 uM) increased DA outflow, but had no effect on DOPAC outflow. Only high doses of nomifensine (100 uM) increased both DA and DOPAC outflow. Amphetamine (10-100 uM) increased DA outflow while decreasing DOPAC outflow. PCP had no effect on DA or DOPAC outflow. In general, DA overflow and DOPAC overflow were increased and decreased, respectively, by all the drugs examined. The efficacy of the increased DA overflow was nomifensine >> cocaine = PCP = amphetamine. These drugs decreased DOPAC overflow to approximately 12% of control. Increased levels of DA in superfusate reflect enhanced DA release and/or blockade of re-uptake. If a drug acts only to release DA, then DOPAC would also be expected to increase in superfusate. However, if a drug acts only to block re-uptake, then DOPAC would be expected to decrease. Therefore, under the conditions of these experiments (following a 60-min exposure to drug) all of the drugs appear to act primarily via blockade of re-uptake. Supported by USPHS NS09199, GM07635, DA04216 and AG06434.

307.3 RELEASE OF CORTICOTROPIN-RELEASING FACTOR (CRF) FROM RAT PREFRONTAL CORTEX IN VITRO. M.J. Owens, B. Maynor* and C.B. Nemeroff, Depts. Pharmacol. & Psychiat., Duke University Medical Center, Durham, North Carolina 27710.

Corticotropin-releasing factor (CRF), a 41 amino acid-containing peptide, is the major physiological regulator of ACTH secretion from the anterior pituitary. In addition, CRF possesses many of the requisite criteria for classification as a neurotransmitter in the CNS. These include: a heterogenous distribution throughout the CNS and specific, high affinity binding sites, putative receptors. In previous studies by our group (Smith et al., Endocrinol. 118:1997, 1986) and others another requisite neurotransmitter criterion for CRF was demonstrated, calcium-dependent, potassium induced release from hypothalamus, amygdala, midbrain and striatum. In the present study we studied release of CRF from rat prefrontal cortex in vitro.

Male Sprague-Dawley rats (21 days old) were decapitated and the prefrontal cortex was sliced into thin (0.75 mm) sections and immediately placed on a superfusion chamber containing a modified Kreb's-Henseleit buffer which was gassed with 95% O_2/5% CO_2; the pH was adjusted to 7.4 at 35°C. At ten minute intervals the buffer was removed and replaced with either fresh buffer in the case of basal release or buffer containing a depolarizing concentration of potassium (40 mM). In addition, other putative secretagogues were studied. Basal release was measured for three consecutive ten minute intervals, and then a test substance was added during the 30-40 minute period. Basal release was continued between 40-60 minutes and then buffer containing 40 mM KCl was added during the 60-70 minute epoch.

The radioimmunoassay for CRF utilizes [^{125}I]-rat/human CRF as a tracer, and has a sensitivity of 1.25 pg/tube. Addition of 40 mM KCl induced a 136% increase (n=16) in CRF release compared to basal levels of CRF release. In an attempt to characterize the neurotransmitter control of cortical CRF release, the effects of d-amphetamine (10 mM) were studied. This psychostimulant produced a small but significant increase in CRF release. Subsequent studies have shown that this response does not appear to be mediated by increased availability of 5-HT because concentrations of this indoleamine of 10^{-8} and 10^{-9} M had no effect on cortical CRF release.

The presence of CRF and CRF receptors in the cerebral cortex and its release by depolarizing concentrations of potassium, taken together, are concordant with the view that this peptide acts as a neurotransmitter in the cerebral cortex. (Supported by NIMH MH-42088 and NIEHS ES-07031.)

307.4 SPECIFICITY OF [^{3}H]1-METHYL-4-PHENYLPYRIDINIUM ION UPTAKE IN STRIATAL SYNAPTOSOMES E.A. Debler*, A. Hashim*, A. Lajtha, and H. Sershen* (SPON: N. Marks). Center for Neurochemistry, N.S. Kline Institute, Ward's Island, New York, NY 10035.

The neurotoxicity of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is attributed to the selective uptake of its metabolite 1-methyl-4-phenylpyridine (MPP^+) into dopamine terminals with subsequent terminal destruction. MPTP neurotoxicity can be prevented by the administration of monoamine oxidase-B specific inhibitors, which prevent the metabolism of MPTP to MPP^+, or by blocking the uptake of MPP^+ into dopamine terminals. Several compounds were evaluated, in vitro, with respect to their ability to block the transport of [^{3}H]MPP^+ (final concentration of 0.1 μM) into striatal synaptosomes. The classical dopamine uptake blockers GBR 12909, cocaine, and mazindol strongly inhibited striatal MPP^+ uptake, exhibiting IC_{50} values of approximately 0.1 μM. Nicotine and its metabolites, compounds potentially involved in the reported reduced incidence of Parkinson's disease in smokers, proved to be weak inhibitors (IC_{50} = 1 mM). The pyridine derivative 4-phenylpyridine (4-PP), recently shown to attenuate MPTP neurotoxicity in vivo, inhibited MPP^+ uptake, exhibiting an IC_{50} of 100 μM. Ascorbic acid, previously shown in our laboratory to attenuate MPTP neurotoxicity in vivo (Neuropharmacology 24:1257, 1985), was also seen to inhibit MPP^+ transport with an IC_{50} value of 100 μM. Kinetic analysis of [^{3}H]MPP^+ uptake in the presence of ascorbic acid indicated that ascorbic acid is a non-competitive inhibitor of MPP^+ uptake. The K_m and V_{max} values are 673 nM and 89 pmol/mg protein per min in the control condition and 654 nM and 31 pmol/mg per min in the presence of ascorbic acid. This effect was not due to conversion by ascorbic acid of [^{3}H]MPP^+ to a metabolite that is not transported, i.e., MPTP. HPLC analysis of [^{3}H]MPP^+ incubated with ascorbic acid and membranes indicated that MPP^+ was not metabolized during the incubation. The IC_{50} values of the above compounds were the same for inhibition of [^{3}H]MPP^+ uptake and for inhibition of [^{3}H]dopamine uptake into striatal synaptosomes, consonant with the idea that MPP^+ is transported by the dopamine carrier.

307.5 EFFECTS OF PHENCYCLIDINE ON EXTRACELLULAR DOPAMINE: AN IN-VIVO VOLTAMMETRY STUDY. F.M. Petracca*, R.A. Gazzara, and S.G. Howard. MRRC, BRI and Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

Phencyclidine (PCP) has been demonstrated to influence a number of different neurochemical systems, including serotonergic, noradrenergic, and cholinergic systems. Although PCP has no direct interaction with dopamine (DA) receptors, behavioral, electrophysiological, and neurochemical data indicate that this drug exerts an effect on the dopaminergic system. Using the technique of in-vivo voltammetry, this laboratory has previously demonstrated a long-lasting decrease in extracellular DA in the striatum after treatment with PCP. It was suggested that this decrease may be due to a non-specific anesthetic property of PCP. The present study addresses this issue by comparing the effects of PCP with those of ketamine (KET), a structurally related anesthetic, on extracellular DA in rat brain. Additionally, it has been hypothesized that one of the specific actions of PCP is to inhibit DA uptake. To address this postulated specific effect, PCP was evaluated in a paradigm which has been used to study known DA uptake inhibitors. It has been shown that nomifensine and other uptake inhibitors antagonize amphetamine(AMP)-induced DA release. In the present study, amphetamine-induced DA release was examined in rats pre-treated with PCP.

Male Sprague-Dawley rats were anesthetized with urethane (1.5 g/kg), and semidifferential voltammetry was performed according to methods previously described (Takeda, H. et.al., Neuropharmacol. 25(12):134, 1986). The doses of PCP and ketamine administered were 0.1, 1.0, and 10.0 mg/kg. D-AMP (1 mg/kg) was administered 60 minutes after PCP treatment for evaluation of uptake inhibition.

KET and PCP induced similar dose-related decreases in extracellular DA in the neostriatum. These results support the hypothesis that the PCP-induced decrease in DA release in anethetized animals is due to the anesthetic properties of PCP. In addition, high doses of PCP attenuated the AMP-induced increase in DA release normally found when AMP is administered alone. These data suggest that inhibition of DA uptake may be one of the mechanisms through which PCP exerts its CNS effects. Taken together, these results support the notion that PCP may have multiple actions in the CNS.

Supported by USPHS grant DA 031519 and NIH grant HD 07032.

307.6 THE ANTAGONISM OF AMPHETAMINE-INDUCED DOPAMINE RELEASE BY DOPAMINE UPTAKE INHIBITORS: A DEVELOPMENTAL IN-VIVO VOLTAMMETRY STUDY. R.A. Gazzara and S.G. Howard. MRRC, BRI and Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA, 90024.

CNS motor stimulants have been categorized as belonging to either an amphetamine(AMP)-like class (antagonized by alpha-methyl-p-tyrosine) or a methylphenidate class (antagonized by reserpine). Studies have shown that AMP-like agents act by releasing dopamine (DA) and that methylphenidate-like agents act through the inhibition of DA uptake (e.g.,Ross,Acta Pharmacol.et Toxicol.,41: 392,1977). In addition, compounds which inhibit DA reuptake have been found to antagonize AMP-induced hyperactivity in reserpinized mice (Ross, Life Sciences, 24:159,1979). These data suggest that DA uptake inhibitors antagonize AMP-induced DA release. The experiments presented here were designed to determine the effect of DA uptake inhibitors on AMP-induced changes in DA release in the neostriatum of 21-22-day-old rat pups and adult rats as measured by in-vivo voltammetry.

We have previously reported (Gazzara et al.,Dev.Brain Res.,28: 213,1986) that AMP(1.0 mg/kg, s.c.) produces a rapid increase in extracellular DA concentration in the neostriatum of adult rats, and a slight increase followed immediately by a prolonged decrease in extracellular DA concentration in the neostriatum of 21-22-day-old rat pups. In both cases we postulated that the results were due to an AMP-induced increase in DA release. In the case of the 21-22-day-old pups, however, we postulated that an increase in DA release in the substantia nigra depressed the firing rate of the nigrostriatal dopaminergic neurons, and resulted in a net decrease in DA release in the neostriatum.

In the experiments reported here, the following inhibitors of DA uptake were injected 60 min prior to AMP in order to test their effect on AMP-induced DA release: methylphenidate, nomifensine, mazindol and cocaine. All four of these compounds abolished the increase in DA release seen when AMP was administered alone to adult rats. In addition, both methylphenidate and nomifensine attentuated the prolonged decrease in extracellular DA concentration found when AMP alone is administered to 21-22-day-old rat pups. These data support the hypothesis that inhibitors of DA uptake antagonize AMP-induced DA release in the neostriatum of adult rats. Furthermore, these data suggest that DA uptake inhibitors may also antagonize AMP-induced DA release in the substantia nigra of 21-22-day-old rat pups as evidenced by the attenuation of the AMP-induced decrease in extracellular DA concentration in the neostriatum. The mechanism of this AMP antagonism remains to be elucidated, however it has been postulated that AMP-induced DA release may require a functional DA uptake carrier mechanism.

307.7 COCAINE ACTION ON STRIATAL DOPAMINE TRANSMISSION STUDIED BY MICRODIALYSIS. Yasmin Hurd* and Urban Ungerstedt* (SPON: C. Hildebrand). Dept. of Pharmacology, Karolinska Institute, Box 60 400, S-104 01 Stockholm, Sweden.

A microdialysis probe (Carnegie Medicin, Stockholm) was implanted into the caudate nucleus to study the neuronal mechanism of cocaine on transmitter release and metabolism. Cocaine, a reuptake inhibitor of dopamine (DA) was administered intravenously (IV) or via the dialysis probe into the caudate nucleus. IV administration of cocaine (1.0, 1.5, and 2.0mg/kg) caused a dose dependent transient increase of DA with a slight decrease in extracellular DOPAC. The maximum increase of DA appeared in the first 10 min perfusate and subsequently declined to baseline within 30 mins. This time pattern fits the fast subjective euphoric "high" that is characteristic for cocaine. To ascertain whether any acute sensitivity to prior cocaine exposure had occured a second dose of cocaine was administered after stable baseline was achieved. The DA and DA metabolite response pattern was similar to that following the first administration.

Via the perfusing medium cocaine was directly administered to the caudate nucleus at different concentrations. A dose dependent increase of DA was observed. Low concentrations (10^{-5} and 10^{-6}M) produced a stable increased level of DA with no change of the metabolites while at the highest dose (10^{-4}M) there was a sharp increase of DA in the second 10 min sample which subsequently declined to a level higher than that produced by the two lower concentrations. Although the DOPAC level declined at the highest concentration similar to that of specific uptake blockers, such as lu19005 and lu17133, the increased stable DA level induced after cocaine did not fit the gradual increasing DA level generally obtained with the other uptake blockers.

The microdialysis probe allows the possibility of not only monitoring endogenous neurochemicals in the brain but also the manipulation of essential intrinisic ions. Thus a Ca^{+2}-free perfusion medium abolished the DA response to intravenously administered cocaine. This indicates that the increased DA release originates from a vesicular pool of DA.

307.8 DISSIMILAR EFFECTS OF HALIDES ON [^{3}H]METHYLPHENIDATE BINDING AND SYNAPTOSOMAL DOPAMINE TRANSPORT. M.M. Schweri* (Sponsor: C.H. Hockman). Mercer U. School of Medicine, Macon, GA 31207.

Many characteristics associated with the binding site for the stimulant drug [^{3}H]methylphenidate ([^{3}H]MP)in striatal tissue suggest that this site may be physically or functionally related to the dopamine (DA) carrier complex in nigrostriatal dopaminergic nerve terminals. Possible anionic influences on both [^{3}H]MP binding and [^{3}H]DA transport were investigated by surveying the effects of varying concentrations of the halide salts on these two functions. When binding of 8-10 nM [^{3}H]MP to rat striatal synaptosomal membranes was studied in the presence of 10-500 mM NaF, -Cl, -Br, and -I, a qualitatively similar pattern of binding was observed in the presence of all of the halides except iodide. Peak binding of a similar magnitude occurred when the assay buffer contained 50-100 mM Naf, -Cl, or -Br, while maximal binding in the presence of NaI occurred at 250 mM and was more than three times that obtained in the presence of the other halide salts. Scatchard analysis of [^{3}H] MP binding in the presence of 100 mM NaCl and NaI demonstrated that the increase in binding observed with the latter was attributable to an increase in the affinity of the radioligand for its binding site rather than a change in receptor number (Kd's = 109 nM when NaCl was added and 46 nM when NaI was used). This increase in affinity was shown by kinetic analysis to be due mainly to iodide's ability to decrease the off-rate of [^{3}H]MP. Interestingly, I- did not enhance DA's affinity for the [^{3}H]MP binding site, even though DA competitively inhibits binding of [^{3}H]MP. The effects of the halides on synaptosomal accumulation of 30 nM [^{3}H]DA differed markedly from their effects on [^{3}H]MP binding. Maximum transport of [^{3}H]DA was observed in the presence of 120 mM NaCl. The same rank order ($Cl^- > Br^- > I^- > F^-$) of halide modulation of [^{3}H]DA transport was observed at all salt concentrations tested (10-150 mM; osmolality was maintained by addition of sucrose to the assay buffer). When [^{3}H] DA transport was compared in synaptosomes suspended in Krebs-phosphate buffer containing equimolar amounts of NaCl or NaI, the K_m in the presence of iodide was found to be almost three-fold greater than in Cl^- containing buffer (496 nM ± 50 vs 168 ± 8, respectively), while the V_{max} was only marginally affected. As predicted from the [^{3}H]MP binding studies, however, MP was found to be more potent in blocking [^{3}H]DA uptake in buffer containing I^- compared to equimolar amounts of Cl^- (K_i in I^- = 124 nM vs 207 nM in Cl^-). This data suggests that separate but overlapping domains with different sensitivity to halides may exist for the binding of MP and DA to the [^{3}H]MP binding site. Although the effect of the halides on MP binding is predictive of the influence of the halides on the potency of MP to inhibit DA transport, it is not predictive of their effect on DA transport itself. Supported by NIH Grant NS-22546

307.9 THE RELEASE OF LABELED AND UNLABELED CATECHOLAMINES FROM RABBIT CAROTID BODY. G.-F. Cheng*, B. Dinger and S.J. Fidone. Dept. of Physiol., Sch. of Med., Univ. of Utah, Salt Lake City, Utah 84108.

The arterial chemosensory tissue of the mammalian carotid body contains concentrated stores of catecholamines (CA), primarily dopamine (DA), in type I parenchymal cells. Previous studies in our laboratory utilized radioisotope techniques to study the release of ^{3}H-DA evoked by hypoxia from rabbit and cat carotid bodies. In the present study we have used our standard radioisotope methods in combination with HPLC and coulometric electrochemical detection to compare the release of tritiated and unlabeled DA from the rabbit carotid body.

Carotid bodies were pooled (3 to 8 per experiment) and incubated for 2 h at 37°C in Tyrode's solution equilibrated with 100% O_2, which contained ^{3}H-tyrosine (23.6 µM; 34 Ci/mmole). The tissue was washed for 90 min in 4 changes of 100% O_2-media (37°C). Superfusion media were collected during 10 min control, 5 stimulus and 6 successive 10 min post-stimulus periods. DA release was evoked by Tyrode media containing 60 mM K^+ (equimolar Na^+ reduction). Media samples and perchloric acid (PCA) extracts of tissue were processed in acid alumina and eluted with 1N PCA. CAs were separated and quantified using reverse phase HPLC with coulometric electrochemical detection (ESA Coulochem 5100; 5021 Conditioning Cell; 5011 Analytical Cell; 10 pg sensitivity). Eluted peaks were quantified on a Waters Data Module 730 and collected for determination of tritium in a Packard Model 1500 liquid scintillation analyzer. The total radioactivity recovered from each eluted sample routinely exceeded 95%. DA release (measured as the sum of DA plus 3,4-dihydroxyphenylacetic acid, DOPAC) is expressed as the percent of tissue content for each method of CA determination.

Less than 10% of the CA stores of the carotid body were labeled during the 2 h incubation in ^{3}H-tyrosine, thus providing two distinct pools of CAs in the tissue. The mean basal release of DA (0.21%/10 min) was sharply elevated by high K^+ superfusion media (9.28%/5 min), and release rapidly returned to basal levels in the succeeding 2 post-stimulus collection periods. The percentage of DA released from the radiolabeled stores during control, stimulus and post-stimulus periods corresponded closely to the release from the total DA stores (labeled plus unlabeled) determined electrochemically. Preliminary experiments in which carotid bodies were stimulated in media equilibrated with 10% O_2 show a similar correspondence between labeled and total release.

Our findings demonstrate the feasibility of utilizing a highly sensitive electrochemical method for determination of CA efflux from the carotid body and, in addition, they show that unlabeled and labeled (newly synthesized) DA is released from the carotid body in identical proportion during stimulus and resting conditions. Supported by USPHS grants NS12636, NS07938.

307.10 VIP RELEASE FROM MOUSE CEREBRAL CORTICAL SLICES : EFFECT OF CALCIUM CHANNEL BLOCKERS AND INVOLVEMENT OF ARACHIDONIC ACID METABOLITES. J.-L. Martin and P.J. Magistretti, Dept. of Pharmacology, CMU, 1211 - GENEVA 4, Switzerland.

The mechanisms of VIP (Vasoactive Intestinal Peptide) release were investigated in mouse cerebral cortical slices. Slices (250 x 250 µm) were preincubated for 90 min at 37° in oxygenated Krebs-Ringer bicarbonate buffer pH 7.4 containing (mM) : NaCl 120; KCl 3; $CaCl_2$ 2.6; $MgSO_4$ 0.67; KH_2PO_4 1.2; $NaHCO_3$ 27.5 and glucose 3 mM. After this period of time, slices were incubated for 6 min at 37° in the same buffer. At the end of incubation, tubes were centrifuged and released VIP was assayed by RIA in the supernatant. VIP tissue content was assayed in the pellet after extraction with 1 M CH_3COOH. The effect of various neuroactive agents on basal VIP release (BVR) was examined. Generally BVR was comprised between 0.2 to 0.4 % of VIP tissue content corresponding to 6-15 pg/mg prot/6 min. Ca^{++} channel blockers such Co^{++} 2.5 mM, Ni^{++} 0.1 mM and Mn^{++} 1 mM inhibited BVR by 50.98 ± 2.61 %, 26.2 ± 4.71 % and 21.32 ± 5.42 % respectively. In contrast Cd^{++} 20 µM, diltiazem 20 µM and nifedipine 10 µM did not affect BVR. The Ca^{++} channel agonist Bay K 8644 10 µM was similarly without effect on BVR. TTX at 2 µM slightly decreased (16.18 ± 3.53 %) BVR. 4-Aminopyridine (4-AP) stimulated in a concentration-dependent manner VIP release, reaching 567.27 ± 25.01 % of BVR at 1 mM. Effects of 4-AP were already detectable at 50 µM (203.15 ± 16.1 % increase over BVR). VIP release evoked by 4-AP 1 mM was completely abolished by Co^{++} 2.5 mM, but partially inhibited (67.78 ± 1.65 %) by TTX 2 µM. Indomethacin, which prevents the formation of arachidonic acid metabolites, decreases at 0.1 mM the effect of 4-AP 1 mM by 43.29 ± 1.2 %. The effect of 4-AP 1 mM was similarly reduced (75.94 ± 4.18 %) by TMB-8 0.1 mM, an inhibitor of Ca^{++} mobilization from intracellular stores. K^+ channel blockers such as Ba^{++} 1 mM, Cs^+ 1 mM and apamin at 1 nM and 1 µM were without effect on BVR. In contrast TEA 10 mM increased BVR by 163.86 ± 20.89 %. The possible involvement of adenylate cyclase and protein kinase C in VIP release was also investigated by testing forskolin (20 µM), TPA and PMA (1 µM) respectively. All these agents, alone or in combination, were without effect on BVR. VIP release was evoked in a concentration-dependent manner by K^+ with significant effects observed already at 15 mM (251.62 ± 25.77 % increase); at $[K^+]_o$ of 20 mM and 25 mM, increases over BVR of 380.91 ± 30.14 % and 677.76 ± 59.21 % respectively were reached. The K^+-evoked release of VIP was insensitive to TTX 2 µM even at $[K^+]_o$ of 50 mM. In contrast, the effect of K^+ 20 mM was antagonized by Co^{++} 2.5 mM (complete antagonism), Mn^{++} 1 mM (89.01 ± 6.2 %) and Ni^{++} 0.1 mM (39.19 ± 4.91 %) but not by Cd^{++} 20 µM, and was potentiated by TEA 10 mM (364.72 ± 16 %), Ba^{++} 1 mM (199.96 ± 27.24 %) and Cs^+ 1 mM (165.49 ± 5.1 %). Other depolarizing stimuli such as veratridine at 15 µM and ouabain at 100 µM evoked a VIP release of 725.55 ± 46.76 % and 460.6 ± 45.3 % respectively. The ouabain effect was partially blocked (42.57 ± 4.21 %) by TTX at 2 µM. Initial results indicate that phosphatidylserine at 100 µM stimulates VIP release by 161.09 ± 13.61 %.

307.11 THE IN VITRO RELEASE OF AMINO ACIDS, PEPTIDES AND CATECHOLAMINES FROM THE KINDLED RAT BRAIN AND THE HUMAN EPILEPTIC FOCUS. P Stoufflet,* NS Nadi, (SPON: Niles Bernick). Rice Univ Sch of Medicine, Houston, TX. and NINCDS, Bethesda, MD 20892.

The study of peptide and amino acid content in the kindled rat brain has shown an increase in the levels of somatostatin (ST) and β-endorphin but no alterations occurred in the content of amino acids when compared to sham-operated rats. The human epileptic (spiking region) focus had an increase in ST, neuropeptide Y (NPY), glutamate (GLU), glycine (GLY), and catecholamines (CA) when compared with non-focal tissue (non-spiking region) from the same patients. Studies of the enzymes for CA have shown an increase in tyrosine hydroxylase in rat and human brain indicating a possible acceleration in the turnover rate. We investigated the alteration in release of neurotransmitters and neuropeptides after depolarization by high K^+ from the kindled rat hippocampus and cortex as well as focal and non focal temporal cortex surgically removed from epileptic patients. The tissue was chopped into 400 um thick cubes and superfused successively with Krebs-Ringer buffer containing 3mM K^+, 60mM K^+, and 0mM Ca^{++}, 60mM K^+. The superfusates were collected at 0.5 min intervals and analyzed for amino acids, CA, and neuropeptides. In the kindled rat hippocampus and cortex the K^+-stimulated release of GLU, aspartate, (ASP) and GLY was 1.5, 1.6 and 2.0-fold higher respectively, when compared with sham-operated rats. The release of ST was also increased 1.9-fold when compared with the sham-operated animals. The release pattern of CA was not changed when compared to sham-operated rats in kindled rat brains collected one day following the last seizure. In the human brain treated in a manner similar to the kindled brain, preliminary studies showed that the release of CA, GLU, GLY, ST, and NPY was increased in the focal region when compared with the non-focal region by 1.5, 1.6, 1.4, 1.7, 1.9, and 2.1-fold, respectively.

The findings that GLU and ASP release were increased in both the kindled model and human cortex may indicate that these amino acids are involved in the excitability of the epileptic brain. The release of GLY was unexpected, but may now be explained in light of recent findings that GLY may activate NMDA receptors. The role of ST in the epileptic focus remains unclear, however, recent evidence demonstrating an increase in the potency of acetylcholine by this peptide may implicate it as a molecule regulating excitability in the focus. The increase of CA in the focus may be a secondary phenomenon, i.e., an increased inhibitory tone to stabilize a depolarized zone. The data will be discussed in view of the interactions of the above mentioned molecules in relation to epilepsy.

307.12 SYMPATHO-ADRENAL CO-STORAGE, RELEASE AND SYNTHESIS OF ENKEPHALINS AND CATECHOLAMINES INDUCED BY STRESS. R. L. Klein, R. W. Duncan*, T. J. Selva*, W. L. West* and A. Thureson-Klein. Dept. of Pharmacol. and Toxicol., Univ. Miss. Med. Ctr., Jackson, MS 39216.

Enkephalins (ENKs) occur at similar molarities and ratios to co-stored catecholamine (CA) in adrenal chromaffin granules and large dense cored vesicles (LDVs) of noradrenergic terminals. Amounts of ENKs tend to increase with animal size and in proportion to LDV populations in certain terminals. Exocytotic release occurs primarily during stress. In pig, ENK-CA co-storage in chromaffin cells and middle cerebral, coronary and mesenteric arteries is relatively high.

In response to 10 min CNS ischemia (CNS-I), there is intense sympatho-adrenal stimulation causing immediate rise in mean arterial pressure and in circulating (femoral vein, adrenal vein outflow) CAs and ENKs. Epinephrine especially is rapidly released from adrenal cells and compensated by resynthesis. Proportional release of ENKs occurs with 40% depletion of met-ENK, but not leu-ENK, even though acute precursor processing is induced. Norepinephrine is moderately depleted (20-30%) from terminals in blood vessels, while met-ENK is depleted 80-95% and leu-ENK 25-60%.

Reserpinization, while depleting CAs to various degrees, induces acute peptide precursor processing in chromaffin cells and in sympathetic terminals to blood vessels, increasing ENK contents 2 to 4-fold. After a lag period, *de novo* synthesis/processing is enhanced to achieve a 6 to 8-fold increase of ENK stores in chromaffin cells by 2 to 4 weeks, while contents in terminals of blood vessels tend to return to control levels. *In vivo*, reserpine causes blunting of CNS sympathetic outflow, so that usual intense stimulation by CNS-I is abolished. Upon recovery from reserpine, CNS-I response to increase blood pressure, and circulating CAs and ENKs gradually returns. Now adrenal release of ENKs reflects maintained reserpine-induced increase in stores. Partially recovered blood vessel innervation shows resistance to CA depletion after CNS-I and both ENKs increase 50-200% above control due to acutely induced precursor peptide processing.

It can be concluded that induction of precursor peptide processing and new synthesis due to cardiovascular stress (CNS-I) occurs in noradrenergic terminals to blood vessels as well as in adrenal chromaffin cells, but with a different pattern of response. Further, upon recovery from reserpine treatment, the noradrenergic innervation and the chromaffin cells undergo homeostatic adjustments which tend to minimize the enkephalin depleting effects of CNS-I. (AHA-Miss. Affil., BRSG RR05386.)

307.13 DIFFERENTIAL EFFECTS OF RESERPINE ON NOREPINEPHRINE AND NEUROPEPTIDES IN PERIPHERAL NERVE FIBERS AND THE ADRENAL MEDULLA OF DOMESTIC PIGS. J. Y. Kong*, A. Thureson-Klein, R. L. Klein and W. West*. Dept. of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS 39216.

Pigs (Sus scrofa) weighing 25-50 kg were treated with reserpine, using a relatively low loading dose of 0.08 mg/kg followed by 0.05 mg/kg every other day for 3 to 14 days and the effects on catecholamine(s) and neuropeptide(s) believed to be costored in peripheral nerve fibers and adrenal medullary cells examined. In other species, eg. guinea pig, a high single dose (5 mg/kg) reserpine causes tissue-specific neuropeptide Y (NPY) depletion along with norepinephrine (NE) from nerve fibers (Lundberg et al. Acta Physiol. Scand. 123:363, 1985) and in rats, adrenal NPY is also rapidly depleted followed by a slow recovery (de Quidt and Emson, Neuroscience 19:1011, 1986).

The pig differs from rodents by its high number of large (75-95 nm) dense cored vesicles (LDV) in the noradrenergic terminals. This should facilitate studies on neuropeptide storage and release because analyses of purified LDV fractions indicate that only this type of vesicles contains NPY and/or opioid peptide, putatively co-stored with NE. Small (45-65 nm) vesicles, that constitute 95% of the total vesicle population in rodents, appear to store only NE and some ATP.

Three to seven days of reserpine increased met-enkephalin 2-3 fold (RIA) in several blood vessels but did not change the levels in vasa deferentia. A decrease of 80% NE in perivascular fibers was paralleled by a loss of small vesicle contents and histofluorescence. NPY immunofluorescent fibers were of similar density as met-enkephalin reactive varicosities but had a somewhat different distribution, particularly in the vas deferens. Control and reserpinized pig had NPY reactive fibers but no reactive chromaffin cells in the adrenal medulla, probably accounting for the low tissue levels.

The reserpine dosage did not destroy the LDV synthesis and storage capability of NE as shown by a rapid recovery of tissue contents and glyoxylic acid reactive fibers while most small vesicles showed low chromaffin reactivity. The results suggest that small doses of reserpine affect NPY and enkephalin differently from co-stored catecholamines. However, the mechanisms involved remain obscure. While reserpine interferes with the NE storage in small and large vesicles there is no evidence that the neuropeptides, prepacked into LDVs in the perikaryon, leak out of the vesicles. Reserpine (0.5 mg/kg) affects cellular calcium levels and can impair the energy metabolism of secretory cells in rodents (Müller et al. Acta Physiol Scand. 123, 1985). Similar effects on the neuron may interfere with exocytosis.

307.14 WHOLE-BODY AUTORADIOGRAPHIC ANALYSIS OF THE TISSUE DISTRIBUTION OF THE CALCIUM CHANNEL ANTAGONIST CI-951 IN RATS. W.P. MCNALLY AND T. CHANG,* Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

Whole-body autoradiography and video-densitometry have been used to examine the distribution and fate of ^{14}C-labeled CI-951 (1,4-dihydro-2-methyl-5-(1-methylethoxy)-4-[2-trifluoromethyl)-phenyl]-1,6-naphthyridine-3-carboxylic acid, ethyl ester). CI-951, a calcium channel antagonist, is a new drug under development which has shown high specificity for cerebral vasculature. CI-951 is considerably more potent than nimodipine in dilation of cerebral arteries, and does not affect calcium channels in myocardial cells at therapeutic doses. These present studies were undertaken to examine the tissue distribution of the compound with special emphasis on the uptake and regional localization in the brain.

Methods: ^{14}C-CI-951 was synthesized at Goedecke AG, Freiburg, West Germany. Drug was administered in PEG solution to male Wistar rats via tail vein injection at a dose of 4 mg (514 uCi)/Kg. Animals were sacrificed by halothane anestesia at 0.25, 1, 4, or 12 hours post dose and prepared for whole-body sectioning and autoradiography. ^{14}C methacrylate standards were exposed simultaneously with sections.

Results and conclusions: CI-951 radioactivity was widely distributed to tissues following an IV dose. Activity in the liver and GI tract suggests significant biliary excretion while uptake in the gastric mucosa may reflect some degree of direct secretion into the gut. There is also evidence of urinary excretion. Radioequivalents in most tissues declined markedly while radioactivity in body fat appeared to increase at early time points and maintained activity over the course of these experiments. There was rapid penetration of considerable radioactivity into the brain with localization into specific areas, notably inferior colliculus, cerebral cortex, mammillary body and pontine nucleus. However, this distributional pattern was not persisent as most brain areas showed significant decrease in activity at 4 hours post dose. At this interval, areas of white matter such as the corpus callosum and spinal white demonstrated a considerable increase in activity compared to other regions. This enhanced uptake remained apparent at 12 hours post dose. CI-951 appeared to have an affinity for tissues rich in lipid, suggesting the possibility of a deep reservoir for the compound, which may have significance in assessing its pharmacologic activity.

307.15 EFFECT OF IN VITRO ADDITION AND IN VIVO TREATMENT WITH VARIOUS CALCIUM ANTAGONISTS ON MET-ENKEPHALIN RELEASE FROM RAT STRIATAL SLICES. S. Di Giovine*, S. Govoni, F. Battaini, M.S. Magnoni* and M. Trabucchi^. (SPON.: V. Olgiati) Institute of Pharmacological Sciences, University of Milan and ^Chair of Toxicology, 2nd University of Rome, Italy.

The brain has a fairly high density of binding sites for calcium entry blockers, which appear to be located on neurons. However, the first studies on synaptosomes were unable to show an action of these drugs on calcium movements and on neurotransmitter release, which represents the prototype of calcium dependent processes in the central nervous system (CNS).

The discovery of various types of neuronal calcium channels (Nowycky et al., Nature 316:440,1985) among which only one is sensitive to calcium antagonist may explain this discrepancy.

In addition, recent data indicate that in opportune experimental models calcium antagonists may indeed inhibit neurotransmitter release. These experiments include studies on cultured PC12, on neuroblastoma-glioma cells, and on brain slices.

Along this line we have studied the effect of in vitro addition and in vivo treatment with various calcium antagonists on the release of met-enkephalin immunoreactive material (ME-IR) from rat striatal slices.

For release experiments striatal slices (300 x 300 microns) were obtained through a McIlwain tissue chopper and incubated in oxygenated Krebs Ringer buffer. Met-enkephalin released in the medium was measured according to Pasinetti et al. (Brain Res. 293:364, 1984).

The results indicate that flunarizine, verapamil and nifedipine at micromolar concentrations are able to inhibit the potassium stimulated ME-IR release (42, 60 and 41% respectively using a 10 micromolar concentration). The stimulated release of ME-IR was inhibited also by the in vivo treatment with the three drugs (flunarizine 40 mg/Kg, 4 hrs; verapamil 40 mg/Kg, 1 hr; nifedipine 10 mg/Kg, 1 hr).

The powerful effect exerted by the acute in vivo treatment with calcium antagonists on ME-IR release is interesting since literature data indicate the existence of an interaction between calcium antagonists and the opiate system. In particular, nimodipine, a dihydropyridine calcium antagonist, inhibits the opiate and ethanol withdrawal syndrome and the chronic treatment with morphine increases the number of brain DHP binding sites.

Whether the effect observed in our experiments is entirely due to an action on calcium ion movements has to be established. On the other hand, the results support the concept that the treatment with calcium antagonist may directly interfere with brain neurotransmission.

307.16 Na^+ TRANSPORT: A REQUIREMENT FOR COPPER AMPLIFICATION OF PROSTAGLANDIN E_2 STIMULATION OF LHRH RELEASE FROM MEDIAN EMINENCE (ME) EXPLANTS. A. Barnea, M. Colombani-Vidal*, D.E. Hartter, and G. Cho*, Depts. OB/GYN & Physiol, The Green Ctr., UTHSCD, Dallas, Tx. 75235

We have previously shown that copper complexed to histidine (Cu) modulates LHRH release from ME explants in 2 ways. Way 1, Cu^+ stimulates LHRH release by a process requiring Na^+ transport, the driving force of which is the Na/K ATPase-generated $[Na^+]$ gradient. This process is inhibited by Li^+ or ouabain (Ouab) but not by tetrodotoxin (TTX) nor amiloride (Amil). Way 2, Cu amplifies PGE_2 stimulation of LHRH release. The question arises: Is Na^+ required also for amplification of PGE_2 action and if so, is it required for Cu uptake or Cu action? ME of adult male rats were incubated at 37 C for 5 min with 150μM Cu and then for 15 min with 10μM PGE_2 (Cu/PGE_2), with Cu alone, or with PGE_2 alone. LHRH release was (mean ± SE):

INHIBITOR	N	L H R H Basal	R E L E A S E ; pg/15min/ME Cu	Cu/PGE_2	Cu/PGE_2-Cu
None	34	4.4±0.4	20.0±1.6	48.0±1.6	28.0
127mM Li^+	9	5.2±0.4	18.8±2.0	24.0±2.4	5.2
0.5mM Ouab	8	29.2±4.0	35.6±2.0	47.6±3.2	12.0
10μM TTX	11	4.0±4.0	21.6±2.4	46.4±6.0	24.8
0.1mM Amil	9	4.4±1.6	27.2±5.2	53.2±4.4	26.0

Only Li^+ and Ouab inhibited (80% and 60%) amplified release (Cu/PGE_2-Cu); the elevated basal release induced by Ouab indicates inhibition of Na/K ATPase. PGE_2-stimulated release was 4.3±.4(15) pg, or 15% of amplified release, and it was not inhibited by Li^+ or Ouab. Cu uptake was measured 15 min after incubation with 100μM 67-copper complexed to histidine. Cu uptake was not effected by Li^+ or Ouab: with 140 mM Na^+ (regular buffer) uptake was 7.6 ± .4; with 127mM Li^+ it was 7.0 ± .2; and with 0.5mM Ouab uptake was 6.8 ± .3 nmol/15'/mg P [mean ± SE; N=10]. Thus, Cu-amplified PGE_2 stimulation of LHRH release requires transport of Na^+ driven by Na/K ATPase, whereas Cu uptake does not require Na^+ transport. In conclusion, Na^+ transport is required for both stimulation of LHRH release and amplification of PGE_2 stimulation of LHRH release, and the Na^+ requirement is for copper action and not for copper uptake.

307.17 LOCALIZATION OF THE DOPAMINE UPTAKE SITE IN RAT BRAIN USING [^{3}H]-GBR 12935: EFFECTS OF LESIONS. J.K. Wamsley, T.M. Dawson, F. Filloux.* Depts. of Psych., Pharmacol., Neurol., Univ. of Utah School of Medicine, SLC, UT 84132.

A number of radioactive ligands including [^{3}H]-mazindol, [^{3}H]-nomifensine, [^{3}H]-cocaine and [^{3}H]-methylphenidate have been shown to label the dopamine (DA) uptake site. [^{3}H]-GBR 12935 has recently been proposed as a more selective ligand for the DA uptake complex (Janowsky et al., J. Neurochem. 46:1272, 1986), and conditions allowing for localization of this uptake site using quantitative autoradiography have been reported (Dawson et al., Eur. J. Pharmacol. 126:171, 1986). In order to further investigate the utility of [^{3}H]-GBR 12935 as a selective ligand for the DA uptake site, the effects of neurotoxin lesions on the autoradiographic distribution of [^{3}H]-GBR 12935 binding have been examined.

Unilateral stereotaxic lesions of the substantia nigra (SN) or of the caudate-putamen (CPu) were performed using ibotenic acid (IA) or 6-hydroxydopamine (6-OHDA). The former toxin destroys local neurons, sparing fibers of passage, while 6-OHDA selectively damages catecholaminergic neurons. Control animals received injections of vehicle alone. Ten micron, slide-mounted serial tissue sections of rat forebrain were incubated in 0.5 nM [^{3}H]-GBR 12935 as described elsewhere (Dawson et al., Eur. J. Pharmacol. 126:171, 1986). Blanks were generated by the addition of unlabeled GBR 12909. Autoradiograms were produced by apposing the labeled tissue sections and brain mash tritium standards to tritium-sensitive LKB Ultrofilm. Quantitation was performed using computerized microdensitometry.

6-OHDA and IA lesions of the SN produced up to 50% loss of [^{3}H]-GBR 12935 binding throughout the ipsilateral CPu and in the substantia nigra compacta (SNC). Significant, but smaller reductions in binding were also seen in the entopeduncular nucleus and the substantia nigra reticulata (SNR), but no losses occurred in the pre-frontal cortex, nucleus accumbens, claustrum and globus pallidus. 6-OHDA lesions of the CPu also resulted in marked loss of [^{3}H]-GBR 12935 in the CPu, but the loss was restricted to the lesioned area (central and anterior CPu) in comparison to the prominent loss of binding seen in the posterolateral CPu of animals with SNC lesions. IA lesions of the CPu resulted in variable (statistically nonsignificant) effects: the most extensive lesion substantially reduced [^{3}H]-GBR 12935 binding in the damaged area, while more restricted CPu lesions failed to do so.

These results provide further evidence that [^{3}H]-GBR 12935 labels the DA uptake site. The regional loss of binding following SNC lesions suggests that DA fibers project not only to the CPu, but also to the ipsilateral entopeduncular nucleus and SNR.

307.18 INFLUX OF CHOLINE ANALOG INTO DOG BRAIN MEASURED BY POSITRON EMISSION TOMOGRAPHY (PET). C. Redies, M. Diksic*, B. Collier, A. Gjedde*, S. Gauthier*, C.J. Thompson*, and W.H. Feindel*. Brain Imaging Center, Montreal Neurological Institute and Hospital, and Department of Neurology and Neurosurgery, McGill University, Montréal, Québec H3A 2B4.

The usefulness of the choline analog pyrrolidinocholine as a tracer for acetylcholine turnover in brain was evaluated by PET. In vitro experiments showed that pyrrolidinocholine is transported by the high-affinity choline uptake system; it is, however, not substrate for acetylcholine esterase (Fisher, A., Hanin, I., Life Sci. 27:1615, 1980).

The brain uptake of C-11 labeled pyrrolidinocholine was measured in 3 dogs by rapid PET imaging (4 s frames) and rapid arterial plasma sampling during the first minutes after the intravenous injection of 5 to 15 mCi tracer (specific activity at end of synthesis 1000-2000 Ci/mmol). Synthesis of the tracer was described previously (Diksic, M., Jolly, D., J. Label. Compds. Radiopharm. 13:987, 1986).

Data were analyzed by plotting the apparent distribution volume of tracer as a function of exposure time to tracer (Gjedde, A., J. Neurochem. 36:1463, 1981). During the first 1.5 min after tracer injection, brain uptake of tracer was found to be unidirectional. For brain tissue, the initial volume of distribution V_0 of pyrrolidinocholine was 0.08 ml/g ± 0.03 SD. The clearance K_{in} was 0.017 ml/g/min ± 0.008 SD; assuming a brain plasma flow of 0.3 ml/g/min, this yields a brain pyrrolidinocholine extraction of 6%. This value is at least 5 times higher than the value expected from simple diffusion of tracer across the blood-brain barrier (BBB) (Cornford, E.M., et al., J. Neurochem. 30:299, 1978). For the carotid artery, K_{in} was 0.07 ± 0.05 ml/g/min, and, for the jugular vein, 0.11 ± 0.09 ml/g/min. Therefore, the endothelium of the capillaries perfusing the walls of major blood vessels is more permeable to tracer than the BBB.

The short initial period of unidirectional uptake of pyrrolidinocholine into brain was followed by rapid clearance of radioactivity from brain and plasma (Friedland, R.P., et al., J. Nucl. Med. 24:812, 1983). Pyrrolidinocholine cannot be used to image the metabolism of choline because of its relatively low extraction in brain, its short plasma half-life, and because it may be incorporated into phospholipids.

This study is the first to measure transport of a choline analog across the BBB in vivo by PET. Such measurements may shed light on the availability of blood choline to brain and other tissues in degenerative diseases and aging in man (Cornford, E.M., et al., J. Neurochem. 30:299, 1978).

308.1 FURTHER CHARACTERIZATION OF A CELL SURFACE CARBOHYDRATE DISTRIBUTED IN A DORSOVENTRAL GRADIENT IN PERINATAL RAT RETINA.
J.R. Sparrow and C.J. Barnstable, The Rockefeller University, New York , NY 10021.

Interest in the coding of positional information in retina has led to the identification of a cell surface molecule which labels with monoclonal antibody JONES. This antigen is distributed in embryonic and early postnatal rat retina in a dorsoventral gradient and persists in the adult as only a punctate band in the outer plexiform layer(Nature 324:459,1986). Analysis has revealed that the gradient in part reflects differing proportions of cells bearing the JONES antigen rather than the amount expressed per cell. Biochemical characterization has indicated that the JONES antigen in retina is a modified ganglioside, 9-O-acetyl GD3. Here we describe an examination in retina of the 1) relationship between JONES and GD3 expression 2) cell-type distribution of JONES antigen .

Monolayer cultures of neural retinae from rat pups (E18-PN2) were grown on collagen or laminin in supplemented MEM at $2x10^5$cells/ml. Freshly dissociated neural retinal cells (PN1-4) were fixed in suspension with 1-2% paraformaldehyde and attached to poly-lysine coated coverslips. GD3 was detected with specific antibody R24 (gift of K. Lloyd) and cell types were identified with previously described monoclonal antibodies.

At PN1 92% of the freshly dissociated cells stained positively for R24 but only 68% were JONES labeled. Virtually all of the JONES positive cells also stained for R24: 1% of the cells were R24 negative being JONES positive. 7% of the cells did not label with either antibody. By PN4 the frequency of JONES positive cells decreased to 41%, while the proportion of R24 labeled cells only declined to 85%.

Immunofluorescent staining of fixed cultures with JONES antibody revealed that both the flat cells, presumably glia and the small round process bearing neuronal-like cells were labeled. Subsequent analysis of freshly dissociated PN2 retinal cells revealed that 53% of ganglion cells, as identified by prior retrograde labeling with the fluorescent dye Fluoro-Gold, were also labeled with JONES. By PN4 the proportion was 39%. At PN2, 43% of rod photoreceptors, as detected with antibody RET-P1, were also labeled with JONES. At PN4 30% of these cells expressed JONES. Amacrine cells, as distinguished with antibody HPC-1, also express the JONES antigen. At PN4 67% of HPC-1 positive cells were labeled with JONES.

We conclude that 1) differences in the percentages of JONES and R24 positive cells and in particular the different rate at which JONES and R24 staining declined with age, indicate that the expression of the JONES epitope is regulated with some independence from its possible precursor GD3 2) JONES is expressed on a variety of retinal cells, both neurons and glia 3) at a given postnatal age the percent of JONES labeled cells varies with the cell-type 4) from PN2-4 there is approximately a 30% decline in number of photoreceptor and amacrine cells expressing the JONES antigen .

308.2 THROMBOSPONDIN IN THE DEVELOPING CEREBELLAR CORTEX
O'Shea, K.S., and Dixit, V.M.*, Depts of Anatomy & Cell Biology and Pathology, Univ. of Michigan Schl of Medicine, Ann Arbor, MI 48109.

Thrombospondin (TSP) is a trimeric glycoprotein of Mr 400,000 which is synthesized and secreted by a variety of cells including: endothelial cells, smooth muscle cells and glial cells. The secreted TSP is incorporated into the extracellular matrix of these cells. Matrix TSP has been implicated in a number of cell migratory and proliferative events in vitro. To date, however, there are no reports of its presence in any developing tissue, including the CNS.

To examine the possible role of TSP in the cell migrations involved in CNS development, we have mapped the differential deposition of TSP during cerebellar cortex formation during: active division of the external granule cells (postnatal day 1; PN1), active inward migration (PN10), and after migration was completed (PN61) in male, CD-1 strain mice.

Blocks of cerebellar cortex were removed from the region of the forming primary fissure and fresh frozen in OCT embedding compound in hexane cooled over acetone/dry ice. Transverse sections were cut at 8 micrometers, washed in PBS and exposed to normal goat serum (1:20) followed by the primary antibody (1:20, 2 h, room temperature). Sections were washed, then exposed to goat anti-rabbit IgG-FITC (1:50,30 min, room temperature), washed extensively, coverslipped, viewed and photographed in a Leitz Dialux Orthoplan photomicroscope.

On PN1, TSP surrounded the external granule cells and was densely deposited in the superficial portion of the Purkinje cell layer. By PN10 during active granule cell migration, TSP still surrounded granule cells but was particularly densely deposited on postmitotic, pre-migratory granule cells. The forming molecular layer stained intensely as did the Purkinje cell layer. In PN61 cortex in which cell migration was complete, there was little staining of the molecular layer, although Purkinje cell and internal granule cell layers stained intensely. White matter was negative for TSP, as were processes of the Golgi epithelial cells.

Presence of TSP on granule cells and in the molecular layer during active granule cell migration suggest that TSP may play a role in granule cell migration during cerebellar histogenesis. Current investigations are in progress to extend these observations to the ultrastructural level.

Supported in part by NIH grant NS-21108.

308.3 A CELL ADHESION ASSAY FOR TRANSMITTER-IDENTIFIED NEURONS.
E. Lieth, D.R. McClay+*, and J.M. Lauder. Dept. of Anatomy, UNC School of Medicine, Chapel Hill NC 27514, and +Dept. of Zoology, Duke University, Durham NC 27707.

Several laboratories have shown that developing neurons interact specifically with astrocytes. We have previously measured the extent to which astrocytes promote neurite outgrowth and stimulate the activity of a transmitter producing enzyme. The fact that astrocytes accelerate the development of these morphological and biochemical aspects of the nervous system raises the question of whether a specific binding may exist between neurons and glia to mediate developmental processes.

We modified the binding assay of McClay et al. (PNAS, 78:4975-4979, 1981) to quantify the specificity of binding between transmitter-identified neurons and glial substrates as compared with binding of neurons to fibroblast substrates. Purified postnatal rat astrocytes or Normal Rat Kidney fibroblasts were maintained in 250ml culture flasks. To measure adhesion, these substrate cells were suspended in a low concentration of trypsin (0.03%) in EDTA (Versene 1:5000) and either plated onto poly-D-lysine coated 96-well flexible assay plates and allowed to grow to confluency overnight, or spun as a confluent monolayer onto poly-D-lysine and glutaraldehyde coated plates just before binding was assayed. Raphe nuclei were dissected from E14 rat embryos. Developing serotonergic (5-HT) neurons of the raphe were labeled by high affinity uptake of ^{3}H-5-HT. The specificity of this labeling was determined by combined autoradiography/immunocytochemistry (^{3}H-5-HT, a-5-HT), and competition with unlabeled fluoxetine. Tissue was dissociated by trituration after incubation in EDTA.

Probe neurons were spun onto monolayers at 20 x g. To measure binding, samples were inverted and spun at 120 x g. The amount of radioactivity remaining bound to the substrate was compared to the radioactivity dislodged to give the percentage of cells bound.

Using high affinity uptake to label probe neurons, the binding properties of virtually any neuronal subclass can theoretically be measured using this assay. PHS Grant #NS21840.

308.4 SELECTIVE *IN VITRO* REASSOCIATION OF EARLY VERSUS LATE POSTMITOTIC NEURONS FROM THE RAT FOREBRAIN.
L.A. Krushel and D. van der Kooy, Department of Anatomy, University of Toronto, Canada M5S 1A8.

The development of pattern in the central nervous system involves cell proliferation, migration and adhesion. Neurons of the patch compartment of the mammalian striatum leave the mitotic cycle earlier in development than neurons of the striatal matrix compartment. Previously we have shown that patch (but not matrix) cells from the embryonic striatum preferentially adhere to each other when allowed to migrate on an artificial substrate *in vitro* (Krushel et al. 1986, Soc. Neurosci. Abstr. 12:238). This selective adherence may underlie striatal compartmentalization. Cell suspension reaggregate cultures have now been employed to allow for greater experimental reassociation of embryonic rat forebrain cells.We asked if telencephalic neurons which become postmitotic at the same embryonic time, selectively adhere to one another. That is,when removed embryonically, dissociated and reaggregated *in vitro* , will cells with similar birthdates selectively reassociate with each other? Timed pregnant Wistar albino rats were injected with 1mCi ^{3}H-thymidine on embryonic day (E) 13 or 18. The E13 injection primarily labeled patch cells in the striatum and deep layer cells in the cortex. The E18 injection primarily labeled striatal matrix neurons and the neurons of the superficial layers in the cortex. Two or seven days later, the striatum and cortex were separately dissected, dissociated into single cells, and each plated at a cell density of approximately $1 X 10^7$ per 60mm dish. The cell suspensions were placed on a shaker at 70 rpm. After five days in culture, the aggregates were fixed in 4% paraformaldehyde in PBS and embedded in paraffin. 5 um sections were cut, defatted, and dipped in Kodak NTB2 nuclear track emulsion. After a two week exposure, the emulsion was developed and the tissue dehydrated and counterstained with cresyl violet.

Both dissociated striatal and cortical cultures formed multicellular aggregates. The largest aggregates were produced by the tissue removed earliest from the embryo (E15). Within their separate aggregates, both striatal and cortical cells labeled on E13 with ^{3}H-thymidine were found to be preferentially located near to one another in small clumps of 3-5 labeled cells. This contrasted with the results from striatal and cortical reaggregates labeled with ^{3}H-thymidine on E18. These cultures exhibited labeled cells which were randomly dispersed throughout the aggregates. The results suggest that the patch cells of the striatum and the deep layer neurons of the cortex possess adhesive factor(s) which allow them to organize *in vivo* . This initial adhesion of early postmitotic neurons may create a template, upon which pattern is formed in the striatum and cortex through the migration of later born and non self-adhesive neurons.

308.5 BINDING OF GRANULE NEURONS TO THE MOLECULAR LAYER IS DEVELOPMENTALLY REGULATED L. M. Bolin and R. V. Rouse*. Department of Pathology, Stanford Univ. Sch. of Med., Stanford, CA 94305

During histogenesis of the mammalian cerebellum, cell-cell interactions involving surface molecules are necessary for pattern formation. In the neonatal mouse, post-mitotic granule neurons traverse the developing molecular layer guided by Bergmann glia fibers. We have devised a binding assay to investigate these heterotypic neuron-glia interactions *in situ*. Single cell suspensions of live granule neurons applied to tissue sections of developing brain will bind only to cerebellum and hippocampus. Within the cerebellum, cells from ten-day-old (P10) mice (the time of presumed maximal contact guidance) adhere preferentially to the molecular layer. With increasing age of substrate tissue, these cells will also bind internal granular layer. This cell-tissue interaction is calcium and magnesium independent. The granule cell surface molecules involved are not trypsin sensitive. To confirm the specificity of this adherence, a variety of other cell types have been applied. While mouse fibroblast cell lines adhere in a non specific manner to all areas of the brain only the mouse neuroblastoma, N2A, binds cerebellum in a pattern similar to migrating granule cells.

The granule cell binding is developmentally regulated. Substrate tissue under one week of age is only bound by granule cells near P10 in age; younger and older cells do not bind to young tissue. With increasing tissue age, binding of granule cells of progressively younger and older ages is seen. This data is compatible with a single receptor-ligand mechanism in which both elements are developmentally controlled. The granule cell component (receptor) must increase in number or affinity from birth to age P10 but decline after that age. P10 represents the peak of migratory activity at which time the necessary receptor would be maximally expressed and/or present in its high affinity form. The tissue substrate ligand must increase in number and/or affinity with postnatal age. These developmentally regulated changes would explain the increase in binding between progressively younger tissue and cells of increasing age until P10. After this age, increasingly older substrate tissues expressing increasingly more ligand are necessary for this interaction with cells whose receptor number or affinity is declining. Cells younger than P10, expressing few or low affinity receptors would require older tissue with high amounts of ligand as substrate.

The system defined by this assay may involve components that participate in phenomena described by others *in vitro*. The binding patterns observed exhibit the same anatomic and temporal characteristics as *in vivo* cerebellar granule cell migration during the postnatal period. It allows for an analysis of a single receptor-ligand system in the complex context of tissue section and predicts independent patterns of regulation of its components.

308.6 NEURON-GLIAL INTERACTION CONTROLS CEREBELLAR GRANULE CELL MATURATION WITH GLUTAMATE-TAURINE INTERPLAY E. Trenkner, Department of Pharmacology, New York University Medical Center, 550 First Avenue, New York, NY 10016

Cell migration is a fundamental process of development. In CNS development, the pathway of neuronal migration determines the general topography of brain regions and the cellular location within regions. In the cerebellum granule cell migration is a timed process leading these cells through different cellular environments (1).

A dynamic relationship between neuron and glia has been documented based on neurotransmission. Glutamate is released in a Ca^{++} dependent manner from cultured glutamatergic cerebella granule cells. Taurine, 2-aminoethane sulfonic acid, is by far the most abundant free amino acid particularly in the cerebellum, exceeded only by glutamate. Viewed as an inhibition amino acid transmitter, taurine has received clinical attention for its anti-convulsant properties. This study focuses on the role of taurine and glutamate since their essential role in cerebellar development appears evident.

Neurological mutations in the mouse provide powerful tools for anlayzing cell migration and assembly. The neurological mutant weaver (wv/wv) is particularly relevant to the analysis of glia-neuron interaction during cell migration and assembly. The defect of weaver is inherent to granule cells (2) Weaver granule cells fail to interact with normal (+/+) astroglia whereas normal granule cells react with astrocytes of wv/wv (3). Biochemical analysis of developing wv/wv cerebellum revealed that in contrast to +/+ the concentrations of glutamate and taurine were reduced during the period of granule cell migration (4).

This study demonstrates that in microwell cultures (5) of wv/wv cerebellum, fiber formation and cell migration is impaired. Whereas normal cerebellar cells subsequently extend cables consisting of fiberbundles between cellular reaggregates, very few such cables were formed by reaggregated weaver cells. In addition the absence of migrating granule cells was characteristic for wv/wv in vitro. These perturbed functions were restored, however, in the presence of 10^{-2}M taurine. In the absence of glutamate cell patterns of both +/+ and wv/wv looked alike, but the pattern was restored in the presence of taurine. Taurine uptake blockers blocked cell migration considerably, independent of glutamate. Taurine was released from glia cell populations when glutamate (10^{-4}M) or enriched granule cell populations were added to ^{3}H-taurine loaded glial cells. In summary, the results reported here support the hypothesis that glutamate stimulates astroglial cells to release taurine. Extracellular (released) taurine, independent of glutamate induces granule cells to sustain their viability and function.

308.7 DEVELOPMENT OF AFFERENTS TO MOUSE SOMATOSENSORY CORTEX S. Senft* and T. Woolsey. Departments of Neurology and Neuro-surgery & McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO. 63110. (Supported by NIH grant 17763)

An in vitro slice preparation (Bernardo, 1986) which makes use of horseradish peroxidase (HRP) and an oblique plane of section to label defined regions of the adult mouse whisker pathway has been adapted for use on neonates. Afferents to the developing "barrel" cortex, from day 1 (the day of birth) to day 7, have been labeled.

Animals were ice-anesthetized and perfused with cold artificial cerebro-spinal fluid (ACSF). After decapitation their brains were removed, bisected, and placed in chilled ACSF. Slices (~1500 mu.) taken 45 degrees from midline were stained with methylene blue to show the ventrobasal nucleus of the thalamus (VB) and the thalamic radiations. Chips of HRP/ethylene glycol were positioned in these slices, which were then kept in warm (36-37 degrees C.) oxygenated ACSF for 4 to 8 hours. They were next fixed, frozen-sectioned at 75 mu. and reacted (after Adams). Sections were carefully mounted to avoid cracks; alternate sections were counter-stained for Nissl. Selected fibers were traced at 800x to 2000x using a camera lucida aided by a par-focal video camera to enhance visual contrast.

Placing HRP either in VB or in the thalamic radiations labeled many presumed thalamocortical afferents (TCA). Fibers were judged "thalamocortical" if orthograde label greatly dominated retrograde label in cortex and somata were retrogradely filled in VB. Enough candidate arbors were followed to invite distinct hypotheses about the strategy of TCA ingrowth, particularly in relation to emerging laminar and barrel boundaries as delineated by Nissl stains. For example, it is clear that TCA's cluster in barrel-like formations before a pattern can be observed in cell somata. Also, this class of fiber is seen to reach and traverse the cortical plate as early as post-natal day one: several days earlier than expected. Another peculiar characteristic of this projection pattern is that fibers from older animals run more perpendicularly to the pia than those from younger animals.

We hypothesize that thalamocortical afferents invade the cortex in several stages. Upon leaving white matter, afferents proceed along fairly direct paths towards the pia, but with an apparently random pitch. At various points along the trajectory, they emit collaterals which rise more rapidly towards the pia. All fibers arborize more when they encounter the cortical plate, so a single afferent can sample a wide area of cortex whereas afferents from a local thalamic zone should overlap and colonize the cortex as a Gaussian around an average center-point. If neighboring thalamic areas correlate highly, in either intrinsic activity or sensory input, and if Hebbian-like mechanisms operate in neonatal cortex, then reinforcement will be most probable at peaks of arbor overlap Transformation to a barrel pattern could then occur: for example via competitive thresholding, with or without fiber retraction.

308.8 THE EARLY POSTNATAL ONTOGENESIS OF VIP/PHI AND CCK-IMMUNOREACTIVE STRUCTURES IN THE CAT VISUAL CORTEX. P.Wahle* and G.Meyer* (SPON:K. Albus).MPI Biophysik.Chemie,Dept.Neurobiology,3400 Göttingen, FRG, and Dept.Anatomy, Fac.Medicine,Univ. La Laguna, Tenerife, Spain.

Immunohistochemistry was performed in kittens aged from postnatal day (P)0 to P50.Neurons were classified on the basis of axonal criteria. Several cell types are only seen in the immature cortex.This means, that they were transient, and immunohistochemistry reveals degeneration and death of these neurons and they were no longer observed in the adult cortex. VIP/PHI 1.Transient cells: Pseudo-Horsetail cells possess axonal bundles descending to and terminating in layer VI, start differentiation around P4, peak from P14 to P20 and become eliminated until P30. Neurons with columnar dendritic fields of layers IV,V and axons projecting to layer VI appear at P7 and disappear at P20. Bipolar cells of layers IV-VI project to the white matter, differentiate around P4, peak from P10 to P16, and become eliminated until P25. Concurrently, the vertical fiber architecture issued by these cell types disappears. 2.Persisting cells: Bipolar cells with short dendrites and intralaminar axons appear in layers II-IV around P12. The main VIP/PHI-ir cell types are neurons with descending axons giving horizontal collaterals (appearing at P 15) and local axon basket cells (appearing at P30) in layers II-IV. The innervation of deep layers largely disappears and only terminal strata in superficial layers persist. Thus, the early postnatal phase ist characterized by transient cell types and innervation pattern which are progressively replaced by the persisting ones. CCK 1.Transient cells: Neurons with columnar dendritic fields (P2 to P14) of layers IV,V project to layer VI. 2.Persisting cells: Multipolar neurons of layer VI, bitufted to multipolar neurons of layer V and III project to and terminate in layer VI, where they establish long horozontal connections. Many neurons of these types (10%) possess two axons. Neurons with intralaminar axons of layer I derive from the marginal zone and appear at P2. Neurons with horizontal axons in layer II and those with descending axons giving horizontal collaterals in layers II-IV appear during the third week. Small local axon cells and neurons with short axonal bundles appear at P30 in these layers. A medium-sized local basket cell with horizontal collaterals appear at P40 in layer IV in area 17. The adult innervation pattern of area 17 comprises a densely innervated upper layer I, small patches of 100 µm in diameter at the layer I/II border, continuous terminal-strata in lower layer III/upper layer IV, in layer IVc and in layer VI. In area 18 the terminalstrata in layer IV and the local basket cells are absent.Thus, in contrast to VIP/PHI, the CCK-innervation pattern is progressively formed during the first month and is completed during the second postnatal month. We do not observe dramatic changes in the innervationpattern and only one transient cell type.We thank Drs. J.M.Polak and M.Tohyama for supply with antisera.

308.9 NEONATAL LESIONS OF THE INFERIOR COLLICULUS REDUCE TRANSIENT ACETYLCHOLINESTERASE ACTIVITY IN DEVELOPING RAT AUDITORY CORTEX. Richard T. Robertson, Fraidoon Mostamand* and Jen Yu. Departments of Anatomy and Neurobiology and of Physicial Medicine and Rehabilitation, College of Medicine, University of California, Irvine, CA 92717.

The presence of transient acetylcholinesterase (AChE) activity is characteristic of some developing thalamocortical systems, including the medial geniculate-auditory cortex projection of the rat. The location and appearance of the AChE histochemical reaction product suggest that the transient AChE is found within terminals of geniculocortical neurons. The purpose of the present study was to determine the effects of neonatal lesions of the inferior colliculus on development of the transient pattern of AChE in auditory cortex.

Subjects were laboratory born Sprague-Dawley rats of 0-30 postnatal days (PND) of age. Animals were anesthetized by hypothermia on PND 0 and one or both inferior colliculi were aspirated under visual control. Animals were sacrificed by aldehyde perfusion on PND 6-30. Frozen sections of 64um were cut in the transverse plane or parallel to the pial surface. AChE activity was detected histochemically by a modified version of the technique of Koelle.

AChE activity in cortical area 41 (primary auditory cortex) of normal animals appears at about PND 6 as a fine fiber-like plexus in deep layer III and layer IV. AChE reaction product reaches peak intensity in animals sacrificed at PND 10-12 and then declines until adult levels are reached by PND 18. The area and laminar extent of the transient AChE plexus correspond precisely to the terminal field of geniculocortical projections.

Neonatal removal of the inferior colliculus results in a marked loss of transient AChE in layer III-IV of cortical area 41 ipsilateral to the lesion. No effects of the lesion were detected on transient AChE in other cortical areas of the lesioned hemisphere or in the hemisphere contralateral to the lesion. Results from animals sacrificed at various ages demonstrate that the normal transient pattern of AChE in cortical area 41 never develops.

These data indicate that transient AChE activity normally found in developing rat auditory cortex is dependent on normal afferent innervation and/or stimulation. These data closely parallel the results reported previously for the visual system (Robertson et al., Dev. Brain Res., 1987).

308.10 INTRAOCULAR INJECTIONS OF TETRODOTOXIN REDUCE TRANSIENT ACETYLCHOLINESTERASE ACTIVITY IN DEVELOPING RAT VISUAL CORTEX. Rajeev K. Ambe*, Richard T. Robertson, and Jen Yu. (SPON: E.A. Davis). Departments of Anatomy and Neurobiology and of Physicial Medicine and Rehabilitation, College of Medicine, University of California, Irvine, CA 92717.

Transient acetylcholinesterase (AChE) activity is characteristic of the geniculocortical projection system of developing rats. The location and appearance of the transient AChE, along with its disappearance following lesions of the lateral geniculate body, suggest that the AChE is found in terminals of geniculocortical axons. Previous work from this laboratory (Robertson et al., Dev. Brain Res., '87) demonstrated that neonatal enucleation disrupts the normal development of transient AChE. The purpose of this study was to determine the effects of repeated intraocular injections of tetrodotoxin (TTX) on development of transient patterns of AChE.

Subjects were laboratory born Sprague-Dawley rats of 0-12 postnatal days (PND) of age. Each animal was anesthetized and received monocular injections of TTX (0.5 ul; 10^{-4}M in saline) on PND 3,5,7,9 and 11. On PND 12, animals were sacrificed by aldehyde perfusion. Frozen sections were cut in the transverse plane or parallel to the pial surface. AChE activity was detected histochemically by a modified version of the technique of Koelle.

AChE activity in cortical area 17 of normal infant rats appears as a fine fiber-like plexus in deep layer III and layer IV. Monocular injections of TTX result in a marked loss of AChE staining in the medial sector of layers III-IV of cortical area 17 contralateral to the injected eye. AChE staining in the lateral sector of the contralateral hemisphere and in the hemisphere ipsilateral to the injected eye appear normal. The cortical region sustaining the loss of AChE corresponds to the monocular segment of area 17. Some animals received injections of HRP along with TTX on PND 11. These cases demonstrated that the optic nerve of the injected eye was still capable of axonal transport, suggesting that the reduction in AChE activity was not attributable to damage to the optic nerve. Other animals were monocularly enucleated at PND 3 and injected with TTX on the standard schedule. Analysis of these cases revealed that monocular enucleation results in a more drastic reduction of transient AChE activity in layer III-IV of cortical area 17 than does the series of TTX injections.

These data indicate the transient pattern of AChE activity normally found in developing rat visual cortex is dependent on normal afferent stimulation.

308.11 PRENATAL DEVELOPMENT OF THE SPINOCEREBELLAR FIBERS IN THE RAT. H. Yaginuma*, (Spon: N. Okado) Dept. of Anatomy, Univ. of Tsukuba, Ibaraki 305, Japan.

To clarify the temporal and spatial relationship between developing cerebellar afferent fibers and their target, the development of the spinocerebellar fibers in the prenatal rats was examined using the anterograde wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) technique. Pregnant rats were anesthetized with pentobarbital. After the uterus was incised, WGA-HRP was injected into the lower thoracic or upper lumbar spinal cord of embryos ranging from embryonic day (E) 16 to E21 (the day of sperm positivity was counted as E1). Following 9-12 hour survivals, the embryos were removed from the uterus, and fixed by perfusion. The sections of the brain stem and the spinal cord were reacted with tetramethylbenzidine. At E16.5, no labeled fibers were found in the cerebellar plate, although unidentified labeled fibers were found in the ventrolateral superficial part of the lower medulla oblongata. Labeled fibers were found first in the cerebellar plate at E17.5. These fibers passed through the ventrolateral superficial part of the medulla oblongata and the superior cerebellar peduncle (SCP), suggesting that these fibers belong to the ventral spinocerebellar tract. They reached the rostral part of the superficial fibrous layer (SF) of the cerebellar plate and ran medially for a short distance. Few labeled fibers reached the cerebellar plate through the inferior cerebellar peduncle (ICP). At E18.5, many labeled fibers, which passed through SCP, were found in the rostral part of SF. They reached the midline region and some of them crossed the midline. A few labeled fibers, which passed through ICP, were seen in the caudal part of SF. At this stage, the external germinal layer (EGL) had not reached the rostral portion of the cerebellar plate which contains labeled fibers. At E19.5, many labeled fibers entered the primitive cerebellum through both SCP and ICP. The fibers which passed through SCP were located in the rostral part of SF, while the fibers which passed through ICP were located in the caudal part of SF. Most of them crossed the midline to enter the contralateral side of the cerebellum. At this stage, the SF containing the labeled fibers was covered with EGL. The Purkinje cell layer (PCL) had not formed between EGL and the labeled fibers. However, a cluster of longitudinally elongated cells, presumably migrating Purkinje cells, was seen immediately beneath the labeled fibers. At E20.5 and E21.5, labeled fibers were present in the rostral part of the anterior lobe; the PCL was formed between EGL and the labeled fibers.

These findings suggest that the spinocerebellar fibers reach the rostral part of the cerebellum before the cellular components (EGL and PCL) of the primitive cerebellar cortex are formed, and that fibers of the ventral spinocerebellar tract reach the cerebellum earlier than those of the dorsal spinocerebellar tract.

308.12 PRENATAL UNILATERAL FRONTAL CORTEX ABLATION IN CATS. B.L. Shook, J.R. Villablanca and D.A. Hovda. Mental Retardation Research Center, Departments of Anatomy and Psychiatry, School of Medicine, University of California, Los Angeles, CA 90024.

Neonatal cerebral hemispherectomy or unilateral frontal cortex ablation in cats results in greater behavioral sparing than similar lesions in adults. The enhanced sparing is accompanied by exhuberant bilateral projections from the intact hemisphere and reduced thalamic-brain stem degeneration (Refs. in Brain Res., 420:219, '87). We sought to determine whether the early lesion effect could be extended to the prenatal period. Towards this aim, the left frontal cortex was ablated in two fetuses on either embryonic day 41 or 43. As adults these cats received multiple 0.02 μl injections of WGA-HRP in the intact (right) pericruciate cortex. Three days postinjection cats were perfused transcardially, the brains frozen sectioned at 50 μ, and alternate sections reacted for HRP or thionin stained.

Gross Anatomy: Lesions were restricted to the sigmoid gyri with subtotal removal of areas 4 and 6. Gyral and sulcal patterns were grossly abnormal throughout the entire injured hemisphere but the cytoarchitecture appeared normal. The ipsilateral thalamus and telencephalon were reduced in area (measured in 5 coronal planes) by, $\bar{X}$ = 13.5% - 24.4% and 8.3% - 10.8%, respectively. The decrease in size covaried with the extent of the lesion.

Cortical Connectivity: Tracer injections were restricted to areas 4 and 6 with minor involvement of area 3a in one animal. The intact pericruciate exhibited normal ipsilateral subcortical connections. As in neonatally lesioned cats, terminal label (minimal) was found in the contralateral thalamic intralaminar, ventral and ventrobasal nuclei. More dense, homotopically distributed, label was evident in the contralateral red nucleus and the crossed corticocaudate projection was abnormally widespread with reaction product distributed over much of the mediolateral extent of the head of the nucleus. Sparse anterograde label was also evident in the ipsilateral n. gracilis and dorsal horn of the cervical cord. The medullary crossing of the pyramidal tract was apparently normal.

Behavior: In contrast to neonatally frontal lesioned cats (Exp. Neurol., 61:615, '78), tactile, visual and chin contact components of the contralateral limb placing responses failed to develop in the present cats.

It is concluded that in utero unilateral pericruciate ablation can induce widespread changes in the gross structure of the injured hemisphere as well as anomalous sparse crossed projections from the intact frontal cortex. However, unlike neonatal lesions, embryonic frontal cortex injury may prevent the development of various aspects of the contralateral limb placing responses. Grants USPHS HD-05958 and HD-04612.

308.13 ABNORMALITIES OF GRANULE CELL DENDRITES AND AXONS IN THE DENTATE GYRUS OF THE NZB/BINJ MOUSE.
R.S. Nowakowski and M. Sekiguchi*. Dept. of Anatomy, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

In the dentate gyrus of NZB/BINJ mice there are ectopic granule cells in the molecular layer. We have studied the dendritic and axonal processes of ectopic and normally positioned granule cells in the dentate gyrus using the Golgi method.

The ectopic granule cells of the molecular layer and also the granule cells situated at the border of the molecular and granule cell layers have abnormal dendritic trees. The ectopic granule cells have three different dendritic morphologies: inverted, horizontal, and large-angled. The inverted granule cells are characterized by one or more primary dendrites extending from the soma down towards the granule cell layer. These dendrites usually turn toward the pial surface before reaching the granule cell layer and then arborize in a seemingly normal fashion. Many of the ectopic granule cells are only partially inverted in that they have primary dendrites extending both towards and away from the pial surface. The horizontal granule cells have primary dendrites which extend parallel to the granule cell layer. The large-angled granule cells have primary dendrites extending at a large obtuse angle towards the pial surface. The distal dendrites of both the horizontal and large-angled granule cell turn towards the pial surface and arborize normally as they pass through the molecular layer. The granule cells located at the border of the molecular and granular cell layers are usually of the large-angle type, and, in general, they have a less atypical appearance than the ectopic granule cells. The dendritic morphology of the granule cells within the granule cell layer appears to be normal.

Many of the ectopic granule cells have an axon that emerges from a primary dendrite and project horizontally or sometimes upward through the molecular layer. This indicates that heterotypical (granule cell to granule cell) synapses may be present.

The fact that the ectopic granule cells in the dentate gyrus of NZB/BINJ mice have abnormal dendritic and axonal morphologies, whereas normally positioned granule cells have normal dendritic morphologies is in marked contrast to the situation in the dreher mutant mouse (Nowakowski et al., 1987, Anat. Rec. 218:99A) in which both ectopically and normally positioned granule cells have abnormal dendritic and axonal arborization patterns. It is likely that the dendritic abnormalities of the granule cells in NZB/BINJ mice are secondary to disruptions of neuronal migration that produced their ectopic position.

308.14 DENDRITIC AND AXONAL ARBORIZATION OF ECTOPIC PYRAMIDAL CELLS IN THE HIPPOCAMPUS OF THE DREHER MUTANT MOUSE.
M. Sekiguchi*, R.S. Nowakowski and D. Wahlsten. (SPON: N.L. Hayes). Dept. of Anatomy, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854 and Dept. of Psychology, University of Waterloo, Waterloo, Ontario.

Dreher (gene symbol: dr, also known as shaker short-tail) is an autosomal recessive mutation located on chromosome 1. Among the various abnormalities typical of homozygous dreher (dr/dr) mice is the presence of numerous ectopic pyramidal cells in the stratum radiatum in area CA3 of the hippocampus (Nowakowski and Wahlsten, '85, Anat. Rec., 211: 140A). We have studied the morphology of these ectopic pyramidal cells with the Golgi method.

The most striking difference between the dendrites of ectopic pyramidal cells and those of normally positioned pyramidal cells is that the dendritic trees of the ectopic cells almost always lack a radially-oriented, apically extending dendrite. Instead, their primary dendrites exit from the soma at a large-angle and can extend in any direction. However, they invariably have at least one primary dendrite which emerges from the lateral or basal surface of the soma and which extends down through the pyramidal cell layer into the stratum oriens. Those dendrites which pass through the pyramidal cell layer usually have small dendritic excresences indicative of contact with mossy fibers; usually there are smaller and fewer excrecences than on normally positioned pyramidal calls.

The axon of normally positioned pyramidal cells typically emerges from the base of the soma and extends downward into the stratum oriens. In contrast, the axon of ectopic pyramidal cells often emerges from a primary dendrite or a lateral surface of the soma and then extends upwards into the stratum radiatum or parallel to the pyramidal cell layer. The impregnated axons were not seen to enter the alveus, but, in general, they could not be followed very far because they left the plane of section.

Thus, the ectopic pyramidal cells in the dreher hippocampus which are located in the stratum radiatum make synapses with mossy fibers. They lose, however, the radially directed, apical orienta tion of their dendrites, and the initial direction of projection of their axon is abnormal. These characteristics are markedly different from the Hld mutant mouse in which there are ectopic pyramidal cells located at the border of the stratum oriens that retain their radially directed, apical orientated dendrites. We believe these differences are the result of different types of disruptions in neuronal migration.

308.15 HETEROZYGOUS DREHER MICE HAVE ABNORMALITIES IN THE HIPPOCAMPAL FORMATION.
P.R. Patrylo*, M. Sekiguchi* and R.S. Nowakowski. (SPON: D.C. Miller). Dept. of Anatomy, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Dreher (gene symbol: dr) is an autosomal recessive mutation located on chromosome 1. Homozygous dreher (dr/dr) mice are ataxic, have a white belly spot, a short-tail and a variety of CNS abnormalities, including disruptions of cerebellar foliation and cytoarchitecture of the hippocampal formation, tectum, olfactory bulb and neocortex. Spontaneous mutations at the dreher locus have occurred in several laboratories, and at least five different alleles exist. Recently, in our dreher colony (the dr^{sst-J} allele on a B6C3Fe background) we noticed mice which were not ataxic and which had a normal length tail but which had one or more white belly spots typical of dr/dr mice. Wild-type mice (+/+) of the same genetic background do not have similar belly spots. We hypothesized that these were dr/+ mice and matings of the putative heterozygotes were set up. Of the 31 progeny produced so far, 5 clearly had the typical dr/dr phenotype, 15 had white belly spots but no other overt dr/dr traits, and 11 were wild-type. Chi-square tests were consistent with the interpretation that the non-ataxic animals with white belly spots and normal tail length were heterozygote dreher (dr/+) mice.

Histological examination of the putative heterozygotes revealed clear abnormalities in the cytoarchitecture of the hippocampus and dentate gyrus. The observed abnormalities are similar to those that occur in homozygous dreher mice, but are less severe. Most frequently, there is an increase in the number of pyramidal cells in CA3 and a marked thickening of the pyramidal cell layer. Sometimes, the additional pyramidal cells extend out into either or both, the stratum oriens and the stratum radiatum and may occur either unilaterally or bilaterally. In the dentate gyrus, there are numerous ectopic granule cells in the molecular layer above the suprapyrmidal limb.

Thus, we conclude that a new mutation at the dreher locus may have occured in our breeding colony and further experiments are in progress to test this idea. The major difference between this new allele (tentative gene symbol: dr^{Now}) and the other dreher alleles is that its effects are observable in heterozygotes. Homozygous dr^{Now}/dr^{Now} mice do not appear to be more severely affected than either homozygous dr^{sst}/dr^{sst} or dr^{sst-J}/dr^{sst-J} mice. The existence of an allele at the dreher locus that adversely affects the development of the CNS in heterozygotes may be useful in identifying the primary developmental defect in dreher mice.

308.16 FASCICULAR ORGANIZATION OF THE RADIAL GLIAL FIBERS IN DEVELOPING MURINE NEOCORTEX; A IMMUNOCYTOCHEMICAL STUDY COMBINED WITH 3H-THYMIDINE AUTORADIOGRAPHY.
J.F. Gadisseux*, Ph. Evrard*, J.P. Misson*, V.S. Caviness, Jr. E.K.Shriver Center, Waltham, MA 02254.

Migrating neurons destined for the cerebral cortex and elsewhere in the CNS are guided in their ascent by following the surfaces of radial glial cells (RGC). The bipolar RGC which serve as migratory guides in the embryonic cerebrum are ordered into fascicles which vary in their organization at different depths in the cerebral wall (Gadisseux and Evrard, Dev. Neurosci. 7:12 1985, Levitt and Rakic, JCN. 193:815 1980). In particular, compact fascicular arrays characteristic of the trans-intermediate zone span appear to "defasciculate" within the trans-cortical span. The present analysis, based upon RGC staining with a sensitive and selective monoclonal antibody marker, RC2 (Misson et al,Soc. Neurosci Abstr. 13, 1987), provides a precise characterization of the relation of radial glial fiber fascicles (RGFF) organization to the separate strata of the developing cortex and the relation of migrating neurons to the RGFF as they ascend through the separate strata. Cohorts of migrating neurons are defined by prior in utero labeling with 3H-thymidine. Defasciculation of the transcortical fibers advances progressively in the interval E14-P0. The change in fascicle order is initiated precisely at the intermediate zone (IZ) interface with the external sagittal stratum (ESS), a fiber stratum including the thalamic projection which marks reliably the inferior margin of the future layer VI. A spatial correction is also achieved in the trans-ESS segment of the fascicles in that the glial fibers are deflected tangentially as they cross the ESS into the base of their "target" cortical region. Thus, as they ascend from the ESS into the cortical subplate (future layers V/VI), they are re-deflected to a true radial ascent across they full width of the cortex. In layers V/VI, from E14 to P0, RGFF are progressively reduced to several fibers at most; within the final segment spanning the cortical plate (CP), single fibers are fully separated at the end of the neuronal migration. The relation of migrating cells in their ascent through the successive levels of defasciculation is as one might predicted. Thus, in the IZ and ESS spans, the migrating neuron is in contact with multiple fibers. This ratio of fibers to neurons is markedly reduced in the cortical subplate. Within the CP at E17, the young neuron appears to contact only isolated glial fibers. These systematic changes in the organization of the fibers may represent cortical strata-specific differences in the affinity of the fibers for each other. Alternatively, they may reflect changes in neuron to fiber affinities which result in greater fiber dissection by the migrating neurons, as it ascends through the successive cortical strata. [Supported by NIH grant NS12005 and the Princess Marie-Christine Foundation].

308.17 PARASAGITTAL ZONATION IN THE CEREBELLAR CORTEX DEVELOPS INDEPENDENT OF AFFERENT INPUT. N. Leclerc*, C. Gravel, R. Hawkes* (SPON: M. Colonnier), Dept. Biochemistry and Lab. of Neurobiology, Laval University, Quebec, Canada G1J 1Z4.

Monoclonal antibody mabQ113 recognizes a polypeptide antigen that, in the adult cerebellum, is confined to a subset of the Purkinje cells distributed in parasagittal zones. By immunocytochemistry, peroxidase reaction product is found throughout the cell, including the dendritic tree, the soma and the axon. The mature pattern of expression of the mabQ113 antigen appears during postnatal development in three stages. Until P5, all Purkinje cells are mabQ113$^-$. In the following week mabQ113 antigen expression spreads throughout the cerebellar cortex until at P12, all Purkinje cells are mabQ113$^+$. Subsequently, immunoreactivity is suppressed in a subset of the Purkinje cells leaving behind the adult pattern of parasagittal antigenic bands. There is a close correlation between the parasagittal bands and patches detected in the adult with mabQ113 and the topography of the olivocerebellar projection. Therefore, selected lesions of the cerebellar afferent projections were made to explore the interplay of cerebellar hodology and mabQ113 expression. Lesions were made in the adult to test the role of afferent input in the maintenance of antigen expression, and in the newborn, prior to synaptic contact between afferents and Purkinje cells, to explore the role of afferent input in antigen induction.

The olivocerebellar projection was ablated bilaterally by using 3-acetylpyridine in the adult. Animals were sacrified either 3 or 30 days after treatment. In the newborn rat, the inferior olivary complex was destroyed by electrolytic lesion. Animals were sacrified 30 days post-lesion. Mossy fibers inputs were disturbed both in adult and in newborn rats by unilateral electrolytic lesion of either the spinal trigeminal nerve interpositus nucleus or the gigantocellularis reticular nucleus, or by surgical ablation of dorsal and ventral spinocerebellar tracts. Finally, the consequences of total blockage of vibrissal and hind-limb inputs by peripheral nerve sectioning were also explored in both adults and neonates. None of these precedures led to a modification in the pattern of mabQ113 epitope expression in the adult cerebellar cortex nor did they alter the developmental timetable. Taken together, these results suggest that the mabQ113$^+$/mabQ113$^-$ band display develops independently of postnatal afferent input.

308.18 PATTERNS OF ASTROCYTIC DEVELOPMENT IN REAGGREGATE CEREBELLAR TRANSPLANTS. E. B. Ezerman. Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405

Cerebellar (CB) reaggregate transplants in the rat have been shown (Ezerman, E. and L.F. Kromer, Dev. Brain Res. 23:287, 1986) to develop a mature cytoarchitectural organization similar to that of intact CB transplants. Thus, although initial cell associations are disrupted in reaggregate transplants, the substrates for development of the mature cytoarchitectural pattern are present. Using antibodies to the intermediate filaments vimentin and glial fibrillary acidic protein (GFA), the present study examines the structure and relationships of astrocytes to other components of the transplant during development of the mature cytoarchitectural pattern.

During transplant development, changes are seen in the structure and regional patterns of the astrocytes. At one week survival, transplants show modest GFA staining including slender, long processes running in numerous directions with relation to the plane of section. No particular distribution has been noted although processes may be oriented along blood vessels and encircling cell bodies. Staining with antibody to vimentin shows a similar pattern: astrocytic processes are seen extending radially with respect to blood vessels or pial surfaces, determined by staining with antibody to laminin. By 2 weeks survival, there is increased staining, regional patterns are beginning to emerge, and there are numerous processes along or abutting blood vessels or pia. Often large cell somas are outlined, a long astrocytic process extending away from the encircled cell body. Central regions of the transplant appear relatively devoid of astrocytes in comparison with cortical areas. Stellate astrocytes often appear in the central areas; the cortical areas have a preponderance of astrocytes with longer processes often oriented perpendicular to blood vessels. Staining for GFA in 6 week survival transplants confirms that Bergmann (B.) glia orient themselves in reaggregate transplants as in intact transplants (and in vivo). Areas can be seen in which parallel arrays of B. glial fibers traverse the molecular layer from the Purkinje cell layer to a blood vessel or pial membrane. The regional pattern is better defined in the 6 week transplant: in deep nuclear regions, small, stellate GFA-positive astrocytes; in cortical regions either the typical B. glial arrangement or, near the edge of the transplant, numerous "reactive" astrocytes, dense with thick and irregular processes. These features also are seen in mature intact transplants, as described previously (Bjorklund, H. et. al., Exp. Brain Res. 55:7, 1984). Clearly, inductive and/or environmental cues for B. glial fiber orientation are present in reaggregate transplants. Thus, the same scaffolding is present for migration of granule cells as in vivo and in intact transplants. More detailed relationships among astrocytes, neurons, and blood vessels will be presented.

308.19 THE INFLUENCE OF CELL INTERACTIONS ON THE DEVELOPMENT OF THE DENDRITIC ARBORS OF HIPPOCAMPAL NEURONS IN CULTURE. A.B. Waxman and G.A. Banker. Department of Anatomy, Albany Medical College, Albany, NY 12208

We have analyzed the influence of cell interactions on dendritic development by preparing cultures of hippocampal neurons at different plating densities, ranging from 1,000 to 32,000 cells/cm^2. At the higher densities the density of axonal processes, and therefore the opportunity for contacts between axons and developing dendrites, was greatly increased. After development for 7 or 24 days in culture dendrites were selectively stained using an antibody against Microtubule Associated Protein 2. Dendritic trees were reconstructed using a computer-based cell analysis system and the length and diameter of each segment was determined.

At higher plating densities there was a 2.5 fold increase in the frequency of dendritic branching, but no change in the area occupied by the dendritic tree. As a result the average interval between branch points decreased by about 50% and the total dendritic length increased by about 50%. The changes in frequency of branching and segment length were already apparent after 7 days in culture.

Many parameters of dendritic diameter did not change during development between 7 and 24 days, and were not influenced by cell density. These included stem diameter, terminal diameter, and the branch power relationship, which consistently followed the 3/2's power rule. At each plating density there was a linear relationship between stem diameter and the extent of branching; as plating density increased, the slope of this line approached that seen in situ. Intrasegment taper, which was particularly prominent in terminal segments, decreased at higher plating densities.

These results suggest that stem diameter can be thought of as setting an upper limit on the extent of dendritic branching. The decrease in diameter between stem and terminal segments can occur either at branch points or by taper within terminal segments. As the opportunity for cell interactions increases there is more branching and consequently less taper.

(This research was supported by NIH grant NS17112. We thank Dr. D. Hillman for the use of his computer-based cell analysis system.)

308.20 REGIONAL EFFECTS OF OPIOID RECEPTOR BLOCKADE ON CORTICAL THICKNESS. J. Reyes*, D. Lewis* and M.C. Diamond (SPON: L. Stark). Department of Physiology-Anatomy, University of California, Berkeley CA 94720.

Investigators have demonstrated that some regions of the brain increase in size and cellular content when opioid receptors are blocked (Zagon, I.S. Life Sciences., 35:2057, 1984). However, the effects of opioid receptor blockade on the frontal and occipital cortex have not been investigated. This study examines the relationship between opioid receptor blockade, cortical thickness, and laterality in 9 regions of the rat cortex. Male and female Long-Evans rats were injected subcutaneously with either saline, 1, 10, or 50mg/kg of Naltrexone, an opioid receptor antagonist, for the first 21 days of postnatal life. On day 21, animals were sacrificed and morphometric analysis of 2 frontal, 3 somatosensory and 4 occipital cortical regions were made on transverse, frozen, 40 mu sections stained with a modified Thionin stain. Results indicated significant dose effects in the frontal and occipital cortical regions. The 50mg/kg group showed increases in cortical thickness, while 1mg/kg animals decreased in cortical thickness in comparison with saline injected controls. The frontal and occipital association cortices were most affected. In somatosensory cortex, no significant effects were found with any dose, thus, not offering support to the findings of previous investigators. Lateralization of the frontal, somatosensory and occipital cortices were affected in a dose and sex dependent manner. As the concentration of Naltrexone increased, male lateralization shifted from right to left; in female animals, the opposite occurred. In conclusion, our results support previous findings that opioid receptor blockade increases growth in neural tissue. However, we do not confirm previous work indicating a dose dependent growth in the somatosensory cortex. In addition, our results reveal a reversal in cortical lateralization in both male and female rats as a consequence of receptor blockade.

309.1 GANGLIOSIDES STIMULATE THE BREAKDOWN OF POLYPHOSPHOINOSITIDES IN CNS NEURONS IN VITRO. S.D. Skaper, M. Favaron*, L. Facci* and A. Leon. Fidia Neurobiological Research Laboratories, Abano Terme, Italy.

GM1 ganglioside has been shown to ameliorate the deficits following injury to the adult mammalian CNS. In addition, cultured neurons, both from the CNS and PNS respond to gangliosides with morphological changes characteristic of cell differentiation, the latter in the presence of defined neuronotrophic proteins. An understanding of ganglioside effects on neuronal performances will first require elucidation of the underlying molecular mechanism(s) operating in vitro.

Hydrolysis of membrane polyphosphoinositides is now a widely accepted transmembrane signalling pathway for a variety of external stimuli. These extracellular signals rapidly induce the breakdown of phosphatidylinositol 4,5-bisphosphate into inositol 1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol. Very strong evidence supports the view that these two inositol lipid intermediates serve as second messengers, one by inducing a transient rise in $(Ca^{2+})_i$, the other by activating protein kinase C.

With this in mind, the following experiments were carried out. Neuronal cultures from embryonic avian and rodent CNS were prelabeled with ^{3}H-inositol for 24 hr, presented with ganglioside and the formation of inositol phosphates evaluated in the presence of Li^+. The different inositol phosphates were separated using ion exchange chromatography. GM1 elicited, in a dose-dependent manner a several-fold increase in IP_3 in neurons from E8 chicken cortex, as well as in inositol 1,4-bisphosphate (IP_2). Similar results were obtained using neurons from E8 chicken neural retina, E18 rat hippocampus, and E14 mouse mesencephalon. Elevations of IP_1 were also detected, but depended upon the tissue and species used. AsialoGM1 and oligosaccharideGM1 were without effect. Thus, gangliosides appear able to activate polyphosphoinositide breakdown. These results provide the first evidence for a direct action of gangliosides in transmembrane signalling in neurons. A possible relationship between this effect of gangliosides and neuronotrophic factor action is currently being explored.

309.2 MORPHOLOGICAL AND IMMUNOCYTOCHEMICAL CHARACTERIZATION OF HUMAN FETAL BRAIN CULTURES. F. Gremo, S. Torelli*, V. Sogos*, A. Riva *, C. Marcello * and U. Lecca* Dept. of Cytomorphology and Inst.of Clinical Obstetrics and Gynecology, School of Medicine, 09100 Cagliari, (Italy)

Tissue cultures provide a very useful tool to study the effects of endogenous and exogenous substances on neuronal differentiation and maturation. Primary cultures from brain contain different types of cells and cell precursors which need to be characterized.

Human brains, obtained from either spontaneous or medically induced abortions, were freshly dissected, when possible divided into regions and incubated with sterile trypsin. Cells were mechanically dissociated, diluted with medium (DMEM) + 10% fetal calf serum and plated on polylysine-treated dishes. At different intervals, cells were fixed and processed for Scanning Electron Microscopy (SEM) and for immunocytochemistry. Monoclonal antibodies against acetylcholine-esterase (AChE), glial fibrillar acidic protein (GFA-P), vimentin (VT), neurofilament subunits (NF68K, NF160K, NF200K), proliferating cells (PC) and peanut lectin (a-PNA) were used. Also fluorescein-conjugated peanut lectin (PNA) was used.

Results showed that cultures were enriched in neurones, which survived in vitro for several weeks. Cell passages produced a decrease in neuron content and an increase in non-neuronal cells. Microglia-like cells were also observed. Double staining showed the presence of both VT and NF in immature neurones. Non neuronal cells were positive for both VT and GFA-P in early cultures. PNA stained non-neuronal cells, but never well differentiated neurones. Among the PNA-positive cells, some were also GFA-P positive. Interestingly, GFA-P positive cells were negative for a-PNA. On the contrary many cells positive for a-PNA were also NF200 positive. a-PNA staining was both intracytoplasmatic and on the surface of the cells. These results suggest that during development neuronal and non-neuronal migration might be regulated by the production of lectin-like proteins and lectin-receptors from different cells. PC never stained well differentiated neurons, but only flat cells on the bottom of neuronal aggregates. Whether PC-positive cells are non-neuronal or neuronal precursors is under investigation.

309.3 MORPHOMETRIC ANALYSIS OF PYRAMIDAL CELLS IN ADULT AND IMMATURE HAMSTERS FOLLOWING PYRAMIDOTOMY. T.E. Durica. Department of Anatomy, Rush Medical College, Chicago, IL 60612.

Pyramidotomy in the adult and immature (15 day old) hamster results in a differential morphological response of the pyramidal cells that is age dependent. A morphometric analysis of normal and injured pyramidal cells was performed to determine if the cytological changes are accompanied by changes in neuronal size.

Unilateral pyramidal tract lesions were made in the medulla, rostral to the pyramidal decussation, in adult and 15 day old hamsters. Animals were cardiac perfused with a formal saline-gum acacia solution at 4 or 8 days postoperative (dpo). The cerebral cortices were serially sectioned, every 10th section collected, mounted and stained with buffered Thionin. Point counting was used to measure the total cell, cytoplasmic, and nuclear areas.

In the adult, at 4 and 8 dpo, most of the pyramidal cells displayed a slight paling of their Nissl substance without any noticeable changes in other cellular components. Also, there were a few neurons that were rounded and pale with a mottled nucleolus. In the 15 day old, at 4 and 8 dpo, the pyramidal cells displayed a focal chromatolysis; at 8 dpo there were a few rounded and pale neurons with a mottled nucleolus as in the adult.

Measurements of injured neruons included both types of reacting cells. Normal adult pyramidal cell measurements, in square microns, for total cell, cytoplasmic, and nuclear areas were 194.85, 115.64, 79.21 respectively. After pyramidotomy there was a slight decrease in total cell and cytoplasmic areas at 4 dpo but measurements at 8 dpo were not significantly different from normal. Normal 15 day old pyramidal cells measurements were 192.48, 111.48, 80.99, which are the same size as in the adult. There were no changes in the area of any of these components at either postoperative times.

The pyramidal cells of the 15 day old hamster have characteristics of both immature and mature neurons. This may account for a morphological response that is typical of an immature neuron and the lack of change in the size of the measured areas which is similar to the adult.

309.4 ELECTROPHYSIOLOGICAL PROPERTIES OF CEREBELLAR PURKINJE CELLS AFTER DISSOCIATION FROM LATE EMBRYONIC AND EARLY POSTNATAL RATS. P.E.Hockberger, H.Y.Tseng*, and J.A.Connor, Dept. of Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974

Cerebellar Purkinje cells (PCs) display several stages of morphological development during late embryonic and early postnatal periods. These stages correspond to a progressive differentiation from round neuroblasts to mature neurons with extensive dendritic arborization (J.Altman, *J. Comp. Neurol.* 165:31,1976). Electrophysiological correlates of this differentiation process have been restricted to extracellular recordings. A more cellular analysis is difficult *in vivo* because developing PCs are small and inaccessible with conventional intracellular recording techniques. We have chosen therefore to examine the electrophysiological properties of these cells at various stages of development following tissue dissociation. This approach yields isolated cells some of which can be identified and examined immediately after dissociation (<1 hr.), while offering the prospect of long-term studies of development *in vitro* (>30 days).

Whole-cell patch recording (intracellular and voltage clamping) from isolated PCs was performed immediately (0.5-3 hrs.) following tissue dissociation between embryonic day 20 (E20) and postnatal day 9 (P9). PCs were identified by size, morphology, and immunocytochemical staining patterns. Between E20-E22 isolated PCs were 10μm spheres which stained moderately for neuron-specific enolase (NSE; 1:1000 dilution)) and G-kinase (GK; 1:2000). These cells were inexcitable and showed no membrane potential response to iontophoretically-applied glutamate. Under voltage clamp most of these cells exhibited small voltage-dependent conductances. Between P1 and P4 isolated Purkinje cells were 12μm in diameter with a prominent apical dendrite, and they stained moderately for NSE, GK, and Thy-1 (1:40). By this stage most of the Purkinje cells were excitable, depolarized by glutamate, and displayed several large voltage-dependent conductances. By P9 PCs were 15μm in diameter and stained more intensely for NSE and GK than at earlier stages, and these cells were also excitable. We found no evidence for spontaneous activity in isolated PCs at any of these stages.

Cultures were prepared from dissociated cerebella using methods described elsewhere (Ahmed et al., *J. Neurosci.* 3:2248, 1983) for studies of PC development *in vitro*. Purkinje cell survival was significantly better in embryonic cultures compared with those prepared from postnatal cerebella (by P9 PCs did not survive for more than a few hrs.). Embryonic PCs cultured for several weeks had larger somata (up to 25μm in diameter) and thicker apical dendrites than cultures of postnatal cells.. The most impressive dendritic arbors developed on PCs maintained in normal potassium growth media. However the development of excitability required growth media containing high potassium (25mM). Supplementing the growth media with glutamate (0.5 or 5μM) or aspartate (0.5 or 5μM) did not mimic the effects of high potassium in either embryonic or postnatal cultures. In fact these treatments were toxic to all nerve cells which rarely survived under these conditions for more than 2-3 weeks. on the other hand PCs from embryonic cultures grown in high potassium media survived as long as cultures were maintained (40-50 days). They developed electrical excitability after 1-3 weeks, displayed several large voltage-dependent conductances, and were depolarized by glutamate, kainate, NMDA, or quisqualate.

That work not sponsored by AT&T Bell Laboratories was funded by the Air Force Office of Scientific Research under grant #F49620-85-C-0009.

309.5 **ONTOGENY OF SUBSTANCE P- AND SEROTONIN-CONTAINING NEURONS IN THE MOUSE.** Ni Li* and G. Miller Jonakait, (Spon: Joan Morrell) Dept. of Biological Sciences, Rutgers University, Newark, New Jersey 07102

Substance P (SP) is located in serotonin (5-HT)-containing neurons of the rodent medulla (Johansson *et al.* 1981). In order to investigate possible pharmacological interactions between these transmitters during mouse embryonic development, we have initiated an immunohistochemical study to compare the developmental profile of serotonin and its co-existing peptide partners.

Adjacent 15 um sections from mice of gestational day 11 (E11) through postnatal day 3 (P3) were prepared for detection of 5-HT (Newton, B.W., B.E. Maley & R.W. Hamill [1986] *Brain Res.* 376, 155-163) and SP (Kessler et al. [1984] *Devel. Biol.* 103, 71-79) using the peroxidase-antiperoxidase method with 4-Cl-naphthol as chromagen. To determine the percentage of co-localized cells, the 5-HT-antibody complex was removed and tissue was reacted for a second time with antibody to SP (Tramu *et al.* 1978).

SP and 5-HT initially appear on E12. 5-HT cells and fibers are found in the midline just caudal to the mesencephalic flexure as well as in bilateral columns on either side of the medullary midline. Early SP-positive cells are clustered at the pontine flexure and in a continuous bilateral column of cells extending from rostral levels of rhombencephalon throughout the entire length of the neural tube. These small, round SP-positive cells have neither dendrites nor fibers and do not contain 5-HT. Preadsorbed controls show no SP immunoreactivity.

Over the next 4 gestational days, SP-positive cells appear in areas of both diencephalon and telencephalon including the pyriform cortex, bed nuc. of the stria terminalis, striatum, amygdala, and in more caudal regions including the nuc. parabrachialis colliculi, central gray, n. tractus spinalis trigemini and vestibular nuclei. Immature cells seen in the medulla and neural tube at E12 are no longer evident by E14, but SP-positive cells are, at these later stages, included in the medullary raphe nuclei and in the neural tube lateral to the central canal. During this period, 5-HT-positive cells increase their number and attain a mature distribution into recognizeable B1-B9 subgroups.

SP and 5-HT are co-localized in cells of the medullary raphe nuclei (and only there) as early as E13. The percentage of 5-HT cells containing both neurotransmitters attains its highest value at E15 (34.9±.29%; n=3). Thereafter, the intensity of SP staining in the medulla diminishes. Concomitantly, the percentage of 5-HT cells with detectable SP falls to about 10% by postnatal day 2. (Supported by NS 23687. GMJ is a Johnson & Johnson Discovery Research Fellow.)

309.6 PRENATAL ONTOGENY OF THE CHOLINERGIC SYSTEM IN THE MOUSE FOREBRAIN: AN IMMUNOCYTOCHEMICAL STUDY. U.B. Schambra*, K.K. Sulik*, P. Petrusz*, and J.M. Lauder. (Spon: D.L. McIlwain). University of North Carolina, Chapel Hill, North Carolina.

Prenatal development of cholinergic neurons in the forebrains of C57Bl/6J mice has been studied with a monoclonal antibody to choline acetyltransferase (anti-ChAT, Boehringer) from gestational day 14 (GD14) to 18. Embryos or fetuses were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer, sectioned at 80 μm using the Vibratome, and immunostained using the ABC peroxidase method. At GD14, immunoreactive (IR) neurons arising in the ventricular zone (VZ) of the olfactory ventricle were seen to form the olfactory tubercle and olfactory nuclei, while IR neurons developing in the anterodorsal VZ of the lateral ventricle (LV) migrated anteriorly to form part of the frontal cortex. More caudally, IR neurons for the pre-optic nuclei and the nucleus basalis magnocellularis developed in the VZ of the floor of the third ventricle, while other IR neurons were formed in the roof. The epiphysis stained intensely at this time. IR neurons were also formed in the dorsomedial VZ of the LV from which the hippocampus arises, and were later seen to mature within the hippocampus proper (GD17). At GD15 most of the neurons designated for the nucleus of the diagonal band of Broca, the nucleus accumbens and the septal nuclei developed from the mediventral VZ of the LV. The VZ of the ganglionic eminence produced IR neurons which migrated into the interior to form cholinergic neurons of the striatum. IR neurons designated for the cingulate cortex differentiated last with a peak of development at GD16. In the VZ of the LV and third ventricle distinct clusters of IR neurons were observed, some of which were located next to the lumen. Based on their position, some of these cells could be mitotic suggesting that ChAT may be present in dividing cells in certain regions of the developing brain. IR cells were also observed in the meninges and in regions where structures such as the frontal cortices and olfactory bulbs adjoined in the midline.

309.7 CARBOHYDRATES AND HISTOGENESIS IN CEREBELLAR DEVELOPMENT IN THE ABNORMAL (REELER) AND NORMAL MOUSE. G.P. Sinson*, M. Breen*, R.G. Higbee, W. Goossens*, D.G. McLone and P.A. Knepper. Division of Neurosurgery, The Children's Memorial Hospital and Northwestern University Medical School, Chicago, IL 60614; and V.A. Medical Center, North Chicago, IL 60064.

Neurohistogenesis requires the timely and orderly migration of cells away from the germinative zone toward often distant sites. Cell-surface and extracellular carbohydrates have been implicated in certain cell contact relationships, including migration and differentiation. To define the carbohydrates that accompany cerebellar differentiation: 1) serial plastic sections (1 um) of prenatal (E-14, 16, and 18) and postnatal (P-1, 4, 6, 8, 10, 14, and 28) day Reeler (a mouse mutant with cerebellar ataxia) and age-matched normal mice (C57BL/6J) were stained with fluorescent-labeled lectins; and 2) the results were correlated with polyacrylamide gel electrophoresis under reduced conditions and 3) Western blots using biotinylated Concanavalin A. The staining patterns of five lectins (Con A, recognizes mannose and glucose; WGA, N-acetylglucosamine and sialic acid; RCA, galactose; Ulex, fucose; and LPA, sialic acid) were determined by low-light intensity video image analysis and computer-automated densitometry.

The normal cerebellum was characterized by time-dependent expression of Con A-, RCA-, and WGA-positive material. The external granular cells were moderately stained by Con A, RCA, and WGA prior to migration (P-1, P-4, and P-6) and during migration (P-8 and P-10) through the Purkinje layer of cells. The molecular layer (i.e., parallel fibers and Purkinje dendritic projections) exhibited intense focal areas of transient FITC staining: WGA, days P-8 and P-10, and Con A, days P-10 and P-14. The normal Purkinje cells displayed RCA granular cytoplasmic staining on day E-18 and all subsequent time points, whereas the Reeler Purkinje cells were delayed by 7 days, and the granular cells were only moderately stained. Western blots of Con A-binding proteins of normal cerebellum showed: a) a time-dependent increase in two proteins (44 and 46 Kd) from P-8, which increased with age; and b) a transient increase in a 66-Kd protein in the time frame of P-8 to P-14. Studies are in progress to further characterize these differences by additional lectins.

These results indicate: 1) time-dependent points occur in the appearance of carbohydrates during cerebellar histogenesis; 2) the different patterns of lectin staining suggest the presence of a transient glycoprotein during granular cell migration and interction with the Purkinje cells; and 3) modifications of carbohyrates in the Reeler may relate to abnormal differentiation, cell positioning and/or maturation of parallel fibers.

Supported in part by Kiwanis International.

309.8 EXPRESSION OF NEURON-SPECIFIC ENOLASE IN THE RAT SENSORIMOTOR CORTEX: A MARKER FOR DIFFERENTIATION? K.M. Hamre, M.D. Cassell* and J.R. West. Dept. of Anatomy, Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

During development, the expression of the enolase enzyme changes from the non-neuronal isoform to the neuron-specific isoform. It has been suggested that the timing of this change is correlated with the arrival of afferent inputs and/or cellular differentiation. This correlation has not been demonstrated in rat sensorimotor cortex where the cell layers and afferent inputs are arranged in the adult pattern by postnatal day 7. The purpose of this study was to examine the time course of laminar differentiation in the sensorimotor cortex of the rat, as measured by staining with an antibody against neuron-specific enolase (NSE). Male rats from timed pregnancies were perfusion-fixed on postnatal days 1 (gestational day 23), 3, 5, 8, 10, 12, 15 and 20. Frozen sections (10 μ) were stained with an anti-NSE antibody (Polysciences, Inc.) in a dilution of 1:1000 using the avidin-biotin immunocytochemical method. On day 1, the sensorimotor cortex consists of no adult pattern cell layers, but of a molecular layer and cortical plate. There is considerable staining in the upper, more densely packed area of the cortical plate. By day 3, layer V is definable and well stained, but there is only sparse staining in the cortical plate above it. Layer VI also exhibits staining with a conspicuous band of stained cells in its deepest layer, just superficial to the corpus callosum. On day 5, layer V is intensely stained and scattered cells in layers II and III are also stained. There is an increase in the number of scattered cells stained in layer VI. On day 8, the pattern of staining is similar except that more cells are stained in layers II and III. On day 10, layers II and III are intensely labelled, however the staining in layer VI is diminished and the deep band of stained cells has disappeared. The pattern is continued on days 12, 15 and 20 with an increasing number of scattered cells in layer VI being labelled on successive days. The adult pattern of staining shows labelling in layers II, III and V and in scattered cells in layer VI -- the majority of neurons in layer IV do not stain. The laminar expression of NSE in the sensorimotor cortex loosely follows the "inside-out" developmental age gradient but appears poorly correlated with arrival of afferents. Moreover, in layer VI, there is a decrease in the number of NSE positive cells from days 8 to 12. These observations, and the finding that cells in layer IV seldom express NSE, question the validity of NSE as a definitive marker for differentiation in the sensorimotor cortex. (Supported by NIAAA grant AA05523 to J.R.W.).

309.9 PROTOONCOGENE EXPRESSION IN EMBRYONIC MAMMALIAN FOREBRAIN: COLUMNAR ORGANIZATION OF THE LATE EMBRYONIC VENTRICULAR ZONE
J.Johnston* and D. van der Kooy (spon:J.A.Connolly) Department of Anatomy, Univeristy of Toronto, Toronto, Canada, M5S 1A8

Oncogenes are homologues of normal cellular genes called protooncogenes. Protooncogenes may help regulate the normal development of embryonic tissues. We have used monoclonal antibodies to four different oncogenic proteins to investigate the distribution of their corresponding protooncogene products proteins during the late embryonic development of the rat forebrain. Rat brain sections obtained at 18 days of gestation were first incubated in mouse monoclonal antibodies directed against synthetic MYC, RAS, SIS and SRC peptides, and then incubated in fluorescent secondary antibodies. The predominant staining pattern in coronal sections was one of interdigitating labeled and unlabeled columns in the ventricular zone, with the MYC, RAS and SRC antibodies. The labeling appeared to be in groups of cells (3-15 cells) which had cell bodies near the edge of the ventricle and long processes that extended through the ventricular zone and sometimes out into the region containing postmitotic cells. Morphologically, the stained elements appeared to be columns of radial glial cells interdigitating with unstained columns. This supposition was supported by the dense staining of the same oncogene antibody labeled columns in the ventricular zone at embryonic day 18 with a rabbit polyclonal antiserum against vimentin, an intermediate filament protein that is expressed in radial glial cells during late embryogenesis. The columns unlabeled by the oncogene sera showed relatively less vimentin staining. The staining of ventricular zone columns did not appear to be an artifact of fixation or cutting. Antibodies against Dl.1, a marker of proliferating ventricular zone cells (provided by J. Levine, Stony Brook), stained uniformly through the protions of the ventricular zone where columnar staining was seen with the other markers. Adsorption controls with the appropriate synthetic peptides abolished the ventricular zone columnar staining seen with the MYC, SRC and RAS antibodies. These results suggest that cellular protooncogenes may play a more important role in the early differentiation, rather than in the internal regulation of proliferation, of embryonic brain cells. The oncogene staining of ventricular zone columns at embryonic day 18 may be marking groups of more metabolically active radial glial cells in the ventricular zone. This is suggested by the denser vimentin staining of similar columns and by preliminary results showing a slightly higher rate of neuronal proliferation (as judged by 3H - thymidine labeling) in the region of these oncogene stained columns. Perhaps the activated radial glial cells are regulating the proliferation and/or migration of columns of ventricular zone neuroblasts.

309.10 SEPARATE BLOOD AND BRAIN ORIGINS FOR PROLIFERATING CELLS FOUND AT KAINIC ACID LESION SITES IN THE MOUSE STRIATUM. C. Morshead*, M. Bradford* and D. van der Kooy. (SPON: P.A. Stewart). Department of Anatomy, University of Toronto, Toronto, Canada, M5S 1A8.

Gliosis, the accumulation of small darkly stained cells at a site of damage is one of the responses of the brain to injury. We attempted to characterize the properties and origin(s) of the gliotic response in an adult mouse model using kainic acid (KA) to induce a local striatal lesion and tritiated thymidine (3H-Thy) to follow the proliferating cells. Animals were pulse labeled with 3H-Thy 4 hours before sacrifice. The proliferative response was limited to the ipsilateral forebrain and could be divided into two phases depending on time post-lesion and distribution of 3H-Thy labeled cells. First, an early proliferative response 3 days post-lesion was seen in the caudate surrounding the injection site and to a lesser extent in the cortex. Second, at day 6 post-lesion the 3H-Thy labeling of cortical cells disappears, the number of labeled cells in the caudate is similar to that seen at day 3 post-lesion, and most dramatically there is a large increase in the number of labeled cells in the immediate vicinity of the striatal injection site. To trace the arrival of the labeled cells found in the immediate vicinity of the injection site at day 6 we pulse labeled mice on day 3 after KA injection and sacrificed them on day 4, 5, or 6. Over days 4 to 6 post-lesion the number of labeled cells in the caudate remained unchanged, the number in the cortex decreased dramatically, the number of labeled cells in the immediate vicinity of the injection site continued to increase despite the fact the 3H-Thy was administered only once at day 3. We hypothesized that the source of the labeled cells appearing in the immediate vinicity of the injection site is exogenous to the brain. It seems unlikely that migration of cells within the brain can explain this phenomenon as the cells in the immediate vicinity of the injection site continue to increase after a single pulse labeling while the population of labeled cells in the caudate does not decrease. In order to test whether a peripheral (haemopoetic) source was the origin of the late population of 3H-Thy labeled cells at the injection site, mice were irradiated (900rad) to kill the proliferating bone marrow precursors. Three days after irradiation KA was injected into the striatum. The mice were sacrificed 6 days after the KA injection and injected with 3H-Thy 4 hours before sacrifice. Preliminary results indicate that after irradiation , the population of 3H-Thy labeled cells found in the immediate vicinity of the injection site is significantly reduced compared to the number of labeled cells found at the injection site of non-irradiated mice. Furthermore, the number of labeled cells seen in the striatum farther away from the injection site is not affected by the irradiation treatment.

These results suggest that two populations of cells make up the proliferative gliotic response at the site of injury in the brain. The large population of late appearing cells found in the immediate vicinity of the site of injury are of heamopoetic origin while further from the injection site, in the striatum and cortex, there appears to be an early proliferative response of a population of uncharacterized cells that is endogenous to the brain at the time of lesion.

309.11 GENETIC MAPPING AND MOLECULAR CHARACTERIZATION OF THE MOUSE GENE ENCODING THE ALZHEIMER'S DISEASE-RELATED CEREBROVASCULAR AND NEURITIC PLAQUE AMYLOID PEPTIDE. R. Reeves*, R. Morgan, M.L. Oster-Granite, J.T. Coyle, J.D. Gearhart* and N. Robakis*. Depts. of Neurosci. and Physiol., Johns Hopkins Univ. Sch. of Med., Balto. MD 21205 and NYS Inst. Basic Res., Staten Island, N.Y. 10314.

Individuals with trisomy 21 (Down Syndrome, DS) who survive past the third decade invariably develop the neuropathologic stigmata of Alzheimer's Disease (AD), including deposition of cerebrovascular and neuritic plaque amyloid peptide (CVAP). The gene encoding a precursor molecule, including the CVAP, has been molecularly cloned and mapped in humans to chromosome 21 (HSA 21), band q21. This larger protein is expressed throughout development in many tissues of normal individuals. To understand the normal function of this protein and the relationship of its overexpression to the pathogenesis of AD in DS individuals, we have undertaken a molecular and genetic analysis of this gene and its product in the mouse. Genes linked to the "DS region" of HSA 21 are also found linked on mouse chromosome 16 (MMU 16). Trisomy 16 (Ts16) mice develop many stigmata resembling those seen in DS, and thus serve as a genetic model system for studies relevant to DS.

Using a human cDNA as a molecular probe, we mapped the mouse *Cvap* gene to the portion of MMU 16 distal to the T(2H3-4;16C3)28H breakpoint. This region of MMU 16 also contains two HSA 21 genes encoding the purine synthesis enzyme phosphoribosylglycinamide synthetase (*Prgs*) and the protooncogene *Ets-2*. A third HSA 21 gene, *superoxide dismutase-1* (*Sod-1*), is present in the region just proximal to the T28H breakpoint. Using a backcross [(Czech II x BALB/c) x Czech II] for genetic localization, we found that *Cvap*, *Ets-2*, and *Sod-1* are linked tightly within a region of 3.2 cM near the distal end of MMU 16.

At autopsy, normal aging human brains occasionally display neuritic plaques, while the brains of aged mice do not. To determine whether sequence variations in the protein may contribute to a difference in abnormal processing, we have cloned a mouse cDNA which contains 1.4 kb of information, including the entire region which, in humans, encodes the 42 amino acid (aa) residue A4 amyloid, characteristic of the neuritic plaques. The predicted aa sequence is similar overall, but includes variations near the 5' boundary of the plaque amyloid peptide.

In Northern blots of brain using this probe, we can demonstrate the presence of two forms of mRNA, a predominant 3.5 kb message and a 5.0 kb message expressed at lower levels. With *in situ* hybridization using this mouse cDNA probe we can demonstrate elevated expression of *Cvap* in the brains of fetal trisomy 16 mice (See abstract by Bendotti *et al.*).

Thus, we have determined that the gene encoding CVAP is located on the distal tip of MMU 16, linked tightly to other genes located in the putative "DS region" of HSA 21. Using a mouse cDNA probe for CVAP, we have shown that the gene is expressed in normal adult mice and is overexpressed in fetal Ts16 mice. Whether aging Ts16 ↔ normal mouse chimeras develop plaques containing CVAP remains to be determined; normal aging mice do not. *Supported by Grants PO1 HD 19920, RO1 HD 19932, and the McKnight Foundation.*

309.12 **ANALYSIS OF CELL BIRTHDATES AND CELL CYCLE DURATION IN TRISOMY 16 FETAL MOUSE BRAIN.** **M.L. Oster-Granite, J.T. Coyle, S. Fisher*, C.F. Hohmann, T. Huang-Chong*, J.E. Sweeney, and R. Wetts. (SPON: E. Lotter). Depts. of Neuroscience and Environ. Health, The Johns Hopkins University Schools of Medicine and Public Health, Baltimore, MD 21205 and Develop. Biol. Center, UC Irvine, Irvine, CA 92717.**

Down Syndrome (DS) usually results from triplication of human chromosome 21 (HSA 21). Of the five genes localized to the distal portion of HSA 21, all have been located on the distal quarter of mouse chromosome 16 (MMU 16) (see abstracts by Reeves *et al.*; Bendotti *et al.*), thus making murine trisomy 16 a good candidate for an animal model of DS. In addition to genetic homology, Ts16 mice exhibit a number of neurochemical, neuropathologic and neuroanatomic features found in DS individuals. Reduction in the number of cholinergic neurons has been noted in DS patients; therefore, we examined cells in regions of high and low cholinergic activity in Ts16 mice, namely the nucleus basalis magnocellularis (nBM) and cerebellum, respectively. We examined whether the hypocellularity observed in these regions was the result of 1) decreased proliferation during neurogenesis, 2) altered cell birthdates, and/or 3) premature cell death.

Pregnant mice were injected with single or multiple doses of [^{3}H]thymidine on days 9-15 of gestation (E9-15). For cell cycle studies, mice were killed at hourly intervals on days 10 - 16 gestation. For cell birthdating experiments, mice were killed on E16. Liver tissue (for karyotype analysis) was taken from each fetus prior to transcardial perfusion with 4% paraformaldehyde in 0.1M phosphate buffer. The brains were divided at the mesencephalon and processed for frozen sections (anterior portion) or paraffin sections (posterior portion).

We analyzed birthdates and cell cycle duration of neurons of the rhomencephalon, especially in the cerebellum, from E10-15 on 5-8 μm paraffin sections counterstained with toluidine blue following development of the autoradiograph. In 50 μm frozen sections stained for acetylcholinesterase (AChE), we determined cell birthdates of nBM neurons from E11-15.

As early as E9, the rhombencephalon contained 30-40% fewer cells in Ts16 mice. When we analyzed the duration of the cell cycle in the rhombencephalon, we found no change in the Ts16 mice versus normal littermates sufficient to account for the disparity in cell numbers that already existed at E10.

Cell birthdates were similar to those of normal littermate controls for both the cerebellar Purkinje cells and the AChE-stained neurons of nBM, presumptive cholinergic neurons. Most neurons in these regions were generated on E11-13, but continued through E15. Qualitatively, fewer cells were generated, although in both regions the proportions of mitotic to non-mitotic cells were similar.

In conclusion, these results indicate that the reduction in cell number observed in the rhombencephalon and nBM region of Ts16 mice is not due to alterations in the duration of the cell cycle or to alterations in the birthdates of principal neurons. The events that result in reduced cell number apparently occur before significant neurogenesis in these structures has taken place in Ts16 mice.

309.13 NEUROCHEMICAL CHARACTERIZATION OF EMBRYONIC BRAIN DEVELOPMENT IN MURINE TRISOMY 19 (TS19): IMPLICATIONS CONCERNING THE SPECIFIC CONTRIBUTION OF ANEUPLOIDY IN NEURAL DEVELOPMENT. M.D. Saltarelli, G.L. Forloni, M.L. Oster-Granite, J.D. Gearhart*, and J.T. Coyle. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Autosomal aneuploidy is invariably asssociated with mental retardation in human infants who survive birth. Unfortunately, little is known about the neurochemical and neuroanatomical substrates underlying these profound behavioral alterations. While spontaneous chromosomal aneuploidy is rare in mice, one can generate trisomy for each autosome with high frequency through the use of selective breeding schemes involving mice with Robertsonian translocations. In our previous studies of trisomy 16 (Ts16) mice, we observed neuronal hypoplasia and a specific reduction of choline acetyltransferase (ChAT) activity in the developing basal forebrain. Coupled with demonstrated genetic synteny between human chromosome 21 (HSA 21) and mouse chromosome 16 (MMU 16), these studies support the Ts16 mouse as a model system for studies of brain development in human trisomy 21 (Down Syndrome; DS). However, the specfic contribution of qualitative effects of trisomy of specific genes on MMU 16 to abnormal neurogenesis has not been separated from the more quantitative effects of generalized autosomal aneuploidy itself. We have therefore characterized the neurochemical development of murine trisomy 19 in an attempt to clarify the qualitative versus quantitative effects of aneuploidy in the mouse.

Male mice doubly heterozygous for Robertsonian translocations Rb(5.19)1Wh and Rb(9.19)163H were mated to normal C57BL/6J female mice. The Ts19 conceptuses and their littermates were collected by caesarian section on days 14 to 18 gestation (plug date = day 0), and distinguished phenotypically by their developmental growth retardation and cerebral petecchiae. Their brains were removed rapidly, dissected, and frozen at -70°C until karyotypic confirmation.

We observed reductions in the total protein and wet weights of both the diencephalon/brainstem and cerebral hemisphere sections in Ts19 mice. While we observed no significant alteration in ChAT activity in the diencephalon/brainstem, we did observe a significant reduction in hemispheric ChAT activity compared to controls, progressing from 1.7 ± 0.2 nmol/mg protein/hr (X ± S.E.M., N=6, p<.01, 14% reduction) at E15 to 2.2 ± 0.2 nmol/mg protein/hr (X ± S.E.M., N=4, p<.03, 31% reduction) at E18. In addition, we found that synaptic neurochemical markers for GABA-ergic systems were not significantly reduced in either brain region.

Therefore, a specific reduction in hemispheric ChAT activity in Ts19 mice occurs without a corresponding decrease in the developing basal forebrain, suggesting selective vulnerability of striatal and/or cortical intrinsic cholinergic neurons. Since the pattern and character of neurochemical alterations differs depending upon the particular trisomy, the qualitative effects of the triplication of specific genes on chromosomes, rather than the quantitative effect of aneuploidy in general, may be responsible for the maldevelopment observed in neurochemical and neuroanatomical markers. *Supported by grants PO1 HD 19920, postdoctoral fellowship #MH 15330 (M.D.S.), and by the McKnight Foundation.*

309.14 *IN SITU* HYBRIDIZATION STUDIES OF EXPRESSION OF THE GENE ENCODING CEREBROVASCULAR AMYLOID PEPTIDE (CVAP) IN THE BRAINS OF NORMAL AND TRISOMY 16 MICE. C. Bendotti, R. Reeves*, R. Morgan*, M.L. Oster-Granite, J.D. Gearhart*, and J.T. Coyle. Depts. of Neurosci. and Physiol., Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Cerebrovascular amyloid peptide (CVAP) has been identified as a major extracellular component of senile neuritic plaques and cerebrovascular amyloid in Alzheimer's disease (AD) patients and in Down Syndrome (DS; trisomy 21) individuals with AD pathology. Recently, the gene encoding CVAP has been cloned and mapped to human chromosome 21 (HSA 21), suggesting a genetic relationship between AD and DS. In studies showing a genetic homology between HSA 21 and mouse chromosome 16 (MMU 16), it has been proposed that mice with trisomy 16 (Ts16) might serve as a genetic animal model for studies relevant to DS. The genetic homology between HSA 21 and MMU 16 has been extended recently to the gene encoding the A4 amyloid protein (see abstract by Reeves *et al.*). Thus, the Ts16 mouse may also provide an experimental model system to examine the developmental expression of CVAP, when present in three copies as it is in DS, and possibly in AD as well.

We used the *in situ* hybridization technique on 10 um frozen coronal sections of normal adult mouse brain to localize the CVAP mRNA. By using a [35S]cDNA clone homologous to the mouse CVAP gene (see abstract by Reeves *et al.*), we observed an uneven distribution of hybridization signal throughout the mouse brain with highest densities in the frontal and parietal cortices, the tuberculum olfactorium, the pyramidal layer of the hippocampus, the medial habenula, and the cerebellar cortex, with intermediate levels in the hypothalamus, pons-medulla, and ventrotegmental area and with low levels of expression in the striatum, thalamus, and mesencephalon. The density of hybridization overlying individual positive neurons exhibited substantial regional differences. The specificity of the DNA-RNA hybrid was confirmed by a loss of hybridization signal after pretreatment of the sections with RNAse.

The same *in situ* hybridization procedure was used to study the CVAP gene expression in fetal Ts16 mice and their normal littermates. Again, 10 um frozen coronal sections were prepared from the heads of day 15 gestation, karyotypically identified, normal and Ts16 fetuses. With the same [35S]cDNA probe, we observed a clear amplification of the hybridization signal in the brain tissue of the Ts16 mice compared to their normal littermates on Ultrofilm autoradiographic images. Quantitative analysis of these images with a computer assisted RAS analyzer (Amersham) confirmed a significant increase in hybridization signal in various regions of the Ts16 mouse.

These data confirm the recent finding of overexpression of the CVAP gene as measured by Northern blot analysis in the brain tissue of DS fetuses and provide further evidence for considering Ts16 mice as a genetic model system for studies of DS. Moreover, a comparison of the developmental profile of CVAP expression at postnatal ages in normal and Ts16 ↔ normal chimeric mice may provide evidence for early changes that may occur in the brains of AD patients before symptoms become apparent. *Supported by grants PO1 HD 19920, RO1 HD 19932, and by the McKnight Foundation.*

309.15 SOMATOSTATIN EXPRESSION IN DWARF (*dw/dw*) MICE: GENETIC, PHARMACOLOGIC, AND MOLECULAR STUDIES. B. O'Hara*, R. Reeves*, C. Bendotti, J.D. Gearhart*, M.L. Oster-Granite, and J.T. Coyle. Depts. of Neuroscience and Physiology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Mice homozygous for the gene *dwarf* (*dw*), located on mouse chromosome 16 (MMU 16), have elevated levels of somatostatin (SMST) in extra-hypothalamic brain regions (Fuhrmann *et al.*, Brain Res. 328:161, 1985). When the gene encoding preprosomatostatin *Smst* was localized to MMU 16 as well, strength was added to the hypothesis that excess SMST may be a primary molecular defect in these mice. To localize abnormalities in SMST regulation further, we analyzed SMST mRNA levels in the brains of homozygous *dw* mice and their normal littermates by *in situ* hybridization. Qualitatively, *dw* mice have higher levels of expression of SMST mRNA in cortical and hippocampal regions, but lower levels in the hypothalamus. Presumably, the low levels of SMST mRNA (and of SMST peptide) in the hypothalamus result from a lack of growth hormone feedback in the hypopituitary *dw* mouse.

To ascertain whether *dw* and *Smst* were alleles, a backcross using *dw* and the subspecies *Mus musculus molossinus* (MOLD/Rk) [(*dw/J* x MOLD/Rk) x *dw/J*] was used to generate a three point cross with the immunoglobulin light chain lambda (*Igl-1*) as the third gene. We isolated a genomic clone of mouse *Smst* and used it as a probe to detect restriction fragment length polymorphisms (RFLPs) between *dw/J* and MOLD/Rk. Coupled with RFLPs for *Igl-1* that distinguished these subspecies, we were able to identify the *Smst* and the *Igl-1* allele contributed by each parent. When we analyzed 72 backcross progeny, we found the following map: (centromere) *Igl-1* - 0.04 - *Smst* - 0.31 - *dw*, showing conclusively that *Smst* and *dw* are distinct genes.

It was still possible that the dwarfism associated with *dw* resulted from a *dw*-mediated increase in *Smst* expression, and that excess levels of SMST caused the death of somatotrophs in the late stages of pituitary cell differentiation. To test this hypothesis, we injected neonatal mice with a potent SMST agonist, cyclo (N-Me-Ala-Tyr-D-Trp-Lys-Val-Phe) II. Their growth curves, while reduced, were quite distinct from those of *dw* mice. On histologic examination, the pituitaries of these treated mice were essentially normal, with little or no change in the number of somatotrophs. Once treatment with cyclo II ceased, treated mice experienced a period of catch-up growth. While it is still possible that excess SMST could affect *dw* mice prenatally, the levels of SMST observed may be a secondary effect in *dw* mice. Currently, we are using specific hormone therapies to test this hypothesis.

In conclusion, although *dwarf* mice do exhibit increased expression of the gene encoding somatostatin, and both genes are located on MMU 16, they are distinct genes. Additionally, excess levels of somatostatin during the early postnatal period in the mouse do not account for the loss of somatotrophs in the anterior pituitary, nor the decreased levels of somatostatin in the hypothalamus that is observed in *dwarf* mice. *Supported by grants PO1 HD 19920, RO1 HD 19932, and the the McKnight Foundation.*

310.1 EFFECT OF FFX LESIONS ON CONCURRENT OBJECT AND CONDITIONAL PLACE/OBJECT DISCRIMINATIONS. C.G. Wible, S. McGinn*, S. Graham*, and D.S. Olton. Department of Psychology, Johns Hopkins University, Baltimore, MD 21218.

Animal models of human medial temporal lobe amnesia address questions about the anatomical and functional locus of the amnesia. Animal models using monkeys have predominately used nonspatial tasks with objects. Animal models using rats have predominately used spatial tasks. In order to develop a rat model of amnesia using tasks more similar to the ones used to test monkeys and human amnesics, we have trained rats to perform object discriminations. The performance of normal control (C) rats and those with fimbria/fornix (FFX) lesions were compared on two tasks. Experiment I used a concurrent object discrimination with 2 pairs of objects, Experiment II used a conditional place/object discrimination in which the correct object was conditional upon the location of the pair of objects within a room. Different groups of rats were trained on the two tasks. Rats in Experiment I and II were trained preoperatively and were then given either FFX lesions or underwent surgical procedures without a lesion (C).

Two pairs of objects were used in the concurrent discrimination; the same object in each pair served as the S+ on every trial. Both the FFX and C groups learned the task; there was no difference in performance between the two groups.

In the conditional place/object discrimination, two testing areas were located in distinct locations in a room. In place 1, one of the two objects was correct; in place 2, the other object of the same pair was correct. Rats with FFX lesions failed to learn the conditional place/object discrimination, but C rats did learn the task.

The results of both the concurrent and conditional object/place tasks show that normal rats can learn object discriminations relatively easily. FFX lesions have an effect on conditional place/object tasks, but not on a concurrent discrimination using two pairs of objects. This opens avenues for further research in which more difficult object discriminations can be used to identify the brain mechanisms involved in memory.

310.2 AN ANATOMICAL AND BEHAVIORAL STUDY OF THE FOREBRAIN CHOLINERGIC SYSTEM IN THE MARMOSET (CALLITHRIX JACCHUS). A.C. Roberts*[1], T.W. Robbins*[1], B.J. Everitt*[2], T.E. Sirkia*[2] and G.H. Jones*[1]. (SPON: B.J. Sahakian). Depts. of Psychology[1] and Anatomy[2], Univ. of Cambridge, Cambridge, CB2 3EB, United Kingdom

This study investigates the anatomy and function of the forebrain cholinergic system, particularly that arising from the nucleus basalis of Meynert (nbM), and its projections to the cerebral cortex, in the Common marmoset.

The distribution of choline acetyltransferase immunoreactive (ChAT-IR) neurons was studied using immunohistochemistry. In the forebrain, ChAT-IR neurons were found in the medial septal nucleus, vertical and horizontal limb of the diagonal band and the nbM. Of particular interest to this study was the organisation of the projections from ChAT-IR neurons of the nbM to the overlying cortex. Combining the retrograde transport of HRP-WGA with ChAT immunohistochemistry revealed the distribution of neurons in the nbM projecting to the dorsolateral pre-frontal cortex. In addition, lesions at various loci within this nucleus resulted in differential patterns of ChAT loss in the cortex, suggesting some degree of topographical organisation of nbM projections.

The second phase of the study investigated the role of the anterior nbM, innervating mainly pre-frontal/anterior frontal areas, in visual discriminationand reversal performance. Computer generated visual stimuli were presented on a VDU screen which was fitted with a touch sensitive screen for monitoring the animals responses. All animals were first trained to discriminate between two shapes followed by training on a series of reversals, using banana-favoured milkshake as the reinforcer. Animals then received either a lesion of the anterior nbM using N-methyl-D-aspartic acid or a sham lesion (vehicle injection). Post-operative retention of the discrimination and, to some extent, reversal performance was impaired in the nbM-lesioned animals. In addition, these animals showed a significant and long-lasting perseveration of the consummatory response of licking the spout that provided the reinforcement, indicating impaired stimulus control.

These results will be discussed in terms of the possible "frontal" nature of the behavioral deficits.

310.3 ACQUISITION OF A COMPLEX PLACE TASK IN RATS WITH SELECTIVE IBOTENATE LESIONS OF HIPPOCAMPAL FORMATION: COMBINED LESIONS OF SUBICULUM AND ENTORHINAL CORTEX VS. HIPPOCAMPUS. J.P. Bouffard* and L.E. Jarrard (SPON: H.E. King). Dept. of Psychology, Washington and Lee Univ., Lexington, VA. 24450.

Examination of the brains of patients diagnosed as having Alzheimer's disease has revealed an extensive loss of cells in the deep layers of the entorhinal cortex and the subiculum (Hyman et al, 1984). This pattern of damage was interpreted as effectively isolating the hippocampus from the neocortex by interrupting the major inputs from entorhinal cortex and major outputs to the subiculum. One purpose of the present study was to determine the effects of combined ibotenate damage to subiculum and entorhinal cortex on the acquisition of a complex spatial task designed to vary temporal contextual information (massed vs. distributed practice trials). A second purpose was to compare the performance of rats with subiculum and entorhinal cortex lesions with performance of animals having the hippocampus removed and controls.

Rats were divided into 2 control (operated, unoperated) and 2 lesion groups. Multiple injections of IBO were made into the subiculum and entorhinal cortex in one group and the hippocampus in the other. Using a within-subjects design the rats underwent training on a series of problems (4 arms baited out of 8) in an 8-arm radial maze. Eight problems were presented for 11 trials each, with half the problems given under massed (45 sec) and the other half under distributed (10 min) practice trials.

Even though histology indicated that the cell loss in the subiculum and deep layers of entorhinal cortex was extensive, acquisition in these rats was like that of controls. In contrast, removing the cells in the hippocampus had a devastating effect on acquisition of the complex spatial task. Distributed practice trials (10 min) served to improve performance of hippocampals over massed practice (45 sec) more than was found in the other groups. These data show that removing the cells in the hippocampus with an axon-sparing neurotoxin impairs acquisition of a complex place task, but eliminating most cortical inputs to and outputs from hippocampus has no effect under the conditions studied.

(Supported by NSF grant BNS 85-07259.)

310.4 LESIONS OF THE ANTERIOR TEMPORAL STEM IMPAIR DELAYED MATCH TO SAMPLE PERFORMANCE IN MONKEYS. R.A. Cirillo[1]*, J.A. Horel[2]*, P.J. George[1]*, and S.G. Spence[2]*. 1. Dept. of Psychology, Syracuse University, Syracuse, NY, 13244. 2. Dept. of Anatomy and Cell Biology, SUNY Health Science Center at Syracuse, Syracuse, NY 13210.

Resection of the medial temporal lobe in humans produces a profound anterograde amnesia in which past memories are seemingly intact, but the ability to form new memories is severely compromised. Efforts to develop a model of this human amnesia using non-human primates have relied extensively on the delayed non-match-to-sample (DNMS) task, and its relative, the delayed match-to-sample (DMS) task. DNMS deficits have been found with combined damage to the amygdala and hippocampus, but not to the adjacent white matter (the temporal stem) that connects the temporal cortex to other brain areas (S. Zola-Morgan et al., Science, 218: 1337-1339, 1982). Previous work in our laboratory, however, has produced delayed match-to-sample (DMS) deficits with lesions to anteroventral temporal cortex (J.A. Horel et al., Soc Neurosci Abstr, 200.13, 1986), and lesions to orbitofrontal cortex (M.L. Voytko, Physiol. Psych., 13 (4): 219-229, 1985). The antroventral temporal cortex and the orbitofrontal cortex are interconnected through the temporal stem.

In the present study, we examined the hypothesis that the temporal stem lesion of Zola-Morgan et al., (1982) was not sufficiently rostral to include the fibers exiting from the anteroventral temporal cortex and the temporal pole. We transected the anterior extreme of the temporal stem via an incision through the superior temporal sulcus. Our cut begins deep to the temporal pole and continues posteriorly for 2 cm.

We have found that animals with this preparation exhibit a severe deficit on DMS, particularly at longer delays (30-45 seconds). In addition, these animals were impaired in relearning a preoperatively learned visual discrimination, and in the postoperative learning of a new visual discrimination. Therefore, it would appear that insofar as DMS is a measure of human amnesia, this syndrome can be produced by damage to the temporal stem. (This work was supported by NINCDS Grant NS 1829-05.)

310.5 EFFECT OF MEDIAL FRONTAL CORTEX LESIONS ON OBJECT RECOGNITION MEMORY IN THE RAT. L.A. Rothblat and L.F. Kromer, Dept. of Psychology, George Washington University, Washington, D.C., 20052 and Dept. of Anatomy and Cell Biology, Georgetown University School of Medicine, Washington, D.C., 20007.

Delayed nonmatching-to-sample with trial unique stimuli (DNMS) has become the currently accepted standard for demonstrating object recognition memory in monkeys (e.g. Mishkin and Delacour, J. Exp. Psych., 1:326, 1975), and, as such, is being widely used to identify critical brain regions which when damaged produce amnesia (e.g. Mishkin, Nature, 273:297, 1978; Zola-Morgan and Squire, Behav. Neuorsci., 100:155, 1986). Thus far, this work has been successful in demonstrating the involvement of a number of different neural structures, e.g. hippocampus, amygdala, medial thalamus and frontal cortex, but there is still disagreement as to whether these brain areas can function independently in recognition memory, or work in combination. To further explore this question, we began testing rats on DNMS utilizing procedures which are virtually identical to those used with primates (Rothblat and Hayes, Behav. Neurosci., In press). Previously, we showed that rats with septo-hippocampal damage were not impaired on DNMS, even though they displayed a marked deficit on a test of spatial memory (Rothblat, Hayes and Kromer, Soc. Neurosci. Abstr., 12:742, 1986). The present study was an attempt to further define the neural circuitry of memory by evaluating the role of rat frontal cortex in object recognition.

For testing on DNMS, we used a pool of 250 small "junk" stimuli. On each trial, 2 stimuli were selected from the object pool; one member of the pair was designated as the sample. On the first part of a trial, the sample run, the rat traversed an elevated runway and displaced the sample object for food reward. On the second part of a trial, the choice run, the rat had to choose between the previously presented sample and the second member of the pair. Reward on the choice run followed selection of the novel object. DNMS performance of previously trained rats was evaluated following bilateral aspiration lesions of medial frontal cortex. In addition, performance on a measure of spatial memory, discrete trial rewarded alternation, was assessed.

The results of the study showed that rats with lesions of medial frontal cortex, as is the case with hippocampally damaged animals, are not impaired on DNMS. Medial frontal animals were impaired on the spatial alternation task, though the magnitude of the deficit was less severe than that displayed by rats with damage to the septo-hippocampal system. Thus, although both brain regions seem to play a role in spatial memory, the critical structures for object recognition remain to be determined. (Supported by the March of Dimes and a NIH Biomedical Research Support Grant to G.W.U.).

310.6 FIMBRA-FORNIX LESION IMPAIRS LEARNING PERFORMANCE OF RATS IN A 14-UNIT T-MAZE. E. Bresnahan, H. Kametani*, E. Spangler*, M. Chachich*, P. Wiser*, and D. Ingram*. Essex Comm. College, Baltimore, MD 21237, Dept. Psychol., Towson State Univerity, Towson, MD 21204, and Gerontology Res. Ctr., NIA, NIH, Baltimore, MD 21224

Results from a previous study demonstrated that systemic injections of the muscarinic antagonist, scopolamine, impaired learning of young (3 mo) rats in a shock-motivated 14-unit T-maze (Spangler, E. et al., Pharmacol. Biochem. Behav., 25:673, 1986). This drug-induced dysfunction simulated the age-related impairment in learning of rodents observed in this task (Ingram, D., Annals NYAS, 444:312, 1985). The objective of the present study was to determine the involvement of the septo-hippocampal cholinergic pathway in memory systems required to learn this task. Young (3-mo) male F-344 rats received electrolytic lesions to the fimbra-fornix or served as sham-operated or unoperated controls. One week later, rats received one-way active avoidance training (US = 0.8 mA) in a straight runway (1 m long). The criterion of 8/10 successful avoidances on the last of three consecutive 10-trial daily sessions was met equivalently by all groups. Beginning 24 hours later, rats were provided two 10-trial daily sessions in the complex maze task. The rat was required to traverse each of five maze segments within 10 sec to avoid footshock (0.8 mA). Dependent measures of maze performance analyzed included errors (deviations from the correct path as detected by photocells), run time, number of shocks, duration of shock, and alternation errors (errors made if the rat were using an alternation strategy). According to t-test analyses, the sham-operated and unoperated controls significantly differed only in alternation errors ($p = 0.046$). For all other analyses the two control groups were combined and compared to the lesioned group on each variable by way of 2 (group) by 4 (block of 5 trials) ANOVAs. Control and lesioned groups demonstrated learning by significantly ($p < 0.01$) reduced error rate across trial blocks. However, the results also demonstrated that the fimbra-fornix lesion produced significant ($p's < 0.01$) impairment relative to controls in all performance measures. Further analysis of subgroups among lesioned animals indicated that significantly ($p < 0.05$) greater impairment was observed when transection of the fimbra-fornix appeared complete across several thionin-stained serial sections. This dysfunction in maze performance was similar to that observed following high doses of scopolamine (3 mg/kg). Performance with partial transections simulated that observed in young rats with lower doses of scopolamine (0.5 - 1.0 mg/kg) or that of aged rats (22-24 mo). Thus, the integrity of the septo-hippocampal pathway affects the proficiency of learning performance in this task and is implicated as a system involved in the age-related impairment observed.

310.7 THE EFFECTS OF NUCLEUS BASALIS OR FIMBRIA-FORNIX LESIONS ON A SPATIAL T MAZE ALTERNATION OR MATCHING TASK. R. Etherington* and S.B. Dunnett. Dept. of Experimental Psychology, University of Cambridge, Downing Street, Cambridge, CB2 3EB, England.

Recent research has suggested that there is a dissociation between the effects of lesions of the cortical and septo-hippocampal cholinergic pathways. A reference memory deficit is seen on a radial arm maze task after lesions of the nucleus basalis magnocellularis (Murray and Fibiger, Neuroscience, 1985,14:1025-1032) while in contrast there are impairments in working memory functions after lesions of the fimbria-fornix (Olton et al., Behav and Brain Sciences, 1979,2:313-365) . In the present experiment different groups of rats were trained on either an open T maze matching or alternation task. This procedure required the rats to make a forced choice entry into one arm then, after a 10 second delay, a recognition choice entry into the relevant arm depending on the type of task. Rats in each condition were given either quisqualic acid lesions of the NBM, or aspiration lesions of the fimbria-fornix, and both post op. acquisition and retention tests were carried out. The performance of the fimbria-fornix rats was impaired on both matching and alternation tasks and these animals showed a bias to respond to a particular arm of the maze. NBM lesions, on the other hand, produced a more variable effect. On the alternation task the rats showed no deficit during either acquisition or retention performance at the 10 second delay, although a small but significant deficit was apparent at longer delays (30-120 seconds). NBM rats in the matching task appeared to learn the task faster than controls in the early trials but did not reach criterion levels of performance, and this lesion x trials effect was highly significant. The pattern of performance on the two tasks suggests that the nature of the deficit induced by fimbria-fornix lesions was not mnemonic, but rather was of the classic perseverative type. In contrast, the NBM animals showed more clear cut deficits on the matching than the alternation task, which could be attributable to the former task requiring more "effortful" levels of cognitive processing than the latter, where spontaneous alternation strategies are reinforced.

310.8 HANDLING STIMULATION IN INFANCY AND GENDER: EFFECTS UPON MAZE LEARNING AND BEHAVIORAL ASYMMETRY. S. H. Freter*, A. Mikolowski* R. H. Fitch*, A. S. Berrebi, D. A. Yutzey and V. H. Denenberg. Biobehavioral Sciences Graduate Degree Program. Univ. of Conn., Storrs, CT 06268.

Extra handling stimulation in infancy enhances left-right behavioral asymmetry (Sherman et al., Brain Res., 1980, 192:61; Camp et al., Physiol. Beh., 1984, 33:433); and females have a different asymmetry pattern than males (Sherman et al., Life Sci., 1983, 33:189). Better left-right spatial discrimination is associated with cerebral laterality (Zimmerberg et al., Brain Research, 1976, 140:194), suggesting that animals with greater behavioral asymmetry should learn a complex maze more easily. We tested this hypothesis.

Newborn Purdue-Wistar rat pups were not disturbed or were handled daily for 3 min for the first 21 days of life, resulting in four groups: handled males (N = 13), handled females (N = 13), nonhandled males (N = 10), and nonhandled females (N = 9). Starting on day 70 the rats were given one trial a day for 12 days on a water version of the Lashley III maze. Two kinds of errors were recorded: T-Choice errors (making the wrong choice at a T point) and Perseveration errors (continuing straight ahead into a blind alley rather than making a turn).

On the initial trial the rats do not know the location of the goal. At T-choices the animals were more likely to go left than right ($p<.01$), a bias which is indicative of endogenous asymmetry. This is consistent with prior findings from this laboratory that our rat is behaviorally asymmetrical with a left preference.

Thereafter, females made more errors than males while learning ($p<.01$). Handling in infancy interacted with Sex, Kind of error, and Trials ($p<.02$). Analysis of this interaction revealed that three general rules, or strategies, were used to learn the maze: (1) at choice points go left rather than right; (2) use extramaze cues as guides toward the goal box; and (3) learn the internal structure of the maze. Nonhandled females only used the first two strategies; whereas the other three groups used all three rules.

Animals that only use spatial information will get through the maze but will make errors. To eliminate errors, it is necessary that intramaze cues be employed for associative learning. These results indicate that males make better use of associative learning than females, possibly indicating gender differences in use of strategies to solve this task.

310.9 IBOTENATE LESIONS OF THE RAT NUCLEUS BASALIS CAUSE ENDURING IMPAIRED PERFORMANCE OF A NON-MATCH-TO-SAMPLE DISCRIMINATION. B. E. Lerer, D. Hepler, K. Zeller*, J. Bradd* and R. Pierdomenico*. DuPont Pharmaceuticals, Medical Products Dept., Wilmington, DE 19898.

CNS cholinergic neurons mediate critical learning and memory processes; in fact, the cognitive deficits observed in Alzheimer's Disease have been correlated with the extent of loss of neocortical cholinergic integrity. In the rat, neurotoxic lesions of the nucleus basalis magnocellularis (NBM) produce significant decreases in markers of cholinergic neurons in frontal and parietal cortex and also behavioral deficits suggestive of learning and memory dysfunction.

Male Sprague-Dawley rats were trained to respond for food on a fixed-ratio 5 (FR5) schedule with a food reward and retractable lever located beneath a cuelamp. The location of the lever on each trial varied randomly from the right to the left side of the experimental chamber. After training, rats were randomly assigned to either a NBM or SHAM surgery group. Bilateral NBM lesions were induced with 40 nmol injections of ibotenic acid. The SHAM group had a clean cannula inserted into the NBM without injection. Three weeks after surgery, all rats were tested in the barpressing procedure and, when they were responding without error, discrimination training began. The non-match-to-sample (NMTS) test consisted of a SAMPLE trial followed by a CHOICE trial. On the SAMPLE trial, rats were rewarded for FR5 responding on the lever extended below a lit cuelamp. The SAMPLE varied randomly from the right to the left lever on each trial. On the CHOICE trial, two levers were extended and a FR5 to the uncued lever was rewarded.

NBM rats were severly impaired on this NMTS discrimination (although they are not impaired in a match-to-sample discrimination) and after 18 sessions they made about 65% correct responses while the SHAM group made over 80% correct responses. Testing was suspended about 4 months and resumed for an additional 15-21 sessions. Although it had been almost 6 months since surgery, the NBM rats were still significantly impaired relative to SHAM performance. After 4 sessions, the NBM group reached an asymptotic level of about 65% as compared to 87% correct responses in the SHAM group. At 27 weeks post-surgery, several animals from each group were sacrificed and cortical samples were assessed for acetylcholine release and choline acetyltransferase activity. In the NBM group, both markers were significantly reduced by about 35% as compared to the SHAM group.

Our results indicate that bilateral NBM lesions produce profound and sustained behavioral and biochemical deficits that appear stable and non-recovering for at least 6 months.

310.10 **DISRUPTION IN MAZE PERFORMANCE AFTER CORTICAL LESIONS IN TURTLES (Chrysemys picta).** **M. A. Petrillo* and A. S. Powers. Department of Psychology, St. John's University, Jamaica, NY 11439.**

The dorsal cortex (cd) of turtles, a three-layered structure on the surface of the hemisphere, has been implicated in learning (Grisham & Powers, 1986, Society for Neuroscience Abstracts, 12). Like the neocortex of mammals, the cd receives input from cholinergic cells in the basal forebrain (Mufson et al., 1982, Brain Research, 323, 103-108). The present study was undertaken to investigate the role of the cd in retention of a maze habit.

Postoperative maze performance was assessed in turtles after bilateral ablation of the cd. The turtles were required to learn a four arm maze for water reward. Each arm ended with a well, one of which was filled with water (the goal well). The turtles were placed in another well, the start well, and after a sixty second adjustment period, allowed to make an unlimited number of choices until they reached the goal well or until five minutes had elapsed. From the start well, the turtles had to make a left turn in the center to reach the goal well. A ratio of number of correct choices to total number of choices for a day was computed for each turtle. The turtles were trained until they reached a criterion of 67% correct choices per day for two successive days. Once criterion was met, the turtles were anesthetized with Equithesin (ip; dose .20 ml per 100 g body weight). Lesions of the cd (n=4) were made by aspiration. Control lesions (n=4) consisted of merely opening the skull. After a five to seven day recovery period, the turtles were reintroduced to the maze. The turtles were run postoperatively until they reached criterion or until they amassed three times as many days postoperatively as preoperatively. Postoperative days to criterion were computed for each turtle. Turtles with cd lesions were significantly impaired relative to shams ($U \leq 1$, p=.029). These data suggest that spatial memory, as measured by maze performance, involves the cd. Previous research on the Morris milk maze has yielded similar results in rats after lesions of the nucleus basalis (Dokla et al., 1985, Society for Neuroscience Abstracts, 11, 332).

310.11 **THE IMMUNOHISTOCHEMISTRY AND CYTOARCHITECTURE OF THE AVIAN HIPPOCAMPUS.** J.R. Krebs*, J.T. Erichsen and V.P. Bingman. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794

The avian dorsomedial forebrain (Hp-APH) was considered by early comparative anatomists (Ariens-Kappers et al., 1936) as homologous with the mammalian hippocampal complex (Hp). Recently, behavioral and anatomical studies have provided further support for this suggested homology. First, like the mammalian Hp (e.g. O'Keefe & Nadel, 1978; Olton et al., 1979), the avian Hp-APH has been shown to play an important role in spatially guided behavior and memory (Bingman et al., 1987; Sherry & Vaccarino, in press). Second, a pathway tracing study has found similarities in the connectivity of avian Hp-APH and mammalian Hp (Casini et al., 1986). In the present study, we have employed immunohistochemical techniques to investigate the distribution of a variety of neuropeptides and neurotransmitter-related enzymes in the homing pigeon, a bird known to suffer spatial behavior deficits following damage to Hp-APH. Our goals were to: (1) characterize the subdivisions of Hp-APH, and (2) explore further the hypothesis of homology with mammalian Hp by comparing the distributions of different kinds of immunoreactivity.

Antibodies to five neuropeptides (somatostatin [SS], avian pancreatic polypeptide [APP], cholecystokinin [CCK], leu-enkephalin [ENK], and substance P [SP]), an indoleamine (serotonin [5-HT]) and three transmitter-related enzymes (choline acetyltransferase [ChAT], glutamic acid decarboxylase [GAD] and tyrosine hydroxylase [TOH]) were used in the immunohistochemical analysis of Hp-APH. A variety of SS-positive cell types, including pyramidal-like cells, were located in medial Hp-APH. APP-positive cells were also found medially and were characterized by the regular orientation of their dendrites. A sparse population of small cells, lying ventrally and along the medial wall, contained CCK. Immunoreactivity for these three peptides, as well as for SP and ENK, was also found in dense terminal fields in restricted regions. A population of 5-HT-positive fibers appeared to terminate in a dense dorsomedial field. This serotonergic projection probably arises from the medial raphe nucleus (Casini et al., 1986). ChAT-positive fibers were observed medially with terminals sparsely distributed dorsomedially. This projection may originate from the ventral septum where a few ChAT-positive cell bodies were observed (Casini et al., 1986). GAD- and TOH-positive terminal fields were also situated dorsomedially.

The distribution of immunoreactive staining for these peptides and transmitter-related enzymes revealed the existence of several distinct subdivisions of Hp-APH. Based on these results, we will offer a tentative cytoarchitectural characterization of Hp-APH and a comparative analysis of the avian and mammalian hippocampus.

310.12 EXPLORATORY BEHAVIOR OF LONG-EVANS HOODED RATS ON THE MAIER 3-TABLE MAZE FOLLOWING NEUROTOXIN-INDUCED LESIONS OF THE HIPPOCAMPUS. C. Wages. Dept. of Psychology, Georgia State Univ., Atlanta, GA

O'Keefe and Nadel (1978) stressed the necessity of locomotion through an environment if the animal is to acquire information concerning the distance and direction between stimuli in the environ-ment (i.e., cognitive map). Specifically, they argued that as the dentate cells can only fire at one phase of the theta cycle (Ranck, 1975), they could gate stimulus input; so that stimuli detected at different locations in the environment would be encoded in different areas of the CA3 field.

O'Keefe and Nadel further contrasted exploratory activity with general activity suggesting that exploratory activity would decrease across time as a neural representation of the environment was formed; whereas general activity would not decrease.

While impairment on certain spatial tasks may indicate that some cognitive map process has been impaired, it is usually difficult to determine whether the the impairment reflects an inability to access information encoded in the map, or a disruption of the neural systems that had encoded the distance and direction information.

To the extent that locomotor activity decreases when a cognitve map is encoded, one can identify if an impaired animal has a cognitive map by observing its locomotor activity. Animals with damage to the septum, medial frontal cortex, or hippocampus are deficient on many spatial tasks. In contrast to normal animals, animals with septal damage failed to decrease activity during a daily 15 minute opportunity to explore a test environment (Ellen and Weston, 1983; Herrmann, Poucet, and Ellen, 1985) indicating that they were not able to encode spatial information into a cognitive map. Animals with medial frontal cortex damage failed to habituate locomotor activity during early exploration of the test environment, but with repeated exposure the activity within an exploration session decreased (Herrmann et al, 1985) indicating that the failure on the task indicated an inability to use the encoded spatial information.

In this experiment, the exploratory behavior of animals with dentate damage, or massive or minor CA damage was analyzed on a spatial problem that could only be solved if the animals were able to use spatial information that was acquired on separate days.

310.13 SPATIAL BEHAVIOR AFTER HIPPOCAMPAL LESIONS IN PIGEONS V. P. Bingman and W. Hodos. Dept. of Psychology, Univ. of Maryland, College Park, MD 20742.

The avian hippocampal (Hp) and parahippocampal (APH) areas have been suggested as the homolog of the mammalian hippocampal complex. Indeed, a recent pathway-tracing study revealed considerable similarity in the extrinsic connections of the avian Hp-APH and the mammalian hippocampus (Casini, et al., J. comp. Neurol., 245, 454-470, 1986). Given the important role of the hippocampus in the neural organization of spatial behavior, as revealed by laboratory studies in rodents, the role of the Hp-APH complex in naturally-occurring spatial behavior in birds was examined.

Homing behavior of pigeons with Hp-APH lesions was compared to homing in pigeons with control lesions in the anterior telencephalon. The Hp-APH-ablated pigeons showed a persistent impairment in the amount of time required to return home, which suggests a spatial deficit. The basis of the deficit is obscure at present, although anecdotal evidence suggests that Hp-APH-ablated pigeons are impaired in their ability to rely on landmarks to locate their loft. This hypothesis, if verified, would be consistent with data from mammals that indicate a mapping function for the hippocampus.

Psychophysical techniques were used to test the possibility that the deficits in homing behavior might be due to sensory losses. Hp-APH ablation was found to have no effect on either visual acuity or size-difference thresholds. Thus, an explanation based on visual impairment would seem unlikely as a cause of the homing deficit.

Currently, a "spatial relations" test is being used to examine the ability of pigeons to make use of the location of landmarks (colored squares on a video monitor) as cues to which pecking responses would lead to a food reward. Preliminary results indicate that the post-operative performance of Hp-APH ablated pigeons is impaired.

310.14 ACCELERATED RATE OF FORGETTING OF SPATIAL INFORMATION WITH AGING AND LONG TERM ETHANOL CONSUMPTION IN MICE: EVIDENCE FOR TWO FORMS OF AMNESIA. R. Jaffard, D.J. Béracochéa and A.N. Tako*. Lab. Psychophysiologie, Univ. Bordeaux I, 33405 Talence, France.

Studies of amnesic patients have consistently produced evidence for two dissociable forms of amnesia (Squire, Ann. Rev.Neurosc., 5:241, 1982). The purpose of the present experiment was twofold: (i) to compare the rates of forgetting of aged and alcohol-treated mice; (ii) to determine whether the observed deficits correspond to two different types of amnesia.

At 2 months of age, mice of the alcohol groups were given a solution of ethanol (12% v/v) as their only source of fluid for periods ranging from 2 to 12 months; they were compared to pair-fed and free-feeding animals after ethanol had been omitted from the diet for at least 4 weeks. Spontaneous alternation behavior (S.A.) in a T maze was used as a learning paradigm consisting of two forced trials (acquisition) followed, at varying retention intervals (R.Is) by a free test trial (retention). Thus, performance was measured both as a function of age (4,9,12 and 17 months) and alcohol consumption duration (respectively 2,6,9 and 12 months). No between-groups differences were observed for S.A. rates at the shorter (5 mn) R.I. (between 78.1 and 82.9 %). However, as compared to younger subjects (4-12 months) which still significantly alternated at the 24 hrs R.I. (mean: 70.2 %), older mice (17 months) responded at chance level at the 6 hrs interval (53.2%). The same accelerated rate of decay of S.A. was observed in young (9 months) alcohol-treated mice which exhibited chance level performance at 6 hrs (51.3 vs 75.0 % for controls).

The second part of the experiment was aimed at testing whether a change of intra-maze context occuring on the retention test trial would improve performance of aged and alcohol-treated mice (see Béracochéa and Jaffard , Behav. Neurosc., 101:101, 1987 for a similar procedure which was found to reverse the spatial memory deficits of mammillary body-lesioned mice). Results showed that this change of context totally alleviated the deficit of alcohol-treated mice but had no effect in aged animals. Moreover, this procedure was totally ineffective in improving performance of untreated young subjects whatever the R.I.(from 6 to 72 hrs).

These results suggest that both alcohol consumption and aging result in an accelerated rate of forgetting of spatial information but that the alcohol-induced deficit would stem from a basic failure in retrieval while the age-related one would result from a faster decay of the memory trace.

310.15 DIFFERENTIAL EFFECTS OF ELECTROLYTIC AND CYTOTOXIC CINGULATE CORTEX LESIONS ON ACQUISITION RETENTION AND REVERSAL OF A SPATIAL DISCRIMINATION TASK IN MICE .M.Meunier*,R. Jaffard, C. Messier and C.Destrade. Lab. Psychophysiologie, Univ. Bordeaux 1, Avenue des Facultés, 33405 TALENCE Cedex FRANCE.

We have shown that restricted electrolytic lesions of the posterior but not anterior cingulate cortex produced a transitory facilitation of learning in Balb/c mice (Meunier et al., Physiol. Behav. 37,903,1986). In the present experiments we compare the effects of bilateral electrolytic (HF) or ibotenic acid (IBO) lesions of the anterior (ANT) or the posterior (POST) cingulate cortex on acquisition,retention and reversal of a spatial discrimination task in a T-maze.

HF Lesions were produced by passing anodal high frequency current (500 KHz; 0.35 mA) for 30 sec through the tip of an stainless-steel electrode. The IBO injections were made through a glass micropipette.(0.24 µl at a rate of 0.02 µl/min). One week after surgery the lesioned mice and the sham operated controls were food deprived and tested over 5 consecutive days. The baited T-maze arm was reversed each test day. The daily test ended when 5 consecutive correct responses were made. An additional session was carried on 10 days later. Three single-trial retention tests were given 5min, 6h and 24h after the end of each session.

POST-HF lesioned animals reached the criterion significantly faster on the first 2 days of testing (acquisition and 1st reversal). This effect disappeared on the 3 following days, and was reversed (impairment) ten days later. However,the POST-HF group was significantly impaired in the 24h-delay retention test. In contrast, ANT-HF lesioned mice reached the criterion significantly later on the 3rd day of testing (2nd reversal) but did not differ from controls in any of the other 5 sessions.Retention was slightly but not significantly impaired for the 3 retention intervals (5min, 6h and 24h).

The behavioral effects observed in POST-HF lesioned group were not found in POST-IBO lesioned animals. However certain POST-IBO mice were impaired on the first two days of testing when compared to controls. In contrast to POST-HF mice, POST-IBO animals were not impaired in the 24h-delay retention test. No significant effects were observed in ANT-IBO lesioned animals.

These results indicate an involvement of the posterior cingulate cortex, and in particular the cingulum bundle,in both the initial acquisition and long-term memory processes.

310.16 ISOLATION OF NEURAL REGIONS MEDIATING OLFACTORY LEARNING IN RATS. David Kucharski and W.G. Hall. Department of Psychology, Duke University, Durham, NC 27706.

Memory for conditioned olfactory preference can be functionally confined to one side of the brain in young rat pups by restricting odor input to one naris and corresponding olfactory bulb during training pairings of an odor with milk reward. While the memory is stored on the trained side of the brain, information can be accessed contralaterally from the untrained side of the brain. Twelve-day-old pups show a conditioned increase in preference for the odor when tested with either the trained or untrained naris stimulated, but the capacity for responding by the untrained naris depends on mature and intact components of the anterior commissure. These commissural fibers appear to provide contralateral access and "read-out" of unilaterally stored memories. The ability to probe olfactory memory from the untrained side provides the opportunity to further identify structures and substrates involved in conditioning and memory retrieval by anatomically isolating specific projections of the anterior commissure. Here, we trained 12-day-old rat pups to associate cedar odor with sucrose reward while olfactory input was restricted to one naris by a soft rubber plug in the opposite naris. We then made knife cut transections of commissural fibers near their projection site in anterior olfactory nucleus or piriform cortex, or transected the entire olfactory bulb on the trained side of the brain. If memory for the odor preference is indeed stored in one or more of these locations, then the animal should demonstrate a retrieval deficit when tested with the untrained naris open. Selectively disrupting the commissural projection to the AON resulted in a disruption of retention for animals tested with the untrained naris open. Neither presence of the trained bulb nor projections to the olfactory bulb or piriform cortex appear necessary for accessing olfactory memories. Thus, the anterior olfactory nucleus is implicated as a structure that once innervated, provides critical sites for, or pathways to, olfactory preference memories.

310.17 THE ACQUISITION OF ASSOCIATIVE HABITS BY MONKEYS WITH MEDIAL THALAMIC LESIONS. E.C. Gower, S. Jacobsen, N. Butters & D.L. Kasdon*. VA Medical Center, Boston, MA 02130.

Damage to the primate medial thalamus impairs the acquisition and performance of a task which requires the retention of information over temporal epochs measured in seconds and minutes. Such monkeys further exhibit postoperative retention deficits for visual discriminations learned preoperatively, a result implying that medial thalamic damage may also accelerate forgetting over longer intervals, and for repeatedly experienced events (Gower, E.C., et al., Soc. Neurosci. Abstr. 11:831, 1985). The present experiment characterizes associative learning in monkeys with medial thalamic lesions, and compares postoperative with preoperative rates of acquisition exhibited by the same subjects for the same type of visual discrimination problem. Three monkeys (M. fascicularis) with radiofrequency lesions of the medial thalamus instituted under visual guidance comprised the experimental group. Two monkeys in the control group of 5 sustained the transcallosal approach surgery.

Pattern Set I (learned preoperatively) consisted of 3 pairs of stimuli, and Set II (learned postoperatively) of 4 pairs. The discriminanda were geometric figures or letters mounted on plaques. Each pattern pair was learned individually to a criterion of no more than 3 errors in 3 consecutive 10-trial blocks. The discriminanda and the procedure encountered in the two training periods were thus similar. Moreover, exposure to Sets I and II was separated by nearly 2 years and a lengthy series of other tasks based on the non-matching principle.

The number of trials required for acquisition of Set I preoperatively did not differentiate the two groups (t_{20} = .92, $p > .10$). Normal monkeys learned the second problem set more rapidly than the first (t_{31} = 2.15, $p < .025$). However for the experimental subjects, the mean acquisition score for Set II did not differ from Set I (t_{18} = 1.06, $p > .10$). In addition, they were significantly impaired in the acquisition of Set II when compared with normal monkeys learning Set II (t_{29} = 3.46, $p < .005$).

The results provide further evidence that the impairment sustained by monkeys with medial thalamic lesions is not restricted to the time course exemplified by the recognition memory task, but also extends into the domain of associative learning. Whether the deficits revealed by these two task types are dissociable, or have a common underlying cause is a question that requires further analysis. (Supported by VA Medical Research funds).

310.18 THIAMINE DEFICIENCY IN THE RAT PRODUCES BILATERALLY SYMMETRICAL LESIONS OF MEDIAL THALAMUS AND IMPAIRS ACQUISITION OF AVERSIVELY CONDITIONED BEHAVIOR. R.L. Knoth, T.A. Otto, T.P. Goodness*, R.G. Mair. Psychology Department, University of New Hampshire, Durham, NH. P.J. Langlais. VA Medical Center, Brockton, MA.

A subacute bout of thiamine deficiency in the rat (pyrithiamine [0.5 mg/kg/day] + thiamine deficient diet) produces consistent medial thalamic lesions in the region of the intralaminar nuclei (examined in one hemisphere only) and significant alterations in the concentrations of brain monoamine and aminoacid neurotransmitters (BRAIN RES, in press; P.J. Langlais, et al., this meeting). Behavioral tests of these animals revealed a long lasting impairment in some appetively motivated tasks (spatial delayed alternation, spatial delayed non-matching-to-sample) but no impairment in others (light/dark discrimination) (BRAIN RES 360, 273-284; NEUROSCI ABST 12, 745). The purpose of the present experiments was to extend the neuropathological findings in PTD animals and to assess the behavioral deficits in tasks employing aversive motivation.

In this study, 8 post-thiamine deficient (PTD) rats were compared with 8 controls in a variety of aversively conditioned tasks: one way escape, one way active avoidance, spatial non-match-to-sample escape, and in a series of habit learning tasks (see below). Although PTD rats exhibited escape latencies comparable to controls after three training sessions, they exhibited a consistent and significant impairment of avoidance responses throughout four training sessions. In the non-match-to-sample escape task, controls improved from 54% correct in the first 24 trials to errorless performance after 120 trials. The PTD group performed significantly worse, improving from 54% to only 77% correct after 120 trials and showed no further improvement over 72 additional training trials. PTD rats were also impaired on a left-right discrimination escape task but were equivalent to controls on all other habit learning measures (spatial reversal, light/dark discrimnation; 24 hr. savings on spatial, spatial reversal, and light/dark tasks). These results are consistent with those obtained using appetitive motivation. Histopathological analyses of behaviorally impaired animals showed consistent bilaterally symmetrical lesions in medial thalamus involving ventral portions of the mediodorsal, as well as the entire extent of central median, paracentral, and central lateral nuclei.

These results, together with those cited above, suggest that PTD animals are unimpaired on tasks requiring only "procedural" types of memory but show consistent deficits on both appetitively and aversively conditioned tasks requiring "declarative" types of memory. The results also demonstrate the bilateral nature of the thalamic lesions associated with post thiamine deficiency.

310.19 APPETITIVELY-MOTIVATED BRIGHTNESS AND SPATIAL DISCRIMINATION LEARNING ARE IMPAIRED FOLLOWING LESIONS OF THE N.BASALIS IN RATS. A.C. Santucci*, V. Haroutunian, and K.L. Davis (SPON:V. Guanowsky). The Mount Sinai Sch. of Med., New York, N.Y. 10029.

Lesions of nucleus basalis of Meynert (nbM) in rats produce learning and memory deficits on aversively and appetitively motivated tasks. In general, lesion-induced learning and memory deficits have not been assessed on different tasks in identically-lesioned animals, nor have lesioned rats been challenged by reversal paradigms. Accordingly, the present study examined whether lesions of the nbM would impair original and reversal learning of a brightness (Expt. 1) or complex spatial (Expt. 2) discrimination.

Both experiments employed male adult rats which received either bilateral ibotenic acid (5 ug in 1 ul/side) lesions of the nbM or sham operations. In Expt.1, animals were required to approach the "dim" arm of a Y-maze in order to receive water reinforcement. Entrance into the incorrect arm, stem, or correct arm without drinking was scored as an error. Training (1 trial/day) continued until a criterion of 4 out of 5 consecutive errorless days was reached. After reaching acquisition criterion, reversal procedures were implemented by reinforcing "bright" arm choices (criterion=4/5 errorless days). In Expt. 2, subjects were trained on a complex spatial discrimination identical to the one employed by Murray & Fibiger (Behav. Neurosci., 100, 23, 1986) for six consecutive days (1 trial/day). Animals were required to find a receptacle containing saccharine-flavored water located among a 6x5 array of receptacles. An error was recorded when an animal searched an unbaited receptacle. For some animals, reversal training followed.

Lesioned animals were severely impaired on the acquisition ($p<.01$) and reversal ($p<.02$) of the brightness discrimination task, often failing to reach reversal criterion. Lesioned rats were similarly impaired on the complex spatial task. Although both lesioned and sham operated groups made an equivalent number of errors during the first two days of training ($ps>.10$), controls continued to improve on subsequent days, whereas lesioned subjects did not ($ps<.05$). These data extend the generality of nbM-lesion learning deficits and show that lesion-induced learning deficits persist despite extensive training and prolong post-lesion survival times.

310.20 RADIAL MAZE PERFORMACE IN AN ANIMAL MODEL OF STATUS EPILEPTICUS. R.M. Sapolsky, B.T. Volpe and H.P. Davis (Spon: F.McDowell). Dept. Biol. Sci., Stanford Univ., Stanford, CA 94305, Cornell Univ. Med.Coll., and Univ. Colorado.

Severe epilepsy in both humans and animal models can eventually injure neurons. The hippocampus which plays a critical role in learning and memory is among the most vulnerable of brain regions to seizure induced neurotoxicity. Our recent work has uncovered endocrine and metabolic manipulations which substantially decrease hippocampal damage in a rat model of epilepsy. Naturally, it is of interest to determine whether such interventions reduce functional as well as neuropathological consequences of epilepsy. Thus, we have developed an animal model of the effects of status epilepticus upon hippocampal dependent behavior. Male Sprague Dawley rats were injected every third day with kainic acid (10mg/kg ip) for 15 days. Kainic acid, a glutamate analogue, produces status epilepticus seizures which share a number of traits with human temporal lobe epilepsy including paroxysmal discharge originating in the hippocampus and preferential damage to hippocampal CA3 neurons. In order to characterize the behavioral impairment in these animals after seizure, we used a 12-arm radial maze to examine their performance for memory of trial specific information (working memory) and trial independent information (reference memory). After three weeks of recovery, animals with seizure treatment (N=12) and control animals (N=32) were adapted to the maze for three days, placed on a food deprivation schedule that maintained them at 80% of ad lib weight, and then given a daily training trial for 32 days. Seven of the 12 arms were baited with food pellets and the baited arms remained constant relative to room cues throughout the experiment. Entry into a baited arm was considered a correct response, entry into a nonbaited arm a reference error, and reentry of an arm a working error. Both control and seizure rats improved on reference and working performance over trials ($p,<.001$), and there was no significant interaction between condition and trials ($p>.25$). However, seizure animals were significantly impaired compared to control animals on reference ($p<.001$) and working performance ($p<.001$). Thus, the behavioral impairment of seizure animals for both reference and working performance remained constant relative to control rats throughout behavioral testing. This preliminary study extends the assessment of this animal model of status epilepticus to behavior. Additionally, this initial behavioral characterization provides a paradigm for assessing whether pharmacological interventions which have been shown to reduce the neuropatholotical consequences of seizures will also reduce the behavioral sequelae of seizures.

311.1 LOCALIZATION OF SEROTONIN 5-HT_{1B} BINDING SITES: EFFECTS OF NEURONAL LESIONS. E. Edwards, P.M. Whitaker-Azmitia and E.C. Azmitia. Dept. Psychiatry, SUNY at Stony Brook, NY 11794 and Dept. Biology, New York University, NY 10003.

We have recently demonstrated by binding and competition studies that ^{125}Iodo-cyanopindolol ((±) ^{125}I-CYP) labels a 5-HT_{1B} site in the rat hippocampus (Neuropharmacology 26(1), 1987). The present experiments were devised to gain some information about the cellular localization of this site by examining the effect of various types of neuronal lesions on the binding of (± ^{125}I-CYP) to rat hippocampal membranes.

The selective degeneration of serotonergic neurons two weeks after an injection of 5,7 dihydroxytryptamine in the fornix-fimbria region (5 μg in 400 nl of .025% ascorbic saline; 15° angle from the vertical line, coordinates in mm: P 6.7, L 1.0, V 4.5 to bregma) was associated with a significant decrease in ^{3}H-serotonin uptake (-70%) and a loss of 5-HT_{1B} binding sites to the hippocampus (-37%).

The possible localization of 5-HT_{1B} sites on cholinergic projections in the hippocampus was examined by assessing the effect after nine days of unilateral kainic acid lesions in the septum and substantia innominata region (1 μg kainic acid in 0.9% saline; coordinates in mm: A 6.5, L 2.3, V 2.0 to lambda). Choline acetyl transferase (ChAT) activity was decreased by 76% in the hippocampus but no significant decrease in ^{125}I-CYP binding was observed.

We have also examined the effect of a kainic acid injection in the dorsal hippocampus (0.5 μl, 4 mg/ml in 0.9% saline; 90° angle to skull, coordinates in mm: A 4.5, L 1.5, V 3.7 to lambda). Nine days after lesions, the destruction of hippocampal intrinsic neurons was evident with a significant loss of 5-HT_{1B} binding sites in the hippocampus (-73%).

We conclude from these experiments that the 5-HT_{1B} sites in hippocampus, labeled by ^{125}I-CYP, occur both pre- and post-synaptically. Approximately one-third of these sites occur on serotonergic terminals and the remainder on neurons or astroglia intrinsic to the hippocampus.

311.2 ANALYSIS OF SEROTONERGIC RECEPTOR SUBTYPES IN AUTONOMIC REGIONS OF THE RAT MEDULLA USING QUANTITATIVE AUTORADIOGRAPHIC TECHNIQUES. K.B. Thor, A. Blitz*, and C.J. Helke. Dept. Pharm., Uniformed Services Univ., Bethesda, MD 20814

The nucleus tractus solitarius (NTS), as well as parasympathetic efferent nuclei in the medulla, contain high levels of serotonin (5HT). Furthermore, injections of 5HT drugs into these regions can change autonomic function. The present study was conducted to determine the distribution of 5HT receptor subtypes associated with these regions.

Adult male rats were killed by decapitation. Frozen sections (20μm) were mounted on slides and incubated in buffered solutions of ^{3}H-5HT (5 nM) to label 5HT_1 sites, ^{3}H-8OH-dipropyl-aminotetraline (^{3}H-8OHDPAT, 2 nM) to label 5HT_{1A} sites, ^{125}I-cyanopindolol (^{125}ICYP, 50 pM) with 30 μM isoprenaline (ISOP) to label 5HT_{1B} sites, and ^{125}I-lysergic acid diethylamide (^{125}I-LSD, 1 nM) with 1 μM domperidone (DOMP) to label 5HT_2 sites. Nonspecific binding of 5HT_1 ligands was assessed by adding 1 μM 5HT to incubation buffers, while nonspecific binding of ^{125}I-LSD was assessed by adding 10 μM ketanserin to incubation buffers. Blocking experiments were conducted by adding 1 μM cold 8OHDPAT, 10 μM propranolol (PROP), or 10 μM chlorimipramine (CMI) to incubation buffers. Slides were apposed to ^{3}H-sensitive Ultrafilm for 2-5 days (^{125}I compounds) or 3-6 months (^{3}H compounds). Sections were scraped from slides and radioactivity measured directly with scintillation or gamma counters.

^{3}H-5HT binding in medullary sections was saturable, and >85% of the total binding at a concentration of 5 nM was specific. Since 20-35% of the specific ^{3}H-5HT binding was CMI sensitive, it was included in incubation buffers. Blocking experiments with 8OHDPAT and PROP indicated specific ^{3}H-5HT binding was to the 5HT_{1A} (30%) and 5HT_{1B} (60%) receptors. ^{3}H-5HT binding was high in NTS, dorsal motor nucleus of the vagus nerve (DVN), and hypoglossal nucleus (HN). Nucleus ambiguous (NA) exhibitted an abscence of binding. Because CMI reduced specific ^{3}H-8OHDPAT binding 40-50%, it was included in the incubation buffer. 80% of the remaining ^{3}H-8OHDPAT binding was specific for 5HT_{1A} binding sites. Autoradiographs of ^{3}H-8OHDPAT binding will be presented. 66% of the ^{125}I-CYP binding was specific for 5HT_{1B} sites. Specific ^{125}I-CYP binding was high in the NTS, DVN, and HN. NA showed an abscence of binding. Nonspecific binding was high in the HN, and the 7th motor nucleus. Only 33% of the ^{125}I-LSD binding was specific for 5HT_2 sites and was primarily associated with the inferior olives.

These results indicate that 5HT_1 binding sites are present in the NTS and DVN, while few are in NA. Furtheremore, 5HT_{1A} and 5HT_{1B} sites appear in a ratio 1:2. 5HT_2 sites are few in all autonomic portions of the medulla. Support: NS20991 and MD. AHA

311.3 DIFFERENCES BETWEEN THE IN VIVO DISTRIBUTION OF ^{3}H-IMIPRAMINE IN BRAIN WITH THE TOPOGRAPHY OF ^{3}H-IMIPRAMINE BINDING TO BRAIN SECTIONS IN VITRO. G.E. Duncan*, I.A. Paul,* G.R. Breese, and W.E. Stumpf. Dept. of Anatomy and Biol. Sci. Res. Center, Univ. of North Carolina, Chapel Hill, NC 27514.

We have applied high resolution autoradiographic techniques to examine ^{3}H-imipramine binding in vivo and in vitro. For the in vivo study, rats were implanted with chronic jugular catheters. Three to 5 days after surgery, the rats were injected via the catheter with ^{3}H-imipramine (2 μCi/g body weight) and killed 1 hr later. Four micron cryostat sections were thaw-mounted on Kodak NTB-3 nuclear emulsion coated slides to produce autoradiograms. For in vitro binding, 4 micron cryostat sections of brain were thaw-mounted on coverslips, incubated in 5 or 10 nM ^{3}H-imipramine, and apposed to NTB-3 nuclear emulsion coated slides. The neuroanatomical topography of ^{3}H-imipramine binding in vitro was identical to that reported by others. Striking differences were observed in the patterns of ^{3}H-imipramine binding in vitro, compared to in vivo. Some brain regions that exhibited very high binding of ^{3}H-imipramine in vitro displayed low binding in vivo. Among such regions are the molecular layer of the dentate gyrus, central grey, and caudate putamen. In other regions, such as the striatum radiatum of the hippocampus and basolateral nucleus of the amygdala, binding of ^{3}H-imipramine was high both in vivo and in vitro. Low delivery of ^{3}H-imipramine in vivo does not explain the differences observed compared to in vitro binding, since high levels of ^{3}H-imipramine occur in all brain regions 5 min after i.v. injection of the compound. It is unlikely that metabolism of ^{3}H-imipramine in vivo accounts for the observed differences. Relatively higher binding in vivo, compared to in vitro would be expected if the radioactivity in brain in vivo represents a metabolite of ^{3}H-imipramine. Endogenous compounds have been extracted from brain that compete for ^{3}H-imipramine binding in brain homogenates. The highest concentrations of these compounds were found in regions (Barbaccia et al., Eur. J. Pharmacol. 123:45), where we find large differences between the in vivo and in vitro conditions . We are currently examining the possibility that the low binding of ^{3}H-imipramine in certain brain regions in vivo, relative to in vitro, is due to endogenous compounds competing for ^{3}H-imipramine binding sites in vivo. Supported by USPHS Grants MH-36294, HD-03110 and NS-09914.

311.4 DIFFERENT CATECHOLAMINE TURNOVER RATES IN STRIATAL COMPLEX IN THE PRESENCE OF REMOXIPRIDE. L.D. Loopuijt* and J.B. Sebens* (SPON:ENA) Dept. Biological Psychiatry, Psychiatric Clinic, Oostersingel 59, 9713 EZ Groningen, the Netherlands.

The striatal complex can be considered as an entity, but is a heterogeneous structure, in which the dopaminergic afferents from the substantia nigra and ventral tegmental area are fitting into the striatal mosaic. In addition, different types of dopaminergic fibers have been described on the ground of morphological criteria (Fuxe et al., Acta Pharm. Suppl. 1983, pp 60-79; Gerfen, Neurosci. Abstr.10,1984,9). Recently, the dopamine D2 receptor antagonist remoxipride has been shown to decrease the turnover of dopamine in a subpopulation of dopaminergic fibers (Fuxe et al. In: Recent Developments in Parkinsons Disease, Raven Press 1986, pp 17-32). Thi prompted us to study the location of the dopaminergic fibers with slow dopamine turnover in the presence of remoxipride. As a marker for the anatomical heterogeneity of the striatal complex was chose acetylcholinesterase (ACHE) histochemistry.

17 days old rats or adult male rats were injected with the tyrosine hydroxylase inhibitor alpha-methyl-DL-p-tyrosine /aMPT) or remoxipride plus aMPT (Astra, Sweden) and sacrificed 2 h later by decapitation, after freezing the brain, sections were cut and subsequently subjected to a procedure for catecholamine fluorescence (de la Torre, J. Neurosci. Meth.3(1980)1-5 or, alternatively, ACHE histochemistry (Geneser-Jensen and Blackstad, Z.Zellforsch. 114 (1971)460-481).

In 17 days old rats, 2 h after injection of remoxipride plus aMPT, fluorescence intensity is high in the mediodorsal part of the nucleus accumbens, at the dorsal end of the major island of Calleja and at the medial rim of the caudate, adjacent to the lateral ventricle. The rest of the caudate-putamen or nucleus accumbens does not show fluorescence above background level. In adult rats, in the nucleus accumbens, its mediodorsal part plus a small area dorsal to the major island of Calleja shows fluorescence. In the entire caudate-putamen fluorescence is above background level, but the intensity is non-homogeneous, being highest in the medial rim of the caudate and in discrete areas in the medial caudate. Comparison of the patterns of fluorescence with ACHE staining show that intense fluorescence coincides with low ACHE staining; in adult animals this includes striosomes.

So, under the conditions used, two populations of catecholaminergic fibers can be shown, which differ in catecholamine turnover rate. Fibers with slow turnover rates are located in areas that do not receive afferents from the motor cortex, but from the prelimbic cortex (striosomes; Donoghue and Herkenham, Brain Res.365 (1986)397-403) or hippocampus (dorsomedial nucleus accumbens; Kelley and Domesick, Neurosci. 7(1982) 2321-2335).

311.5 DIVERGENT PROJECTIONS OF NORADRENERGIC CELLS OF THE A7 GROUP TO THE MOTOR NUCLEUS OF THE TRIGEMINAL NERVE AND THE SPINAL CORD. W.E. Lyons* and R. Grzanna. Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Cells of the A7 group are the principal source of the noradrenergic (NA) innervation of the motor nucleus of the trigeminal nerve (MoV). We have previously shown that approximately 40% of the cells in the A7 group project to MoV and that more half project to the spinal cord. The present study was conducted to determine whether NA projections to MoV and the spinal cord originate from the same or separate populations of A7 cells. Rhodamine (Rh) labeled latex beads and True Blue (TB) were used as retrograde tracer in combination with immunohistochemistry of NA neurons. Rh-labeled beads were injected into MoV and TB was injected into low thoracic segments of the spinal cord of rats. Following a two week survival period, brainstem sections were processed for immunohistochemistry using antibodies to dopamine-beta-hydroxylase (DBH), a marker protein of NA neurons. NA neurons were visualized by the indirect immunofluorescence method using fluoresceinisothiocyanate (FITC) as label. Sections were viewed in the fluorescence microscope using different filter combinations for TB, Rh and FITC. NA cells and retrogradely labeled NA cells were mapped using a computer assisted fluorescence microscope. The position of each Rh and TB labeled NA cell in the A7 group was recorded and the percentage of NA cells containing both retrograde tracers was determined. Since the NA projection to MoV is strictly unilateral, only A7 cells ipsilateral to the injection site were mapped. Following tracer injections into MoV and spinal cord, 47% of the ipsilateral A7 cells contained Rh and 60% contained TB; 26% of the A7 cells did not contain any tracer. The most striking finding of this study was that 71% of Rh-labeled A7 cells also contained TB and that 55% of TB filled A7 neurons contained Rh.

The results of this retrograde transport study demonstrate that divergent projections to brainstem and spinal cord are a prominent anatomic feature of A7 cells. Although the exact site of termination of descending A7 cell axons remains to be determined, one might predict that collaterals of A7 cell axons which innervate motoneurons in MoV terminate on motoneurons in the spinal cord. We propose that A7 cells have widespread projections to spatially separate but functionally similar populations of neurons at different levels of the neuraxis. (Support: NIH grants MH 41977 and NS 16654).

311.6 QUANTIFICATION OF REGIONAL AND LAMINAR DENSITIES OF THE NORADRENALINE INNERVATION IN ADULT RAT CEREBRAL CORTEX. M.A. Audet, G. Doucet, S. Oleskevich and L. Descarries (SPON: J. de Champlain). Centre de recherche en sciences neurologiques (Dép. physiologie), Université de Montréal, Montréal, (Québec), Canada H3C 3J7.

To quantify noradrenaline (NA) innervation density in adult rat cerebral cortex, we have applied an improved method for the radioautographic visualization of these axonal varicosities in semi-thin sections of whole brain hemisphere (Doucet, G . and Descarries, L., 1984, Soc. Neurosci. Abstr. 10: 422). Brain slices (200 µm-thick) were incubated with 1 µM [^{3}H]NA in the presence of a monoamine oxidase inhibitor (10 µM pargyline) and of an inhibitor of catecholamine uptake by dopamine neurons (10 µM benztropine (BZ) or 5 µM GBR-12909 (GBR)). Control incubations were carried out with no uptake inhibitor and in the presence of the NA uptake blocker, desipramine (DMI, 5 µM), with or without BZ or GBR. The slices were fixed with glutaraldehyde and osmium, dehydrated, embedded in Epon and radioautographed as 4 µm-thick sections. NA axonal varicosities, detected as small silver grain aggregates, were numbered with the aid of a computer-based image analysis system (Dapple ImagePlus+). Comparison with control conditions indicated that, in the presence of BZ or GBR, NA varicosities were specifically labeled, and that neither BZ nor GBR reduced their number (paired t-test). In order to estimate the total number of NA varicosities per mm^3 of cortical tissue, correcting factors for incomplete detection at the chosen section thickness and exposure times were determined experimentally, and the average diameter of the labeled profiles was measured by electron microscope radioautography. Counts were then obtained across cortical areas Cg3 and AID at the transverse level A-11.7 mm (interaural), and Cg2, Pr1, Par1, AID and Pir at level A-9.7 mm (Zilles stereotaxic atlas, 1985). The mean regional density of cortical NA innervation (± s.d.) amounted to 1.2 ± 0.2 x 10^6 varicosities per mm^3 without significant difference between these cortical regions (one-way ANOVA). The laminar distribution also showed only minimal variations between regions. Laminar density was always the highest in layer I, with a mean of 1.46 ± 0.2 x 10^6 per mm^3, and showed a slight decreasing gradient towards deeper layers, with 0.96 ± 0.1 x 10^6 per mm^3 in the intermediate layers and 0.53 ± 0.1 x 10^6 per mm^3 in the deepest portion of layer VI. These data indicate that the NA innervation of cerebral cortex is significantly denser than was previously estimated (Lapierre, Y. et al., 1973, Brain Res. 63: 175), and substantiate the rather uniform regional and laminar distributions of these nerve terminals. (Supported by FRSQ and MRC grant MT-3544).

311.7 EPINEPHRINE IN RAT CORPUS STRIATUM: IN VIVO MICRODIALYSIS AND HPLC ANALYSIS. J.L. Baird*, S.D. Glick, J.N. Carlson and K.L. Drew (SPON: L.B. Hough). Department of Pharmacology and Toxicology, Albany Medical College, Albany, New York 12208.

While a high density of B adrenergic receptors has been demonstrated in the rat corpus striata, the presence of epinephrine in this brain region has not been reported. We now report, for the first time, the presence of epinephrine in rat corpus striatum.

In vivo microdialysis has become a powerful tool in the neurochemical analysis of discrete brain regions. In this study bilateral probes were inserted into the corpus striatum using the following coordinates (Pellergrino et al., 1979): anterior, +2.2 (from bregma) and lateral, ±3.0. The probes were lowered to a dorsoventral position of -4.0 (from dura) and the dialysate was recovered from -4.0 to -6.0. Samples were analyzed by reverse phase HPLC on the ESA Coulechem with a model 5011 detector cell. Baseline epinephrine concentrations (N=20) were approximately 50% of baseline dopamine concentrations.

Epinephrine was also assayed in striatal homogenates. The samples were analyzed by reverse phase HPLC on the BAS LC 48 electrochemical detector. Once again peaks corresponding to those of epinephrine were identified; epinephrine concentrations were 36.1±2.9 nmol/gram tissue weight (mean ± SE; N=8), or about 0.3% of dopamine concentrations. These whole tissue homogenates were then spiked with an epinephrine standard and the peak previously identified as epinephrine was increased in peak height and area corresponding to the concentration of epinephrine added. We are currently pursuing the functional role of epinephrine in this brain region. The relatively greater levels of epinephrine in dialysates, compared to homogenates, suggest that epinephrine may be released from a highly active neuronal system. (Supported by NIDA grant DA03817.)

311.8 LOCALIZATION OF ALPHA-2 ADRENORECEPTORS IN THE RAT CNS WITH THE SELECTIVE ANTAGONISTS, [3H]-YOHIMBINE AND [3H]-IDAZOXAN. M. Madar*, D. Bylund, J. P. Yezuita*, J. K. Wamsley (SPON: A. S. Unis) Depts. of Pharm. and Tox. and Psych., Univ. of Utah, Sch. of Med., SLC, UT 84132, and Dept. of Pharm., Univ. of Missouri Columbia, MO 65212.

Alpha adrenoreceptors have been subclassified according to their pharmacological selectivity for agonists and antagonists irrespective of their anatomical localization. There is established evidence for the existence of alpha-1 and alpha-2 adrenergic receptor sites. Distribution of alpha-2 adrenoreceptors has been defined using only the alpha-2 agonist, para-aminoclonidine. Since tritiated agonists appear to preferentially label a high affinity guanine nucleotide sensitive alpha-2 receptor site, use of these ligands may provide only a partial assessment of the entire alpha-2 receptor population. Anatomic localization of these receptors using [3H]-Yohimbine and [3H]-Idazoxan, two selective alpha-2 antagonists, will define both the high and low affinity alpha-2 adrenoreceptors.

The binding characteristics of the selective alpha-2 antagonists have previously been established under less than optimal conditions. After extensive trial and error we determined what appear to be the optimal binding parameters for both [3H]-Yohimbine and [3H]-Idazoxan. Use of a glycylglycine buffer (25mM, pH 7.6) and a 2nM concentration of each drug provided a specific to nonspecific (signal to noise) ratio of 75-90%, with specific binding defined as that inhibited in the presence of 300uM phentolamine. Results of the experiments for both ligands indicate that a 25mM glycylglycine buffer (pH 7.6), devoid of any additional ionic compounds, optimizes the binding of both ligands. From our experiments it was clearly demonstrated that divalent and monovalent cations have a pronounced effect on the specific binding of these radioligands. Equally profound alterations of specific binding were also seen with slight pH changes.

It is now possible to localize the alpha-2 adrenoreceptors using the two antagonists by autoradiographic techniques. The distribution of alpha-2 receptors, as reported by Unnerstall, using [3H]-Para-aminoclonidine, were found in areas innervated by norepinephrine and epinephrine containing neurons as well as in discrete areas of the brain where alpha-2 agonists have been shown to elicit an effect. Qualitatively, the initial experiments correlate well with the regional distribution of alpha-2 adrenergic receptors as defined by [3H]-Para-aminoclonidine. Quantitatively, however, subtle differences were noted in the density and distribution of alpha-2 sites, presumably due to labeling of the low affinity sites.

311.9 **QUANTITATIVE AUTORADIOGRAPHY OF SUBTYPES OF β-ADRENERGIC RECEPTORS FOLLOWING ADMINISTRATION OF DESMETHYLIMIPRAMINE.** E. W. Johnson, B. B. Wolfe and P. B. Molinoff. Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104-6084.

Antidepressant drugs are thought to exert their effects through modulation of the noradrenergic innervation of the CNS. Adult male rats were treated with desmethylimipramine (DMI; 10mg/kg twice daily), a tricyclic antidepressant that blocks the neuronal reuptake of norepinephrine. Animals were sacrificed after 14 days and the brains sectioned for autoradiography to measure the densities of β_1- and β_2-adrenergic receptors. Receptors were labeled with ^{125}I-iodopindolol (^{125}I-IPIN). Specific binding to total β-adrenergic receptors was the binding of ^{125}I-IPIN minus nonspecific binding defined in the presence of 100 μM l-isoproterenol. Binding to β_1-adrenergic receptors was defined as binding of ^{125}I-IPIN in the presence of 11 nM ICI 118,551, a β_2-selective antagonist, minus nonspecific binding. Binding to β_2-adrenergic receptors was defined as binding of ^{125}I-IPIN in the presence of 12 nM ICI 89,406, a β_1-selective antagonist, minus nonspecific binding. Decreases in the density of β-adrenergic receptors were observed in a number of cortical regions. The density of β_1-adrenergic receptors was decreased in the motor and somatosensory cortices while the density of β_2-adrenergic receptors did not change in those regions. The densities of both β_1- and β_2-adrenergic receptors decreased in the lateral and medial septal nuclei. There was no change in the density of either subtype in the dorsolateral caudate putamen following chronic treatment with DMI. These findings support the idea that the subtypes of the β-adrenergic receptor are independently regulated in the rat CNS. The observation that administration of DMI results in changes in the density of β_2-adrenergic receptors in some areas of the rat CNS suggests that these receptors receive a functional neuronal input. (Supported by USPHS Grant GM 34781.)

311.10 CHARACTERIZATION OF A NORADRENERGIC PATHWAY FROM THE DORSOMEDIAL MEDULLA (A2) TO THE HYPOTHALAMIC SUPRAOPTIC NUCLEUS (SON) IN THE RAT. Wilfrid Noel Raby and Leo P. Renaud, Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Quebec, H3G 1A4.

The SON contains both vasopressin (VP) and oxytocin (OXY) synthesizing neurons. This nucleus receives a catecholaminergic input from the A1 noradrenergic cells in the ventrolateral medulla (Sawchenko and Swanson, Brain Res Rev, 4:275, 1982), which selectively excites VP cells (Day and Renaud, Brain Res.,303: 233, 1984). Anatomical tracer studies (e.g. Tribollet et al., Neuroscience 15: 135, 1985) have reported that the A2 neurons in the dorsomedial medulla also project to SON. We now confirm that discrete SON injections of rhodamine labelled latex beads are transported retrogradely to approximately 10% of ipsilateral A2 catecholamine fluorescent cells, and a smaller number of contralateral A2 neurons.

The electrophysiology of this pathway was examined in pentobarbital anesthetized male Sprague-Dawley or Long-Evans rats. A transpharyngeal approach to the hypothalamus and brain stem allowed placement of a glass coated tungsten monopolar electrode in the dorsomedial medulla to activate A2 neurons (0.2 msec, < 150 microamps). A bipolar electrode in the neurohypophysis served to antidromically activate neurosecretory neurons. During recordings, VP cells were characterized by their phasic or continuous firing pattern, and a depression in activity when blood pressure was elevated by i.v. alpha-agonists; OXY cells fired in a continuous fashion, and remained unaffected by blood pressure elevation. Results indicate that 70% of both VP cells (n=40) and OXY cells (n=20) demonstrate a brief (30-50 msecs) increase in firing probability, (latency range: 50-75 msecs) following ipsilateral A2 stimulation. Similar responses were also noted after contralateral A2 stimulation.

These findings support the anatomical tracer studies and identify an excitatory A2 noradrenergic innervation of SON, distributed to both VP and OXY neurons. The neural information conveyed by this pathway may relate to cardiovascular, visceral, or osmotic homeostasis. (Supported by the MRC)

311.11 AN ULTRASTRUCTURAL CHARACTERIZATION OF A GABA-MEDIATED INPUT TO RAT SUPRAOPTIC NUCLEUS (SON) FROM THE DIAGONAL BAND OF BROCA (DB). J.H. Jhamandas, J. Rogers*, R.M. Buijs* and L.P. Renaud. Neurosciences Unit, The Montreal General Hospital and McGill Univ. Montreal, Quebec, Canada, H3G 1A4

Recent electrophysiological evidence suggests that γ-aminobutyric acid (GABA) may serve as an inhibitory neurotransmitter in a pathway from the DB that selectively depresses the excitability of the vasopressin (VP)-secreting neurons of the hypothalamic SON. The present study was conducted to ascertain the anatomical configuration of this input at the ultrastructural level using a combined horseradish peroxidase (HRP) and immunocytochemical approach.

Animals received an injection of 30% HRP in the DB. After survival (18-24 hrs), animals were perfused and fixed brains processed for HRP enzymatic activity using diaminobenzidine (DAB). Injection sites were verified at the light microscopic level and the distribution of the anterogradely labelled terminals in the region of the SON evaluated at the ultrastructural level. GABA-synthesizing terminals were identified by a post-embedding colloidal gold technique. Simultaneous localization of VP and GABA on DAB stained sections was obtained by a combined pre- and post-embedding immunocytochemical approach. HRP- and GABA-positive terminals were counted both within and outside the SON.

The greatest accumulation of HRP-labelled terminals was found in a region immediately dorsal to the SON (18,000 per mm^2). Substantially lower values (1200 per mm^2) were recorded within the SON. Terminals displaying GABA immunoreactivity were preferentially distributed within the SON and constituted two thirds of terminals contacting VP-immunopositive elements. GABA was seldom co-localized within HRP-labeled terminals either in the SON or the perinuclear area.

These observations indicate that the axons of DB coursing towards the SON terminate preferentially in the perinuclear zone. The lack of GABA immunoreactivity within these perinuclear terminals, but its presence in the SON suggests that a GABAergic inhibitory interneuron, located in the perinuclear area, is interposed in the pathway from DB to SON VP-secreting neurons. (Supported by MRC).

311.12 IN VIVO BINDING OF [^{3}H]HALOPERIDOL AND [^{3}H]d-SKF 10,047 IN MOUSE BRAIN. A.D. Weissman, E.P. Broussolle* and E.D. London. Neuropharm. Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224.

Quantitative autoradiographic studies of slide-mounted sections of guinea pig brain in other laboratories and ours have demonstrated specific labelling of sigma binding sites using [^{3}H]d-SKF 10,047 (SKF) and [^{3}H]haloperidol (HAL) as ligands (Largent, B.L. et al., J. Pharm Exp. Ther. 238:739 1986). As an extension of these experiments, we examined the regional in vivo specific binding of the same radioligands used in vitro.

Male ICR mice received an injection of tracer amounts of HAL or SKF via the tail vein (3 μCi/mouse). Total and nonspecific binding were determined in different mice which received s.c. injections of either saline or a combination of sigma and phencyclidine (PCP) receptor agonists or antagonists, respectively. HAL binding to sigma sites was assayed with spiperone to block binding of the ligand to D2 dopamine receptors and haloperidol or d-pentazocine to displace specific binding. Specific SKF binding to sigma sites was defined by displacement with N-(1-[2-thienyl]cyclohexyl)3,4-piperidine (TCP) and haloperidol. SKF binding to PCP sites was identified by displacement with TCP alone. The doses and the times of injection of these cold displacer drugs were selected from information about their behavioral effects, brain entry, metabolism and toxicity. The mice were killed by decapitation 30 min after injection of the radioligands. Brains were rapidly removed, and several regions dissected out, dissolved in hyamine hydroxide and counted by liquid scintillation spectroscopy.

Specific HAL binding to sigma sites was highest in the cerebellum, medulla-pons and midbrain. Specific binding in the thalamus, striatum and cortex was approximately half of that in the former regions, and was even lower in the hippocampus. A similiar distribution of in vivo sigma binding was obtained with SKF. In these experiments, the medulla-pons had the highest specific binding, but all other brain regions showed the same relative level as that seen with HAL. Specific binding of SKF to PCP receptors appeared to have a more uniform regional distribution in the brain in contrast to the results obtained with this ligand in vitro.

The results of this study demonstrate a similar pattern of regional sigma receptor binding in the mouse brain using either HAL or SKF, in agreement with in vitro data in several rodent species. In vivo specific binding of SKF to PCP receptors, however, does not show the regional distribution seen with in vitro studies, indicating that SKF may not be a satisfactory ligand to visualize PCP receptors in vivo.

311.13 CORTICAL LESIONS DECREASE BASAL AND AMPHETAMINE-INDUCED RELEASE OF ASCORBATE IN THE NEOSTRIATUM. Allison Basse-Tomusk and George V. Rebec. Dept. Psychol., Indiana Univ., Bloomington, IN 47405

The neostriatum contains very high levels of extracellular ascorbate (AA) that show marked circadian (O'Neill et al. (Neurosci. Lett, 42:105, 1983) and drug-induced changes (Kamata et al. Brain Res. 362:331, 1986). However, the source or sources of neostriatal AA release are unknown. O'Neill et al. (1983) have suggested that basal extracellular AA levels in the neostriatum are regulated by the corticostriate pathway since cortical lesions decrease extracellular AA levels by 80%. In the present experiment, we sought to determine whether the corticostriate pathway also is involved in amphetamine-induced AA release.

Adult, male rats received bilateral-suction lesions of the dorsal aspect of the neocortex from 1mm posterior to bregma to the frontal pole. Another group of animals received sham lesions in which only the dura was removed. Following an 8 to 10 day recovery period, basal and amphetamine-induced (2.0 mg/kg, i.v.) AA release were assessed with in vivo voltammetry using electrochemically-modified carbon fiber electrodes. These electrodes provide a voltammetric wave for AA that is resolved easily from that for catechols and all other electroactive species in the mammalian brain. Voltammetric scans, obtained at 2-min intervals, were displayed in a differential form.

Consistent with previous reports, cortical lesions decreased basal levels of AA by 80%. Furthermore, amphetamine-induced AA release also was reduced dramatically. These results suggest that the corticostriatal pathway plays a crucial role in the neuromodulatory actions of neostriatal AA.

Supported by NSF Grant BNS 84-16303 (GVR).

311.14 HALLUCINOGENS BIND TO COMMON RECEPTORS IN THE RAT FOREBRAIN: A COMPARATIVE STUDY USING ^{125}I-LSD AND ^{125}I-DOI, A NEW PSYCHOTOMIMETIC RADIOLIGAND. D. J. McKenna*[1], C. A. Mathis*[2], A. T. Shulgin*[2], & J. M. Saavedra[1] (SPON: N. Buckholtz). 1. Section on Clinical Pharmacology, Laboratory of Clinical Science, NIMH, Bethesda, MD 20892 2. Donner Laboratory, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.
