EFFECTS OF LOCAL INFUSION OF PHARMACOLOGICAL AGENTS ON TONIC ACTIVITY OF SUBSTANTIA NIGRA DOPAMINE NEURONS. J.H. Carlson and S.L. Foote. Dept. Psychiatry, Univ. Calif. San Diego, La Jolla, CA 92093.

Most electrophysiological studies of drug effects on substantia nigra (SN) dopamine (DA) neurons have used systemic or iontophoretic routes of administration; we have recorded from individual SN DA neurons while infusing small (25-150 nl) volumes of drugs at a distance of 0.3-0.4 mm. The major advantages of this method are that it permits local application without the possible artifacts of iontophoresis and affects a substantial yet selected population of neurons. The sites of action of drugs can be elucidated and the effects of pharmacologically altered DA cell activity on target areas can be analyzed. Extracellular activity of individual DA neurons was recorded with a metal microelectrode in halothane-anesthetized rats. The nonselective D-1/D-2 DA agonist apomorphine (APO) and the selective D-2 agonist LY 163502 (which was more potent) reduced and nicotine increased tonic discharge rates. Onset of these effects was 0.5-1.5 min after infusion. APO and LY 163502 could induce a complete cessation of neuronal activity, which began to recover within 1-2 min. Full recovery often required >1 hr. The duration of nicotine's effect was usually <10 min. Repeated infusions of APO or LY 163502 frequently led to desensitization to the effects of subsequent infusions or i.v. injections. These effects are compatible with previous findings using other routes of drug administration.

FAILURE OF ACUTE DIPHENYLHYDANTOIN (DPH) TO AFFECT DOPAMINE CELLS ACTIVITY. F. Marrosu*, G. Carcangiu*, M. Giagheddu* and G. Mereu. Lab. of Neurobiology, Univ. of Cagliari, Italy.

An incidence of extrapyramidal side effects (ESE) has recently been reported in epileptic patients under long-term treatment with the anticonvulsant DPH. Although the origin of these effects is unknown, their similarity to those produced by neuroleptics and the fact that chronic DPH produces in rats behavioural signs of hypersensitivity to dopamine (DA) agonists, have suggested that DPH would negatively interfere with DA receptors somehow mimicking the action of neuroleptics. To clearly evaluate this possibility DPH was tested in one of the most sensitive paradigm for DA receptors functionality within the basal ganglia, i.e. the spontaneous activity of mesencephalic DA and GABA cells. It was observed that DPH, at cumulative doses ranging from 1.0 to 40 mg/kg i.v., failed to modify the basal firing of DA cells as well as their response to DA agonists and antagonists. Therefore is unlikely that the reported ESE by DPH might be mediated by a direct inactivation of DA receptors. However the interference of chronic DPH on different neuronal systems remains to be detailed.

DOPAMINE (DA) AUTORECEPTOR (AR) INACTIVATION: COMPARISON OF IMPULSE-REGULATING AND SYNTHESIS-MODULATING ARs. M. Jeziorski, M.P. Galloway, and F.J. White, Dept. of Psychiatry, Wayne State Univ. Sch. Med., and NPRU and NPPL, Lafayette Clinic, Detroit, MI 48207.

The comparative effects of inactivation of a proportion of DA ARs by a moderate dose of the irreversible DA antagonist EEDQ (2 mg/kg) was examined for impulse-regulating somatodendritic (SD) ARs on mesolimbic (A10) DA cells and synthesis-modulating nerve terminal (NT) ARs on A10 and nigrostriatal (A9) DA cells. Extracellular single-unit recording methods in chloral hydrate-anesthetized rats revealed that neither EEDQ treatment nor repeated treatment with low (50 µg/kg) doses of the DA agonist apomorphine (APO; 2 x 7 days) altered the sensitivity of SD ARs to the inhibition caused by the D2 agonist quinpirole (QUIN) relative to control. Repeated APO combined with EEDQ did induce subsensitivity, providing evidence for the existence of spare SD ARs masking down-regulation. This was supported by the reduced sensitivity of SD ARs in APO-treated rats to the partial DA agonist (-)3-PPP. In contrast, studies of NT AR function, i.e. DOPA accumulation after treatment with the DOPA decarboxylase inhibitor NSD-1015, revealed decreased inhibition by NT ARs in EEDQ-treated rats. EEDQ also lowered the sensitivity of NT ARs to reversal by QUIN of GBL-induced DOPA elevations. These findings indicate differences between SD and NT ARs with respect to the effects of EEDQ and suggest a possible difference in the degree of receptor reserve for the two populations of ARs.

164.11

DOPAMINE NEURON ONTOGENY: ELECTROPHYSIOLOGICAL STUDIES. D.K. PITTS, A.S. FREEMAN and L.A. CHIODO. Lab. of Neurophysiology, Center for Cell Biology, Sinai Res. Inst., 6767 W. Outer Drive, Detroit, MI 48235.

The anatomy, physiology, biochemistry and pharmacology of dopamine (DA)-containing neurons have been extensively studied over the past two decades. Although the electrophysiological characteristics and neuropharmacology of single identified DA neurons have been reported by many investigators, such studies have not yet examined these neurons during postnatal development. Standard extracellular electrophysiological techniques were used to record from single antidromically-identified nigrostriatal DA neurons in rats at postnatal ages of 4 weeks (wk, n=10), 5wk (n =8) and > 7wk (n=11, adult) old. The mean baseline firing rate (spikes/sec) and conduction velocity (c.v., m/sec) for each group were as follows (baseline, c.v.): adult: 3.4 +/- 0.5, 0.54 +/- 0.03; 5wk: 3.0 +/- 0.5, 0.57 +/- .06; 4wk: 4.5 +/- 0.3, 0.58 +/- 0.04. The mean ED50 values (µg/kg, i.v.) for apomorphine cumulative dose-response (percent inhibition) curves were as follows: adult: 8.6 +/- 2.2; 5 wk: 14.0 +/- 3.6; 4 wk: *32.8 +/- 14.6 (* P<0.02, Mann-Whitney, 4 wk vs. adult). These results suggest that there is decreased somatodendritic autoreceptor function in 4wk old animals. Iontophoretic studies employing DA agonists will need to be conducted to confirm these findings. (MH41557-LAC.)

SEROTONERGIC AFFERENT REGULATION OF NIGROSTRIATAL DOPAMINE NEURONS. M.D. KELLAND, A.S. FREEMAN and L.A. CHIODO. Lab. of Neurophysiology, Center for Cell Biology, Sinai Res. Inst., Detroit, MI 48235.

We have begun to examine the influence exerted by serotonergic (5-HT) afferents from the dorsal raphe nucleus on the activity and pharmacological responsiveness of nigrostriatal dopamine (NSDA) neurons.

Lesions of 5-HT systems by 5,7-DHT or MDMA-induced reductions in 5-HT levels eliminate the rate-dependent nature of i.v. quinpirole-induced inhibition of NSDA neuronal firing, without affecting the responsiveness of these cells to quinpirole. 5,7-DHT appears to preferentially raise the quinpirole ED50 of more slowly firing NSDA neurons. In contrast, acute administration of 5-HT-1A selective compounds 8-OH-DPAT or 5-MeO-DMT preferentially excite slow NSDA cells, while failing to alter quinpirole-induced inhibition of NSDA neurons.

Sciatic nerve stimulation inhibits NSDA neurons (a response dependent upon intact 5-HT systems). We have preliminary evidence that the D1 selective agonist SKF 38393 both decreases the latency to this inhibition and increases its duration. The D1 antagonist SCH 23390, while having no effect on its own, reverses the SKF 38393-induced enhancement. Thus, a mechanism appears to exist which allows NSDA neurons not under tonic influence by sensory afferents to come under phasic control. (MH41557 [LAC], Sinai Res. Inst.).

164.13

Aging and Dopamine Electrophysiology. A.S. Freeman and L.A. Chiodo, Lab. of Neurophysiology, Center for Cell Biology, Sinai Research Institute, Detroit, MI 48235.

We have begun to examine the in vivo electrophysiology of DA neurons in rats of different age (3, 18, 24 mos). Overall A9 and A10 DA cell firing rates were examined as were the sensitivities of antidromically identified nigrostriatal DA (NSDA) cells to the inhibitory effects of i.v. apomorphine (APO) and d-amphetamine (AMP), and to iontophoretic DA. The incidence of spontaneously active DA cells was determined for the A9 and A10 regions with the cell/track sampling technique. The activities and DA agonist sensitivities of the DA neurons in the three age groups were remarkably similar. Mean A9 and A10 cell firing rates did not differ from each other and did not change with age. Dose-response profiles for APO and AMP on NSDA cells were not statistically different across ages. Similarly, the ability of iontophoretic DA to depress cell discharge was largely unchanged with age. Finally, the observed incidence of active A9 and A10 DA neurons did not change with age. Previous studies described reductions in DA receptors, levels and synthesis in rats by the age of 24 mos. Thus, apparently normal DA electrophysiological function is maintained in 24 mo. rats despite these biochemical changes. It is currently being determined whether this "compensatory maintenance" of activity erodes in still older rats or can be compromised by other drug challenges. (MH-43401-ASF.)

DISSOCIATION OF IDENTIFIED NIGROSTRIATAL DOPAMINE-CONTAINING NEURONS FROM ADULT RATS. L.A. Chiodo, Lab. Neurophysiology, Ctr Cell Biology, Sinai Res. Inst., Detroit, MI 48235.

Over the past few years, several groups have turned to a variety of in vitro preparations which contain mesencephalic dopamine (DA)-containing neurons in order to further characterize the active membrane properties of these cells. We have now established a protocol for the dissociation of identified nigrostriatal DA neurons from adult rats. In intact animals, it was observed that 24-48 hrs after the injection of rhodamine-conjugated microspheres into the head of the caudate nucleus, these beads were retrogradely transported and appeared in neurons concentrated primarily in the zona compacta subdivision of the substantia nigra. Over 95% of those neurons which were intensely labeled with microspheres were also tyrosine hydroxylase positive (as demonstrated with indirect immunocytochemical methods and employing the monoclonal antibody for this enzyme, LNC1). Using modifications of the dissociation procedure of Kay and Wong (J. Neuro. Meth. 16, 1986), we have been able to dissociate the zona compacta region of adult rats and recover individual nigrostriatal DA neurons (cells filled with microspheres). These cells remain viable and have been sampled electrophysiological using whole-cell patch recording techniques for up to 4 hrs. (Supported by MH41557)

165.1

REGIONAL EFFECTS OF PHARMACOLOGICAL REGULATION ON THE AFFINITY STATES OF THE D-1 RECEPTOR. Leslie M. Higuchi and Paul McGonigle. (SPON. S.J. Offord) Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

The affinity states of the D-1 receptor were examined by measuring inhibition of the binding of ^{3}H-SCH-23390 by dopamine. In sections of caudate putamen (CPu) mash from Sprague Dawley rats, competition curves in the absence of guanine nucleotide were markedly biphasic and the K_L to K_H ratio obtained from two-site analysis was greater than 1000. Corresponding competition curves measured in homogenates of CPu exhibited a K_L to K_H ratio of less than 100. In the presence of 300 μM GTP, dopamine competition curves were monophasic, confirming that the two components of binding resulted from agonist affinity states. Serial coronal sections containing CPu and nucleus accumbens (NAc) or substantia nigra (SN) were cut at a thickness of 20 μm. Dopamine competition curves were obtained from each region using autoradiography with care to avoid subregions that exhibit gradients of receptor density. The proportions of the affinity states were similar in all three regions, with 35% of the sites in the high affinity state and 65% in the low affinity state. The ratio of K_L to K_H was approximately 1000 in each region. To measure the effects of receptor regulation on the affinity states, animals received 12 daily injections (i.p.) of SCH-23390 (3 mg/kg) or vehicle. Chronic administration of SCH-23390 increased the density of D-1 receptors in the CPu (30%), NAc (35%) and the SN (50%). The proportion of high and low affinity states was unaffected by the increase in receptor density. In contrast, the ratio of K_L to K_H declined to 80 in the CPu and 110 in the NAc. (Supported by USPHS grant GM 34781)

165.2

DOPAMINE (DA) RECEPTOR OCCUPANCY BY DA AGONISTS AND ANTAGONISTS IN VIVO. C.F. Saller, L.D. Kreamer*, M.J. Czupryna* and A.I. Salama ICI Pharmaceuticals Group, ICI Americas Inc. Wilmington, DE 19897.

The occupation of D-1 and D-2 DA receptors by drugs was assessed by measuring their abilities to protect against DA receptor inactivation by N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ), an irreversible receptor modifying agent. Rats were pretreated with drugs and given EEDQ (10mg/kg, i.p.). Generally, drugs were given 30 min. before EEDQ. Twenty-four hr after EEDQ, the rats were decapitated and the numbers of D-1 and D-2 receptors in striatal membrane preparations were estimated using saturating concentrations of[^{3}H] SCH 23390 and [^{3}H] spiperone, respectively.

Both DA agonists and antagonists protected DA receptors from inactivation by EEDQ in a dose-dependent manner. SKF 38393, a selective D-1 agonist, and SCH 23390, a selective D-1 antagonist, protected D-1, but not D-2, DA receptors from inactivation. Conversely, quinpirole, a selective D-2 agonist and haloperidol, a D-2 antagonist, protected D-2 receptors. Likewise, chlorpromazine and several other neuroleptics protected only D-2 sites. Apomorphine, a mixed D-1/D-2 agonist, clozapine, an atypical antipsychotic, and D-butaclamol, a typical neuroleptic, were also active at both sites, but D-butaclamol was far more tightly bound to D-2 receptors than to D-1 receptors. Thus, EEDQ protection experiments provide a simple and reliable means of assessing DA receptor occupancy in vivo.

165.3

SPECIFIC [^{3}H]SCH23390 BINDING TO DOPAMINE D_1 RECEPTORS IN CEREBRAL CORTEX AND NEOSTRIATUM: ROLE OF DISULFIDE AND SULFHYDRYL BONDS. **K.M. Dewar, L. Grondin* and T.A. Reader.** Département de physiologie, Université de Montréal, Montréal, Québec, H3C 3J7, Canada.

Receptor binding studies were performed with membrane preparations from rat cerebral cortex (CTX) and neostriatum (CPU; caudate-putamen) using the dopamine D_1 antagonist [^{3}H]SCH23390. Pretreatment of the membranes with the thiol reactives DTE, L-DTT and DTNB as well as with the alkylating agent NEM produced dose-dependent decreases of specific [^{3}H]SCH23390 binding in CTX and CPU membrane preparations. These changes were not reversible after up to two washes, so that saturation curves could be performed with pretreated membranes in the absence of reactives. The alkylation of sulfhydryl (-SH) groups by NEM reduced the binding mainly through an affinity change while L-DTT and DTNB decreased the number of sites. In both regions the dopamine D_1 receptor requires the integrity of -SH bonds to maintain a high affinity of the receptor protein while disulfides (-SS-) are essential to keep the maximum binding capacity. Based on the stereospecificity of both enantiomers of the dopamine D_1 agonist SKF38393 and the sensitivity towards -SS- and -SH reactives, it can be concluded that [^{3}H]SCH23390 binds to receptor sites in the cerebral cortex and in the neostriatum that not only share pharmacological properties but also exhibit a similar molecular configuration. [Supported by the MRC and FRSQ].

165.4

BINDING OF PERMANENTLY CHARGED CHLORPROMAZINE ANALOGS TO THE STRIATAL D-1 DOPAMINE RECEPTOR. R.A. Wallace, L.J. Wallace*, M. Harrold*, D.D. Miller*, N.J. Uretsky. College of Pharmacy, The Ohio State University, Columbus, OH 43210.

The objective of these studies was to determine the role of the side chain amine group of chlorpromazine (CPZ) in binding to the D-1 dopamine (DA) receptor. Consequently, we synthesized and studied the abilities of structural analogs of CPZ to inhibit the binding of ^{3}H-SCH 23390, a D-1 selective receptor antagonist, to rat striatal membranes. CPZ, a trimethylammonium analog (CPZ-N^+) and a dimethylsulfonium analog (CPZ-S^+) of CPZ were all found to inhibit ^{3}H-SCH 23390 binding with the maximal inhibition being the same for the 3 compounds. The steep slopes of the inhibition curves suggested that all 3 compounds were binding to a single site. However, the potencies of the analogs were much less than that of CPZ. Thus, the apparent equilibrium binding dissociation constants (K_i's) were 6.2 ± 2.0 nM for CPZ, 2.75 ± 0.37 uM for CPZ-S^+ and 12.3 ± 1.6 uM for CPZ-N^+. These studies show that the nitrogen atom on the side chain of CPZ is not required for binding to the D-1 DA receptor and, in addition, that compounds containing a permanent positive charge can bind to this receptor. This latter observation is consistent with the presence of an anionic site on the striatal D-1 DA receptor and is similar to our previous findings on the binding of CPZ and its analogs to the striatal D-2 DA receptor.

PHOTOAFFINITY LABELLING OF AN APOMORPHINE BINDING PROTEIN FROM BOVINE STRIATUM. G.M. Ross, B.E. McCarry*, K. Gatermann* and R.K. Mishra. Depts. of Psychiatry and Neurosciences, and Dept. of Chemistry, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Apomorphine has several effects on the central nervous system thought to be mediated primarily through dopamine receptors. We report here the photoaffinity crosslinking of a 49 kDa apomorphine binding protein from bovine striatum with [^{125}I]-N-(4'-azido-2'-nitrobenzamidyl-propyl)2-amino-6-hydroxy-7-iodo-1,2,3,4-tetrahydronaphthalene. Incorporation of [^{125}I]ANB-AP-ATN is blocked by coincubation with apomorphine or N-propyl-norapomorphine (NPA); (-)NPA is more effective than (+)NPA in blocking incorporation, suggesting stereospecific requirements. Other dopaminergic ligands, including SKF-38393, SCH-23390, spiperone and LY-171555 (all 100 μM) were ineffective in blocking photolabel incorporation; the dopamine uptake blocker GBR 12909 and putative autoreceptor ligands (+)PPP and (-)PPP were also ineffective (100 μM). Other compounds (all at 100 μM) which failed to prevent covalent incorporation include serotonergic (metergoline and 5-HT), adrenergic (phentolamine and isoproterenol) and opiate (dipenorphine and etorphine) ligands. The functional significance of this protein is not currently understood.

165.6

POLYCLONAL ANTISERUM AGAINST THE DOPAMINE AGONIST ADTN AS A PROBE FOR DOPAMINE BINDING PROTEINS. A.J. Keukens*, G.M. Ross, B.E. McCarry*, L.K. Srivastava and R.K. Mishra (SPON:G. Madhavan). Depts. of Psychiatry and Neurosciences and Dept. of Chemistry, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

High affinity antibodies are useful for the isolation of antigens (e.g., ligands) from mixtures. In the case where such ligands are covalently attached to proteins, the use of antibodies against the ligand should facilitate the isolation and identification of that protein. For this study, antibodies against a derivative of the dopamine agonist 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydro-naphthalene (ADTN) were obtained as potential aids for the isolation of proteins crosslinked to photolabile ADTN derivatives. Rabbit polyclonal antiserum was raised against aminopropyl-ADTN (AP-ADTN) conjugated to bovine serum albumin; conjugation was achieved by using glutaraldehyde and $NaBH_4$, resulting in a ratio of 60 mol AP-ADTN per mol BSA. Reactivity of the polyclonal antiserum towards the hapten conjugate was established using an enzyme-linked-immunoabsorbent assay (ELISA). Antibody specificity was tested by measuring the ability of various aminotetralins to compete for AP-ADTN-G-rabbit serum albumin binding sites in the antiserum. High affinity antibodies against conjugated ADTN and its analogues were obtained. These are currently used to probe dopamine binding proteins crosslinked to ADTN derivatives. Supported by MRC Canada & OMHF

PROPERTIES OF CHOLATE-SOLUBILIZED DOPAMINE D_1 RECEPTOR. L.K. Srivastava, S.B. Bajwa*, G.M. Ross and R.K. Mishra. Neuropharmacology Lab., Depts. of Psychiatry and Neurosciences, McMaster Univ., Hamilton, Ont., Canada L8N 3Z5.

The dopamine D_1 receptor from bovine striatal membranes was solubilized with cholate-NaCl in the presence of phospholipids in a form sensitive to guanine nucleotides. The solubilized receptor was reconstituted into lipid vesicles by gel-filtration. The solubilized and reconstituted preparation binds [^{3}H]SCH-23390 to a homogeneous site in a saturable, stereospecific and reversible manner with a K_d (0.95 nM) and the B_{max} (930 fmol/mg protein) similar to that observed with the membrane-bound receptors. The competition curves of dopaminergic antagonists for [^{3}H]SCH-23390 binding were monophasic and exhibited a rank order of potency (SCH-23390)+ butaclamol)cis-flupenthixol)haloperidol)spiroperidol) which is clearly a D_1 dopaminergic order. The competition curves of agonists vs. antagonist fit best to a two-site model showing the following order of potency: SKF-82526)SKF-38393)NPA)ADTN)DA. The high affinity component of agonist binding showed requirement of Mg^{2+} ions while Gpp(NH)p, at 100 μM concentration, caused full conversion of high affinity agonist binding sites to the low affinity ones, suggesting that the solubilized receptor is coupled to a guanine nucleotide binding protein. The solubilization procedure described will aid in understanding the mechanisms of receptor-G-protein interactions and the purification of the receptor. (Supported by MRC and OMHF.)

COMPARISON OF MEMBRANE-ASSOCIATED AND DETERGENT-SOLUBILIZED BINDING SITES FOR ^{125}I-SCH-23982. T. Filtz*, R.R. Luedtke* and P.B. Molinoff. Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104-6084.

^{125}I-SCH-23982 is a high-affinity antagonist selective for the D_1 subtype of dopamine receptors. This radioligand has also been shown to label 5-HT_{1C} receptors in the choroid plexus. The rank order of potency for the inhibition of the binding of ^{125}I-SCH-23982 to membrane preparations of canine caudate by a panel of agonists and antagonists is consistent with the pharmacological specificity of the D_1 receptor. Competition curves for antagonists and agonists (in the presence of 100 μM GTP) fit best to a one-site model.

A polyethylene glycol precipitation binding assay was used to characterize binding sites for ^{125}I-SCH-23982 after extraction of membranes with 1% digitonin. Solubilized binding sites adsorbed to heparin-agarose and Q-Sepharose FF when applied in the absence of NaCl. In contrast to results of studies carried out with membranes, the data from inhibition experiments using solubilized preparations and ^{125}I-SCH-23982 consistently fit best to a two-site model for antagonists. A high-affinity site for 5-HT suggests that ^{125}I-SCH-23982 may bind to both D_1 and 5-HT_1 receptors in detergent-solubilized preparations. (Supported by the USPHS NS18591 and the Scottish Rite Research Program)

PHOTOAFFINITY LABELLING OF HUMAN BRAIN D2 DOPAMINE RECEPTORS IN SCHIZOPHRENIA, ALZHEIMER'S, PARKINSON'S & HUNTINGTON'S DISEASES. N.H. Bzowej*, H.B. Niznik and P. Seeman (Spon: L. Spero). **Department of Pharmacology, University of Toronto, Ontario, Canada, M5S 1A8.**

Considerable evidence exists to suggest abnormal brain dopamine transmission in schizophrenia, Alzheimer's, Parkinson's and Huntington's diseases. The molecular structure of the striatal D2 receptor binding subunit in these diseased brains was identified by photoaffinity labelling with [^{125}I]Azido-NAPS. In all diseased tissues studied, [^{125}I]Azido-NAPS specifically and covalently labelled a broad band of Mr ≅ 94,000, as assessed by autoradiography following sodium dodecyl sulfate polyacrylamide gel electrophoresis, which was similar to human control brain D2 subunits and that observed in canine striatal membranes. Further work will assess the relative electrophoretic mobilities of deglycosylated photo-labelled D2 binding subunits in these tissues.

This work was supported by the MRC of Canada, The Canadian Friends of Schizophrenics, OMHF and NARSAD.

SOLUBILIZATION AND AFFINITY CHROMATOGRAPHY OF THE DOPAMINE D2 RECEPTOR FROM BOVINE STRIATUM. C. Chung*, M. Dame*, R. Schoenleber* and J. McKelvy (SPON: R. S. Janicki). Neuroscience Research Division, Pharmaceutical Discovery, Abbott Laboratories, Abbott Park, IL 60064.

The dopamine D2 receptor has been purified from bovine striatum using a two step detergent solubilization procedure followed by chromatography on AES-Sepharose, an antagonist affinity resin prepared as described previously (Dame, M., *et al.*, FASEB J., 2:A1400, 1988). [^{3}H]Spiroperidol binding activity was solubilized from membranes using 0.25% cholate/1.5M NaCl, followed by precipitation and subsequent treatment with 0.5% digitonin. This solubilization scheme resulted in a preparation with 1.5 to 2 times the specific activity of the starting membranes. The binding activity is saturable and of high affinity (0.5 nM). Solubilized preparations maintain the ligand binding characteristics of a dopamine D2 receptor as assessed by agonist and antagonist competition for [^{3}H]spiroperidol binding sites. 100% of the soluble [^{3}H]spiroperidol binding activity was retained by the affinity matrix at a receptor to resin ratio (v/v) of 2:1 whereas 55-65% was retained at a ratio of 10:1, the ratio used in affinity experiments. After adsorption at 4°C for 16 hr and extensive washing, 15% of the adsorbed activity was eluted using 50 μM haloperidol. Protein was not measurable by Bradford assay but was estimated at <0.5 μg/ml based on silver stained gels. Using this estimate, >1400 fold purification was achieved. Experiments are underway to determine whether additional receptor activity can be recovered from the affinity column eluate using reconstitution procedures.

165.11

SOLUBILIZATION AND PURIFICATION OF D_2 DOPAMINE (DA) RECEPTORS FROM A RAT ANTERIOR PITUITARY TUMOR. J.Y. Lew and M. Goldstein. N.Y. Univ. Med. Center, Neurochem. Res. Labs, New York, NY 10016.

D_2 DA receptors were characterized in a rat anterior pituitary tumor (APT) (Lin et al., J. Pharm. Exp. Ther. 242:950, 1987). We have investigated whether the APT is a suitable source for purification of D_2 DA receptors. The D_2 DA receptors in the APT were solubilized with 10mM CHAPSO, purified by precipitation of the proteins with 15% polyethylene glycol and chromatography on wheat germ agglutinin (WGA) and on a DEAE-Sepharcyl column or on a Mono Q column. The recovery from the WGA column is only 20-30%, suggesting that the D_2 DA receptor is present as a glycoprotein to a lesser extent in tumor than in brain. Purification on Mono Q or on DEAE-Sepharcyl columns results approximately in a 10-fold increase in specific binding of ^{3}H-spiroperidol. SDS-gel electrophoresis of the [^{125}I] labeled proteins following Mono Q or DEAE-Sepharcyl column chromatography revealed four major peptides with M.W. of 205, 110, 85 and 55 KDa. The association of these peptides with the D_2 DA receptor binding sites is under investigation. Suppported by NIMH 02717 and NINCDS 06801.

165.12

IDENTIFICATION AND CHARACTERIZATION OF D1 AND D2 DOPAMINE RECEPTOR SUBTYPES EXPRESSED IN CULTURED NEUROBLASTOMA AND RETINOBLASTOMA CELL LINES. Frederick J. Monsma, Jr., and David R. Sibley. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20892

The recent availability of high specific activity radiolabeled dopaminergic antagonists with specificity for dopamine receptor subtypes has allowed us to screen a wide variety of cultured mammalian cell lines for the presence of D_1 and D_2 dopamine receptors. Initial screening of cell lines was carried out using both radioiodinated and tritiated dopamine receptor ligands and has resulted in the identification of two cell lines which contain either D_1 or D_2 dopamine receptors.

Specific binding of the D_1 selective antagonists [^{125}I]-SCH 23982 and [^{3}H]-SCH 23390 was detected in membranes prepared from NS20Y cells, a clonal cell line derived from the C1300 murine neuroblastoma cell line. Saturation analysis of [^{125}I]-SCH 23982 binding revealed saturable, high affinity binding with a dissociation constant (K_d) of 630 pM and a receptor density of 16 fMoles/10^6 cells (≈10,000 receptors/cell). Inhibition of [^{125}I]-SCH 23982 binding by a series of dopaminergic antagonists exhibited appropriate stereoselectivity and pharmacological specificity, verifying the D_1 nature of this site. Dopamine inhibition of [^{125}I]-SCH 23982 binding reflected the presence of high and low affinity agonist binding sites, and, in the presence of GppNHp the inhibition curve for dopamine was shifted to the right.

In membranes prepared from the human retinoblastoma cell line WERI 27, specific binding of the D_2 antagonist [^{3}H]-methylspiperone was observed. Saturation analysis revealed the presence of a single class of high affinity binding sites with a K_d of 100 pM and a B_{max} of 5.5 fMole/10^6 cells. [^{125}I]-Sulpride, another D_2 specific antagonist also bound to a single class of sites with high affinity (K_d=600 pM). Inhibition of [^{125}I]-Sulpride binding by dopaminergic antagonists exhibited a rank order of potency consistent with the identification of a D_2 dopamine receptor subtype. In addition, dopamine inhibition curves of [^{125}I]-Sulpride binding exhibited both high and low affinity sites, and were shifted to the right by addition of GppNHp.

These results represent the first direct demonstration of D_1 and D_2 dopamine receptors in cultured mammalian cell lines. These cells should provide useful model systems for investigating the molecular mechanisms involved in dopamine receptor /effector coupling and regulation.

165.13

STABLE EXPRESSION OF PUTATIVE RAT D-2 RECEPTOR IN TRANSFECTED MOUSE L-CELLS. T.S. Khurana[1,*], P. Sajovic[1,*], K. O'Malley[2], and R. D. Todd[3,*] (SPON: E. H. Rubin) Department of Biology[1], City College of New York, New York, NY, 10031 and Departments of Anatomy and Neurobiology[2] and Psychiatry[3], Washington University School of Medicine, St. Louis, MO 63110

Dopamine receptors have been implicated as the site of dysfunction or therapeutic intervention for a variety of neuropsychiatric disorders. To develop model culture systems for the study of D-2 receptors and as a first step in isolating the D-2 receptor gene, we have established a mouse fibroblast line which appears to express rat D-2 receptors.

Rat genomic DNA was partially digested with Msp I, ligated to Msp I digested ϕX174 DNA and co-transfected into TK⁻ mouse L-cells (ATCC CCL.1.3) with an HSV-TK containing plasmid. Transfected cells were selected in HAT media and replica plated onto polyester filters at low density. Subsequently, filter colonies were screened for the ability to binding 0.25 nM ^{125}I-spiperone. Out of one million colonies screened, one colony bound ^{125}I-spiperone. This colony (DA-10) was subcloned by limiting dilution, analysed by Southern blotting, and found to contain integrated ϕX174 hybridizing fragments.

DA-10 cells were grown in quantity, briefly trypsinized and assayed as single cell suspensions for [^{3}H]-spiperone binding. Specific [^{3}H]-spiperone binding was completely blocked by 1 uM eticlopride, but not by 1 uM SCH (+) 23390, ketanserin, or 8-OH-DPAT. The (+) isomer of butaclamol had a six to ten-fold greater affinity for the [^{3}H]-spiperone binding sites than did the (-)isomer. The concentration of [^{3}H]-spiperone binding sites was about 3500 per cell.

These findings suggest that the DA-10 cell line is stably expressing a transfected D-2 like gene. The ϕX174 tagging should allow us to isolate the DNA sequences responsible for this effect.

ESTABLISHMENT OF A PROLACTIN-SECRETING CELL LINE WITH FUNCTIONAL DOPAMINE D-2 RECEPTORS. K.J. Nicklaus, J.C. Lin* and P.B. Molinoff. Dept. of Pharmacology, Univ. of Penn. School of Medicine, Philadelphia, PA 19104-6084.

Studies of the regulation of dopamine receptors have been impeded by the lack of cell lines which express either D-1 or D-2 receptors. The transplantable pituitary tumor 7315a has been shown to contain D-2 receptors negatively coupled to adenylate cyclase. We have used the 7315a tumor to isolate cell lines that express D-2 receptors. Tumors were dispersed into single cell suspensions with collagenase, and cell lines were established by limiting dilution. These cell lines were screened for the presence of binding sites for ^{125}I-IBZM, a radioligand selective for D-2 receptors. One of the cell lines with binding sites for ^{125}I-IBZM, SUP1, secretes prolactin measurable by RIA. Analysis of the binding of ^{125}I-IBZM to membranes prepared from SUP1 cells is consistent with the existence of a single population of binding sites with a high affinity for ^{125}I-IBZM (K_d = 0.8 nM; B_{max} = 30 fmoles/mg of protein). The order of potency of ligands at this site, domperidone > sulpiride > ketanserin, is consistent with the properties of the D-2 receptor. Furthermore, dopamine inhibits adenylate cyclase activity in membranes prepared from SUP1 cells, and this inhibition is blocked by the D-2 receptor antagonist spiroperidol. These results suggest that SUP1 cells contain D-2 receptors negatively coupled to adenylate cyclase. SUP1 cells will represent a useful model system for future studies of the regulation and function of D-2 receptors *in vitro*. (Supported by USPHS Grant NS 18591 and an NSF Predoctoral Fellowship to K.J.N.)

FURTHER CHARACTERIZATION OF THE FUNCTIONAL D-2 DOPAMINE RECEPTOR ON THE MMQ CELL. R.G. MacKenzie, M.S. Ackerman*, R.R. Bhatt*, R.M. MacLeod, G.L. Snyder, and J.W. Kebabian. Neuroscience Research Division, Pharmaceutical Discovery, Dept. 47U, Abbott Laboratories, Abbott Park, IL 60064.

The MMQ cell line, derived from the rat anterior pituitary 7315a tumor, is the only cell line expressing functional D-2 dopamine receptors. In the present study, we used radioligand binding and cAMP accumulation assays to further characterize this receptor. Saturation binding with [3H]-spiperone resulted in binding parameters determined by Scatchard analysis of Kd=55pM and Bmax=27 fmoles/mg protein. In the presence of 0.5mM IBMX, dopamine inhibited forskolin(0.1uM)-stimulated cAMP accumulation by 50% (EC50=0.59uM) and this effect was completely reversed by the D-2 antagonist spiperone (1uM). The specific D-2 agonists LY-171555 and N-0437 were also effective inhibitors of cAMP accumulation (EC50s=0.33uM and 0.25 nM respectively). Surprisingly, the specific alpha-2 adrenergic agonist UK 14,304 also inhibited cAMP accumulation in these cells, apparently via an alpha-2 receptor since its maximal effect, achieved at 1uM, was reversed by 0.3uM yohimbine whereas 10uM spiperone was ineffective. The effect of the specific D-2 agonist LY-171555 was clearly mediated via a D-2 receptor since its maximal effect at 10uM was reversed by 0.1uM spiperone and 1 uM raclopride (another D-2 antagonist) while the alpha-2 antagonists yohimbine and phentolamine were both ineffective at 10uM. In summary, MMQ cells express D-2 dopamine receptors which, upon activation, inhibit cAMP accumulation. However, the presence of an alpha-2 adrenergic receptor inhibitory to cAMP accumulation suggests caution before drug effects be attributed to selective activation of the D-2 receptor.

165.16

MODULATION BY CATIONS OF [^{3}H]SPIPERONE BINDING TO DOPAMINE RECEPTORS IN 7315a AND MtTW15 TUMORS. K. Coenen*, D. Cloutier* and T. Di Paolo, (SPON.: M. Fleury). Dept. of Molecular Endocrinology, Laval University Medical Center, Quebec, G1V 4G2 and School of Pharmacy, Laval University, Quebec, G1K 7P4.

The effect of sodium (Na^+), potassium (K^+), magnesium (Mg^{2+}) and calcium (Ca^{2+}) were studied on dopamine (DA) receptors in prolactin (PRL) secreting 7315a and MtTW15 tumors grown in intact female rats. At 25°C in 7315a tumors, Mg^{2+} and Ca^{2+} increase the dissociation constant (Kd) of [^{3}H]spiperone binding compared to the Kd obtained using a buffer without ions while these ions have no effect on the Kd values when the assay was performed at 37°C. Na^+ and K^+, at 25°C, do not change the Kd of [^{3}H]spiperone binding while a decrease is observed at 37°C. In the presence of all cations (Ca^{2+}, Mg^{2+}, Na^+, K^+) [^{3}H]spiperone binding affinity is unchanged at 25°C while it is decreased at 37°C compared to Kd values obtained using a buffer without these cations. At 25°C and 37°C in 7315a tumors choline chloride does not change the Kd of [^{3}H]spiperone binding compared to the Kd obtained using a buffer without ions, indicating that the effect of ions are specific and not due to differences in ionic strength. At 25°C, in MtTW15 tumors as for 7315a tumors, an increase of Kd is observed in presence of bivalent cations. For monovalent cations, by contrast to 7315a tumors, at 25°C in MtTW15 tumors an increase of Kd is seen with K^+ whereas the affinity is unchanged with Na^+. In the presence of all cations (Ca^{2+}, Mg^{2+}, Na^+, K^+) [^{3}H]spiperone binding affinity is unchanged at 25°C compared to values obtained using a buffer without these cations. The density of [^{3}H]spiperone binding to DA receptors in 7315a and MtTW15 tumors assessed at 25°C or at 37°C is unaffected by the cations under study. In the intact anterior pituitary, Na^+ and K^+ decrease the Kd values of [^{3}H]spiperone binding whereas Mg^{2+} increases it. Thus, our results suggest a different modulation by monovalent cations of DA receptors in 7315a and MtTW15 tumors compared with intact tissue.

165.17

CONCURRENT EXAMINATION OF D2 RECEPTOR BINDING AND TH-IMMUNOCYTOCHEMISTRY. K.A. Steece, B.C. Blanchard*, R.H. Roth[1] and J.R. Sladek, Jr. Dept. of Neurobiol. & Anat., Univ. of Rochester Sch. of Med., Rochester, NY and Dept. of Pharmacol.[1], Yale Univ. Sch. of Med., New Haven, CT.

The ability to examine immunocytochemistry (ICC) and receptor binding in adjacent, or nearby, brain sections would provide important information on the relationship between anatomy and biochemistry at the receptor level. Of particular interest to us was the potential to examine dopamine (DA) neuron degeneration morphologically and relate this to D2 receptor regulation during varying degrees of the neurodegeneration found in animal models of Parkinson's disease. A standard protocol for TH-ICC is 4.0% paraformaldehyde fixation of brain tissue. Thus a combination of morphology and receptor chemistry would require determining whether the receptor of interest survives fixation. Our preliminary data suggested that although D2 receptors in rat brain did appear viable following intracardiac perfusion with 4.0% paraformaldehyde, there was an apparent decrease in number of binding sites compared to control tissue. Further characterization of D2 specific [3H]-Spiperone (SP) binding using biochemical 'wipe' techniques, indicates there is no significant effect of 4.0% fixation on receptor binding capacity or affinity compared to controls. In addition, IC50 analysis of D2 specific, sulpiride displacement of SP was not different in 4.0% brain compared to control. However, 4.0% perfusion significantly decreased the affinity of butaclomol displacement of SP. Butaclomol binds to both serotonin (S2) and DA (D2) receptors. The effect of fixation on butaclomol binding may reflect a differential sensitivity of D2 and S2 receptors to 4.0% fixation. Studies are underway to elucidate this finding. D2 binding was also examined using autoradiography. Computer-assisted analysis of autoradiograms revealed similar D2 specific striatal binding of SP in 4.0% and control brains. In addition to perfusion, other processing of brain tissue often is utilized in ICC. Data from 'wipe' studies indicate that while 1 hour of immersion post-fixation is compatible with D2 binding, longer duration post-fixation, and storage in ethylene glycol-based cryoprotectant is not. A demonstration of concurrent ICC and receptor binding will be presented in intact and 6-OHDA lesioned animals. (Supported by PHS grant NS24032 and MH18260-02)

[^{125}I]-SPECTRAMIDE: A NOVEL BENZAMIDE LIGAND DISPLAYING POTENT AND SELECTIVE EFFECTS AT THE D_2 DOPAMINE RECEPTOR. P.M. Sanchez-Roa*, J.Sharkey*, A.A. Wilson*, D.E. Grigoriadis, R.F. Dannals*, D.F. Wong*, and M.J. Kuhar. (SPON: A. Goldberg). NIDA Addiction Research Center, Baltimore, MD 21224 and Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Spectramide, (N-[2-[4-iodobenzyl-N-methylamino]-2-methoxy-4-ethyl]-5-chloro-methylamine]benzamide), is a novel benzamide derivative. In the present study we show that it can be used as a potent and highly selective ligand for the dopamine D_2 receptor. In competition studies, spectramide potently inhibited [^{3}H]-N-methylspiperone (100pM) binding from the dopamine D2 receptor with a K_i of 400pM. Spectramide also exhibited a weak affinity for the a_1-adrenergic receptor (K_i of 62nM). By contrast, spectramide did not significantly inhibit binding at the D_1, S_2 receptors or to the dopamine transporter, at concentrations up to 1uM. Kinetic and saturation studies in rat striatal homogenates, revealed that [^{125}I]-spectramide exhibits reversible, saturable and high affinity binding characteristics. Preliminary kinetic analysis showed a K_{off} = 0.0567min^{-1}, a K_{on} = 0.71 min^{-1}.nM^{-1} with the calculated K_D from the off/on rates of 80pM. The estimated K_D from saturation analysis was 24.4pM, with a Bmax = 173fmol/mg wet weight tissue. These data indicate that spectramide is a potent and highly selective D_2 ligand, which may prove useful for imaging D_2 receptors in brain using either PET or SPECT.

165.19

CNS DOPAMINE RECEPTORS MODULATION BY CONFORMATIONALLY CONSTRAINED ANALOGUES OF L-PRO-L-LEU-GLYCINAMIDE (PLG). R.K. Mishra, C. Barlas*, L.K. Srivastava and R.L. Johnson* Depts. of Psychiatry and Neurosciences, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

The tripeptide L-prolyl-L-leucyl-glycinamide (PLG) has been shown to possess a variety of pharmacological activities in the CNS including modulation of dopamine receptors. Several conformationally constrained analogues of Pro-leu-gly-NH_2 (PLG) have been synthesized. In one series of analogues, the Leu-gly-NH_2 dipeptide segment of PLG was replaced with the δ-lactam residues 3(S)- and 3(R)-amino-2-oxo-pyrrolidineacetamide and the δ-lactam residue 3(S)-amino-2-oxo-piperidineacetamide. The corresponding δ-lactam analogues of <Glu-leu-gly-NH_2 were also synthesized. In another series Gly-NH_2 was replaced with 2-keto-piperazine, 3(S)-amino-2-pyrrolidone. Of all the conformationally constrained analogues of PLG synthesized in the study, only the δ-lactam analogue 3(R)-N(L-prolyl)amino-2-oxo-1-pyrrolidineacetamide was found to posses significant activity under preincubation conditions, this analogue was 1000-5000 times more potent than PLG. The binding of ADTN was significantly increased at concentrations of 10^{-10} - 10^{-9} M. Furthermore, the conversion of high affinity state of D_2 receptor to low affinity state by GTP was also partially prevented by this compound.

Supported by MRC, OMHF, and NIH.

ADRENERGIC RECEPTORS I

166.1

DIFFERENTIAL EXPRESSION OF IMIDAZOLE AND α_2-ADRENERGIC RECEPTORS AND CLONIDINE-DISPLACING SUBSTANCE (CDS) IN NG108-15, GLIAL, AND CHROMAFFIN CELLS. *G. Feinland*, P. Ernsberger, M.P. Meeley, M.J. Evinger, and D.J. Reis* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Clonidine binds to imidazole as well as α_2-adrenergic receptors in brain (Ernsberger et al., *Eur J Pharmacol* 134:1 '87). We sought to determine whether (a) imidazole and α_2 receptors coexist on single cells, (b) these receptors necessarily coexist, and (c) cells with imidazole receptors also contain CDS, the putative endogenous ligand at these sites (Ernsberger et al., *Brain Res* 441:309 '88). Membranes (P_2) were prepared from cultured NG108-15, glial, and chromaffin cells and incubated with 1 nM ^{3}H-*p*-aminoclonidine (^{3}H-PAC) for 40 min at 25°C. Nonspecific binding was defined by 10μM phentolamine. In NG108-15 clonal cells, the non-imidazoles epinephrine (100μM) and guanabenz (10μM) displaced 48±3% and 49±2%, respectively, of total specific ^{3}H-PAC binding. In glia, however, guanabenz inhibited 109±4% of specific ^{3}H-PAC binding as defined by phentolamine. In contrast, the imidazole cimetidine (10μM) inhibited ^{3}H-PAC binding in NG108-15's (40±1%), but not in glia (-12±8%). Thus, in glial membranes, ^{3}H-PAC labeled α_2-receptors exclusively. In chromaffin cells, epinephrine inhibited only 15±12% of total specific ^{3}H-PAC binding, while cimetidine inhibited 68±25%, indicating that imidazole but not α_2 receptors were labeled. Specific ^{3}H-PAC sites were enriched in chromaffin cells relative to P_2 membranes from the source tissue, adrenal medulla (B_{max}= 1600±300 and 63±17 fmol/mg protein, respectively) but exhibited similar affinity (K_d=4±1 and 2±1nM) and ligand specificity. CDS was isolated (Meeley et al., *Neurosci Lett* 84:84 '88) from osmotically shocked P_2 fractions of NG108-15's. CDS from NG108-15's was active in ^{3}H-PAC and ^{3}H-cimetidine radioreceptor and smooth muscle bioassays (yield=10-18 Units from 7 x 10^7 cells). Thus, although imidazole and α_2 receptors coexist in a 1:1 ratio in NG108-15's, these receptors occur independently in glia (α_2 only) and in chromaffin cells (imidazole only). NG108-15 cells may serve as a model system for both the imidazole receptor and its endogenous ligand, CDS.

166.2

A NOVEL ALPHA-2 ADRENERGIC RECEPTOR IS EXPRESSED IN THE OK CELL LINE. T.J. Murphy, J.C. Baker*, C. Ray-Prenger* and D.B. Bylund, University of Missouri, Columbia, MO 65212.

OK cells, a cell line derived from an American opossum kidney, contain alpha-2 adrenergic receptors (A2AR). We wished to determine which subtype of A2AR these receptors represented. The pharmacological properties of the OK cell A2AR were compared to those in tissues expressing a single A2AR subtype. Human platelet and HT29 cell line membranes served as a source for the A2AR-A subtype, whereas neonatal rat lung and NG108 cell line membranes were used to supply the A2AR-B subtype. K_i values were obtained for several drugs in each tissue by competition binding analysis using either [^{3}H]yohimbine or [^{3}H]rauwolscine. Comparisons were made by linear regression of plots of log [K_i] values to assess correlations of drug affinities. As is shown below, the OK cell A2AR correlates poorly with both the A2AR-A or A2AR-B subtype. We conclude that OK cells express neither the A2AR-A nor A2AR-B subtypes.

	r	Slope	n
OK Cells vs. Rat Lung (2B)	0.87	0.69	30
OK Cells vs. HT29 Cells (2A)	0.84	0.85	30
Rat Lung (2B) vs. HT29 Cells (2A)	0.71	0.91	30
Rat Lung (2B) vs. NG108 Cells (2B)	0.99	1.02	13
Human Platelet (2A) vs. HT29 Cells (2A)	0.98	0.97	19

166.3

EVIDENCE FOR ALPHA$_2$-ADRENORECEPTOR HETEROGENEITY IN RAT CORTEX. RK Zolfoski and CE Dunlap, III. Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103.

Previous studies by others have provided pharmacological and anatomical evidence for alpha$_2$-adrenoreceptor heterogeneity within rat brain. In an attempt to further elucidate the extent of this heterogeneity, a series of experiments utilizing [^{3}H]-Guanabenz (^{3}H-GB) have been undertaken in our laboratory.

Initial studies with ^{3}H-GB in rat cortex were conducted to determine the kinetics of GB binding. Association and dissociation experiments yielded two binding sites; a high affinity site with association rate constant (k_1) of 7.67±6.86x10^7 min^{-1} and dissociation rate constant (k_{-1}) of 1.34±4.50x10^{-2} min^{-1} and a low affinity site with k_1 of 6.70±4.03x10^8 min^{-1} and k_{-1} of 0.24±0.08 min^{-1}. K_d values calculated from these rate constants were 3.76±1.72 and 0.9±0.65 nM, respectively. Saturation experiments yielded a K_d of 5.83±1.01 nM and B_{max} of 266.40±67.43 fmoles/mg protein. Competition studies were then used to determine the displacement of ^{3}H-GB. GB displayed a two-site displacement; a high affinity site with K_i of 2.43±1.58nM and a low affinity site with K_i of 271.47±141.98 nM. Various other adrenergic agents were also tested, and the following K_i values (nM) were obtained:

Clonidine	24.28±1.58	UK-14304	9.98±0.19
Epinephrine	17.32±10.70	Propranolol	no displacement
Idazoxan	24.33±10.59	Yohimbine	no displacement

Studies by others indicate that idazoxan labels a heterogeneous population of alpha$_2$-adrenoreceptor sites; one population of these sites are selectively labeled by raulwolscine. Also parallel competition studies indicate that clonidine and GB have separate high affinity binding sites. From these studies, we hypothesize that there may be a large pharmacological heterogeneity of alpha$_2$-adrenoreceptors in rat brain, a select population of which binds GB.

This research was supported by NIH grant HL34460.

166.4

PHARMACOLOGICAL CHARACTERIZATION OF [^{3}H]GUANFACINE BINDING. T.D. Smith, and F.M. Leslie, University of California, Irvine, CA. 92717, USA.

Guanfacine is an α_2 agonist which is used clinically as a potent antihypertensive. Recently it has also been shown to selectively improve cognitive function in aged monkeys (Arnsten et al. J.Neurosci., in press). Previous work in our laboratory has provided evidence for two α_2-adrenoceptor subtypes in rat brain and kidney which exhibit differential affinity for guanfacine. We have currently used radioligand binding and autoradiographic techniques to characterize the pharmacological properties and anatomical localization of [^{3}H]guanfacine binding sites in these tissues. Specific binding was defined as the difference in binding in the absence and presence of unlabeled guanfacine (10μM). In brain, radioligand binding data provided evidence that [^{3}H]guan labels a single high affinity binding site. Clonidine and several other selective α-adrenoceptor ligands yielded greater than eighty percent displacement of specific binding. Autoradiographic distribution of [^{3}H]guan binding paralleled that of [^{3}H]clonidine and was completely displaced by excess unlabeled clonidine (1μM). In kidney, radioligand binding provided evidence that [^{3}H]guan labels two sites with high affinity. A number of selective alpha adrenergic ligands failed to displace more than thirty percent of [^{3}H]guan specific binding. The autoradiographic distribution of [^{3}H]guan was also distinct from that of [^{3}H]clon. Whereas [^{3}H]guan densely labeled the renal cortex, the inner medulla and the outer zone of the outer medulla, [^{3}H]clon labeled only the inner medulla and the outer zone of the outer medulla. Clonidine failed to displace [^{3}H]guan labeling in the renal cortex. These data suggest that in peripheral tissues, guanfacine may bind with high affinity to a site other than the α_2-adrenoceptor.

This work was supported by NIH grant NS 19319.

166.5

HETEROGENEITY OF [3H]PRAZOSIN BINDING SITES IN CANINE BRAIN AND LIVER S.S. Bowersox, J. Mignot*, E. Maddaluno*, W. C. Dement, and R. D. Ciaranello Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California 94305.

We have identified two classes of putative alpha-1 adrenoceptors in canine brain and liver using conventional radioligand binding methods. Scatchard plots of specific [3H]prazosin (Pz) binding to brain and liver homogenates prepared from 100 day old Doberman pinscher dogs were consistently curvilinear and best fit a two-site binding model [Brain: Kd1= 57.7± 10.0 pM, Bmax1 = 64.6 ± 17.1 fmol/mg protein, Kd2 = 1.5 ± 0.5 nM, Bmax2= 159.5±37.6 fmol/mg protein; Liver: Kd1= 82.6±36 pM, Bmax1= 7.0±5.1 fmol/mg protein, Kd2= 0.8±0.2 nM, Bmax2= 62.1±8.7 fmol/mg protein]. Kinetically-derived affinity constants from association and dissociation experiments agreed with those obtained by Scatchard analysis of equilibrium binding data. Binding sites were saturable, heat labile, bound ligand reversibly, and were appropriately distributed in relation to endogenous neurotransmitter. Saturation studies performed on brain tissues from dogs killed on the same day as the binding experiments and without any intervening freezing steps, yielded findings similar to those obtained using frozen tissue preparations. Competitions for [3H]Pz binding to canine frontal cortex membranes were conducted with WB-4101, corynanthine, benoxathian, phenoxybenzamine, chlorethylclonidine, thymoxamine, prazosin, and yohimbine. All ligands but prazosin competed for specific [3H]Pz binding in a statistically significant, biphasic manner. Benoxathian and WB-4101 displayed highest affinity (benox: Ki1= 0.26nM, WB-4101: Ki1=0.20nM) and selectivity (benox: Ki1/Ki2= 0.11, WB-4101: Ki1/Ki2= 0.007) for the high affinity [3H]Pz binding site; chlorethylclonidine and phenoxybenzamine showed highest affinity (CEC: Ki2= 91nM, phenox: Ki2= 3.4nM) and selectivity (CEC: Ki1/Ki2= 375, phenox: Ki1/Ki2= 225) for the lower affinity [3H]Pz binding site. Yohimbine competed with nanomolar affinity (Ki = 16.1nM) for the highest affinity [3H]Pz binding site. These findings raise new questions about the validity of current adrenoceptor classification schemes which posit a primary alpha-1 and alpha-2 adrenoceptor subdivision on the basis of presumed differential binding profiles of prazosin (alpha-1) and yohimbine (alpha-2). The fact that Pz possesses higher affinity for both classes of binding site than does yohimbine favors identification of these sites as alpha-1 adrenoceptors.

166.6

ALPHA$_2$ ADRENERGIC BINDING FOLLOWING BENZODIAZEPINE TREATMENT IN BORDERLINE PERSONALITY DISORDER. R. Yehuda*[1], B.D. Perry[2], S.M. Southwick*[1], and E.L. Giller[1]. Psychiatry, WHVA-Yale, West Haven, CT 06516. [2]Harris Center, Chicago.

We investigated the effect of benzodiazepines (BZ) on platelet alpha$_2$ adrenergic receptor regulation in patients with both Major Depression and Borderline Personality Disorder (n=17), and in normal controls (n=17). Extended saturation radioligand binding assays (0.1-35nM ^{3}H-rauwolscine) and epinephrine competition studies assessed both high and low affinity states of the receptor. The number of alpha$_2$ adrenergic receptor sites in platelets from nonmedicated patients (n=10) was significantly reduced compared to controls, owing to a decreased number of high affinity ("coupled") sites. BZ-treated patients were comparable to controls on this measure. Both patient groups showed a higher degree of receptor "uncoupling" compared with controls. Clinically, BZ-treated patients reported significantly less anxiety than nontreated patients, but Hamilton Depression Scores were similar in both groups. Platelets obtained from a subgroup of patients (n=5) before and during BZ administration revealed that the number of alpha$_2$ adrenergic receptor sites doubled following this treatment to a level comparable to controls. In contrast, repeat determinations in control platelets (n=5) revealed little variation in receptor number over time.

166.7

REGULATION OF PINEALOCYTE INTRACELLULAR pH BY α_1-ADRENERGIC RECEPTOR. A.K. Ho*, C.L. Chik*, and D.C. Klein* (SPON: A.S. Basile). Section on Neuroendocrinology, Lab. of Developmental Neurobiology, and Developmental Endocrinology Branch, NICHD, NIH, Bethesda, MD 20892.

The purpose of the present study was to investigate the regulation of intracellular pH (pHi) in pinealocytes. The fluorescent pH indicator 2'7'-bis(carboxyethyl)-5(6)carboxyfluorescein (BCECF) was used. With an extracellular pH of 7.2, the pHi was 7.09. Treatment of pinealocytes with the physiological regulator of pineal function, norepinephrine (NE) resulted in a dose-dependent increase in pHi. NE (1μM) or phenylephrine (PE) (10μM) treatment increased pHi by about 0.07; isoproterenol (10μM) had no effect. The response of NE (1μM) was almost completely blocked by prazosin (1μM), but only slightly inhibited by propranolol (1μM), indicating that NE is acting via an α_1-adrenoceptor to influence pHi. In rat pinealocytes, α_1-adrenergic receptor activation translocates calcium-phospholipid dependent protein kinase (PKC). One possible consequence of PKC translocation is activation of the Na^+/H^+ antiport resulting in an increase in pHi. This was examined using activators of protein kinase C. Phorbol esters which directly activate PKC increased pHi by 0.06. An inactive analog had no effect. K^+, which activates PKC in the pinealocyte, increased pHi in a dose-dependent manner. An inhibitor of the Na^+/H^+ antiport, amiloride (50 μM), reduced pHi by 0.08 suggesting that the Na^+/H^+ antiport is involved in maintaining pHi in the pinealocyte. These findings indicate that α_1-adrenoceptor activation may increase pHi through PKC-dependent activation of the Na^+/H^+ antiport.

166.8

REGULATION OF CHICK PINEAL N-ACETYLTRANSFERASE ACTIVITY BY LIGHT AND NOREPINEPHRINE: INVOLVEMENT OF ALPHA-2 ADRENERGIC RECEPTORS. J.A. Creighton*, P.K. Rudeen and D.B. Bylund. Depts. of Anatomy and Pharmacology, University of Missouri School of Medicine, Columbia, MO 65212.

Cultured chick pineal glands show a diurnal oscillation in the activity of serotonin N-acetyltransferase activity (NAT). Light exposure of the gland leads to a rapid decline in activity. Norepinephrine (NE) treatment also inhibits NAT activity, indicating an adrenergic inhibition which is mediated through alpha-2 adrenergic receptors.

We demonstrate that light and NE inhibition of NAT is preceded by a transient increase in activity, evident at 5 min after light exposure or NE administration. The effects of NE are biphasic and dose-dependent. Stimulation of NAT by NE occurs at a concentration between 1-3uM with inhibition of enzyme activity occurring within 30 min. Propranolol given immediately prior to NE did not block the NAT increase by 3uM NE. Treatment of chick pineal glands with UK 14,304, an alpha-2 agonist, resulted in a similar stimulation at a dose of 0.1-1.0uM. These data further demonstrate that chick pineal melatonin biosynthesis is regulated by alpha-2 adrenergic receptors. The unanticipated transient stimulation of NAT by light and NE indicate a complex mechanism whereby these agents regulate NAT activity.

EFFECT OF LONG-TERM DESIPRAMINE ON α_2-ADRENOCEPTORS AND NOREPINEPHRINE UPTAKE REGULATION: AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT HIPPOCAMPUS. D. Lacroix, O. Curet and C. de Montigny. Dept. of Psychiatry, McGill University, Montreal, Quebec, Canada H3A 1A1.

Sprague-Dawley rats were treated for 2 weeks with desipramine (DMI) (5 or 10 mg/kg, i.p.). Experiments were carried out 24 h after the last dose.

The responsiveness of CA$_3$ dorsal hippocampus pyramidal neurons to microiontophoretic application of norepinephrine (NE) was unchanged, indicating that the sensitivity of postsynaptic α_2-adrenoceptors was not modified.

The effectiveness of the electrical stimulation of the locus coeruleus in suppressing firing activity of dorsal hippocampus pyramidal neurons was not modified. However, clonidine (2 µg/kg, i.v.) reduced to a much smaller extent the effectiveness of the locus stimulation in DMI rats than in controls. These results indicate that long-term DMI treatment reduces the function of terminal α_2-autoreceptors.

The time required for pyramidal neurons to recover by 50% (RT_{50}) from microiontophoretic application of NE was similar in DMI rats and controls. However, the acute administration of high doses of DMI (6 and 8 mg/kg, i.v.) produced a smaller increase of RT_{50} values in DMI rats then in controls. This suggests that long-term DMI treatment reduces the number of [^{3}H]DMI sites without affecting the number of NE transport sites.

MEDIATING MECHANISM FOR THE ANESTHETIC ACTION OF ALPHA-2 ADRENERGIC AGONISTS. M.Maze* V.A.Doze*, B-X. Chen*, Z. Li* (SPON: D.L.Tanelian) Department of Anesthesia, Stanford University, Stanford, CA 94305

This study examined central alpha$_2$(A2) adrenergic receptor mediated loss of righting (LOR) reflex in rats. Neurotoxins specific for the functional components of the A2 adrenoceptor-effector mechanism, were used to determine if: i) a postsynaptic site, ii) a G_i/G_o protein, and iii)a K^+ conductance are involved in A2 receptor mediated hypnosis. Dexmedetomidine (DEX), a highly-selective A2 agonist, dose-dependently increased the duration of LOR reflex or sleep-time(ST). Centrally-active (idazoxan, MPV-1248) but not peripherally active (DG-5128) A2 antagonists blocked the hypnotic action of DEX. After depletion of monoamine stores with alpha-methyl-para-tyrosine and reserpine, the [DEX]-ST response curve was shifted to the left. Pertussis toxin (PT) pretreatment completely attenuated the hypnotic action of DEX. In both naive and monamine-depleted rats, 4-aminopyridine (4-AP) dose-dependently reduced DEX-induced ST while the peripherally acting 3,4-DAP was without effect. These data suggest that DEX-induced hypnosis is mediated *via*: i) a postsynaptic as well as a presynaptic A2 adrenoceptor ii) a PT-sensitive G protein; and iii) a 4-AP sensitive effector mechanism. Thus, activation of central A2 adrenergic receptors produces anesthesia in rats. This represents the first definitive example of a specific receptor-mediated anesthetic action.

RECOVERY OF POSTSYNAPTIC SENSITIVITY TO METHOXAMINE AFTER SPINAL CORD TRANSECTION IN THE CAT. S.L. Stoddard, L.K. Harstad*, S.W. Carmichael and T.L. Yaksh*. Dept. of Anatomy, Indiana Univ. Sch. of Med., Fort Wayne, IN 46805 and Depts. of Anatomy and Neurosurgery, Mayo Clinic, Rochester, MN 55905.

We previously reported that the adrenal medulla becomes hyperreactive to visceral and somatic stimuli over time following high spinal transection in the cat (Soc. Neurosci. Abstr. 13:271, 1987). Such increased reactivity might be related to generalized postsynaptic hypersensitivity, as occurs following denervation. To test this we determined the changes in mean arterial blood pressure (MAP) following iv administration of methoxamine, an alpha-adrenergic agonist, in non-transected cats (control; N=4) and as a function of time following surgical transection of the spinal cord at T3. Cats were tested acutely (4 hr post-transection, N=6), and at 4-5 days (N=5), 14-19 days (N=7) and 61-69 days (N=6) with methoxamine at 5, 10, 20, 40 and 80 ug/kg. The sensitivity to methoxamine (slope of the regression line of the log of methoxamine dose vs. change MAP) was significantly decreased from control values in both the 4-5 and 14-19 day groups. Sensitivity to methoxamine returned between 19 and 61 days; the response at 61-69 days was significantly greater than that seen at 14-19 days, and was not different from control values. Since the decreases in alpha-adrenergic receptor activity return to non-transected levels by 9 wk, these data do not support the concept that adrenal medullary hyperreactivity is due to a generalized denervation hypersensitivity occurring after spinal cord transection.

166.12

MEDETOMIDINE AND LOCUS CERULEUS NEURON FIRING. A. L. Curtis and J. Marwah. Wayne State University, Detroit, MI 48202.

In the current study, the effects of medetomidine (ME), d-medetomidine (d-ME), l-medetomidine (l-ME) and clonidine (CLD) on locus ceruleus (LC) neuron firing were compared in urethane anesthetized rats. Single, spontaneously firing noradrenergic LC neurons were invariably inhibited by the systemic administration of ME; d-ME and CLD. L-ME had no effect on neuron firing at doses up to 1 mg/kg, i.v. The inhibitory effects of ME; d-ME and CLD on LC neuron firing were antagonized by the alpha$_2$ adrenoceptor antagonist yohimbine. The rank order for inhibition was d-ME > ME > CLD. It is concluded that medetomidine inhibits noradrenergic neurons in the LC by specifically interacting with alpha$_2$ adenoceptors.
(Supported in part by a grant from NIDA DA 04158 and the Farmos Group.)

THE PUTATIVE ANTIPSYCHOTIC AGENT AMPEROZIDE PRODUCES BEHAVIORAL STIMULATION IN RATS. K. Svensson* N. Waters* G. Pettersson*[1] and L. Löfberg* (SPON: J. Engel). Dept of Pharmacol., Univ. of Göteborg, Sweden. [1] Dept. of Pharmacol., Ferrosan AB, Malmö, Sweden.

Amperozide (which is currently being evaluated as an antipsychotic in humans) has been shown to possess strong antiaggressive properties in various species (e.g. rats and pigs). The compound also antagonizes d-amphetamine-induced hyperlocomotion (at about 1 mg/kg), but not stereotypies, in mice. Furthermore, amperozide fails to induce catalepsy in rodents. This suggests that amperozide has a limbic profile of action (A. Björk et al., Proceedings VIIIth Internat. Med. Chem. Meeting, Uppsala, Sweden, 1984). In vitro binding studies indicate a high affinity for brain 5-HT2 receptors (Ki = 16 nM) whereas the affinity for central D2 and α1 receptors is lower (Ki = 540 and 172 nM, respectively).
Recently we found that amperozide dose-dependently (5-80 mg/kg) reverses reserpine (5 mg/kg,18h)-induced hypokinesia. The behavioral stimulation consisted of periodic locomotion (backward and forward locomotion), weak sniffing, and stereotyped movements with the forelegs. This behavioral syndrome was not blocked by high doses of raclopride (D2 antagonist), SCH 23390 (D1 antagonist), propranolol (β-receptor blocker), idazoxan (α2-receptor antagonist) or ritanserin (5-HT2 antagonist). However, pretreatment with the catecholamine synthesis inhibitor α-MT (250 mg/kg, 1 h) or the dopamine-β-hydroxylase inhibitor FLA 63 (40 mg/kg, 2.5 h) partially blocked the amperozide-induced behavioral stimulation. These results suggest that amperozide produces behavioral stimulation via an indirect effect on central α-receptors. We recently found that amperozide can induce a similar behavioral syndrome in habituated, non-pretreated rats. Behavioral and biochemical data will be presented and discussed in relation to the clinical effects of amperozide.

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT I

167.1

NMDA CURRENT IN HIPPOCAMPAL SLICES FROM NEWBORN RATS. Ben-Ari, Y., Cherubini, E. and Krnjević, K., INSERM U-29, 123 Blvd. Port-Royal 75014 , Paris, France. (SPON:G. Mandl)

NMDA (5-10 μM)-evoked inward currents (I_{NMDA}) were compared in single-electrode voltage-clamped CA3 neurons in slices from adult Wistar rats (>120 g) and from pups at post-natal days 1-8. In most cases, recording was with 3M CsCl microelectrodes and fast Na currents were routinely blocked with TTX. Similar peak I_{NMDA}'s were evoked at various stages of development. In mature neurons, I_{NMDA} consistently showed the characteristic negative slope in the region between -60 and -30 mV (-12.4 ± 2.35 pA/mV, n=13) and had a reversal potential at -21.1 ± 3.29 mV (n=5). In immature neurons (1-8 days), the voltage-dependence was much more variable, giving a *positive* slope in the -60 to -30 mV region in 6 cells out of 17 and an overall mean slope of -0.89 ± 3.17 pA/mV (for n=17); moreover, the reversal potential was at a less negative level, -8.3 ± 2.08 mV (n=11). In addition, NMDA tended to trigger sharp, periodic inward currents - superimposed on the slow I_{NMDA} - much more frequently in immature neurons. These observations suggest that endogenous NMDA-agonists may activate Ca^{2+} influx particularly readily in the young hippocampus, perhaps thus facilitating maturational and other "plastic" changes.

167.2

CHANGES IN MESSENGER RNAs CODING FOR NEUROTRANSMITTER RECEPTORS IN THE DEVELOPING RAT CEREBRAL CORTEX. M.K. Carpenter*, I. Parker*, and R. Miledi (SPON: K.Sumikawa). Laboratory of Cellular and Molecular Neurobiology, Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

The developmental changes in the expression of mRNAs coding for several neurotransmitter receptors (kainate, glutamate, ACh, and serotonin) were examined by injecting mRNA isolated from the cerebral cortex into Xenopus oocytes. The oocytes translate the foreign mRNA and incorporate functional receptor/ion channel complexes into the cell membrane (Gundersen, C., Miledi, R., and Parker, I. Nature, 308:421, 1984). Thus, recordings of agonist-evoked membrane currents in voltage-clamped oocytes give a measure of the relative amounts of different messengers. In these experiments poly (A)$^+$ mRNA was isolated from rats of different embryonic (E) and postnatal (P) ages, and 50 ng was injected into each oocyte. Responses induced by kainate (10^{-4} M), glutamate (10^{-3} M), ACh (10^{-4} M), and serotonin (10^{-5} M) all increased with age reaching a maximum in oocytes injected with mRNA from adult cortex. The earliest ages examined, E15 and E18, gave little or no response to kainate, glutamate, or ACh. Responses to these agonists increased with age, reaching 50-70% of the adult response by P10. In contrast, the serotonin-induced response was relatively large (16% of adult) in oocytes injected with E15 mRNA and increased postnatally to adult levels.

Flow cytometric analysis of membrane potential responses in the embryonic chick spinal cord. A. Prasad*, E.A. Novotny*, G.D. Lange and J.L. Barker. Laboratory of Neurophysiology; NINCDS, NIH; Bethesda MD 20892.

The development of receptor and ion channel responses in the embryonic chick spinal cord was examined using a combination of flow cytometry and a fluorescent voltage-sensitive dye. This approach has been successfully used in developmental studies of the mammalian nervous system (Mandler et al., (1988) J. Neurosci. Methods; 22:203). Results from the current studies indicate that these techniques are also applicable to the developing avian nervous system.

Acutely dissociated spinal cord cells from chick embryos ranging in age from E5 - E9 (St. 26 - St. 35) were incubated in the fluorescent, voltage-sensitive dye oxonol. It was found that muscimol (a $GABA_A$ agonist) and GABA depolarized (increased oxonol staining) spinal cord cells in a dose-dependent manner. These effects were blocked by the $GABA_A$ antagonist bicuculline and were evident as early as E5 (St. 26, 27) in a subpopulation of spinal cord cells. However, glycine, another inhibitory neurotransmitter, had no apparent effect at the ages examined. The sodium channel blocker TTX effectively blocked the massive depolarization caused by veratridine. Again, these responses were evident at E5. Experiments designed to examine the onset of GABA receptor modulatory responses and the development of other amino acid responses in the embryonic chick spinal cord are currently in progress.

RETINAL CULTURES AS A MODEL FOR EXCITATORY AMINO ACID RECEPTOR DIFFERENTIATION. F. Somohano* and A.M. López-Colomé. Instituto de Fisiología Celular, U.N.A.M., 04510 México, D.F., México.

In vitro differentiation in primary cultures has been used to study the mechanisms regulating the characteristics of membrane proteins; among these, uptake- and synaptic-receptors for neurotransmitter substances. During synaptogenesis, the establishment of adequate synaptic contacts depends on feedback mechanisms mediated, at least in part, through neurotransmitter receptors with certain characteristics at a particular moment. We have studied the maturation of receptors to excitatory amino acids (EAAR) in primary cultures of neurons from chick retina. Assays were performed at 1,5,8, and 12 days in vitro (DIV). Uptake receptors were assayed through the incorporation of ^{3}H-D-Asp; synaptic receptors were measured by binding of ^{3}H-AMPA, ^{3}H-Glu, ^{3}H-Asp or ^{3}H-KA to frozen membranes or whole cells. Na^+ and temperature-dependent uptake of ^{3}H-D-Asp showed a single saturable system at all ages studied ($Km \simeq 10$ uM); B_{max} increased 10 times from DIV 1 to 8. Synaptic EAAR were enriched in cultures versus membranes from embryonic retina, indicating preferential localization in neurons. EAAR subtypes vary in time of expression: ^{3}H-Glu binding increases between 5 and 8 DIV, and then decreases; ^{3}H-AMPA binding remains constant; ^{3}H-KA binding could not be detected at any stage; ^{3}H-Asp binding increases at day 8 in vitro. Data suggest a trophic role for EAAR during differentiation.

167.5

DEVELOPMENTAL REGULATION OF NEUROTRANSMITTER RECEPTORS ON CHICK PREGANGLIONIC NEURONS. B. Clendening and R.I.Hume. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109

We have studied the expression of neurotransmitter receptors on chick sympathetic preganglionic neurons (SPN) in dissociated cell culture. The sensitivity of SPN to GABA, glycine and glutamate was measured by making whole cell voltage clamp recordings. The time of appearance of sensitivity to these three substances differed. At 24 hr after plating, more than 90% of the SPN gave detectable responses to 100 uM GABA, and most of these responses were easily detectable (> 50 pA with a 50 mV driving force). In contrast, less than 40% of SPN gave detectable responses to 100 uM glycine or glutamate at 24 hours, and when currents were evoked they were quite small (< 20 pA with a 50 mV driving force). Over the first 7 days *in vitro* there was a gradual threefold rise in the amplitude of GABA evoked currents. In contrast, glycine and glutamate evoked currents did not begin to increase until day three, and the relative increase in current at day 7 was more dramatic. Mean glycine sensitivity and mean glutamate sensitivity were both increased by more than tenfold over their values at 24 hours.

It is unlikely that the low level of responsiveness to glycine and glutamate at early times was due to the selective removal of receptors for these transmitters by enzyme treatment during dissociation. Treatment of 5-7 day cultures with enzyme did not reduce the sensitivity to either transmitter. It also seemed possible that receptors to these two transmitters might be down-regulated or desensitized by glutamate and glycine in the culture medium. However, we found no difference in the amplitude of the peak currents evoked by glutamate and glycine, or in the time of onset of sensitivity, when these amino acids were absent from the medium.

These data are consistent with the idea that independent mechanisms regulate the expression of multiple neurotransmitter receptors.

167.6

HETEROGENEITY OF TARGET SPECIFIC POPULATIONS OF SYMPATHETIC NEURONS IN THE RAT SUPERIOR CERVICAL SYMPATHETIC GANGLION. A.J. Smolen Dept. of Anatomy, The Medical College of Pa., Philadelphia, PA 19129.

We have begun to investigate morphological and biochemical differences among sympathetic neurons in the superior cervical sympathetic ganglion (SCG) of the rat. Two target specific populations of neurons were studied: one that projects to the submandibular gland (SMG), and the other that innervates the iris.

The perikarya of sympathetic neurons that project to the SMG are significantly larger than those that project to the iris, and their dendritic trees are more highly elaborated. In addition the rate of turnover of the neurotransmitter, norepinephrine (NE), is much greater in the SMG than in the iris.

These two groups of neurons also differ in their responses to altered synaptic input. Neonatally denervated iris neurons do not release significant amounts of NE at their terminals, while release of NE is normal from terminals of denervated SMG neurons. Denervation results in a decrease in the size of the neuron soma in both groups, but dendritic maturation is unaffected. Neonatally hyperinnervated SMG neurons respond by an enhanced release of NE from their terminals, and a significant increase in both perikaryal size and dendritic arborization.

Studies are in progress to relate these morphological and biochemical variations to differences in the level of activity of these two populations of neurons.

167.7

THE EFFECTS OF $MgCl_2$ INFUSION ON THE PERIODICITIES IN PHRENIC (PHR) AND SYMPATHETIC (SYMP) ACTIVITY OF NEONATAL SWINE. P.M. Gootman, H.L. Cohen, B.W. Hundley*, M. Brust*, L.P. Eberle*, G. Condemi*, B.T. Altura,* B.M. Altura*. Dept. Physiol., SUNY-Hlth Sci. Ctr. Bklyn, Bklyn,NY 11203

The effects of changes in plasma concentration of magnesium on efferent PHR, cervical sympathetic (CS) and splanchnic (SPL) activity were examined in piglets <1 day to 5 weeks of age, lightly anesthetized with Saffan, paralyzed, tracheotomized and artificially ventilated on 100% O_2; pO_2,pCO_2 and pH were monitored. Infusion of $MgCl_2$ for 15 min at rates ranging (depending upon age) from 0.191 to 0.76 mmoles/min increased arterial plasma levels of Mg from 1.82 mg/dl to 4.61 mg/dl. Neuronal activity was analyzed by averaging, correlation and power spectral techniques. Spectral densities of SYMP activity demonstrated peaks in the range of 5-30 Hz; locking to both the cardiac and respiratory cycle was present. Following $MgCl_2$ infusion, there was a significant increase in the respiratory modulation of SYMP activity; CS power appeared to increase in > 1 month old piglets. While there was no systematic change in PHR high frequency oscillations, there were age-related changes in inspiratory and expiratory durations. The results suggest that changes in serum Mg can alter both the sympathetic rhythm generating systems and phase switching in the respiratory rhythm generator in the brainstem of neonatal swine. (Supported by NIH grant HL-20864.)

167.8

ALTERED BRANCHING OF 5HT-NEURONS IN *Drosophila* MUTANTS UNABLE TO SYNTHESIZE SEROTONIN AND DOPAMINE. V. Budnik, C.-F. Wu, and K. White. Biophysics program, Dept. of Biology, Brandeis University, Waltham, MA 02254, and Dept. of Biology, University of Iowa, Iowa City, IA 52242.

The neurotransmitters serotonin (5HT) and dopamine (DA) have been implicated in the regulation of developmental processes in a number of animals. In the fruit fly *Drosophila melanogaster*, genetic manipulation of the gene *dopa decarboxylase* (*Ddc*), allows the generation of flies which are completely deficient in 5HT and DA (*DfDdc*). Previous studies demonstrated that in the absence of serotonin and dopamine, 5HT-neurons in the CNS appear to develop normally, and express normal selective 5HT uptake properties. In this study, we have examined the pattern of branching of 5HT-neurons in a peripheral target, the proventriculus and midgut of *Drosophila* larvae, by immunofluorescent techniques. Developmental studies showed that most of these peripheral 5HT-projections are present, and contain 5HT before the larvae hatch. We found that *DfDdc* larvae show a dramatic increase in the number of ramifications of 5HT-fibers in the proventriculus and midgut, as revealed by 5HT uptake experiments. Mutant flies that have low, but detectable levels of 5HT and DA throughout embryogenesis (Ddc^{ts2}, 30°C) did not show this mutant phenotype. Feeding *DfDdc* larvae with 5HT-containing medium resulted in the incorporation of 5HT into appropriate neurons and fibers in the nervous system. However, this postembryonic increase in the levels of 5HT did not rescue the aberrant branching in the mutant. The nature of this phenomenon is being further analyzed by additional genetic and physiological manipulations.

167.9

THE APPEARANCE OF SEROTONIN AND PROCTOLIN DURING DEVELOPMENT IN THE LOBSTER NERVOUS SYSTEM. B. S. Beltz, Department of Biological Sciences, Wellesley College, Wellesley, MA 02181, & M. C. Pontes*, and E. A. Kravitz, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115. The form and behavior of lobsters changes dramatically in the transition from the 1st-4th larval stages (L1-L4). Serotonin (5-HT) and proctolin, neurohormones widely distributed in the lobster nervous system, have been implicated in various behaviors. Using immunocytochemical and biochemical methods, we have screened for the appearance of these substances during development. In mid-stage embryos, the adult complement of 5-HT-staining cells is already present. Embryonic serotonin cells are proportionally very large and more well developed than other neurons, suggesting possible developmental roles. In one case, an unpaired 5-HT-containing cell is very prominent in embryos, L1, and L2, but stains weakly in juveniles. The development of proctolinergic neurons is very different. Only 2% of the proctolin-staining neurons of juvenile animals are seen in mid-stage embryos. The number of immunoreactive cells gradually increases, but even by L6 only half the number of cells that will eventually stain for proctolin are observed. 5-HT and proctolin coexist in large pairs of neurons in the adult A1 and T5 ganglia. These cells already contain 5-HT in mid-stage embryos. Proctolin appears in these cells only after L1. Thus in the same cells, proctolin and 5-HT first appear at very different times in development. Quantitative measurements for 5-HT in lobster larvae were performed by HPLC with dual electrochemical detection, and for proctolin were performed using RIA. A gradual growth-related increase in the amount of 5-HT was seen during larval development. This is consistent with the immunocytochemical data showing that no new 5-HT cells appear during this period. Proctolin levels during development are currently being quantified. (Supported by NIH and Klingenstein Foundation).

167.10

SEROTONERGIC PROPERTIES OF GROWTH CONES ISOLATED FROM FETAL RAT BRAIN. N. Ivgy-May*, H. Tamir, and M.D. Gershon, (SPON: D. Colman) Dept. Anat. and Cell Biol. Columbia Univ. P&S, New York, N.Y. 10032.

High affinity ^{3}H-imipramine binding sites are associated with the 5-HT transporter in neuronal plasma membranes. The ontogeny of ^{3}H-imipramine binding sites (displaceable by 1μM norzimelidine) in subcellular fractions derived from developing rat brain was studied. Analysis of saturation isotherms indicated that ^{3}H-imipramine bound to a single class of sites. Specific high affinity ^{3}H-imipramine binding ($K_D \cong 3.2 \pm 0.6$ nM [adult $K_D \cong 2.8 \pm 0.1$ nM]) was first detected at day E15 at which time the B_{max} was ~20% of the adult level (adult $B_{max} \cong 298 \pm 33$ fmol/mg). The B_{max} increased with age and reached ~70% of the adult value by day P9. Previous studies have shown that ^{3}H-imipramine binding sites in the adult rat brain are mainly located on the membranes of serotonergic axon terminals. Our observation that high affinity ^{3}H-imipramine binding sites are present at day E15, before serotonergic synapses have begun to form, implies that the binding sites may be present on the growth cones of serotonergic axons. To test this possibility, isolated growth cones (IGC) were prepared from developing rat brain homogenates. High affinity ^{3}H-imipramine binding sites were significantly ($p < 0.05$) enriched in the IGC fraction, 4.5-fold, at day E15, and 1.4-fold at day E 20. No enrichment was found in the IGC fraction at later ages, when ^{3}H-imipramine binding was found in synaptosomes. Specific ^{3}H-imipramine binding sites were radioautographically detected in the cerebral cortex of fetal rats at day E20. At this age, serotonergic axons are found in the cortex, but they have not yet formed synapses; therefore, since serotonergic growth cones are present, while synapses are not, the binding of ^{3}H-imipramine found in cortical radioautographs is probably to serotonergic growth cones. Fractions containing intact IGC had detectable levels of endogenous 5-HT as early as day E15. These studies suggest that the growth cones of serotonergic axons have at least some of the properties of mature serotonergic axon terminals. POSTNATAL EFFECTS OF PRENATAL ADMINISTRATION OF NEUROPEPTIDES ON ^{3}H-5HT UPTAKE BY SEROTONERGIC NEURONS. Davila-Garcia M. I., Hlibczuk V., Akbari H., Alves, S., and Azmitia E.C. Washington Square Center for Neuroscience, New York University, NY. NY. 10003.

Based on tissue culture experiments, neuropeptides have been shown to affect serotonergic neurons during development as endogenous regulatory factors. In this study we examined the postnatal effects of prenatally administered neuropeptides on high affinity ^{3}H-5HT uptake by brainstem, hippocampus and spinal cord.

Pregnant rats were injected daily from 7 to 21 days of gestation (7-21DG) with the ACTH 4-9 analog Organon 2766 (10ug/kg), leu-enkephalin (1ug/kg), or saline (9% NaCl). A group of untreated pregnant rats was included as control. At 26 (DPN) the pups were weighed, sacrificed, and the brainstem, hippocampus and spinal cord were dissected. A synaptosomal preparation was obtained to measure 3H-5HT uptake by serotonergic neurons during a 20 min incubation.

The Organon 2766 group showed a significant increase in ^{3}H-5HT uptake in brainstem and hippocampus suggesting the ascending serotonergic system is affected by prenatal administration of this peptide. Leu-enkephalin, however, showed an increase in ^{3}H-5HT uptake in spinal cord suggesting this peptide affects the descending serotonergic system.

POST-NATAL DEVELOPMENT OF SUPRAEPENDYMAL 5-HT FIBERS: IMPLICATIONS FOR 5-HT1c RECEPTOR ONTOGENY. J. Giordano*[1], G.A. Barr[2] and P. Hartig[1]; (SPON: R. Thompson) (1) Environ. Hlth. Sci., The Johns Hopkins Med. Inst., Baltimore, MD. and (2) Biopsychology Program, Hunter College, CUNY, New York, NY.

Supraependymal (SE) 5-HT fibers are the probable source of CSF-borne 5-HT that activates and regulates the 5-HT1c receptor in the choroid plexus. Using antibodies to serotonin, this study examined whether the normal postnatal maturation of these projections correlates with the previously reported pattern of 5-HT1c receptor ontogeny (Zilles et al., Brain Res. 380, 1986). Serotonin immunohistochemistry was accomplished using Sternberger PAP method on coronal and horizontal brain section of rat pups aged 0 to 21 days and of adults. Serotonin-like immunoreactivity was discernable at birth; individual varicose fibers were sparsely arranged along the SE surface. In 3-5 day olds, staining was somewhat more intense than in the newborn and fibers were more aggregated, notably on the dorsomedial ventricular walls. By 8 days postnatal, dense staining was observed and fibers formed networks along the SE surface. This pattern of staining persisted in the 14 and 21 day olds as well as the adult. We were unable to detect 5-HT hyperinnervation at any age. These results indicate that maturation of SE fibers parallels the development of 5-HT1c receptors from days 1-21.

167.13

CHANGING LEVELS OF CSF 5-HT PARALLEL DEVELOPMENT OF SEROTONIN 5-HT1c RECEPTORS IN CHOROID PLEXUS. C. Eastman*, J. Giordano*, T. Guilarte* and P. Hartig. (SPON: Z. Annau) Dept. of Environ. Hlth. Sci., The Johns Hopkins Medical Institutions. Baltimore, MD.

Levels of serotonin 5-HT1c receptor in choroid plexus undergo rapid down regulation immediately after birth; followed by a linear increase in sites to adult levels by 2 weeks postnatal (Zilles et al., Brain Res. 380:1986). CSF-borne 5-HT from supraependymal (SE) fibers appears to activate and regulate this receptor. The present study examined CSF indole levels in the developing rat using HPLC-EC.

CSF 5-HT levels were high at birth, followed by a precipitous drop at day 1 and increased from day 3 to 14. A significant rise in CSF 5-HT levels was measured between 14-21 days, at which point levels were comparable to the adult. 5-HIAA levels followed a similar ontogenetic pattern. Taken together with the pattern of SE fiber maturation (Giordano et al., this volume), these findings suggest that 1) a prenatal 5-HT surge may subserve rapid changes in 5-HT1c receptor levels immediately following birth, and 2) the gradual postnatal development of SE fibers parallels the developmental expression of 5-HT1c receptors from days 1-21 postnatally.

AMPHETAMINE-INDUCED ALTERATIONS IN DOPAMINE RELEASE AND METABOLISM IN THE NEOSTRIATUM OF DEVELOPING AND ADULT RATS. R.A. Gazzara, X.Y. Xuan* and S.G. Howard. MRRC, BRI and Dept. of Pharmacology, UCLA, Los Angeles, CA 90024.

Amphetamine (AMPH) has been shown to produce several effects on the dopaminergic neurotransmitter system in the CNS, including: facilitation of dopamine (DA) release; inhibition of DA re-uptake; and the inhibition of MAO.

The study reported here analyzed the effect of AMPH on the extracellular levels of DA and the DA metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), in the neostriatum of urethane-anesthetized adult rats, and 21-22-day-old and 35-36-day-old rat pups, using in-vivo microdialysis. Samples were collected every 10 min and levels of DA, DOPAC and HVA were measured by HPLC-EC. Rats were injected s.c. with 0.1, 1.0 or 5.0 mg/kg d-AMPH, or saline vehicle. In the adult group, AMPH produced an increase in DA release, in a dose-dependent manner, that peaked at 20-30 min postinjection. Conversely, AMPH produced a decrease in levels of DOPAC and HVA also in a dose-dependent manner. Minimum levels were reached at various times postinjection depending on dose. Preliminary data from the 21-22 day and 35-36 day groups suggest that the effect of AMPH on DA release is generally similar to that of the adult group. However, levels of DOPAC and HVA were generally higher in the 21-22 day and 35-36 day groups especially at the lower doses. These data suggest that AMPH may have a lesser effect on DA re-uptake in immature animals. Supported by USPHS HD 22548.

SIGNIFICANCE OF THE DIFFERENCE IN TIME OF APPEARANCE DURING DEVELOPMENT OF THE A AND B FORMS OF MONOAMINE OXIDASE IN THE RAT STRIATUM. G.S. Carter and A.J. Azzaro. Departments of Neurology and Pharmacology/Toxicology and Psychiatry West Virginia University Health Science Center, Morgantown, WV 26506.

The development of the MAO subtypes in the striatum of Sprague-Dawley rats was studied from birth to maturity. The development of the glial cell enzyme, glutamine synthetase, the monoaminergic neuron enzymes, tyrosine hydroxylase and tryptophan hydroxylase, and the intrinsic striatal neuron marker enzymes, choline acetyltransferase and glutamic acid decarboxylase were also studied and correlated with the MAO subtypes. Rats were lesioned at birth with the selective neurotoxins 6-hydroxydopamine or 5 7-dihydroxytryptamine and the development of the MAO subtypes studied. The postnatal studies showed that MAO type A activity preceded MAO type B activity in early development. The early development of both subtypes, however, was highly correlated with astrocytic development as demonstrated by glutamine synthetase activity. Neonatal lesioning of the monaminergic afferent neuronal terminals caused no decrement of the activity of either MAO subtype at the peak of astrocytic enzyme activity on the 15th postnatal day. It would thus appear that the difference in development of the two subtypes of MAO represents a phenomena of astroglial mitochondrial development in which MAO type B is a later addition to the mitochondrial membrane.

ISOLATED HYPOTHALAMIC NEURONS IN CULTURE RAPIDLY DISPLAY IMMUNOCYTOCHEMICALLY-DETECTABLE TYROSINE HYDROXYLASE AND VASOPRESSIN. C.A. Dudley, R.L. Moss, & P.W. Coates. Dept. Physiol., Univ. Tex. SW Med. Ctr., Dallas, TX 75235 & Cell Bio. & Anat., TTUHSC Sch Med., Lubbock, TX 79410.

Hypothalamic neurons cultured on three-dimensional (3-D) matrices rapidly express characteristic neuronal morphologies as single cells (Coates, SN Abs.12:1504,'86). To determine if such individual neurons contain vasopressin (VP) or tyrosine hydroxylase (TH), a series of immunocytochemical studies was performed. Hypothalamic neurons from late gestation fetal rats were plated onto 3-D matrices at low cell densities to assure wide separation of cells. After 1, 2 or 3 days, cultures were fixed with aldehydes in phosphate or cacodylate buffer. A modified version of Sternberger's peroxidase anti-peroxidase technique (Immunocytochemistry, Prentice Hall, Inc.'74) was used to detect immunostaining for antibodies (Ab) to VP and TH. When examined with light microscopy, control cultures (no exposure to primary Ab) contained no accumulation of reaction product. In neurons exposed to Ab, some positive staining was observed as early as 1 day after plating. In these and later cultures, two basic staining patterns were observed: 1) Smooth brown reaction product evenly distributed throughout the cytoplasm of the soma, and 2) Punctate deposits of reaction product localized to one side of the cell body. Some neurons showed intensely stained beaded fibers characteristic of intact tissue. Results demonstrate that isolated hypothalamic neurons quickly display TH and VP immunoreactivity. The data suggest that hypothalamic neurons, not in contact with cells of any other kind, are inherently capable of rapid functional as well as morphological differentiation. Supported by HD09988-V and HD22806.

EXCITATORY AMINO ACIDS: EXCITOTOXICITY I

168.1

GLUTAMATE BLOCKS KAINATE NEUROTOXICITY IN THE CHICK EMBRYO RETINA. J.L. Mosinger, M. T. Price, J. Labruyere, M. E. Mueller, E. Silverman and J.W. Olney. Washington University Sch. of Med., St. Louis, MO 63110.

N-methyl aspartate (N), quisqualate (Q) and kainate (K) are excitatory amino acid (EAA) analogs of glutamate (G) which mimic the excitotoxic action of G in the chick embryo retina. We postulate that each of these three analogs acts at a different subset of EAA receptors since certain agents which antagonize the neurotoxicity of N do not antagonize Q or K and the quinoxaline CNQX (FG 9065) antagonizes the neurotoxicity of K more potently than that of N or Q. In addition, although retinal neurons in the inner half of the inner nuclear layer (INL) are affected by all three agents (implying that such cells are endowed with all three receptor subtypes), somata in the position of horizontal cells are damaged only by Q and K while others in the outer half of the INL are damaged only by K. The cells that are damaged only by K are of particular interest in that the toxic action of K on these cells is blocked by G or Q.

At least two possible models might explain the protective effect of G/Q against K toxicity, one based on 3 EAA receptor subtypes and the other based on 4. In either case, they can be designated as G receptor subtypes since G appears to interact at all sites. In the triadic model G-1 = the N receptor through which either N or G exerts excitotoxic action and various N receptor ligands selectively block N toxicity; G-2 = the Q receptor through which either Q or G exerts excitotoxic action and Q toxicity is blocked by CNQX (50 μM) but not by N receptor ligands; G-3 = the K receptor through which only K exerts excitotoxic action and this is blocked by CNQX at 15 μM or by G or Q at concentrations which are excitotoxic to other cells. The other model postulates the same three receptor subtypes but divides the G-3 receptor into two subsets (Ka and Kb) each of which is sensitive to K agonist action but only one of which (Kb) is sensitive to Q antagonism. Regardless which of these taxonomic models best describes the true situation, possible mechanisms which might explain the antagonist properties of G/Q at K sites include receptor blockade, agonist-induced ion channel block and/or the promotion of desensitization. Q is known to exert a very rapid desensitizing action in some systems; thus, if Q were to displace K as agonist at the G-3 site but not express agonist excitotoxic action because of rapid receptor desensitization, the net effect would be a blockade of K toxicity. However, since Q expresses excitotoxicity at G-2 sites, it apparently does not desensitize so rapidly at this receptor. Supported by RSA MH 38894 (JWO), HD 24237 and DA 05072.

168.2

ROLE OF THE N-METHYL ASPARTATE RECEPTOR IN DEVELOPMENTAL PSYCHONEUROPATHOLOGY. J. W. Olney, C. Ikonomidou*, J. Mosinger, K. Shahid Salles and G. Frierdich*, Washington University Sch. of Med., St. Louis, MO 63110.

Accumulating evidence suggests that the endogenous excitotoxins, glutamate (Glu) and aspartate, acting at excitatory amino acid (EAA) receptors may be responsible for hypoxic/ischemic brain damage. Presumably such damage is mediated either by N-methyl aspartate (NMA) or kainic acid (KA) receptors (or both) since they are the most abundant EAA receptor subtypes in brain. We have observed that hypobaric/ischemic (H/I) conditions cause a Glu-like neurodegenerative reaction in the 10 day old rat brain and that there is a period in early neonatal life when rat CNS neurons are hypersensitive to both H/I degeneration and the toxic action of NMA (but not KA). This suggests that NMA receptors may play a special role in perinatal H/I brain damage. In support of this hypothesis, we now report that systemic administration of MK-801, a potent NMA antagonist, protects the immature rat brain against H/I damage.

Following unilateral carotid ligation, 10 day old rats were subjected to hypobaric conditions for 75 min (vacuum chamber maintained at a pressure of 225 mm Hg and temperature 38° C). MK 801 (1 mg/kg sc) or saline was administered to experimental or control pups respectively 15 min prior to hypobaric exposure. In each experiment, 10 pups (5 experimental and 5 control) were placed in the chamber together so that each experienced the same conditions. After hypobaric exposure, the pups were observed for 2 hrs, during which body temperatures were maintained at 37 ± 0.5° C ; then they were sacrificed by perfusion fixation under halothane anesthesia for histopathological evaluation of the brains. Amount of brain damage was rated as 0, mild, moderate or severe based on the size of lesions and number of brain regions involved. Among 49 control pups, the majority qualified for a severe rating, whereas among 47 experimental pups, only 1 qualified for a severe rating and the majority had 0 brain damage.

Based on these and other recent findings, we suspect that the NMA receptor-ionophore complex may play an important role in developmental psychoneuropathology; specifically, we propose that it may be a characteristic of immature NMA receptors to be hypersensitive to excitatory (excitotoxic) stimulation, in which case CNS neurons bearing such receptors might be destroyed by relatively minor degrees of hypoxic/ischemic exposure. Conditions for which this concept could conceivably have relevance include cerebral palsy, schizophrenia and mental retardation. 168.3

ZINC CENTRAL NEUROTOXICITY MAY REQUIRE OPEN NMDA CHANNELS. D.W. Choi and J. Koh. Stanford Univ. Med. Sch., Stanford, CA 94305.

Large amounts of Zn can be released from excitatory synaptic terminals with nerve stimulation, and may contribute to neurotoxic injury in certain disease states. We have previously reported that a 15 min exposure to 1 mM Zn is sufficient to produce widespread neuronal injury in murine cortical cell cultures. We report here that this Zn neurotoxicity can be largely blocked by both competitive (APV) or non-competitive (MK-801) NMDA antagonists. However, Zn neurotoxicity is probably not simply mediated through the toxicity of endogenous excitotoxins (such as glutamate): 1) removing extracellular Na and Ca blocks the neurotoxicity of NMDA or glutamate, but enhances Zn toxicity; 2) the antagonism of Zn neurotoxicity by MK-801, but not APV, can be overcome by increasing Zn concentration - a situation reversed from that seen in the antagonism of NMDA neurotoxicity; and 3) the concentration of MK-801 required to block Zn neurotoxicity (IC_{50} 5 - 10 μM) is higher than the concentration required to block NMDA neurotoxicity (IC_{50} 0.3 μM).

We speculate that Zn may require open NMDA channels to injure neurons. Zn may pass through this channel (perhaps interacting at or near the PCP binding site) to accumulate intracellularly and disrupt cellular processes, leading to neuronal damage.

168.4

BETA-N-METHYLAMINO-L-ALANINE (BMAA) NEUROTOXICITY ON MURINE CORTICAL NEURONS. J.H. Weiss, J. Koh and D.W. Choi Stanford Univ. Med. Sch., Stanford, CA 94305.

BMAA is a cycad plant excitotoxin recently implicated (Spencer et al., Science 237: 517) in the pathogenesis of Guam amyotrophic lateral sclerosis - Parkinsonism - dementia (ALS-PD). The basis for BMAA excitotoxicity is unclear, as it lacks the omega-acidic moiety characteristic of other excitatory amino acids. We have investigated the neurotoxicity of BMAA in murine cortical cell cultures, and report three observations:

1) BMAA, unique among excitotoxins we have tested (including BOAA), required the presence of physiological concentrations of bicarbonate to produce either neurotoxicity or neuroexcitation. We suggest bicarbonate interacts non-covalently with the positively charged beta amino group of BMAA to produce in combination a configuration appropriate for activation of glutamate receptors.

2) Even in the presence of bicarbonate, BMAA is a weak neurotoxin (toxic EC_{50} with 24 h exposure about 1 mM).

3) The widespread neuronal injury produced by intense BMAA exposure was largely blocked by APV, consistent with mediation by NMDA receptors. However, at the lower exposures likely relevant to ALS-PD, BMAA selectively damaged the small subpopulation of cortical neurons staining for NADPH-diaphorase, a finding suggesting predominant non-NMDA receptor-mediated toxicity.

168.5

EXCITOTOXICITY IN CHICK RETINA CAUSED BY THE UNUSUAL AMINO ACIDS BOAA AND BMAA:EFFECTS OF MK-801 AND DIDS. G. Zeevalk, S. Olynyk* and W. Nicklas. UMDNJ-Robert Wood Johnson Medical School, Dept. of Neurology, Piscataway, N.J. 08854

β-N-oxalylamino-L-alanine (BOAA) and β-N-methylamino-L-alanine (BMAA) have been shown to cause a glutamate (GLU)-like lesion in CNS. Since the retina is sensitive to GLU toxicity, we have examined the effects of these amino acids on retinal histology and amino acid release. Retina from E13 chicks was incubated with various amounts of agonists: BOAA (0.025-0.5mM), BMAA (0.75-3mM), NMDA (0.002-0.2mM), kainate (KA 0.002-0.2mM) with or without the NMDA antagonist, MK-801 (1μM) or the Cl^-/bicarbonate channel blocker, DIDS (0.6mM). All agonists produced an excitotoxic lesion. BOAA was only slightly less potent than KA; BMAA had a potency similar to GLU. BOAA, like KA, caused a large release of GABA and taurine. NMDA-induced release was similar to the other agonists except that serine efflux was also increased. MK-801 completely blocked the lesion caused by 0.05mM NMDA or 2mM BMAA, but was ineffective against KA (0.05mM) or BOAA (0.1mM). Consistent with histological findings, MK-801 prevented amino acid release caused by NMDA but not that caused by KA or BOAA. DIDS was effective in blocking all agonist induced lesions and in returning amino acids back to basal levels. These studies demonstrate that BOAA and BMAA produce retinal damage that is most likely mediated via an excitotoxic mechanism; BOAA appears to induce toxicity through a nonNMDA type GLU receptor and BMAA through the NMDA receptor.

PROTECTION OF HIPPOCAMPAL NEURONS FROM A PLANT NEUROTOXIN-INDUCED CELL DEATH BY ACIDIC AMINO ACID ANTAGONISTS IN VITRO. S. Rapp*, E. Sun* and D. Roufa (SPON :P. Manning) G. D. Searle/CNSDR, St Louis, MO 63198.

A neurotoxic plant "uncommon" amino acid β-N-methyl amino-L-alanine (L-BMAA) isolated from the seed of the plant Cycas circinalis has been implicated as an environmental factor mediating Guam Amyotrophic Lateral Sclerosis-Parkinsonism-Dementia (ALS-PD) (Spencer et al., Science 237:517, 1987). The same authors reported that L-BMAA-induced excitotoxicity is attenuated by N-methyl-D-aspartate (NMDA) receptor antagonists. Cultures of dissociated rat hippocampal neurons were used to investigate L-BMAA toxicity and its inhibition by competitive and noncompetitive NMDA receptor antagonists. The addition of L-BMAA to the culture medium resulted in concentration (10^{-3}-10^{-6}M) and time (1- 24 hr)- dependent selective neuronal cytotoxicity. Co-administration of 2-amino-7-phosphonoheptanoate (AP7), 3-((±)-2-carboxypiprazin-4-yl) propyl-1-phosphonic acid (CPP), phencyclidine (PCP) or MK801 with L-BMAA afforded the neurons protection from cytotoxicity. The rank order of antagonist potency corresponded to the relative binding affinities of these compounds for NMDA and PCP receptors. These results are consistent with the hypothesis that the accumulation of L-BMAA, or L-BMAA metabolite, within the brain can affect hippocampal neurons and lead to the dementia component of ALS-PD.

ANTAGONISM OF STRIATAL QUINOLINIC ACID TOXICITY BY VARIOUS POSSIBLE NMDA ANTAGONISTS S.-G. Zhu*, E.G. McGeer and P.L. McGeer (SPON: P.C.K. Leung). Kinsmen Lab, Dept Psychiatry, Univ of British Columbia, Vancouver, B.C., Canada, V6T 1W5

The effect of systemic pretreatment of rats with a variety of agents given once (MK-801, dextrorphan, dextromethorphan and tetrahydroaminoacridine (THA)) or repeatedly (dextrorphan, glycine, 4-acetylpyridine, and kynurenic acid) on the neurotoxicity of intrastriatal injections of quinolinic acid (QUIN) in rats was assessed by measuring choline acetyltransferase (ChAT) and glutamate decarboxylase (GAD) in the striata. The results with MK-801 confirmed and extended the report of Woodruff et al. (Neuropharmacology 26:903, 1987) since doses as low as 4 mg/kg were totally protective against 75-150 nmoles QUIN. The other agents were not protective at the doses used except for a mild effect of kynurenate at 75 nmoles QUIN. THA inhibited binding of [^{3}H]TCP to rat hippocampal membranes with a $K_i \cong 18$ μM but had no significant effect on QUIN toxicity. Measurements of γ-glutamyl transferase (γGT) activity indicated significant, but minimal, effects of both toxin and pretreatment with no significant interaction between the two. Overall, γGT did not correlate with either ChAT or GAD, indicating the small group differences seen were not a reflection of extent of neuronal loss.

EXCITOTOXIC BRAIN INJURY ENHANCES QUISQUALIC ACID (QA) STIMULATED PHOSPHOINOSITIDE(PPI) TURNOVER IN DEVELOPING BRAIN. D. Statman, C.K. Chen, M.V. Johnston, S.K.Fisher, F.S. Silverstein. University of Michigan, Ann Arbor, MI

QA, a potent excitotoxin in 7 d.o. rats, stimulates PPI hydrolysis at this developmental stage. Inositol phosphate(IP) release is a sensitive measure of PPI hydrolysis. We examined QA stimulated IP release after intra-striatal QA injections to learn more about the pathogenesis of excitotoxic injury in immature brain. Stereotaxic intra-striatal injections of QA (100 nmol) were done in 7 d.o. rats;pups were sacrificed 1,2, or 5 days later (9 experiments; in each, n=16 QA, 8 controls). After incubation with 3H-myoinositol and lithium, in vitro QA stimulated 3H-IP release was measured in lesioned brain & control striatal tissue slices. To assess the specificity of observed lesion-induced effects, cholinergic (carbachol) stimulated 3H-IP release was also assayed. IP release was expressed as % of basal in controls. 1,2, or 5 days post-lesion, incubation of lesioned brain tissue with QA (10^{-5} M) resulted in a paradoxical enhanced stimulation of IP release (mean ± SEM at 2 days, 1153±207% vs 576±118% in controls, $p<.01$, t-test). In contrast, there was no difference in carbachol stimulated IP release between lesioned & control striatum. These data suggest altered coupling of EAA recognition sites with phospholipase C; this may represent an adaptive synaptic response to injury.

168.9

CNQX POTENTLY AND SELECTIVELY BLOCKS KAINATE EXCITOTOXICITY IN THE CHICK EMBRYO RETINA. M.T. Price, T. Honore*, M.E. Mueller*, J. Labruyere*, E. Silverman* and J.W. Olney. Washington University Sch. of Med., St. Louis, MO and Ferrosan Research Division, Denmark.

The excitatory amino acid (EAA) agonists, N methyl-D-aspartate (NMDA), quisqualate (Quis) and kainate (KA), induce distinctive excitotoxic lesions in the ex vivo chick embryo retina. The toxic action of NMDA is selectively blocked by various antagonists which are ineffective against Quis or KA. Mixed EAA antagonists, such as kynurenic acid and cis-2,3-piperidine dicarboxylic acid, block the toxic actions of all three agonists but are of low potency, especially against KA and Quis. Recently, Honore et al (Neurosci. Abstr. 13, 383, 1987) described CNQX as a selective antagonist of EAA receptors of the non-NMDA type based on electrophysiological experiments conducted in rat spinal cord.

We have studied the anti-excitotoxic properties of CNQX in the chick embryo retina and found that at 15 uM concentration it totally prevents the neurotoxic action of KA, and at 50 uM prevents either NMDA or Quis toxicity. This identifies CNQX as the most selective and potent antagonist of KA excitotoxicity yet described. While CNQX also qualifies as the most potent known antagonist of Quis excitotoxicity, it is not selective against Quis compared to NMDA toxicity in this retinal preparation.

Previously we described MK-801 as the most potent known antagonist of NMDA toxicity, but we found MK-801 relatively impotent in preventing ischemic damage in the chick retina; for example, it blocked NMDA toxicity at 100 nM concentration but did not block ischemic damage at >100 uM. Here we report that concentrations of CNQX up to 100 uM are ineffective in blocking ischemic damage but a combination of MK-801 (500 nM) plus CNQX (100 uM) does effectively prevent ischemic damage. This supports the interpretation that endogenous EAA acting at both NMDA and non-NMDA receptors mediate ischemic neuronal degeneration in the chick retina, and that both classes of receptor must be blocked for optimal protection against retinal ischemic damage. Supported in part by DA 05072, HD 24237, DAMD 17-86-C6010 and Research Scientist Award MH 38894 (JWO).

GLUTAMATE IS TOXIC AT THE N-METHYL-D-ASPARTATE (NMDA) RECEPTOR WHEN ENERGY LEVELS ARE COMPROMISED. M.A. Vigano*, A. Novelli*, J.A. Reilly*, P.G. Lysko* and R.C. Henneberry*, (Sponsor: J.P. Bressler.) NINCDS, NIH Bethesda, MD. 20892.

We have found that excitatory amino acids (EAAs) are neurotoxic for cerebellar granule cells in primary culture when neuronal energy metabolism is compromised. Glutamate stimulated cGMP synthesis in metabolically competent granule cells, but killed the cells when ATP levels were reduced or ion pumps inhibited. Glucose starvation, oxygen deprivation, or oxidative phosphorylation inhibition enabled NMDA agonists to become lethal. Toxicity was blocked by both competitive antagonists such as AP5, AP7, and CPP and by noncompetitive antagonists such as MK-801, ketamine, and phencylidine (which are thought to block the NMDA receptor channel). Results indicate that compromised energy levels in the neuron are reflected in decreased ion pump activity leading to sufficient depolarization to relieve the voltage-dependent Mg^{++} block of the NMDA receptor, which permits the opening of large numbers of NMDA receptor channels. Again due to reduced availability of ATP, ion pumps are unable to keep pace with the influx of Na^+ and Ca^{++}, and neuronal death follows. This mechanism may be involved in the death of neurons following ischemia due to stroke or cardiac arrest, or in a variety of neurodegenerative disorders in which neuronal energy is compromised.

168.11

MODULATION OF GLUTAMATE-INDUCED NEUROTOXICITY BY THE PUTATIVE NEUROTOXIN β-N-OXALYLAMINO-L-ALANINE. P.G. Lysko* and R.C. Henneberry* (SPON: J.W. Thomas). Molecular Neurobiology Section, Lab. of Molecular Biology, NINCDS, National Institutes of Health, Bethesda, MD 20892.

The unusual amino acids β-N-methylamino-L-alanine (BMAA) and β-N-oxalylamino-L-alanine (BOAA) have been implicated as environmental neurotoxins when consumed in food. We have tested these putative neurotoxins for interaction with the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor found in our model system of cultured rat cerebellar granule cells. Neither BMAA nor BOAA (10 mM) was itself toxic to glucose-depleted cells, as shown by fluorescein diacetate staining for viability. However, the toxicity of glutamate at normally sublethal levels (10 μM) was potentiated by as little as 10 μM BOAA, resulting in complete killing; 1 mM BMAA did not potentiate. The lethal effects of BOAA with 10 μM glutamate were completely abolished by 1 mM 2-amino-5-phosphonopentanoate (AP5), 1 μM MK-801, or 5.6 mM glucose. The modulation by BOAA of glutamate-induced neurotoxicity may be mediated via membrane depolarization. When Ca^{++}-dependent cGMP synthesis under energy-compromised conditions was monitored as an indicator of ion channel activity, either 100 μM BOAA or 10 μM glutamate alone stimulated low levels of intracellular cGMP production; BOAA together with glutamate resulted in a strongly synergistic stimulation of cGMP synthesis which was blocked by AP5 and MK-801.

NMDA RECEPTOR LOSSES IN HUNTINGTON'S DISEASE PUTAMEN SUPPORT A NEUROTOXIC HYPOTHESIS. A.B. Young, J.T. Greenamyre, Z. Hollingsworth, R. Albin, C.J. D'Amato, I. Shoulson, and J.B. Penney. Depts. of Neurology and Pathology, Univ. of Michigan, Ann Arbor, MI 48109 and Dept. of Neurology, Univ. of Rochester, Rochester, NY 14642.

N-Methyl-D-aspartate (NMDA)-and phencyclidine (PCP) receptor binding were compared to quisqualate, benzodiazepine, GABA and muscarinic cholinergic receptor binding in the putamen and cerebral cortex of Huntington's disease (HD) brains and control brains. NMDA and quisqualate receptors were measured with [^{3}H]glutamate; PCP receptors with [^{3}H]N-(1-[2-thienyl]cyclohexyl)-3,4-piperidine (TCP); muscarinic cholinergic receptors with [^{3}H]quinuclidinyl benzilate; GABA receptors with [^{3}H]muscimol and benzodiazepine receptors with [^{3}H]flunitrazepam. NMDA and PCP receptor binding were reduced 93% and 68%, respectively, in HD putamen compared to binding in controls. Quisqualate receptors were reduced 67% and the binding to other receptors was reduced 55% or less. Cerebral cortex receptor binding was unchanged in HD compared to controls. The prominent loss of NMDA receptors supports the hypothesis that NMDA receptor mediated neurotoxicity plays a role in the pathophysiology of HD.

MONOSODIUM-L-GLUTAMATE(MSG)- AND KAINIC ACID(KA)-INDUCED NEUROCHEMICAL CHANGES IN ADULT AND AGED RATS. D.R. Wallace and R. Dawson Jr. , Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, Fl. 32610.

The neurochemical effects of the exogenous excitotoxins, KA and MSG, were evaluated in adult(6 month) and old(20-30 month) rats. Female Long Evans rats received KA at a dose of 15mg/kg (i.p.) and were sacrificed two hours later. Male Fischer-344 rats received MSG at a dose of 500mg/kg (i.p.) and were sacrificed 30 minutes later.

KA treatment resulted in significant ($p<0.001$) decreases in norepinephrine (NE) levels in the entorhinal cortex [ECX], frontal cortex [FCX], and striatum[STR] in the old rats. Levels of 5-HIAA and HVA however, increased in the ECX and FCX of old rats. KA decreased levels of aspartate and glutamate in the ECX, but only aspartate was lowered in the FCX of old rats. KA treatment in adult rats produced trends similar to the old rats, although these effects were not statistically significant.

NE levels were decreased by MSG administration in the cerebellum and hypothalamus of adult rats, but NE content was increased in the CER of old rats. MSG elevated ($p<0.05$) glutamate in the posterior cortex of old rats.

These data point to important in vivo relationships between excitatory amino acids and central noradrenergic systems. Age-induced alterations in NE-excitatory amino acid interactions may contribute to cognitive and memory deficits associated with aging. This work was supported by the American Federation for Aging Research.

168.14

EXCITATORY AMINO ACID-EVOKED RELEASE OF [^{3}H]GABA FROM STRIATAL NEURONS IN PRIMARY CULTURE. Dorothy E. Kemp* and Samuel Weiss (SPON: J. Bevan). Dept. of Pathology, University of Calgary, Calgary, Alta., Canada T2N 4N1

The actions of excitatory amino acids (EAAs) on the release of previously incorporated [^{3}H]GABA was examined in purified (>93%) striatal neurons in primary culture. Glutamate, KCl and veratrine evoked a dose-dependent, saturable and reversible release of [^{3}H]GABA. Glutamate actions were not reduced in the absence of calcium, and were insensitive to tetrodotoxin. The dose-response relationships of EAAs demonstrated the following rank order of potency: glutamate > aspartate = N-methyl-D-aspartate > kainate >> quisqualate. Kainate was the most effective agonist, evoking an 8-fold increase over baseline levels of [^{3}H]GABA release. Aspartate- and N-methyl-D-aspartate-evoked release was abolished in the presence of either APV or γ-DGG. Release due to glutamate and kainate was ineffectively attenuated by these agents. Glutamate-, aspartate- and N-methyl-D-aspartate-evoked GABA release were augmented when calcium was omitted and reduced when sodium was replaced with choline or lithium. Kainate-evoked release was unaffected when calcium was omitted, unchanged when choline replaced sodium, and markedly potentiated when lithium substituted for sodium. These findings suggest that two distinct receptor systems for EAAs mediate the evoked release of [^{3}H]GABA from striatal neurons.

168.15

EVALUATION OF THE ANTI-EXCITOTOXIC ACTION OF MK-801 IN THE RAT STRIATUM BY MEANS OF APOMORPHINE-INDUCED ROTATIONAL BEHAVIOR: COMPARISON WITH NEUROCHEMICAL MEASUREMENTS. Z. Susel*, T.M. Engber and T.N. Chase. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20892.

MK-801 can prevent the production of excitotoxic lesions caused by excessive stimulation of the N-methyl-D-aspartate (NMDA) receptor. Previous reports have demonstrated this effect *in vivo* by means of histological examination of brain tissue or by measurement of neurochemical markers. In the present study, the ability of MK-801 to preserve the functional integrity of the rat striatum following intrastriatal injection of the NMDA agonist quinolinic acid was assessed by measurement of apomorphine-induced rotational behavior. In addition, choline acetyltransferase (CAT) activity was determined in the striata of these rats. Apomorphine-induced rotations were recorded six days after injection of quinolinic acid (300 nmoles) into the left striatum. MK-801 (3, 5 or 10 mg/kg, i.p.) or saline was administered 30 minutes before injection of quinolinic acid. One day after rotation tests, rats were sacrificed and the striata dissected for measurement of CAT activity. Pretreatment with MK-801 at a dose of 10 mg/kg virtually eliminated ipsilateral rotational behavior but had no effect compared to saline-pretreated controls at doses of 3 and 5 mg/kg. CAT acitivity in the lesioned striata of MK-801-pretreated rats (which ranged from 48% of the unlesioned striatum at 3 mg/kg to 93% at 10 mg/kg) was significantly different from that of saline controls (10-12% of unlesioned striatum) at all three doses of MK-801. Thus apomorphine-induced rotational behavior can be used to assess the functional integrity of the rat striatum following excitotoxic lesion. The relationship between rotational behavior and other neurochemical markers in the striatum remains to be investigated.

EXCITATORY AMINO ACIDS IN EXPERIMENTAL SPINAL CORD TRAUMA: INJURY-INDUCED CHANGES IN TOTAL TISSUE LEVELS AND PHARMACOLOGICAL INTERVENTION WITH THE COMPETITIVE ANTAGONIST CPP. P. Demediuk* and A.I. Faden. Center for Neural Injury, VA Medical Center, San Francisco, and Neurology Department, University of California, San Francisco, CA 94121.

Changes in total spinal cord tissue content of amino acids were followed over time after 25, 50, and 100 g-cm impact injury (Allen method) to the T9 segment of pentobarbital-anesthetized rats. Samples were frozen *in situ* with liquid nitrogen, and amino acids were quantitated electrochemically as their O-pthalaldehyde, 2-propanethiol derivatives after HPLC separation. Trauma resulted in time-dependent, injury-dependent alterations among the various measured amino acids. Glu and asp were significantly reduced at all postinjury sampling times, whereas GABA, gly and tau were decreased at 5 min, with partial recovery at 4 hr and 24 hr. For pharmacological studies, intrathecal perfusion with 10 and 100 μg of the competitive inhibitor CPP [(±-4-(3-phosphonopropyl)-2 piperazinecarboxylic acid] at 15 min postinjury (50 g-cm) significantly improved both motor function and ability to remain on an inclined plane. The outcome measures were affected in a dose-dependent manner when compared with saline-treated injury controls. These studies provide evidence for the role of "excitotoxins" in delayed injury following spinal cord trauma.

PICOLINIC ACID PROTECTS AGAINST QUINOLINIC ACID-INDUCED CORTICAL CHOLINERGIC DAMAGE. K. Jhamandas, R.J. Boegman, R.J. Beninger†, and M. Bialik* (SPON: J.V. Milligan). Departments of Pharmacology and Toxicology, and Psychology†, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Quinolinic (QUIN) injections into the nucleus basalis magnocellularis (nbM) destroy cortical neurons, and kynurenic acid (KYA) prevents this action. This study examined whether picolinic acid (PIC), and several other products of the kynurenine pathway of tryptophan metabolism, share these actions. PIC injection into the nbM did not produce cholinergic damage, but fully protected against the excitotoxic action of QUIN or kainic acid. Histological examination of nbM confirmed the antagonistic action of PIC and protected neurons showed normal release of ^{3}H-acetylcholine when stimulated with potassium (35 mM). While PIC was less potent than KYA, it was more potent than quinaldic acid, hydroxy-quinaldic acid or anthranilic acid. None of these agents were excitotoxic when injected singly into the nbM. It is concluded that to KYA, PIC and several other tryptophan metabolites can antagonize the toxic action of QUIN on basal forebrain cholinergic neurons. (Supported by the Ontario Mental Health Foundation)

INHIBITION OF CYSTINE UPTAKE MEDIATES QUISQUALATE TYPE GLUTAMATE TOXICITY IN A NEURONAL CELL LINE. T.H. Murphy, M. Miyamoto *, A. Sastre, R.L. Schnaar and J.T. Coyle. Depts. of Pharmacology, Physiology and Neuroscience, The Johns Hopkins School of Medicine, Balto. MD, 21205.

Quisqualate (Quis) type glutamate (Glu) toxicity in N18-RE-105 cells is delayed in onset, calcium dependent, not caused by depolarization, not prevented by putative Quis receptor antagonists, nor produced by the agonist AMPA. The pharmacologic specificity of the cytotoxic effect exhibits similarities to that of cystine (Cys) sensitive Cl^- dependent Glu transport, prompting an examination of the role of Cys in cytotoxicity. Increasing the Cys concentration of the culture medium from the usual 0.2 mM to 1.0 mM prevented the toxic effects of both 1.0 mM Quis and 10 mM Glu, whereas medium containing 0.005 mM Cys caused cell death itself, with a cytopathology, time course, Ca^{++} dependence, and protection by antioxidants similar to 10 mM Glu. [35S]Cys and [3H]Glu are transported into the cells with apparent K_ts of 9 and 45 μM , respectively. The observed K_is for inhibition of [35S]Cys or [3H]Glu uptake by Glu, Cys, and Quis were nearly identical, suggesting that Cys and Glu compete at the same uptake site. Alterations in media Cys concentrations (5-200 μM) affected the toxic potency of Glu and Quis in a manner which could be predicted from their apparent affinities for the Cys/Glu transporter; the correlation between cell death and occupancy of the Cys transporter was linear with a slope of 1. Glu treatment reduced glutathione (GSH) levels to less than 50% of control in 4 h. Consistent with the reduction in GSH levels being the critical factor in Glu toxicity, the GSH synthesis inhibitor buthionine sulfoximine was also toxic. These data suggest that the Quis sensitive, Cl^- dependent Glu transport is a mechanism for Cys sequestration for maintenance of redox homeostasis by GSH synthesis. Furthermore, inhibition of this process by extracellular Glu or Quis kills these neuron-derived cells by oxidative stress (Miyamoto *et al.* and De Long *et al.*, these proceedings) through GSH depletion.

168.19

ANTIOXIDANTS PROTECT AGAINST GLUTAMATE CYTOTOXICITY IN A NEURONAL CELL LINE. M. Miyamoto*, T. H. Murphy, R. L. Schnaar and J. T. Coyle . Depts. of Neuroscience and Pharmacology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

L-Glutamate (Glu) and quisqualate (Quis) cause a delayed Ca^{2+}-dependent cytotoxicity in the N18-RE-105 cell line between 8-24 hours of exposure (Murphy *et al.*, Brain Res. 444:325, 1988). Since the competitive inhibition of cystine uptake by Glu and Quis correlates precisely with their cytotoxic potency, cystine deprivation likely accounts for the cell lysis (Murphy *et al.*, this meeting). In this study, the effects of antioxidants and reducing agents on Glu cytotoxicity were examined in the N18-RE-105 cell line.

Reducing agents, cysteine (10-1000 μM), dithiothreitol (DTT, 10-250 μM) and glutathione (GSH, 10-1000 μM) protected the cells against the cytotoxicity of 10 mM Glu in a concentration dependent manner. Antioxidants, α-tocopherol (10-100 μM), idebenone (0.1-3 μM) and vinpocetine (30-300 μM) also provided marked protection. Furthermore, these agents prevented delayed cell death caused by lowering the concentration of cystine in the medium from 200 μM to 5 μM. Incubation with 10 mM Glu caused a marked decrease in the GSH levels of the cells. Whereas cysteine and DTT prevented the GSH reduction caused by Glu, the antioxidants were ineffective. The cellular levels of oxidants were assessed using 2,7-dichlorofluorescin, a probe that accumulates within cells and is converted to a fluorescent product by oxidation. α-Tocopherol and idebenone markedly reduced the number of fluorescent cells caused by 10 mM Glu. These results indicate that oxidative stress due to loss of cellular levels of GSH is one mechanism whereby Glu/Quis exert cytotoxicity and suggest that centrally active antioxidants may reduce neuronal damage in pathologic conditions associated with excessive Glu release.

168.20

NAD(P)H:QUINONE REDUCTASE PROTECTS AGAINST GLUTAMATE TOXICITY IN A NEURONAL CELL LINE. M.J. DeLong *, T.H. Murphy, M. Miyamoto* and J.T. Coyle (SPON: L. Fechter) Depts. of Environmental Health Science and Psychiatry, The Johns Hopkins University School of Hygiene and School of Medicine, Baltimore MD 21205.

A select population of surviving neurons in the neostriatum of Huntington's disease (HD) patients stain intensely for NAD(P)H-diaphorase, a histochemically defined group of enzymes postulated to be 70-80% NAD(P)H:quinone reductase (QR) in the brain. Glutamate (Glu) toxicity of neurons may involve oxygen radical reactions. QR (also known as DT diaphorase) is uniquely capable of eliminating oxygen free radicals, thus protecting cells from oxidative stress. We have investigated the role of QR in the delayed quisqualate-sensitive Glu toxicity in N18-RE-105 cells.

Exposure of these cells to 10 mM Glu causes a 50-70% loss of QR in 2-3 hr similar to decreases observed with menadione and paraquat, oxidative stress producing compounds. Glu exposure of these cells is associated with a greater than 50% loss of glutathione (GSH) in 4 hr due to inhibition of cystine uptake which is associated with oxygen radical formation (Murphy *et al.* and Miyamoto *et al.*, these proceedings). Induction of QR levels to 2 to 4-fold by treatment with tert-butyl hydroquinone (3-20 μM) prior to Glu exposure protects against cell death by 50 to 100% over control cells. Dicumarol, a specific inhibitor of QR, potentiates cell death by 30-60% in a dose-dependent manner with 1 mM Glu. We speculate that the initial rapid loss of both QR and GSH potentiates cell death by perturbation of the redox homeostasis which they regulate. These *in vitro* data demonstrate QR protection against Glu toxicity and suggest a possible protective role of QR against neuronal degeneration as in HD.

EXCITATORY AMINO ACIDS: EXCITOTOXICITY II

PHENCYCLIDINE (PCP) REDUCES INFARCT SIZE IN A MODEL OF FOCAL CEREBRAL ISCHEMIA: L.F. Copeland, P.A. Boxer, F.W. Marcoux. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

NMDA antagonists have been shown to prevent global ischemic injury to the hippocampus. Phencyclidine (PCP) is a potent noncompetitive NMDA antagonist. We have evaluated PCP in a model of focal brain ischemia induced by permanent combined common carotid and ipsilateral middle cerebral artery (MCA) occlusion in male Fisher 344 rats. PCP was administered IV via a femoral catheter 30 min and 24 hrs post MCA occlusion. The areas and estimated total infarct volume were determined by measuring Evan's Blue extravasation in three cross-sectional slices. PCP, at 3 mg/kg (N=10), produced disruptive behavioral effects and a 35% reduction in infarct volume compared to saline controls ($p<0.05$, ANOVA). At 10 mg/kg (N=10), PCP produced anesthesia and a 24% decrease in infarct volume that was not statistically significant. These results suggest that PCP can reduce infarct volume in focal brain ischemia. The NMDA antagonist actions of PCP may contribute to its neuroprotective and disruptive behavioral effects.

169.2

QUISQUALIC ACID(QA) AND ITS ANALOGUE AMPA ENHANCE PHOSPHOINOSITODE(PPI) TURNOVER IN N-METHYL-D-ASPARTATE (NMDA) LESIONED BRAIN OF PERINATAL RATS. C.-K.Chen, D.Statman, F.S.Silverstein, M.V.Johnston, Univ. of Michigan, Ann Arbor, MI 48104

Excitatory amino acid(EAA) mediated receptor responses may be one of the factors which trigger a cascade of neurotoxicity in ischemic-hypoxic brain damage. We previously reported that QA mediated PPI turnover was increased after ischemic-hypoxic brain insult in perinatal rats(*J. Neurochem.*,in press), suggesting altered coupling of receptors and phospholipase C. We examined this QA mediated PPI turnover in an excitotoxic model which replicates several important features of ischemic-hypoxic injury in the immature brain.

NMDA, 17 nmole in 0.5 uL, was injected into the right posterior corpus striatum of ether anesthetized 7 day old rats and the pups were sacrificed 3 days later. Hippocampal or striatal tissue slices were prepared from both ipsilateral and contralateral side of the injected brain as well as uninjected controls. Slices were incubated with ^{3}H-myoinositol plus QA(10^{-5}M) or AMPA(10^{-3}M) in the presence of lithium and inositol monophosphate(IP1) accumulation was measured. Both QA(7 experiments) and AMPA(2 experiments) incubation enhanced IP1 release(expressed as % of basal in controls) in tissue ipsilateral to the NMDA injection(Mean±SEM, Hippocampus: 1237±334 vs. 510±178 in contralateral, $p<0.05$, paired *t* test; Striatum: 1381±576 vs. 562±279 in contralateral, $p<0.05$). AMPA had a similar though weaker effect(Hippocampus: 260±79 vs. 176±84, $p<0.05$; Striatum: 319±46 vs. 117±31, $p<0.05$), whereas there were no differences between contralateral and controls in both cases.

These results suggest that both the ischemic-hypoxic insults and NMDA lesion in 7 day old rats have the similar effects to enhance QA receptor coupled PPI turnover.

169.3

3H-TCP BINDING IN HYPOXIC-ISCHEMIC (HI) BRAIN. F.S. Silverstein, J.W. Mcdonald, M.V. Johnston. (Sponsored by G.W. Goldstein). Univ. of Michigan, Ann Arbor, Mi.

Recently, we found that MK-801, a non-competitive antagonist of N-methyl-D-aspartate (NMDA), protects the neonatal brain from HI damage (Eur J Pharm 140:359). MK-801 binds to a phencyclidine (PCP) site associated with the NMDA receptor. 3H-N-(1-[2-thienyl]-cyclohexyl)-3,4-piperidine (3H-TCP), a PCP derivative, binds to the channel associated with the NMDA receptor. We used in vitro autoradiography to examine 3H-TCP binding in HI brain and in MK-801 pre-treated animals that underwent the same HI insult. 8 d.o. rat pups were sacrificed 24h after right carotid ligation followed by a 2.5h exposure to 8%02 [n=7 saline treated, n=7 MK-801 (1mg/kg) treated]. To prepare ARG's, frozen sections were incubated with 3H-TCP; binding density was quantitated bilaterally in 10 brain regions. In regions susceptible to irreversible neuronal damage e.g. hippocampus, 3H-TCP binding declined ipsilateral to ligation in HI brain [e.g. dentate gyrus (DG) -35+5%, $p<.001$ ANOVA vs control]. In ligates treated with MK-801, inter-hemispheric asymmetries in 3H-TCP binding were reduced (for DG, $p< .01$, ANOVA, HI vs HI + MK-801); however, diffuse suppression of 3H-TCP binding in MK-801 treated pups contributed to this result. Acute disruption of 3H-TCP binding appears to be a sensitive marker for brain regions susceptible to HI injury.

GLUTAMATE-INDUCED INCREASE OF Ca^{2+} IN NEURONAL CEREBELLAR GRANULE CULTURES STUDIED AT THE ULTRA-STRUCTURAL LEVEL. P. Putzolu and H. Alho. FGIN, Georgetown Univ., Medical School, Washington, D.C. 20007.

Glutamate receptors, sensitive to NMDA stimulation and Mg^{2+} inhibition, are members of a family of ionotropic and metabolotropic receptors that included allosteric regulatory centers. Stimulation of the primary transmitter recognition sites is transduced into transient cationic (Ca^{2+}) influxes followed by an activation of Ca^{2+}-regulated enzymes which, can cause neuronal death. Hence it is presumed that glutamate neurotoxicity is due to a sustained increase of the cytosolic concentrations of Ca^{2+} followed by H_2O influx and activation of Ca^{2+}-dependent enzymes. In this study, the presence of Ca^{2+} was demonstrated by electron spectroscopic element imaging using a Zeiss-902 transmission electron microscope. Prefixation with glutaraldehyde followed by postfixation with osmium-$K_2Cr_2O_7$ was used to precipitate and visualize endogenous Ca^{2+} without the addition of external Ca^{2+}. In cerebellar granular neurons, electron dense precipitates containing Ca^{2+} were found in intracellular compartments. In the glutamate-treated neurons, the intracellular signal for Ca^{2+} was considerably increased. Using the present method, it is possible to obtain ultrastructural information concerning the molecular mechanism of glutamate neurotoxicity.

EXCITATORY AMINO ACID MECHANISMS OF ZERO-CALCIUM INDUCED DEATH OF CEREBELLAR GRANULE CELLS P. P. McCaslin Dept. Pharmacol.& Toxicol., UMC, Jackson, Ms, 39216

Primary cultures of cerebellar rat neurons were grown for 18-22 days *in vitro*. After this time, growth medium was washed from slides with a balanced salt solution containing the following mM concentrations: 154 NaCl, 5.6 KCl, 2.5 $CaCl_2$, 10 glucose and 5 HEPES (pH 7.4; r.t.). Cells were left in this buffer for 15 minutes and then rinsed and placed in the above buffer lacking calcium (no EGTA was added). Changes in the cells were evident within 2 min and included an apparent cellular granulation with a loss of cell body birefringence at 10x magnification with complete cell death by 30 min. Cells were protected from zero-calcium induced death by the excitatory amino acid (EAA) antagonist, 2-amino-7-phosphonoheptanoic acid (APH; 200 *u*M). Also, the addition of 2 mM $MgCl_2$ to the buffer protected against death. Evidence that zero-calcium was inducing the secretion of a toxic compound was obtained by the following experiments. Cells were protected from death by continuously washing zero-calcium buffer over the cells, thus washing away substances released by the cells. This was accomplished by placing slides in 50 ml of zero calcium buffer and gently swirling the dish. After 30 min the swirling could be stopped and the cells would survive in zero-calcium buffer. A 0.2 ml drop of zero-calcium buffer placed onto fresh cells and swirled for 3 min resulted in the secretion of amino acids into the buffer. Adding $MgCl_2$ to this amino acid-containing buffer placed onto fresh cells resulted in cell death. Examination of select amino acids secreted into 0.2 ml of zero-calcium buffer revealed a decrease in GABA (2- to 5-fold) and increases in glutamate (10-fold) and glycine (5-fold) when compared to amino acids secreted into calcium buffer under the same conditions. No change was seen in the secretion of threonine between these 2 groups. Collectively, the data suggest that zero-calcium induces the release of glutamate and glycine by unknown mechanisms, since vesicle fusion with the membrane would not be expected in the absence of calcium. The released glutamate then activates the EAA receptor which ultimately leads to cellular death. Death is prevented by 1] washing glutamate from the cells, 2] preventing the release of glutamate with magnesium or 3] blocking the EAA receptor with APH. Under the non-physiologic condition of zero-calcium, cerebellar neurons can release a compound which results in the auto-stimulation of an EAA receptor, ultimately leading to cell death.

DEVELOPMENTAL SUSCEPTIBILITY TO EXCITATORY AMINO ACIDS IN RAT STRIATUM. L. Arcavi*, D.M. Ferriero, S.M. Sagar and R.P. Simon. Dept. of Neurology, Univ. of Calif., San Francisco, CA 94143

In immature rats, there is selective sparing of NADPH diaphorase-reactive (NADPHd+) neurons after forebrain hypoxic-ischemic injury. This pattern is mimicked by intrastriatal injection of the endogenous excitotoxin, quinolinic acid (QUIN). The vulnerability of these NADPHd+ neurons seems to change during development. To test this hypothesis, we examined the effects of intrastriatal injection of either QUIN (80 nm), quisqualate (QA; 100 nm) or kainate (KA; 15 nm) at postnatal day (P) 7, P14, and in the adult Sprague Dawley rat. After 1 week survival, the brains were processed for NADPHd histochemistry. Despite significant loss of striatal tissue, there was a striking preservation of NADPHd+ neurons in the striatum of P7 rats after QUIN infusion. P14 and adult animals, however, lacked NADPHd+ cells in the area of damage. With QA infusion, severe neuronal damage without sparing was seen at all ages. Intrastriatal injection of KA did not affect the P7 brains, whereas total cell death was seen after P14. These findings show that, early in development, NADPHd+ neurons are resistant to NMDA and KA; QA susceptibility appears early and does not seem to change.

LESION-INDUCED CHANGES IN GLUTAMATE UPTAKE SITES. R.J. Bridges, K.J. Anderson, A.L. Tavoularis*, D. Bhatt* and C.W. Cotman. Department of Neurology and Psychobiology , Univ. California, Irvine, CA 92717.

The termination of the excitatory action of L-glutamate and the prevention of subsequent excitotoxic neuronal damage is dependent upon the activity of high affinity transport systems. In the present investigation we have used *in vitro* autoradiography to examine the response of glutamate uptake sites in the hippocampal formation to a lesion of the entorhinal cortex. Binding to the Na^+-dependent site was studied using [^{3}H] D-aspartate and binding to the Cl^--dependent site was visualized using [^{3}H] L-glutamate. Animals were subjected to a complete unilateral lesion of the entorhinal cortex and killed at various times postlesion.

Both the Na^+- and Cl^--dependent transport sites were found to transiently increase in the dentate gyrus molecular layer in response to entorhinal ablation. An approximate 25% increase in binding was seen at 5 and 7 days postlesion. The levels of binding returned to control values by 12 days postlesion. No significant changes in binding to these uptake sites was seen at long postlesion times (3-6 months). Enhancement in binding was seen to parallel the increase in GFAP immunoreactivity, supporting the hypothesis that these uptake sites are present on reactive astroglia. An increased ability to transport glutamate may represent a mechanism by which the molecular layer is protected, at least in part, from possible excitotoxic damage mediated by L-glutamate.

169.8

AUTORADIOGRAPHIC COMPARISON OF NA^+ AND CL^--DEPENDENT EXCITATORY AMINO ACID UPTAKE SITES. K.J. Anderson, R.J. Bridges, A.L. Tavoularis*, D. Bhatt* and C.W. Cotman. Department of Psychobiology and Neurology, Univ. California, Irvine, CA 92717.

The density, distribution and pharmacology of binding to the two major excitatory amino acid uptake carriers was studied in rat brain using *in vitro* autoradiographic techniques. Binding to the Na^+-dependent site was studied using [^{3}H] D-aspartate and binding to the Cl^--dependent site was visualized using [^{3}H] L-glutamate. Both were studied on fresh-frozen 6 µm tissue sections. We found that in fresh tissue sections, up to 50% of the total pool of bound radioactivity appeared to be sequestered in membranes. This pool was decreased by 1) stimulation of homoexchange, 2) the additon of cellobiose to the incubation buffer and, 3) by rinsing the tissue in H_2O. Uptake into the transported pool was reduced by incubating the tissue sections in fresh xylenes for 10 minutes prior to incubation with radiolabeled substrate. Xylene pre-treatment did not affect the pharmacology of binding to either site. Autoradiographic analysis of the binding sites showed a complimentary distribution; the Na^+-dependent binding was highest in the cerebellar molecular layer, lateral septum, entorhinal cortex and hippocampus while Cl^--dependent binding was highest in thalamic nuclei, striatum, outer cortical layers and dentate gyrus molecular layer. These sites also differed by their pharmacology. Na^+-dependent binding was most potently inhibited by D,L-threo-β-hydroxyasparate>cysteine sulfinate>quisqualate. Cl^--dependent binding was most potently inhibited by α-aminoadipate>quisqualate>ibotenate. The density of uptake sites was compared between 10 day-old, 3 month-old and 26 month-old rats. A reduction in binding was seen to occur in select regions of the aged brain, indicating that these circuits may be more vulnerable to excitotoxic damage.

CORRELATION BETWEEN EXCITATORY AMINO ACID INDUCED ELECTROPHYSIOLOGICAL RESPONSES AND NEUROTOXICITY.
W.J.Koroshetz, A.Freese, M.DiFiglia and D.P. Corey. Department of Neurology and Howard Hughes Med Inst., Mass General Hospital, Boston, Ma.

Evidence suggests that activation of excitatory amino acid receptors mediates glutamate-induced neurotoxicity (Rothman and Olney, 1987). In animal models of stroke and Huntington's disease, EAA toxicity is selective for specific neuron types. As a first inquiry, we asked whether *in vitro* selectivity was simply a function of the presence of responses to glu or NMDA

Freese et al.(abstr., this meeting) have shown that *in vitro* glutamate is weakly toxic in 6 d old cultures of P0 neurons but a potent neurotoxin in older cultures. In cultures prepared as in Freese et al., cells were patch clamped and held at -60mv. First, responses were recorded to 2.5 sec pressure applications of 100uM NMDA. Next, after a delay (>1 min), responses to 10uM glu were obtained in the same cell. Peak responses (picoAmps) to 100uM NMDA and 10uM glu in 6-7 d old cells varied widely (N=19; NMDA:60$\pm$154; glu:57$\pm$123). Frequency histograms of responses in cells>12 d old (N=23; NMDA:29.4$\pm$33.5; glu:31.7$\pm$21.2) showed considerable overlap with those from younger cells. However, cells from 6-7 day old cultures were more likely to give a small or absent response to 100uM NMDA: 31% had no response and 11% had <10pA response. In >12 d old cultures, all cells had NMDA responses; only 17% were <10pA. Peak responses were also recorded in 8 cells(>11 d old, different culture conditions) within 12 hours of a 3 hour, 1mM glu treatment. All had NMDA responses (19$\pm$14 pA). **In summary**, younger cultures which are less responsive morphologically to glu's toxic effects have a greater proportion of cells with small or absent NMDA responses than do older cultures in which glu toxicity is pronounced. Results also suggest that additional mechanisms influence which cells with glutamate activated channels survive glu exposure. Supported by the Huntington's Society of America.

CHARACTERIZATION AND MECHANISM OF GLUTAMATE NEUROTOXICITY IN PRIMARY STRIATAL CULTURES.
A. Freese, M. DiFiglia, M.F. Beal, and J.B. Martin. Dept. Neurology, Mass General Hospital and Harvard Medical School, Boston, MA 02114

Excitatory amino acids may play a role in the toxicity associated with many neurodegenerative diseases, including Huntington's Disease (HD). In an attempt to develop a tissue culture model for HD, the toxicity of glutamate (GLU) was examined in striatal cultures derived from newborn rats. Morphological criteria were used to determine the toxic effects of GLU exposure to 6, 12, and 18 day old cultures. In all experiments, the same groups of neurons were photographed and analyzed before and after GLU introduction. Neuronal susceptibility to GLU was age dependent, with older cultures showing significantly greater cell death than younger cultures ($p<.001$). Toxicity was dose-dependent (ED50 $\simeq$ 300uM) and maximal within 3 hr after GLU exposure. Affected cells demonstrated somal swelling w/in 1 hr and disruption of somal integrity and neuritic processes w/in 2-3 hr. GLU-induced toxicity was increased in the presence of high extracellular Ca++ concentrations ($p<.001$) and could be diminished by the addition of Mg++ to the media ($p<.001$). The NMDA receptor agonist, quinolinate, achieved a similar toxicity profile as GLU and the NMDA antagonist, APV, significantly reduced the toxic effects of GLU ($p<.005$). These results provide evidence that GLU can be toxic to striatal neurons in vitro and that the toxicity is largely mediated by the NMDA receptor. TRANSIENT AChE IN VB THALAMUS: DEVELOPMENTAL AND EMHISTOCHEMICAL EVIDENCE FOR RELATION TO NEURITIC GROWTH.
D.A.Kristt. Univ. of Md. Medical System/Hospital, Dept. of Pathol., Balto., MD.

Ultrastructural observations were made on VB from fetal-neonatal rats during the initial phase of neuritic outgrowth, when AChE reactivity is maximal. AChE was localized to the nuclear envelope, RER, Golgi stacks and vesicles, as well as vesicles and tubules in distal processes. On the cell surface, AChE occurred in small patches on distal processes. It is proposed that the AChE is transported to **growing neurites,** intracellularly, in association with membranous structures. At these distal sites, **AChE-associated membrane would be inserted** into the surface membranes. With maximum expression between 18 dg - 4 dpn, the following conclusions are suggested: AChE does not play a role in **migration.** Ultrastructurally, onset of AChE reactivity preceded ingrowth of most afferents. Therefore, AChE is unlikely to result from a transient **cholinergic input.** Since AChE disappears as synaptogenesis proceeds, it is unlikely that AChE is part of the synaptic complex. On the other hand, AChE could play a role in defining sites suitable for synaptogenesis.

170.2

DEVELOPMENT OF THE SENSORY INNERVATION IN THE RAT HINDLIMB.
W.J.T. Wessels*, H.K.P. Feierabend* and E. Marani*. (SPON: P.G.M. Luiten). Anatomisch Embryologisch Laboratorium, University of Leiden, Wassenaarseweg 62, NL-2300 AL Leiden, The Nederlands.

This study was undertaken to describe the development of the sensory innervation of the rat hindlimb with special attention to the dorsal root ganglia (DRG) and the plexus lumbosacralis. Injections of WGA-HRP were made into the hindlimb of rat embryos of gestational ages ranging from E15 to E19. After a survival time of approximately 24 hours the embryos were perfusion fixed, partially eviscerated and then embedded in gelatine blocks of which serial sagittal 40 um frozen sections were cut. The sections were further processed according to Mesulam (1978, J. Histochem. Cytochem. 26:106). Camera lucida drawings of the sections were used for computerized 3D-reconstruction. Circumscribed injections of the tracer into the hindlimb of the embryos give rise to completely and partially labelled DRG. In case of partially labeling this always concerns a rostral or caudal part of the DRG. The associated dorsal roots of partially labelled DRG were also partially labelled in a rostro-caudal fashion. These observations indicate that there is, at least during development, a topographical relationship between the sensory innervation of the hindlimb and the rostro-caudally organized parts of the DRG. Such a somatotopic organization within the DRG has not been reported so far.

DEVELOPMENT OF SPECTRAL SENSITIVITY IN GOLDFISH.
De-Mao Chen and Maureen K. Powers. Department of Psychology, Vanderbilt University, Nashville, TN 37240

The rod:cone ratio changes throughout life in goldfish. Both rods and cones contribute to dark-adapted spectral sensitivity in adult fish. We asked whether this was also true of juvenile fish, and if so whether spectral sensitivity at any given age reflected the relative numbers of rods and cones present at that age. Electroretinograms were recorded intravitreally from anesthetized and paralyzed fish 3-10 cm standard body length (approx. 2-5 yrs old), and b-wave thresholds were measured as a function of wavelength. We found that dark-adapted spectral sensitivity changed shape with body length: larger fish were more sensitive in the mid-wavelength region of the spectrum than were smaller fish, and they tended to be more sensitive at 400 nm as well. The heightened sensitivity to mid-spectrum lights can be explained by the relatively greater influence of rods compared to cones in larger fish. The heightened sensitivity at 400 nm cannot easily be explained by neural factors or by pre-retinal absorption factors (which would predict the opposite result with growth), but may be explained by fluorescence in the lens. We conclude that dark-adapted spectral sensitivity is mediated by rods and cones in both juvenile and adult fish, and that absolute threshold is determined by the rod:cone ratio over most of the visible spectrum.

DEVELOPMENTAL ALTERATIONS IN OLFACTORY BULB AND SENSORY EPITHELIUM IN GOLDFISH.
J. Silveira* and P.C. Brunjes. Dept. of Psychology, Univ. of Virginia, Charlottesville, VA 22903.

Goldfish exhibit central neurogenesis during most of their lifespan, making them an excellent model for examining both normal developmental processes and plasticity in an adult animal. While the goldfish visual system has been extensively examined from such a perspective, no similar study of the goldfish olfactory system exists. Our data indicate considerable growth occurs within the olfactory system. For example, fish length correlates extremely well with rosette area ($r = .94$), a pattern nearly identical to that described by Johns & Easter (1977) for the retina. Rosettes appear to grow via two processes: elongation of existing lamellae and addition of new lamellae (number of lamellae correlates .84 with fish length, although none appear to be added once a certain body length is attained). ^{3}H-thymidine autoradiography is being used to identify regions of mitotic activity in bulbs and rosettes. Olfactory bulbs are being examined to determine how patterns of innervation by receptors change during development. (Supported by NS 23154, ONR N00014-86-K-0342 and MH 18411)

170.5

INDUCTION AND STABILIZATION OF OLFACTORY GLOMERULI IN THE DEVELOPING INSECT BRAIN. Peter A. Sirianni & Leslie P. Tolbert, Dept. of Molecular and Cellular Biology & ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Sensory axons are required for the development of olfactory glomeruli in the CNS of the moth Manduca sexta. In our ongoing effort to understand the nature of the instructive influence exerted by the sensory axons, we have asked: how many axons must be present, and for how long? In the first set of experiments, different lengths of antenna (i.e. different amounts of the olfactory epithelium) were allowed to innervate the antennal lobe (AL) of the brain of developing moths, and brains were examined histologically at a semi-mature stage. The AL neuropil was scored from 1 to 5 for degree of glomerular formation: control ALs (with normal glomeruli) averaged a score of 1.6, and ALs that developed in the total absence of olfactory axons (and thus lacked glomeruli) scored 4.7. Innervation by up to 11% of the normal antenna produced aglomerular or "protoglomerular" ALs with an average score of 3.8. However, 12.5%-antennae were sufficient to produce normal-looking, but smaller, glomeruli; ALs in these animals averaged a score of 2.1 0.5. In experiments designed to test how long the axons must be present, developing antennae were removed various days after axons begin to grow into the AL. Preliminary results indicate that axons present for only 2 days (the 2 days during which glomeruli form) can sometimes produce stable glomeruli; axons present for 3 days always do. Our results indicate that glomeruli can be induced to form by a small proportion of the normal olfactory input, and that glomeruli are stable after they have formed. (NIH grant #NS 20040)

170.6

GLIAL CHANGES DURING FORMATION OF OLFACTORY GLOMERULI IN AN INSECT BRAIN. LA Oland & LP Tolbert. ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Partitioning of the first-order olfactory neuropil into glomeruli in the developing CNS of the moth Manduca sexta appears to be mediated by changes in glial cells (Oland et al., J. Neurosci., 1988). The arrival of sensory axons in the brain (beginning early in stage 4 of the 18 stages of metamorphosis) triggers changes in glial-cell shape and position that result (by late stage 6) in the formation of glial envelopes for the glomeruli. Our previous studies indicated that the emergence of glomerular walls depends also upon proliferation of glial cells. To determine whether glial proliferation is induced by olfactory axons, we have used ^{3}H-thymidine to label dividing cells starting at stage 3. Comparison of the patterns of proliferation in normal and chronically unafferented olfactory neuropils showed no significant differences in mitotic indices through stage 6, indicating that the proliferation required for initial glomerular formation is not under afferent control.

As a first step in determining the mechanisms for the glial changes that are induced by olfactory axons, we have examined in the electron microscope regions of interface between ingrowing axons and glia during stages critical in glomerular formation (stages 3-7). Before axons arrive, glial cells are interconnected by numerous close appositions which may be gap junctions and by scalariform-like junctions (SJs; Tolbert et al., J. Neurosci., 1983). During stages 5 & 6, however, as glial cells extend processes and migrate into the neuropil to form septa, the glia lose their close appositions and the SJs lack their differentiated structure. At no stage did we observe specializations between afferent axons and glial cells, suggesting that the inductive signal is not mediated via intercellular junctions. (NIH #NS07602 and NS20040.)

UNILATERAL ODOR DEPRIVATION: RAPID EFFECTS ON PROTEIN SYNTHESIS. D.L. Korol and P.C. Brunjes, Neuroscience Program and Dept. of Psych., Univ. of Virginia, Charlottesville, VA 22903.

Unilateral naris occlusion in neonatal rats leads to a 25% decrease in the volume of ipsilateral olfactory bulbs by Day 30. Large alterations such as these undoubtedly represent secondary consequences of more basic cellular regulatory events. We examined the possibility that deprivation has rapid effects on protein synthetic activity. Pups underwent either right nares closure or sham surgery on Day 1 and were injected with ^{3}H-leucine 1, 12, 24, or 48 hrs later. After 30 min pups were sacrificed and bulbs processed for emulsion autoradiography. Amino acid incorporation was quantified by grain counts. Rapid changes were observed: reduced labelling in deprived bulbs was evident 24 hrs post-occlusion. Interestingly, after 48 hrs of deprivation, higher grain densities were observed in certain regions of deprived bulbs compared to contralateral controls. Sham operated subjects demonstrated no laterality at any time examined. The data indicate that olfactory bulb cellular regulatory processes change rapidly after naris occlusion. NEURONS THAT SURVIVE FETAL TRANSECTION OF THE INFRAORBITAL NERVE RESPOND LIKE NORMAL GANGLION CELLS TO TRANSECTION OF THEIR AXONS ON THE DAY OF BIRTH. N.L. Chiaia and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

We have previously demonstrated (Chiaia, N.L. et al. Dev. Brain Res. in submission) that transection of the rat's infraorbital nerve (ION) on embryonic day 17 (E-17) results in much more extensive reinnervation of the brainstem by regenerate ION axons than is the case after similar lesions carried out on the day of birth (P-1). This difference occurred even though the number of cells that survived fetal ION transection was no greater than that observed after neonatal nerve cuts. To test whether the differential response to transection in the fetal animals may have been due to some special characteristic of the surviving cells, we cut the ION on E-17 and transected it again on P-1. In neonatally nerve damaged, adult rats (N=9), 5,001 ± 1,287 ganglion cells send axons into the regenerate ION; in fetally nerve damaged rats (N=6), this value is 5,476 ± 3,056. In the rats that sustained ION transections on E-17 and P-1, this value was 1,799 ± 1,050. In the last group of rats, reinnervation of the brainstem was almost completely restricted to layers I and II of subnucleus caudalis, as is the case in rats that sustain only neonatal ION transections. Supported by DE 07734 and BNS 17537.

170.9

NORMAL DEVELOPMENT OF, AND EFFECTS OF INFRAORBITAL NERVE DAMAGE UPON, SUBSTANCE P AND FLUORIDE RESISTANT ACID PHOSPHATASE IN THE RAT'S MEDULLARY DORSAL HORN. P.R. Hess*, N.L. Chiaia, H.L. Enfiejian and R.W. Rhoades (SPON: A.M. Golub). Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

We have used immunocytochemistry and histochemistry to determine the distributions of substance P-like immunoreactivity (SPLI) and fluoride resistant acid phosphatase (FRAP) from 0-10 days of age in rats that sustained transection of the infraorbital nerve (ION) on the day of birth. Neonatal transection of the ION produced no reduction in the density of SPLI in the ipsilateral brainstem at any time between 6 hrs and 10 days after the nerve cuts. However, there was a naturally occurring reduction in the distribution of SPLI in the developing brainstem. At birth, SPLI was heaviest in subnucleus caudalis (SpC) and subnucleus oralis (SpO), but it was also present in nucleus principalis (PrV) and subnucleus interpolaris (SpVi). By day 10, the density of the labelling in PrV and SpVi was much reduced and its distribution in SpO was also restricted. SPLI remained heavy in SpC. FRAP staining in the V brainstem complex was also heavy on the day of birth. Neonatal ION damage caused a reduction in the density of FRAP staining that was apparent within 10 hrs and remained into adulthood. Supported by DE 07734 and BNS 85-17537.

EXPRESSION OF CHOLINERGIC PROPERTIES BY SENSORY NEURONS OF THE CHICK EMBRYO. S.V. Bhave* and A.R. Wakade (Spon.: F. Kao), Dept. of Pharmacology, SUNY-HSC at Brooklyn, 450 Clarkson Ave., Brooklyn, NY 11203.

The cholinergic properties of sensory neurons of the chick embryos were studied by measuring the choline acetyltransferase (ChAT) activity and ^{3}H-choline uptake. Dorsal root ganglia of 8-day-old chick embryos showed significant amounts of ChAT activity (24 ± 2.52 pmol ACh/min/mg protein), which increased to 45.4 ± 9.69 pmol ACh/min/mg protein in the ganglia of 12-day-old embryos. Sensory neurons derived from dorsal root ganglia of 10-day-old embryos and maintained in a serum-free culture medium supplemented with nerve growth factor (NGF) also showed significant amounts of ChAT (21.9 pmol ACh/min/mg protein). The cultures maintained in absence of NGF had a negligible amount of ChAT activity. A dose-dependent inhibition of ChAT activity was observed after the addition of hydroxyethyl naphthylvinyl pyridine, a specific inhibitor of ChAT, to the assay mix. Cultured sensory neurons incubated with ^{3}H-choline followed by repeated washouts retained significant amounts of ^{3}H-choline. Replacement of NaCl with LiCl from incubation medium reduced ^{3}H-choline uptake by about 45%, whereas in presence of a specific inhibitor of choline uptake, hemicholinium-3, it was inhibited by about 75%. These results suggest that sensory neurons of the chick dorsal root ganglia can express the classical cholinergic properties during development.

INFLUENCE OF SEGREGATED AFFERENT PATTERNS ON LOCAL CIRCUITS IN RODENT SOMATOSENSORY CORTEX. A. Peinado, T. Murakoshi*, and L.C. Katz. Lab. of Neurobiology, The Rockefeller Univ. NY, NY.

The role of thalamocortical afferents in shaping intrinsic cortical circuits remains largely unknown. Although earlier studies in the rodent somatosensory "barrelfield" cortex have shown that dendrites of stellate cells in layer 4 were confined primarily to one barrel (e.g. Harris & Woolsey, Br. Res. 161:143, 1979), the use of Golgi staining and relatively thin sections made distinguishing stellate and pyramidal cells, or visualizing the intrinsic axons of cells difficult. We have approached this question by using intracellular staining to reveal the dendritic and axonal arborizations of layer 4 neurons in rat barrelfield cortex in relation to the segregated pattern of afferent axons. Thalamic afferents were labelled by anterograde transport of rhodamine (TRITC) injected into the thalamus. Tangential cortical brain slices (350 µm thick) were prepared, and layer 4 neurons in the barrels were intracellularly stained with Lucifer Yellow while simultaneously visualizing the TRITC-labelled barrels. The dendrites and intrinsic axons of three classes of stained cells show distinct relationships to the segregated afferent pattern. Both the axons and dendrites of spiny stellate cells invariably remain strictly confined to one barrel as defined by labelled afferents, frequently making sharp turns in order to do so. The axons of non-spiny stellate cells also remain largely confined to one barrel. Their dendrites, however, can project into the sides and septal region separating barrels. In contrast, the axons of pyramidal cells freely cross barrel boundaries. The dendrites of pyramidal cells located within a barrel remain primarily, although not exclusively within that barrel.

Each whisker termination zone (barrel) represents a region of highly correlated afferent activity. Our observations reveal that the construction of axonal and dendritic arbors of cortical neurons can be greatly influenced by these patterns in a fashion that is cell-type specific and which distinguishes between dendrites and intrinsic axons. EARLY DEVELOPMENT OF FORELIMB REPRESENTATION IN SI CORTEX: BARREL SUBFIELD IN NEONATAL RATS AS DEMONSTRATED WITH PEANUT AGGLUTININ BINDING: EVIDENCE FOR DIFFERENTIAL DEVELOPMENT OF FORELIMB AND FACE. R.S. Waters, C. McCandlish,* and N.G.F. Cooper. Dept. Anatomy & Neurobiology, Univ. of Tennessee, Memphis, Sch. of Med., Memphis, TN 38163.

Physiological studies have demonstrated a highly organized somatotopic representation of the body surface in SI cortex of rat. This representation is correlated morphologically with the presence of barrel-shaped structures in layer IV. Conventional staining techniques reveal barrels in the second postnatal week. Recently, the peroxidase conjugate of peanut lectin (PNA), which recognizes glycosylated molecules, has been used to study barrel field formation. PNA binds primarily to prospective barrel sides and septae as early as postnatal day 4 (PND–4). To date, investigations of SI cortex using PNA have been confined to the study of the barrel field representation of the face and mystacial vibrissae. In the present study we extend these findings to the development of the forelimb representation. Rats ranging from PND–1 (first 24 hrs after birth) to PND–11 were anesthetized with Nembutal and perfused with buffered saline followed by 4% paraformaldehyde and 2% glutaraldehyde in 0.2 M sodium cacodylate buffer. Brains were removed, flattened tangentially, and sectioned on a vibrotome at 30–120 micron thickness. Sections were blocked in 2% bovine serum albumin and incubated in peanut lectin at 4° C. Following incubation, sections were washed with TBS and processed using peroxidase histochemistry.

Lectin binding in the prospective forelimb representation was apparent between PND–7 and PND–10 whereas PNA binding to the prospective face-mystacial vibrissae representation occurred before PND–6 and extended through PND–11. Unlike previous reports in mouse, barrel field labeling in rat was not seen before PND–4. These results suggest that body part representations show individual variations during early pattern formation. In rat, limb formation may lag behind the development of the face–mystacial vibrissae during early postnatal development.

MYSTACIAL PELAGE INFLUENCES VIBRISSA DENERVATION-PRODUCED METABOLIC PLASTICITY IN RAT SI CORTEX. S-C Sheu[1] and P. Hand[2]. [1]Dept. Anat., Nat. Yang-Ming Med. Col., Taiwan, R.O.C.; [2]Dept's Animal Biol. and Neurol., Sch's. Vet. Med. and Med., Univ. Penna., Phila., PA 19104

Neonatal vibrissa denervation produced 2-deoxyglucose (2DG) labeling differences in rodent SI may be partly due to surgical procedures used. Under ice anesthesia, 2 different procedures were used in 2 day old rats to produce identical unilateral vibrissa follicle removals, sparing C3 (SC3): #1 (skin flap removal method; Kossut, J. Neurophys., 1988; N=6) spared row C pelage and #2 (row A-E skin incisions method of Rice; N=6) spared the entire mystacial pelage. 90 days later, SC3 and control C3 (CC3) vibrissae were stroked (4-5hz, rostro-caudally) during the ^{14}C-2DG exp't. Qualitative 2DG changes in lamina IV of SI are reported. SC3 labeling (CC3 comparison) was en-larged, oval-shaped, and diffusely overlayed barrel rows B-D, edges of rows A&E, and involved interrow septa in #1. SC3 labeling was comparably enlarged, primarily overlayed row C (C1-C4), less densely involved a part of row D (typically D3) and occasionally B3, and largely spared interrow septa in #2. Thus the presence of different amounts of mystacial pelage markedly alters neonatal vibrissa denervation produced SI metabolic plasticity. [Grant's NS-22283 (USPHS); NSC77-0412-B010-12 (NSC, Taiwan, R.O.C.)]

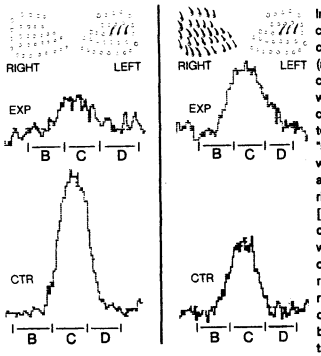
LEFT-RIGHT INTERACTIONS DETERMINE THE CENTRAL EFFECT OF WHISKER CLIPPING IN THE ADULT MOUSE; A DEOXYGLUCOSE (DG) STUDY.

J. Dörfl*, E. Welker*, P. Melzer* and H. Van der Loos (SPON: E.M. Rouiller)
Institute of Anatomy, University of Lausanne, Rue du Bugnon 9, 1005 Lausanne, Switzerland.



In adult mice (n=8) all whiskers were clipped, except left whiskers C1-3 (left column in Fig); in another set of mice (n=4), all whiskers on the left side were clipped, except C1-3, while the right side was kept intact (right column). The clipped mice (EXP) and a number of untouched mice (CTR) were left in a "stimulus-rich" environment for 5 days; whiskers of all mice were checked daily and clipped when regrown. After this period the animals were injected with [^{14}C]2-DG and left freely-moving in their cage for 45 minutes. Prior to injection the whiskers of CTRs were clipped in either one of the two configurations. In autoradiograms of tangential sections of the right hemisphere grain densities were determined in a strip of cortex across barrels B2, C2 and D2 by the transmittance of light as measured by a tv-camera densitometer (inversely plotted in Fig). In EXP, left column, DG uptake was considerably lower than CTR. In EXP, right column, the maximal DG uptake remained equal to CTR, but in B and D, DG uptake was increased. In CTR of left column DG uptake is higher than that of CTR in right column. We conclude that DG-uptake in the cortex depends not only on the number but also on bilateral distribution of whiskers over a given period of time. Support: Swiss NSF grant 3.158.

IMPROVEMENT OF TACTILE ROUGHNESS DISCRIMINATION BY EXERCISE IS NOT RESTRICTED TO THE AREA OF TRAINING STIMULATION. M.Pause*, M.Halmanns*, T.Nöcker*, K.H.Mauritz. Rehabilitation Clinic, University of Cologne, D-5000 Köln, FRG.

With the stimulation method described by Lamb(J.Physiol. 338:551,1983) we investigated 1. if tactile roughness discrimination can be improved by exercise and 2. if an improvement is generalized or observed only at the trained area.

Patterns of raised nylon dots (fixed on a rotating disc, velocity 20cm/s) with dot diameters of 1mm (height 0.98mm) and a period of 3.0mm (0%),3.06mm (2%),3.09mm (3%),3.15mm (5%),3.21mm (7%) and 3.3mm (10%) were used. Four subjects were tested for all pattern variants (forced choice for 40 stimulus pairs, 20 identical (0%/0%), 20 different (0%/2,3,5,7,10%) in random order) first at the left index finger pad then at the left little finger pad (stimulated area about 11x11mm) within one session. During the next 10 days all patterns which could not be discriminated better than the 75% level were presented daily in 40 exercise trials only at the index finger pad with confirmation of right decisions and then tested again without feedback. Thereafter the initial test was repeated. In all four subjects there was a clear learning effect: initially discrimination above the 75% level was observed only for the 10% (versus 0%) pattern, after exercise for the 5% or even 2% pattern. In all subjects the learning effect was in the same range at the non-trained little finger. A localized improvement which might have been expected by a plasticity effect of the somatosensory cortex could not be demonstrated.

170.16

AGE DEPENDENT CHANGES IN ACETYLCHOLINESTERASE ACTIVITY IN CAT PRIMARY SOMATOSENSORY CORTEX. C.S.Heck, S.L. Lui*, H.L. Davis & P.A. McKinley. Department of Anatomy, and School of Physical and Occupational Therapy, McGill University, Montreal, Quebec H3A 2B2.

Total acetylcholinesterase (AChE) activity and activity in membrane bound and soluble fractions were measured in cat somatosensory cortex using the method of Ellman et al. (Biochem. Pharmac. 7: 88, 1961). Cats were killed on postnatal days 4, 10, 12, 14, 17 and 28 days by drug overdose. The isolated somatosensory cortex was removed, homogenized and centrifuged and the three fractions were prepared for biochemical assays (electrophoretic analyses and esterase activity). From birth to 10 days, total AChE activity was low (5 moles of substrate hydrolyzed/min/mg protein), increased dramatically by day 12 (20 moles/min/mg), and reached a plateau by day 14 (30 moles/min/mg). Activity in the soluble fraction was low throughout the 28 days studied (2 moles/min/mg), while the activity of the membrane bound fraction increased significantly at day 12 (14 moles/min/mg). It is concluded that the increase in membrane bound activity is responsible for the dramatic increase in total AChE activity by day 12. This change in activity is coeval with other maturational changes in the central nervous system (McKinley, P.A. et al., Dev. Brain Res. 31: 136, 1987), and may have important ramifications for changes in cortical plasticity. (Supported by MRC and J.W. McConnell Fellowship to CSH).

170.17

SEQUENTIAL WAVES OF DIFFERENTIATION IN THE COCHLEA OF MONODELPHIS DOMESTICUS F.H. Willard and B.L. Munger*, Depts. of Anatomy, Univ. of New England, Biddeford, ME, and The Milton S. Hershey Med. Ctr., The Penn. State Univ., Hershey, PA.

Complex interactions exist between the development of the receptor organ, peripheral nerve and brainstem nuclei in the auditory system. We have begun investigating these interactions using an age-graded series of Monodelphis domesticus pups prepared with a silver stain for axons. Sequential sections through the temporal bone were recorded. The cochlear duct developed from 0.75 turn at birth to approximately 2.25 turns by 8 postnatal days. Subsequently, successive waves of differentiation were observed sweeping from base to apex in the cochlea. In order, the waves consisted of 1.) differentiation of stainable axons, 2.) appearance of identifiable hair cells, and 3.) opening of the tunnel of Corti. Movement for all three waves was fastest in the basal and middle turns, requiring only 3 days to accomplish each turn; whereas 4-5 additional days were required to complete the apical turn. These observations agree with the notion that sensorineural differentiation precedes that of the transducer cells.

170.18

EFFECTS OF UNILATERAL COCHLEAR ABLATION IN NEONATAL AND MATURE FERRETS ON NEURON SIZE AND NUMBER IN THE COCHLEAR NUCLEUS. David R. Moore, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K.

Perinatal cochlear ablation in chicks and rodents results in neuron loss and shrinkage in all divisions of the cochlear nucleus (CN), whereas cochlear ablation in adults produces less severe transneuronal atrophy. Similar results have been suggested in the cat, although no study has provided a quantitative analysis of the age dependency of these phenomena in any carnivore or primate. I have examined the effects on anteroventral CN (AVCN) neuron size and number of rearing ferrets with a unilateral cochlear ablation from postnatal day (P)5, P24, P90 or P180 for 90 days. Ablations were confirmed histologically by the total absence of cochlear ganglion cells. Brain tissue was paraffin-embedded, sectioned at 10μm in the frontal plane and Nissl-stained. Ablations at all ages produced similar mean neuron size reductions [9%(P5), 12%(P24), 13%(P90) and 12%(P180)]. In contrast, neuron loss in the AVCN was only observed after cochlear ablation in the two youngest age groups [57%(P5), 13%(P24)]. Detailed analysis of the whole CN in three ferrets ablated at P24 showed a slight gradient of increasing neuron shrinkage and loss towards the rostral CN. These results confirm earlier observations on adult cats and show that, unlike chicks, neuron loss and shrinkage do not occur over the same time course in ferrets.

170.19

THE EFFECT OF AGE AND EXPERIENCE ON INHIBITION OF THE ACOUSTIC STARTLE RESPONSE (ASR) BY GAPS IN BACKGROUND NOISE. K.F. DEAN,* L.P. SHEETS,* K.M. CROFTON, AND L.W. REITER (SPON:R. JANSSEN). U.S. EPA, Research Triangle Park, NC 27711.

The acoustic startle response (ASR) is inhibited when the eliciting stimulus is preceded by a brief gap in background noise (gap inhibition)(Ison, 1982). We have observed that adult rats show increased inhibition over the first three test sessions. This improvement in inhibition over sessions may explain a previous report in which gap inhibition was absent in rats repeatedly tested on postnatal days (PND) 21 and 25, but present on PND 28 (Kellogg et al., 1983). The present experiment examined the ontogeny of ASR gap inhibition in the rat and the role of experience on its development. Independent groups of Long-Evans rats were tested for three consecutive days, at eight ages ranging from PND 14-16 to PND 98-100. Gaps (0, 2, 4, 8, 16, 32, or 64 msec) in broad-band background noise (80 dB ON/35 dB OFF) were presented 190 msec prior to the eliciting stimulus (13-kHz, 120-dB, 40-msec tone with 2.5 msec rise/decay). Results show that longer gaps (16-64 msec) inhibited the ASR at all ages; however, the magnitude of inhibition increased with age and experience. The efficacy of shorter gaps (8-4 msec) in the inhibition of the ASR improved until PND 35-37, when the adult pattern was achieved. These findings indicate that the magnitude of ASR gap inhibition and the efficacy of gaps < 16 msec are dependent on the age and experience of the animal.

MASSETER INHIBITORY PERIODS AND SENSATION TO ELECTRICAL TOOTH-PULP STIMULATION IN CHILDREN AND ADULTS. Y. Sharav* & M. Tal. School of Dental Medicine, Jerusalem, Israel

Sensory detection and masseter inhibitory periods (MIP) to electrical tooth-pulp stimulation were recorded in 10 children and 5 adults. The MIP thus induced is normally copmosed of a two-phase EMG activity with early and late components.

In the adult group sensation was always detected and usually associated with a two-phase MIP configuration. Sensory detection in 1/2- and 3/4-formed roots of teeth in the younger children was absent or markedly reduced and was accompanied by the absence of the late component of the MIP. In the older children with fully-formed roots (10-12 year-old) sensation did not differ from that of the adults, but the late MIP component occured significantly less ($p<0.01$).

It is suggested that the following developmental stages of response to electrical tooth-pulp stimulation occured, and in that order: 1)the early, oligosynaptic, component of the MIP, 2) detection of sensation, and 3) the late, polysynaptic, component of the MIP. It is concluded that the development of sensory detection and MIP activity to electrical tooth-pulp stimulation are two distinct processes.

DIFFERENTIATION AND DEVELOPMENT III

171.1

MYELINATION OF AXONS BY SCHWANN CELLS IS F-ACTIN DEPENDENT, AS DETERMINED BY THE USE OF CYTOCHALASIN. D.S. Gorman* and M.B. Bunge. Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Linkage between Schwann cell (SC) basal lamina formation and myelination has been well-established in the dorsal root ganglion culture system; SCs that are unable to form basal lamina are also unable to ensheathe and myelinate axons (Bunge et al., 1986, Ann. Rev. Neurosci. 9:305). Could the basal lamina initiate SC elongation and myelination by causing SC surface polarization and/or modification of the cytoskeleton? To determine the dependence of SC differentiation (elongation, ensheathment and myelination) on actin, neuron + SC cultures were initially grown in serum-free defined medium which does not promote SC differentiation and then switched to differentiation-supporting medium containing cytochalasin D (CD, 0.25 - 1.0 ug/ml). During the two subsequent weeks, cultures were processed for light and electron microscopy. The effects of CD were visible as early as 5 hr; SCs retained a more rounded appearance compared with SCs in control cultures. After 1 wk, SCs were abnormally balled-up on axon fascicle surfaces. The severity of effects was more prominent as CD concentrations increased. Sudan black staining revealed small amounts of early myelin at the lowest concentration and none at the highest concentration. Electron microscopy showed 3-4 partially compacted turns of myelin at the lowest concentration and no myelin and a paucity of SC elongation and ensheathment at the highest concentration. These experiments indicate the dependence of SC elongation, ensheathment, and myelination on a functional actin system. (Supported by NIH NS09923)

SCHWANN CELLS ARE IMMUNOREACTIVE FOR ALBUMIN DURING NERVE DEVELOPMENT. M. Mata and D.J. Fink, Neurology Research Laboratory, University of Michigan and VA Medical Center, Ann Arbor, MI 48105.

We have demonstrated immunocytochemically that albumin is found extracellularly but not intracellularly in normal nerve endoneurium (J Neuropathol Exp Neurol, 1987), and that during regeneration after a nerve crush injury Schwann cells demonstrate albumin immunoreactivity, but lose that immunoreactivity as myelination of regenerating sprouts proceeds (J Neuropathol Exp Neurol, in press). In order to better define the role of albumin uptake by Schwann cells during myelination, we studied albumin immunoreactivity in developing sciatic nerve.

Neonatal Sprague Dawley rats from 1 to 14 days of age were perfused with 0.5% glutaraldehyde and 4% paraformaldehyde and the sciatic nerves embedded in LR White. Ultrathin sections were exposed to goat anti-rat serum albumin antibody at dilutions of 1:1500 or 1:2000 for 1.5-2 hrs, followed by rabbit anti-goat IgG bound to 15 nm colloidal gold (1:10) for 1 hour. The specificity of the anti-RSA antibody was tested by immunodiffusion and by Western blot.

At 1 d albumin immunoreactivity was confined to the endoneurium, Schwann cells and axons were not immunoreactive. From 3 d to 7 d the Schwann cells showed albumin immunoreactivity, though the axons did not. By 14 d the the immunoreactivity was again limited to the extracellular space of the endoneurium. Neither the Schwann cells nor the axons were immunoreactive.

In vitro studies recently have shown that a serum factor (for which albumin may be substituted) is required in the medium for Schwann cells to myelinate axons in tissue culture. Our results suggests that albumin uptake by Schwann cells may be necessary in vivo as well. Albumin may serve as a carrier for substances required by the Schwann cell.

SCHWANN CELL BASAL LAMINA FORMATION AND ENSHEATHMENT OF UNMYELINATED NEURITES ARE INCREASED IN CULTURES CONTAINING FIBROBLASTS. V.J. Obremski*, M.I. Johnson+, and M.B. Bunge (SPON: M. Luskin). Depts. Anatomy and +Pediatrics, Washington Univ. Sch. Med., St. Louis, MO 63110.

The ability to culture and combine relatively pure populations of nerve cells (NCs), Schwann cells (SCs), and fibroblasts (FBs) has enabled us to examine the contribution of FBs to SC ensheathment of unmyelinated rat superior cervical ganglion (SCG) neurites in vitro. Purified perinatal SCG neurons were grown in culture with SCs alone or with SCs and FBs derived from SCG capsule or periosteum. These cells were maintained for 10-12 weeks on a collagen substratum in a medium known to promote differentiation of SCs with dorsal root ganglion neurites (Eldridge et al., JCB 105:1023, '87). The extent of ensheathment was determined by assessing the proportion of neurites enclosed individually by SC cytoplasm in electron micrographs of cross sections of neurite outgrowth. In all NC/SC cultures without FBs, SCs achieved only a moderate degree of ensheathment; also SC basal lamina was often discontinuous, and extracellular collagen fibrils were not abundant. The addition of FBs to NC/SC cultures enhanced the neurite-ensheathing ability of the SC. Moreover, basal lamina surrounding SC/neurite units was continuous and collagen fibril content was increased. Additional secretion by cells in FB supplemented cultures was suggested by the presence of dense fibrous extracellular material near the FBs. We conclude that the presence of FBs in cultures of SCG neurons increases the ability of the SC to ensheathe neurites, possibly through an augmentation of specific extracellular matrix components. NEURON-GLIA INTERACTIONS IN HIPPOCAMPAL CULTURES. U.E. Gasser* and M.E. Hatten. Dept. of Pathology, College of Physicians & Surgeons of Columbia University, New York, NY 10032

In previous studies, our laboratory has used a microculture system to analyze neuron-glia interactions of cerebellar cells. Here we have adapted this system to study neuron-glia interactions and astroglial differentiation of developing hippocampus. Hippocampal tissue, harvested from neonatal rats, was dissociated into a single cell suspension and plated in glass coverslip microcultures coated with poly-lysine (PLYS), poly-ornithine (PORN), Concanavalin A (Con A), Matrigel (MAT) or wheat germ agglutinin (WGA). In some experiments, neurons were washed off 45 min after the cells were plated, leaving a pure glial population. After 24h *in vitro*, the cells were immunostained with antibodies against the glial filament protein (GFP) to visualize glial cells and measure the distribution of neurons relative to astrocytes.

In the absence of neurons, purified astroglia had flat, undifferentiated profiles on all substrates tested. In co-culture with neurons, the extent of neuronal association with glia and of glial process extension varied with the culture substrate. On WGA, Con A and MAT, neurons exhibited a marked affinity for astrocytes, and astroglial cells expressed short (WGA, Con A) or elongated (MAT) processes which were intensely stained with GFP. On PLYS and PORN, however, the neurons were randomly distributed on the culture substrate, and astrocytes expressed flat, undifferentiated shapes. These results suggest that the extent of neuron-glia association *in vitro* varies with the culture substrate, and that, as previously shown for cerebellar cultures, the morphological differentiation of hippocampal astroglia is dependent upon contact with neurons.

DUAL POPULATIONS OF RADIAL GLIAL CELLS IN THE DEVELOPING OPOSSUM SUPERIOR COLLICULUS. P.C. Barradas*, R. Mendez-Otero, A. Madeira-Vieira* and L.A. Cavalcante*(SPON:C.Timo-Iaria),IBCCF,Univ. Fed. Rio de Janeiro and Inst. Biology, UERJ, 21941,Rio de Janeiro, Brazil.

Uptake of HRP following an eye injection reveals radial glia-like cells, the processes of which course through the developing opossum superior colliculus(SC). Such cells persist for long periods and are consistently absent from median and paramedian regions. We report here the results of an analysis of radial glial cells in the opossum SC by GFAP and vimentin(VIM) immunoreactivities and by glycogen histochemistry. We have used pouch youngs of ages ranging from postnatal days 12 to 60 (PND12 to PND60), i.e., developmental stages ranging from the end of collicular neurogenesis to the onset of myelination in the optic layer. Weanlings(PND90) and adult animals were also used to test for long-term radial glia. GFAP and glycogen reactions revealed a median system of tortuous processes(median ventricular formation-MVF) in all but adult animals. Lateral to MVF, GFAP reaction is weak or absent except in rare sub-pial endfeet. GFAP+ astrocytes of the optic layer appear in a medial-to-lateral sequence from PND40 to PND60. VIM reaction shows both MVL and a lateral system (LS) of straight radial processes from PND 12 to PND40 with progressive reduction of LS thereafter and occasional staining of widely dispersed astrocytes. VIM reaction is limited to MVF in PND60 and PND90 and is absent in adults. The results suggest a dual population of radial glia which differ in the degree of interactions with the neuropil as well as in the GFAP expression and glycogen accumulation. Supported by CNPq, FINEP and CEPG/UFRJ.

OLIGODENDROCYTE DIFFERENTIATION IS ACCELERATED BY A PULSE OF CYCLIC AMP. David W. Raible* and F. Arthur McMorris (Spon.: B. Wolfe). TheWistar Institute, Philadelphia, PA 19104.

Oligodendrocytes develop in primary cultures established from 1-day-old rat brain on a specific schedule, similar to that seen *in vivo*. We have shown previously that this differentiation schedule is accelerated by the addition of the cyclic AMP analog sdibutyryl cAMP (dbcAMP) and 8-bromo cAMP, which accelerate the expression of the myelin components 2',3'-cyclic nucleotide 3'-phosphohydrolase, myelin basic protein and galacto-cerebroside. Dibutyryl cAMP also inhibited DNA synthesis in A2B5-positive oligodendrocyte-type 2 astrocyte (O2A) progenitor cells, consistent with the relationship between cessation of proliferation and onset of differentiation seen *in vivo* and *in vitro*, but had no effect on the proportion of O2A progenitors that became oligodendrocytes rather than type 2 astrocytes. We now report that a pulse of 1 mM dbcAMP as short as five minutes has the same effect as treatment with dbcAMP for two days, implying that oligodendrocyte differentiation can be accelerated by a trigger mechanism. Pulses of dbcAMP obviate the problem of cell detachment that occurs after prolonged dbcAMP exposure, allowing us to study the effects of dbcAMP on oligodendrocyte differentiation over longer periods of time. As observed in continuously treated cultures, a pulse of dbcAMP initially accelerated of the appearance of oligoden-drocytes. Several days after treatment, the number of oligodendrocytes in dbcAMP-pulsed cultures decreased compared to controls. This decrease in oligodendrocyte number may be due to the inhibition of progenitor proliferation reported previously, or to early cell death after accelerated differentiation. Oligodendrocyte numbers eventually return to normal in cultures pulsed with dbcAMP. Supported by NSF BNS 85-18023, NMSS RG1767-A-1 and NIH CA 09171 and NS 11036.

STRIATAL ASTROGLIA DOPAMINE RECEPTORS ARE AFFECTED BY NEURONS FROM SUBSTANTIA NIGRA. E.Hansson, Institute of Neurobiology, University of Göteborg, Göteborg , Sweden.

Using selective D1 agonists the presence of a dopamine receptor with cyclic AMP as second messenger was demonstrated on astroglial cells in primary culture from striatum. The D1 receptors were not identified in cultures from cerebral cortex, hippocampus or brain stem. In a co-cultivation system neurons from substantia nigra affected the striatal astroglia to shift the dose-effect curve of the D1 cyclic AMP system to the left and thus increase the potency and efficacy of the second messenger of the receptor. The specificity of the results were ensured in two ways: co-cultivating the astrocytes with hippocampal neurons or with another astrocyte culture had no effect on the D1 receptor cyclic AMP system. In addition there was no effect on the β-adrenoceptor cyclic AMP system on astroglia after co-cultivation with neurons from substantia nigra. The results provide evidence for a heterogeneity among astroglia with respect to the expression of receptors. Furthermore, astrocytes in one brain region were influenced upon by neurons from a natural projection area to increase the receptor activated second messenger stimulation.

GROWTH CHARACTERISTICS OF PRIMARY HUMAN FETAL ASTROCYTE (HFA) STRAINS. J.J. Chao*, R.W. Keane, and W.P. Parks* (SPON: L. Glaser). Depts. of Micro. Immuno., Physiol. Biophys., and Pediatrics, University of Miami School of Medicine, Miami, FL 33136.

Human cell strains consisting predominantly of glial fibrillary acidic protein (GFAP)-positive astrocytes were established from abortuses of 8 - 18 weeks gestation. Several media and substrates were evaluated to determine optimal plating efficiency and growth. Media were supplemented with 5% horse serum; N5, a medium free of selected amino acids and Dulbecco's modified Eagle's medium were comparable as measured by growth rates whereas RPMI 1640 supported only limited growth. Plating efficiency was evaluated using a rat tail collagen preparation, commercial collagens, and poly-L-lysine to pretreat tissue culture flasks. A combination of rat tail collagen and poly-L-lysine treatment yielded the highest plating efficiency (70% ± 5). Under optimal conditions in the logarithmic phase of culture growth, HFA have a doubling time of 30 hours (±6). Cell growth occurs as multilayered foci even in sparsely plated cultures. Over time, cells radiate from foci until confluence is established at cell densities of $2.5 \times 10^5/cm^2$. GFAP-positive HFA can be maintained in culture for up to 9 months with over 25 passages without obvious changes in morphology or growth characteristics. Thus, it is possible to establish and to define growth requirements and characteristics of in vitro HFA cultures for long-term studies.

SUBSTRATUM EFFECTS ON MELANOGENESIS IN NEURAL CREST CULTURES. S.L. Rogers, K.S. Vogel*, J. Leyba*, A. Waite*, and J.A. Weston*. Univ. of New Mexico Sch. of Med., Albuquerque, NM 87131 and Univ. of Oregon, Eugene, OR 97403.

The role of the extracellular enviroment in neural crest differentiation remains unresolved. In neural crest cultures, the extent of cell-cell association appears to influence both neuronal and melanocyte differentiation (Vogel and Weston, J. Cell Biol. 103: 232a). Clusters of quail neural crest cells were isolated from explanted neural tubes at 24 or 48 hours of culture and then subcultured on fibronectin (FN) and laminin (LM). In cultures of 24 hour clusters, cells plated on FN disperse evenly and approximately 20% of the population differentiates into melanocytes. On LM and untreated substrata, cell dispersal is not as extensive and, consequently, many cells remain in close contact with one another. Close to 40% of cells in these cultures pigment. 48 hour clusters plated on untreated substrata pigment to a much greater extent than do 24 hour clusters (Glimelius and Weston, Cell Diff. 10: 57). When cultured on FN or LAM, dispersal of cells in 48 hour clusters exceeds that of controls, and 20-50% fewer cells pigment. Therefore, crest-derived cells in the two culture paradigms differ in their response to the three substrata. Differences in selectivity and responsiveness to these substrata appear to alter the patterns of cell-cell interaction, which may lead to differences in phenotypic expression. EXPRESSION OF MUSCARINIC CHOLINERGIC RECEPTORS ON RAT SWEAT GLANDS. M.P. Grant* and S.C. Landis. (SPON: S.W. Jones) Center for Neuroscience and Dept. of Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

The mechanisms which regulate the expression of neurotransmitter receptors on target cells are poorly understood. Sweat glands provide an interesting model to explore the possible relationship between transmitter phenotype and receptor expression because the transmitter properties of its innervation changes during development.

We have developed a protocol to examine muscarinic ligand-binding sites in gland-rich foot pad with the radiolabeled muscarinic antagonist ^{3}H-N-methyl scopolamine(^{3}H-NMS). Scatchard analysis indicated that the concentration of ^{3}H-NMS sites is 230 fmoles/mg protein. Autoradiographic studies have demonstrated that the ^{3}H-NMS sites are localized on glands. During development the distal portion of the forming glands initially expresses low levels of ^{3}H-NMS sites. As the glands mature and the innervation becomes functionally cholinergic the concentration of ^{3}H-NMS sites increases. Glands which are acutely or chronically denervated express a reduced level of ^{3}H-NMS sites which are not responsive to agonists. Our results suggest that functional cholinergic innervation is one of several factors that regulate the expression of muscarinic ligand-binding sites in rat sweat glands.

CHARACTERIZATION OF NEURONS DIFFERENTIATING IN CULTURES OF MOUSE NEURAL CREST CELLS. S.G. Matsumoto* (SPON: R.B. Levine) Dept. Physiology, Univ. Ariz. Coll. Med., Tucson, AZ. 85724

Neural crest cells are obtained from E 7.5 to 9.5 mouse embryos. Several thousand neurons eventually differentiate in cultures that initially contain 100-200 crest cells, indicating the presence of persistant neuroblasts. Only the morphologically differentiated neurons stain with antibodies to neurofilament. At least 2 classes of neurons differentiate in the cultures; one resembling sensory neurons and a second adrenergic class. The first class of neurons appear after 4 days to a week in vitro. Some of these show substance P immunoreactivity. These neurons do not label with antibodies to VIP, SOM, NPY, TH or display glyoxylic acid induced fluorescence (GIF). Electrophysiological recordings reveal that a subpopulation of these neurons are sensitive to capsaisin. A second, numerically larger group of neurons appears over a period of 1-3 weeks. These neurons all stain with anti-TH and show intense GIF.

171.12

A NOVEL METHOD FOR MARKING NEURAL CREST CELLS USING DiI. George Serbedzija, Scott Fraser, and Marianne Bronner-Fraser. Developmental Biology Center, University of California, Irvine, Ca. 92717.

Neural crest migratory pathways have been well-mapped in avian embryos using quail/chick chimeric techniques and the HNK-1 antibody. Far less is known about neural crest pathways in other species because the HNK-1 antibody is avian specific. Furthermore, in avians the HNK-1 antibody recognizes cell types other than neural crest cells, and quail-chick chimeras require surgical disruption of the environment through which neural crest cells migrate.

To confirm neural crest migratory pathways in chick and to define pathways in other species, we have used a nondeleterious membrane intercalating dye, diI (Honig and Hume, 1986, JCB 103:171), to label neural crest cells before they emigrate from the neural tube. Using a picospritzer, diI (0.5% in 95% ethanol/5% DMSO) was pressure injected into the lumen of the neural tube of chicks having 18-28 somites. Only neural tube and premigratory neural crest cells are labelled with the dye, because they are the only cells in contact with the lumen. As expected, migrating neural crest cells, motoraxons, and ventral root cells are the only cells types stained with diI external to the neural tube. Discreetly labeled cells were found adjacent to the neural tube and within the rostral half of each sclerotome within the first day after injection, confirming previous cell marking studies. A few cells were also found subepidermally. In embryos fixed two or more days after diI injection, dorsal root and sympathetic ganglia and some cells around the dorsal aorta were brightly labeled with diI. Recently, we have successfully used this technique for studying mouse neural crest development, indicating its broad applicability.

STABLE EXPRESSION OF A TEMPERATURE SENSITIVE V-SRC GENE IN PC12 CELLS REVERSIBLY MIMICS DIFFERENTIATION BY NGF. D.M. Rausch*, and L.E. Eiden* (SPON. D. Lewis). Unit on Molecular and Cellular Neurobiology, Laboratory of Cell Biology, NIMH, Bethesda, MD. 20892

The PC12 rat pheochromocytoma cell line has been used extensively as a model system to study neuronal differentiation. Morphologically, these cells resemble adrenal chromaffin cells, but develop into sympathetic neuron-like cells when cultured in the presence of nerve growth factor (NGF), or following infection with an avian retrovirus carrying the viral oncogene, src (Alema et al., 1985, Nature 316:557-559). In this study, a recombinant retrovirus was used to introduce a temperature sensitive src gene (provided by H. Hanafusa, Rockefeller University) along with the gene encoding for a neomycin resistance protein into PC12 cells. Following selection of these cells in G418, a stable cell line was produced that proliferates at the non-permissive temperature of 40° C with a rate similar to uninfected cells. When switched to the permissive temperature (37° C), the majority of these cells stop dividing and extend neurites resembling cells that have been cultured with NGF. Long term growth at the permissive temperature results in small colonies of cells with extensive neuritic networks.

$pp60^{c\text{-}src}$ is the normal cellular homologue of $pp60^{v\text{-}src}$. Like $pp60^{v\text{-}src}$, $pp60^{c\text{-}src}$ is a tyrosine kinase that is strongly expressed in developing neurons in vivo and may play a role in neural differentiation. This population of PC12 cells expressing v-src is now being used to study src induced neural differentiation, and to compare it with NGF induced differentiation with respect to its reversibility, effects on membrane potential (see Lewis et al., these abstracts), and expression of neuronal markers.

171.14

PC12 CELLS FORM TUMORS IN THE BRAINS OF FETAL AND EARLY NEONATAL, BUT NOT LATE NEONATAL OR ADULT RATS. J.D. Hatton, P.Y. Kelley and H.S. U. Division of Neurosurgery V-151, U C San Diego, La Jolla, CA 92093

PC12 cells represent a rat pheochromocytoma clonal line generally thought of as a neoplastic counterpart of neurons. They respond to nerve growth factor (NGF) treatment in vitro by differentiating into post-mitotic, process-bearing and action potential-competent cells. We injected PC12 cell suspensions into the brains of fetal, neonatal and adult Sprague-Dawley rats. Even small numbers of cells (10^{3}-10^{4}) produced prolific tumors within 3-4 weeks when placed into the frontal lobes of fetal (E17-E20) and early neonatal (day 1-4) rats. This tumorigenic potential declined linearly with neonatal age (day 5-10). No tumors were produced in adult hosts whether cells were placed stereotaxically or into preformed cavities. Such injections and cavities were examined in cortex, cerebellum and hippocampus. No tumors were seen in these adults even if cells were densely packed and/or in very high numbers (10^{6}-10^{7} cells pelleted before implantation). However, suviving post-mitotic cells were seen in these latter brains, suggesting that the grafts were not simply rejected. The relationship of PC12 tumor growth to the the local expression of NGF gene product(s) is being studied.

171.15

NEURONAL SPECIFIC PROPERTIES EXPRESSED BY K-RAS INFECTED PC12 CELLS. J.Bressler, H.Miyake*, C.Chiueh and M.Brightman. NIH, Bethesda, MD 20892

PC12 cells respond to ras virus infection by mitotic arrest, neuritic extension and enhanced acetylcholinesterase(AChE) activity (Noda,M.,et al., Nature 318:73, 1985). Do changes in dopamine(DA) synthesis and release also occur after ras infection? PC12 cells were seeded ($6X10^3$cells/cm^2) under standard conditions and infected with K ras virus. Control cultures were treated similarly but without virus. Four-10 days after ras infection, conditioned medium and cells were assayed for DA levels by an HPLC-Electrochemical method. Control and infected cultures were assayed for DA before and after stimulation with d-amphetamine and K^+. While amphetamine and K^+ resulted in a 7% release above basal levels in controls, there was a 25% rise in DA release by stimulated infected cells. AChE activity in these cells rose by 63%, (cf Noda et al). Tyrosine hydroxylase and choline acetyl transferase are also present in our infected cells. Protein synthesis levels were unchanged. Most PC12 cells had emitted neurites about 4-200um long. Some cells did not emit neurites; we infer from our data on DNA synthesis and from our ^{3}H-thymidine radioautography, that such cells are still mitotic. Although there was a greater release of DA from infected cells, the amount may be smaller than that from wild PC12 cells, despite an augmented neuritic outgrowth from the ras treated cells.

171.16

C-SRC EXPRESSION IN THE BRAIN OF VERTEBRATES AND INVERTEBRATES. X. Yang* and G. Walter. (Spon: J.M. Le Beau). Department of Pathology, University of California, San Diego, La Jolla, CA 92093

The proto-oncogene c-src, the cellular homolog of the transforming gene v-src of Rous sarcoma virus, encodes two closely related protein-tyrosine kinases. The larger form, pp60c-src+, differs from the smaller one, pp60c-src, by an insert of six amino acids in the amino-terminal region (Martinez R. et al., Science, 237:411, 1987; Levy J. B. et al., Mol. cell. biol., 7:4142, 1987). pp60c-src+ is neuron-specific, whereas pp60c-src is expressed in neuronal as well as non-neuronal cells. To study the evolutionary conservation of the six amino acid insert, we assayed for pp60c-src+ in the brain of different animal species using two different kinds of antibodies. One, generated against a synthetic peptide corresponding to the insert, reacted only with pp60c-src+. The other, raised against pp60v-src, reacted with pp60c-src+ and pp60c-src in different species. pp60c-src+ was detected only in the brain of higher vertebrates (mammals, birds and reptiles), but not lower vertebrates (amphibians and fish), or invertebrates (such as lobster). pp60c-src was present in the brain of all species tested. Although we cannot rule out the possibility that pp60c-src+ is expressed at low levels in brain tissues of lower vertebrates and invertebrates, our data show that significant levels of pp60c-src+ expression are correlated with increasing neuronal complexity across animal species. This finding suggests that pp60c-src+ may assume a role in events associated with higher brain function, such as plasticity.

Butyrate-Induced Differentiation of NG108-15 Cells is Preceded by Heterologous Desensitization of Adenylyl Cyclase and Decreases in $G_s\alpha$ and its mRNA. M.E.Charness and M.Henteleff* Department of Neurology and the Gallo Center, Univ. Cal. San Francisco, CA. 94143.

G proteins are developmentally regulated and may in turn regulate cell division, differentiation, and synaptogenesis. We studied G protein regulation during butyrate (Bu) -induced differentiation of NG108-15 cells. Addition of 1 mM Bu to NG108-15 cells cultured in defined medium arrested cell division after 24 h and induced neurite formation after 24-48 h. Cells treated with Bu for 4 days had long thick neurites, resting potentials below -50 mV and fired fast action potentials. Bu did not change intracellular cAMP after 15 min or 6 h; however, after 1 or 4 days, Bu-treated cells showed a decrease in cAMP accumulation stimulated by prostaglandin E_1 (30% and 40% of untreated cells, days 1 and 4, respectively), phenylisopropyladenosine (16% and 18%), or cholera toxin (56% and 37%) and a concomitant increase in maximal inhibition of forskolin-stimulated cAMP accumulation by δ-opioid, α_2-adrenergic, and muscarinic agonists.
Western blots of membranes from Bu-treated NG108-15 cells showed a significant decrease in $G_s\alpha$ (74% and 54% of untreated cells; $p<.05$,.005; days 1 and 4 respectively) and a small increase in $G_i\alpha$ (119% and 116% of control, $p>.05$). Bu also reduced $G_s\alpha$ mRNA after 1 and 4 days. Thus, changes in G protein-mediated signal transduction occur early during butyrate-induced differentiation of NG108-15 cells and may influence later events of differentiation.

OLFACTORY BULB INFLUENCE ON G-PROTEIN EXPRESSION IN RAT OLFACTORY EPITHELIUM. B. Mania-Farnell* and A.I. Farbman. Northwestern University, Evanston, IL, 60208.

Olfactory bulbectomy in mammals results in degeneration of olfactory epithelial neurons (ON). With time new neurons differentiate from basal cells in the epithelium, but the epithelium never reaches pre-bulbectomy conditions in cell number, thickness or olfactory marker protein expression (Costanzo & Graziadei 1983; Monti Graziadei, 1983). In vitro studies have shown that maturation of receptor cells is enhanced by the presence of the olfactory bulb (Chuah & Farbman, 1983; Chuah et al., 1985). We wanted to determine if the expression of G-proteins, believed to be involved in the transduction of stimuli in ON (Pace et al., 1985; Sklar et al., 1986), is affected by bulbectomy. Harlan rats were unilaterally bulbectomized; 17 and 30 days postoperatively frozen sections of ON were prepared for indirect immunoperoxidase staining. The primary antisera were monospecific polyclonal antibodies generated in rabbits by immunization with synthetic peptides (Mumby et al., 1986): 1) one peptide had an amino acid sequence common to the alpha subunits of Gs, Gi, Go and transducin; 2) the second peptide was specific to the 35,000 MW form of the beta subunit. With both antisera the reaction product was limited to the control side. Our results indicate that the olfactory bulb is necessary for G-protein expression in the ON.

COMPARISON OF THE EFFECTS OF RETINOIC ACID AND NGF/db cAMP ON DIFFERENTIATION OF EMBRYONAL CARCINOMA CELLS. S.A.D. Sharma, J.T. Hansen and M.F.D. Notter. Dept. of Neurobiol. and Anat., Univ. of Rochester, Rochester, NY 14642.

P19S18O1A1 (O1A1) embryonal carcinoma (EC) cells can be induced to differentiate into a number of different cell types, including neurons. We have reported that retinoic acid (RA) or nerve growth factor/dibutyryl cyclic AMP (NGF/db cAMP) can induce neuron-like changes in O1A1 cells. Here we compare the effects of RA and NGF/db cAMP on the expression of AEC3A1-9 antigen, Band-3 protein, and on the ultrastructure of O1A1 cells.

O1A1 cells were grown for 2 days as monolayers followed by 2 days as aggregates in the presence of RA (500 nM) or NGF/db cAMP (375 ng/ml/ 500 ug/ml). The dissociated aggregates were then plated onto coverslips and maintained for 6 days in the absence (RA) or presence (NGF/db cAMP) of growth modulators.

RA had a much more striking and reproducible effect than NGF/db cAMP on inducing the neuronal phenotype in O1A1 cells. AEC3A1-9 is a surface antigen expressed on undifferentiated EC cells but not by differentiated EC cells. RA induced an almost complete loss of AEC3A1-9 expression by O1A1 cells. Treatment with NGF/db cAMP caused a major loss of AEC3A1-9 expression but there were many cells left which expressed some AEC3A1-9. Band-3 glycoprotein is found on red blood cells and, in neurons has been shown to be altered during aging. RA caused a dramatic increase in Band 3 expression compared to undifferentiated O1A1 cells. NGF/db cAMP also produced an increased Band 3 expression, though not as significantly as RA. Transmission EM of undifferentiated O1A1 cells showed cells with large nuclei and multiple nucleoli, and no evidence of neurofilaments. RA treated O1A1 cells showed microtubules, neurofilaments and nuclei with one nucleolus. NGF/db cAMP produced cells with only one nucleolus per nucleus, but with no intermediate filaments as seen by TEM. The data suggest that RA induces a more complete differentiation of O1A1 cells than NGF/db cAMP.

Funded partially by Training Grant T32AG00107 (SADS).

31P NMR STUDIES OF THE CHANGES IN INTERNAL INORGANIC PHOSPHATE, ATP, PHOSPHOCREATINE AND PHOSPHOETHANOLAMINE IN DIFFERENTIATED AND UNDIFFERENTIATED N1E-115 NEUROBLASTOMA CELLS WHICH HAVE BEEN SUBJECTED TO 80mM EXTRACELLULAR KCl. P. Glynn* and S. Ogawa*. AT&T Bell Laboratories, 600 Mountain Avenue, Murray Hill, N.J. 07974 and R.L. Chappell. Hunter College, 695 Park Avenue, New York City, N.Y. 10021.

Neuroblastoma cells were seeded on Cytodex III microcarriers, put in the life-support system, which was put into an NMR 360 WB magnet and superfused with a growth medium supplemented with 10 mM creatine to insure that the cells were charged with phosphocreatine (PCr). KCl was added to the recirculating superfusate of the life support system to a final concentration of 80 mM. The undifferentiated cells showed no difference in their phosphate profile after the addition of KCl. In the first 7.5 minute interval after the addition of KCl the differentiated cells showed a phosphocholine decrease of 12% and a phosphoethanolamine increase of 15%. Within 15 minutes these levels returned to their normal control values. Pi in the sample holder increased 33% within 30 minutes and stayed high. There were comparable decreases in the PCr and nucleotide phosphates. The PCr started to decline in concentration before the nucleotide phosphates. When the superfusate was switched to medium without KCl and the creatine was dropped to 0.2 mM, the PCr recovered in the time frame of one hour demonstrating that Cr was not lost from the cells. These experiments show that upon depolarization with 80 mM KCl, the phosphate profile of the differentiated N1E-115 cells changed. It has been shown here that chronic depolarization of these cells drains energy reserves at a rate faster than they can be restored by oxidative phosphorelation and glycolysis.

MORPHOLOGY OF NEURONS IN FETAL SPINAL CORD TRANSPLANTS J.G. Broton, R.P. Yezierski, and A. Seiger, Dept. Neurological Surgery, University of Miami School of Medicine, Miami, FL 33136.

A modified Golgi technique was used to study E14 spinal cord tissue which had developed in the anterior eye chamber of adult rats. The grafts, hemisections of single lumbar spinal cord segments, had been transplanted seven months previously and measured approximately 2.0mm L x 2.5mm W x 1.0mm H at the time the tissue was processed. Rats were overdosed with pentobarbital, perfused with aldehydes, and the graft and part of the attached iris removed from the eye. The Golgi protocol of Gobel (1978) was followed. Tissue was placed in 5% $K_2Cr_2O_7$ for 4-14 days, then 0.75% $AgNO_3$ for 24 hours. It was then dehydrated and sectioned (100um) on a Vibratome^R. Sections were transferred to xylene, put on slides, coated with DPX, and coverslipped.

Although the grafted tissue lacked projection targets and afferent input, many stained neurons examined thus far were comparable in appearance to those seen in the in situ spinal cord. Neurons often had spines on their dendrites, and axons of partly-stained neurons at the edge of the graft sent terminal arbors with varicosities near dendrites of well-stained neurons. Similar-shaped neurons were often grouped together in the graft. Large neurons (ave. cell body diam. > 30um) often resembled motorneurons and fusiform and multipolar dorsal horn neurons. Smaller neurons (ave. diam. < 12um) were also stained; extensively arborized dendrites were not seen for any of these neurons.

This study has demonstrated that many fetal spinal cord neurons which develop in the anterior eye chamber are morphologically similar to neurons seen in previous Golgi studies of the intact spinal cord.

IMPLANTATION OF IMMATURE ASTROCYTES INTO THE NORMAL AND CONTUSED ADULT RAT SPINAL CORD. D.W. Hoovler, M.D. Castro*, G.M. Smith*, J. Silver and J.R. Wrathall. Dept. of Anat. and Cell Biol., Georgetown Univ., Washington, D.C. 20007 and Dept. of Develop. Genet., Case Western Reserve Univ., Cleveland, OH 44106.

Immature brain astrocytes reduce scar formation, support axonal growth and alleviate functional deficits following implantation into rat brains. To begin to investigate their therapeutic potential for spinal cord injury, we implanted immature astrocytes into spinal cord after standardized contusive injury (*Exp. Neurol.* **88**:108, 1985). Astrocyte cultures were prepared from embryonic rat spinal cord and labeled with ^{3}H-thymidine. Cell suspensions (10^5 viable cells in 10 µl) were implanted into adult rat spinal cord (T8) that was uninjured or had received a standardized mild contusive injury immediately prior to implantation (n = 8 each group). At 1 week, cryostat sections were examined by autoradiography, immunohistochemical staining for GFAP, and H&E staining. Samples of the cells used for implantation showed that virtually all were positive for GFAP and heavily labeled with ^{3}H-thymidine. Thymidine-labeled cells were detected in all implanted spinal cords. The labeling was less dense and the lateral and rostrocaudal distribution of labeled cells more extensive in implants into contused as compared to uninjured spinal cord. The contusion site appears to permit the survival and proliferation of implanted immature astrocytes. Investigation of the chronic effects of such implants should therefore be feasible.

SENSORY AXONS IN THE CHRONICALLY INJURED RAT SPINAL CORD CAN REGROW INTO AND THROUGH INTRASPINAL TRANSPLANTS OF FETAL SPINAL CORD TISSUE. J.D. Houle, Dept. of Anatomy, Univ. of Arkansas Med. Ctr., Little Rock, AR 72205

Primary afferent axons can regenerate if cut dorsal roots are immediately apposed to transplanted fetal spinal cord (FSC) tissue (Tessler *et al.*, '88). The present study utilized transplants of FSC tissue into the chronically injured spinal cord to determine whether certain classes of sensory fibers retain their capacity for regrowth long after their initial injury. A partial hemisection lesion or a complete transection of the L1 spinal cord was made in adult rats. After a delay of 3-6 weeks, encapsulating glial scar tissue was excised from the cavity and a suspension of E14 FSC tissue was placed into the lesion site. Animals were sacrificed 3-4 months later and tissue processed for calcitonin gene-related peptide (CGRP) immunoreactivity.

Ascending CGRP-like immunoreactive axons in Laminae II, III, V, and X and descending fibers in Laminae II and III of the host spinal cord crossed the graft-host inferface and spread diffusely throughout the transplant, with some extending greater than 4mm. Numerous CGRP axons also crossed from transplant tissue back into the host spinal cord rostrally and appeared to terminate directly on ventral motoneurons. These results demonstrate the ability of FSC tissue transplants 1) to promote and sustain extensive growth of ascending sensory axons from the chronically injured spinal cord and 2) to act as a bridge for the growth of these fibers across an extensive spinal cord lesion in the effort to reestablish anatomical continuity. Supported by Spinal Cord Research Foundation of the PVA.

STUDIES OF HINDLIMB REFLEXES AFFECTED BY IMPLANTS OF FETAL BRAINSTEM TISSUE IN THE SPINAL CORD OF THE RAT. S.J. Moorman*, L.R. Whalen* and H.O. Nornes (SPON: M. Anderson). Dept. of Anatomy and Neurobiology, Colorado State Univ., Ft. Collins, CO 80523 (supported in part by NS21309-02 to H.O.N.)

Cell suspensions of fetal noradrenergic (NA) tissue were implanted in the lumbar region of the spinal cord 2 weeks after catecholamine (CA) denervation by intracisternal injection of 6-hydroxydopamine (6-OHDA). Animals with implants were evaluated either 2 or 4 month post-implantation as were age matched control and lesioned animals. Force production and electrophysiologic parameters associated with the hindlimb withdrawal reflex were evaluated. Testing was performed after injection of pargyline, again after L-DOPA injection, and again after phentolamine injection. Presence or absence of the long latency EMG component of the withdrawal reflex and changes in maximal force production were used to evaluate effects of the fetal implants. CA fluorescent cells in the implants were counted and correlations with the reflex changes were determined.

Control animals have a long latency EMG component of the withdrawal reflex that can only be elicited after injection of L-DOPA. This component cannot be elicited in 6-OHDA lesioned animals and therefore the force associated with this component is significantly reduced. Lesioned animals with NA implants have a long latency EMG component of the reflex before injection of L-DOPA, and show a significant increase in maximum force production compared to lesioned animals before L-DOPA injection. This force production in implant animals is significantly increased after L-DOPA injection and blocked by injection of phentolamine. In these animals the maximum force production was correlated with the number of CA fluorescent cells (r=.78).

Conclusions: In the electrophysiologic test of the hindlimb withdrawal reflex where the long latency component has been found to be dependant on NA, implants of fetal NA tissue in lesioned animals result in a recovery of NA dependant function proportional to the number of CA fluorescent cells in the implants.

A PRELIMINARY STUDY OF COMBINED CORTICAL AND SPINAL EMBRYONIC NEURAL TRANSPLANTS IN ADULT RATS. J. B. Gelderd and J. E. Quarles,* Dept. of Anatomy, College of Medicine, Texas A&M University, College Station, Texas 77843.

Cerebral cortex was exposed 2 mm caudal to the bregma and 2 mm left of the midline in anesthetized adult Long-Evans hooded rats. A 1 mm^2 area of cortical tissue was aspirated and rat embryonic cortical tissue (E_{16-17}) from the same area was placed in the host lesion cavity. A laminectomy (T_{8-10}) was performed on the same host animal and 3-4 mm of spinal cord and meninges were removed. Embryonic spinal cord from the same embryo was placed in a rostro-caudal orientation between the stumps of host spinal cord, either on the floor of the vertebral canal or embedded in a bovine collagen matrix (Collagen Corporation, Palo Alto, CA). Animals survived for varying periods from 4 days to 8 months postimplantation. Neural tissue was processed for a variety of light microscopic stains. Eight month animals underwent spinal cord transection at the T_6 vertebral level followed by implantation of horseradish peroxidase (HRP)-impregnated Gelfoam into the lesion site. Seventy-two hours later, tissues were processed using the TMB method. Although some gliosis occurred at the host/transplant interface, all cortical transplants showed good growth and integration with host neuropil. In addition, HRP animals showed labeled neurons in the cortical transplants. Only collagen-embedded spinal cord transplants appeared to survive, with one transplant exhibiting large neurons containing two nuclei.

AXONAL PROJECTIONS BETWEEN FETAL SPINAL CORD TRANSPLANTS AND THE ADULT RAT SPINAL CORD L.B. Jakeman and P.J. Reier. Departments of Neuroscience and Neurological Surgery, Univ. of Florida, Coll. of Med. Gainesville, FL 32610.

Recent work in this laboratory has demonstrated successful transplantation of fetal spinal cord (FSC) tissue into the adult rat spinal cord (SC). In the present study, neuronal tracers and immunocytochemical markers were used to examine the neuronal interactions between host and graft tissues. Transplants of E14 FSC tissue were placed into acute hemisection lesions in adult rats. After 2 - 6 months, localized injections of HRP or Flouro-gold were made into transplants or the SC at various distances from the interface between host and graft tissues. Although 2 um plastic sections of the interface region often show extensive interdigitation of processes, these injections revealed only modest host-graft interactions. Immunocytochemical staining showed ingrowth of host fibers containing serotonin-, oxytocin-, and calcitonin gene-related peptide- like activity; however, the distance of these projections was usually limited to 1 - 2 mm. Other recipients received iontophoretic injections of PHA-L, placed into FSC transplants or the host SC in close proximity to the host-graft interface. Anterogradely labeled axons illustrated extensive intragraft projections. In addition, short distance axonal projections were observed between host and graft tissues. These results indicate that axonal growth can occur between FSC grafts and the host SC. Many of the projections across the interface may be limited to short distances, while donor neurons extend axons for long distances within the grafts. Together, intragraft connectivity and the presence of afferent and efferent axonal projections suggest that FSC grafts may provide an anatomical substratum for the formation of a relay circuit at the site of a spinal cord injury. Supported by NIH MH15737-09.

INTRASPINAL BRAINSTEM TRANSPLANTS: REINNERVATION OF SYMPATHETIC PREGANGLIONIC NEURONS. M. Gonzalez-Carvajal* and V.R. Holets (SPON: B.A. Green). Dept. of Neurological Surgery, Univ. of Miami, Miami, FL 33136

Adult rats received an intrathecal injection of either 5,7-dihydroxytryptamine (5,7-DHT) or 6-hydroxydopamine (6-OHDA) one week prior to transplantation. The medullary raphe nucleus (RN) or the locus coeruleus/subcoeruleus area (LC) from E15 rats was dissected and dissociated. The RN and LC cell suspensions were prelabeled with DiI and injected into the T10 spinal cord segment of 5,7-DHT- or 6-OHDA-treated rats, respectively.

One to 4 weeks post-transplant, DiI-labeled RN and LC cells were present in the spinal cord, and fiber outgrowth was observed. The innervation of the dorsal and ventral horns by serotonin (5-HT)-, thyrotropin-releasing hormone (TRH)- phenylethanolamine-N-methyltransferase (PNMT)-, tyrosine hydroxylase (TH)-immunoreactive fibers was sparse. However, a moderately dense innervation of the sympathetic preganglionic neurons in the intermediolateral cell column and lamina X by 5-HT-, TRH-, PNMT- and TH-postive fibers was observed, suggesting a specificity of reinnervation. Control lesion animals showed no regeneration of 5-HT-, SP- or TRH-immunoreactive fibers (5,7-DHT-treated), or of PNMT- or TH-immunoreactive fibers (6-OHDA-treated) in the thoracic and lumbar spinal cord segments. Animals with longer survival times post-transplant are being evaluated. Funded by The Miami Project.

INTRAOCULAR CO-GRAFTS OF FETAL RAT THORACIC SPINAL CORD AND BRAINSTEM AREAS: REINNERVATION OF SYMPATHETIC PREGANGLIONIC NEURONS. V.R. Holets, M. Gonzalez-Carvajal*, E. Jakobsson* and Å. Seiger. Dept. of Neurological Surgery, Univ. of Miami, Miami, FL 33136.

An E14 rat thoracic spinal cord graft was placed in the anterior eye chamber of an adult rat 1 month prior to grafting an E14 medullary raphe nucleus (RN), E15 locus coeruleus/subcoeruleus (LC) or E14 C1-2 area (C1) graft. The grafts were evaluated 6 to 12 months post-grafting for the innervation of the thoracic spinal cord graft by serotonin (5-HT)-, thyrotropin-releasing hormone (TRH)- and substance P (SP)-immunoreactive fibers from RN co-grafts; neuropeptide Y (NPY)-, tyrosine hydroxylase (TH)- and galanin (GAL)-positive fibers from LC co-grafts; and phenylethanolamine-N-methyl-transferase (PNMT)-, TH-, SP- and NPY-immunoreactive fibers from C1 co-grafts. Motoneurons and sympathetic preganglionic neurons (SPNs) were identified with an anti-acetylcholine esterase (AChE) antibody.

Clusters of AChE-immunoreactive motoneurons and SPNs were seen in the spinal cord graft. Dense innervation of the spinal cord graft by 5-HT-, SP- (RN) and TH- (LC and C1) immunoreactive fibers was observed. PNMT- (C1) positive fibers preferentially innervated SPNs, while TRH- (RN) immunoreactive fibers were seen surrounding SPNs and motoneurons. These results suggest a specificity of reinnervation of the SPNs by fibers from the brainstem co-grafts. Funded by The Miami Project.

NEUROGLIA: BIOLOGY OF ASTROCYTES I

173.1

CHARACTERIZATION OF ASTROGLIAL MEMBRANE ASSEMBLIES BY AGENTS WHICH ACTIVATE PROTEIN KINASE C. J.H. Tao-Cheng, J.P. Bressler, & M.W. Brightman. NINCDS, NIH, Bethesda, MD

The function of the astroglial membrane assemblies, the orthogonal arrays of intramembranous particles revealed by freeze-fracture electron microscopy, is unknown. Previously, we have shown that agents which raise cAMP levels increased the astroglial assembly concentrations. In order to further characterize the assemblies, we have now used agents that affect protein kinase C (PKC).

Phorbol 12-myristate 13 acetate, which activates protein kinase C, did not affect the assemblies. Choline-specific phospholipase C (PLC), which generates diacylglycerols, a PKC activator, did not change the size, shape or concentration of the assemblies. A PKC inhibitor, H-8, had no effect on assemblies either. Thus, PKC probably is not linked to the presence of assemblies in the astroglial membrane.

Background, non-assembly particles in the astroglial membrane were affected by PLC, however. After 6-7 hrs of exposure (0.1-1ug/ml), individual intramembranous particles redistributed into patches of aggregates interspersed with particle-free areas. The assemblies remained unchanged, but were flanked by other aggregated particles. By 26 hrs and without changing the media, the astroglial membrane structure recovered its pattern of evenly distributed particles and assemblies. It appears that assemblies are not affected by changes in choline containing phospholipids.

ASTROCYTIC ABNORMALITIES IN CAPRINE β-MANNOSIDOSIS: AN IMMUNOHISTOCHEMICAL ANALYSIS OF OPTIC NERVE. **P.J. Boyer and K.L. Lovell. Dept. Pathology, Michigan State Univ., E. Lansing, MI 48824.**

Central nervous system features of caprine β-mannosidosis, an autosomal recessive disease of glycoprotein catabolism, include myelin deficiency, with consistent regional variation in severity, and widespread cytoplasmic vacuolation. A previous study of one affected fetal optic nerve demonstrated, by ultrastructural analysis, a substantial increase in the number of astrocytes compared to control values. In order to further characterize astrocytic changes in affected animals, an immunohistochemical investigation of GFAP (glial fibrillary acidic protein) staining distribution was undertaken in optic nerves of animals ranging in age from 115/150 days gestation to 31 days postnatal.

At the light microscopic level, a qualitative increase in density of GFAP-positive astrocytic process profiles in affected optic nerves, compared to control optic nerves, was present at all ages studied. However, fewer GFAP-positive cell body profiles were prominent in affected goats. At 115 days gestation, optic nerve myelination is in an early stage and myelin deficiency is already evident. Thus astrocytic abnormalities are present relatively early in the progression of the dysmyelinating process. Morphometric analysis of the area occupied by GFAP reaction product showed an increase in all affected animals. This study defines quantitatively the extent of change in optic nerve GFAP-positive astrocytic processes during development in β-mannosidosis.

INTERMEDIATE FILAMENT-ASSOCIATED PROTEINS AS MARKERS OF SUBTYPES OF RAT ASTROCYTES IN PRIMARY CULTURE. H-Y. Yang*, J.C. Chen*, and G.D. Pappas (SPON: E.G. Anderson). Dept. of Anatomy and Cell Biology, Univ. of IL at Chicago, Chicago, IL 60612.

Intermediate filament-associated proteins (IFAPs) have been thought to play an important role in the regulation of the organization of intermediate filaments (IFs) and the interrelationship among IFs and other cellular components. IFAP expression has been shown to be related to the functional and developmental status of the cell. Therefore, the IFAPs can be used as markers for the identification of various functional subtypes of astrocytes, that have long been speculated but little is known. Recently, we have initiated the study of the IFAPs in astrocytes. We have previously identified several IFAPs in kidney cell line (BHK-21) that contains both vimentin and desmin as the structural proteins of their IFs (Yang et al., 1985, JCB, 100:620 and 101:15a). Because vimentin and/or desmin are also found in some normal and reactive astrocytes, the immunoreactivity of these IFAPs was tested in primary cultures of astrocytes prepared from neonatal rat brain, as well as in those from stab-lesioned rat brain. The results revealed that one of the BHK IFAP (IFAP-70/280kD) is also a glial IFAP, as demonstrated by double-label immunofluorescence microscopy using antibodies to glial fibrillary acidic protein, the astrocyte specific IF structural protein, and the IFAPs. In primary cultures of neonatal astrocytes that are composed of both stellate and non-stellate astrocytes, the anti-IFAP-70/280kD staining was found only in some of the non-stellate ones, but not in the stellate ones. The immunostaining was also shown in some of the adult 'reactive' astrocytes in primary cultures that are composed only of non-stellate astrocytes. Thus, we now can divide the non-stellate ('protoplasmic'; Miller and Raff, 1984, J. Neurosci., 4:585) astrocytes into two subgroups based on the presence of a glial IFAP.

173.4

ASTROCYTE MEMBRANE DIFFERENTIATION IS INFLUENCED BY CO-CULTURE WITH ENDOTHELIAL CELLS.

L.A. Weinstein*, C.J. Skordeles*, and D.M.D. Landis, Dept Neurology, Case Western Reserve University, Cleveland, OH 44106

We have co-cultured primary astrocytes derived from neonatal rats and brain endothelial cells derived from mature rats. A larger proportion of astrocytes in these co-cultures acquire "assemblies" of intramembrane particles as compared to astrocytes cultured alone. The average density of assemblies is also increased: astrocytes cultured alone had an average density of 4.4 assemblies/μm^2, while astrocytes co-cultured with endothelial cells acquired 7.1 assemblies/μm^2. This effect is not observed when astrocytes are cultured on the basal lamina remaining after the removal of endothelial cells, though astrocytes grew very rapidly to confluence in such cultures. Potential effects of serum supplementation and of culture medium composition seemed not to play a role in the influence of endothelial cells on astrocyte differentiation; similar results were obtained when cells were cultured in HAM F12 media supplemented with calf serum and when cells were cultured in L15CO_2 media supplemented with fetal calf serum. No consistent differences in intramembrane structure were evident as endothelial cells in co-culture with astrocytes were compared to endothelial cells cultured alone.

The increased concentration of assemblies in the co-cultured astrocytes may reflect in vivo interactions. In the adult mammalian central nervous system, astrocytic membranes adjacent to vascular structures are characterized by a high concentration of assemblies. Co-culture thus replicates certain aspects of the normal blood-brain interface, and suggests that trophic interactions between the two cell types may occur during development.

173.5

DEXAMETHASONE AND FORSKOLIN EXERT OPPOSITE INFLUENCES ON MEMBRANE DIFFERENTIATION IN CULTURED ASTROCYTES.

C.J. Skordeles,* L.A. Weinstein,* and D.M.D. Landis (Spon: R.B. Daroff). Dept. Neurology, Case Western Reserve University., Cleveland, OH 44106

Astrocytes in confluent secondary cultures exposed to 5 μM dexamethasone acquire very high densities of "assemblies," aggregates of intramembrane particles packed in orthogonal array: after 7 days of culture in dexamethasone, average density was 13.65 assemblies/μm^2, as compared to control values of 3.98 assemblies/μm^2. Not all cells in the culture are affected. While the proportion of cells expressing assemblies is somewhat increased, the more striking effect is that some cells acquire densities of assemblies greater than that observed under any other conditions in vitro. We hope to learn whether this glucocorticoid effect in vitro is related to the therapeutic benefits of glucocorticoids used to treat cerebral edema.

When 50 μM forskolin is added to confluent secondary cultures of astrocytes for 72 hours, there is a significant but transient increase in c-AMP levels (50-131 fold increase at 24 hours, 4.5-4.7 fold increase at 48 hours, and 1.5-5.0 fold increase at 72 hours). As previously observed in cultures of astrocytes exposed to elevated c-AMP or analogues, the flat, epitheliod cells undergo a remarkable shape transformation to become process bearing. Many cells detach from the substrate, and cells remaining adherent have a lower concentration of assemblies. In one plating, densities at 24 hours were 2.34 assemblies/μm^2 (control 3.39 assemblies/μm^2), at 48 hours were 0.66 assemblies/μm^2 (control 4.14 assemblies/μm^2), and no cells bearing assemblies could be found at 72 hours. Astrocytes in such cultures thus resemble astrocytes in white matter.

173.6

DIFFERENCES IN ASTROCYTE DEVELOPMENT IN STRAINS OF MICE INBRED FOR DIFFERENT ETHANOL SENSITIVITY. N. Sakellaridis, D. Mangoura, J. M. Masserano, V. Detsis,* C.J. Leoni,* J.D. Jones,* R. Deitrich,* and A. Vernadakis.* Depts. of Pharmacology and Psychiatry, Univ. of Colorado School of Medicine, Denver, CO 80262

Differences in astrocyte development were investigated in mice selectively bred for ethanol sensitivity: a) Short Sleep (SS) or Long Sleep (LS) and b) Severe Ethanol Withdrawal (SEW) or Mild Ethanol Withdrawal (MEW). Astrocyte development was assessed using glutamine synthetase (GS) activity as a marker. GS was assayed in the forebrain, cerebellum and remaining brain in LS and SS mice at 8, 10, 12, 15, 30, 45, and 60 days of age. GS activity rose linearly up to 30 days of age and leveled off thereafter in all brain areas. Activity was lower early in development in SS mice in all three brain areas until day 15 when the activities were identical except in 60 day old forebrain when again GS was lower for SS mice. The same ages / brain areas were assayed for MEW, SEW and were compared to CEW their controls. GS activity was lower in the cerebellum and forebrain of both SEW and MEW mice as compared to the control line before 15 days of age. Comparing the developmental profiles of GS activity with the developmental emergence of ethanol sensitivity we propose that astrocytes play a role in the ethanol related line differences. EVIDENCE FOR THE EXISTENCE OF SUBTYPES OF TYPE-1 RAT ASTROCYTES IN CULTURE. Y.J. Oh*, G.J. Markelonis and T.H. Oh, Dept. of Anat., Univ. of MD Sch. of Med., Balto., MD 21201

Studies of certain cell surface receptors or intermediate filament markers suggest that cultured CNS astrocytes exhibit different subtypes. Experiments in our laboratory have focused upon other appropriate metabolic cell markers which can be used to clearly differentiate astrocytic subtypes. Antibodies against mitochondrial malate dehydrogenase (MDH) appear to be excellent markers for this purpose. We have examined MDH immunoreactivity in primary cultures of type-1 astrocytes (non-stellate) or type-2 astrocytes prepared from neonatal rat brain by standard methods. Double immunofluorescent staining with anti-MDH serum (rabbit) and anti-GFAP antibody (mouse monoclonal) suggested that there are at least two different subtypes among type-1 astrocytes. The predominant pattern consisted of numerous punctate fluorescent vesicles; the remaining astrocytes showed far fewer of these discrete flourescent profiles. Some type-1 astrocytes did react in an intermediate pattern to anti-MDH. These MDH results were consistent for cells cultured for 3-21 days. Experiments with rhodamine 123, a mitochondrial-specific fluorochrome, showed that all astrocytes contained mitochondria. In contrast, type-2 astrocytes uniformly showed strong immunoreactivity to anti-MDH with no apparent subtypes being evident. We conclude that different metabolic subtypes of type-1 astrocytes can be distinguished by anti-MDH. (Supported by NIH grants NS20490 and NS 15013)

173.8

IMMUNOHISTOCHEMICALLY LABELED ASTROCYTES IN RAT OLFACTORY BULB WITH MONOCLONAL ANTIBODIES. M.S. Bailey*, M.T. Shipley, R.A. Akeson. (SPON: R.V.W. Dimlich) Dept. of Anatomy & Cell Biology and Division of Basic Research, Children's Hospital Research Foundation, Univ. Of Cincinnati Med. Ctr., Cincinnati, Ohio 45267.

Three monoclonal antibodies (Mabs) 1F10, 2C8 and 2F10 yeild excellent immunohistochemical staining of astrocytes in the rat CNS. These Mabs were generated by immunizing against neonatal rat olfactory bulb after tolerizing the mice to cerebellum with cytoxan treatment. Western anaylsis suggests that the Mabs bind protein(s) that co-migrates with GFAP on SDS-PAGE. Mabs 1F10, 2C8, 2F5, as well as a polyclonal anti-GFAP antibody, demonstrate differential distribution of astrocytes in the rat olfactory bulb. The heaviest label is in the synaptically active glomerular and external plexiform layers. The internal plexiform and granule cell layers have much lower density of astrocytes, with higher density in the subependymal zone. 2C8 and 2F5, but not 1F10 or anti-GFAP, also label the nerve layer. In addition, 2C8 strongly labels mitral and tufted cells in the postnatal day 9 rat olfactory bulb and only faintly labels mitral cells in the adult. The Mabs will be used for further study of organization and development in the rat olfactory bulb. (Supported by : NIH 23348, 20643, 22053, U.S. Army DAMD 17-86-C-6005)

INCREASED GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) WITHIN THE HYPOGLOSSAL NUCLEUS FOLLOWING HYPOGLOSSAL NERVE TRANSECTION OR ELECTRICAL STIMULATION. L.L. Hall[1] and R.C. Borke[2]. Depts. of Physiology[1] and Anatomy[2], Uniformed Services University of the Health Sciences, Bethesda, MD 20814-4799.

Astrocytic processes, containing intermediate filaments, hypertrophy around axotomized neurons. The stimulus and function for this response remain unknown. In this study, GFAP expression within the hypoglossal nucleus was investigated following axotomy. The influence of hypoglossal nerve stimulation on the astrocytic expression of GFAP within the hypoglossal nucleus was also examined. At various intervals following either unilateral hypoglossal nerve transection or electrical stimulation (10 mins. of stimulation, 0.5-2.0 V, 1 Hz pulses of 0.05 ms duration), the hypoglossal nuclei from Sprague-Dawley rats were analyzed for GFAP immunoreactivity. Hypoglossal nerve transection induced a marked, unilateral increase in GFAP expression within the hypoglossal nucleus 4 to 20 days following axotomy. A dramatic enhancement of GFAP immunoreactivity within the hypoglossal nucleus was also observed 5 to 20 days following nerve stimulation. Thus, either hypoglossal nerve lesion or electrical stimulation provoked an increase in GFAP-positive staining astrocytes within the hypoglossal nucleus.

3-DIMENSIONAL RECONSTRUCTION OF VOLUME REGULATION IN SWOLLEN ASTROCYTES USING HIGH VOLTAGE ELECTRON MICROSCOPY (HVEM). H.K. Kimelberg[1], S. Goderie[1]*, R. Cole[2]* & D.F. Parsons[2]*, Albany Medical College[1] & Wadsworth Center for Laboratories & Research, N.Y.S. Dept of Health[2], Albany, NY

During exposure to hypotonic media astrocytes in primary monolayer culture swell and then regulate their volume back to control levels, a property termed regulatory volume decrease (RVD). Using thick (0.5µm) sections viewed by a 1MV HVEM and using a 3-dimensional graphic reconstruction computer program, we confirmed these results previously obtained using radiolabelled markers of the intracellular space. We found that upon swelling the shape of the cell changes from being relatively flat to cone-shaped, and then regains its initial volume and shape during RVD. Transmission electron microscopy (TEM) showed that the cytoplasm became much less electron-dense during swelling, the bundles of intracellular filaments appeared to dissociate into single filaments, the mitochondria showed marked swelling and the numerous surface infoldings became smoothed-out and deconvoluted. All these effects were reversible. We have found that in swollen cells the "normal" stress fibers, composed of longitudinal actin filaments are reconfigured into a radial pattern, which rapidly reverts to the "normal" pattern with RVD. There is a loss of poly-peptides of both low (< 40 kDa) and high (> 66 kDa) MW from a detergent extract of swollen cells, and partial recovery of these poly-peptides after 30 mins exposure to hypotonic medium. (Supported by NIH grants NS23750(HKK) & PHS RR01219 (DFP)).

173.11

ASTROCYTE VOLUME REGULATION FOLLOWING EXPOSURE TO SERA FROM REYE'S SYNDROME (RS) PATIENTS. J.E. Olson, J.F.S. Crocker*, and M.G. Murphy, Dept. Emerg. Med., Wright State Univ., Dayton, OH and Depts. Pharmacol. and Pediatr., Dalhousie Univ., Halifax, NS, Canada.

Elevated intracranial pressure, one of the neurological hallmarks of RS, is thought to be caused by astrocytic swelling. This cytotoxic brain edema may be caused by toxic factors in the circulation. To test this hypothesis directly, we determined the morphology and volume regulation of cultured astrocytes following exposure to sera from RS patients.

Astrocyte cultures (more than 85% GFAP positive) were exposed to media containing 5% serum from RS patients in the acute (ARS) or recovery (RRS) phases of the disease or normal human serum (NHS) for 30 min or 2-5 days. Volume regulation was analyzed by measuring cell volumes for 30 min during suspension in hypoosmotic medium (165 mOsm). Astrocytes exposed to ARS or RRS sera for 30 min showed volume regulation similar to cells exposed to NHS. Cells cultured in ARS sera for 2-5 days had normal cell volumes in isoosmotic medium (257 mOsm), but in hypoosmotic medium these cells were initially 10% smaller than cells grown in RRS sera from the same patient. Volume regulation following hypoosmotic swelling was reduced or absent for cells grown in ARS serum and, in general, correlated with abnormal cell morphology. These observations support the hypothesis that during the acute phase of RS, serum contains a factor(s) that contributes to the pathogenesis of cytotoxic edema.

REACTIVE ASTROCYTES EXPRESS HIGH LEVELS OF MICROTUBULAR ASSOCIATED PROTEIN 2 (MAP2): A POSSIBLE MARKER FOR REACTIVE GLIOSIS. E.E. Geisert and L.I. Binder.* Dept. Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

Reactive astrocytes are a major component of the scar that forms following injury to the CNS. To study the process of scar formation, 26 Sprague-Dawley rats received lesions in different regions of the CNS: 16 lesions of the internal capsule; 6 lesions of the corpus callosum; and 4 lesions of the spinal cord. The animals were allowed to survive from 0 to 50 days. Frozen sections were stained with three different monoclonal antibodies against MAP2. Two different monoclonal antibodies and one rabbit polyclonal antiserum were used to stain for GFAP. From an analysis of these sections, reactive astrocytes appeared to express high levels of MAP2. In sections double stained for both MAP2 and GFAP, all of the GFAP-positive astrocytes near the edge of the lesion were also positive for MAP2, while astrocytes in normal tissue were not. The high levels of the cytoskeletal protein MAP2 in reactive astrocytes may represent a terminal differentiation of the astrocyte as it becomes reactive and may serve as a marker for reactive gliosis.

PROTEIN KINASE C INHIBITORS ALTER ASTROCYTE MORPHOLOGY. C. A. Bedoy* and P. L. Mobley, St. Mary's University and The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Shape changes appear to play an important role in astrocyte function. In astrocyte cultures activators of either protein kinase C (PK-C) or cyclic AMP activated protein kinase (PK-A) can alter cell shape. While conducting studies to determine if kinase inhibitors could block morphological changes induced by the PK-C activator phorbol 12-myristate 13-actetate (PMA), we found that PK-C inhibitors also induced morphological changes similar to those observed with PMA. In confluent cultures treated with 50 μM H-7 cells rapidly converted from their flat, polygonal form to stellar shaped cells with processes. Changes in morphology were also observed with 500 nM staurosporine, another inhibitor of PK-C. No effects were observed with 100 μM or 200 μM HA-1004, a PK-A inhibitor. In cells pretreated 24 hrs with PMA, no measurable PK-C activity is found using a histone substrate, and subsequent exposure to PMA does not affect morphology or alter protein phosphorylation; however morphological changes are still observed with H-7. These studies indicate the both activators and inhibitors of PK-C can alter astrocyte morphology and suggest that this kinase plays an important role in astrocyte function.

PROTEIN KINASE C SUBSTRATES AND OTHER MEMBRANE PHOSPHOPROTEINS IN RAT ASTROCYTES. L. Vitković, V. J. Aloyo, H. W. Steisslinger*, D. Benzil*, and J. P. Bressler. Lab. Mol. Biol. & Surgical Neurol. Branch, NINCDS, NIH, Bethesda, MD 20892 and Dept. Pharmacol., Med. Col. Penn., Phyladelphia, PA 19129.

Membrane phosphoproteins are likely mediators of signal transduction and their characterization in astrocytes contributes to defining these cells' ability to interact with their environment. Among polypeptides with relative molecular weights (Mr) between 20 kDa and 120 kDa and isoelectric points (pI) between 4.2 and 8.5, 10 were phosphorylated when crude membranes from cultured rat astrocytes were incubated under conditions optimal for activities of Ca^{2+}-dependent kinases. The same acidic plasma membrane proteins from astrocytes and 1-day old cortex were phosphorylated, but to an apparently different degree, by partially purified rat brain protein kinase C (pkC). The two most prominent among these were characterized by four criteria as major substrates of pkC in brain: growth-associated protein 43 (GAP-43) and the Mr 87 kDa protein. Addition of phorbol 12-myristate 13 acetate to cultured astrocytes led to an increase in the degree of phosphorylation of these two proteins. These results suggest that the two prominent pkC substrates in brain, GAP-43 and the 87 kDa protein, are endogenous substrates of pkC in astrocytes.

EXTRACELLULAR POTASSIUM AND OSMOLARITY INFLUENCE DNA SYNTHESIS AND GLIAL FIBRILLARY ACIDIC PROTEIN EXPRESSION IN CULTURED GLIAL CELLS. K. S. Canady*, F. Ali-Osman* and E. W Rubel (SPON: A. Towe), Depts. of Physiol. & Biophys., Otolaryngol. & Neurol. Surg., Univ. of Washington, Seattle, WA 98195.

Extracellular potassium (K^+_o), which varies with neuronal activity, is thought to play an important role in neuron-glia interactions. We have previously shown that changes in glial fibrillary acidic protein (GFAP) immunopositive astrocytic processes can result from changes in neuronal activity levels. Here we tested the hypothesis that changes in $[K^+]_o$ stimulate these glial reactions by varying the $[K^+]$ of the media in which glial cells were cultured. We varied $[K^+]_o$ in two ways: (1) by adding KCl to Dulbecco's modified Eagle's medium (DME) to achieve final $[K^+]$'s of 5-50 mM; or (2) by adding both KCl and NaCl to K^+,NaCl-free DME. The latter was done to hold osmolarity constant and to achieve final $[K^+]$'s of 1-50 mM. To vary osmolarity without altering K^+_o, we added NaCl to DME to achieve final [NaCl]'s of 110-155 mM. In these cultures, we measured GFAP expression by a dot-immunobinding assay, and we measured the incorporation of ^{3}H-thymidine and ^{3}H-leucine into cellular DNA and protein, respectively. Glial cells cultured in hyperosmolar media (50 mM K^+ or 155 mM NaCl) showed decreased DNA synthesis and increased GFAP expression. When osmolarity was held constant, however, GFAP expression was inversely related to K^+_o over the 1-50 mM range. The syntheses of DNA and protein did vary with physiologically significant $[K^+]_o$'s (1-10 mM), regardless of the small changes in osmolarity. We conclude that the DNA synthesis and GFAP expression of cultured glial cells are sensitive to both small changes in $[K^+]_o$ and relatively large changes in osmolarity. These data suggest that changes in neuronal activity, by altering K^+_o, may play a role in glial reactions observed *in vivo*. Supported by PHS grants NS24518 and GM07108.

DIFFERENTIATION OF CULTURED RAT ASTROCYTES: LIMITATION IN MINIMAL MEDIUM. E. T. Browning, E. J. Hoff* and S. E. Farinelli*, Dept. of Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Past studies indicated that glial fibrillary acidic protein (GFA) containing rat astrocytic cultures express monoamine oxidase-B (MAO-B), and glutamine synthetase (GS) only if culture conditions are properly selected. Expression of significant levels of MAO-B activity occurred only if culture pH was kept near 7-7.4 and if culture continued for 40 days or longer. GS expression required control of pH but was also greatly increased in cultures grown in DMEM compared to those grown in BME. Present work indicates that cultures (25 cm^2 growth surface/3ml medium) deplete their growth medium of three essential amino acids, leucine, isoleucine and valine, within approximately 24 hr indicating that these cultures are starved for these amino acids for the remaining 24-48 hr of the usual period between feedings. Cultures grown in DMEM contain 4-times the initial concentration of amino acids present in BME and are not depleted during this usual feeding cycle. Isotope studies indicate that 2/3 of the C^{14}-labeled leucine, isoleucine or valine which is taken up by the cultures is incorporated into protein and 1/3 is oxidized to CO_2. In addition the cultures grown in either medium consume the 5.5 mM glucose of their medium within 24 hr, converting it largely to lactic acid. Experiments are in progress to determine if addition of leucine, isoleucine and valine to BME will increase GS expression.

COMPACT ASTROGLIAL SCAR FORMATION IN VIVO AND IN VITRO IS ALTERED WHEN MYELIN IS PRESENT. P.A. Trimmer. Dept. of Neurosci., Univ. of Virginia, Charlottesville, VA 22908.

Little is known about what factor(s) influence compact glial scar formation by reactive astrocytes. To study this question, the retina was unilaterally removed surgically to induce scar formation in the optic nerve. Light and electron microscopic examination of scars formed in newborn, juvenile and adult rat optic nerves suggested that the presence of myelin affects the time course of compact glial scar formation. Before myelination in vivo, scar formation took less than one week. In older rats, compact scar formation took from one to five months. Astroglial scar formation was also studied in explant cultures prepared from newborn, juvenile, and adult rat optic nerves as previously described (Trimmer, P.A., Soc. Neurosci.,11:396,1985). Compared with in vivo, the time course of myelin removal in vitro seemed to be delayed. Even after several weeks in vitro, explants from older rats consisted of degenerating myelin. The number of reactive astrocytes in explants appeared to be greatly reduced. Glial scar formation in vitro was more successful in optic nerve explants which did not contain myelin. This suggests that the formation of a compact glial scar by reactive astrocytes in vivo and in vitro is altered by conditions which favor the persistance of myelin debris. MIGRATION AND PHENOTYPE OF TRANSPLANTED ASTROCYTES C.J.Emmett, J.M.Lawrence, P.J.Seeley and G Raisman (SPON: R.E.Rydel), Norman & Sadie Lee Res.Ctr., Lab of Neurobiology, N.I.M.R., The Ridgeway, London NW7 1AA, U.K.

Type 1 astrocytes were derived from post-natal (P5-8) corpus callosum rat. They were characterized by histology and immunocytochemically. After rotational purification and a complement-mediated cytolosis with antibodies to G_{GIC} (A2B5) and galactocerebroside (GalC), the final population of cells contained 99% GFAP-positive astrocytes. The astrocytes were labelled by mitotic uptake of tritated thymidine prior to grafting. Over a series of transplant survival times astrocytes were visualized autoradiographically.

They divided *in vivo* and migrated extensively into host brain within one week of implantation. As routes for migration, they commonly appeared to use blood vessels and neuronal dendrites. Labelled cells were found in the optic track and thalamus. Ultrastructural autoradiography of transplanted astrocytes demonstrated a bimodal distribution of cell morphology, although the original population was homogeneous. One cell phenotype was small, darkly-stained, relatively heavily radiolabelled and found at quite large distances from the original grafting site (class S cells). The other was large, lightly-stained, with relatively low levels of radioactivity (class L cells). They were found close to the host transplant interface. Material from longer survival times revealed an apparent progressive conversion of class S cells to the L form.

COMPARISON OF MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) ANTIGEN EXPRESSION ON HUMAN ADULT ASTROCYTES IN SITU AND IN VITRO. Y. Grenier*, C. Szwarc*, J.P. Antel (SPON: I. Hunter). Montreal Neurological Institute, Montreal, Quebec H3A 2B4.

We compared in situ and in vitro (tissue culture) expression of MHC antigens by astrocytes of young adult humans (i.e. age most at risk for autoimmune CNS disease) by using surgically resected temporal lobe tissue and immunohistochemical labelling of cells, both in cryostat sections and in tissue culture. Histopathologic examination indicated variable degrees of gliosis in the tissue specimens. Monoclonal antibodies (mcAbs) W6/32 and SG465 directed to framework epitopes of the class I and class II molecules respectively, as well as B7-21, TV22A, D1-12, which recognize the class II DP, DQ, DR gene products respectively, were used. Astrocytes were identified by double immunostaining the cultured cells or tissue sections with anti-GFAP antibody. In tissue culture, a mean 75% of GFAP+ cells express MHC class I. A mean of 25% of astrocytes grown in DMEM + 10% fetal calf serum express MHC class II compared to <10% of such cells grown in DMEM 10% human serum. MHC reactivity on GFAP+ cells was absent in tissue sections, including examples with severe gliosis. MHC expression was detected using all 5 mcAbs on non-GFAP+ cells in sections of a case of encephalitis. Our results parallel studies of fetal murine tissue, in which MHC antigen expression on astrocytes is immunohistochemically detected in vitro but not in situ.

PRIMARY ADULT HUMAN ASTROCYTES CONTAIN FACTORS SUFFICIENT FOR JC VIRUS REPLICATION. A. J. Aksamit* and J. Proper*. (SPON: Julie Cunningham) Dept. of Neurology, Mayo Clinic, Rochester, MN 55905.

Factors specific for glial cells have been shown to be important in determining the selective transcription and replication of JC virus, the etiologic agent of progressive multifocal leukoencephalopathy, a demyelinating disease of the human central nervous system. These factors determine tropism. Cultured, purified adult human astrocytes taken from temporal lobectomy specimens and identified by staining with anti-glial fibrillary acidic protein antibody were examined for the ability to support JC virus production. Infected cells underwent nuclear enlargement but showed no signs of transformed growth characteristics. Early viral gene translation was demonstrable by immunohistochemistry. JC virus DNA replication quickly followed, as demonstrated by biotinylated DNA:DNA in situ hybridization. Late gene structural protein synthesis followed and was accompanied by infectious virion assembly, as demonstrated by immunocytochemistry and hemoglutination inhibition assay, respectively. This is the first demonstration that adult human astrocytes are capable of productive JC virus infection, whereas human oligodendrocytes or human fetal spongioblasts were thought to be the only primary cells containing specific glial factors capable of replicating this virus. We conclude that glial factors required for JC virus expression are sufficiently present in primary adult human astrocytes.

NEURAL PROGESTIN RECEPTORS FOLLOWING DIFFERENT ESTRADIOL TREATMENTS IN FEMALE GUINEA PIGS: BIOCHEMISTRY AND IMMUNOCYTOCHEMISTRY. D.H. Olster and J.D. Blaustein. Neuroscience and Behavior Program and Psychology Department, Univ. of Mass., Amherst, MA 01003

Estradiol (E_2), administered as two pulses or as a single injection of estradiol benzoate (EB), is effective in priming ovariectomized (OVX) guinea pigs for progesterone facilitation of lordosis. Because E_2-induced progestin receptors (PRs) appear to mediate progesterone-facilitated lordosis, neural PRs were evaluated biochemically (by in vitro binding) and immunocytochemically following EB and E_2 pulse treatment. The concentration of combined hypothalamic-preoptic area PRs measured biochemically was higher in EB (10 µg) as compared to E_2 pulse (two 2-µg injections) treated OVX guinea pigs. Immunocytochemistry revealed this to be an effect localized primarily to the preoptic area, where PR-immunoreactivity (IR) was markedly reduced in the E_2 pulse- as compared to EB-treated animals. In contrast, PR-IR in hypothalamic areas appeared similar following EB and E_2 pulse treatment. These data suggest that hypothalamic cells are exceptionally responsive to the inductive effects of E_2 pulses on PRs, and further support the hypothesis that hypothalamic PRs may mediate the facilitation of lordosis by progesterone in E_2-primed guinea pigs.

POSSIBLE INTERACTION OF VASOTOCIN AND CENTRAL VISUAL PATHWAYS IN THE FROG, RANA PIPIENS. G.J. De Vries, K. Fite, J. Brewer*, and S. Numan*. Neuroscience and Behavior Program and Department of Psychology, University of Massachusetts, Amherst, MA 01003.

Visually guided behaviors involved in prey-catching vary seasonally in anuran amphibians. So do certain responses of visual neurons. These seasonal variations may have a hormonal basis. Specific hormonal effects on visual systems, however, have not been described. Here, we are identifying neurotransmitter systems that may be involved in seasonal modulation of visual functions. We have started to stain brains of the leopard frog, Rana pipiens, immunocytochemically for vasotocin. This peptide shows seasonal variations in certain anura, just like its homologous peptide vasopressin in mammals, where it is under strict steroid hormone control. Vasotocin fibers were found in several thalamic and mesencephalic regions that receive direct retinal afferents: specifically, in the dendritic zone between visual terminals in the Nucleus of Bellonci and the postsynaptic neurons in the anterior thalamus, the ventral thalamus including the rostral visual nucleus, the pretectal nucleus lentiformis mesencephali, and the deep layers of the tectum. As all these areas appear to be involved in visually guided behaviors associated with prey-catching, we suggest that vasotocin may play a role in their seasonal variations.

SOCIAL STIMULI INCREASE ESTROGEN RECEPTOR BINDING IN CELL NUCLEI OF THE FEMALE BRAIN. M. Cohen-Parsons and E.J. Roy. Department of Psychology, University of Illinois, Champaign, IL 61820.

In female prairie voles, the onset of puberty is induced by exposure to an unfamiliar male. Circulating estrogen levels rise after a female is exposed to a male and consequently, the binding of estrogen within cell nuclei of the brain also rises. The present study was conducted to determine whether social stimuli can also increase the level of estrogen receptor binding in brain cell nuclei (ERN) independent of corresponding alterations in circulating estradiol. When ovariectomized females were given a fixed amount of estradiol and exposed to males, the females were found to have 31 to 101% higher levels of ERN in the preoptic area than did females given estrogen and not exposed to males. This treatment difference was statistically significant ($p<.01$). Differences were not observed within the medialbasal hypothalamus although the area is also rich in estrogen receptors. These results suggest that social stimuli can influence estrogen concentrating cells within the brain by modifying estrogen receptor activity within select areas.

174.4

MODULATORY EFFECTS OF NOREPINEPHRINE (NE) ON ESTROGEN RECEPTORS IN THE HYPOTHALAMUS OF THE FEMALE RAT. M.E. Montemayor and E.J. Roy. Neural and Behavioral Biology Program, Univ. of Illinois, Champaign, IL 61820.

It has been demonstrated that the NE neurotransmitter system modulates estrogen receptors and accompanying synthesis of progestin receptors in the medialbasal hypothalamus (MBH) of female rats and guinea pigs (Blaustein, 1987; Clark et al.,1985; Nock et al., 1981, 1984). After administration of alpha-1 antagonists, in the presence of estradiol, decreases in nuclear estrogen receptors and cytosol progestin receptors appear to be associated with a decrease in estrogen dependent lordosis behavior. We have replicated the finding that prazosin decreases nuclear estrogen receptors after estradiol administration in rats (Blaustein, 1987). In addition, NE input to the hypothalamus has been manipulated by direct infusion of 6-OHDA onto NE cells in the medullary brainstem. After significant depletion of NE input, as verified by HPLC measurement of NE from the same tissue, differences in the levels of estrogen receptors measured by exchange assay were not detected in the MBH or preoptic area (POA). Are the pharmacological effects of prazosin generated by blocking NE receptors other than those on estrogen concentrating cells, i.e. effects on cerebral vasculature? At present, we are investigating whether MBH and POA tissue levels of estrogen measured by RIA are altered as a result of prazosin treatment.

174.5

EFFECTS OF HYPOPHYSECTOMY ON SALT HUNGER AND ON BRAIN AND LIVER ANGIOTENSINOGEN mRNA LEVELS. Jay Schulkin, Bruce S. McEwen, Jesus Angulo and Randall Sakai, Dept. of Anatomy Univ. of Pennsylvania and Lab of Neuroendocrinology Rockefeller University. (SPON: S. Williamson)

Hypophysectomized (HYPOX) rats ingest less salt following body sodium depletion than pituitary intact rats. The hormones angiotensin and aldosterone that are active during body sodium depletion generate the behavior of salt ingestion in the rat. Mineralocorticoid-induced salt hunger is normal in the HYPOX rat, while salt hunger generated by increasing the angiotensin levels is reduced in the HYPOX rat. We next examined whether the message for angiotensinogen, the precursor for the production of angiotensin, is reduced in the sodium replete HYPOX rat. We found that HYPOX rats mRNA for angiotensinogen is reduced in preoptic, medial amygdala and the ventral and dorsal medial hypothalamus when compared to control rats. The mRNA in liver was also reduced in the HYPOX rat. Therefore, the diminished ingestion of salt that results from body sodium depletion in the HYPOX rat may be due to a reduced production of angiotensin in both brain and liver.

DIFFERENTIAL EFFECTS OF ANDROGENS AND ESTROGENS ON CATECHOLAMINE LEVELS AND TURNOVER IN HYPOTHALAMIC AND VOCAL CONTROL NUCLEI IN THE MALE ZEBRA FINCH. S.R.Barclay and C.F.Harding. Biopsychology Program, Hunter College, NYC 10021

Behavioral and biochemical studies indicate that most male courtship behaviors, including singing, are induced by the combined actions of estrogens and androgens. The precise mechanism by which these steroids exert their effects is unknown. We recently presented evidence that castration alters catecholamine (CA) levels and turnover in steroid-sensitive brain areas which modulate sexual behavior and vocalizations in the male zebra finch and that these changes in CA levels and turnover can be reversed by treatment with an aromatizable androgen.

This study separated the effects of estrogenic and androgenic metabolites on CA function in the hypothalamus and vocal control system. Castrated male zebra finches were implanted with hormone-filled Silastic capsules (containing estradiol, dihydrotestosterone or both) and housed with a female for one week. To determine turnover as well as initial levels of CA, the males were divided into two subgroups: one group received αMPT, the other saline. The appropriate dosage and time course of αMPT treatment was empirically determined in a preliminary study. Brain nuclei were microdissected from 180μ frozen sections and expelled into sodium acetate buffer containing an internal standard. The concentrations of NE, DA and 5HT were determined by HPLC with electrochemical detection.

Differential control of steroid induced changes in CA levels and turnover in various vocal control and hypothalamic nuclei was found. Changes in NE levels and turnover were induced by estrogen alone. However, in most nuclei, changes in DA levels and turnover required both estrogen and androgen, or in a few areas, only androgenic stimulation. *(Supported by HD15191 and MH00591 to CFH, and MH09425 to SRB)*

174.7

IMMUNOCYTOCHEMICAL COLOCALIZATION OF SUBSTANCE P AND PROGESTIN RECEPTORS IN NEURONS OF THE FEMALE GUINEA PIG HYPOTHALAMUS. K.H. Nielsen*, J. Farkas* and J.D. Blaustein. (SPON: E.W. Westhead). Neuroscience and Behavior Program, and Psychology Department, University of Massachusetts, Amherst, MA 01003.

Recent studies have suggested that substance P (SP) is involved in the steroid-induced sexual behavior of female rats (W.A. Dornan, et al., Neuroendocrinolgy, 45:498, 1987). Adult female guinea pigs were ovariectomized and subsequently estradiol-primed. Two days before perfusion, 25 μg of colchicine were injected intraventricularly. SP and progestin receptors were labelled by a double immunocytochemical sequence. Distributions of SP-containing cells and progestin receptor-containing cells overlapped in regions such as the periventricular nucleus, the ventrolateral area of the hypothalamus (VLA), and the caudal arcuate nucleus. Colocalization of SP and progestin receptor immunoreactivity within the same cells was observed only in the VLA, where most of the progestin receptor-containing cells were also SP-immunoreactive. This provides neuroanatomical evidence that the mode of action of estradiol and progesterone may involve SP. (Supported by NS 19327 and RCDA NS 00970 from the NIH).

174.8

NEURAL SITE OF ACTION OF ESTRADIOL IN THE INDUCTION OF SEXUAL RECEPTIVITY IN FEMALE GUINEA PIGS. Y. Delville* and J.D. Blaustein (SPON: N.R. Carlson). Neuroscience and Behavior Program and Psychology Department, Univ. of Mass., Amherst, MA 01003.

Recent immunocytochemical studies performed in our laboratory have demonstrated that estradiol treatments that result in induction of progesterone-facilitated sexual behavior in guinea pigs also induce progestin receptor-immunoreactivity (PR-IR) in the preoptic area and the hypothalamus. To localize discrete areas sufficient for estradiol-induced sexual receptivity, behavioral response and PR-IR were evaluated after bilateral implantation of estradiol-containing cannulae in the the mediobasal hypothalamus. The animals were exposed to the estradiol released by the cannulae for two days. They were then injected sub cutaneously with progesterone. A dilution of 1% crystalline estradiol in cholesterol was sufficient to induce progesterone-facilitated sexual receptivity only when the implants were located in the rostral part of the ventrolateral area of the hypothalamus. These implants resulted in localized induction of PR-IR. This suggests that estradiol stimulation of a site in the rostral ventrolateral area of the hypothalamus is sufficient to induce behavioral response to progesterone.

AUTORADIOGRAPHIC LOCALIZATION OF PROGESTIN-CONCENTRATING CELLS IN THE BRAIN OF THE ZEBRA FINCH (POEPHILA GUTTATA). J.L. Lubischer and A.P. Arnold. Dept. of Psychology, UCLA, Los Angeles, CA 90024.

In the male zebra finch, the steroid hormones testosterone and estradiol are known to control the development and production of song. Although the role of progesterone in male behavior is not well understood, plasma levels of progesterone in young male zebra finches are higher than those observed for testosterone or estradiol (Prove, 1983). In the current study, the autoradiographic method was used to investigate the distribution of progestin-accumulating cells in the male zebra finch brain.

Three adult male zebra finches were castrated 24 hr before intramuscular injection of the synthetic progestin [17alpha-methyl-^{3}H]-promegestone (5.7 μCi/g), then decapitated 90 min after injection. The brain was immediately removed and processed for autoradiographic analysis. Cells were defined as being progestin-labeled if the density of silver grains over their somata exceeded by a magnitude of three the density over an adjacent area of neuropil. The loci of such cells were noted on section sketches drawn with the use of a microprojector.

Groups of progestin-accumulating cells were found in the dorsolateral region of the telencephalic hyperstriatum accessorium, the medial lobus parolfactorius, the preoptic area, and through much of the medial hypothalamus, including nucleus periventricularis magnocellularis, nucleus medialis hypothalami posterialis, and area infundibularis. Known song regions were not found to be sites of progestin accumulation. The general pattern of progestin-accumulating cells reported here is consistent with the pattern of steroid hormone accumulation observed in vertebrates studied to date, and suggests possible sites of progesterone action.

THE CENTRAL FACILITATION OF RESPIRATION BY PROGESTERONE IS ESTROGEN-DEPENDENT. D.A. Bayliss, J.B. Dean, J.A. Cidlowski*, and D.E. Millhorn. Dept. of Physiology, University of N. Carolina, Chapel Hill, NC 27599.

We examined the possibility that the central, receptor-mediated facilitation of respiration by progesterone (PNAS,84:7788,1987) is estrogen-dependent. Ovariectomized cats were anesthetized, paralyzed and ventilated. Carotid sinus and vagus nerves were cut and end-tidal PCO_2 and temperature were maintained constant. Phrenic nerve activity was used as an index of central respiratory output. Repeated i.v. doses of progesterone (0.1 to 2.0 μg/kg, cumulative) caused a long-lasting (>45 min) facilitation of respiration in animals pretreated with 17β-estradiol (20 μg/kg/day) the 3 days prior to study; progesterone was without effect in animals not pretreated with 17β-estradiol. Thus, prior estrogen exposure is necessary for the respiratory response to progesterone in ovariectomized cats. The estrogen-dependent respiratory response to progesterone was attenuated by the progesterone receptor antagonist, RU486 (500 μg/kg). An estrogen receptor antagonist, CI628 (10 mg/kg/day), administered jointly with 17β-estradiol, caused a marked diminution of the respiratory response to progesterone. These results indicate that interaction of both progesterone and estrogen with their receptors is required in the mediation of this response.

STRESS, ESTROGEN RECEPTORS AND SEXUAL BEHAVIOR IN MALE ZEBRA FINCHES. M. Walters, A. Gonzalez* and C. F. Harding. Biopsychology Program, Hunter College, CUNY, New York, NY 10021.

Although male zebra finches exhibit a variety of estrogen-dependent sexual behaviors, binding studies have revealed relatively low levels of neural ^{3}H-estrogen binding in castrated males. To determine if these low levels of binding could have resulted from competition from endogenous estrogen, we conducted a series of *in vitro* exchange assays to measure occupied nuclear estrogen receptors (nER) in the basal hypothalamus-preoptic area (BH-POA) of castrated males. BH-POA cell nuclei were isolated and purified by resuspension and centrifugation in a series of sucrose solutions, and hormone-receptor complexes were extracted by dispersing the nuclei in a 0.4 M KCl solution. Extracts were then incubated with ^{3}H-estradiol for 5 hr at 25°C. Parallel incubations contained a 500-fold molar excess of unlabelled estrogen to correct for nonspecific binding. The assays revealed substantial levels of specific nER's in the BH-POA of castrated males (Kd = 0.39 nM; Bmax = 50 fM/mg DNA). However, substantial nER levels were also detected in the BH-POA of castrates treated with ATD, an inhibitor of estrogen synthesis. The nER levels in these birds appeared to be related to the stress of being transported from the housing facilities to the laboratory: nER levels were significantly reduced when the animals were not subjected to the stress of the transport procedure. These results suggest that neural estrogen receptors in male zebra finches bind a hormone which is i) stress-related and ii) not an estrogen. In behavioral experiments, intact males subjected to a simulated transport procedure exhibited significantly less estrogen-dependent behavior than unstressed controls. These data suggest that the unknown hormone may play a role in suppressing normal breeding behavior during periods of acute stress.

MACRONUTRIENT INTAKE OVER THE ESTROUS CYCLE S. Montanez*, J. Williams*, N. DiMarco*, K.Eckols*, and L. Uphouse, Texas Woman's University, Denton, Texas, 76204

Carbohydrate and protein intake were examined during the female rat estrous cycle and in response to gonadal hormones. There was a significant effect of the estrous cycle on macronutrient intake (ANOVA, P< .001). The lowest levels of carbohydrate intake occurred during the stages preceding ovulation. In a second study, females were ovariectomized and injected for 5 consecutive days with 10 μg estradiol, 500 μg progesterone, or 1 day each of 10 μg estradiol, vehicle, 500 μg progesterone. Estrogen treatment produced a rapid (within 24 hours) reduction (20-40%) in carbohydrate intake which was partially reversed by the progesterone treatment. Progesterone alone had no effect on macronutrient intake. The present results suggest that it is the macronutrient intake, rather than total caloric intake, which is regulated during the estrous cycle. Since standard laboratory rat chow is high in carbohydrates, observations of a reduced caloric intake may result from the females' attempt to modulate carbohydrate intake. The pattern of estrous cycle changes and the effects of estradiol in ovariectomized females support the hypothesis that estrous cycle modulation of carbohydrate intake results from cyclic variations in gonadal steroids.

ANDROGEN, NOT ESTROGEN, AFFECTS ELECTRIC ORGAN DISCHARGE AND EXTERNAL MORPHOLOGY IN *GNATHONEMUS PETERSII*. R.E. Landsman*, C.F. Harding and P. Moller. Psychology Dept., Hunter College, CUNY, New York, NY 10021.

Electric fish use electric organ discharges (EODs) to communicate. Our previous work showed adult male *G. petersii* have shorter wave-form durations than females, but surprisingly, methyltestosterone treatment increased duration and decreased peak power spectrum frequency (PPSF) of Fourier-transformed EODs. To investigate the hormonal control of EODs and sex-related anal fin indentations of *G. petersii*, immature fish were gonadectomized and implanted with low-dose (1mm/2.5g b.w.) or high-dose (1mm/1g b.w.) silastic capsules of testosterone (T), DHT, estradiol (E) or cholesterol (C). At low doses, T increased EOD durations and decreased PPSFs compared to nonhandled controls, while the other implants had no effects. High-dose implants of T and DHT, but not E or C, increased EOD durations. High doses of T caused faster, more profound duration changes. Both doses of T and DHT induced typical male anal fin indentations.

Thus, EOD waveforms are affected by androgens, not estrogens. Similarly, the anal fin indentation characteristic of adult males appears to be under androgenic control. However, the effect of exogenous androgens on EODs is in the opposite direction from the reported sex difference in untreated fish.

EFFECTS OF SUSTAINED STRESS ON ADENYLATE CYCLASE ACTIVITY IN PITUITARY AND RAT BRAIN REGIONS. G.S. Dhillon* & G.J. Kant (Sponsor: M.L. Koenig) Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307-5100.

Acute stress activates brain adrenergic and CRF neuronal pathways. Chronic stress has been shown to decrease the number of brain beta-adrenergic receptors and to lower NE-stimulated cAMP responses in cortex and hypothalamus. Recently, we found that following chronic intermittent footshock, CRF receptor binding is decreased in pituitary, cortex and hypothalamus. The present study investigated NE and CRF-stimulated adenylate cyclase activity in pituitary, frontal cortex and hypothalamus following intermittent footshock.

Rats were sacrificed following 1 hour or 1, 3, 7 or 14 days of around-the-clock intermittent footshock (1 trial/5 minutes, avoidable on 90% of trials). Basal, NE and CRF-stimulated adenylate cyclase activity was measured in the P_2 fractions. Following one hour of footshock, there was an increase in basal adenylate cyclase activity in the hypothalamus. One day of footshock resulted in decreased basal adenylate cyclase activity in the anterior pituitary. In fractions prepared from three day stressed rats, basal adenylate cyclase activity increased in the hypothalamus and decreased in the frontal cortex. At all other time intervals, we did not observe any significant changes in basal or stimulated adenylate cyclase activity.

SEXUAL BEHAVIOR, EPISODIC GONADOTROPIN SECRETION, AND BRAIN NEUROPEPTIDE AND MONOAMINE LEVELS IN AGING MALE RATS. A.M. Clancy, F. Macrides, F.H. Bronson*, M.S.A. Kumar* and R.M.Kream*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545, University of Texas, Austin, TX 78712, Tufts University Schools of Medicine, Boston, MA 02111.

The relationships among sexual interest in estrous females, episodic secretion of luteinizing hormone (LH), and brain levels of luteinizing hormone-releasing hormone (LHRH), methionine-enkephalin (MET), beta-endorphin (END), dynorphin$_{1-17}$ (DYN), substance P (SP), cholecytokinin$_{1-8}$ (CCK), vasoactive intestinal polypeptide (VIP), norepinephrine (NE), dopamine (DA) and serotonin (5HT) were studied in male naive or retired breeder Fischer-344 rats across the age range of 8-29 mos. Each subject was paired with females on 3 occasions, then prepared for serial blood sampling via a femoral arterial bypass catheter. Following 3 hrs of blood collection, a 4th female pairing was initiated with sampling continued for another hour. Each male was then sacrificed for pathological workup and its brain dissected for measurements of neuropeptides by RIA and monoamines and metabolites by HPLC combined with electrochemical detection. The ratio of 5HT to 5HIAA was used as a measure of 5HT turnover. Time and amplitude series analyses of circulating LH levels demonstrated an aging-related decline in the pulsatility of spontaneous LH secretion, and both age and experience dependent changes in the ability of female-related olfactory and/or behavioral stimuli to elicit secretion episodes. The differences in LH secretion patterns were correlated with age and experience dependent differences in copulatory behavior. There were no significant neurochemical changes in the olfactory bulbs or rhinitic pathology that could account for these findings on the basis of a sensory impairment. LHRH, SP, CCK and VIP levels in the hypothalamus showed no significant changes with age or correlations with sexual behavior. In contrast, the hypothalamic levels of opioid peptides and monoamines, and 5HT turnover in the hypothalamus, did covary in relation to age, behavioral measures of sexual interest, and differences in LH secretion patterns. The changes in MET and NE levels showed the closest correlations with the endocrine and behavioral changes, suggesting that these transmitters or neuromodulators are integrally related to the regulation of episodic gonadotropin secretion and sexual arousal.

AUGMENTATION OF ANDROGEN-DEPENDENT BRAIN AROMATASE ACTIVITY BY ESTROGEN IS NOT ANDROGEN RECEPTOR MEDIATED C.E. Roselli and T.A. Fasasi*. Physiology Dept., Oregon Health Sciences University, Portland, OR 97201

Estradiol (E) appears to increase cytosolic androgen receptor levels in the preoptic area (POA) of male rats. Thus, we were interested to determine whether a paradigm of combined treatment with E and dihydrotestosterone (DHT) would: 1) augment the stimulatory effect of DHT on aromatase activity (AA) and 2) increase the concentration of nuclear androgen receptor (ARn). To this end we measured simultaneously the concentrations of ARn and microsomal AA in POA and basal hypothalamus (BH) of adult male rats that were castrated (CX) and treated for 1 week with either vehicle, E (2 ug/day, sc), DHT (3 cm Silastic implant), E + DHT, or testosterone (T, 3cm Silastic implant). DHT stimulated AA ($p<.05$ vs. CX) in both POA and BH, but not as effectively as T. E alone did not change AA in POA, but potentiated the stimulation of AA by DHT ($p<.05$, DHT vs. E+DHT) to levels comparable to the T group. By comparison E did not enhance the induction of AA by DHT in the BH. Despite the ability of E to augment the induction of AA in POA, combined treatment with E and DHT had no effect on the concentrations of ARn in either the POA or BH. Futhermore, T appeared to be the most effective treatment for increasing the levels of ARn in both tissues. These results suggest that E augments androgenic responses in the POA by a mechanism that is independent of its effects on ARn levels. Supported by HD 23293.

ESTRADIOL (E) REGULATION OF RIBOSOMAL RNA (rRNA) PROCESSING IN RAT VENTROMEDIAL HYPOTHALAMIC (VMN) NEURONS : EARLY DETECTION BY QUANTITATIVE *IN SITU* HYBRIDIZATION. K. J. Jones[1,2], C. A. Harrington[3], D.M. Chikaraishi[3], and D.W. Pfaff[2]. [1]The Chicago Medical School, North Chicago, IL 60064, [2] The Rockefeller University, New York, NY 10021, and [3]Tufts University, Boston, MA 02111.

We have previously demonstrated that E acts very early, at structural, RNA and protein levels, in the rat VMN, a brain region critical in the control of reproductive behavior. Cellular organelles involved in ribosome production and function, including the nucleolus and RER, are morphologically altered, and nucleoplasmic changes consistent with increases in overall gene activity occur, in VMN neurons after 2 h of E. Six h of continuous E administered to ovariectomized (OVX) rats is sufficient to increase product rRNA levels in the VMN. In this study, we used quantitative *in situ* hybridization to determine the early effects of E on rRNA processing. Three OVX rats per group received E implants for 15 min, 30 min, or 2 h; OVX rats, sham-implanted under the same time courses, served as controls. Fresh, frozen brain sections containing the VMN were prepared. For detection of precursor and product levels of rRNA, 2 ^{3}H-labeled DNA probes, complementary to an external transcribed spacer region near the beginning of the rRNA gene and 28S product rRNA, respectively, were used. We additionally used ^{3}H-labeled poly U fragments to detect poly A$^+$ sequences in VMN neurons. Following prehybridization to eliminate nonspecific binding, hybridization was done overnight at Rm T. The sections were washed, dried, and processed for autoradiography. Quantitative analysis was accomplished using a computerized image analysis system to measure number of grains per cell, somal size, and grain density. Precursor rRNA levels rose to a statistically significant 30% increase after 30 min and a 110% increase after 2 h of E, relative to control values. Product rRNA levels were unaffected at any of the time points examined. Poly A$^+$ levels increased to 50% above control after 2 h of E. The rRNA data are consistent with the hypothesis that the increase in ribosomes after 6 h of E is preceded by rapid alterations in processing of newly transcribed pre-rRNA. We are currently exploring whether the preliminary data obtained with the poly U probes are reproducible and represent actual changes in poly A$^+$ sequence levels. THE AROMATIZATION INHIBITOR, ATD, INHIBITS ANDROGEN RECEPTOR BINDING IN MALE RATS. M.Y.McGinnis and M.E.Kaplan*(SPON:J.E.Shriver). Dept. Anatomy, Mt. Sinai Sch. Med., NY, NY 10029.

The aromatization inhibitor, ATD, has been shown to inhibit sexual behavior, suggesting that aromatization to estradiol is required for the activation of male sexual behavior. In the present study, we examined 1) the effects of both systemic and intracranial ATD on male sexual behavior, and 2) the effects of systemic ATD on androgen receptor (AR) and estrogen receptor (E_2R) binding. Daily injections of 15 mg ATD suppressed sexual behavior in T-treated males. Bilateral MPOA implants of ATD inhibited sexual behavior, but were less effective than systemic injections. To determine whether ATD affects cell nuclear AR or E_2R binding, T-treated or castrated males were given ATD (15 mg/day for 7 days). Binding of T to AR's was significantly decreased in the presence of ATD. There was no effect of ATD on E_2R's. In vitro competition studies indicated that ATD markedly reduced cytosol AR binding, though it did not compete for nuclear AR's. Thus ATD appears to act both as an antiandrogen and as an aromatization inhibitor, and may inhibit male sexual behavior by blocking AR's rather than by inhibiting aromatization.

IDENTIFICATION OF THE AUTOPHOSPHORYLATION SITE AND REGULATORY DOMAINS IN BRAIN Ca^{++}/CALMODULIN-DEPENDENT PROTEIN KINASE II. T.R. Soderling, R.J. Colbran, and C.M. Schworer*. Howard Hughes Medical Institute, Vanderbilt University, Nashville, TN 37232

Ca^{++}/calmodulin-dependent protein kinase II (CaM-kinase II) is a multifunctional kinase, highly concentrated in neural tissues, which can be converted to a Ca^{++}-independent (indep.) form by intramolecular autophosphorylation. Through analysis of CNBr ^{32}P-peptides, we have identified thr-286 as the site of this autophosphorylation. A synthetic peptide containing residues 281-309 of the 50 kDa subunit sequence contains this phosphorylation site and also the CaM-binding domain and an inhibitory domain. Peptide 281-309 is not phosphorylated by the Ca^{++}-indep. form of CaM-kinase II, and it inhibits the kinase activity against other substrates. However, when Ca^{++}/CaM binds to peptide 281-309, the peptide is no longer inhibitory and it is phosphorylated. Additionally, the phosphorylated peptide in the absence of Ca^{++}/CaM is also less inhibitory. These results suggest the following model: 1) the inhibitory domain in residues 281-309 of CaM-kinase II is responsible for basal inhibition of the kinase, 2) binding of Ca^{++}/CaM to the adjacent CaM-binding domain relieves this inhibition, allowing phosphorylation of thr-286 and substrate proteins, 3) the phosphorylation of thr-286 diminishes the effect of the adjacent inhibitory domain, allowing for the Ca^{++}-indep. activity of the kinase.

CALCIUM/CALMODULIN STIMULATED Mg-ATPASE ACTIVITY ASSOCIATED WITH A NOVEL CALMODULIN-BINDING PROTEIN. R.E.Larson*, F.S.Espindola*, E.M. Espreafico*, M.V.Coelho* and D.E.Pitta*(SPON:J.A. Ricardo). Dept♀Bioquímica, Fac.Med.Rib.Preto Univ.Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil

Ca^{2+}/calmodulin(Ca/CaM) is the essencial link of a major signal transduction system in brain. Cytoskeletal proteins are important targets for the Ca/CaM complex. We reported the presence in mammalian brain of a novel calmodulin-binding protein(CaM-BP$_{190}$) which is tightly associated with brain actomyosin(Braz.J.Med.Biol.Res.21:213 1988).CaM-BP$_{190}$ precipitates with actomyosin from 1% Triton X-100 and 10mM EGTA, and accompanies actomyosin thru a solubilization-precipitation cycle by 1-0.1M KCl.Here we report the separation of CaM-BP$_{190}$ and brain myosin by differential centrifugation, gel filtration and ion exchange chromatography, and show that distinct ATPase activities are associated with the two proteins. Purified brain myosin has characteristic K-EDTA ATPase activity,whereas CaM-BP$_{190}$ has Mg-ATPase activity stimulated 5 fold by Ca/CaM and no detected K-EDTA activity. Polyclonal antibodies of CaM-BP$_{190}$and brain myosin show specific reactions for their respective antigens with no immunological cross-reaction detected by immunoblot technique.Grants:FAPESP 2056-7;CNPq 40.3824.

Involvement of Calmodulin in the potentiation of synaptic transmission by 4AP and the modulation of the AHP in the rat hippocampus. P. Perreault and M. Avoli MNI, McGill University, Quebec, Canada, H3A-2B4.

It has been suggested that 4-Aminopyridine (4AP) potentiates neurotransmission by directly promoting Ca^{++} entry in nerve terminals or indirectly, by blocking K^+ conductances. This enhanced Ca^{++} entry might in turn activate Ca^{++}-dependent second messengers. Here, we recorded intracellularly CA1 pyramidal neurons of rat hippocampal slices to asses whether the Ca^{++}-binding protein Calmodulin was related to 4AP effects. Bath application of the Calmodulin antagonist Trifluoroperazin (TFP,10-50uM) resulted in a marked decrease of the amplitude of orthodromic EPSPs and IPSPs. 4AP (50uM) applied on TFP-treated slices failed to potentiate synaptic potentials although its ability to increase neuronal intrinsic excitability was not impaired (n=5). After TFP washout, the amplitude of EPSPs and IPSPs increased markedly (above control levels) and spontaneous synaptic potentials became prominent. TFP also reduced the firing adaptation and decreased by up to 60% the amplitude of the slow AHP evoked by depolarizing current pulses. This effect was not due to a decrease in Ca^{++} entry since Ca^{++} spikes observed in the presence of TTX (1uM) and TEA (5mM) were not reduced. These results suggests that Calmodulin might be involved in the regulation of neurotransmitter release and modulate Ca^{++}-dependent K^+ conductances.

175.4

STIMULATION OF Ca^{2+}/CALMODULIN-DEPENDENT PROTEIN KINASE II BY BRAIN GANGLIOSIDES. K. Fukunaga and T.R. Soderling (SPON: D. Buxbaum), Howard Hughes Med. Inst., Vanderbilt Univ., Nashville, TN 37232

Gangliosides are ubiquitous, sialic acid-containing glycosphingolipids which are thought to play a role in the regulation of growth and proliferation. The actions of gangliosides may be partly related to modulating protein phosphorylation. The purified rat brain Ca^{2+}/calmodulin (CaM)-dependent protein kinase II (CaM kinase II) is stimulated by brain gangliosides. Among the various gangliosides tested, GT1b was found to be the most potent activator, whereas GD1a and GM1 were slightly less effective and asialo-GM1 had no effect. The activation process was rapid and did not require the presence of Ca^{2+}. Half-maximal activation by GT1b was observed at 25 μM and was nearly full at 125 μM. Using syntide 2 or synapsin 1 as substrate, the phosphorylation rate by CaM kinase II in the presence of GT1b was approximately 50% of the rate in the presence of Ca^{2+} and CaM. Gangliosides also stimulated the autophosphorylation of CaM kinase II, mainly on serine residues, but resulted in little formation of the Ca^{2+}-independent species. This ganglioside-stimulated autophosphorylation was also found in the synaptic membrane fractions from rat brain. These observations suggest that the activation of CaM kinase II by gangliosides may be different from activation by Ca^{2+} and CaM and relate to certain functions of gangliosides in the nervous system.

175.5

EFFECTS OF ADRENALECTOMY AND STRESS ON cAMP ACCUMULATION AND CALMODULIN SENSITIVE ADENYLATE CYCLASE IN RAT BRAIN REGIONS M.N. Gannon, R.E. Brinton, P. Choo* and B.S. McEwen, Laboratory of Neuroendocrinology, Rockefeller University, New York, N.Y. 10021

Glucocorticoids (GC's) have widespread effects on cAMP generating systems. Since GC's induce Ca2+ binding proteins in peripheral tissues, we studied whether GC`s modify calmodulin-sensitive (CaM) adenylate cyclase (AC) activity in rat brain membranes and measured in parallel their effects on cAMP accumulation in slices. Adrenalectomy (ADX, 6d) reduced CaM AC activity by 25% in hippocampus, dentate gyrus and Ammon's horn, with a similar trend in cerebral cortex. No effect of ADX on basal or forskolin AC activities was found. Noradrenaline-stimulated accumulation of cAMP in hippocampal slices in the presence of a phosphodiesterase inhibitor was also reduced by ADX. In contrast, 21d repeated, daily stress decreased maximal CaM AC activity in cortex membranes, which is consistent with work of Stone et.al. JPET 237:702,1986 who subsequently showed that adrenal steroids mediate this effect. Hippocampus is less affected. Thus adrenal secretions may have biphasic effects on the adenylate cyclase system of brain, although the effects of repeated stress are more pronounced than those of ADX. (Supported by MH41256.)

175.6

REGULATION OF PROTEIN TYROSINE KINASE BY CORTICOSTERONE IN DISCRETE REGIONS OF RAT BRAIN. E.J. Nestler, R.Z. Terwilliger*, and E. Halm*. Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Several lines of evidence suggest that protein tyrosine kinases play an important role in neuronal function, even though it has been difficult to demonstrate regulation of the enzyme in nervous tissue by first or second messengers. We now report such regulation for the first time: chronic corticosterone (CORT) treatment increases protein tyrosine kinase activity in discrete regions of rat brain.

Rats were treated with CORT for 1 week, and then isolated brain regions were analyzed for protein tyrosine kinase activity. It was found that such treatment increases protein tyrosine kinase activity by 20-25% in the locus coeruleus (LC), dorsal raphe, and ventral tegmentum, brain regions known to contain high levels of corticosterone receptors, but not in several other brain regions studied.

This phenomenon was characterized further in the LC. CORT was found to produce a time-dependent increase in protein tyrosine kinase activity, which plateaued between 4 and 7 d of treatment. This increase was found to be localized to the microsomal fraction of the LC, and to be associated with a 60% increase in the amount of phospho-tyrosine present in the LC, as determined by immunoblot analysis. Bilateral adrenalectomy led to a 25% decrease in enzyme activity, an effect reversed by CORT replacement.

These results demonstrate that protein tyrosine kinase is regulated by corticosterone in specific regions of the nervous system, and raise the possibility that some of the effects of glucocorticoids on neuronal function are achieved through alterations in the phosphorylation of target proteins on tyrosine residues.

175.7

GLYCOPROTEIN-ASSOCIATED SERINE PROTEIN KINASE FROM RAT BRAIN SYNAPTOSOMES. E. Suwita* and N. Sahyoun. (SPON: J. Reinhard). The Wellcome Research Laboratories, 3030 Cornwallis Road, Research Triangle Park, NC 27709.

A glycoprotein preparation was obtained from Triton X-100 extracts of purified rat brain synaptosomes by wheat germ agglutinin (WGA) affinity chromatography. The glycoprotein eluate was examined for protein kinase activity in the presence of several potential substrates. A broad spectrum of substrates was phosphorylated by a putative glycoprotein-associated protein kinase including myelin basic protein, protamine, tubulin, casein and a mixed histone preparation. Myelin basic protein was phosphorylated solely on a serine residue with a substrate K_m of 0.33 µM. The K_m for ATP was 92 µM and GTP could not replace ATP. The protein kinase had a K_m of 0.38 mM for $MgCl_2$ and was inhibited by $MnCl_2$. Several protein kinase regulators such as cyclic AMP, Ca^{2+}, calmodulin and phosphatidylserine did not alter enzyme activity. The presence of a glycoprotein-associated serine protein kinase suggests an additional mechanism for synaptosomal transmembrane signalling.

175.8

A RAT BRAIN NA^+/K^+-ACTIVATED PROTEIN KINASE. C.H. Reynolds* and N. Sahyoun. (SPON: R. Ferris) The Wellcome Research Laboratories, 3030 Cornwallis Road, Research Triangle Park, NC 27709.

An endogenous brain polypeptide (Mr 42,000) was avidly phosphorylated by a soluble brain protein kinase in a reaction which required the presence of K^+ or Na^+. NH_4Cl but not LiCl or Tris-HCl could substitute for KCl or NaCl. The activation process was highly cooperative with respect to monovalent cation concentration with an n value of 3.4 for KCl such that maximum change in activity occurred between 100 mM and 150 mM salt. NaCl alone was less potent than KCl; however, when the enzyme was 'primed' with 100 mM KCl, further addition of NaCl was as effective as KCl. The apparent K_m values for ATP and protein substrate at 150 mM KCl were about 10 µM and 50 nM, respectively. Enzyme activation largely involved an increase in the V_{max} values. GTP replaced ATP as a phosphate donor and the enzyme activity was inhibited by 2-10 µM heparin. The protein kinase was purified on octyl-Sepharose and heparin-Sepharose affinity columns, and appeared to have a narrow spectrum of substrates although it did phosphorylate casein poorly and phosvitin more effectively. The detection, characterization and purification of a brain protein kinase which has an obligatory requirement for K^+ or $Na^+ + K^+$, at physiological intracellular concentrations, suggests a significant regulatory role for these ions whose levels can be altered by neuronal activity.

175.9

ISOLATION AND CHARACTERIZATION OF PKCAM-GR.
C.A. Ohmstede*, K.F. Jensen and N. Sahyoun. The Wellcome Research Laboratories, 3030 Cornwallis Road, Research Triangle Park, NC 27709.

Previously, we described the isolation of cDNA clones from a rat brain expression library which encoded a novel brain-specific, calmodulin-dependent protein kinase (Soc. for Neurosci. 13:1136 1987). Comparison of the cytosolic fractions from forebrain and cerebellum by Western blotting with a polyclonal antibody against the recombinant protein showed a greater concentration of the enzyme in cerebellum than in forebrain with the presence of a common Mr 65,000 polypeptide and a unique Mr 67,000 polypeptide only in cerebellum. We purified the enzyme to apparent homogeneity from rat cerebellum and obtained a fraction with two subunits (the Mr 65,000 and 67,000 polypeptides) both of which bound the specific antibody by Western blot analysis. In the presence of calmodulin, the purified enzyme phosphorylated homogeneous synapsin I as well as a Mr 100,000 polypeptide from 55°C-treated cerebellar cytosol. This Mr 100,000 polypeptide was also phosphorylated in non-heated extracts in a calmodulin-dependent fashion but was not phosphorylated by the addition of purified calmodulin-dependent kinase type II. The immunohistochemical localization of the kinase showed the protein to be highly enriched in the perikaryon of cerebellar granule cells, therefore we have named this enzyme PKCAM-Gr.

175.10

CASEIN KINASE II AND ITS SUBSTRATES IN BRAIN.
J.-A. Girault*, H.C. Hemmings Jr., S.H. Zorn, and P. Greengard, Lab. of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021

We have studied the characteristics and distribution in brain of casein kinase II (CK II). CK II purified from bovine caudate nucleus or cerebral cortex exhibited a subunit composition and many properties similar to those reported for CK II from other tissues, including inhibition by heparin and stimulation by polylysine. CK II activity was higher in rat brain than in liver and, within brain, was highest in hippocampus and caudate-putamen. CK II activity decreased by 50% following injection of the neurotoxin quinolinic acid into the caudate-putamen showing relative enrichment of CK II in neurons. In addition to known substrates for CK II, several major substrates for this enzyme could be identified in all brain regions studied that were not found in peripheral tissues. Moreover, three substrates had a limited regional distribution. These included DARPP-32, enriched in caudate-putamen, and proteins of Mr 77,000 and 240,000 enriched in spinal cord and cerebellum, respectively. In conclusion, the high activity of CK II in brain as well as the number of its substrates suggest that this enzyme may play an important role in signal transduction in the CNS.

HYPOTHALAMIC - PITUITARY - GONADAL REGULATION I

176.1

EVIDENCE OF LOCALIZED DA-LHRH INTERACTION IN EWE HYPOTHALAMUS. JP Advis*, CD Conover*, AM Contijoch* and RO Kuljis. (SPON: L. Grandison) Animal Sci, Rutgers, New Brunswick, NJ 08903 & Sec Neuroanat, Yale Sch Med, New Haven, CT 06510.

Pharmacological evidence has implicated hypothalamic (hyp) catecholamines in the neuroendocrine control of reproduction. We assessed: **a)** localization of Lutainizing Hormone (LH)-Releasing Hormone (LHRH)-, tyrosine hydroxilase (TH)-, and dopamine (DA)-β-hydroxylase (DBH)-like immunoreactivities (IR, PAP), and **b)** contents of LHRH, DA and its metabolites (HVA, DOPAC) in samples of discrete hyp regions from ewes killed in anestrus and at each estrous cycle stage (1-2 PM, RIA & LCED, n=26). Reproductive stages were assessed by estrous behavior and serum progesterone and serum pulsatile LH. Ewes were killed in early luteal (EL), mid-luteal (ML), late luteal (LL), estrus (E), and anestrus (A). Perikarya containing TH-IR but not DBH-IR were scattered throughout the hyp. Particularly dense collections of them were situated in the region of the arcuate (arn) and paraventricular nuclei and the medial preoptic area (mpoa). Most LHRH-IR cell bodies were observed in the mpoa. Many of their axons descend into the infundibulum (inf) through the arn. In EL ewes, inf-content of DA (81± 3 pg/µgP, mean ±sem) and LHRH (24±2 pg/µgP) was 4 times higher than in the arn ($p<.01$) and a medio-lateral gradient of decreasing content exist through inf, arn, peri-arn, lateral (l) peri-arn, and l-hyp. In inf DA, DOPAC, and HVA-content increases continuosly from EL through LL (100%) to suddenly decrease in E (to EL values). In contrast, LHRH content kept increasing ($p<.01$) even further in E ewes (400%). DA and LHRH inf-content in A was 10-20% of EL ($p<.01$). LHRH mpoa-content was highest in EL (5±1 pg/µgP) and gradually decreased ($p<.01$) in lpoa, lhyp, diagonal band of Broca, as well as in ML, LL, E, and A ewes. DA, DOPAC, and HVA contents were similar in mpoa, lpoa and lhyp at all times studied, but gradually decreased ($p<.01$) in the diagonal band of Broca from their highest values in ML to their lowest values in EL, which were similar to those shown in A. These findings support the possibility that regulatory DA-LHRH interactions might occur at the level of the median eminence in adult cycling ewe. (Supported by Wetterberg Foundation, Hatch 08616 and USDA 87CRCR-1-2558).

ACCESS OF LHRH NEURONS TO THE VASCULATURE IN RATS.
J. Witkin, A. Giordano and A.J. Silverman. Anat.& Cell Biol., Col. U. Coll. P&S, New York, NY 10032.

LHRH neurons form neurosecretory terminals on fenestrated blood vessels and make synapses on neurons. The distribution of neurons making these contacts is not completely understood. Wheat germ agglutinin, when applied directly to the median eminence (ME), retrogradely labeled about 50% of the LHRH neurons in all brain regions in male rats (J. Neurosci. 7: 2312,'87). Intravenous infusion of horseradish peroxidase labeled a similar subpopulation of LHRH neurons in the female mouse (Jennes and Stumpf, Neurosci. 18:403,'86). We used intraperitoneal injections (2 doses: 20mg/kg, 8 and 4 d. prior to sacrifice) of fluorogold (FG). LHRH was demonstrated (Texas red) in 40um brain sections from septum to medial basal hypothalamus. More than 90% of all LHRH neurons contained tracer in intact males (2mo and 24 mo), in cycling females (when FG injections were timed around the LH surge), and in ovariectomized (30d) rats treated with estradiol benzoate and progesterone. Since uptake of the tracer accompanies exocytosis, virtually all LHRH neurons in these animals apparently have access to the vasculature. Which of these neurons projects to the ME must be dissected by additional studies. USPHS AG05366 (JW) and HD10665 (AJS).

DYNAMIC CHANGES IN LHRH CONCENTRATION IN HYPOTHALAMIC SITES FOLLOWING PREMATURE INDUCTION OF THE PROESTRUS LH SURGE WITH AN OPIOID ANTAGONIST. W. Jacobson*, A. Sahu*, and S.P. Kalra, (SPON: P.S. Kalra). Dept of Ob Gyn, University of Florida, Gainesville, FL, 32610.

An infusion of the opioid receptor antagonist naloxone (NAL) can advance the onset of the LH surge during proestrus (PE) in the rat. However, the effects of this decrease in opioid tone on dynamic changes in hypothalamic LHRH have not been examined. Because the cell bodies and neuronal processes of the LHRH neurons are widely distributed within the preoptic area (POA) and the mediobasal hypothalamus (MBH), we examined naloxone-induced changes in the LHRH concentration of several hypothalamic nuclei previously implicated in the generation of the proestrus LH surge. Female rats which had demonstrated at least 2 consecutive 4 day estrous cycles were implanted with an indwelling atrial cannula at 0800-0900 hours on the morning of PE. Naloxone was infused (2 mg/hr; 600 µL/min) starting at 1100 hours, and animals were sacrificed at 0, 90, and 180 minutes later. Trunk blood was collected for LH determination and brains were removed, frozen on dry ice, and sectioned at 300µ. Median eminence (ME), medial preoptic area , arcuate nucleus , and ventromedial hypothalamic nuclei were punched out by the method of Palkovits, and the concentration of LHRH was determined. Serum LH was significantly increased over control levels in animals infused with both SAL and NAL by 180 minutes ($p<.025$; $p<.005$ respectively), however, the NAL group had significantly higher levels than the SAL group at 180 minutes ($p<.025$). LHRH concentrations (pg/µg protein) were unchanged in all hypothalamic nuclei except the ME at 180 minutes after the onset of NAL infusion, where it was significantly elevated ($p<.01$). We conclude from these studies that NAL can activate hypothalamic LHRH neuronal systems in association with the LH surge, but such action is restricted to the ME. Consequently, opioid interactions with LHRH neurons for the induction of the LH surge may occur in the median eminence. (NIH HD08634.)

LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) NEUROSECRETION FOLLOWING NEUROTRANSMITTER EXPOSURE IN PERIFUSION TISSUE CULTURE: DIFFERENTIAL REBOUND RESPONSES TO OPIOID AND ADRENERGIC AGENTS. Richard W. Clough. Department of Anatomy, Southern Illinois University School of Medicine-Carbondale, Carbondale, Illinois 62901

Previous studies in this laboratory have demonstrated the utility of preoptic area-mediobasal hypothalamic-median eminence (POA-MBH) explants for the study of LHRH neurosecretory control. In this regard, we and others have described a stimulatory role for adrenergic agents (Clough, et al., Br. Res. 446, 1988) and an apparent inhibitory effect of endogenous opiates (Clough, et al, Brain Opioids in Repro. Cambridge, UK, 1987) on LHRH neurosecretion in vitro. Modulation of luteinizing hormone and follicle stimulating hormone secretion by adrenergic and opiate systems in vivo have been described which parallel our findings on LHRH release in vitro. The present abstract reports that a consistent observation in the perifusion of POA-MBH explants is a rebound reduction in LHRH release to sub-baseline levels following a stimulatory episode such as provided by phenylephrine or norepinephrine. A similar rebound reduction is found following exposure of POA-MBH explants to the opiate antagonist naloxone, which also provides a stimulatory signal to LHRH neurosecretion. Concomitant naloxone and phenylephrine which have additive stimulatory effects also induces a rebound reduction in LHRH release. In sharp contrast, we have found that beta-endorphin (10-6 M) negates the stimulatory effect of phenylephrine on LHRH neurosecretion and furthermore induces a rebound increase of LHRH release following washout of beta-endorphin. These observations suggest that exposure of LHRH neurons to stimulatory or inhibitory neurotransmitter agents induces a differential redistribution of the releasable pool of LHRH following stimulation or inhibition. Hypothetically, this may be necessary to maintain a steady state condition in LHRH synthesis. Supported by HD 24426 and Southern Illinois University.

BETA-ENDORPHIN (B-E) and GnRH INNERVATION OF GnRH NEURONS. W.-P. Chen*, J.W. Witkin and A.J. Silverman. Columbia Univ., P&S, N.Y., N.Y. 10032.

Endogenous opiates play a role in the tonic inhibition of gonadotropin secretion, presumably via a modulation of GnRH release. To determine if this effect could be mediated by a direct synaptic input from B-E terminals we studied the organization of B-E input to the GnRH neuron quantitatively. A double label EM procedure that utilizes DAB and TMB (Olucha et al., '85, Norgren and Lehman, '88) as chromogens was employed. 4 month old male rats were perfused with 4% paraformaldehyde and sections immunostained for both peptides. The two antigens could be distinguished by the morphology of the reaction product; flocculent for DAB, sharp crystals for TMB. Each of ten preoptic area/diagonal band GnRH neurons were analysed in 20 serial sections. 22 synapses were found innervating these cells of which 2 were B-E +, 1 was GnRH +. In the same tissue sections numerous GnRH dendritic profiles were present and found to receive 31 synapses of which 7 contained B-E, 7 GnRH. Most, if not all, of these terminals had symmetrical synaptic densities but physiological analysis is required to determine their inhibitory or excitatory characteristics. These results suggest (1) that B-E may act directly on GnRH neurons and need not act via changes in catecholamine release and (2) B-E and GnRH may have equally important roles to play in the direct modulation of GnRH secretion. HD 10665, China Medical Board (WPC).

SEX DIFFERENCES IN THE RESPONSES OF HYPOTHALAMIC LUTEINIZING HORMONE-RELEASING HORMONE AND CATECHOLAMINE SYSTEMS TO OVARIAN HORMONES AND NALOXONE: IMPLICATIONS FOR SEXUAL DIFFERENTIATION. W.R. Crowley. Dept. of Pharmacology, University of Tennessee College of Medicine, Memphis, TN 38163

Normal male rats do not respond in adulthood to ovarian hormone treatments that stimulate preovulatory-like surges of luteinizing hormone (LH) in normal females. The present experiments tested whether sex differences exist with respect to important neural events that are antecedent to the LH surge. In estrogen-primed females, but not males, progesterone induced a sequential accumulation and decline of LH-releasing hormone in the median eminence prior to the LH surge, and increased turnover rates of norepinephrine (NE) and epinephrine (EPI) in the medial basal hypothalamus during the time of the LHRH accumulation. To test whether direct blockade of opiate action would produce equivalent neuroendocrine and neurochemical responses in males and females, gonadectomized, estrogen-primed rats of both sexes were treated with the opiate antagonist naloxone. In contrast to females, males did not respond to naloxone with either LH release or increases in NE or EPI turnover. These data indicate that the adrenergic systems that control the neurosecretion of LHRH are insensitive to ovarian hormones in adult male rats, and further, that this may be due in part to sex differences in the control of adrenergic transmission by opioid systems.

LHRH NEURONS HAVE LIMITED RESPONSIVENESS TO NOREPINEPHRINE (NE) IN ESTROGEN-TREATED OVARIECTOMIZED RATS. R.D.Hartman, S.L.Petersen and C.A.Barraclough. Dept. Physiol., Univ. Maryland, Sch. of Med., Baltimore, MD 21201.

We previously reported that electrical stimulation (ES) of the locus coeruleus or the A1 noradrenergic cell groups did not alter basal LH secretion. One explanation is that LHRH neurons in this animal model have limited responsiveness to NE. To test this hypothesis, we infused NE into the third ventricle of chloral hydrate anesthetized rats. LH levels increased 144% within 10 min and rapidly returned to baseline. In contrast, MPN electrochemical stimulation (ECS) induced a LH rise of 637% and when NE was given icv 30 min later a further 340% increase in LH occurred. A second study, examined the effects of bilateral MPN microinfusions of NE (20 ug, 1ul/1min) and failed to obtain any change in basal LH release over 90 min. To avoid LHRH neuronal damage which occurs after ECS, we bilaterally ES the MPN for 5 min and LH rose about 90% within 15 min. If MPN-ES was performed for 5 min and 1 min later NE was infused into the MPN, LH release increased 330% and release was sustained over 45 min. Taken together the data suggest that LHRH neurons are severely limited in their responsiveness to NE. For LHRH neurons to acquire responsiveness to endogenous NE release seems to require the removal of some inhibitory influence which may serve to protect these neurons from extraneous NE secretion except for specific hours during the day of the LH surge. NIH grant HD-02138.

NEUROENDOCRINE GNRH AND DOPAMINE NEURONS IN THE MONKEY HYPOTHALAMUS IDENTIFIED BY RETROGRADE TRACING AND IMMUNOSTAINING. P.C. Goldsmith, K.K. Thind and J.E. Boggan*. Reproductive Endocrinology Center and Dept. of OB/GYN & Repro. Sci., Univ. Calif., San Francisco, CA 94143.

In order to localize hypophysiotropic neurons in the monkey hypothalamus, 4 juvenile cynomolgus were each given 3 microinjections (30-70 ul each) of the retrograde tracer WGA-apoHRP-gold into the infundibular stalk. Five to 15 days following surgery, the brains were fixed by perfusion, and vibratomed at 40 um in the frontal plane. Every 12th section was immunostained (IMM+) with rabbit anti-GnRH or anti-tyrosine hydroxylase for dopamine (DA) neurons using the PAP technique with DAB. Neuroendocrine neurons (NEU+) were easily identified as brown, DAB-labeled cell bodies containing more than 3 dark blue, tracer-filled lysosomes. Neuron counts in camera lucida maps from a single representative series of sections are compiled here by anatomical region:

GnRH	MPOA	LH	SON	VHT3	VHT2	VHT1
NEU+	19	9	6	2	11	20
IMM+	73	27	11	8	19	28

DA	A11	A12	A14	SCN	SON	ZI
NEU+	134	33	198	63	9	0
IMM+	213	47	436	144	44	240

Significantly more GnRH NEU+ occurred in the medial ventral hypothalamic tract (VHT1 71%) than laterally (VHT3 25%), while the SON (55%), LH (33%) and MPOA (26%) had intermediate amounts. DA NEU+ were more numerous in A12 (70%) and A11 (63%) than anterior periventricular regions (A14 45%; SCN 44%), but were absent from zona incerta (ZI). These results verify the greater NEU+ importance of VHT GnRH and DA neurons near the infundibulum, and suggest 50-75% of more distant IMM+ neurons in primates function otherwise.

ESTROGENIC REGULATION OF proGnRH mRNA IN THE RAT PREOPTIC-ANTERIOR HYPOTHALAMIC REGION. M. Jakubowski*, M.Blum, P. Seeburg* and J.L. Roberts. (SPON: L. Fricker) Fishberg Center for Neurobiology, Mt. Sinai School of Medicine, CUNY, New York, NY 10029.

The role of ovarian secretions on the content of pro-gonadotropin-releasing hormone (proGnRH) mRNA in the preoptic-anterior hypothalamic (POA-AH) continuum was studied. Female Sprague-Dawley rats, maintained under 12:12 h light/dark cycle (lights on at 07:00 h), were sacrificed by decapitation between 10:00 and 12:00 h. Dissections of the POA-AH were homogenized individually and fractionated. RNA of the cytoplasmic fraction was purified using the proteinase K procedure followed by phenol/chloroform extractions and ethanol precipitation, yielding approximately 0.5 µg total RNA per mg wet tissue. Cytoplasmic proGnRH mRNA was quantitated using solution hybridization/RNase protection assay, with the protected fragments separated on 5% polyacrylamide gel. The level of sensitivity was 40 fgm of a 370-b-long-protected RNA fragment, and the levels measured in individual tissue dissections ranged between 450 and 2100 fgm, depending on the amount of total RNA loaded. The mean ± SEM fgm of protected proGnRH mRNA/µg total RNA was 57.4 ± 2.8 in regularly cycling rats, 42.6 ± 5.9, 26.6 ± 5.0, 38.0 ± 4.7 and 29.8 ± 4.6 in rats sacrificed 2, 9, 16, and 24 day after ovariectomy, respectively, and 47.0 ± 4.3 and 45.6 ± 3.1 in 24-day ovariectomized rats treated with estardiol for 1 or 4 days, respectively (7 rats/group; $p < 0.05$, by one-way ANOVA across the 7 groups). The results suggest that the content of proGnRH mRNA in the rat POA-AH region decreases in the absence of ovarian steroids, and increases following estrogenic stimulation.

EFFECTS OF SUPRACHIASMATIC NUCLEUS (SCN) OR ANTERIOR MEDIAL PREOPTIC NUCLEUS (AMPO) LESIONS ON GONADOTROPIN RELEASING HORMONE(GnRH) AND PROGnRH LEVELS IN THE FEMALE RAT. Y.J. Ma*, M.J. Kelly and O.K. Ronnekleiv, Dept. of Physiology, OHSU, Portland, OR 97201

Experiments were designed to investigate the changes in proGnRH and GnRH levels after bilateral electrolytic lesions of the SCN or AMPO in the female rat. These lesions produced persistent estrus (PE), and were done as described (Neuroendocrinology 43: 566, 1986). The rats were sacrificed 2-3 months later, the brains were frozen, microdissected and radioimmunoassays were done to measure proGnRH and GnRH. In PE rats, proGnRH in the preoptic area (POA) was dramatically reduced (0.91 ± 0.1 fmoles/mg tissue) vs. proestrous controls (7.99 ± 1.1 fmoles/mg) ($P<0.01$). In contrast, GnRH levels in the POA were not significantly different in PE rats (15.6 ± 2.1 fmoles/mg) vs. controls (15.3 ± 0.5 fmoles/mg). Also, in basal hypothalamus, GnRH levels were not significantly different (94.2 ± 10.6 fmoles/mg) vs. controls (96.3 ± 8.7 fmoles /mg). Thus, lesions of SCN or AMPO cause PE without a reduction in GnRH, while proGnRH levels are reduced, suggesting that these nuclei may control GnRH synthesis and/or release. DISTRIBUTION OF proGnRH AND GnRH IN THE HYPOTHALAMIC-PREOPTIC AREA OF THE FEMALE GUINEA PIG. J.E. Thornton, M.J. Kelly and O.K. Ronnekleiv, Dept. of Physiol., OHSU, Portland, OR 97201.

To gain insight into the cellular biosynthesis and processing of gonadotropin releasing hormone (GnRH), we have examined the localization of proGnRH and GnRH in the adult female guinea pig. Ovariectomized females were injected with 25 μg EB or oil, were perfused 38 h later with 4% paraformaldehyde, and 50 μm vibratome sections were made. ProGnRH was localized with ARK-2 antiserum, and GnRH was localized with EL-14 antiserum, using avidin-biotin-HRP immunohistochemistry (Neuroendocrinology (1987), 45: 518). Specificity was determined by preabsorption of the antisera with their respective antigen. ProGnRH immunopositive perikarya were seen throughout the septal-preoptic-hypothalamic area, with the majority of cells in the preoptic area. Staining was confined to cell bodies and to a few proximal fibers. GnRH was also seen in cell bodies and the distribution and number of GnRH cells was similar to that of proGnRH cells ($r=.89$, $p<.05$). However, in contrast to proGnRH, GnRH was also seen in many small distal fibers and nerve terminals. These data suggest that, similar to the rat and monkey, proGnRH processing to GNRH in the female guinea pig appears to be initiated in the cell soma. (Supported by HD16793 and HD19905).

DISTRIBUTION OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH)-CONTAINING NEURONS WITHIN THE BRAIN OF A MUSTELID, THE EUROPEAN FERRET. Y.P. Tang and C.L. Sisk, Neuroscience Program and Dept. of Psychology, Michigan State University, East Lansing, MI 48824.

LHRH-containing neurons were identified immunocytochemically in three adult male European ferrets (Mustela putorius furo). Anti-LHRH LR-1 (obtained from Dr. R. Benoit) was used as primary antibody and LHRH cells were visualized in 40 um coronal sections using the Vecastain ABC kit and diaminobenzidene as chromagen. Every other section from rostral forebrain through the mammillary bodies was reacted, counterstained with cresyl violet, and examined microscopically. The total number of LHRH cell bodies within the ferret brain was estimated to be 500-700 (2x absolute number of identified cell bodies). LHRH cell bodies were diffusely distributed in structures ranging as far anteriorly as septum and diagonal band of Broca, in medial preoptic area, and in structures extending as far caudally as the arcuate nucleus and median eminence. Approximately 20% of the somata were located rostral to optic chiasm and 80% were within or caudal to the chiasmatic region. Most hypothalamic LHRH somata were located at the base of the brain. The distribution of LHRH cell bodies in the ferret thus resembles that of primates in that a significant proportion of the somata are within retrochiasmatic mediobasal hypothalamus.

PULSATILE RELEASE OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) DURING SEXUAL MATURATION IN THE FEMALE RAT. H.F.Urbanski and S.R.Ojeda. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Blocks of hypothalamic tissue (POA-MBH) were obtained from female rats at 6, 12, 18, 24, 30 and 36 days of age and individually perifused for 5 hr using the Endotronics Acusyst system. The perifusate was collected in 5-min fractions (375 μl) and the LHRH content determined by RIA. In most cases the in vitro release pattern of LHRH was found to be pulsatile though pulse amplitude was quite variable, both within and between age groups. On the other hand, the LHRH interpulse interval (40-50 min) was similar in all of the groups and was lower than the LH interpulse interval observed in vivo (ca 35 min). These findings demonstrate that the hypothalamus of developing female rats can release LHRH in a pulsatile manner in vitro in the absence of extrahypothalamic inputs. Moreover, they show that the intrinsic rhythmicity of the hypothalamic pulse generator is established very early in life and is therefore unlikely to be a limiting factor for puberty to occur. Consequently, LHRH-dependent changes in gonadotropin secretion associated with sexual maturation are likely to depend upon alterations in extrahypothalamic inputs to the LHRH-releasing system. PULSATILE SECRETION OF LHRH INTO THE HYPOPHYSEAL PORTAL BLOOD: EFFECT OF OVARIECTOMY AND ESTRADIOL REPLACEMENT. M. Ching, F.J. López*, M.G. Wisniewski*, and A. Negro-Vilar. Reprod. Neuroend. Sect., LMIN, NIEHS, NIH, Research Triangle Park, NC 27709.

Recently, we reported that LHRH secretion was reduced at 10-12 days after orchidectomy (ORDX) when compared with intact or ORDX rats given testosterone replacement (Abstr. #608, Endocr. Soc. 69th Mtg., 1987). The present study extended these observations to the adult female rat and evaluated the differences in LHRH secretion between intact metestrous (MET), 10 day-ovariectomized (OVEX) and OVEX-estradiol (E_2)treated rats. The collection and processing of portal blood for LHRH analysis was described recently (Brain Res. 443:325, 1988). Mean portal plasma LHRH levels were significantly reduced in OVEX rats and restored to MET levels with E_2 therapy. As observed in male rats, LHRH secretion occured in a pulsatile pattern. LHRH pulse frequency and duration were unaffected by the treatments. Analysis of area under the pulse revealed 2 populations of LHRH pulses in portal blood: small mass (SM) and large mass (LM) pulses. LM pulses occurred usually after 15.00 h and were absent in OVEX rats. They represented 14% of all pulses during MET and 29% after E_2 treatment ($P<0.02$ vs the OVEX rats). Evidently, E_2 can induce the appearance of LM pulses in the portal blood in the late afternoon. In conclusion, OVEX induces a decrease in mean LHRH levels and a disappearance of LM LHRH pulses. Both changes are reversed by E_2 treatment.

HYPOTHALAMIC-PITUITARY-GONADAL REGULATION II

177.1

REPRODUCTIVE PHOTOREFRACTORINESS IN MALE RHESUS MONKEYS: APPEARANCE OF ENDOGENOUS CIRCANNUAL RHYTHMS. E.A. Libré*, C.L. Chik* and G.R. Merriam, Developmental Endocrinology Branch, NICHD, NIH, Bethesda, Maryland 20892.

In seasonally breeding primates such as the rhesus monkey, short days activate and long days suppress reproductive function. When other mammals with a similar pattern of seasonality, such as the sheep, are subjected to constant long days over an extended period of time, gonadal function eventually reactivates. This phenomenon of "photorefractoriness" has not been documented in primates. In the present study, we analyzed the reproductive function of 5 male rhesus monkeys subjected to continuous long days (16h light:8h dark) for a period of 96 weeks. Responses were compared to 4 controls housed under alternating 16 week cycles of long and short days (8h light:16 h dark). Measurements of body weight and testis volume were obtained at 2 week intervals, and blood was drawn for testosterone, prolactin and gonadotropins. The data were examined for cyclicity using least squares sine wave analysis. Under continuous long day conditions, gonadal function was initially suppressed. After ≃12 weeks, there was an escape from suppression, with an increase of mean testis volume from 15 cc to 21 cc, followed by repeated cycles of gonadal regression and recovery, with a periodicity of 49 ± 3 weeks. In contrast, the control animals' testes grew under short days and regressed under long days, displaying a 36 ± 3 week cycle. These findings indicate that the phenomenon of photorefractoriness exists in primates. When housed under continuous suppressive lighting conditions, the animals eventually show a reactivation of the reproductive function, with emergence of an endogenous circannual cycle that is independent of photoperiodic cues.

177.2

EFFECT OF OVARIECTOMY AND ESTRADIOL TREATMENT ON PLASMA LH IN HYPOGONADAL (HPG) FEMALE MICE WITH PREOPTIC AREA (POA) GRAFTS. M.J. Gibson and A.J. Silverman. Dept. of Medicine,Mount Sinai Sch of Medicine,New York,NY 10029.

POA grafts containing GnRH cells implanted into the IIIrd ventricle of adult hpg mice, genetically unable to produce GnRH, correct their hypogonadism. Fibers from grafted GnRH cells project to the median eminence of host brains; increased gonadotropin release and gonadal development is seen. Hpg females with POA grafts (HPG/POA) generally do not have ovulatory cycles but may show an LH surge and ovulation after mating. 1/4 to 1/3 of HPG/POA also exhibit positive feedback with increased plasma LH and/or ovulation after progesterone administration. The present studies were planned to evaluate negative feedback responses.

HPG/POA mice were ovariectomized (OVEX) 3, 6,or 9 months after graft surgery and subsequently received sc 17beta-estradiol(E2) implants. Blood for LH RIA was obtained prior to and post OVEX, and post implant. Age-matched normal females were studied 3 months post OVEX. HPG/POA mice (including individuals previously showing positive feedback) did not show the significant increase in plasma LH after OVEX or decrease after E2 implant seen in normal mice. Negative feedback, previously reported absent in male HPG/POA mice, may require early steroid priming, or the establishment of certain afferents to GnRH cells.

177.3

INTACT GONADOTROPIN RESPONSE TO STEROID FEEDBACK AND ALTERED PROLACTIN CONTROL IN FEMALE RATS WITH ARCUATE NUCLEUS MALDEVELOPMENT AS A RESULT NEONATAL GLUTAMATE.

Ruth L. Callahan* and Richard W. Clough, Department of Anatomy, Southern Illinois University School of Medicine, Carbondale, IL 62901 (D. King,Sp.)

Positive and negative feedback of the gonadal steroids on gonadotropin secretion are mediated through the pituitary gland and the central nervous system (CNS) in rats and other species. Deafferentation and lesion studies have suggested that positive feedback is subserved through the "medial preoptic area" whereas negative feedback is mediated through the mediobasal hypothalamus (MBH), particularly the arcuate nucleus. This abstract reports that maldevelopment of the MBH, as a result of neonatal treatment with MSG, a neurotoxin to developing arcuate neurons, results in many endocrinopathies including obesity and reduced somatic development; however, MSG-treated female rats remain responsive to the positive feedback effect of 10 ug/kg estradiol on luteinizing hormone secretion in the prepubertal period and display normal compensatory ovarian hypertrophy, an indirect measure of the negative feedback of steroids on gonadotropin secretion. In contrast, the tuberoinfundibular dopamine system controlling secretion of prolactin is dramatically altered in MSG-treated female rats. In this regard there is an apparent loss of MBH neurons expressing tyrosine hydroxylase, a catecholamine synthesizing enzyme. Concomitantly, the ability of anesthesia and intraventricular beta-endorphin to stimulate prolactin release in female rats is abolished or severly attenuated in glutamate-treated rats. Although recovery or sparing of arcuate function in regards to negative feedback in MSG-treated rats needs to be considered in more detail, these studies suggest that a reanalysis of the role of the arcuate-MBH in negative feedback of steroids on gonadotropin secretion is warranted. Supported by HD-24426.

INCREASED SERUM GONADOTROPIN LEVELS FOLLOWING GONADECTOMY ARE NOT ASSOCIATED WITH CHANGES IN PITUITARY RESPONSES TO GnRH IN VITRO. P.C. Fallest*, E.S. Hiatt*, J.B. D'Agostino* and N.B. Schwartz* (SPON:J. Levine). Dept. of Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

We sought to determine if increased responsiveness of the anterior pituitary to pulsatile GnRH contributes to the acute rise in serum gonadotropins following gonadectomy. Pituitaries obtained from intact male and female (metestrous) rats and rats gonadectomized 2 or 6 days earlier were cut into eighths and perifused with Medium 199 at a flow rate of 10 ml/hr. The GnRH pulse protocol consisted of 5 brief (~1 min) GnRH pulses (peak amplitude: 50 or 500 ng/ml) delivered 1/h. Five minute fractions were collected for LH and FSH RIA. The response to each GnRH pulse was calculated as the net LH or FSH secreted above baseline. Two-way ANOVA indicated that both baseline and total secretion of FSH increased in female pituitaries following gonadectomy. There was no effect of gonadectomy, however, on the net secretion of LH and FSH in either sex. These results suggest that at 2 and 6 days after gonadectomy, the increases in serum LH and FSH are not mediated by changes in the sensitivity of the rat anterior pituitary to GnRH. Supported by PHS Grants PO1-HD21921 and T32-HD07068.

BILATERAL TRANSECTION OF THE LATERAL OLFACTORY TRACT (LOTX) PREVENTS SHORT PHOTOPERIOD INDUCED TESTICULAR REGRESSION IN GOLDEN HAMSTERS. D.R. Pieper*, C. Lobocki and S.W. Newman*, Providence Hospital, Southfield, MI + U. Mich, Ann Arbor,MI

Removal of the olfactory bulbs (BX) increases tonic serum gonadotropin levels and prevents the testicular regression associated with short photoperiod. If LOTX mimicked the effect of BX on gonadotropin secretion, this, combined with previous data showing no effect of vomeronasal organ removal (VNOX), would suggest that the olfactory bulb influence on reproductive hormone secretion was due to main olfactory pathway neurons in LOT. Sixteen 23 day old male golden hamsters underwent either LOTX or sham (SH) surgery and were maintained on 14L:10D for another 4 wks. All hamsters were then transferred to a 10L:14D photoperiod for 11 wk. The most caudal damage of any of the lesions was at the level of the mid olfactory tubercle. All 8 of the hamsters in the SH group underwent testicular regression but only 1 of 8 in the LOTX group regressed. The serum LH and FSH levels at the end of the study were much higher in the LOTX group ($p < 0.01$ for both LH and FSH). These results combined with the earlier data on VNOX, suggest that MOB input to the pyriform cortex, amygdala or entorhinal cortex is involved in the influence of the olfactory bulbs on gonadotropin secretion and the effects of short photoperiod. NSF DCB8509789 (DRP) + NINCDS NS 20629 (SWN)

HORMONAL AND HYPOTHALAMIC NEUROCHEMICAL RESPONSES TO DORSAL RAPHE STIMULATION STUDIED USING MICRODIALYSIS PROBES IN RATS. J.H. Johnson. Dept. of Anatomy, Medical College of Va., Virginia Commonwealth University, Richmond, VA 23298.

We have shown that electrical stimulation of the dorsal raphe nucleus of the rat inhibits the release of luteinizing hormone (LH) while stimulating release of prolactin (Prl). The effects on LH appear to involve serotonergic and adrenergic links. Thus we undertook a study of medial hypothalamic and preoptic neurochemical correlates of these events. Ovariectomized rats were prepared with stereotaxically placed guide cannulae above the arcuate nucleus and medial preoptic area, and received jugular catheters as well. Experiments were performed in unanesthetized animals after insertion of a microdialysis probe (Carnegie Medicin, 2 mm membrane exposure) into each guide. Modified saline solution was perfused through the probes at a rate of 5 μl/minute. Fractions of dialysate (50 μl) and blood (0.3 ml) were collected every 10 minutes during a 60-min. control, a 50-min. stimulation, and a 50 min. recovery period. Dialysates were stored frozen prior to assay using HPLC with electrochemical detection. Plasma LH was measured by double antibody radioimmunoassay. Significant changes in LH and in dialysate contents were identified using ANOVA followed by a contrast procedure. LH decreased during stimulation, while reversible increases were observed in hypothalamic MHPG, DOPA, and DOPAC, and in preoptic EPI, MHPG, DOPAC and HVA. Hypothalamic 5HTP decreased during stimulation, and remained depressed during the recovery period. The importance of these changes to release of LH is under further study. (Supported by NIH grant HD12165).

MORPHOMETRIC ANALYSIS OF TH-IMMUNOREACTIVE NEUROSECRETORY NEURONS IN THE ARCUATE NUCLEUS OF THE RAT AFTER OVARECTOMY. J.-H. Rho, R.B. Simerly, and L.W. Swanson. Neural Systems Laboratory, The Salk Institute and Howard Hughes Medical Institute, La Jolla, CA 92037.

The effects of estrogen replacement, after ovarectomy of female adult rats, on tyrosine hydroxylase (TH)-immunoreactive neurosecretory neurons in the arcuate nucleus were characterized by an intracellular method to characterize changes in their detailed morphology. Two weeks after ovarectomy, and implantation of either a 25 mg. pellet of 17 β-estradiol (E2) or a control pellet (CP) subcutaneously, neurosecretory neurons were first labeled by an intravenous injection of fast blue and then selectively penetrated in fixed tissue slices and filled intracellularly. TH-containing neurons were further distinguished from other neurosecretory cells by immunostaining the tissue with antiserum to (TH). From two CP replaced rats, 77 neurosecretory neurons, of which 19 stained intensely with TH antiserum and 45 others stained less intensely, were visualized and reconstructed graphically to quantitatively analyze their morphological features. These neurons had extensive dendrites that are smooth proximally, with a sparse complement (6.5/100 microns) of spines, and varicose distally. These spines varied in length from 0.5 to 3 microns and often had a bulbous head. Their soma were small and ovoid, with a mean cross-sectional area of 75 sq. microns. From two E2 replaced rats, the morphology of 61 neurosecretory neurons were analysed, of which 36 neurons stained weakly for TH. These neurons appeared morphologically similar to CP neurons, with similar types of spines and a mean somal cross-sectional area of 73 sq. microns. However, the number of spines was somewhat less (4.2/100 microns) on these neurons. This preliminary evidence suggests that gonadal steroids, in addition to regulating TH synthesis, may also affect the morphology of neurons in the arcuate nucleus.

ADRENERGIC AND NORADRENERGIC REGULATION OF PULSATILE LH RELEASE. R.V.Gallo, A.Bona-Gallo*, and D.O'Sullivan*.Dept. Physiol. Neurobiol., Univ. Connecticut, Storrs, CT 06268.

This study examined the roles of both norepinephrine (NE) and epinephrine (EPIN) in regulating pulsatile LH release in 8-day OVX rats. Rats were injected ip with vehicle or drug at -27,-20,-5 and -3h prior to a 3h blood sampling period. Hypothalamic-preoptic area (HPOA) levels of NE and EPIN were determined by HPLC. Compared to controls, FLA-63 (25 mg/kg, DBH inhibitor) given at -3h produced 50 and 22% declines in HPOA NE and EPIN, resp., and reductions in pulse amplitude and frequency. LY134046 (LY; 50 mg/kg,PNMT inhibitor) given at -27,-20 and -5h, or -27, -20, -5 and -3h, produced no change in NE, 88 and 86% declines in EPIN, resp., and reductions in pulse frequency only. Either LY treatment protocol produced the same decline in EPIN and pulse frequency. Thus EPIN levels were maximally decreased by 3 LY injections. When rats were given LY at -27,-20 and -5h, and FLA-63 at -3h, compared to rats treated with LY alone there was no further decrease in HPOA EPIN (82% decline), a 46% decline in NE, and a further reduction in both pulse amplitude and frequency. This further suppression of LH release must be due to a reduction in HPOA NE levels since no further decrease in EPIN levels occurred. These data demonstrate within the same animal that NE and EPIN are both stimulatory to pulsatile LH release. NE stimulates the amplitude and frequency, and EPIN stimulates the frequency of pulsatile LH secretion. Supported by NIH HD 17728.

ENDOGENOUS OPIOID INHIBITION OF LUTEINIZING HORMONE (LH) SECRETION IN THE ABSENCE OF OVARIAN STEROID FEEDBACK IN THE DEVELOPING SHEEP. F. J. P. Ebling and D. L. Foster*. Consortium for Research in Developmental and Reproductive Biology, and Departments of Obstetrics and Gynecology, and Biology, The University of Michigan, Ann Arbor, MI 48109.

Puberty in the sheep results from an increase in the *frequency* of episodic LH secretion. The aims of the current study were to determine whether endogenous opioid regulation of LH pulse frequency changes during sexual maturation, and to determine whether opioid inhibition of LH secretion is dependent on the presence of ovarian steroids. The experimental approach was to determine the effects of an opiate antagonist (naloxone) on the pattern of LH secretion in ovariectomized female sheep at both pre- and postpubertal ages. Lambs (n=8) were ovariectomized at 3 weeks of age, and treated with a constant release 17β-estradiol implant to provide an invariable steroid negative feedback signal. At a prepubertal age (15 weeks) the implants were removed. Three weeks later, blood samples were collected at 6-min intervals (hours 0-4 of experiment) to establish the pattern of endogenous LH secretion. The lambs were then sampled during hourly treatment with naloxone (1 mg/kg BW i.v., hours 4-8 of experiment). As expected, pretreatment LH pulse frequency was high in the absence of steroid negative feedback (4.2 ± 0.3 pulses/4h, mean ± sem). However, naloxone treatment further increased LH pulse frequency (to 6.3 ± 0.5 pulses/4h). The estradiol implants were replaced so that the experimental protocol could be repeated at a postpubertal age in the same animals, but at an equivalent length of time after removal of steroids. Therefore, the estradiol implants were removed at 35 weeks of age, and blood sampling and naloxone treatment carried out again at 38 weeks of age. Pretreatment pulse frequency was higher at this postpubertal age (6.0 ± 0.6 pulses/4h) than during the prepubertal period; naloxone again induced an increase in LH pulse frequency (to 7.8 ± 0.6 pulses/4h). LH pulse amplitude was not affected by the naloxone treatments at either age. These responses to naloxone demonstrate that opioid mechanisms inhibit pulsatile LH secretion in the absence of ovarian steroids. Furthermore, the disinhibitory effects of naloxone on LH secretion at both pre- and postpubertal ages do not support the hypothesis developed in the rat (*Endocrinology* 113:596, 1983) that a decrease in opioid inhibition is responsible for the increase in gonadotropin secretion at puberty. Rather, they suggest that endogenous opioid mechanisms tonically inhibit LH secretion, perhaps contributing to the homeostatic regulation of the reproductive neuroendocrine axis. *(Supported by NIH grants HD-18258 and HD-18394).*

DIFFERENCES IN THE STIMULATORY AFFERENT REGULATION OF TUBEROINFUNDIBULAR DOPAMINERGIC (TIDA) NEURONAL ACTIVITY IN MALE AND FEMALE RATS. A.C. Barton, K.T. Demarest, K.J. Lookingland and K.E. Moore. Dept. of Pharm./Tox., Mich. State Univ., E. Lansing, MI 48824

In female rats TIDA neurons are tonically activated by afferent input from the rostral hypothalamus. The present study tested whether a similar afferent input exists in the male rat. TIDA neuronal activity was estimated by measuring rates of synthesis and turnover of DA in the median eminence (ME). Complete and retrochiasmatic (RC) deafferentations of the mediobasal hypothalamus (MBH) were made to isolate completely TIDA neurons from the rest of the brain or to interrupt neuronal connections from rostral brain regions. Both deafferentations decreased TIDA neuronal activity in female but not male rats. Rat prolactin (icv) increased DA synthesis in the ME of both sham- and RC-deafferentated female and male rats. These results suggest that afferents originating rostral to the MBH tonically stimulate TIDA neurons in female but not male rats, and that the action of prolactin is not blocked by RC deafferentation. TIDA neuronal activity may be influenced by the stimulatory effect of estrogen and inhibitory effect of testosterone. Ovariectomy decreased DA synthesis in the ME but RC deafferentation did not cause a further decrease. These results suggest that RC deafferentation and ovariectomy remove tonic stimulatory input to TIDA neurons which is mediated through a common afferent pathway. These afferents may not function in male rats since RC deafferentation did not reverse the castration-induced increase in DA synthesis in the ME. (NIH grant MH42802)

STREPTOZOTOCIN-INDUCED DEFICITS IN SEX BEHAVIOR AND NEUROENDOCRINE FUNCTION IN MALE RATS. R.W.Steger* (SPON: W. Yau). Physiology Dept, Southern IL Univ Sch of Medicine, Carbondale, IL 62901.

Diabetes is often associated with sexual dysfunction and abnormalities in gonadotropin and gonadal steroid secretion. Diabetes is known to affect central neurotransmitter metabolism but little is known about diabetes-induced changes in neurotransmitter turnover in hypothalamic areas known to control anterior pituitary hormone secretion and/or sex behavior. Adult male rats were tested for copulatory performance and then made diabetic by injecting them with streptozotocin (STZ; 50mg/kg) or citrate buffer. At 1 week after STZ, only 5 of 10 rats ejaculated in a 30 minute test of copulatory behavior compared to 10 out of 12 control rats. At 3 weeks, 3 of 10 STZ rats and 11 of 12 control rats reached ejaculation. Four weeks after the induction of diabetes, the animals were injected with saline or alpha methyltyrosine (250mg/kg) and killed 1 hour later. Plasma glucose levels in the STZ rats were elevated 4-fold over control levels . Plasma levels of testosterone (T), prolactin and luteinizing hormone were all depressed in the STZ rats. Norepinephrine (NE) turnover in the median eminence (ME), medial basal (MBH) and anterior hypothalamus (AH) and in remaining brain areas was significantly reduced by STZ treatment. Dopamine turnover in the ME was unaffected by STZ while it was increased in the MBH and decreased in the AH and remaining brain. In a second series of experiments, testosterone injections were shown to reverse the effects of STZ on sexual behavior. They also reversed STZ-induced changes in ME and MBH but not AH NE turnover. In conclusion, it appears that diabetes-induced changes in copulatory behavior are due to reductions in T levels which may be secondary to catecholamine-induced changes in pituitary LH and prolactin release. (Supported by the American Diabetes Association)

STEROID-INDUCED CHANGES IN HYPOTHALAMIC AND PITUITARY ENDOPEPTIDASE-24.15. A.R. Pierotti*, A. Lasdun*, J.L. Roberts, M. Orlowski* and C.J. Molineaux. (SPON: G Cohen.) Dept. of Pharmacology and Fishberg Ctr. for Neurobiology, Mount Sinai Sch. of Med., CUNY, New York, N.Y. 10029

Degradation of LHRH within the hypothalamus and/or the anterior pituitary (AP) by endopeptidase-24.15 may play a significant neuroendocrine role in modulating the release of luteinizing hormone (LH) and follicle stimulating hormone (FSH). Previous studies in this laboratory have shown that LHRH is cleaved at the Tyr^5-Gly^6 bond by purified endopeptidase-24.15, and that the cleavage of LHRH by membrane preparations of hypothalamus and pituitary is inhibited by active-site-directed inhibitors of endopeptidase-24.15. These and other data strongly indicate that endopeptidase-24.15 is the enzyme directly responsible for LHRH degradation in the hypothalamus. The release of LHRH from neurons in the mediobasal hypothalamus (MBH) is regulated by negative feedback from gonadal target organs. In the present studies we have measured the activity of endopeptidase-24.15 in the MBH and AP, with the aim of determining whether the enzyme is regulated by gonadal steroids in these tissues.

Endopeptidase-24.15 activity was measured in soluble factions of hypothalamus and AP in pre- and post-pubertal male and female rats. The enzyme activity significantly dec4reased in the hypothlamus with age in both males and females and in the AP of male rats. Thus, a decrease in endopeptidase-24.15 may in part be responsible for the increase in LHRH release from the median eminence which occurs at puberty. The activity of endopeptidase-24.15 was measured in OVX rats treated with estrogen and progesterone. Steroid-treated rats showed a significant increase in the activity of endopeptidase-24.15 relative to OVX controls. These findings are consistent with the hypothesis that endopeptidase-24.15 is regulated by gonadal steroids and may, in part, mediate the negative feedback effects of steroids upon AP LH release.

CNS SPECIFICITY OF Tor 23 IN THE RAT S. Wright,* D.T. Stephenson*, and P.D. Kushner (SPON: L.E. Muske) A.L.S. and Neuromuscular Research Foundation, Pacific Medical Center, San Francisco CA 94115

The monoclonal antibody, Tor 23, made to Torpedo synaptosomes, has been shown to bind to the surface of a subset of neurons in the rat CNS (J. Neurosci.,1988). In this study we have examined other tissues including the peripheral nervous system, endocrine structures and other organs to determine if the Tor 23 epitope is present elsewhere. PNS structures tested include the sciatic nerve and ventral and dorsal roots of the spinal cord. Endocrine structures tested were the adrenals, intestine, ovaries, pancreas, parathyroid, pineal gland, pituitary (anterior and posterior), placental tissue and the thyroid gland. Other organs examined were the liver, kidney, lung and spleen. All tissues were negative for Tor 23 except the anterior pituitary in which a discrete population of cells was positive. These cells were only a small fraction of total cells present and the binding appeared to be cytoplasmic (in contrast to the surface staining in the CNS). Costaining with antibodies to various pituitary hormones showed Tor 23 binding to be to the luteinizing hormone (LH) positive cells (as defined by an antibody to the beta-subunit of LH) of the anterior pituitary although Tor 23 does not appear to bind the LH molecule itself. Thus Tor 23 binding in the rat is specific to CNS tissues with the exception of the anterior pituitary. This finding merits further study to explore this heretofore undescribed and potentially exciting neural-endocrine connection.

INHIBIN β- AND SOMATOSTATIN-28-IMMUNOREACTIVE PROJECTIONS FROM THE NUCLEUS OF THE SOLITARY TRACT TO OXYTOCINERGIC CELL GROUPS. P.E. Sawchenko, S.W. Pfeiffer*, P.M. Plotsky, V.J. Roberts, E.T. Cunningham Jr., R. Benoit, M.R. Brown, and W. Vale. The Salk Institute, La Jolla, CA, 92037.

While several prominent neural inputs to vasopressinergic components of the magnocellular neurosecretory system have been identified, major pathways subserving afferent control of oxytocin (OT) secretion have remained elusive. Light-level immunohistochemical analyses suggested a preferential innervation of OT-immunoreactive (ir) neurons in magnocellular compartments of the paraventricular (PVH) and supraoptic (SO) nuclei by inhibin β- (Iβ-) and somatostatin-28- (SS-28-) ir fibers. Combined retrograde transport-immunohistochemical studies indicated that both projections arise principally from non-catecholaminergic cells centered in the caudal part of the nucleus of the solitary tract (NTS), but extending also into dorsomedial aspects of the medullary reticular formation. Preembedding immunoperoxidase staining at the EM level established that Iβ- and SS-28-ir are contained within presynaptic elements in the PVH and SO. Concurrent immunoperoxidase and autoradiographic (using ^{125}I-labeled secondary antisera; J. Histochem. Cytochem., 34:707, 1986) localization at the ultrastructural level identified terminals ir for each peptide in conventional synaptic contact with OT-ir elements (primarily dendrites) in the PVH and SO.

Both SS-28 and Iβ have been found to stimulate oxytocin secretion after central administration. Because the region of the NTS from which these peptidergic pathways arise appears to receive somatosensory (J. Comp. Neurol., 255:438, 1987), as well as visceral, afferents, these projections constitute candidate substrates for parturition- and suckling-related controls of OT secretion.

DISTRIBUTION OF INHIBIN SUBUNITS IN THE RAT BRAIN AND PITUITARY. V.J. Roberts, H. Meunier*, J. Vaughan*, C. Rivier, W. Vale, and P.E. Sawchenko. The Salk Institute, La Jolla, CA 92037.

Two related glycoproteins, inhibin and activin, are produced and secreted by the gonads and act at the pituitary to regulate FSH secretion. Recent studies, however, have revealed that the mRNAs encoding the subunits of inhibin (α/β_A and α/β_B) and activin (β/β) are also expressed in other tissues including the brain and pituitary. The aim of this study was to examine the distribution of these polypeptide subunits in the brain and pituitary and explore their regulation by ovarian factors.

Inhibin subunits were localized using antisera that read preferentially the α-, β_A-, or β_B-subunit. In brain, both β-subunits were localized in a group of cells centered in the nucleus of the solitary tract (NTS). Fibers and terminals consistent with known NTS efferents were also stained. Hypothalamic oxytocin-containing neurons appear to comprise prominent targets of immunoreactive (ir) fibers. In the pituitary, the α- and β_B-subunits were colocalized in the cytoplasm of most all FSH- and LH-ir cells. Ovariectomy dramatically increased the size and number of gonadotropes immuno-positive for these subunits. The levels of the α and β_B mRNAs were also greater following ovariectomy. These results suggest that (1) inhibin-related peptides, in the brain, may mediate reproductive-related functions at the neuronal level, and (2) these peptides, produced by gonadotropes, may play an endocrine role in the modulation of gonadal secretions and/or have a paracrine function in the anterior pituitary.

STRESS, HORMONES AND AUTONOMIC NERVOUS SYSTEM I

178.1

EFFECT OF STRESS AND ADRENALECTOMY ON LONG-TERM POTENTIATION IN RAT HIPPOCAMPUS. T.J. Shors, S.Levine, and R.F. Thompson. Dept. Psychol., Univ. Southern Calif., LA,CA 90089, Dept. Psychiatry, Stanford Univ., Stanford,CA 94305.

Stress impairs long-term potentiation (LTP) in the rat hippocampal slice (Foy et al., Behav. Neural Bio.,48:138,1987). To investigate the possible role of the stress hormone, corticosterone, LTP was measured in adrenalectomized (ADX) rats immediately following restraint/shock. Field potentials were recorded in vitro from CA1 after tetanic stimulation of the Schaffer collaterals. Percentage of pre-tetanus amplitude at 30 minutes was 191% for controls, 142% for ADX, 111% for stress, and 124% for ADX/stress. Both stress and ADX alone resulted in a significant decrease in LTP. The difference between ADX and ADX/stress was significant ($p<0.05$), but the difference between stress and ADX/stress was not. Therefore, even though there was decreased potentiation with ADX, stress resulted in a further decrease. This further reduction suggests that neurogenic factors may be either responsible for or interacting with the adrenal component to impair LTP in response to stress.

HIPPOCAMPAL DAMAGES ASSOCIATED WITH PROLONGED AND FATAL SOCIAL STRESS IN VERVET MONKEYS. H. Uno, R. Tarara*, J.G. Else*, M.A. Suleman and R.M. Sapolsky. Reg. Primate Res. Ctr., Univ. Wisconsin, Madison, WI 53715; Institute of Primate Res., Nairobi, Kenya; and Dept. Biol. Sci., Stanford Univ., Stanford, CA 94305

Although the incidence of spontaneous gastric ulcer in nonhuman primates is very low, macaques are highly susceptible to gastric ulcer induced by psychosomatic stress. Eight adult vervet monkeys *(Cercopithecus aethiops)* succumbed to cachexia associated with multiple gastric ulcers in the captive social groups at the Institute of Primate Research, Nairobi, Kenya. These animals appeared to have suffered atypically high rates of social harassment and attack from peers, suggestive of social subordinance. All animals were cachectic with persistent diarrhea, anorexia, dehydration and died as early as 1 month and 6 months to 4 years. We observed microscopic changes of the brain from all 8 ulcer-laden animals as well as 6 healthy, euthanized animals in the same colony. The neural degeneration representing shrinkage, disarrangement, and loss of the pyramidal neurons was prominent in the CA3 and CA1 regions. Ultrastructurally, edematous swelling of the dendritic branches and disappearance of the synaptic terminals of the mossy fibers were noticed. Numerous swollen oligodendrocytes were seen in the overall hippocampus, cerebral cortex, midbrain, and striatal ganglia. Numbers of the pyramidal neurons in CA1 and CA3 were reduced substantially in stressed animals. Degenerative changes and depletion of the neurons were more prominent in males than females. These hippocampal changes were similar to those found in our earlier experiments with dexamethasone in prenatal rhesus monkeys. The adrenal cortex of ulcer-laden animals showed a moderate degree of hyperplasia. The prolonged and fatal social stress appeared to induce hippocampal damage as well as gastric ulcers and severe generalized maladies in adult monkeys. (Supported by NIH grant RR00167.)

178.3

SEX DIFFERENCE IN BINDING AFFINITIES OF TYPE I AND TYPE II GLUCOCORTICOID RECEPTORS IN RAT HIPPOCAMPUS. B.B. Turner and M.S. Ansari*. Dept. of Physiology, Coll. of Med., East Tenn. State Univ., Johnson City, TN 37614.

We previously reported a sex difference in the affinity of 3H-dexamethasone (3H-Dex) and 3H-corticosterone (3H-Cort) binding in hippocampus, with males having the greater affinity (Brain Res. 343:16, 1985). We have also found that in vivo injection of a tracer dose of 3H-Cort results in greater nuclear uptake in males (Soc. Neurosci. Abstr. 13:1027, 1987), suggesting either greater receptor density or greater affinity of Type I receptors in males. We report here that the affinity of Type I receptors is much greater in males than in females. No difference in receptor number was found between sexes for either Type I or Type II receptors.

Rats were killed 12 h post-adrenalectomy and bound steroid was separated on LH-20 columns. Using 3H-Dex and unlabelled RU-28362, the Kd obtained for the Type I receptor was 0.53 $\pm$ 0.05 nM in males vs. 1.30 $\pm$ 0.25 nM in females, $p<0.025$. Using 3H-RU 28372, the Kd for Type II receptors was 1.41 $\pm$ 0.03 nM in males vs. 1.30 $\pm$ 0.04 nM in females, $p<0.025$. The Type I receptor affinity difference was confirmed using 3H-Cort and hydroxylapatite. Under basal conditions, the occupancy of Type I receptors and consequent spill-over to Type II receptors may be greater in males, thus limiting the range of the male stress response. Supported by NIH grant NS-22158.

178.4

CORTICOSTERONE HYPERPOLARIZES PYRAMIDAL NEURONS OF THE HIPPOCAMPUS IN VITRO. J.B. Aldenhoff, and S. Hennig*, Dept. Psychiatry, Univ. of Mainz, Untere Zahlbacher Str. 8, 6500 Mainz, FRG

Different types of receptors for glucocorticoids occur in the brain with particular density in the hippocampus (1) suggesting neuromediator function. However, except earlier findings (2) mainly genomic actions have been considered.

Hippocampus slices from rats (100-200g) were superfused with oxygenated Ringer solution at 35°C in a perfusion chamber (3). Intracellular recordings and current injections were made with a bridge amplifier and glass microelectrodes filled with 2 M KCl (resistance 30 to 40 MOhm). Pyramidal neurons with stable resting potentials (> -45 mV) were used. Corticosterone 10^{-6} to 10^{-9} Mol (solved in ethanol 0.1-0.0001 %.) was applied to the superfusate for 15 to 20 min. Within 3 to 5 minutes after application, neuronal activity ceased and a hyperpolarization of about 10 mV occurred. Membrane resistance decreased as well as the post-stimulus hyperpolarization. Both, effects of corticosterone on Cl-currents as well as on K-currents could underly this action. Hypothetically, corticosterone might serve as negative feedback mechanism for the excitatory action of Corticotropin-releasing factor such as described before (3).

GLUCOCORTICOID-STIMULATED 35 S-LABELING OF A PROTEIN FROM THE RAT HIPPOCAMPUS. L.K. Schlatter* and L.A. Dokas. Departments of Biochemistry and Neurology, Medical College of Ohio, Toledo, OH 43699.

Following treatment of rats with 5 mg of corticosterone (s.c.), hippocampal slices in vitro show increased labeling from [^{35}S]-methionine of a protein with an apparent molecular weight (M_r) of 35,000 and IEP of 6.6. These characteristics are similar to those of glycerol-3-phosphate dehydrogenase. Since responses to an injection of this magnitude may be pharmacological, several experiments have been done to determine whether stimuli that increase endogenous levels of corticosterone have the same effect on labeling of the 35,000 M_r protein. One hour after various stresses (immobilization, cold, ether or sham-injection), when plasma levels of corticosterone are elevated, labeling of the 35,000 M_r protein is increased. Injection of ACTH also stimulates the synthesis of this protein. A dose-response curve for corticosterone with adrenalectomized rats shows that the protein's synthesis is maximally increased when the injected dosage causes serum corticosterone to increase to levels seen during stress. Injections of the corticosterone receptor agonist RU 28362 and the mineralocorticoid aldosterone into adrenalectomized animals differentially stimulates the synthesis of the 35,000 M_r protein. The increase appears to be due to short-term glucocorticoid increases such as those observed during stress. Supported by the Van Ness-Thompson Foundation and AFAR.

178.6

THE EFFECT OF SHOCK PREDICTABILITY ON HORMONAL STRESS INDICANTS. D. Pitman*, B.Natelson, T. Pritzel,* J. Ottenweller* and R.McCarty. (SPON: S.D. Cook). Primate Neurobehavioral Unit, VAMC and Dept of Neurosciences, New Jersey Medical School, East Orange, NJ 07019.

Male Sprage-Dawley rats were implanted with femoral artery catheters and subcutaneous flank electrodes for shock delivery. The rats were then placed into an apparatus we described earlier (Neurosci Abs 13: 1293, 1987) which allows for undisturbed blood sampling and complete experimental control. Groups of rats were given either 100%, 66%, 33%, or 0% predictable shock by varying the number of times a light (CS) preceded each of 42 daily shocks (US) in a 21.5 h session. Each morning for six consecutive days, animals were sampled and then given a CS-US pair. Area under the corticosterone (cort) response curve (AUC) following the CS-US pair partially habituated by day 3 in all of the shocked groups (p's<0.05). In the 100% group, the AUC increased on day 6 of the experiment (p<0.05). This suggests sensitization of the cort response to the probe in this group. On the 6th day, basal cort levels varied directly with predictability levels, p<0.01;R=.47. The pattern of plasma catecholamine (cat) responses was the opposite of the cort responses; on day 6, the 100% group manifested a decrement in response to the CS-US probe (p<0.05), while the 0% group continued to respond to the probe (p<0.05). Using basal cort as the stress indicant, these data suggest chronic stress may track shock predictability. Additionally, the way the adrenal responded to highly predictable shock varied by the end of the experiment; the cort response was actually greater than levels after animals had habituated while the cat response was a decrement following shock. Supported by VA research funds.

178.7

HABITUATION OF THE ADRENOCORTICAL STRESS RESPONSE. B. Natelson, D. Pitman*, E. Grover*, and J. Ottenweller*. Primate Neurobehavioral Unit, VAMC and Department of Neurosciences, New Jersey Medical School, East Orange, NJ 07019

Frequency and intensity of stressor presentation are known to influence the rate at which the adrenocortical stress response (ACSR) habituates over time. This study was designed to further evaluate stressor intensity as a variable. Chronically catheterized rats bearing subcutaneous shock electrodes were placed in an apparatus developed to permit remote blood sampling without the need to touch the rat (Neurosci Abs 13: 1293, 1987). Rats were assigned to low and high shock groups or a sampling- only group which was treated as were the shocked groups but was never shocked. On days 1,2,4,6, and 8 of the study, animals were sampled, given a single shock probe, and sampled again. Thereafter, animals in the low and high shocked groups were given a daily 3 h shock session consisting of 18 shocks. The ACSR of rats receiving high shock probes was greater than that of low shock and no-shock groups (p's<0.05) on the first day of the experiment. Animals in this group then showed evidence of sensitization on the 8th probe day (p<0.05). Low shocked animals showed partial habituation to the shock probe by the fourth day and then a return of ACSR to levels seen following the first probe. Samples taken 1 h after sessions finished revealed comparable AC levels in both shocked groups on the fourth day. However, AC levels on days 6 and 8 were greater in low shocked than in high shocked rats (p's<0.01). Rats receiving high shock had heavier adrenals, and a greater ACSR to ACTH than the other groups. These data indicate that parametric analysis of habituation of ACSR is possible. Supported by VA research funds.

178.8

BEHAVIORAL CHANGES ELICITED BY CHRONIC STRESS IN RATS. J.E. Ottenweller*, B.H. Natelson, S.D. Drastal*, D.L. Pitman* (SPON: J. Jacoby). Primate Neurobehavioral Unit (127A), VA Medical Center, East Orange, NJ 07019.

We recently reported that basal plasma corticosterone levels were elevated in repeatedly stressed rats and in rats that were simply moved into the same room as stressed rats (P&B 43[1], 1988). We have now replicated these results with 10 daily 2 hour sessions of intermittent tail shock. Before and during the 10 days of stress, activity patterns were monitored with tilt cages and afterwards with Wahmann running wheels. During stress, shocked rats and those in the room with them decreased their activity in the 4 hours before the stress sessions were to begin, and not at other times of day. Thus, these rats appeared to develop a stress-induced, anticipatory fear state that suppressed activity in the 4 hours before stress sessions. This anticipatory suppression of activity was not evident on the last 3 days of stress, but reappeared in shocked rats on the first 2 days in running wheels. 3 hours after the last stress session, shocked rats showed a prolonged latency to drop from a wire suspended 18 inches off the ground. This effect was present 4 days (but not 7 days) later. The response to novelty was measured after the hanging wire test by placing these rats in running wheels, and shocked rats ran less in the first hour than either other group. We believe these behavioral disruptions and elevated basal glucocorticoids characterize a state of chronic stress. Supported by VA Medical Research Funds.

178.9

EFFECT OF BILATERAL ADRENALECTOMY ON LEARNED HELPLESSNESS INDUCTION AND 5-HT RELEASE IN RATS. W. Kornrich, F.A. Henn and E. Edwards. Dept. of Psychiatry, SUNY. Stony Brook, NY 11794

Rats exposed to intermittent inescapable shock develop a transient behavioral deficit when later tested in a shock escape paradigm. We have recently demonstrated that deficient rats or "learned helpless" rats can be distinguished by an abnormal hypothalamic-pituitary-adrenal axis. The present experiments examine the effects of bilateral adrenalectomy on the induction of learned helplessness in rats. Hippocampal 5-HT release was examined as the biochemical marker showing some correlation with the effect of adrenalectomy on LH behavior. We have found that rats having bilateral adrenalectomies exhibit a significantly higher number of failures than sham operated controls and non-operated controls (11.07 ± .63 ADX vs 5.67 ± .75 sham and 6.8 ± .44 non-operated controls). The release of ^{3}H-serotonin from hippocampal slices one day after shock escape testing was significantly lower in ADX rats with pronounced LH behavior compared to non-escape deficient sham controls. Oral corticosterone replacement did not reverse the behavioral deficit, but hippocampal 5-HT release in ADX + CORT replacement rats was comparable to sham controls and non-operated controls. These results implicate the serotonergic system as a possible mediator of the accentuated behavioral deficit observed in ADX rats (supported by grants BNS-8614098 and MH4404801 to E. Edwards).

STRESS-RELATED EFFECTS OF LONG-TERM CALORIC RESTRICTION ON PLASMA CORTICOSTERONE AND VASOPRESSIN IN THE FEMALE RAT: A NEW METHODOLOGICAL APPARATUS. J.K. Nishita, E.H. Ellinwood, Jr., W.J.K. Rockwell*, J.C. Ritchie*, and C.M. Kuhn. Depts. of Psychiatry and Pharmacology, Duke Univ. Med. Cntr., Durham, NC 27710.

A new method for studying stress of prolonged caloric restriction in the rat was used. In this paradigm weaning rats were required to crawl back-and-forth across Plexiglass tubes in order to obtain food and water that was placed on opposite sides of a barrier. If a rat could not squeeze through the tube passageway, it was denied access to either food or water. We have previously shown that the onset and severity of caloric restriction can be controlled by changing the diameter of the tube passageway (Small tube (ST)=3.3 cm, Large tube (LT)=4.2 cm; Nishita et al., 1987) and these rats learn to reduce their daily food and water intakes to compensate for the ST and LT conditions.

Because our paradigm could also impose significant stress, we measured plasma corticosterone (CORT) and vasopressin (VP) levels in rats housed for 90 days in ST and LT conditions and in littermate controls housed without tube conditions. Only ST rats (n=8) showed elevated CORT (27.5 ug/dl) and VP (17.9 pg/ml) compared to LT littermates (12.3 ug/dl and 5.1 pg/ml, respectively) and controls (9.8 ug/dl and 5.6 pg/ml, respectively).

178.11

ANORECTIC EFFECT OF CRF DECREASES WITH REPEATED ADMINISTRATION.

D.D. Krahn, B.A. Gosnell and M.J. Majchrzak. Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109-0116.

CRF(icv) causes acute anorexia, and CRF levels are elevated in the CSF of patients with depression and anorexia nervosa. Therefore, it has been hypothesized that repeated, stress-induced elevations of CRF cause the symptom of chronic anorexia seen in these disorders. However, the effects of repeated CRF(icv) administration on feeding and body weight have not been studied. In this study, rats were treated daily with CRF (1.1 nmole icv) or a daily 2-hour restraint stress period. Controls received daily icv injections of saline. Nocturnal food intake (2,4,12, and 22 hours) and body weight were measured over 5 consecutive days. Both CRF (icv) and restraint caused significant reductions in short-term food intake. There was a significant treatment X day interaction which was due to a decreased anorectic effect of CRF and restraint. CRF treatment decreased 4-hour intake to 10% of control on day 1 but only decreased intake to 50% of control on day 5. Restraint-treated animals showed smaller but similar changes over time. A second experiment with a lower dose of CRF (0.22 nmole) showed similar results. In both experiments, saline-, CRF- and restraint-treated animals showed no differences in daily weight-gain increments. Thus, repeated exposures to CRF or restraint result in an adaptation to their anorectic effects. Further research will examine the effects of CRF administered continuously or with different frequencies.

178.12

MORPHINE INCREASES ACTH AND B-ENDORPHIN PLASMA LEVELS DURING HYPOTHERMIA.

C. Alcaraz*, M. Lovitz*, H. Turndorf* and M.M. Puig, Dept. Anesthesiology, N.Y.U. Medical Center, New York, NY 10016.

The effect of intravenous morphine (MS) on plasma levels of ACTH, B-endorphin (B-END), histamine (HIS) and catecholamines (CA) was determined in two groups of dogs at 37 and 30°C. Animals were anesthetized with isoflurane and MS (1 mg/kg IV) administered two hours after the desired temperature was obtained. ACTH, B-END, HIS and MS were determined by RIA and CA levels by REA. Cooling from 37 to 30°C significantly increased CA plasma levels. MS produced a significant increase in ir ACTH, B-END and HIS, and a reduction in CA levels at 30 but not at 37°C. At all sampling times, MS plasma levels were significantly higher at 30 than at 37°C. Our results show that mild hypothermia enhances the effects of MS on hormonal release.

	37°C		30°C	
	Pre	Post	Pre	Post
MS (ng/ml)	0	353±64	0	648±65a
HIS (ng/ml)	12.5±2	17.8±3	12±1	21.8±3b
B-END (pmol/l)	32.3±4	34±5	27±2	44.6±2b
ACTH (pg/ml)	106±5	143±24	140±18	296±52b
CA (pg/ml)	733±67	647±98	1310±280a	320±47b

Post: Values obtained five minutes after MS. a, $p<0.05$ when compared to 37°C group and b, $p<0.05$ when compared to pre-values in the same group. (Student's t-test)

178.13

AN EXTRACTION PROCEDURE FOR PLASMA ACTH.

E.H.Mougey*, L.M.Lambe*, J.L.Meyerhoff and G.J.Kant. (Spon: H.C. Holloway). Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

The need for a specific, sensitive, reproducible assay for ACTH in human plasma capable of detecting relatively small changes in levels following emotional stimuli in human subjects led to the development of an extraction procedure for use in conjunction with a readily available ACTH radioimmunoassay (RIA) kit (INCSTAR Corp.).

The extraction was performed by adding 500 ul of plasma and 500 ul of water to 150 mg of (methanol pre-rinsed) PrepPAK-500/C18 (Waters) in 12X75 mm tubes. After standing for 30 min with mixing and centrifugation at 6000 rpm, the supernatants were removed by aspiration. The adsorbent in each tube was rinsed three times with 1 ml of distilled water and ACTH was eluted with two 1 ml rinses of acetone:water (50:50). Following evaporation to dryness at 45°C under nitrogen, the concentration of ACTH in each tube was determined by RIA.

Recovery of ^{125}I-ACTH (Peninsula Labs.) added to plasmas (endogenous range 5-76 pg/ml) was 64.7 % with no indication of deviation from the mean at high or low plasma levels. Sensitivity of the assay was 2pg/ml. Plasma samples from volunteer subjects were assayed directly and as well as after the extraction procedure for comparison purposes. In some subjects there was a good correlation between the extracted vs non-extracted values while in others there were significant differences indicating that routine extraction is necessary to insure the accurate measurement of ACTH in human plasma using this antiserum.

178.14

COCAINE-INDUCED CARDIOVASCULAR (CV) AND PITUITARY-ADRENAL STIMULATION: ROLE OF DOPAMINE (DA) AND CORTICOTROPIN RELEASING HORMONE (CRH).

J.A. Kiritsy-Roy, S.M. Standish*, R.D. Whitmore*, M. Smith*, J.B. Halter* and L.C. Terry. Dept. of Neurology, Inst. of Gerontology, Univ. of Michigan and Veterans Admin. Med. Center, Ann Arbor, MI 48105.

Cocaine is a potent CV stimulant but its mechanism of action is unclear. It appears that the reinforcing properties of cocaine relate to inhibition of DA uptake, and cocaine self-administration is blocked by D-2, but not D-1 blockers. Recently, Rivier and Vale (Brain Res. 422:403, 1987) reported that cocaine induces ACTH secretion by a CRH-dependent mechanism. These studies examine the role of CRH in the CV effects of cocaine, and also determine if the selective D-1 antagonist, SCH 23390 (SCH), or the D-2 antagonist, eticlopride (ETC) modify CV or pituitary-adrenocortical responses to cocaine.

Experiments were conducted using freely behaving rats with a cannula in the carotid artery for blood sampling and CV recording. Arterial pressure (AP) and heart rate (HR) were monitored continuously and blood samples (0.5 ml) were drawn before and at intervals following treatment with cocaine (25 mg/kg ip) in combination with saline, SCH (0.1 mg/kg ip), ETC (0.075 mg/kg ip), CRH antiserum (1.0 ml ia), or pre-immune serum. Concentrations of ACTH and corticosterone (CS) were determined in plasma by radioimmunoassay.

Cocaine increased systolic and diastolic AP by 31±4 and 24±4 mmHg and decreased HR by up to 60±10 bpm. These effects were not altered by pretreatment with CRH antiserum, SCH or ETC. Cocaine also increased plasma ACTH from 47±9 to 585±60 pg/ml and CS from 13±4 to 38±5 ug%. Although CRH antiserum completely antagonized ACTH responses to cocaine, CS responses were not blocked. Both SCH and ETC blocked the ACTH response to cocaine. Conclusions: 1) CRH, D-1 and D-2 receptors mediate ACTH releasing but not CV effects of cocaine and 2) cocaine may stimulate CS secretion directly.

178.15

CLASSICAL CONDITIONING OF A CRF MODULATED ELEVATION OF ARTERIAL BLOOD PRESSURE.

M.Kreutz#, D.Hellhammer, H.Lehnert and R.Murison#, Universities of Bochum, Trier, Mainz (F.R.G), and Bergen (Norway)

It has recently been shown that an i.c.v. application of CRF results in an elevation of arterial blood pressure. To investigate the role of CRF as a possible mediator of a psychologically induced elevation of blood pressure, we tried a classical conditioning of these autonomic effects of CRF. Six adult male Wistar received implants of guided cannulas into the lateral ventricles, and chronic catheders into the abdominal aortis. A Stathan pressure transducer combined with a Siemens Sirecust recorder were used for monitoring of arterial blood pressure. After recovery from surgery, the animals were exposed to 8 daily sessions, where they received 4 conditioning and 4 control trials in an alternating way. As the CS, the rats received an i.a. injection of .2 ml of a 0.154 molar saccharine solution, and, at the same time, 2 ul i.c.v. hCRF (150 pmol) as the UCS. During the control sessions the animals received same volumes of a Ringer solution (icv) and isotonic saline solution (i.a.), respectively. A significant increase of arterial blood pressure from 93.1 to 103.8 mm Hg was observed 30 min after CRF, while no changes occured after placebo application. Two test sessions were performed one and three days later, where the rats received the CS, but the UCS was replaced by Ringer solution (i.c.v.). Under these conditions, CS presentation alone resulted in a significant increase of blood pressure from 92.0 to 97.3 mm Hg, suggesting a classical conditioning of CRF effects on blood pressure. (Supported by a twinning grant of the European Science Foundation to D.H. and R.M.)

CORTICOTROPIN-RELEASING FACTOR (CRF) MEDIATES LOCUS CERULEUS (LC) ACTIVATION BY HEMODYNAMIC STRESS.

Rita J. Valentino and Richard G. Wehby*. Department of Pharmacology, George Washington University Medical Center, Washington, D.C. 20037.

CRF has been hypothesized to act as a CNS neurotransmitter, being released by stressful stimuli in brain circuits to initiate a multicomponent response to stress. The LC, may be a target for CRF neurotransmission because CRF-containing fibers have been localized in LC, and exogenous CRF alters LC discharge. To test this hypothesis, the effects of a hemodynamic stressor, i.v. nitroprusside infusion (NIT), on LC discharge of halothane-anesthetized rats were compared to those of i.c.v. CRF. Like CRF, NIT increased LC spontaneous discharge rate and attenuated LC discharge evoked by sciatic nerve stimulation. To determine whether endogenous CRF mediates these effects of NIT, the ability of dexamethasone or α helical CRF_{9-41}, a CRF antagonist, to attenuate NIT effects was determined. Dexamethasone, which decreases hypophyseal CRF release by NIT, did not alter NIT effects on LC discharge. In contrast, α helical CRF_{9-41} (50 µg, i.c.v.) completely blocked increases in LC spontaneous discharge produced by NIT. The results indicate that certain hemodynamic stressors activate the LC and this is mediated by extrahypophyseal CRF. These findings support a neurotransmitter role for CRF in the LC. Supported by NIH Grants DA 03695 and MH 40008.

EFFECT OF CHRONIC STRESS ON THE LEVEL OF CORTICOTROPIN-RELEASING FACTOR (CRF) mRNA IN RAT BRAIN T.Imaki*, J.L.Nahon*, C.Rivier, P.Sawchenko and W.Vale. Clayton Foundation Laboratories for Peptide Biology, Developmental Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037.

CRF plays a physiologically important role in the response to stress. However, the molecular mechanisms which control CRF biosynthesis during stress are not known . We examined the effect of chronic stress on the level of CRF mRNA in the rat brain by Northern blot analysis and *in situ* hybridization. Male Sprague-Dawley rats were exposed to intermittent footshock stress (1.5 mA. 1 sec duration, 60 times during 30 min, twice daily for 1, 3 or 7 days). Twenty-four hours after the last shock session, the rats were decapitated and RNA was extracted from 8 different brain regions by Glowinski's method. By Northern blot analysis, CRF mRNA (1.4kb) was detected in brainstem>olfactory bulb>hypothalamus>cortex>midbrain. CRF mRNA levels increased about 1.6 times over control values after 3 days of stress, while no significant change was seen in extrahypothalamic area after stress. Using *in situ* hybridization, CRF mRNA-positive grains were detected predominantly in the parvocellular division of the paraventricular nucleus (PVN). CRF mRNA levels in the PVN selectively increased after stress. Maximum induction was seen after 3 days of stress; CRF mRNA levels had returned to control level after 7 days of stress. These results suggest that chronic stress induced in increase in CRF mRNA levels in PVN.

SEROTONERGIC REGULATION OF CORTICOTROPIN-RELEASING FACTOR (CRF) NEURONAL ACTIVITY IN VIVO. P.E. Bond*, M.J. Owens, G. Bissette and C.B. Nemeroff (SPON: M. Bowman). Duke Univ. Med. Ctr., Durham, NC 27710.

Corticotropin-releasing factor (CRF) is the principal physiological regulator of the hypothalamic-pituitary-adrenocortical (HPA) axis. Previous studies have demonstrated a potassium-induced, calcium-dependent CRF release from hypothalamus, amygdala, midbrain, and striatum. In the present studies, we examined the effects of acute and chronic treatment with several drugs which act on serotonergic systems in order to elucidate which serotonergic receptor subtypes alter CRF neuronal activity.

Rats were treated with a single (acute) or daily (chronic) injections of the following serotonergic drugs: ketanserin (a $5HT_2$-specific antagonist), quipazine (a 5HT agonist), 4-bromo-2,5-dimethoxyamphetamine (DOB, a $5HT_2$-specific agonist), or vehicle. The rats were decapitated and blood was collected for measurement of plasma ACTH and corticosterone concentrations by radioimmunoassay. Anterior pituitary glands were removed and CRF receptor affinity (K_D) and density (Bmax) were measured. Brains were removed and 18 brain areas were microdissected. Brain samples were assayed for CRF concentration, CRF mRNA levels and autoradiographic analysis of CRF receptor density.

Acute and chronic treatment with quipazine and DOB produced an increase in plasma concentrations of corticosterone and ACTH. In contrast, ketanserin did not alter plasma ACTH or corticosterone concentrations. In agreement with the above findings, acute quipazine decreased the concentration of CRF in the median eminence, although not significantly. Chronically, quipazine produced pituitary CRF receptor down-regulation.

These preliminary data suggest that hypothalamic serotonergic neurons activate the HPA axis perhaps via both $5HT_1$ and $5HT_2$ receptor mechanisms. (Supported by NIMH MH-42088)

RELEASE OF CORTICOTROPIN-RELEASING FACTOR (CRF) FROM THE BOVINE MEDIAN EMINENCE (ME) IN VITRO. T.H. WELSH*, M.R. SUTTON*, D.D. ZALESKY*, P.G. HARMS*AND N.H. MCARTHUR. Texas A&M Univ., College Station, TX 77843

The effect of norepinephrine (NE) on CRF release from the ME was studied. Individual ME halves from heifers (n=10) were perifused for 400 min with Krebs-Ringer bicarbonate medium (500-µl chambers; 5.5 mM glucose, 95% O_2:5% CO_2; 37°C; 1 ml/10 min fractions for CRF RIA). ME halves were challenged with NE (0.5 or 5 mM) or 5 mM clonidine for 30-min periods at 130 and 220 min of perifusion. The initial 0.5 mM NE challenge did not affect CRF release whereas the second 0.5 mM NE challenge increased CRF release 2-fold. The initial 5 mM NE challenge increased CRF release (25±6 pg/ml pre-NE to 140±6 pg/ml 30 min post-NE). Similarly, the second 5 mM NE challenge increased CRF release (from 9±2 up to 121±13 pg/ml). Clonidine (an α_2 agonist) treatment did not alter CRF release. Potassium (60 mM) challenge increased (∿10-fold) CRF release from NE and clonidine treated ME. In summary, NE stimulated CRF release from the bovine ME in vitro. This model system may facilitate the study of neurotransmitter regulation of hypothalamic release of CRF.

STRESS-INDUCED GH FALL IS INDEPENDENT OF CRF IN NEONATAL RATS. C.M. Kuhn, L. Nathan* and S.M. Schanberg*. Dep't of Pharmacology, Duke University Medical Center, Durham, NC 27710.

Corticotropin releasing factor (CRF) is postulated to organize stress responses, including the decline of growth hormone (GH). However, in 3-4 day old rats, separation from the mother (MS) causes a fall of GH but no rise in corticosterone (CS). To determine if this fall in GH is mediated by CRF, two strategies were used. Serum GH was measured in 4-10 day old rats after CRF injection intraventricularly (ivt). Also, the ability of the CRF antagonist alpha helical CRF 9-41 (CRF-A) to block the separation-induced GH fall was studied. CRF (.001-1 ug) did not suppress, and actually stimulated GH 88% at 0.1 ug ($p<.001$) in 4 d.o. pups, although it produced a significant 4-5 fold rise in CS. Adrenergic agonists increased CS but did not suppress GH. Finally, CRF-A (50 ug ivt) did not block the fall in GH during MS. These results suggest that during ontogeny, stress-induced inhibition of GH secretion precedes stimulation of CRF release, and raise the possibility that stress-induced GH inhibition can occur independently from CRF. STRESS, HORMONES AND AUTONOMIC NERVOUS SYSTEM II

179.1

ALTERED GLYCEMIC AND NEUROCHEMICAL RESPONSES TO HYPOXIC STRESS IN STREPTOZOTOCIN-DIABETIC RATS. L.L. Bellush & W.N. Henley*, Depts. of Psychology and Zoological & Biomedical Sciences, Athens, Ohio 45701

Diabetic (D) and nondiabetic (N) rats were exposed to hypobaric hypoxia (simulated altitude=12,000 ft) for 24 hrs and compared with normoxic control(n=7). All D rats had lower DOPAC/DA ratios in hypothalamus (HYP) and striatum (STR), and lower 5HIAA and 5HIAA/5HT ratios in HYP, brainstem (BST), STR and frontal cortex (FCX), than N rats. They also excreted more urinary NE than N. Hypoxic D and N rats had significant (17%) reductions of NE in HYP and signigicant reductions of DOPAC/DA ratios in HYP and STR. Hypoxia had no effects upon 5HIAA or 5HIAA/5HT ratios in D rats, while it reduced both in N rats, with significant interactive effects in BST. Hypoxic D and N rats had reduced food and water intakes. Hypoxic D rats also experienced significant elevations in plasma glucose concentration and NE excretion. Taken together, these results indicate that diabetic rats show enhanced vulnerability to hypoxic stress, making it a useful tool for exploring mechanisms of metabolic decompensation associated with stress in diabetes.

179.2

CARDIORESPIRATORY, PLASMA CATECHOLAMINE AND BEHAVIORAL RESPONSES FROM STIMULATION OF THE PERIAQUEDUCTAL GREY REGION IN THE RABBIT. C.G. Markgraf, D.R. Liskowsky, P.M. McCabe, R.W. Winters*, and Neil Schneiderman. Dept. of Psychology, Univ. of Miami, Coral Gables, FL 33124.

Stimulation of the periaqueductal grey region (PAG) of the midbrain in cats and in rats is known to elicit the 'defense' reaction. This response is characterized by a constellation of behavioral and cardiovascular changes that are thought to prepare the animal for 'fight or flight'. Although stimulation of PAG and regions of the hypothalamus produce the defense reaction in cats and rats, identification of the neuroanatomical substrates of the defense reaction in rabbits has been more problematic. The present study assessed cardiovascular, respiratory, hormonal and behavioral changes elicited by electrical stimulation of the ventrolateral PAG of New Zealand albino rabbits.

The electrical stimulus was a 10 second stimulus train (100 hz, 100-250 uA). Heart rate (HR), arterial blood pressure (BP), hindlimb blood flow (BF), respiration rate and volume, and catecholamine levels were measured in pentobarbital anesthetized animals. Behavioral changes were assessed in unanesthetized, unrestrained animals by passing current through stimulating electrodes that were chronically implanted in the ventrolateral PAG.

Stimulation of the ventrolateral PAG produced a response profile in anesthetized animals that was, for the most part, characteristic of the defense reaction. Electrical stimulation led to increases in BP (20-40 mmHg), BF (0.6-1.25 cc/min), norepinephrine and epinephrine levels, and in the rate and volume of respiration; these changes were accompanied by bradycardia (20-60 beats/min). In unanesthetized rabbits, ventrolateral PAG stimulation elicited increased motor activity, which is consistent with HR increases that are characteristic of the defense reaction in freely behaving animals. Supported by NIH grants HL 07426 and HL 36588.

179.3

STRESS-INDUCED RENIN AND CORTICOSTERONE (CORT) SECRETION IS MEDIATED BY CATECHOLAMINE TERMINALS IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN). K.D. Richardson Morton, L.D. Van de Kar, M.S. Brownfield#, S.A. Lorens, J.H. Urban (SPON. W.H. Simmons). Dep. Pharmcol. Loyola U. Chgo., Med. Maywood, IL 60153 and #U. Wisconsin, Madison.

Cell bodies in the PVN mediate stress induced increases in renin and CORT secretion. In order to determine if catecholamine terminals in the PVN play a role in the neuroendocrine response to conditioned fear (CER), 6-hydroxydopamine (6-OHDA; 8.0 μg in 1.5 μl vehicle) was injected bilaterally into the PVN. Damage to noradrenergic nerve terminals in the PVN was verified by dopamine β-hydroxylase immunohistochemistry. The PVN 6-OHDA lesions prevented the CER induced increases in plasma renin activity (PRA), plasma renin concentration (PRC) and CORT levels. Subsequently, the β-receptor blocker sotalol (2.0 μg in 0.5 μl) was injected bilaterally into the PVN, 5.0 min before placement in the CER chamber for 10 min. Sotalol prevented the stress induced increase in CORT levels, but did not block the CER induced increases in PRA and PRC. These results suggest that catecholaminergic terminals in the PVN mediate the effect of stress on both renin and CORT secretion. The CER induced increase in CORT secretion, furthermore, appears to be mediated by β receptors, whereas stress-induced increases in renin secretion are mediated by another type(s) of catecholamine receptor.

INCREASES IN URINARY EPINEPHRINE ASSOCIATED WITH REALISTIC TRAINING EXERCISES. M.A. Oleshansky, F.J. Manning and C.F. Tyner*. Division of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

The stress associated with training exercises at the Chemical Decontamination Training Facility (CDTF) at the USA Chemical School, Ft. McClellan, Alabama was assessed by measurement of overnight urinary catecholamines. Military trainees at the CDTF undergo three mornings of detection and decontamination exercises while wearing a standard issue protective suit. The first morning of training takes place outdoors and simulants are employed; the second and third mornings of training take place in a controlled indoor environment and trainees are exposed to small amounts of toxic chemical warfare agents. For the purpose of this study, overnight urines were collected from 125 voluntary subjects during training with toxic agents and from 125 subjects who underwent training with simulants on all three days.

Overnight urinary epinephrine values were significantly higher on each of the three nights before the toxic agent training exercises as compared with values from the nights before the simulant exercises. Enlisted soldiers and officers who were new to the Army had higher epinephrine values during toxic agent training than seasoned non-commissioned officers and senior officers. These findings suggest that anticipation of toxic agent training was sufficient to stimulate epinephrine secretion and that prior experience influences the stress-related increases in urinary epinephrine excretion associated with toxic agent training.

ONE STRESSFUL EVENT SENSITIZES THE INCREASED FRONTAL CORTICAL DOPAMINE (DA) AND PLASMA CORTICOSTERONE ACTIVITY, BUT ATTENUATES THE ANALGESIC RESPONSE TO STRESS 10 DAYS LATER.
A. R. Caggiula, S. M. Antelman*, E. Aul*, S. Knopf* and D. J. Edwards Depts. of Psychol., Behav. Neurosci., Psychiat., and Physiol./Pharmacol., Univ. of Pittsburgh, Pittsburgh, Pa. 15260

A 40 sec. footshock (1.6 mA), administered to male rats, induced analgesia, as reflected by a significant increase in latency of tail withdrawal from a 55.5^0 C water bath. Animals exposed to a 1 hr. shock session (15, 0.5 sec. shocks) 10 days earlier showed a significant attenuation of shock-induced analgesia. Animals were sacrificed immediately after testing, and plasma corticosterone and regional brain catecholamines determined. Animals exposed to shock 10 days before testing exhibited higher corticosterone levels than all other groups. NE levels in the frontal cortex, and DA and DOPAC levels in frontal cortex and nucleus accumbens were not altered in any group. However the DOPAC/DA ratio in the frontal cortex was increased by analgesia testing, and this increase was enhanced only by the combination of shock 10 days before testing and shock immediately before the test. These results are consistent with previous reports from this laboratory which indicate that assessment of an animal's acute response to a stressor can only be understood by taking into account its past history of stress. Similar studies dealing with the effects of stress on the immune system are currently underway.

REDUCTION IN NOREPINEPHRINE WITH FLA-63 BLOCKS EXCESSIVE WHEEL RUNNING AND GLANDULAR ULCERATION DURING ACTIVITY-STRESS. N.S. Morrow and S.W. Kiefer. Department of Psychology, Kansas State University, Manhattan, KS 66506.

The role of norepinephrine (NE) in triggering excessive wheel running and gastric ulceration during restricted feeding was examined. Rats were initially matched by body weight and divided into 3 activity groups (n=10 each) and 1 home-cage group (n=10). During the 18 day testing period, each group was injected (ip) twice daily with either FLA-63 (a dopamine-B-hydroaxylase inhibitor) or saline in the 7 hr preceding the feeding session. Two activity groups were fed for 1 hr each day and injected with either FLA-63 (10 mg/kg) or saline; the third activity group was fed ad lib and injected with FLA-63. The fourth group also was injected with FLA-63 but lived in home cages during restricted feeding. Results indicated that activity rats injected with FLA-63 during restricted feeding ran less and had fewer ulcers than rats injected with saline; there were no differences in food intake, body weight, or survival between rats injected with FLA-63 or saline. Neither the home-cage nor free-feeding rats became ulcerated during testing. FLA-63 had neglible effects on food intake and body weight. It is suggested that NE contributes to diurnal increases in running and that adequate stores of NE are necessary for the survival of rats during activity-stress procedures.

SOUND STRESS-INDUCED INCREASES IN TRYPTOPHAN HYDROXYLASE (TrpH) ACTIVITY BLOCKED BY ADRENALECTOMY (ADX). V.B. Singh*, K.C. Corley, T-H. Phan*, M. Kalimi* and M.C. Boadle-Biber. Dept of Physiology, Virginia Commonwealth University, Richmond, VA 23298.

Acute sound stress (SS)(2 sec, 110 dB sound pulses, VI-1 min for 120 min) produces a 50% increase in in vitro TrpH activity, that is reversed with alkaline phosphatase or disappears in vivo if the rats are killed 1 hr after the SS. When repeated 3 days/week for 1, 2 or 6 weeks, SS produces a persistant 45% increase in enzyme activity measured 24 hr after the final SS (Boadle-Biber et al., Fed. Proc. 46:3780, 1987: Soc. Neurosci. Abstr. 13:370.20, 1987). We now report that the adrenal gland is required for both the reversible and stable increases in TrpH activity. Male Sprague Dawley rats (175-200g) were adrenalectomized (ADXD) 4 days prior to exposure to an acute SS or 1 week of repeated SS (100 msec, 110 dB sound pulses, VI-1 min, for 1 hr). This modified SS protocol increased TrpH activity in sham-operated and normal rats. However enzyme from midbrain or cerebral cortex of ADXD rats showed neither the reversible nor the stable increases in activity in response to acute or repeated SS respectively. Dexamethasone (300 or 500μg/ day i.p. in DMSO for 3 days) 4 days after ADX restored the response in ADXD animals and did not alter the response in sham operated rats. Aldosterone (5μg/day, pellet s.c) was ineffective. Supported by NIH NS14090 to M.C.B-B.

STRESS CAN AFFECT DIFFERENTIALLY THE HUMORAL AND CELLULAR IMMUNE RESPONSES. J. Amat* and A. Torres* (SPON: E. Jaffe). Inst. Med. Exp., Univ. Central Ven., Apartado 50587, Caracas, Venezuela.

Stress is generally reported to depress or enhance the immune response depending on certain characteristics of the stressor. Since the immune response involve a variety of cellular elements and mechanisms, we decided to explore the effects of a single type of stress on some of the principal types of immune responses. Sprage Dawley (SD) and Wistar (W) female rats, and SD/W hybrids, of 180-250 g were used. Inescapable footshock stress was administered for 4 consecutive days. Immediately after the last shock session the rats, and their controls, were subjected to one of the following protocols: 1) Intraperitoneal injection of 10^7 sheep red blood cells (RBC) followed by tail blood extraction, every three days for 20 days, for testing anti sheep RBC seric antibodies, 2) Removal of the spleen (SD strain) and isolation of limphoid cells for hindlimb footpad injection in unstressed hybrids, whose popliteal ganglia were isolated and weighted 7 days later (graft vs host assay), 3) subcutaneous injection of a standarized dose of syngenic Walker carcinoma cells. It was found that the anti sheep RBC titer of stressed rats was significantly lower than that of controls. However, the graft vs host response and tumor rejection were higher in stressed animals. Therefore, it appears that stress may affect differentially the humoral and cellular immune responses.

ACUTE STRESS LOWERS SERUM CHOLESTEROL EVEN IN RATS ON A CHOLESTEROGENIC DIET. G.D. Coover and B.W. Santi*. Dept. of Psychology, Northern Illinois Univ., DeKalb, IL 60115.

Male rats aged 200 days were fed a mash diet for 10 days before assessing total- and high density lipoprotein-cholesterol (total-c and HDL-c) in jugular vein serum before and after a 3-hr stress period. Subgroups were given a cholesterogenic diet (lab chow plus 1% cholesterol and .5% cholic acid), and a 160-min session of moderate footshocks (2 s each on a VI 2-min schedule). Rats receiving the high cholesterol diet for 10 days exhibited a 98% increase in serum total-c (control mean = 79 mg/dl) along with a 38% decrease in HDL-c (control mean = 51 mg/dl).

The jugular sample/footshock stress decreased total-c by decreasing lower density lipoprotein-cholesterol (lDL-c). In the rats fed plain lab chow diet, the 12% decline in total-c ($p<.01$) and non-significant decrease in HDL-c replicate results with younger (90-day) rats (Coover & Murry, Soc. Neurosci. Abstr., 1987). Present results also show that a jugular blood sample alone does not cause any change in lDL-c, while causing a small (3 mg/dl) decrease in HDL-c, even in rats on the cholesterogenic diet.

Rats on the cholesterogenic diet exhibited a 20% decrease ($p<.001$) in total-c during the 3-hr stress of a jugular blood sample plus footshock. The effects of acute stress are clearly at odds with the expected effects of chronic stress (Bryant, Story & Yim, Life Sciences, 1987, 41, 545. (Supported in part by BRSG S07 RR07176, NIH.)

ULTRASONIC VOCALIZATIONS ARE PART OF THE RAT'S CONDITIONED EMOTIONAL RESPONSE. R.J. Frysztak*, L. Plopa & E.J. Neafsey Dept. of Anatomy, Loyola Univ Med Ctr, Maywood, IL 60153

Six male Sprague-Dawley rats were conditioned to a tone paired with a footshock. The following day heart rate (HR), respiration (R), and ultrasonic vocalization (USV) were recorded continuously during three trials in which only the tone was presented. Animals responded initially to the tone with increases in HR (+15 bpm) and R rate. Behaviorally, the rats "froze" during and after the tone. USV began after a variable latency period (5 to 45 sec after tone offset), and R rate and pattern changed dramatically with the onset of USV. R rate at rest was 1.5 Hz; during the tone the rate increased to 2.7 Hz; during USV the rate became highly variable, but averaged <1 Hz. USV varied in both intensity and duration (0.5 to 2 sec). HR increased 20 bpm from baseline during USV, and HR variability was also markedly increased. Freezing was paired with USV, such that during USV there was no movement. The average number of USV per trial decreased over the 3 trials (from 220 to 65), as did the total time period for USV and freezing (5:56 to 2:48). The number of USV/burst also decreased over the 3 trials (11.2 to 3.75). USV in rats has been reported following footshock (Tonue, Psychoneuroend 11. 1986) and during the natural stress of being introduced into the home cage of a dominant rat (Fokkema, LS 38. 1986). To our knowledge this is the first report of classically conditioned USV to the CS alone. (Funded by Potts Estate Fund Grant 842-04).

SYMPOSIUM. NEW INSIGHTS INTO THE FUNCTIONS OF THE BASAL FOREBRAIN CHOLINERGIC SYSTEM. R.T. Richardson, Johns Hopkins Univ. (chairperson); M.M. Mesulam, Beth Israel Hospital; M. Steriade, Univ. of Laval; R. Dykes, Univ. of Montreal; D. Olton, Johns Hopkins Univ.

Recent advances in understanding the anatomical and physiological properties of the basal forebrain cholinergic system (BFCS) indicate how it may be specifically involved in various functions including cortical activation and memory formation. **Dr. Mesulam** will provide an overview of the anatomical connections of the BFCS emphasizing the strong interconnections with limbic-related areas. **Dr. Steriade** will review evidence for a projection from the BFCS to the reticular thalamic nucleus. He will also discuss the role of basal forebrain and brainstem cholinergic afferents in thalamocortical activation. **Dr. Dykes** will review recent studies of the effects of ACh applied directly to neurons. He will emphasize the long-term duration of the changes in cortical neurons produced by application of ACh or stimulation in the basal forebrain. **Dr. Richardson** will summarize recent studies of the activity of single BFCS neurons in behaving animals. He will discuss the implications of the responses of BFCS neurons to stimuli associated with reinforcement. **Dr. Olton** will conclude the symposium with a review of the effects of BFCS manipulations on several behaviors, particularly on memory and attention.

182

NEURONAL GENE EXPRESSION: PHYSIOLOGICAL ACTIVATION, TRANSCRIPTIONAL CONTROL AND DNA BINDING PROTEINS.
M.J. Iadarola, NIH (chairperson) **W.S. Young III**, NIMH; **J. Douglass***, Oregon Health Sci. Univ.; **M. Comb***, Mass. Gen. Hospital; **M. Montminy***, Salk Inst. and **D. Levens***, NIH.

Many genes important to nervous system function and structure have been isolated and their protein products characterized. This has provided a foundation of structural information at the genetic, cellular and neuroanatomical levels. Relatively recent developments built upon this foundation have led to new insights into the mechanisms by which neuronal gene expression is regulated and the in vivo situations in which regulation occurs. This symposium will examine control of neural gene expression from experimental, conceptual and methodological standpoints. An initial analysis of enhanced expression due to specific physiological or environmental stimuli will progress to an examination of DNA enhancer/promotor sequences responsible for tissue- or stimulus-specific expression. The precise nucleotide sequences of several of these regulatory regions, termed cis-acting DNA elements have been identified. They are known to mediate enhanced gene expression due to activation of adenylate cyclase and/or phosphatidyl inositol second messenger systems. These sequences are also recognition sites for specific DNA binding proteins or trans-acting factors. The enhancer elements can be composed of multifunctional domains that interact with several specific proteins. Several proteins that mediate or participate in trans-activation have been isolated and the dynamic process that regulate their binding and thereby the expression of the target gene will be discussed. Experimental evidence suggests that phosphorylation and cooperative interaction between several such proteins are important factors in governing enhanced transcription and ensuring specificity. Supported by Genentech, Inc. and Bethesda Research Laboratories.

AMINO ACIDS: GABA AND BENZODIAZEPINES IV

183.1

BENZODIAZEPINE RECEPTOR SUBTYPES IN THE RAT SPINAL CORD: MODULATION BY γ-AMINOBUTYRIC ACID (GABA). M.G. Corda, B. Longoni* and G. Biggio. Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy.

In the present study we evaluated the relationship between GABA receptors and benzodiazepine (BZD) recognition site subtypes in the rat spinal cord. Scatchard analysis of saturation data indicated that Type I sites labelled with ^{3}H-2oxoquazepam (^{3}H-2-OQ) and ^{3}H-ethyl-β-carboline-3-carboxylate (^{3}H-βCCE) were approximately 20% of the sites labelled by ^{3}H-flunitrazepam (^{3}H-FNT) (Bmax, fmoles/mg prot.: ^{3}H-FNT 0.23 ± 0.04; ^{3}H-2-OQ 0.05 ± 0.01; ^{3}H-βCCE 0.04 ± 0.01). The "in vitro" addition of GABA (10^{-8} to 10^{-4} M) stimulated both ^{3}H-FNT and ^{3}H-2-OQ binding in a concentration-dependent manner. The maximal enhancement, produced by 10^{-4} M GABA, was 48 and 85% above control values for ^{3}H-FNT and ^{3}H-2-OQ binding, respectively. We also evaluated the effect of BZDs on the binding of ^{3}H-GABA to spinal cord membranes, as compared with brain areas that contain a higher proportion (≥ than 40%) of Type I BZD recognition sites. Diazepam and 2-OQ (10^{-7} to 10^{-5} M) increased the specific binding of ^{3}H-GABA in membranes from the cerebral cortex, cerebellum and hippocampus, but not in spinal cord membranes. The results indicate that: a) both Type I and Type II sites in the spinal cord are linked to GABA receptors, and b) the stimulation of ^{3}H-GABA binding by BZDs is present only in areas that contain more than 40% of Type I BZD recognition sites.

183.2

QUAZEPAM AND 2OXOQUAZEPAM ARE THE MOST EFFECTIVE BENZODIAZEPINE (BZ) RECEPTOR LIGANDS AS INHIBITORS OF ^{35}S-TBPS BINDING IN THE RAT BRAIN. A. Concas*, M. Serra*, T. Atsoggiu* and G. Biggio. Dept. of Exp. Biol., Univ. of Cagliari, Italy.

The effect of several BZ receptor ligands on ^{35}S-TBPS binding sites associated to the GABA-dependent chloride channel was studied in unwashed membrane preparations from rat cerebral cortex. Quazepam and 2oxoquazepam were the most effective inhibitors of ^{35}S-TBPS binding producing 100% inhibition at concentrations near 30 μM, an effect similar to that induced by GABA (100 μM) and muscimol (10 μM). In contrast, other BZs were much less potent. In fact the maximal inhibition (23 ± 2% of control) was observed in the presence of 100 μM diazepam or flunitrazepam. Flurazepam inhibited ^{35}S-TBPS binding in the presence of 300 nM to 10 μM concentrations; concentrations higher than 10 μM induced an opposite effect. Zolpidem and Cl 218872, two non BZ compounds having high affinity for the Type I BZ recognition site inhibited ^{35}S-TBPS binding with less efficacy than BZs (49 and 40% of control at 100 μM, respectively). The rank order of efficacy for the above compounds as inhibitors of ^{35}S-TBPS binding was muscimol > quazepam >GABA=2oxoquazepam> flunitrazepam=diazepam> Cl 218872> zolpidem> flurazepam. The different efficacy of these BZ receptor ligands on ^{35}S.TBPS binding may reflect:a)a different interaction with the Type I and/or Type II BZ receptors, b)a different coupling of these receptors with the Cl channel. This mechanism may be responsible of their different pharmacological profile.

183.3

DEVELOPMENTAL HETEROGENEITY OF THE POSTSYNAPTIC GLYCINE RECEPTOR IN RAT SPINAL CORD. **C.-M. Becker*, W. Hoch*, and H. Betz. ZMBH, Universität Heidelberg, Im Neuenheimer Feld 282, D-6900 Heidelberg, Fed. Rep. of Germany**

The inhibitory glycine receptor from spinal cord is a glycoprotein of ≈250k composed of three polypeptides of 48k, 58k, and 93k. The ^{3}H-strychnine binding site is located on the 48k subunit.

^{3}H-strychnine binding is low in neonatal rat spinal cord. A search for glycine receptor-associated antigens, however, revealed the presence of high levels of mAb 4a epitopes which have been assigned to the 48k polypeptide. This neonatal mAb 4a antigen sediments as a protein complex of ≈250k. It could be separated from adult glycine receptor by immunoprecipitation using another mAb. Furthermore, it bound to a 2-aminostrychnine affinity column and was eluted from this column by lower concentrations of glycine than the adult receptor. These data indicate that neonatal spinal cord contains a glycine receptor species of low strychnine binding affinity. Cell cultures of embryonic mouse spinal cord almost exclusively express the neonatal glycine receptor.

TAURINE INDUCED CHANNELS IN MEMBRANE PATCHES EXCISED FROM CULTURED SPINAL CORD NEURONS. D.A. Mathers* and Y. Wang* (Spon: D.F. Schwarz). Department of Physiology, University of British Columbia, Vancouver, B.C., V6T 1W5 Canada.

The monocarboxylic amino acid taurine is present at high levels in the mammalian brain. It has also been shown to exhibit marked anticonvulsant activity in human epilepsy. Available evidence suggests that taurine may activate chloride-dependent membrane conductances controlled by the inhibitory transmitters gamma-aminobutyric acid (GABA) and glycine. To investigate this hypothesis, we compared the properties of chloride channels induced by taurine (40 uM), GABA (1.5 uM) and glycine (1.5 uM) in outside out patches excised from mouse spinal cord neurons growing in primary culture. Experiments took place at 21-23 °C using a List EPC-5 patch clamp amplifier. Taurine induced single channel currents reversed at the equilibrium potential for chloride ions. Compared to events triggered by GABA, taurine induced currents showed less tendency to occur in a burst-like manner. Substate conductance levels were observed for all three amino acids. However, taurine induced events showed a significantly greater tendency to enter the larger conductance states than currents activated by GABA in the same membrane patches.

183.5

BEHAVIORAL CHARACTERIZATION OF GABA/BENZODIAZEPINE (BZ) RECEPTOR SUBTYPES USING A MODIFIED VOGEL CONFLICT PARADIGM. C.Wambebe, A. Berkovich, A. Guidotti and E. Costa., FGIN, Georgetown Univ., Washington, D.C. 20007.

Rat diazepam binding inhibitor (DBI 1-86) extracted from rat brain is a putative precursor of neuropeptides which function as negative allosteric modulators of various $GABA_A$ receptor subtypes. TTN (DBI 17-50), EPN (DBI 26-50) and ODN (DBI 33-50) induced proconflict activity when injected intraventricularly in rats. The nature of the $GABA_A$ receptor involved in the proconflict behavior was unvailed by pretreatment with specific antagonists for various BZ recognition sites. Flumazenil, (a ligand for GABA receptors with beta carboline, $GABA_{A1}$, and anxiolytic BZ, $GABA_{A1}$-$GABA_{A2}$, recognition sites) antagonized the proconflict effects of ODN and that of the anxiogenic beta carbolines (FG 7142) but was ineffective aganist TTN and 4-chloro-diazepam, (Ro 5-4864), a ligand for peripheral BZ sites coupled to brain $GABA_{A3}$ receptors. On the contrary, isoquinoline carboxamide, PK 11195, (an antagonist of modulator sites of $GABA_{A3}$ receptors) blocked the proconflict effects of Ro 5-4864 and TTN but not that of FG 7142 or ODN. Thus, the proconflict activity induced by natural processing products of DBI is mediated through a specific action on different BZ recognition sites that characterize $GABA_A$ receptor subtypes.

183.6

SODIUM-INDEPENDENT ^{35}S-CYSTEINE BINDING TO FROZEN/THAWED AND EXTENSIVELY WASHED SYNAPTOSOMAL-MITOCHONDRIAL FRACTIONS. C.H. Misra. Dept. of Psychiatry and Behavioral Sciences, U.T. Medical School, Houston, Texas 77030.

Previous studies in our laboratory have demonstrated the existence of a specific-independent cysteine binding to synaptic membrane preparation of rat brain (Misra, J. Neurochem., 48S, 1987). This binding however has been done in Tris-HCl medium (containing 2.7 mM $CaCl_2$, 1.2 mM $MgCl_2$, 5 mM KCl, 256 mM sucrose and 50 mM Tris-HCl) buffer, pH 7.4. In an extended study it has been found that the binding increased about one and a half times, when the binding was carried out only in Tris-HCl buffer pH 7.4. Therefore the experiments were conducted in Tris-HCl buffer, pH 7.4 using lysed crude synaptosomal-mitochondrial (P_2) fraction from rat brain tissue, which has been frozen/thawed. Binding reached maximum at 15 minutes, slightly increased thereafter and then remained constant for approximately 90 minutes, whereas the frozen/thawed synaptic membrane preparation reached maximum at 15 minutes, slowed down, and increased at a slow space for 90 minutes. The significance of the binding constants (K_D and B_{max}) of different treatment of synaptosomal-mitochondrial preparations and their displacement constants (IC_{50}) with cysteine, and its analogues and other neuroexcitatory amino acids will be discussed.

183.7

ω-CONOTOXIN GVIA BLOCKS GABA RELEASE FROM CHICK CEREBRAL NEURONS. C.L. Thompson* and E.M. Barnes, Jr. Dept. of Biochem., Baylor Col. of Med., Houston, TX 77030.

Cultured cortical neurons were loaded for 60 min with [^{3}H]GABA (1 μM, 2 μCi/ml) in Hepes-buffered saline. After washing and a 15 min incubation in fresh saline, the cells were transferred to release media containing 40 mM K. Depolarization-evoked [^{3}H]GABA release was determined after 5 min and corrected for the efflux which occurred in normal saline (5 mM K). K-evoked release accounted for 7-9% of the [^{3}H]GABA pool and represented more than twice that observed in 5 mM K. Addition of EGTA (1 mM) and Ca omission blocked over 75% of K-evoked GABA release. ω-Conotoxin GVIA (50 nM) produced a 50% inhibition of GABA release, while nitrendipine (10 μM) gave less than a 15% reduction. However, after 10 min in 40 mM K, nitrendipine produced a 40% inhibition.

We have shown previously that midazolam (0.1 μM) induces a ^{36}Cl uptake into cortical neurons which, although found in the absence of exogenous GABA, is mediated by GABA-A receptors. ω-Conotoxin (50 nM) blocked over 80% of the midazolam-dependent ^{36}Cl uptake, supporting the notion that synaptic release of endogenous GABA is required. The results suggest that synaptic GABA release requires the participation of ω-conotoxin-sensitive Ca channels.

Supported by NIH grants DK 17436 and NS 11535.

183.8

CYCLIC-AMP ACCELERATES GABA-A RECEPTOR DESENSITIZATION. E.M. Barnes, Jr., M.H. Jalilian Tehrani and J.J. Hablitz (SPON: P. Kellaway). Depts. of Biochem. and Neurology, Baylor Col. of Med., Houston, TX 77030.

At a holding potential of -60 mV, the GABA-gated current into chick cortical neurons declines during continued application of agonist. This desensitization process in controls fit a single expotential with a time constant of 7-10 s. After 6 min exposure to 50 μM forskolin, the peak amplitude of GABA-induced currents declined and a fast component of desensitization (τ = 1 s) appeared, while the slow component was essentially unchanged. This effect of forskolin was reversed following washout. Similar, but less robust, effects were produced by 8-Br-cAMP. Desensitization could also be measured by GABA-gated ^{36}Cl flux. A 20 s incubation with 10 μM GABA (5 mM K external) produced a 29% inhibition of subsequent GABA-gated ^{36}Cl uptake (40 mM K). This inhibition was increased to 64% by addition of 100 μM forskolin; this effect was blocked by 100 μM 2',5'-dideoxyadenosine. A similar acceleration of desensitization was produced by 8-Br-cAMP or by isobutylmethylxanthine. These compounds failed to produce desensitization in the absence of exogenous GABA. The results suggest that a cAMP-dependent phosphorylation converts the GABA receptor into a more rapidly desensitizing form.

Supported by NIH grants DK 17436 and NS 11535.

183.9

INHIBITORY MODULATION OF GABA-GATED CHLORIDE INFLUX BY RO5-4864 AND DELTAMETHRIN IN RAT BRAIN SYNAPTONUEROSOMES. L.L. Devaud and T.F. Murray, College of Pharmacy, Oregon State University, Corvallis, OR 97331.

Both pyrethroid insecticides and the convulsant benzodiazepine Ro5-4864 may act to impair GABAergic neurotransmission. To further characterize the mechanism of action of these compounds, we investigated the effects of Ro5-4864 and deltamethrin on the functional coupling of $GABA_A$ receptors to chloride channels by measuring GABA stimulation of $^{36}Cl^-$ influx into rat brain synaptoneurosomes. The stimulation of $^{36}Cl^-$ uptake by GABA (3-300 µM) was significantly antagonized by a concentration of 100 nM Ro5-4864. This dose of Ro5-4864 reduced the E_{max} for GABA-gated $^{36}Cl^-$ influx by approximately 20% without affecting the EC_{50} value for GABA (control EC_{50}=29.7±2.8 µM, in the presence of Ro5-4864 EC_{50}=26.0±1.8 µM). The Type II pyrethroid deltamethrin (DM) also decreased the E_{max} for GABA stimulation of $^{36}Cl^-$ uptake without altering the potency of GABA. DM (0.01-10 µM) elicited a concentration dependent inhibition of GABA-gated $^{36}Cl^-$ influx with a maximal inhibition of 67% occurring at a dose of 10 µM. The IC_{50} value for DM as an inhibitor of GABA-gated $^{36}Cl^-$ influx was 1.24±0.16 µM, which is in excellent agreement with the IC_{50} value of 1.37±0.11 µM for DM as an inhibitor of [^{35}S]TBPS binding to rat cerebral cortical membranes. The noncompetitive inhibition of GABA-gated $^{36}Cl^-$ uptake by both Ro5-4864 and deltamethrin may underlie the pro-convulsant actions of these compounds.

183.10

ENHANCEMENT OF GABA MEDIATED TRANSMEMBRANE CHLORIDE EXCHANGE BY DEUTERIUMOXIDE. J. Kardos & D. J. Cash, Dept. of Pharmacodynamics, Cent. Res. Inst. for Chem. Hungarian Academy of Sciences, Budapest, Hungary H-1525 POB17 and Neurochemistry Unit, Missouri Inst. of Psychiatry, Univ. of MO-Columbia, Sch. of Med., St. Louis, MO 63139.

GABA receptor mediated chloride ion-exchange and receptor desensitization were measured using $^{36}Cl^-$ isotope tracer and quench flow techniques with membrane suspension prepared from rat cerebral cortex suspended in buffer solutions in the presence and absence of D_2O. The chloride exchange was measured by following the uptake of $^{36}Cl^-$ by membrane vesicles in the suspension in the presence or absence of GABA. Reaction times in the sub-second time region were achieved by using quench-flow technique. Specific chloride channels were opened on rapid mixing with GABA and closed on mixing with a solution containing bicuculline methiodide which terminates the GABA mediated $^{36}Cl^-$ uptake. The chloride exchange takes place in two phases terminated by two desensitization processes in different time regions with half times of 230 ms and 2-5 s in 40 µM GABA. These different phases have been attributed to two distinguishable receptors with different activities and different rates of desensitization. In the presence of D_2O the $^{36}Cl^-$ uptake in the faster phase of ion-exchange was increased due to an increase in the initial rate of ion-exchange of the more predominant, faster desensitizing receptor. Deuterium isotope effect on the slower desensitizing receptor was less pronounced. This enhancement reflects differences in dehydration of chloride ion in D_2O.

183.11

THE ß-CARBOLINE DERIVATIVES ZK 93426 AND FG 7142 DO NOT INDUCE ABSTINENCE SIGNS IN DIAZEPAM-DEPENDENT CATS. G. Biggio, M. Corda and O. Giorgi. (Spon.: M.R. Melis) Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy.

Diazepam-dependent cats were treated with different benzodiazepine recognition site ligands 24 h after the last dose of chronic treatment with diazepam (7 mg/Kg, i.p. at 08.00 and 20.00 h, for 21 consecutive days). The benzodiazepine derivatives Ro 15-4513 (a partial inverse agonist), Ro 15-1788 (an antagonist), and the pyrazoloquinoline derivative CGS 8216 (a partial inverse agonist) precipitated abstinence signs when administered at the dose of 10 mg/Kg, i.p. Abstinence signs included tremors, increased muscle tone, irritability, fear, pupillary dilation and vocalizations. On the contrary, the ß-carboline derivatives ZK 93426 (an antagonist) and FG 7142 (a partial inverse agonist) failed to precipitate abstinence signs in diazepam-dependent cats when given at doses (10 mg/Kg, i.p.) that prevented the acute effects of diazepam. These results indicate that the ability to induce withdrawal signs in diazepam-dependent cats depends on the chemical structure of the challenge drug (i.e., benzodiazepine or pyrazoloquinoline), since ß-carboline antagonists like ZK 93426 and partial inverse agonists like FG 7142 lack this property.

183.12

AN ELECTROENCEPHALOGRAPHIC STUDY OF THE BUTYL-BICICLOPHOSPHOROTHIONATE TERTIARY. P.Lorenzini*, D.DeMedici*, L.Mele* and M.Massotti (SPONS:R.del Carmine). Lab di Farmacologia, Istituto Superiore di Sanità, Roma, Italy, 00161.

Butyl-bicyclophosphorothionate tertiary (TBPT) binds with high affinity to picrotoxinin recognition sites in membrane preparations from mammalian brain tissue (Life Sci.,33:2363,1983).

TBPT elicits convulsions in mouse (ED_{50}, 60 µg/kg ip and 50 µg/kg iv), rat (28 µg/kg iv) and rabbits (41 µg/kg iv).

In rats and rabbits, electroencephalographic changes occur which can be divided into two and three dose-responses stages, respectively as reported in the table

	Slow-Waves (Optic Ctx)	Spike-and-Waves (Sensorimotor Ctx)	"Grand-Mal"
Rats	---	5-20	>20
Rabbits	10-20	20-30	>30

Ctx=Cortex The values are expressed as µg/kg i.v.

These changes are similar to those observed after bicuculline, inverse benzodiazepine agonists, picrotoxin and pentilentetrazol (Pharmac.Biochem.-Behav., 23:661,1985).

PROCESS OUTGROWTH, GROWTH CONES, AND GUIDANCE MECHANISMS II

184.1

INHIBITION AND STIMULATION OF NEURITE OUTGROWTH BY SEROTONIN IN NEURONS CULTURED FROM EMBRYONIC AND ADULT *HELISOMA*. J.I. Goldberg, L.R. Mills and S.B. Kater. Dept. of Zoology, University of Alberta, Edmonton, Alberta, T6G 2E9 and Program in Neuronal Growth and Development, Colorado State University, Fort Collins, CO 80523.

While a variety of neurotransmitters have been implicated in the regulation of neurite outgrowth, it is not known whether the same mechanisms operate during both embryonic development and adult neuroplasticity. We now examine the regulation of neurite outgrowth by serotonin in parallel embryonic and adult dissociated cell culture systems. In both classes of neurons (ie. developing and adult regenerating), serotonin can evoke quite different responses: growing neurites can be inhibited and stable neurites can be stimulated to re-initiate outgrowth. In embryo cultures, addition of 50 µM serotonin resulted in cessation of outgrowth in 44.2% of the advancing neurites (N=52). In matched control cultures, spontaneous cessation occurred in only 12.5% of neurites (N=48; p<.001). In adult cultures, 35.5% of the advancing neurites were outgrowth inhibited by serotonin (N=45), while spontaneous cessation occurred in 8.6% of the control neurites (N=58; p<.001). Non-advancing neurites were also examined to test for stimulation of outgrowth by serotonin. In embryo cultures, serotonin re-initiated outgrowth in 44.7% of the non-advancing neurites (N=47), in comparison to spontaneous re-initiation in 21.6% of the control neurites (N=37; p<.05). Similarly in adult cultures, serotonin re-initiated outgrowth in 23.3% of the non-advancing neurites (N=77), in comparison to spontaneous re-initiation in 7.5% of the control neurites (N=53; p<.05). These data demonstrate that serotonin has stimulatory or inhibitory effects on neurite outgrowth in a large number of embryonic and adult neurons. Whether these opposite effects occur in different sets of neurons, or in the same set of neurons during different states of outgrowth, remains to be determined.

This research was supported by the Alberta Heritage Foundation for Medical Research and the NIH.

184.2

AFFERENT GROWTH CONES INTERACT *IN VITRO* WITH TARGET CELLS FROM DEVELOPING CEREBELLUM

D.H. Baird, M.E. Hatten, and C.A. Mason
Dept. of Pathology, College of Physicians and Surgeons of Columbia University, New York, N.Y. 10032

Previous observations of developing cerebellum *in situ* indicate that single afferent axons initially form contacts with several target cell populations before "choosing" a single target cell type. We have devised a culture system to investigate the mechanism of this target cell selection and to define the behavior of growth cones during this process. In a modification of the microcultures used in our lab to analyze neuron-glia contacts, explants from the brainstem sources of cerebellar afferents (pontine nuclei for mossy fibers, inferior olive for climbing fibers) are co-cultured with dissociated and purified populations of cerebellar target neurons. The target cells and the explants are initially plated on either side of a partition that is later removed. Separating the explants from the target cells makes it easier to distinguish explant from target cell neurites, and allows us to test for trophic or tropic interactions.

Video enhanced DIC time-lapse microscopy permits high resolution observation of the behavior of single, identified explant growth cones interacting with identified target cells. Growth cones from pontine axons encountering their appropriate target granule cell growth cones exhibit initial contacts of long duration. Both growth cones have continuous filopodial and lamellipodial activity, yet cease to extend. In contrast, when granule cell growth cones interact with their own type, initial contacts are of shorter duration and neurites continue to extend. EM and immuno-histochemical studies are in progress to correlate the video observations with synaptogenesis. Supported by NIH grant NS-15961.

THE LOCATION OF CYTOSKELETAL ELEMENTS AND ORGANELLES PREDICTS THE SITE OF GROWTH CONE EMERGENCE FROM A GRASSHOPPER PIONEER NEURON OBSERVED IN SITU WITH CONFOCAL IMAGING. Frances Lefcort and David Bentley. Neurobiology Group and Department of Zoology, University of California, Berkeley, CA 94720.

In embryonic grasshopper limb buds, the Til pioneer neurons arise from a mother cell (PMC; Keshishian, 1980), located in the limb tip epithelium, which undergoes a proximo-distally oriented mitosis shortly before pioneer axonogenesis. The growth cone of the proximal daughter cell (Tilp) emerges perpendicularly to the apparent cleavage plane. Using a confocal microscope and fluorescent probes, we have characterized the arrangement of several cytoskeletal elements and organelles from early prophase of PMC through axonogenesis of Tilp. The proximal spindle pole of the PMC (later in Tilp) is defined by the location of (i) telophase chromosomes labeled with propidium iodide, (ii) spindle microtubules labeled with a monoclonal anti-tubulin antibody (gift of Dr. David Asai, Purdue), (iii) centrosomes labeled with anti Drosophila-centrosome serum antibody (gift of Doug Kellogg, UCSF), and (iv) cleavage furrow and mid-body F-actin labeled with rhodamine-phalloidin. After cytokinesis, a brightly labeling tubulin-containing focus at the cell pole, which may be a centrosome or MTOC, persists and is seen later to lie within the base of the nascent growth cone. Initially, the Golgi apparatus, labeled with FITC-WGA, is distributed perinuclearly. At the onset of axonogenesis, transient, focal FITC-WGA label also appears in the base of the nascent growth cone. Formation of the PMC cleavage furrow marked by F-actin is followed by initiation of axonogenesis. To test the hypothesis that displacement of cortical actin into the cleavage furrow may be associated with the initation of axonogenesis at the cell pole, embryos were exposed to 0.1 ug/ml cytochalasin D. Exposure after the onset of axonogenesis does not block further axon extension; however, exposure before PMC cytokinesis blocks axonogenesis while allowing expression of other neural phenotypic characteristics.

EFFECTS OF ENZYMATIC REMOVAL OF THE BASAL LAMINA ON PIONEER NEURONS IN GRASSHOPPER EMBRYOS. Maureen L. Condic and David Bentley. Neurobiology Group and Dept. of Zoology, University of California, Berkeley, CA 94720

Several proteolytic enzymes were tested for their effects on the basal lamina and the disposition of the Til neurons in embryonic grasshopper limb buds. Embryos of Schistocerca americana were incubated at 30°C for 2.5 hrs with either elastase (0.04%), chymotrypsin (0.005%), ficin (0.02%), papain (0.025%), trypsin (0.01%) or saline. Elastase, ficin and papain completely removed the basal lamina when viewed in SEM. Chymotrypsin and trypsin had little or no effect on the structural integrity of the basal lamina. Removal of the basal lamina at 32% of development when the Til axons have extended over the intrasegmental epithelium, but are not in contact with other immature neurons resulted in retraction of the growth cones to the cell somata. This suggests that the Til axons are under tension in vivo and that the cells are dependent on the basal lamina to remain extended over this region of the limb. Removal of the basal lamina later in development (34%) when the Til growth cones are in contact with either nascent neurons or limb segment boundaries resulted in the relocation of the somata proximally. This suggests that neural-neural and neural-segment boundary interactions are at least in part due to adhesive cell-cell interactions that are independent of the basal lamina. The ability of the Til neurons to extend axons in limbs from which the basal lamina had been removed by enzymatic digestion was also investigated. Embryos at 30-32% were treated with either elastase or ficin as described, then rinsed extensively for 30 minutes and cultured for 12-16 hours in the absence of enzyme. The Til neurons extended axons after enzymatic treatment at rates approximately equal those seen in control animals. Til growth cones extended after the removal of the basal lamina frequently exhibit lamella and extend numerous filopodia. The growth cones recognized and were reoriented by immature neurons and limb segment boundaries. The effect of removing the basal lamina on Til pathfinding is currently under investigation.

DIRECTIONAL CUES INFLUENCE, BUT DO NOT DETERMINE STEREOTYPED NAVIGATION OF A GROWTH CONE ARRAY IN THE EMBRYONIC LEECH. J. Jellies & W.B. Kristan, Jr., Dept./Biology, UCSD, La Jolla, CA, 92093.

The oblique muscle of the leech, Hirudo medicinalis, is laid down upon the multiple parallel processes of an identified cell, the Comb- or C-cell. Each segment contains a bilateral pair of mirror-image cells. The ≈70 growth cones on each C-cell navigate along precise trajectories with relatively constant spacing. Injecting C-cells with HRP revealed occasional (<0.1% of processes) deviations in trajectory. Deviating processes were most often oriented along the mirror-image path destined to be followed by the processes of the contralateral C-cell, implying the presence of directional cues. The earliest C-cell processes orient orthogonally, implicating the grid of circular and longitudinal muscle cells in this role. The 1^0 circular muscle cells (22/hemisegment) can each be identified by position and morphology. To examine the influence of these cells in guiding C-cell processes, one pair of them was dye-filled then photoablated during embryonic day 10. When examined later, most C-cell processes had crossed the lesion site normally. There was, however, an approximately 60 fold greater number of navigational errors across the lesion compared to normal. Thus, while the ablated circular muscle cells may provide navigational cues, these must act in concert with other factors to guide C-cell growth cones. Supported by NIH grants NS20746 & NS25916 (WBK).

THE EFFECT OF NEURAL CREST DELETIONS ON THE DEVELOPMENT OF SPECIFIC MOTONEURON PROJECTIONS IN THE EMBRYONIC CHICK HINDLIMB. C. Lance-Jones and J. W. Yip. Depts. of Neurobiology, Anatomy and Cell Science and Physiology, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261.

Schwann cells may play a role in motoneuron axon outgrowth, yet their precise function in this process is unknown. One possibility is that Schwann cells arising from neural crest at specific sites on the neuraxis are uniquely able to recognize specific targets and guide motoneurons to them. To test this idea we excised dorsal neural tube including the neural crest from posterior thoracic (T) through the limb-innervating lumbosacral (LS) regions in stage 14 chick embryos and then examined the specificity of motoneuron projections to selected hindlimb muscles at stage 35-36. The operation gave rise to embryos that lacked dorsal root ganglia (DRG) from posterior T segments through LS4,5,6,7, or 8. Separate analyses of quail/chick neural tube chimeras suggested that these deletions would remove all Schwann cells that would normally be found along nerves originating from the DRG-deleted segments. Retrograde HRP labelling of motoneuron pools to muscles normally innervated by motoneurons in LS1-3 indicated that in all cases the pools were normally positioned. These data suggest that LS motoneurons do not require Schwann cells from corresponding axial levels to make correct projections. Supported by NSF: BNS-8518864 and NIH: NS23916.

PROTEASE INHIBITORS INTERFERE WITH AXONAL OUTGROWTH OF IDENTIFIED MOTONEURONS IN LIVE ZEBRAFISH EMBRYOS. B. Debu and J.S. Eisen, Institute of Neuroscience, University of Oregon, Eugene OR 97403.

During axonal elongation and pathfinding some growth cones release proteases that modify their local environments, a process that may be important in neurite outgrowth. To examine whether such proteolysis might play a role in axonal elongation in embryonic zebrafish, we injected protease inhibitors in vivo and examined axonal pathfinding by identified neurons. In zebrafish each myotome is innervated by 3 identified motoneurons. The motor growth cones initially follow a common pathway, later extending along cell-specific pathways to mutually exclusive regions of muscle. Injection of leupeptin, a serine protease inhibitor, resulted in abnormalities in motor axonal outgrowth. In 16/25 fish the motor axons in injected segments extended along the common pathway, but did not extend along cell-specific pathways. Some axons appeared to stop growing, while others extended branches in inappropriate regions of muscle. Control injections of saline or trypsin inhibitor did not have observable effects on motor axonal outgrowth or pathfinding. These results are consistent with a role for proteolysis in axonal outgrowth by zebrafish motoneurons. Supported by the NIH, NSF and the Chicago Community Trust.

DEVELOPMENT OF MUSCLE INNERVATION IN *DROSOPHILA* EMBRYOS AND LARVAE. J. Johansen, M.E. Halpern and H. Keshishian. Department of Biology, Yale University, New Haven, CT 06511.

In *Drosophila* embryos and larvae each segment contains a precise array of no greater than 31 muscle fibers per side, with each fiber individually identifiable. This is a particularly favorable arrangement for examining motoneuronal exploration and the development of innervation. Previously, we had shown that by the end of larval life (the third instar) many of the muscle fibers have specialized and stereotypic arrays of motor endings, often with characteristic axonal trajectories over the fiber surfaces. Double labelling experiments with neuron-specific antibodies (anti-HRP), together with an antiserum to glutamate, indicate that the entire innervating motoneuronal population in the third instar expresses glutamate as a transmitter (a subset coexpress proctolin and probably octopamine). Using both neuron and neurotransmitter-specific probes we have followed the establishment of these precise and stereotyped projections during embryogenesis and find that: 1. When innervation begins the muscle fibers are already organized into their segmental pattern. 2. That in early stage 16 embryos the glutamate transmitter appears to be expressed in growth cones before the muscles are contacted, and 3. that elements of the muscle fiber-specific axonal trajectories are recognizable from the earliest innervation by growth cones from the developing nerve. A detailed description of synaptogenesis and of the development of the stereotypic glutamatergic muscle innervation during embryogenesis and throughout the larval stages will be presented. (Glutamate antiserum was a gift of Dr. P. Petrusz).

DIRECTING AXONAL REGENERATION BY DIFFUSIBLE FACTORS FROM MUSCLE FIBERS AND NERVE TUBES.
D.P. KUFFLER and B.STOLZ*. Dept. of Pharmacology, Biocenter, Univ. of Basel, Basel, Switzerland.

Earlier studies in this laboratory have shown that the outgrowth of regenerating frog muscle axons can be directed by denervated lengths of nerve tube and the non-synaptic regions of muscle fibers. In the present experiments denervated nerve tubes and muscle fibers were placed inside filters which isolated the target cells but allowed the diffusion away of molecules they released. Target cells inside filters were still able to direct the outgrowth of regenerating axons. These results show that the target cells release a diffusible factor/s that causes regenerating axons to change their direction of growth. Furthermore this influence is effective over millimeters.

The present findings set the stage for tissue culture experiments in which the phenomena can be analyzed in terms of molecular mechanisms. So far Schwann cells, muscle fibers and a variety of adult spinal neurons have been successfully cultured. Our aim is to combine these cells to establish whether directed outgrowth occurs and to characterize the factors involved.

RAT CNS-MYELIN AND OLIGODENDROCYTES IMPAIR THE GROWTH OF GOLDFISH RETINAL AXONS *IN VITRO*
M.Bastmeyer, J.Vielmetter, M.Schwab and C.A.O.Stuermer, Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, Tübingen, FRG and Brain Res. Inst. Zürich, Zürich, CH.

Mammalian oligodendrocytes and CNS myelin are non-permissive substrates for mammalian neurites (Schwab and Caroni , 1988). Responsible for the growth inhibiting effect are two proteins. They are absent from fish CNS myelin (Caroni and Schwab, 1988).

We tested whether goldfish retinal axons are sensitive to the growth inhibiting components of the mammalian myelin and oligodendrocytes. Using time-lapse videomicroscopy we monitored the contacts of goldfish retinal axons 1) with mammalian oligodendrocytes and 2) with myelin. Repeated contacts with myelin were provided by a patterned substrate. It consisted of laminin and rat or fish myelin in alternating stripes of 40-50μm width in its first half and of only myelin in its second half.

1. When fish axons encountered O1-positive rat oligodendrocytes 50% of the axons either degenerated, retracted, branched or curved around the cells. 2. On the patterned substrate of laminin and rat myelin, axons preferred the laminin stripes. When their growth cones met the myelin at the end of the stripes, axons degenerated, performed U-turns, or they reduced their velocity dramatically but kept their growth cones active. When goldfish instead of mammalian myelin was used axons crossed frequently over both substrates, grew onto and elongated on the myelin at the end of the stripes.

Thus, rat CNS myelin and oligodendrocytes are non-permissive substrates for goldfish retinal axons. Whether the avoidance response of fish axons is caused by the inhibitory proteins associated with mammalian myelin and oligodendrocytes will be decided in ongoing experiments.

DIRECTIONALLY SPECIFIC AXONAL REGENERATION IN THE ADULT LAMPREY SPINAL CORD.
D.I. Lurie* and M.E. Selzer. David Mahoney Inst. of Neurol. Sciences and Dept. of Neurology, U. of Penn., Sch. of Med., Phila., PA. 19104.

Larval sea lampreys recover from spinal transection by a process involving directionally specific axonal regeneration (Mackler et al., J. Neurosci., 6:1814, 1986). Is this also true of adult lampreys? Thirteen Petromyzon marinus adults were transected at the level of the 5th gill and allowed to recover for 10 wks. Muller and Mauthner axons were then impaled with microelectrodes and injected with HRP. Wholemounts of brain and spinal cord were prepared and regenerating neurites traced with camera lucida. Twelve animals recovered coordinated swimming. In these, 72 of 116 (62%) neurites from 25 axons regenerated beyond the scar. Of the neurites which had grown beyond the scar, 93% were correctly oriented, i.e. caudalward and ipsilateral to the parent axon. A 13th animal showed no behavioral recovery. Mechanical deformity prevented apposition of the cut ends of the cord and no axons regenerated across the site of injury. Retransection in 2 additional animals eliminated the recovered swimming. Thus, behavioral recovery in adult sea lampreys involves directionally specific axonal regeneration. (NIH grants NS14837 and NS25581).

LARGE-SCALE COMPUTER SIMULATIONS OF AXONAL GROWTH: PARAMETERS WHICH RESULT IN "TWO-CENTER EFFECTS" LIKE THOSE FOUND IN DRG CULTURES.
G.E.Schneider and W.F.Davis*. Dept. Brain & Cognitive Sciences, MIT, Cambridge, MA 02139; Davis Assoc., Newton, MA 02165. (Spon.: W.A. Rosenblith)

Results of computer simulations of the simultaneous growth of many axons following specified rules of development will be presented. The program allows the user great flexibility in defining boundaries, cell populations and densities and initial distributions, initial growth directions, rates of extension, and various parametrized reactions. Reactions used in this study included "wander" for specifying properties of non-rectilinear elongation, and "retraction" for specifying the consequences of contact between a growing axon tip and another axon. Simulations of up to 988 elongating axons were run. Output of each simulation was used to create plot files for producing displays of the results at specified simulated times after initiation of growth. Resulting displays were plotted, or were used to create motion-picture sequences of small time segments of selected simulations.

Initial parameters, and their statistical variability, for the wander and retraction reactions were chosen with the aid of data from published tissue culture studies. Two populations which follow identical growth rules were specified, representing a pair of explants. Neuronal densities, retraction probability, retraction distance (d) and the post-retraction growth-direction algorithm were varied. With sufficiently high densities of outgrowth, both major types of "2-center effects"--P. Weiss's fasciculated "attraction" effect and G. Dunn's non-fasciculated "repulsion effect"--were obtained by using different settings of d, e.g. 2.5 µm for "attraction" and 30 µm for "repulsion". (Fasciculation occurred with the smaller values of d without any rule to force parallel growth.) A critical role for this parameter has not previously been proposed. [Support: NSF grant BNS 85-16984; IBM.]

DOPAMINE RECEPTORS II

185.1

SUBSTRATE DEPENDENT INTERACTIONS WITH THE DOPAMINERGIC SYSTEM OF THE ERGOLINE FCE 23884.
Buonamici* M., Achilli* G., Caccia* C., Cervini* M.A., Pegrassi* L. and Rossi* A.C. Farmitalia Carlo Erba, R&D, C.N.S. Line, 20014 Nerviano, Italy.

FCE 23884, an ergoline derivative, was investigated for central dopaminergic activity in several animal models. In normal animals it displayed a variety of pharmacological effects reminiscent of dopamine antagonism i.e., selective suppression of avoidance responding in rats, dose-related blockade of amphetamine-induced toxicity in aggregated mice and prevention of apomorphine-induced stereotypic behaviour either in mice or rats.

In vitro binding studies of the compound showed its affinity for both D-1 and D-2 receptors (nM range) and in vivo experiments led to a marked increase of DA turnover and of serum prolactin levels. These results obtained in normal animals are suggestive of antagonistic effects to DA-ergic neurotransmission afforded by FCE 23884.

Conversely, FCE 23884 showed a strong agonist DA-ergic activity in two denervated animal models. In rats bearing unilateral nigrostriatal 6-hydroxydopamine lesions the compound induced dose-related contralateral turning (0.05-0.1 mg/kg s.c.).

In preliminary studies in non-human primates with severe MPTP-induced Parkinson-like syndrome, FCE 23884 completely reversed the akinesia and incoordination of movement (0.05-0.25 mg/kg s.c.). The compound FCE 23884 could be of therapeutic interest in Parkinson's disease due to its unusual ability to stimulate denervated supersensitive DA-receptors while depressing normosensitive ones.

185.2

A FULL REPETITIVE JAW MOVEMENT (RJM) RESPONSE WITH ONLY TWENTY PERCENT OF THE D_1 RECEPTORS.
H.Rosengarten , J.W.Schweitzer , A.J.Friedhoff. Department of Psychiatry Millhauser Laboratories,NYU School of Medicine,New York N.Y. 10016

We have previously demonstrated that repetitive jaw movements (RJM) in rats can be produced through activation of dopamine D_1 receptors with SKF 38393 in a dose dependent manner and facilitated through D_2 receptor blockade.These movements are antagonized by the specific D_1 antagonist SCH 23390 or by specific D_2 receptor stimulation.In the present study we have further explored quantitative relationships between D_1 receptor activation and RJM.The D1 receptors were inactivated with the irreversible antagonist EEDQ while the D_2 receptors were protected with the selective D_2 antagonist eticlopride . This treatment resulted 24 hours later in 78% destruction of the D_1 receptors and only 10% of the D_2 receptors in the rat caudate . EEDQ treated and control rats were tested for the frequency of SKF 38393-inducible RJM .Although only 22% of caudate D_1 receptors were present following exposure to EEDQ , a full RJM response was elicited by a high dose of SKF 38393 . From these findings it appears that there is a functional reserve in D_1 mediated RJM in rat.The implications of these findings will be discussed.

185.3

ROTATION INDUCED BY THE D2 AGONIST LY 171555 FOLLOWING UNILATERAL IRREVERSIBLE INACTIVATION OF STRIATAL DOPAMINE RECEPTORS BY N-ETHOXYCARBONYL-2-ETHOXY-1,2-DIHYDROQUINOLINE (EEDQ). O. Giorgi and G. Biggio. Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy.

A novel rotational model was used to study the interactions between D1 and D2 dopamine (DA) receptors. Male Sprague-Dawley rats (280-320 g) were unilaterally injected with the irreversible DA receptor blocker EEDQ into the head and body of the striatum (10 mmoles/ 1 μl / 3 min, x 2) and the effects of different agonists and antagonists for D1 and D2 DA receptors on circling behavior were evaluated 24 h thereafter. EEDQ treatment decreased the density of striatal D1 (-51%) and D2 (-46%) DA receptors labeled with ^{3}H-SCH 23390 and ^{3}H-Spiperone, respectively. LY 171555 (1 mg/Kg, i.p.) induced ipsilateral rotation (141 ± 11 turns/rat/15 min, N = 10) in animals with a 40 to 60 % decrease in the Bmax of striatal D1 and D2 DA receptors, but not in rats in which these receptors were reduced by 15 to 25 % after EEDQ. In contrast, SKF 38393 (10 mg/Kg, i.p.) failed to induce circling behavior. Rotations elicited by LY 171555 were antagonized (-88%) by L-sulpiride (100 mg/Kg, i.p.) and by SCH 23390 (-70% at 1 mg/Kg, i.p.). The inhibitory effect of SCH 23390 was reverted by SKF 38393 (40 mg/Kg, i.p.). These results indicate a permissive role of D1 DA receptors for the expression of D2 DA receptor-mediated effects and are consistent with the existence of a DA receptor reserve (i.e., "spare" receptors) in the rat striatum.

185.4

DIFFERENTIAL RECEPTOR RESERVE AT PRE-VS. POSTSYNAPTIC D2 DOPAMINE (DA) RECEPTORS ACCOUNTS FOR THE AUTORECEPTOR SELECTIVITY OF DA AGONISTS. E. Meller, A. Enz* and M. Goldstein. Dept. of Psychiatry, NYU Medical Center, New York, NY 10016 and Preclinical Research, Sandoz, Ltd., Basel, Switzerland.

We have recently demonstrated the presence of a large receptor reserve at DA autoreceptors in rat striatum mediating local negative feedback inhibition of neurotransmitter synthesis (Meller et al., Mol. Pharmacol. 31:592-598, 1987), and proposed that a differential receptor reserve at pre- vs. postsynaptic D2 receptors could account for the autoreceptor selectivity of DA agonists. We now report the results of studies examining the relationship between receptor occupancy and response at postsynaptic striatal D2 receptors regulating cholinergic activity.

N-Propylnorapomorphine (NPA) dose-dependently increased rat striatal ACh levels (ED_{50}=18 ug/kg). After irreversible DA receptor inactivation with N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 6 mg/kg), neither the ED_{50} nor the slope of the dose-response curve for NPA was altered, whereas the maximal response was reduced to 56% of control. Analysis of the results yielded a linear relationship between receptor occupancy and response (i.e. no receptor reserve). The results support the hypothesis that a differential receptor reserve at pre- vs. postsynaptic DA receptors in rat striatum accounts for the autoreceptor selectivity of DA agonists. Supported in part by PHS grants NS 23618, MH 02717 and MH 35976.

185.5

DIFFERENT RECEPTOR RESERVE TO R(-)NPA FOR NIGRAL AND VTA DOPAMINE (DA) NEURONS. R.F. Cox and R.L. Waszczak. Pharmacol. Sect., Northeastern Univ., Boston, MA 02115.

Differences in autoreceptor density between nigral (SN) and VTA DA neurons were suggested by previous studies. To explore this possibility, i.v. dose-response curves (drc) were constructed for inhibition of SN and VTA DA cell firing by R(-)NPA before and after partial DA receptor inactivation with EEDQ (6 mg/kg in ethanol). For SN cells, EEDQ caused a 3-fold parallel rightward shift of the R(-)-NPA drc but no change in maximal response relative to vehicle-treated controls. For VTA cells, this EEDQ dose caused not only a greater (8.6-fold) drc shift, but also reduced maximal response by 25%. Furchgott analysis showed a steep, hyperbolic occupancy-response (O-R) relationship for R(-)NPA in SN, with 50% and full responses occurring at 3.5% and 28% occupancies. The O-R curve for VTA cells was less steep, with 50% and full responses at 10% and 78.5% occupancies. While these analyses reveal a 3-fold larger receptor reserve to i.v. R(-)NPA for SN than VTA cells (72% vs 21.5% reserve), K_A's were similar (7.7 and 5.5 ug/kg) indicating no difference in affinity between the regions.

In related ongoing studies, the same dose of EEDQ seems to cause greater declines in responsiveness to iontophoretically applied DA than were seen for i.v. NPA. Additional work will focus on whether this difference can be attributed to differing sizes of receptor pools available to i.v. vs iontophoresed agonists, to different intrinsic efficacies of DA and NPA, or both. (Supported by NS 23541)

185.6

D-1 SPECIFIC AGENTS MODULATE DOPAMINERGIC TERMINAL EXCITABILITY. M. Diana, S.J. Young* & P.M. Groves. Dept. of Psychiatry , U.C.S.D., La Jolla, 92093.

Recent studies provide evidence for D1 receptors on dopamine neurons within substantia nigra pars compacta suggesting that these receptors may also be present on dopaminergic axon terminals in the neostriatum. We have examined the action of locally applied D1 specific drugs on the terminal excitability of dopaminergic terminals in the neostriatum.

Infusion cannulae and an adjacent bipolar stimulating electrode were implanted in the neostriatum or medial forebrain bundle(MFB) of urethane anesthetized rats. Terminal excitability was assessed in terms of the current neccessary to evoke an antidromic response from nigral dopaminergic neurons before and after drug infusion.

Striatal infusion (300nl., 5min.) of 10uM R-SKF38393, a D1 specific agonist, produced a decrease in excitability which was reversed by subsequent infusion (300nl., 5min) of 10uM SCH23390, a D1 specific antagonist. These effects did not depend on D1 receptors on striatal neurons as they occurred following destruction of these cells with kainate. Since infusions of SCH into the MFB produced a slight decrease in excitability of MFB axons while SKF produced no change, a nonspecific axonal effect can be excluded. Experiments involving dopamine depletion will also be presented. The results are consistent with the possibility that D1 receptors exist on dopaminergic terminals in the striatum. (Supported by NIDA grants DA 02845 and RSA DA 00079.)

185.7

D_1 DOPAMINE RECEPTORS IN FRONTAL CORTEX OF NON-HUMAN PRIMATES. B.K. Madras, C.E. Pfaelzer*, M. Fahey*, D. Canfield*, R.D. Spealman. Harvard Medical School and New England Regional Primate Research Center, Southborough, MA 01772.

In order to compare D_1 dopamine receptors in frontal cortex with caudate-putamen (Madras et al. 1988), we characterized D_1 dopamine receptors in washed frontal cortex membranes of non-human primates (Macaca fascicularis). D_1 receptors were labeled with [^{3}H]-SCH 23390 using (S)-butaclamol (1 μM) to define non-specific binding. Membranes bound [^{3}H]-SCH 23390 with high affinity (Kd: .41±.076 nM). The density of these sites was 7.8±2.3 pmoles/g (n=4) which is 25-30% of the density detectable in monkey striatum. Na^+ ions (120 nM) increased receptor affinity 2.7-fold and decreased apparent density by 45%. In striatum only affinity was affected by Na^+. A serotonergic component of [^{3}H]-SCH 23390 binding was suggested by the shallow displacement curves of ketanserin and cinanserin which were resolvable into two sites; the high affinity site represented approx. 25% of the sites. Dopamine receptor agonist and antagonist binding affinities were similar to those found in striatum. These results indicate that [^{3}H]-SCH 23390 labels primarily, but not exclusively, D_1 dopamine receptors in monkey frontal cortex. Supported by USPHS Grants DA00499, DA03774 and RR00168.

ADENYLATE CYCLASE CHANGES IN CAUDATE OF 6-OHDA-LESIONED RATS. L.L. Watkins,* H.E. Criswell, R.A. Mueller and G.R. Breese. UNC Sch. Med., Chapel Hill, NC 27599.

Adult rats treated neonatally with 6-OHDA (n.6OH) exhibit hyperlocomotion following systemic administration of the D_1-DA receptor agonist SKF 38393 (JPET 234:447, 1985). This investigation examined whether changes in caudate adenylate cyclase activity (ACA) accompany this 6-OHDA treatment. Crude homogenates from caudate nucleus of control and n.6OH rats were incubated with D_1-DA agonists (SKF 38393 or SKF 82526) or a D_2-DA agonist (RU 24213) in the absence or presence of forskolin or NaF. Caudate homogenates from n.6OH rats exhibited no change in ACA to the D_1-DA agonists, but showed increased inhibition of ACA to the D_2-DA agonist. Forskolin (20 μM) and NaF (10mM) stimulation of AC was 20 and 40% lower, respectively, in n.6OH rats than in controls. Forskolin showed a biphasic effect on receptor-mediated changes in caudate ACA in control rats. Low forskolin (.01 to 5 μM) facilitated D_1-DA agonist stimulation of ACA and high forskolin (10 to 50 μM) facilitated D_2-DA agonist inhibition of ACA. In caudate of n.6OH rats, forskolin enhanced only D_2-DA agonist inhibition of ACA. The decreased responsiveness to AC stimulation by forskolin and NaF, the failure of forskolin to enhance D_1-DA receptor-mediated ACA, and the increased inhibition of ACA by D_2-DA agonists provides evidence that D_2-DA, but not D_1-DA receptors linked to AC, are hyperresponsive in n.6OH rats. (Supported by NS-21345 and HD 23042.)

17β-Estradiol Regulation of DA Receptor Interactions with G-proteins. Robert E. Hruska. Univ. Buffalo, NY*

17β-Estradiol produces a variety of pre-synaptic and post-synaptic effects on the nigro-striatal DA system. These effects include an increase in the densities (without affinity changes) of the D1 and D2 DA receptors by a process which appears to be located post-synaptically and be time-dependent and dose-related. While these actions have been demonstrated biochemically and behaviorally after in vivo administration, no direct in vitro effects of 17β-estradiol have been demonstrated on these receptors unless high μM concentrations are used. This report demonstrates that nM concentrations of 17β-estradiol in vitro alter the GTP-dependent shift of agonist displacement curves at the D2 DA receptors isolated from rat striatal tissue. GTP produces a well-known shift of the DA displacement curve to lower affinity. At a concentration of 1.0 nM, 17β-estradiol prevents the GTP shift. This action is concentration dependent (half-maximal effect at 0.1 nM), stereospecific (1000-fold greater concentration of 17α-estradiol required), and limited to the D2 subtype (the GTP shift at the D1 subtype was not altered). These results suggest that 17β-estradiol can act directly and rapidly on the interaction of D2 DA receptors with the specific Gi-protein. This is observed in vitro at nM concentrations and suggests that this could occur in vivo at physiological concentrations.

DOPAMINE D_2 RECEPTOR BINDING SUBUNITS: DIFFERENCES IN GLYCOSYLATION ACCOUNT FOR THE EXISTENCE OF HIGH MOLECULAR WEIGHT FORMS. K.R. Jarvie, H.B. Niznik, and P. Seeman. **Dept. Pharmacol., Univ. of Toronto, Toronto, Canada, M5S 1A8.**

Dopamine D_2 receptor binding subunits can be photoaffinity labeled with [^{125}I]NAPS and visualized autoradiographically following sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). [^{125}I]NAPS has been shown, in several species, to incorporate into a band of Mr=94,000. In contrast, in porcine striatal homogenates, [^{125}I]NAPS labels a protein with an estimated molecular mass greater then that previously observed. In porcine striatal homogenates, [^{125}I]NAPS labels two bands (Mr=140,000 and 94,000). Exoglycosidase treatment (neuraminidase) caused the two labeled bands to migrate as one band with an increased mobility (Mr=51,000). Complete N-linked deglycosylation with Glycopeptidase F (PNGaseF) resulted in a shift in the labeled band to a Mr=44,000. This value coincides with the estimate for the molecular mass of the PNGaseF-treated D_2 binding subunit of canine brain. These data indicate that variable glycosylation may account for the observed differences in the mobility of the dopamine D_2 receptor binding subunits on SDS-PAGE gels.

STRUCTURAL ANOMALIES IN THE D_2 RECEPTOR COMPLEX OF DOPAMINE-RESISTANT, PROLACTIN-SECRETING RAT PITUITARY TUMORS. C. Bouvier*, G. Lagacé* and R. Collu. **Research Unit on Biology of Reproduction and Development, Pediatric Research Center, Hôpital Ste-Justine and Université de Montréal, Montréal, Québec, Canada, H3T 1C5**

The structure of the dopamine (DA) D_2 receptor complex of DA-resistant, and prolactin (PRL)-secreting rat pituitary tumors 7315a and MtTW15 was evaluated to determine the reason for tumors insensitivity to DA inhibitory action on PRL release and tumor growth. The size of the receptor complex in active form, as determined by radiation inactivation (RIS) after preincubation with the DA agonist NPA, was found to be abnormally large in the two tumors (RIS, kDa; Normal, 140; 7315a, 210; MtTW15, 280). The GTP-binding protein G_o-α was found to be greatly decreased or absent in the two tumors, both by immunoblot and by pertussis toxin (PT)-induced [^{32}P] ADP-ribosylation. On the other hand, the binding unit of the tumors receptor was found, by photoaffinity labeling with [^{125}I]-N_a-NAPS with or without pretreatment with the alkylating agent N-ethyl-maleimide (NEM), to be normal and to contain SH- groups essential for ligand binding. These groups were found also to be essential for G-protein ADP-ribosylation in normal and tumoral preparations. These data suggest that tumors insensitivity to DA may be due to failure of transmission of the inhibitory message after agonist binding because of multiple anomalies in the receptor complex.

POTASSIUM CHANNELS I

186.1

FOUR cDNA CLONES FROM THE SHAKER LOCUS OF DROSOPHILA INDUCE KINETICALLY DISTINCT A-TYPE POTASSIUM CHANNELS IN XENOPUS OOCYTES. Leslie. C. Timpe, Yuh Nung Jan & Lily Y. Jan, Howard Hughes Med. Inst. and Dept. of Physiol., UCSF, San Francisco, CA 94143-0724.

Genetic evidence suggests that the Shaker gene of D. melanogaster encodes the A channel of larval and pupal muscle, or one of its subunits. At least four distinct messages derive from the Shaker locus by alternative splicing. We have previously shown that two cDNA clones, ShA and ShB, direct the synthesis of active A channels when expressed in Xenopus oocytes. Two additional clones have now been expressed. Specific messenger RNA was synthesized in vitro, injected into oocytes, and the ionic currents were examined with a two electrode voltage clamp. Oocytes injected with either ShC or ShD mRNA have voltage-dependent , transient, outward currents. The ShÇ currents recover very slowly from inactivation at -80 mV. The ShD currents, in contrast, resemble the ShB currents: they recover from inactivation within seconds at -80 mV. The inactivation kinetics of ShB and ShD are not identical, however. The ShD current inactivates more slowly at positive potentials, and recovers from inactivation more slowly at negative potentials, than does ShB. Comparison of the sequences of the four predicted proteins indicates that the large difference in rate of recovery from inactivation between ShA and ShC versus ShB and ShD is due to amino acid differences at the carboxyl terminal. The subtler differences between ShB and ShD result from sequences at the amino terminal. Although it is not known whether the A currents expressed in oocytes accurately reflect the properties of fly A currents, these results indicate that the products of the Shaker locus may be components of several kinetically distinct A channels in flies.

186.2

IMMUNOCYTOCHEMISTRY AND WESTERN -BLOT ANALYSIS OF A-CHANNELS IN DROSOPHILA.

T.L. Schwarz, D.M. Papazian, R.P. Carretto, Y.N. Jan & L.Y. Jan. Howard Hughes Med. Inst., University of California, San Francisco, CA 94143-0724.

Although the Shaker locus, a gene that encodes a family of alternatively spliced potassium channels, has been cloned, little about the protein products is known. Antisera were raised to a protein produced in E. coli by the fusion of a beta-galactosidase gene with a portion of a cDNA (ShA1) . The antigen included residues from a hydrophilic region that is found in all of the predicted variant products of the Shaker locus. On Western blots, the antisera recognized a broad band (M r = 70 - 80 kD) that is consistent with the predicted sizes of ShA, ShB, ShC, and ShD (64 - 74 kD) with the posssibility of some glycosylation. This protein was enriched in a membrane preparation. On sections of fly brains, the sera stained regions of the neuropil in wild-type flies, but not in a mutant that lacks Shaker products. The darkest staining was in synaptic regions and it was not evenly distributed; cell types appear to differ in the levels to which they express these channels. Within the optic lobe, for example, the lobular plate and the margin of the medulla and lobula where they border on the secondary optic chiasm contained particularly densely stained regions. Major axon tracts, such as that in the neck or the optic chiasms showed some staining, but were generally less densely stained then synaptic regions. Electron microscopy may reveal if there is a concentration of the channel in terminals or dendrites.

186.3

DIVERSE TRANSIENT K^+ CURRENTS IN DROSOPHILA NEURONS DELETED FOR THE SHAKER LOCUS PREDICT OTHER GENES HOMOLOGOUS TO SHAKER. K.H. Baker*, L. Salkoff. Dept. of Anatomy and Neurobiology, Wash. U. Sch. of Med., St. Louis, MO. 63108.

Diversity in transient K^+ currents as generated by differential splicing at the Shaker locus appears extensive (Schwarz et al. Nature 331, Pongs et al. EMBO 7, Kamb et al. in press). Apart from the diversity generated by Shaker, we have direct physiological evidence for a diversity of transient K^+ currents encoded by at least one other locus. Molecular evidence is also suggested by a cDNA clone with homology to Shaker cDNA's (Butler et al. Soc. Neurosci. Abst. This issue). In flies whose Shaker locus is deleted (B55/W32) we have characterized at least three types of transient K^+ currents in neurons using the whole-cell voltage clamp. The classes differ with respect to rates of inactivation and recovery from inactivation. In flies deleted for the Shaker locus approximately 60% of cells have transient K^+ currents. In wild-type, a significantly higher percentage had transient K^+ currents indicating that Shaker gene products are expressed in these cells.

186.4

A DROSOPHILA ION CHANNEL ON CHROMOSOME 3 IS SIMILAR TO THE SHAKER POTASSIUM CHANNEL ON CHROMOSOME 1. A. Butler*, A. Wei, N. Scavarda*, and L. Salkoff. Dept. Anatomy and Neurobiology, Wash. U. Sch. Med., St. Louis, MO. 63110.

Based on observations that a multitude of fast transient K^+ currents exist in Drosophila which are not coded by the Shaker locus, (Baker & Salkoff, Soc. Neurosci. Abst., this issue), we postulated the existence of other Drosophila genes homologous to the Shaker potassium channel. We report here the existence of such a gene on chromosome 3L in region 62-63. The gene encodes an ion channel protein containing homology to the gating charge region of both the Shaker K^+ channel and the Drosophila Na^+ channel. However, the overall similarity is closer to the Shaker protein; membrane spanning regions have an average of 50% identity and most changes are conservative. The low DNA sequence homology between these genes in regions of amino acid identity suggests that they are derived from an ancient ancestral form. The different chromosomal locations also supports the hypothesis of ancient divergence.

186.5

GENES CONTROLLING SYNAPTIC TRANSMISSION IN *DROSOPHILA*. M. Stern* and B. Ganetzky (SPON: G. Robertson) Laboratory of Genetics, University of Wisconsin, Madison, WI 53706

One way to identify genes that control ion channel activity and synaptic transmission in the *Drosophila* neuromuscular system is by their interactions in double mutant combination with other ion channel mutations. The *Shaker (Sh)* gene encodes the rapidly inactivating potassium A channel (Tempel et al, *Science* 237: 770, 1987). Mutations in *Sh* interact with several other genes affecting ion channels. Therefore we have screened for mutations that interact with *Sh*. Five mutations, which define at least three genes, each confer reduced viability to *Sh* mutants. Two of these mutants (2-19 and 2-68) display extremely prolonged dorsal longitudinal muscle (DLM) responses to giant fiber stimulation. In all five mutants, single stimulations of larval motor neurons evoke multiple responses. This phenotype resembles that of *eag* mutants (Ganetzky and Wu, *J. Neurogenet* 1:17, 1983). In addition, the 2-60 mutation shows a striking increase in synaptic transmission in combination with *eag*. Possible involvement of these genes on potassium channels is being investigated.

We have also studied the induction of long term facilitation at the larval neuromuscular junction. We have found that *Hyperkinetic (Hk)* mutants exhibit an abnormally rapid induction of long term facilitation. Results from *Hk Sh* double mutants suggest that *Hk* mutations exert their effects on synaptic transmission via I_A, the current affected by *Sh* mutations. Supported by Research Grant NS15390 from the National Institutes of Health, a Klingenstein Fellowship, and postdoctoral fellowships from the NIH and Damon Runyon Walter Winchell Cancer Research Fund.

CLONING & EXPRESSION OF A PROBABLE POTASSIUM CHANNEL GENE FROM MOUSE BRAIN. B.L Tempel, J. Urban*, D.M. Dorsa*, L.C. Timpe, Y.N. Jan & L.Y. Jan. Howard Hughes Med. Inst. & Depts. of Physiol. & Biochem. Univ. of Calif., San Francisco, CA 94143-0724. *Depts. of Pharmacology & Med., U. of Washington & VA Med. Ctr., 1660 S. Columbia Wy, Seattle, WA 98108.

Potassium channels are a diverse class of ion channels that are important for neuronal excitability and plasticity. The recent cloning of the Shaker locus fron Drosophila has provided a starting point for molecular studies of potassium channels. Predicted Shaker proteins appear to be integral membrane proteins and have a sequence similar to the S4 sequence, which has been proposed to be the voltage sensor in the vertebrate sodium channel. Expression studies in frog oocytes confirm that Shaker encodes a component of a potassium channel (the A channel) that conducts a fast transient potassium current.

Using a probe derived from one of the Shaker cDNA, we have recently isolated clones from the mouse brain that predict a protein which is 65% identical to the predicted Shaker protein. In two stretches of over 50 amino acids the mouse and Shaker proteins are over 95% identical; in the S4-like region they are 100% identical. Because of their remarkable similarity, it is likely that these mouse brain cDNA clones also encode a component of a potassium channel.

In spite of their strong protein homology, the nucleotide sequences of the fly and mouse clones are quite different. For example, in the identical S4-like regions, 77% of those nucleotides that could change (based on codon redundency) are in fact different between fly and mouse. This high level of nucleotide divergence suggests that strong selective pressure has maintained functionally important portions of the proteins. In this light, we observe that the S4-like and predicted membrane-spanning regions are well conserved. In addition, the hydrophillic amino-terminal region preceeding the hydrophobic domain is highly conserved although its functional role is not known.

We are currently studying the expression of this gene in frog oocytes, using Northern analysis of various tissues and by in situ hybridization against sections of the mammalian brain.

186.7

CLONING OF A SHAKER POTASSIUM CHANNEL HOMOLOGUE FROM RAT BRAIN. L.K.Kaczmarek, M.B.Boyle, E.Blumenthal* and J.Marshall*. Dept. Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510 and Unit of Mol. Neurobiol. MRC, Cambridge, U.K.

Tempel et al. (Science **237**:770, 1987) have recently cloned the gene for a *Drosophila* channel that generates the transient A-current, and which is encoded by the Shaker locus. We have synthesized oligonucleotides derived from two different regions (S4 and H4) of the *Drosophila* channel. Northern analysis of 12-day rat brain poly-A^+ RNA showed that these probes bound to RNA species of approximately 6 kB. We have found that when such RNA is fractionated on a sucrose gradient and injected into *Xenopus* oocytes, fractions containing this size RNA cause the expression of the transient A-current in the oocyte.

A size-selected cDNA library was constructed from 12 day rat brain RNA in the vector gt10 and screened with a mixture of the two labelled probes. In a screen of 240000 independent clones, two positive clones were identified and purified. One of these (K41) was found to bind both probes independently and has been partially sequenced. The regions for which sequence has been obtained are highly homologous to the Shaker sequence (59% homology in nucleotides; 66% homology in predicted amino acid sequence). The 5' end of the K41 insert matches the 5' end of the H3 segment of the Shaker sequence. These results suggest that K41 represents a partial clone of the sequence encoding a transient A-potassium channel in rat brain. Hybrid selection and depletion experiments are in progress to test this hypothesis.

186.8

DIFFERENTIATION OF I_{KA} IN AMPHIBIAN SPINAL NEURONS. A.B. Ribera, C.R. Kintner, B.L. Tempel and N.C. Spitzer. Department of Biology, UCSD; The Salk Institute; Department of Physiology, UCSF.

Embryonic *Xenopus* spinal neurons exhibit voltage-dependent Ca, Na, K and Ca-dependent K currents at the time of primary neurite extension early during the first day in culture (O'Dowd et al., 1988). By the second day *in vitro*, all neurons express a third potassium current. This current is activated rapidly, inactivates during a voltage step and at depolarized holding potentials, is sensitive to mM concentrations of 4-aminopyridine, and thus resembles "A" currents of other neurons. The inactivation of this current during a depolarizing voltage step becomes more rapid during the second day. Neurons at both 1 and 2 days exhibit a relatively slow component of inactivation with a time constant of ~40 msec. However, by 2 days, a faster component with a time constant of 9 msec is apparent.

An A current is expressed in *Drosophila* nerve and muscle cells, and both the gene and trancsripts encoding this ion channel have been elucidated (Tempel et al., 1987). A *Xenopus* genomic library was screened for sequences with identity to a cDNA (ShA1) from the fly. The nucleotide sequence of one isolated clone can be aligned with the *Drosophila* sequence over the regions of 4 putative transmembrane domains: S4, H4, H5 and H6. Over a stretch of 390 nucleotides there is a 66% identity; if the analysis is restricted to the H4 segment, the identity is 80%. At the conceptual amino acid level, 79% identity is observed over 130 amino acids. Similar comparison with the mouse sequence (MBK1; Tempel et al., 1988) indicates that over the same region there are 72% and 90% identities at the nucleotide and amino acid levels, respectively. Northern blot analyses, RNase protection assays and *in situ* hybridizations using probes from this genomic clone (XSha) are likely to provide information about the molecular bases for developmental expression of this current as well as the changes in its functional properties.

186.9

MOLECULAR CHARACTERIZATION OF AN ESTROGEN-INDUCIBLE K CHANNEL mRNA FROM RAT MYOMETRIUM. M.B. Boyle, S. Cooperman*, J.S. Trimmer*, N. J. MacLusky, F. Naftolin*, and L.K. Kaczmarek. Depts. Pharmacol., Cell. Molec. Physiol. and Ob. Gynecol., Yale Univ. Sch. Med, New Haven, CT 06510 and Dept. Molec. Med., Tufts-NE Med Center, Boston, MA 02111.

We have previously reported the apparent induction by estrogen of a rat myometrial mRNA species capable of causing expression of a very slowly activating K current in *Xenopus* oocytes. We hypothesize that this mRNA species encodes a K channel whose level of expression varies during the estrous cycle and pregnancy. We have now subjected polyA+ uterine RNA from estrogen-treated animals to size-fractionation on a sucrose gradient. RNA fractions migrating near the 18S ribosomal RNA yielded expression of the slowly activating K current when injected into *Xenopus* oocytes. Using 0.8 µg of this size-selected RNA, we constructed a directional cDNA library consisting of 3 million recombinants in Lambda GEM 4 (Promega). The library was screened by injecting oocytes with sense cRNA made using 8 pools of 20,000 recombinants apiece. One pool yielded RNA capable of inducing the slowly activating K current in oocytes, implying that it contains a cDNA encoding a functional protein. We are now attempting to isolate this clone.

CHARACTERIZATION AND SOLUBILIZATION OF RAT BRAIN DENDROTOXIN RECEPTORS ASSOCIATED WITH POTASSIUM CHANNELS. R. G. Sorensen. Dept. Physiol., University of Maryland School of Medicine, Baltimore, MD. 21201.

The venom of the green mamba, Dendroaspis angusticeps, contains components (dendrotoxins, DaTx) that block brain voltage-dependent K channels. Two of these components, α-DaTx (selective for a rapidly-inactivating K channel) and β-DaTx (selective for a non-inactivating K channel), have been radioiodinated, and used in ligand binding studies and for receptor solubilization.

Monovalent and divalent cations inhibit [^{125}I]α-DaTx and [^{125}I]β-DaTx binding. The order of potency of monovalent cations for inhibiting the binding of both radiolabelled toxins is: Cs >> Rb > Li > K > Na. Only Cs inhibited toxin binding by 100% (IC_{50} = 5 mM). Dixon Plot analysis indicates that Cs is a non-competitive inhibitor. Of the divalent cations tested, Ba (IC_{50} = 5 mM) was more potent than Ca (IC_{50} = 11 mM). Because Cs and Ba block K channels, the ability of these ions to also inhibit [^{125}I]α-DaTx and [^{125}I]β-DaTx binding suggests that the toxin binding sites are at or near the ion binding site(s) of the channel.

Synaptic membranes were equilibrated with [^{125}I]α-DaTx, and the receptor solubilized as a toxin-bound complex. Approximately 75% of the specifically-bound radioactivity was solubilized, and 33% of the soluble radioactivity remained bound to the receptor. There was little change in the apparent K_D for toxin binding to the soluble receptor.

Neurotoxic action of β-Bungarotoxin may involve K channel blockade. Christina G. Benishin, Dept. of Physiology, Univ. of Alberta, Fac. of Med.,Edmonton, Alberta T6G 2H7

β-Bungarotoxin (β-BTX) isolated from the venom of Bungarus multicinctus has been previously reported to be a neurotoxic protein. The phospholipase A_2 (PL) activity of β-BTX may account for some, but not all of the neurotoxic actions. Because of the structural similarities between a portion of β-BTX, and other snake toxins reported to block K channels (Benishin et al. Fed. Proc, 46:504, 1987), β-BTX was examined for its ability to block 86Rb efflux from synaptosomes, as described earlier (Bartschat & Blaustein, J.Physiol. 361:419, 1985). β-BTX, when preincubated with synaptosomes for 30 min in the absence of Ca2+, selectively inhibited the slowly-inactivating, voltage-dependent (S) component of 86Rb efflux. The EC50 for inhibition is 3 to 5 nM. Inactivation of the PL activity with p-bromophenacylbromide does not effect the ability of β-BTX to block the 86Rb efflux, suggesting that inhibition is not associated with PL activity. Reduction and carboxymethylation of disulfide bonds dissociated the A and B chains of β-BTX. K channel inhibition is associated with the B (smaller) chain. These results suggest that the neurotoxic action of β-BTX may involve K channel blockade. Additionally, the active fragment of β-BTX may prove to be a useful tool with which to further examine functions of synaptosomal K channels. (Supported by AHFMR Scholarship)

RED/GREEN OPPONENT-COLOR INPUT TO MOTION AT LOW SPATIAL FREQUENCIES. P. Cavanagh* and S. M. Anstis* (SPON: M. Ptito) Département de Psychologie, Université de Montréal, Montréal, Québec, Canada H3C 3J7 and York University.

The contribution of color to motion was estimated by determining the contrast of a drifting luminance grating that could just null the motion of a superimposed color grating drifting in the opposite direction. Our results showed that color contributed to motion only for very low spatial frequencies, specifically only for the range of spatial frequencies for which chromatic aberration does not generate a suprathreshold luminance artifact in uncorrected viewing (less than 2 cpd). Above this range chromatic aberration ensures that there will always be some response to a chromatic grating in a luminance pathway. The color contribution to motion below 2 cpd therefore fills a functional role in providing a response to stimuli for which a luminance-based motion system would be otherwise unresponsive. The contribution of color to motion also varied substantially as a function of chromatic axis. As much as 20% luminance contrast was necessary to null the motion of chromatic gratings modulated along the red/green opponent-color axis but negligible contrast was necessary for those modulated along the tritanopic axis. Additional tests showed that the contribution of color to motion could not be attributed to a residual response in a luminance pathway resulting from retinal inhomogeneity, response nonlinearities, phase lag, chromatic aberration or interunit variation of equiluminance points. We conclude that there is a substantial contribution of red/green, opponent-color units to the motion pathway and therefore that the separation between magnocellular and parvocellular streams that is clear at early levels of the visual system becomes less so at higher levels.

187.2

THE ROLE OF THE COLOR-OPPONENT (C-O) AND BROAD-BAND (B-B) CHANNELS IN VISION. **Peter H. Schiller, Nikos K. Logothetis and Eliot R. Charles, Massachusetts Institute of Technology, Cambridge, MA 02139.**

Localized ibotentic acid lesions were made in either the parvocellular (PLGN) or magnocellular (MLGN) portions of the monkey LGN to disrupt either the C-O or B-B channels in a small region of the visual field. The consequences of these lesions were examined for a range of visual functions which included color and luminance contrast sensitivity, color, pattern, shape, texture and brightness discrimination, stereopsis and movement perception. The paradigm we used confined stimuli to either the normal or lesioned representations of the visual field: the stimuli were presented on a color monitor, and each trial began with the onset of a central fixation spot, which when properly foveated, was followed by stimuli appearing in either the intact or lesioned portions of the visual field. Foveation of the correct stimulus with a single saccade was rewarded with drops of apple juice. Catch trials minimized guessing. Eye position was monitored with a scleral search coil. PLGN lesions devastated color and pattern discrimination abilities as well as stereopsis, and had moderate to no effects on the detection of low spatial frequency stationary or moving stimuli and on coarse shape perception. MLGN lesions produced deficits in movement perception but had little or no effect on stereopsis and form vision. These findings will be discussed in relation to current ideas about the role of the C-O and B-B pathways in vision.

187.3

CLOSE CORRELATION OF COLOR, ORIENTATION AND LUMINANCE PROCESSING IN V1,V2, AND V4 OF THE BEHAVING MACAQUE MONKEY. T. Yoshioka*, B. M. Dow and R. G. Vautin*. Dept of Physiology, Sch. of Med., SUNY/Buffalo, NY 14226.

A recent report on the primary visual cortex (V1) of the macaque monkey suggests the segregation of non-oriented and oriented zones for the processing of endspectral colors (i.e., blue and red) and midspectral colors (i.e., yellow and green), respectively (Dow and Vautin, J. Neurophysiol. 57: 712, 1987). The phenomenon was further examined in the present study by adding luminance as a third variable, and by recording from cells in areas V2 and V4 as well as V1. Each cell was tested with its preferred stimulus color and shape presented on a color video screen (Chromatics) at a variety of luminance levels (both positive and negative) with respect to an intermediate gray background. The data from all 3 areas (400 well-categorized cells) indicate a strong correlation between hue, luminance, and orientation selectivity, such that cells with strongly positive luminance preferences tend to be orientation selective and to prefer midspectral wavelengths, while cells with preferences for lower (but still positive) luminances tend to be orientation unselective and to prefer endspectral wavelengths. The unoriented endspectral and oriented midspectral systems may be associated, in area V1, with the cytochrome oxidase blobs and interblobs, respectively. Supported by NIH EY02349.

UNCONFOUNDING ORIENTATION AND DIRECTION COMPONENTS IN THE VISUAL NEURON'S RESPONSE J.Zhang* and R.L.DeValois* (SPON:D.G.Albrecht) Neurobiology Group, University of California, Berkeley, CA 94720

Using moving bars or gratings as stimuli, information on orientation (which has a period of 180°) and direction (which has a period of 360°) are inherently confounded in the response of visual cortical neurons which are known to be selective for both orientation and direction. In an attempt to unconfound these two components, Wörgötter and Eysel (Biol.Cybern.57(1987),349-355) proposed to use (but incorrectly formulated) the Fourier transform technique. Here we formally develop and extend the technique to obtain from the response curve the peak and bandwidth of each underlying component and their relative strengths. We computed the coefficients of 1-D Fourier expansion of the response along a full cycle of 360° and thus transformed the N data points of equal sampling spacing into N/2 order of sine/cosine-term coefficients. The odd harmonics contain only the direction component, while the even harmonics are contributed to by both orientation and direction components, provided that the two components are linearly additive. Under this linear assumption, it can be shown mathematically that the phase and amplitude of all the harmonics are related, respectively, to the peak angle and bandwidth of the individual components. We tested this with 38 cells in monkey V1 collected and presented earlier, and found that more than half of the population follow this assumption strikingly well.

187.5

COMPUTING OPTICAL FLOW IN THE PRIMATE'S VISUAL SYSTEM: A NETWORK MODEL. **C. Koch, T.-C. Wang* and B. Mathur*, Division of Biology, 216-76, Caltech, Pasadena, CA 91125 and Science Center, Rockwell Intl., Thousand Oaks, CA 91360.**

Computing motion on the basis of the time-varying intensity brightness is an important but difficult problem for both artificial intelligence and biological vision. We here map a classical computer vision motion algorithm (Horn & Shunck, 1981) onto a primate's visual system. The aperture problem is solved by a smoothness constraint: the final optical flow should be 1. compatible with the measured data and 2. the smoothest in a certain sense. Direction sensitive cells in V1 use the time derivative of the retinal image convolved with a Difference-of-Gaussians receptive field to compute local velocity estimates (component selectivity). Sixteen cells at each location code for motion in 16 different directions. In a second stage, assumed to be located in the deep layers of area MT, the smoothness constraint is used to compute the smoothest optical flow. The resulting network was implemented using simple threshold neurons and a population coding scheme: the final optical flow is obtained by a weighted average of the vector contributions from the 16 cells coding for different directions of motion in each location.

If a plaid pattern, consisting of two gratings moving at right angles to each other, is projected onto the retina, cells in the model MT respond to the resultant coherent motion (pattern selectivity), in agreement with psychophysical and electrophysiological studies (Movshon, Adelson, Gizzi & Newsome, 1985). Our system also displays motion capture (Ramachandran & Anstis, 1985): the motion of random dots is perceptually captured by a nearby moving grating. Depending on stimulus conditions, our MT cells can respond to motion both perpendicular and parallel to the moving contour, suggesting that the type I and type II cells reported by Albright (1984) in MT represent a continuum of cells.

187.6

ILLUSIONS OF A PARALLEL MOTION ALGORITHM. H. Bülthoff, J. Little* and T. Poggio. Center for Biological Information Processing and Artificial Intelligence Laboratory, MIT, NE43, Cambridge, MA 02139

Computational theory can tell us that in general it is not possible to recover the correct 2-D projection of the true 3-D velocity from changing images. This holds not only for computer vision algorithms but also for biological motion systems. In human psychophysics many different illusions demonstrate this fact quite dramatically. It is therefore not surprising that artificial vision systems are not free of such movement illusions. A new parallel motion algorithm that we have recently developed suffers from several movement illusions (eg., barber pole illusion, motion capture and a psychophysical observation described recently by Nakayama and Silverman (Vis. Res. in press; 1988). Our algorithm consists of patchwise correlation between image features (such as the filtered brightness data or intensity edges) and then choice of the motion corresponding to the peak of the correlation over the patch around the pixel under consideration. The algorithm has been implemented on the Connection Machine by using a regularization technique which exploits the simple assumption that the optical flow is locally uniform. We propose a physiological equivalent to our "Vote for Motion" scheme which is based on a layered structure of neurons. The comparison between the different "frames" (corresponding to the product in the correlation function) takes place in different layers with progressively larger sampling bases (V1). The voting step (corresponding to the patchwise sum in the correlation function) is performed by cells with a larger receptive field that summate neurons in V1 within a patch (supposedly in Area MT). This model is consistent with psychophysical (Adelson and Bergen; 1982) and physiological data in primate visual cortical areas V1 and MT (Movshon *et al.*, 1985).

187.7

A MOVING TEXTURED BACKGROUND MODULATES THE DIRECTION SELECTIVITY OF MT NEURONS IN MACAQUE MONKEY. L. Lagae*, B. Gulyás, S. Raiguel* and G.A. Orban. Lab. Neuro- en Psychofysiologie, K.U.Leuven, Leuven, Belgium.

The modulation of the response to a narrow moving bar by a moving textured background was investigated in the middle temporal (MT, V5) and surrounding visual areas of anesthetized and paralyzed cynomolgus monkeys. The interaction series was run with the bar moving at optimal speed in either direction on the optimal axis and 7 background conditions, including no background motion and motion in either direction on the optimal axis at three speeds : same speed as the bar, two octaves slower and two octaves faster than the bar.

MT cells are strongly influenced by background motion. Their response to the moving bar is suppressed to less than 50% of their control response and the direction selectivity of most of them is modulated by the background motion. Most MT cells exhibited an antiphase conditional direction selectivity : these cells remain direction selective only when the background moves opposite to the preferred direction for the bar. The background moving in the preferred direction of the bar suppresses the response to the bar. In the areas surrounding MT, cells where less modulated by the background motion and those cells influenced were nondirection-selective cells which preferred the bar directions opposite to the background motion (antiphase cells).

The results in MT are in striking contrast to those obtained with similar methods in V1 and V2 of the monkey : only 12% and 38% of the cells have their direction selectivity modulated by background motion in V1 and V2 respectively.

NEURAL RESPONSES TO TEXTURE PATTERNS IN MACAQUE VISUAL AREA MT. J. Olavarria, E.A. DeYoe, J. Knierim, D.C. Van Essen. Div. Biology 216-76, Caltech, Pasadena, CA 91125.

We have quantitatively studied responses from 116 MT neurons to bar-like figures defined by motion, texture and/or luminance cues. In anesthetized macaques we measured responses to stimuli moved in four orthogonal directions, using a graphics monitor to induce apparent motion by frame to frame displacement. Solid luminance bars or texture bars (containing numerous line elements of identical orientation) could be surrounded by a blank field or by a texture field of the same average luminance. The surround elements were either the same orientation or orthogonal to those in the bar.

As expected, nearly all MT neurons were direction selective for solid bars, and texture bars on a blank field were just as effective. In addition, many cells responded well (88%) and were selective (53%) for the orientation or direction of motion of texture bars on a static texture background. However, both response magnitude and direction selectivity were often reduced by the texture background, and in a few cases the preferred direction of motion was reversed. About half of the cells responded better to a motion bar on a static background than to uniform motion throughout the texture field. Thus, moving texture patterns are usually effective stimuli in MT, but tuning characteristics sometimes depend on the cues used to delineate motion.

COMPARISON OF NEURAL AND BEHAVIORAL SENSITIVITY TO VISUAL MOTION IN ALERT MONKEYS. William T. Newsome, Kenneth H. Britten* and J. Anthony Movshon. Dept. of Neurobiology, Stanford University Medical School and Dept. of Psychology, New York University.

We have trained rhesus monkeys to discriminate direction of motion in dynamic random dot displays containing a variable proportion of correlated motion. We compared behavioral performance with the responses of isolated neurons recorded from extrastriate cortical area MT while the monkey performed the psychophysical discrimination; the stimulus location and direction of motion were optimized for the neuron being recorded. We performed a signal-detection analysis of neural discharge to estimate the best performance that could be based on the signals from the particular neuron under study.

As motion correlation increased, psychophysical and neural performance improved from chance to near perfection. Threshold correlations were typically between 2% and 10%, and the psychometric functions for both neural and behavioral measures were of comparable steepness. For the majority of cells, the neural correlation thresholds were within a factor of 2 of the behavioral thresholds obtained on the same trials. Within this range, some cells were more sensitive than the monkey, while others were less. We conclude that signals from relatively small numbers of MT neurons could support the monkeys' performance. (Supported by NIH grants EY-05603 and EY-2017).

ASSOCIATION BETWEEN CORTICAL UNIT ACTIVITY AND PSYCHOPHYSICAL RESPONSE IN ALERT MONKEYS. Kenneth H. Britten*, William T. Newsome, and J. Anthony Movshon, Dept. of Neurobiology, Stanford University Medical School and Dept. of Psychology, New York University.

As described in the preceding abstract, we compared the visual motion sensitivity of rhesus monkeys with the sensitivity of single neurons in extrastriate area MT. For many neurons we observed an association between the monkey's psychophysical responses and the discharge of the neuron under study. For a given stimulus condition (direction of motion, correlation level), trials eliciting judgements that motion was in the neuron's preferred direction tended to contain neural responses that were 5-10% larger than trials eliciting the opposite judgement. As a rule, this was the case for stimuli in both the preferred and null directions, and also for zero correlation stimuli, which contain no net motion.

Using a method derived from signal detection theory, we computed a statistical estimate of the predictability of the monkey's response based on the neuron's discharge; this prediction is better than chance for most neurons, and for some substantially so. These neurons may, therefore, contribute directly to perceptual decisions concerning visual motion. (Supported by NIH grants EY-05603 and EY-2017).

187.11

MOTION RIVALRY USED TO STUDY NEURONAL ACTIVITY UNDERLYING MOTION PERCEPTION. N.K. Logothetis and J.D. Schall, Department of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139

Rhesus monkeys were trained in a motion detection task. Horizontal gratings drifting up or down were presented to both eyes independently either in the same direction or in opposite directions. The monkeys were trained to signal whether they perceived up or down motion, and we recorded OKN. When the stimuli were not rivalrous, the monkeys performed correctly; hence, we inferred that when the stimuli were rivalrous, the response corresponded to the perceived motion direction. In agreement with an earlier study (Fox et al., Vis. Res. 18:849 77), we found that the perceived direction corresponded to the direction of the slow phase of OKN under rivalrous conditions. Moreover, when the monkey did not pursue either of the rivalrous gratings, he failed to respond. These results were confirmed with human observers who reported a coherent whole field motion percept only when pursuing one of the rivalrous gratings. We are currently studying the responses of single units in MT while monkeys perform this task to determine if the neuronal activity reflects the physical stimulus or the perceived stimulus.

"DEFICITS OF VISUAL MOTION ANALYSIS AFTER POSTERIOR RIGHT HEMISPHERE LESIONS." L. Vaina[1,2], M. LeMay[1]*, S. Naili[1]*, P. Amarillio[1]*, D. Bienfang[2]*, C. Montgomery[1]*, Y. Thomazeau[2]*. Intelligent Systems Laboratory, Boston Univ. Depts. of Biomedical Engineering and Neurology, Massachusetts Institute of Technology-Harvard Medical School, Boston, MA. 02215

Several new experimental tasks have been designed to address the measurement and the interpretation of visual motion in patients with focal brain lesions involving the visually responsive cortical areas. We were interested to learn how motion deficits cluster and what correlation may be established with the anatomical locus of the lesion, the neuro-ophthalmological profile of the subject, and with other aspects of visual processing such as contrast sensitivity, acuity and hyperacuity, stereopsis, texture and form. The most significant findings on the detailed study of 5ROcctemp and 5ROccPar patients were: the ability to appreciate speed of motion is strongly coupled with the ability to derive 3-D structure from motion; the perception of 2-D pattern from motion occurs more quickly than the perception of 3-D structure ($p<.02$); ROT group is able to perform coarse segregation through motion (speed), stereopsis, but they are markedly impaired in determining the specific shape of the figure. Acuity and hyperacuity were in all cases good; the ROP group was significantly impaired on tasks involving the interpretation of motion, random dot stereograms, and the processing of low contrast moving patterns.

188.1

MORPHOLOGICAL DEVELOPMENT OF PRIMATE RETINAL GANGLION CELLS. D. DeJager* and M.A. Kirby. Depts. of Pediatrics and Anatomy, Sch. of Med., Loma Linda University, Loma Linda, CA 92350.

Little is presently understood of the developmental processes that determine the mature dendritic morphology of retinal ganglion cells (RGC). To evaluate this we have employed retrograde transport of horseradish peroxidase (HRP) and cultured retinal wholemount techniques to examine the time course and pattern of dendritic maturation of RGC in the primate (Macaca mulatta).

Fetal monkeys (embryonic day, E60-E150; n=12) were delivered by Cesarean section, deeply anesthetized, and the retinae dissected into oxygenated media. HRP crystals were inserted into the fiber layer and the retinae placed into a 95% O_2-5% CO_2 incubator (37^0 C) for three hours. The retinae were then fixed in aldehyde and processed for HRP. Cells were used for analysis employing a strict criteria that included: (a) an axon that could be followed in the fiber layer toward the optic disk/deposit site (typically 1-2mm), (b) terminal dendritic processes that were densely labeled, continuous, and terminated either in growth cones or high order branches.

At E60 ganglion cells evidenced relatively uniform, small dendritic arbors derived from one or two primary dendrites. When two primary arbors were present these were observed to arborize in opposite portions of the inner plexiform layer. Axons at this age often had small limited branches that rarely entered the optic disk. Over the next several weeks the dendritic arbors continued to increase in size and complexity. By E131-138, ganglion cells had complex arbors with numerous small high order branches; several terminating in growth cones. By E147-150 few growth cones were found, and the majority of cells were similar in morphology to classes described for the adult. Our results suggest that classes of RGC in the fetal monkey can be distinguished morphologically as early as two weeks prior to birth.

188.2

THE NASOTEMPORAL DIVISION OF THE RETINAL GANGLION CELL DECUSSATION PATTERN IN THE FETAL RHESUS MONKEY. Barry Lia, Cara J. Snider* and Leo M. Chalupa, Dept. Psychology & California Primate Research Center, University of California, Davis CA 95616

Primates are distinguished from other mammals by the strict nasotemporal division of their retina: ganglion cells in the nasal hemiretina project contralaterally, while those in the temporal hemiretina project ipsilaterally. In all other mammals, a substantial proportion of cells with contralateral projections is found in the temporal hemiretina. To learn how the unique primate pattern is established, we examined the decussation of retinal ganglion cell projections in 5 fetal rhesus monkeys (*Macaca mulatta*) ranging in age from embryonic (E) days E69 to E129 (gestation: 165 ±2 days). Prior to *in utero* surgery, the optic chiasm and the lateral geniculate bodies were localized in the fetus by ultrasonography of the gravid female. This facilitated the subsequent unilateral injection of horseradish peroxidase into the optic tract.

Analysis of the distribution of labeled ganglion cells in retinal wholemounts revealed that at all fetal ages the retinal decussation pattern is remarkably precise. In the youngest fetus (E69), we found that only 0.3% of the retinal ganglion cells project to the inappropriate hemisphere. This degree of nasotemporal specificity is evident at a time when the projections from each eye are completely intermingled within the lateral geniculate and superior colliculus (Rakic, 1976), and prior to any appreciable loss of retinal ganglion cells (Rakic & Riley, 1983). Our results indicate that the precision of the fetal primate decussation pattern is greater than that of any other mammalian species studied to date, including that of the fetal cat (Lia, Kirby, and Chalupa, 1987). Moreover, there is no 'recapitulation' of the general mammalian plan of decussation.

188.3

TRANSIENT PROJECTION OF BETA RETINAL GANGLION CELLS TO THE SUPERIOR COLLICULUS DURING PRENATAL DEVELOPMENT. C.J. Shatz, A.S. Ramoa and G. Campbell. Dept. of Neurobiology, Stanford University School of Medicine, Stanford CA 94305.

The majority of retinal ganglion cells (RGCs) of the beta class project to the lateral geniculate nucleus (LGN) but not to the superior colliculus (SC) of adult cats. Is this target specificity present initially during development? RGCs that project to the SC at different times were identified by injecting rhodamine labeled microspheres into the SC at E38, E43 or postnatal day 4. Between E56 and P32, when alpha and beta cells are clearly identifiable if filled intracellularly with Lucifer Yellow (LY), retinae were removed and placed in a slice chamber. Microsphere-labeled RGCs from 8 cats were then filled with LY. As expected, beta cells were not retrogradely labeled by microspheres injected in the SC of postnatal cats (0 beta cells out of 47 RGCs filled that also included alpha and gamma cells). In contrast, microspheres injected prenatally in the SC of 3 cats always labeled beta cells morphologically similar to those projecting to the LGN (26 beta cells/ 86 RGCs examined at E56, P8 or P32). This was true even when microspheres were injected only into the caudal pole of the SC. These observations indicate that many beta cells initially send an axon to the SC during fetal life. Then, sometime between E43 and birth they must withdraw this collateral, possibly due to competition with alpha and gamma cells for territory within the SC.(NSF BNS 8616798 and March of Dimes).

188.4

IN VITRO DEVELOPMENT OF RETINAL GANGLION CELL STRUCTURE. P.R. Montague* and M.J. Friedlander (SPON: J.S. Tootle). Neurobiology Research Center, U.A.B. Sch. of Med., Birmingham, AL 35294.

Retinal ganglion cells from kittens postnatal age 2-42 weeks were retrogradely labeled with fluorescent markers and cultured. The development of their structure was followed with a time lapse video system (Soc. Neurosci. Abstr. 13:1299). The growth of the neurites of the cultured RGCs occurs primarily at the growing tips. The occurrence of a branch sprouting proximal to an already established branch is rare, and is independent of the final pattern that the neurites form. No significant overlap of neurites is observed for individual RGCs or between adjacent cells' neuritic arbors. (n = 17 identified RGCs).

We have used an estimate of the Hausdorff dimension of the images to generate a metric for the complexity of the neuritic patterns and to relate these patterns to models of process growth. After the neurons are plated, the Hausdorff dimension of the neuritic patterns increases with time (average **total** increase of 41%), and stabilizes after 10 days in culture. For a local region of an individual neuritic pattern, the Hausdorff dimension is dynamic and can change as much as 30% per hour, thus indicating a major remodeling of the neuritic pattern with time.

188.5

POSTNATAL DEVELOPMENT OF CAT RETINAL GANGLION CELLS. S.J. Ault and A.G. Leventhal. U. Utah Sch. Med., Anat. Dept., Salt Lake City, UT 84132.

We injected HRP into the LGNd and superior colliculi of 1 day old kittens and adult cats. Morphologies of labeled alpha (Y), beta (X) and all other cells (gamma (W) cells) were compared in kitten and adult retinae. In the neonate alpha, beta and gamma cells are recognizable (Ramoa et al., Science 237:522, 1987; Dann et al., Neurosci. Lett. 80:21, 1987). However, kitten alpha and beta cell bodies are significantly smaller than in the adult while remaining cell types are nearly adult sized. In fact, at birth beta cell bodies throughout the retina are significantly smaller than those of gamma cells. During the first 12 weeks of life, alpha and beta cell bodies increase in volume from 5 to 25 times depending upon eccentricity. Gamma (other) cells hardly increase in size at all. Also, the normal adult centro-peripheral cell size gradient for alpha and beta cells is not seen in the neonate. Gamma cells show no such gradient in the neonate or adult.

Thus, cat retinal ganglion cell classes seem to mature at different times. This observation may explain why some cell classes (e.g., alpha and beta) grow to be abnormally large in cell-poor regions while others (e.g., gamma) seem not to be affected when ganglion cell density is reduced by cutting one optic tract at birth (Leventhal et al., J. Neurosci. In press, 1988). These results may also explain why the sizes of LGNd W-cells are affected less by visual deprivation in early life than are those of X- and Y-cells (Hickey, JCN 189:467, 1980; Leventhal and Hirsch, JCN 214:59, 1983). Gamma (W) cells but not alpha (Y) and beta (X) cells normally stop growing soon after birth, prior to the time the foregoing surgical and environmental manipulations are carried out. Our results add to the growing body of evidence that different mechanisms mediate the morphological development of different classes of cells in cat retina.

188.6

RETINAL GANGLION CELL DEVELOPMENT IN PRIMATES. A.G. Leventhal, S.J. Ault and D.J. Vitek. Departments of Anatomy and Radiology, University of Utah School of Medicine, Salt Lake City, UT 84132

We studied the morphologies and retinal distributions of the different classes of ganglion cells in normal infant monkeys and in adult monkeys in which small strips of retina were depleted of ganglion cells at birth as a result of lesions made around the perimeter of the optic disc. New and old world monkeys were studied.

We find that the fovea is immature in neonates (see also Hendrickson and Kupfer, Invest. Ophthal. 15:746-756) as well as in adult monkeys in which the density of ganglion cells in central retina is reduced at birth. In both groups the foveal pit is small and contains many B(midgit) ganglion cells. B cells within the foveal pit project to the lateral geniculate nucleus and are larger than other foveal B cells. All of the morphological classes of retinal ganglion cells are recognizable in infant monkeys; cells in central and paracentral but not peripheral regions are close to adult size. Also, at birth an adult-like 'nasotemporal division' is evident.

In central retina of lesioned monkeys the cell bodies and dendritic fields of ganglion cells in depleted regions are up to ten times larger than normal. Unlike in cat central retina (Leventhal et al., 1988, J. Neurosci., in press) the dendrites of the abnormally large cells on the borders of cell poor zones are directed normally (toward the foveal pit) and are not directed away from neighboring cells.

We suggest that competition for afferents as well as direct interactions among neighboring ganglion cells in the immature retina contribute to the development of the structure and distribution of primate retinal ganglion cells.

188.7

SPONTANEOUS ACTIVITY OF RAT RETINAL GANGLION CELLS IN PRENATAL LIFE. L. Galli* and L. Maffei* (SPON: V. KAMP NIELSEN). Istituto di Neurofisiologia CNR 56100 Pisa, Italy.

The existence of spontaneous spike activity in retinal ganglion cells during early prenatal development has long been postulated. Such activity would play a key role in the formation of retinal connections. We have recorded from the retina of rat fetuses aged from 17 to 20 days post-conception.

Pregnant Long-Evans rats were anesthetized with urethane. Fetuses were taken from the mother uterus and placed in a low melting point wax bath, keeping the umbilical cord intact. Fetuses were then given a supplementary dose of urethane and paralyzed. Fetal body temperature and ECG were monitored continuously. Recordings were made with micropipettes inserted through a hole pierced into the sclera.

Spontaneously active cells were found in the retina at all ages studied. These cells showed irregular firing patterns, with average frequencies 0.5 - 1 spike/s. Relative long periods of silence altered to discharge periods of 4 - 5 spike/s.

These findings, which show for the first time the presence of spontaneous activity in mammalian retinal ganglion cells during prenatal life, strengthen the hypothesis of a possible role of electrical activity in the development of retinal connections.

188.8

TETRODOTOXIN (TTX) INFUSION DOES NOT PREVENT NATURALLY OCCURRING RETINAL GANGLION CELL DEATH. S. Friedman* and C.J. Shatz. (SPON: M. Siegel). Dept. of Neurobiology, Stanford University School of Medicine, Stanford CA 94305.

In the cat, only 20% of the retinal ganglion cells in the fetus will survive to adulthood. To determine whether action potential activity affects nerve cell death, TTX, a voltage-sensitive Na^+ channel blocker, was infused intracranially via osmotic minipumps into cat fetuses starting at E42, before the period of major ganglion cell loss. At E49 and E57, optic nerves were processed for EM to assess the effects of TTX treatment on axon number and ultrastructural organization.

The numbers of axons counted using the procedures of Williams et al. (J. Comp. Neurol. 246:32, '86) in TTX-treated animals examined at E49 or E57 were not significantly different from the counts of normal animals at comparable ages (Sretavan & Shatz, J. Neurosci. 6:990, '86): E48 normal- $3.3x10^5$; E49 TTX- $3.2x10^5$; E59 normal- $2.5x10^5$; E57 TTX- $2.1x10^5$. However, while E49 TTX-treated nerves were indistinguishable from normal nerves at the same age, E57 TTX-treated nerves were quite abnormal. Fasciculation of axons was disrupted by many pale, organelle-poor processes that had large cross-sectional areas. These processes were not axonal: they stemmed from glial cell bodies in longitudinal EM sections and acquired organelles typical of glial cells in serial EM sections. They were therefore not included in our axon counts.

These results indicate that intracranial infusion of TTX for the two week period during naturally occurring cell death does not rescue ganglion cells; they suggest that action potential activity does not control ganglion cell number. However, in view of the observed glial cell abnormalities, we suggest that action potential activity is important for the normal maturation of optic nerve glia. (Supported by NSF Grant BNS 8616798 and the March of Dimes)

188.9

DEVELOPMENT OF CHEMOSENSITIVITY AND ACTION POTENTIAL (AP) ACTIVITY IN RETINAL GANGLION CELLS (RGCs) OF THE RAT. A.S. Ramoa, S.S. Deshpande* and E.X. Albuquerque Lab. Mol. Pharm. II, Inst. Biophys. CCF, Fed. Univ. Rio de Janeiro, Brazil 20540 & Dept. Pharm. Exp. Ther., Univ. MD Sch. Med., Baltimore, MD 21201.

Although a good deal is known about morphology of developing RGCs, surprisingly little is known concerning development of their membrane properties. To address this issue, we labeled RGCs in vivo by retrograde transport with rhodamine-labeled latex microspheres. Next, RGCs obtained from rats at different stages of development were enzymatically dissociated and maintained in culture for up to 8 hours. Whole-cell patch-clamp recordings revealed that the number of RGCs firing APs increased from 40% of 28 cells at P3-5 to 92% of 36 cells at P20-23. At every age tested, tetrodotoxin (1 μM) blocked AP activity. Outside-out patch-clamp recording (n=28) revealed that, as early as P3 RGCs responded to N-methyl-D-aspartate (NMDA-10-50 μM), quisqualate (10-50 μM), and the agonist of the nicotinic-Acetylcholine receptor, (+)anatoxin (1-10 μM). The conductance values and the mean burst duration of the single channel currents elicited by NMDA (about 40 pS and 10 msec) and anatoxin (42 pS and 21 msec) remained unaltered during development. Application of phencyclidine, which is known to block the excitatory effect of NMDA, reduced the frequency and duration of ion channel openings elicited by both NMDA and anatoxin in the retina. In conclusion, concurrent with morphological changes that occur in neonatal retina, an increasing number of RGCs fire APs. In contrast, properties of post-synaptic receptors found in RGC membrane appear to remain unaltered during development. (CNPq-Brazil, U.S. Army Med. Res. Devel. Comm. DAMD17-84-C-4219, NIDA Grant DA02804)

188.10

THE DEVELOPMENT OF INDIVIDUAL RETINOGENICULATE AXONS DURING LAMINAR AND SUBLAMINAR SEGREGATION IN THE FERRET LGN. J. Hahm* and M. Sur. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

We have used an in vitro HRP labeling method (Sretavan & Shatz, J. Neurosci. 6:234, 1986) to study the morphology of individual retinal axons during the (postnatal) development of eye-specific laminae and On/Off sublaminae in the ferret lateral geniculate nucleus (LGN).

In the first 24 hours after birth, the LGN is not yet laminated, and retinal axons are relatively primitive in structure with a single main trunk extending through the nucleus. However, some axons have long, widely diverging branches covering a large portion of the nucleus. At this age the fibers are studded with extremely fine fibrils throughout their extent and have occasional side branches.

At P7-P8 the LGN shows contralateral and ipsilateral laminar zones (Linden *et. al.*, J. Comp. Neurol., 203:189, 1981). Retinal axons have begun to develop arbors which are confined to and span the width of one eye-specific layer. The main axon trunks are smooth, the fine fibrils no longer present. By P15, some retinogeniculate terminal arbors have taken on a distinct, narrow morphology. Arbors are more heavily branched and clearly confined to one eye-specific lamina, although there is no obvious indication of sublaminar segregation.

At P19 the axonal arbors appear to be segregating into sublaminae within the A and A1 layers. Cellular sublamination is definitive at P21. By P28-P35 the retinal axons have taken on an adult-like framework (Roe *et. al.*, Soc. Neurosci. Abs., 12:9, 1986) and well-formed boutons have replaced growth cones on many endings.

We propose the following sequence of events in the development of retinogeniculate axons: 1) fibers grow into the LGN and extend through the entire nucleus; 2) small branches and fibrils in inappropriate zones are lost as axons elaborate arbors in their eye-specific layer; 3) axons further refine their terminal arbors and consolidate their terminations in On and Off sublaminae.

RETINAL PROJECTIONS INDUCED INTO AUDITORY THALAMUS IN FERRETS: VISUAL TOPOGRAPHY IN PRIMARY AUDITORY CORTEX. A. W. Roe, S. L. Pallas, J. Hahm*, Y. H. Kwon*, and M. Sur. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Removing normal retinal targets in neonatal ferrets and deafferenting the medial geniculate nucleus (MGN) induces an aberrant visual pathway from the retina to auditory thalamus and, in turn, to auditory cortex (Sur and Garraghty, Soc. Neurosci. Abstr. 12:592, '86). In these animals, we have studied the spatial pattern of thalamocortical projections to primary auditory cortex (AI) and the physiological map of visual space in AI. In normal adult ferrets and in operated ferrets reared to adulthood, we injected multiple tracers (WGA-HRP, Rhodamine, Fluoro-Gold) in AI, located in the medial ectosylvian gyrus (Kelly *et al.*, Hearing Res. 24:111, '86). AI in operated ferrets receives projections from regions of the lateral posterior/pulvinar complex. Otherwise, connections between the MGN and AI in operated animals closely resemble those in normal animals: single loci in AI receive projections from rostrocaudally oriented slabs of cells in deep dorsal, ventral, and medial divisions of MGN (Pallas et al., *this volume*).

In normal ferrets, the cochlea maps in a tonotopic fashion along roughly the mediolateral dimension of AI, while the anteroposterior dimension contains isofrequency lines (Kelly *et al., ibid.*). We find that the map of the contralateral visual field in AI of operated animals, while not as refined as in normal striate cortex, is two-dimensional and topographic. Azimuths increase in a mediolateral direction, and elevations increase roughly in a posterior-anterior direction in AI, though considerable variability exists along this axis. Since the axis of variable elevation is also the isofrequency axis in normal AI, one interpretation of our results is that this dimension of the visual field map is created physiologically in cortex from a highly overlapped thalamocortical projection system. Alternatively, the two-dimensional topography might arise from visual projections to AI through the LP/pulvinar complex.

188.12

RETINAL PROJECTIONS INDUCED INTO AUDITORY THALAMUS IN FERRETS: CHANGES IN INPUTS AND OUTPUTS OF PRIMARY AUDITORY CORTEX. S.L. Pallas, A.W. Roe, and M. Sur. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Retinal projections can be routed into the auditory thalamus (MGN) as a result of appropriate surgery in neonatal ferrets, conferring visual responsiveness onto primary auditory cortex (AI) (Sur & Garraghty, Soc. Neurosci. Abstr. 12:592, '86; Roe *et al.*, this volume). We have studied the thalamocortical, corticothalamic, and corticocortical connectivity in these animals to see whether the early lesions can influence the connectivity patterns of auditory cortex.

In normal adult ferrets and adult ferrets operated on as neonates, injections of tracers (WGA-HRP, Rhodamine, and Fluoro-Gold) were made into AI, located in the medial ectosylvian gyrus (Kelly *et al.*, Hearing Res. 24:111, '86). In normal ferrets, retrograde and anterograde label was found in the deep dorsal, ventral, and medial divisions of the MGN, and in the lateral division of the posterior thalamic nucleus, as in cats. Retrograde cortical label was found bilaterally in AI, areas anterior to AI, lateral to AI, and far lateral in the ventral convexity of the cortex. In neonatally operated ferrets, thalamic label was found in the same nuclei as in normal ferrets, and in new zones: the dorsal caudal division of the MGN and the LP/Pulvinar complex of the thalamus. Patterns of retrograde corticocortical labelling in operated animals included the same areas as in normal animals, and new zones in the ipsilateral and contralateral anterior lateral gyrus.

These results indicate that novel thalamocortical pathways as well as novel cortical connections can be induced into AI by the early lesions. The neonatal lesions either cause sprouting of these new projections, or stabilization of early exuberant projections that are normally eliminated.

RESPIRATORY REGULATION I

189.1

EFFECTS OF EXPIRATORY MUSCLE AFFERENTS ON INSPIRATORY NEURONS OF THE DORSAL RESPIRATORY GROUP OF CAT. S. Iscoe*, L. Grelot* and A.L. Bianchi* (SPON: P. Zarzecki). Département de Physiologie et Neurophysiologie, Faculté des Sciences et Techniques St.-Jérôme, 13397 Marseille Cedex 13, France.

At elevated end-expiratory lung volumes, inspiratory duration (Ti) does not decrease despite increases in both pulmonary stretch receptor (PSR) feedback and chemical drive. We hypothesized that afferent activity from expiratory muscles inhibits the medullary neurons to which PSR project, blocking their excitation by PSR and, therefore, a decrease in Ti. We recorded intracellularly from 25 bulbospinal inspiratory neurons of the dorsal respiratory group (DRG) of decerebrate, paralyzed and ventilated cats. Sixteen neurons had excitatory monosynaptic projections from PSR. However, in only 2 neurons did the inhibition evoked by conditioning stimuli to afferents of expiratory muscles (internal intercostal or external oblique) block the PSR-mediated excitation. Instead, most neurons were either not affected (17) or excited (6) by stimulation of excitatory muscle afferents. Therefore, fixation of Ti at control values during respiration at elevated lung volumes is not due to inhibition of inspiratory neurons of the DRG by afferent activity from caudal expiratory muscles. Supported by the C.N.R.S. (France) and M.R.C. (Canada).

189.2

INTERRUPTION OF PULMONARY STRETCH RECEPTOR- (PSR) RELATED RESPIRATORY REFLEXES BY A DISCRETE COBALT INJECTION IN THE NUCLEUS TRACTUS SOLITARIUS (NTS) IN RATS. A.C. Bonham and D.R. McCrimmon, Dept. Physiology, Northwestern U., Chicago, IL. 60611.

We previously reported that (1) microinjecting DL-homocysteic acid (DLH, 1-6 nl, 20 mM) into a discrete site in the medial NTS produced an apnea similar to that elicited by activating PSR, and (2) pump cells (single units which discharged with lung inflation and were silent when lung inflation was withheld) were recorded in the DLH-sensitive site (Fed. Proc. 46:6442, 1987; Soc. Neurosci. Abs. 13:1638, 1987). To determine if neurons in this NTS site are important in the Breuer-Hering inspiratory shortening reflex, we interrupted neuronal transmission by microinjecting cobalt chloride (Co^{2+}) in the DLH-sensitive site and studied the effects on baseline respiratory rhythm and the reflex response to maintained lung inflation. We measured phrenic nerve discharge, expired CO_2 and arterial pressure in urethane-anesthetized, spontaneously-breathing or ventilated rats. A double-barrel pipette was used for microinjecting; one barrel contained DLH (20 mM)and the second contained Co^{2+} (20 - 100 mM). Once the site was established where microinjecting DLH produced an apnea (0.5 mm rostral to calamus and 0.7 mm lateral to midline), we maintained lung inflation at pressures from 2.5 cm to 20 cm H_20 and determined the effect on phrenic nerve discharge. Co^{2+} was then microinjected in the DLH-sensitive site and the lung inflation maneuver and DLH injection repeated. Co^{2+} microinjected within the DLH-sensitive site (1) prolonged the inspiratory and expiratory periods and (2) markedly diminished the inhibitory effects on phrenic nerve discharge produced by maintaining lung inflation. Co^{2+} did not prevent the DLH-induced apnea, indicating that Co^{2+} impaired synaptic input but did not directly depress postsynaptic neuronal excitability. The Breuer-Hering reflexes recovered within 1 hour following Co^{2+}. These results suggest that neurons in a discrete site in the medial NTS are important in the Breuer-Hering inspiratory shortening reflex. Supported by NIH grant RR-05370 and NRSA, HL07717-01, to Dr. Bonham.

LOCALIZATION OF THYROTROPIN-RELEASING HORMONE (TRH) RECEPTORS IN SUBNUCLEI OF THE NUCLEUS TRACTUS SOLITARIUS (NTS). S. Manaker and G. Rizio*, Cardiovascular-Pulmonary Division, Dept. of Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA 19104-4283

The nucleus tractus solitarius (NTS) is an important site for the integration of pulmonary vagal afferents with the central nervous system. The NTS is divided cytoarchitectonically into different subnuclei, each of which may have different physiological functions. The neuropeptide thyrotropin-releasing hormone (TRH) is localized within the NTS, and central administration of TRH produces tachypnea. In addition, specific high-affinity receptors that may mediate the respiratory actions of TRH are present within the NTS. In the present study, we determined the concentration of TRH receptors within individual NTS subnuclei using quantitative autoradiography and our previously published technique (Manaker et al, J Neurosci 5:167-174, 1985).

The highest concentration of TRH receptors (200 fmol/mg P) was observed in the gelatinosus subnucleus of the NTS. High concentrations (100-150 fmol/mg P) were also observed in the medial and intermediate NTS subnuclei. Moderate concentrations of TRH receptors (40-80 fmol/mg P) were observed in the remaining NTS subnuclei (commissural, ventrolateral, dorsal) as well as the solitary tract. These results suggest that TRH and TRH receptors may play a role in the integration of pulmonary vagal afferents in the gelatinosus, medial and intermediate NTS subnuclei.

CAROTID BODY CHEMORECEPTOR (CR) INPUT TO INSPIRATORY HYPOGLOSSAL MOTONEURONS (IHMs). S.W. Mifflin Department of Pharmacology, The University of Texas Health Science Center, San Antonio, Texas 78284-7764.

The phasic discharge of IHMs aids in maintaining upper airway patency. To better understand the behavior of IHMs in normal and pathological states IHM responses to CR inputs were examined in pentobarbital anesthetized, vagotomized, mechanically ventilated and paralyzed cats. Intracellular recordings were obtained from 12 IHMs. Injections through an intra-carotid catheter of .1-.5 ml of .15M $NaHCO_3$ gassed with 100% CO_2 increased phrenic nerve discharge. During CR evoked changes in phrenic nerve discharge the inspiratory depolarization and discharge frequency of the 12 IHMs increased. Injection of non-CO_2 gassed saline had no effect. In 5 IHMs during CR activation the depolarization at the beginning of inspiration was 3-8mV greater than under control conditions so that discharge began virtually at the onset of inspiration. The time difference between the onset of inspiratory depolarization and the beginning of IHM discharge ranged from 280-600msec under control conditions compared to 86-320msec during CR activation (paired t-test, $p<.05$).

In conclusion, during a CR evoked increase in inspiratory drive to phrenic motoneurons, the parallel increase in IHM discharge should aid in the maintenance of upper airway patency. (Supported by NIH Grant HL41894).

AGE DIFFERENCES IN CAT RESPIRATORY RESPONSE TO INCREASED INSPIRED CO_2. Bada, F., Archer, P. Jackson, E., Whittaker, J., Bernard, D.G., Millis, R.M., Trouth, C.O. Dept. Physiol., Coll. Med. Howard University, Washington, D.C. 20059.

This study examines the hypothesis that the brainstem respiratory chemosensory system might not be functionally mature at birth. In 3 age groups (newborns 1-6 days; young pups 4-6 weeks, and adult >7 months) of spontaneously breathing cats anesthetized with chloralose urethane, respiratory response to increased inspired CO_2 ($PICO_2$) were examined. In the ADULT and Young minute ventilation ($\dot{V}_E$) increased in response to 7% inhaled CO_2 and arterial pH 7.2 by approx. 138% and 106% respectively whereas in the NEWBORN only a 23% increase in $\dot{V}_E$ was observed. Neurons in the caudal chemosensitive area were tested for their responsiveness to increased inspired CO_2 ($PICO_2$) and CSF-pH. In the ADULT and Young animal, non-phasic pH sensitive units increased their firing rate by approx. 200% and 110% respectively in response to increased $PICO_2$ and acid CSF, whereas in the NEWBORN, increased $PICO_2$ caused only slight increases to no changes in neuronal activity. Electron microscopic examination at the caudal chemosensitive area (Area "L") revealed that evaginations of the ventral surface abutting the overlying pia mater which delimit discrete compartments were more pronounced in the adult animal and least marked in the newborn. Neuronal elements in vascular walls, reminescent of neurovascular junctions in cerebral and systemic arteries and arterioles, were most pronounced in the young. Support: MBRS-2-S06-RR-08016-16.

PHRENIC MOTONEURON PROPERTIES IN THE PERFUSED GUINEA PIG. Corey Cleland and Peter Getting, Department of Physiology and Biophysics, Univ. of Iowa, Iowa City, Iowa 52242

Mammalian respiration arises from neurons in the brainstem and spinal cord, however, the neural mechanisms underlying formation of the respiratory motor pattern remain unclear. Our goal is to characterize the cellular, synaptic and network features of phrenic motoneurons using a brain-spinal cord preparation perfused with artificial blood, which permits stable recordings and control over blood composition [Richerson and Getting, *Brain Res.* 409(1987)128].

Anesthetized guinea pigs (350 gm) were instrumented with EEG, phrenic and vagal electrodes. The C3-C6 segments were exposed and the descending aorta ligated. The rostral half of the guinea pig, including the brain and spinal cord, was kept alive by non-pulsatile perfusion with a fluorocarbon-based artificial blood containing pentobarbital and Flaxedil. Fictive respiration remained normal for up to 9 hours at 37°C. Phrenic motoneurons were identified by antidromic activation.

We have recorded intracellularly from 24 phrenic motoneurons during fictive respiration. Their firing patterns and underlying membrane potential (Vm) oscillations resemble those observed in cat phrenic motoneurons. Fictive respiration, although essential for identifying and characterizing respiratory-related neurons, complicates the determination of cellular properties. Therefore, we reversibly eliminated respiratory modulation by repetitive stimulation of the vagus nerve to evoke the inspiration-supressing Breuer-Hering reflex. Compared to hypercapnea or spinal block, vagal stimulation can be rapidly applied, is easily controlled and does not alter pH or pCO_2, parameters that affect cellular properties and cerebral blood flow. Our preliminary results indicate that Vm during vagal stimulation is constant and similar to that during expiration. Furthermore, stimulus-triggered averaging did not reveal any detectable PSPs. Thus, vagal stimulation appears to produce a stable, reproducible Vm during which we can evaluate the cellular properties of phrenic motoneurons.

BRAINSTEM PROJECTIONS TO THE VENTRAL RESPIRATORY GROUP (VRG) IN THE RAT: COMPARISON WITH CATECHOLAMINE CELL GROUPS. H.H. Ellenberger, C.A. Connelly & J.L. Feldman, Systems Neurobiology Lab., Dept. of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Rhodamine impregnated latex beads (40 nl; 20% in saline) were injected into physiologically identified regions of the inspiratory (rostral) (r)VRG to retrogradely label caudal brainstem neurons projecting to rVRG. Norepinephrine and epinephrine containing neurons were labeled simultaneously by immunoreaction of dopamine β-hydroxylase (DBH) in the same tissue sections. Populations of rhodamine (Rh)-labeled and DBH-labeled neurons formed partially overlapping, yet distinct cell groups in 3 regions of the caudal brainstem: 1) The nucleus of the solitary tract, where Rh-labeled neurons were found lateral, ventrolateral, ventral, medial and dorsomedial to tractus solitarius (TS) and in area postrema. Rh-labeled neurons medial to TS were intermingled with DBH-labeled neurons of the A2 and C2 groups. 2) The ventrolateral medullary reticular formation; where Rh-labeled neurons of the VRG were dorsomedial to, but partially intermingled with the A1 and C1 cell groups. In the rostral medulla, Rh-labeled neurons were clustered dorsal and ventral to the C1 group forming 2 distinct groups in the lateral paragigantocellular nucleus. 3) The Kölliker-Fuse nucleus; where Rh-labeled neurons were dorsal to, but partially intermingled with DBH-labeled neurons of the A7 cell group.

The proximal relationship between presumptive respiratory (rhodamine-labeled) and DBH-labeled neurons in these regions suggests a parallel organization of respiratory and other autonomic pathways in the brainstem. Furthermore, local processing within these regions may be important in the central coordination of respiratory and cardiovascular function. Supported by NIH grants HL-37941 and HL- 07363.

RAPHE PROJECTIONS TO THE VENTRAL RESPIRATORY GROUP (VRG) IN THE RAT: COMPARISON WITH SEROTONIN (5-HT) IMMUNOREACTIVE CELLS. C.A. Connelly, H.H. Ellenberger & J.L. Feldman, Systems Neurobiology Lab., Dept. of Kinesiology UCLA, Los Angeles, CA 90024-1568.

Rhodamine impregnated latex beads (40 nl; 20% in saline) were injected into physiologically-identified regions of the inspiratory (rostral) (r)VRG to retrogradely label caudal brainstem neurons projecting to rVRG. Immunohistochemical methods were then used to identify 5-HT containing neurons in tissue sections containing rhodamine-labeled neurons.

5-HT neurons were found throughout the raphe nuclei from the level of the pyramidal decussation to the inferior colliculus. Rhodamine labeled neurons were located bilaterally, intermingled with 5-HT immunoreactive cells in raphe obscurus, raphe pallidus, and raphe magnus. Rhodamine-labeled neurons projecting to rVRG were similar in morphology (fusiform or multipolar) and size (5-20 μm somal diameter) to the 5-HT neurons; some cells contained both labels. In addition to the raphe nuclei, 5-HT containing neurons in the B3 serotonin cell group were juxtaposed with rhodamine-labeled cell bodies. No rhodamine-labeled neurons were found in raphe dorsalis or pontis. Other rhodamine-labeled neurons were located predominantly within respiratory-related nuclei such as the nucleus of the solitary tract, VRG and Kölliker-Fuse nucleus, substantiating the relative specificity of the injection site within rVRG.

These data suggest that non-serotonergic as well as serotonergic neurons projecting from raphe nuclei may influence activity of rVRG neurons. Supported by NIH grants HL-37941 and HL-07363

AFFERENT-EFFERENT ORGANIZATION AND CYTOARCHITECTURE OF PHRENIC SENSORIMOTOR CORTEX IN THE CAT. J.J. Warner, J.P. Coffey, F.J. Thompson, P. Davenport, M. Davda, G. Schrimsher. Depts. of Neurology and Neuroscience, Colleges of Medicine, Dentistry and Veterinary Medicine, University of Florida, Gainesville,FL 32610.

Phrenic nerve projections to sensorimotor cortex have been proposed to participate in respiratory kinesthesia (Davenport, 1985). Sensorimotor cortical stimulation has been shown to modulate medullary respiratory output (Bassal, 1982) and phrenic activity (Lipski, 1986), (Thompson, Davenport, Warner, 1987). The present study was undertaken to investigate the localization, organization, and cytoarchitectonics of phrenic sensorimotor cortex.

Dorsolateral frontoparietal craniotomy and contralateral C5 phrenic nerve exposure were performed on vagotomized adult cats under chloralose anesthesia. C5 phrenic nerve stimulation was utilized for mapping of cortical evoked potentials. Low-threshold cortical sites for elicitation of contralateral short-latency phrenic nerve action potentials were mapped, and depth penetration laminar analysis performed. Regions producing inhibition of phrenic inspiratory activity were also identified. Following perfusion fixation, Klüver-Barrera and Nissl stained serial coronal or sagittal sections were used for cytoarchitectonic analysis and laminar data correlation.

Phrenic nerve stimulation produced evoked potentials over the posterior sigmoid gyrus, and lateral to the coronal sulcus. Low-threshold efferent sites were identified on the banks of the coronal sulcus and rostral to the ansate sulcus, however their location did not necessarily correspond to maximum evoked potential sites for each experiment. Localization of maximal afferent and efferent sites corresponded to cytoarchitectonic areas 3, 1, and 2 of Hassler and Muhs-Clement (1966).

HIPPOCAMPAL SLOW WAVE CORRELATES OF RESPIRATORY PATTERNING. R.M. Harper, C.A. Richard, H. Ni*, and R.C. Frysinger. Department of Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA, 90024-1763.

Attributes of hippocampal slow wave EEG activity have been associated with particular locomotor patterns in freely moving animals; higher frequencies of rhythmical slow wave activity, for example, have been correlated with enhanced whole body movement, while lower frequencies have been associated with localized movements. Respiratory movements are a form of locomotive patterning that continues during the motoric paralysis of rapid eye movement sleep, a state accompanied by diverse respiratory patterns as well as marked hippocampal EEG variation, including pronounced rhythmical slow wave activity. Since electrical stimulation of the hippocampus elicits profound changes in respiratory patterning, we examined momentary changes in hippocampal EEG patterns during different sleep-waking states along with breath-by-breath attributes of the respiratory cycle. Bipolar macroelectrodes were placed in the hippocampus of cats, together with diaphragmatic EMG leads and electrodes to record eye movements, nuchal EMG, and cortical EEG. Scattergrams were calculated between interpeak intervals of synchronous slow wave hippocampal activity, total respiratory cycle duration, and inspiratory area. Among a number of correlations, higher frequency rhythmical slow activity was frequently associated with diminished respiratory period. Supported by HL 22418-11.

BIOLOGICAL RHYTHMS: MECHANISMS

SUPRACHIASMATIC NUCLEUS TRANSPLANTATION RESTORES DONOR SPECIFIC CIRCADIAN RHYTHMS TO ARRHYTHMIC HOSTS M.R. Ralph, F.C. Davis and M. Menaker. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

The suprachiasmatic nucleus (SCN) contains circadian pacemaker cells that oscillate in vitro. Although ablation of the nucleus or its isolation from the rest of the brain results in behavioral arrhythmicity, there is still some question about the role played by the SCN within the circadian system of mammals especially in view of the finding that methamphetamine can restore rhythmicity to SCN lesioned rats (Honma et al., Physiol. & Behav. 40: 767 (1987). Experiments in which rhythms have been restored to SCN lesioned hamsters with SCN tissue from fetal donors have approached this question; however, as yet, it has not been possible to identify donor derived properties in the restored rhythms.

We have performed reciprocal SCN transplant experiments between wild-type hamsters and a recently discovered period mutant (tau) that shortens the period from 24 hr. to 22 hr. in the heterozygote and to 20 hr. in the homozygote. We have found that implants of fetal (E13.5) tissue containing SCN restore rhythmicity to SCN lesioned, arrhythmic hosts. The period of the restored rhythm always matches that of the donor regardless of the direction of the transplant. These data indicate that a small brain region containing SCN determines the period of the overt locomotor rhythm, and greatly strengthens the currently held view that the SCN occupies a position at the top of the circadian hierarchy in mammals.

FETAL HAMSTER SUPRACHIASMATIC NEURONS EXPRESS VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN DISSOCIATED CELL CULTURES. M.N. Lehman, J.L. Vest* S. Warren* and R.A. Akeson. Dept. Anat.& Cell Biol., Univ. Cinti. Coll. Med., and Inst. Develop Res., Children's Hosp. Res. Found., Cinti, OH 45267.

We recently demonstrated that dissociated cell grafts of the fetal suprachiasmatic nucleus (SCN) restore circadian locomotor rhythms to arrhythmic SCN-lesioned hamsters (Neurosci. Abst., 13:212). To explore the potential for *in vitro* manipulation of SCN cells prior to grafting, their survival and expression of vasoactive intestinal polypeptide (VIP) were examined in primary culture. Tissue chunks of either anterior hypothalamus (containing the SCN) or cortex were microdissected from E13 hamster fetuses, trypsinized and mechanically dissociated; approx. 5 X 10^5 cells were plated upon glass coverslips coated with either poly-L-lysine; poly-L-lysine and laminin; or a primary monolayer of either rat or hamster astrocytes. Cells were grown for 1-4 wks. in Bottenstein/Sato media with 5% horse serum, with or without added glial conditioned media. They were fixed in 4% paraformaldehyde and immunostained for VIP. After 2 wks., SCN cultures plated on either poly-L-lysine alone, or poly-L-lysine in combination with laminin or glial conditioned media, contained 5-10 immunoreactive VIP cells which possessed few if any immunodetectable processes. In contrast, SCN cultures grown on either rat or hamster astrocytes contained 20-30 isolated VIP neurons, most of which had multiple, extended neurites with beaded VIP-containing varicosities. Suprisingly, we saw no immunoreactive VIP cells in any cortical cultures. In preliminary experiments we have found that VIP cells of the SCN grown on astrocytes for 1-2 wks. survive subsequent grafting and ramify within the brains of intact adult hamsters. [Supported by NIH NS24292 (MNL) and NS23348 (RAA).]

FURTHER EVALUATION OF THE TETRODOTOXIN-RESISTANT CIRCADIAN PACEMAKER IN THE SUPRACHIASMATIC NUCLEI USING 50% PROCAINE & 20mM KCl INFUSIONS. W.J. Schwartz & P. Zimmerman*. Dept. Neurol., U. Massachusetts Med. Sch., Worcester, MA 01655.

Previous work (PNAS 84:1694,'87) has shown that chronic TTX infusion into the rat SCN blocks rhythm entrainment & expression without affecting the oscillatory mechanism of the circadian pacemaker in the nuclei. Further experiments now help to validate and extend these findings.

After free-running circadian drinking rhythms were recorded for 2 wks, rats were anesthetized and cannula assemblies stereotaxically inserted into the SCN & connected to subcutaneously implanted mini-osmotic pumps. Free-running rhythms were then recorded during the 14-d infusions (@ 0.5 µl/hr) and for an additional 4 wks.

Like TTX, chronic infusion of 50% procaine (n=5) produced behavioral arrhythmicity, & drinking rhythms were restored without phase shift after infusions ended. Like TTX, procaine suppresses Na^+-dependent spikes; unlike TTX, the mechanism involves binding to an intracellular receptor. Chronic infusion of 20 mM KCl (287 mosm/l)(n=7) also resulted in behavioral arrhythmicity, but these rhythms returned with anomalous phases (advanced by 4.4 $\pm$ 0.5 hr from expected). Thus, the infusion pump paradigm can detect alterations of the pacemaker's endogenous oscillation; the TTX & procaine results are not merely artifacts of an insensitive method. Infusions of 20 mM KCl + 10^{-6}M TTX are currently underway.

SUPRACHIASMATIC (SCN) NEURON ACTIVITY IN VITRO FROM HAMSTERS WITH SPLIT ACTIVITY RHYTHMS. R.Y. MOORE, L.P. MORIN and S.SHIBATA*, Depts. of Neurology and Psychiatry, SUNY, Stony Brook, N.Y. 11794 and Dept. of Pharmacology, Kyushu University, Fukuoka, Japan.

The splitting of activity rhythms in the hamster into two free-running components in constant light is one of the bases for the view that the circadian system contains multiple oscillators. To determine the localization of those oscillators, adult male hamsters were maintained in constant light and a group of 9 animals with clear, split rhythms was studied and compared with 12 control, free-running animals with intact activity rhythms. Hypothalamic slices including the SCN were prepared and single unit recordings made. Slices from controls exhibit the typical pattern of high firing rates of SCN neurons during subjective day and low firing rates during subjective night. The slices from split animals were analyzed to test four hypotheses concerning splitting: 1) dissociation of the two SCN's; 2) dissociation of two anatomically identifiable components of the SCN; 3) dissociation of the SCN from another oscillator outside the SCN; 4) dissociation of components within the SCN on a non-anatomic basis. The data obtained are explicable only by the last hypothesis. Units in all areas of the SCN on each side exhibit a pattern of firing rates which has the appearance of two peaks of lower amplitude than controls but corresponding to the appropriate components of the activity rhythm. Supported by NIH grants NS-16304 and NS-22168.

190.5

OUBAIN MIMICS THE EFFECTS OF DARKNESS ON THE CIRCADIAN PACEMAKER IN CHICK PINEAL CELLS. M. Zatz and D.A. Mullen* Lab. of Cell Biology, N.I.M.H., Bethesda, MD 20892

Chick pineal cells in primary culture display a persistent circadian rhythm of melatonin output in constant red light. Four hour pulses of "unexpected" white light (L), or darkness (D), induce phase-dependent phase shifts in subsequent cycles of the melatonin rhythm, indicating an action on the underlying pacemaker. L and D pulses each cause both phase delays and phase advances, but their phase response curves (PRC's) differ.

Four hour pulses of oubain, a specific inhibitor of the Na,K-ATPase, also induced both phase delays and phase advances, with a PRC similar to that for dark pulses. Eight hours exposure to low external potassium (estimated below 0.5 mM) also caused dark-like phase delays and advances. Exposure of cells to 8 hours oubain before and during exposure to 4 hours L had assymetric effects: the phase advancing effect of L was counteracted by oubain but the phase delaying effect of L was converted to an enhanced phase advance. Such results support and are explained by "instantaneous" and additive shifts of the pacemaker and of its PRC in response to oubain and light. Taken together, these results suggest that inhibition of the Na,K-pump has consequences similar to those of darkness (and thus opposite to those of L) on the circadian pacemaker in chick pineal cells.

[14C] 2-DEOXYGLUCOSE UPTAKE IN SQUIRREL BRAIN ACROSS THE HIBERNATION CYCLE. T. S. Kilduff, C. M. Radeke*, J.D. Miller, and H. C. Heller*. Depts. of Psychiatry and Biol. Sci., Stanford Univ., Stanford, CA 94305.

To provide a comprehensive view of brain activity during hibernation, we used the autoradiographic [^{14}C]2-deoxyglucose (2DG) method to compare the relative metabolic activity of 96 brain regions across 7 phases of the hibernation cycle: euthermia, 3 body temperature (T_b) intervals during entrance (30°C to 25°C; 25°C to 20°C; and 20°C to 15°C), deep hibernation (T_b < 8°C), and both early (T_b < 8°C) and late (T_b = 25°C) arousal. Cluster analysis of relative 2DG uptake (R2DGU) values across these phases resulted in grouping the 96 neural structures into 5 categories. In cluster 1 (N=18 brain regions), R2DGU paralleled the change of T_b (e.g. the cerebellar nuclei). Cluster 2 (N=5), exemplified by VIII nerve efferent nuclei, was similar to cluster 1 in that R2DGU paralleled the change of T_b, but the euthermic R2DGU was lower than the entrance R2DGU. Cluster 3 (N=39) was comprised of gray matter regions whose R2DGU was inversely related to the change in T_b and included reticular formation and hypothalamic nuclei, limbic regions and somatosensory structures. Cluster 4 (N=5) constituted white matter structures in which the R2DGU was also inversely related to T_b. Cluster 5 (N=29) was a heterogeneous group whose R2DGU values could not be readily classified in any particular pattern, but included all 6 cortical regions examined.

190.7

DIURNAL RHYTHM OF CORTICOTROPIN-RELEASING HORMONE (CRH) IN RAT CEREBROSPINAL FLUID (CSF). C.M. Barksdale,* L.K. Takahashi, and N.H. Kalin (SPON: L. Hegstrand). Dept. of Psychiatry, Univ. Wisconsin-Madison, and Psychiatry Service, Middleton Veterans Hospital, Madison, WI 53705.

CSF levels of peptide hormones are thought to reflect function of brain peptidergic systems and have been used to investigate the involvement of these systems in the pathophysiology of neuropsychiatric illnesses. Data suggest that CRH systems modulate the endocrine, autonomic, and behavioral consequences of stress.

We have studied the parameters that affect concentrations of CRH in CSF. Cisternal CSF was obtained from adult male rats at 0300, 0700, 1100, 1500, 1900, and 2300 hr. Eight rats were used for each time point. Rats were maintained on a light-dark cycle with lights on from 0600 to 1800 hr. CSF was aliquotted for each rat, and all CSF CRH-IR samples were measured in one assay.

CSF concentrations of CRH-IR varied rhythmically over time ($F=2.97$; $df=5,43$; $P<.02$). The peak concentration of 9.7±1.3 pg/ml (mean±SEM) occurred at 0300 hr. The nadir, 5.1±0.6 pg/ml, occurred at 1100 hr.

These findings demonstrate a diurnal rhythm in rat CSF CRH-IR similar to reported changes in rat hypothalamic CRH content and plasma concentrations of ACTH and corticosterone. Interestingly, our studies in rhesus monkeys show a diurnal rhythm of CSF CRH-IR opposite to that of peripheral pituitary-adrenal activity.

190.8

ANALYSIS OF THE *Clock* CIRCADIAN RHYTHM MUTATION IN *DROSOPHILA MELANOGASTER*.
John R. Nambu, Mitchell S. Dushay*, Michael Rosbash*, and Jeffrey C. Hall. Department of Biology, Brandeis University, Waltham, MA 02254.

In *Drosophila*, several loci have been identified which when mutated, lead to aberrant circadian and/or ultradian rhythm properties. We are employing genetic and molecular techniques to characterize one such locus, defined by the $Clock^{KO6}$ mutation. *Clock* was originally isolated by D. Orr and R. Konopka (D. Orr PhD thesis, 1982) based on ca. 22.5 hour periods for locomotor activity rhythms (1.5 hours shorter than normal). We have shown that in addition, cultures of $Clock^{KO6}$ exhibit 22.5 hour eclosion rhythms. In contrast, the ultradian rhythm of male courtship song is apparently normal (M. Greenacre and C. P. Kyriacou, unpublished results). Similarly to other rhythm mutations in *Drosophila* and other organisms, the *Clock* mutation is semi-dominant.

The *Clock* gene is X-linked; we have mapped the mutation via recombination analysis to the distal portion of the X chromosome in the region between the *yellow* and *white* genes. Preliminary deficiency mapping data suggest that *Clock* is uncovered by the small *white* deficiency, $Df(1)w^{258-45}$. *Clock* is thus quite near to *white* (3C1-2) yet appears to be distinct from and proximal to another nearby *Drosophila* rhythm gene, *period* (3B1-2), in that we have shown the w^{258-45} deletion to be $period^{+}$. Our cytogenetic data, and extant molecular clones isolated from the 3B-3C X-chromosomal interval, should facilitate the molecular isolation and characterization of this gene and its product(s).

190.9

DROSOPHILA CIRCADIAN RHYTHMS ARE DRASTICALLY DISRUPTED BY *disconnected* VISUAL SYSTEM MUTATIONS. Mitchell S. Dushay*, Michael Rosbash*, and Jeffrey C. Hall (SPON: H. T. Epstein) Dept. of Biology, Brandeis University, Waltham, MA 02254.

Wild-type *D. melanogaster* that are never exposed to light do not express circadian rhythms (Dowse, H. et al., Behav. Genet., 17: 19, 1987). Functional eyes are not necessary for flies to be rhythmic (Helfrich, C., J. Neurogenet., 3: 321, 1986), so flies must have extra-retinal 'circadian' photoreceptors. Blind flies that have defects in their 'circadian' photoreceptors should be insensitive to light and therefore arrhythmic. 96% of *disco* flies were arrhythmic in locomotor activity, and mutants showed weak and variable eclosion rhythms. Since 5-10% of *disco* flies have eyes connected to their brains (Steller et al., Cell, 50: 1139, 1987), we tested whether eye connection is sufficient for rhythmicity. Using both the deep pseudopupil and histological sectioning, we found no correlation between connected eyes and rhythmicity. However, this did not test if eye input is sufficient for rhythmicity, since *disco* phototaxis and optomotor responses were similar to those of blind flies whether the *disco* eyes were connected or not. *disco* flies are able to perceive and to respond to light, however. When tested in an LD cycle, mutant flies showed cyclic activity similar to the behavior of the other arrhythmic mutants; per^{0}. Therefore the *disco* mutations do not entirely abolish light perception, but must disrupt connections between photoreceptors and the circadian pacemaker, and/or disrupt the central pacemaker itself.

190.10

GASTROPOD CIRCADIAN PACEMAKER NEURONS STAINED BY ANTIBODY TO *DROSOPHILA PERIOD* PROTEIN. K.K. Siwicki*, J.W. Jacklet, and J.C. Hall. Biology Dept., Brandeis University, Waltham, MA 02254, and Dept. Biology, Neurobiology Research Center, SUNY Albany, Albany, NY 12222

The *period* (*per*) gene of *Drosophila melanogaster* regulates the period of circadian rhythms of eclosion and locomotor activity, as well as a short-period rhythm in the male fly's courtship song. A polyclonal antibody specific for a small domain (14 amino acids) of the *per* protein has been used immunocytochemically to label the cells and tissues in the fly that express the gene (Neuron *1:* 141-150, 1988). The affinity purified anti-*per* antibody was used to stain the eyes of the marine gastropods, *Bulla* and *Aplysia*, which contain endogenous circadian pacemakers. In the *Bulla* eye, a *per*- like antigen was detected in the cytoplasm of cell bodies of the basal retinal pacemaker neurons, and in the adjacent neuropil. No staining was present in the *Bulla* optic nerve, or in the photoreceptors of the retina. In the *Aplysia* eye, stained pacemaker neurons and varicosities were distributed around the eye, and stained axons were present in the optic nerve. Similar results were obtained in eyes examined during both the light and dark phases of the animals' daily entrainment cycles (12 hr L: 12 hr D). These results suggest that a *per*- like molecule may function in the circadian clocks of diverse species.

MECHANISM FOR REGULATION OF CIRCADIAN AND PINEAL PHYSIOLOGY BY ULTRAVIOLET RADIATION IN RODENTS
G.C. Brainard, R.A. Hoffman,* M.H. Stetson,* F.M. Barker* and M.D. Rollag,* Jefferson Med. Coll. Phila., PA 19107; Colgate Univ., Hamilton, NY 13346; Univ. Delaware, Newark, DEL 19711; Penn. Coll. Optometry, Phila., PA 19141; USUHS Bethesda, MD 20814.

Visible light (400-760 nm) is considered the primary environmental stimulus which regulates circadian and pineal physiology of mammals. Recently, near-ultraviolet radiation (UV-A, 320 -400 nm) has been shown to influence selected circadian and pineal functions in rodents. A set of experiments have been tested for the mechanism by which UV-A exerts these biological effects. These studies indicate: 1) UV-A exerts its CNS effects via the eyes; 2) ultraviolet radiation down to 300 nm is transmitted through the cornea, aqueous humor, lens and vitreous humor to the retina; 3) pigment of the iris and retinal pigment epithelium does not mediate the effects of UV-A on the circadian system; and 4) the harderian gland, anatomically close to the eye, does not mediate the responses to UV-A. These results support the hypothesis that elements in the rodent retina directly transduce UV-A photic information to the circadian and neuroendocrine system in rodents. Supported by Nat. Elec. Manuf. Assoc. (LRI 87:DR:2).

RUNNING ACTIVITY ENHANCES THE PHASE-SHIFTING EFFECT OF DARK PULSES ON HAMSTER RHYTHMS.
S.G. Reebs*, R.A. Lavery* and N. Mrosovsky. Dept. of Zoology, University of Toronto, Toronto, M5S 1A1, Canada.

Dark pulses can phase-shift the activity rhythms of hamsters kept in constant light (Boulos, Z., and B. Rusak, *J. Comp. Physiol.*, 146: 411, 1982; Ellis, G.B., *et al., Am. J. Physiol.*, 242: R44, 1982). Dark pulses under those conditions alter photic input to the circadian system, but they also commonly trigger running activity. Running activity is now known to affect the circadian system of hamsters (Mrosovsky, N., and P.A. Salmon, *Nature*, 330: 372, 1987). Therefore we asked: is the phase-shifting effect of dark pulses caused, at least in part, by running activity?

Male Syrian hamsters in constant light were given 3-h dark pulses at circadian time (CT) 9. Half of the animals did not have normal access to their running wheels. Their phase shifts averaged 0.56 h (S.D. = 0.32, n = 9). The other hamsters had access to their wheels and ran for more than half of the pulse duration; their phase shifts averaged 1.07 h (S.D. = 0.53, n = 8). The difference is significant ($p < 0.05$, t-test). Preliminary results suggest a similar difference for 6-h pulses given at CT 6. This indicates that running activity accounts for at least part of the phase-shifting effect of dark pulses, and warns about the confounding effects of behavioural states in photic manipulations.

FEEDING AND LOCOMOTOR ACTIVITIES OF THE HOMING PIGEON: MELATONIN AND ITS EFFECTS ON RHYTHMICITY.
C.C. Chabot* and M. Menaker. Department of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901.

Measurement of general locomotor activity in homing pigeons often does not allow for accurate interpretation of period or phase of the circadian rhythm. Feeding activity, a more specific behavior, often provides a better assay. Feeding activity of both intact and pinealectomized (P-X) pigeons is rhythmic in L:D (12:12) cycles and in constant darkness (DD). Pigeons exposed to several intensities of constant light (LL) exhibit clear changes in both feeding and locomotor rhythms. In general, rhythms persist at low intensities of LL, while at higher intensities the birds become arrhythmic. The implantation of melatonin filled silastic capsules into intact pigeons abolishes rhythmicity in both behaviors; their removal immediately restores it.

Intra-cardial and sub-cutaneous cannulae were implanted into intact pigeons enabling the simultaneous infusion of melatonin and withdrawal of blood samples in freely moving birds. Melatonin was delivered via the sub-cutaneous cannula for six hours (1.3 ug/hr) each day in the middle of the subjective day to five P-X pigeons in DD. One of the five became arrhythmic while the other four entrained to the exogenous melatonin cycle by shifting their subjective day by about 12 hours. They remained entrained until the timing of the melatonin infusion was changed. The changes in behavior produced by melatonin infusion will be correlated with changes in blood levels of the hormone.

OPIATES, ENDORPHINS AND ENKEPHALINS: PHYSIOLOGICAL EFFECTS III

191.1

OPIOIDS RECIPROCALLY REGULATE THE M-CURRENT IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS IN VITRO.
S.D. Moore, S.G. Madamba and G.R. Siggins. Research Inst. Scripps Clinic, 10666 N. Torrey Pines, San Diego, CA, 92037.

Two opioid systems, one containing enkephalin and one dynorphin, exist in the hippocampal CA3 field. Previous studies in our lab revealed multiple effects of these opioids on CA3 neuronal discharge and membrane potential. To determine if such diverse responses arise from voltage-dependent mechanisms, we voltage-clamped CA3 neurons in submerged, superfused hippocampal slices. At holding potentials of -40 to -45 mV, hyperpolarizing commands elicited ohmic current drops followed by slow carbachol-sensitive current relaxations likely to represent the voltage-dependent K^+ current, I_M. Superfusion of the relatively receptor-unselective opioid D-ala^2, D-leu^5 enkephalin decreased I_M, measured from the instantaneous ohmic step to steady state. High dynorphin concentrations (1 μM) either had no effect or decreased I_M. However, low (0.1 μM) dynorphin (likely to be selective for κ receptors) significantly augmented I_M by 40-70% (n=7). The κ-selective agonist, U-50,488H (5-10 μM) also significantly increased I_M by 66-74% (n=8). This effect is similar to that recently described (Moore et al. Science 239:278,1988) for somatostatin. We propose that μ and κ receptor activation may, depending on membrane potential, reciprocally decrease and increase I_M, respectively, causing the divergent dynorphin effects seen previously. 191.2

POSSIBLE INVOLVEMENT OF LOCUS COERULEUS IN FENTANYL-INDUCED MUSCULAR RIGIDITY IN THE RAT.
P.W. Lui*, T.Y. Lee* and S.H.H. Chan (SPON: T.C. Fu). Department of Anesthesiology and Institute of Pharmacology, National Yang-Ming Medical College and Veterans General Hospital, Taipei 11217, Taiwan, Republic of China.

Whereas muscular rigidity is a well-known side effect that is associated with high-dose fentanyl anesthesia, a paucity of information exists with regard to its underlying mechanism(s). We investigated in this study the possible engagement of locus coeruleus in the pons in this phenomenon, using male Sprague-Dawley rats. Under proper control of respiration, body temperature and end-tidal CO_2, intravenous administration of fentanyl (50 and 100 µg /kg) consistently promoted an increase in electromyographic (EMG) activities recorded from the gastrocnemius and abdominal rectus muscles. Such an induced muscular rigidity by the narcotic agent was significantly antagonized or even reduced by prior bilateral electrolytic lesions of the locus coeruleus or pretreatment with the α-adrenoceptor blocker, prazosin (200 µg/kg, i.v.), signifying the involvement of this norepinephrine-containing pontine nucleus in that process. These data suggest that our hypothesis that locus coeruleus may participate in fentanyl-induced muscular rigidity is valid, although the functional role of this nucleus awaits further investigation.

DIFFERENT MU OPIOID RECEPTOR SUBTYPES MEDIATE SPINAL AND SUPRASPINAL ANALGESIA. G.W. Pasternak, D. Paul,* and R.J. Bodnar. The Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Cornell U. Medical College, NY, NY 10021.

Previous studies have implicated mu_1 receptors in the analgesia produced by microinjection of the opioid peptides DAGO (mu_1 + mu_2) and DSLET (mu_1 + delta) into the PAG, n. raphe magnus, and locus coeruleus, based in part on their sensitivity towards the mu_1-selecitive antagonist naloxonazine. We have examined the relative roles of mu_1 and mu_2 receptors in spinal and supraspinal opioid analgesia in mice following intrathecal (IT) or intracerebroventricular (ICV) injections of the selective agonists DAGO, DSLET and DPDPE. Naloxonazine shifted the analgesic dose-response curves of ICV DAGO and DSLET 7-fold and 10-fold, respectively. In contrast, naloxonazine did not affect the potency of either compound following IT adminstration. Although naloxone reversed IT DAGO and DPDPE analgesia, DAGO was ~10-fold more sensitive, implying that IT DAGO was not acting through delta receptors. The high selectivity of DAGO for mu receptors and its potency both ICV and IT implies mu mechanisms at both levels of the neuroaxis. Yet, naloxonazine dramatically reduces the analgesic potency of DAGO ICV but not IT. These findings suggest that DAGO produces analgesia supraspinally through mu_1 receptors and spinally through mu_2 receptors.

AREA TEMPESTAS MODULATES THE ANALGESIC RESPONSES OF SYSTEMIC INJECTION OF MORPHINE IN THE RAT. M. Massotti, P.Lorenzini*and A.D'Amore*. Lab. di Farmacologia, Istituto Superiore di Sanità, Roma, Italy, 00161.

Various solutions of naltrexone-HCl [NLT] were microinfused into the Area Tempestas [AT] in a volume of 120 nl/rat 20 min after injection of morphine sulfate [MS] (5 mg/kg sc).

Twenty min after systemic MS, an increase in the reaction latencies can be observed in the hot-plate test (from 1.9±0.4 to 19.1±1.1 sec). This effect lasts 100-140 min, returns to the basal values at the 5th h and is not affected by local application of 120 nl of saline. Local application of NLT (8-60 ng/rat) dose-dependently reduces the values of tail-withdrawal reaction between 20-30 min after the end of the infusion.

In the hot-plate test, twenty min after systemic MS the latencies in licking reaction time increases from 6.4±0.8 sec to 35.4±4 sec. Five-ten min after unilateral application of NLT,associated with contralateral application of saline, a dose-dependent reduction in the delay of the response in both the contralateral (8-30 ng/rat) and ipsilateral (15-30 ng/rat) paws is noticed.

EFFECTS OF ACUTE ADMINISTRATION OF NALTREXONE ON PLASMA CONCENTRATIONS OF NALTREXONE, 6-β-NALTREXOL, β-ENDORPHIN AND CORTISOL IN CHILDREN. B.H. Herman, A. Arthur-Smith*, K. Verebey*, J. Alrazi* and M.K. Hammock*. Brain Res Cen & Dept Psychiatry of CHNMC & George Washington Univ Sch Med, Washington, DC and PDLA, South Plainfield, NJ.

The opiate antagonist, naltrexone (NTRX), may be useful in treating self-injurious behavior (SIB) and autism in children (Herman et al. Ann Neurol 22:550, 1987). Here we measured the concentrations of NTRX, 6-β-naltrexol (6βNLT), major metabolite), β-endorphin (β-E) and cortisol (COR) after administration of NTRX in children. Groups studied: autistics (N=5, 4-12 yrs) without SIB and SIB subjects (SIBS) (N=3, 10-17 yrs). Blood was drawn 1h after oral NTRX or placebo (P). NTRX(ug/L) and 6βNLT(ug/L) were analyzed on a GC/MS; β-E(pmol/L) and COR(nmol/L) by RIA. Table presents plasma values for autistics.

		Naltrexone (mg/kg)				
	P1	0.5	1.0	1.5	2.0	P2
NTRX	0±0	13±1	21±2	32±5	42±7	0±0
6βNLT	0±0	50±6	60±12	107±20	159±46	0±0
β-E	8±1	9±2	7±3	8±1	8±2	8±1
COR	357±31	294±88	399±159	415±124	404±132	383±87

Significant concentrations of NTRX and 6βNLT were detected at every dose. There were no significant differences between autistics and SIBS in plasma NTRX and 6βNLT levels. In both groups, there were no significant effects of NTRX on plasma concentrations of β-E or COR.

191.6

β-ENDORPHIN-(1-27) IS A POTENT ENDOGENOUS HYPOTENSIVE AGENT. M.D. Hirsch, W.R. Millington, J.E. McKenzie* and G.P. Mueller. Dept. of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814

Like morphine, β-endorphin(βE)-1-31 has a pronounced influence on peripheral hemodynamics by acting upon putative opioid binding sites in the dorsal medulla. The present study utilized this central regulatory system to elucidate how the post-translational processing of βE-1-31 may contribute to diverse processes of bioregulation. Direct measures of mean arterial pressure (MAP) and heart rate (HR) were made in anesthetized rats. Unexpectedly, βE-1-27 displayed a 10-fold greater central hemodynamic potency as compared to βE-1-31: By 60 min post injection, 0.15 nmol βE-1-27 (i.c.) produced a reduction in MAP (25.9 ± 4.7 mm Hg below control (94.7 ± 1.9 mm Hg)) which equalled that of 1.5 nmol βE-1-31 (29.7 ± 3.9 mm Hg). A higher βE-1-27 dose (1.5 nmol) further reduced MAP (47.3 ± 5.3) to 50% of control values. Thus in contrast to analgesia, in which C-terminal proteolysis converts βE-1-31 to a potent opioid receptor antagonist, βE-1-27, this processing step enhances the hemodynamic potency of the peptide. However, as shown previously for analgesia, C-terminal cleavage of βE-1-27 to βE-1-26 and N-acetylation of both βE-1-31 and βE-1-27 eliminated hemodynamic activity. These results suggest that the C-terminal proteolysis of βE-1-31 subserves quite different roles in defining the cardioregulatory and analgetic activities of the peptide.

191.7

HAMSTER ENKEPHALIN-PEPTIDES AND mRNA ARE ALTERED BY RESERPINE. S.O. Franklin*, A.D. Branch*, H.D. Robertson*, B.C. Yoburn and C.E. Inturrisi. Pharmacology, Cornell Univ. Med. Coll. and Rockefeller Univ., New York, NY 10021.

Hamster adrenal, in contrast to the rat, contains high levels (200 pmole/gland) of enkephalin-containing peptides (ECPs) so that this species is particularly useful for the study of the modulation of ECPs. The adrenal ECPs appear to be proenkephalin while striatal ECPs are low molecular weight (free enkephalins). Two consecutive daily treatments with reserpine produce a dose (1.25 to 10 mg/kg) dependent depletion of adrenal ECPs at day 1 (max. 75% decrease with 10 mg/kg reserpine) and a 60-100% increase in preproenkephalin mRNA at day 1 by Northern analysis. Known amounts of unlabeled proenkephalin RNA transcripts were used for quantitation. Thereafter, ECPs increase above control at days 4 and 12. Adrenal preproenkephalin mRNA is still elevated (200%) at 12 days after reserpine treatment. At day 1 striatal ECP levels show a small (40%) but significant increase which disappears by days 4 and 12 post reserpine. However, at day 1 there is a dose dependent increase in striatal preproenkephalin mRNA of 75 to 200%, which has returned to control values by day 12. Thus, reserpine induced changes in ECPs are associated with changes in proenkephalin gene expression in both adrenal and striatal tissues. Transcriptional regulation after reserpine treatment has a different time-course for adrenal proenkephalin (prohormone) than for striatal enkephalins (neurotransmitter). Supported by DA-01457 and DA-05130.

IN VIVO DIALYSIS MEASURES OPIOID PEPTIDE RELEASE IN THE RAT GLOBUS PALLIDUS. N.T. Maidment*, D.R. Brumbaugh*, V.D. Rudolph*, E.Erdelyi*, K.F. Faull, M.C. Dement, J.D. Barchas and C.J. Evans. Pritzker Laboratory and Sleep Research Center, Dept. of Psychiatry, Stanford University Medical Center, Stanford, CA 94305

We report the measurement of opioid peptides in vivo using both commercially available dialysis probes and smaller custom-made units. The recovery values obtained in 1nM solutions of met-enk were 15-20% and 10% respectively. A "universal" opioid RIA with an IC_{50} of 1 fmole was developed with Ab's directed towards the N-terminal Try-Gly-Gly-Phe sequence. Basal release produced approx. 3fmoles of opioid peptide-like immunoreactivity per 30min sample in the absence of peptidase inhibitors. Incorporation of bestatin (1μM) and thiorphan (200μM) elevated the recovered immunoreactivity approx. 3-fold. The release was increased by a factor of 10-15 by 100mM KCl. Samples were subjected to reverse-phase HPLC and the immunoreactivity tentatively identified as Met-enk, Leu-enk and Met-enk-Arg-Phe. We are investigating changes in this profile in the presence of peptidase inhibitors and the regulation of opioid peptide release by dopamine using the dialysis probes for simultaneous drug administration and peptide measurement.

191.9

THE EFFECTS OF DOPAMINE AGONISTS AND ANTAGONISTS ON PROENKEPHALIN mRNA AND OPIOID PEPTIDES MEASURED IN THE SAME TISSUE EXTRACTS. M.E. Abood*, J.H. Eberwine*, E. Erdelyi*, J.D. Barchas and C.J. Evans, (SPON: Stuart Leff). Nancy Pritzker Laboratory, Dept. of Psychiatry, Stanford University, Stanford, CA 94305.

In order to reduce intraspecies variation, differences in dissection, and the number of animals required for statistical significance, we have developed a technique for analysis of mRNA and opioid peptides in the same tissue extracts. This method involves the extraction of tissue in 5M guanidine thiocyanate, 10 mM EDTA, 50 mM Tris, pH 7.5, 8% ß-mercaptoethanol, and subsequent precipitation of the RNA with 4M LiCl. The RNA is isolated by a second precipitation in 3M LiCl, followed by solubilization in 10 mM Tris, 1 mM EDTA, 0.1% SDS, phenol/chloroform extraction, and ethanol precipitation. After this procedure, the RNA can be quantitated using standard methods. The peptides, which are in the supernatant of the 4M LiCl precipitation, are adsorbed onto Sep Pak (C18 resin) and eluted by acid acetone. The total opioid peptides are measured by chemical acetylation of the eluted peptides, followed by RIA using an assay specific for α-N-acetyl-Tyr-Gly-Gly-Phe-X. We have used this technique to measure the effects of haloperidol and bromocryptine on proenkephalin mRNA and total opioid peptides contained in the tissue samples from various discrete regions of the rat brain.

191.10

EVIDENCE FOR THE ACTIVATION OF SPINAL KAPPA OPIATE RECEPTORS DURING PREGNANCY. H.W. Sander*, P.S. Portoghese*+ and A.R. Gintzler. (Spon: H. Begleiter). Depts. of Biochemistry and *Medicinal Chemistry, SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203 and +College of Pharmacy, Univ. of Minn., Minneapolis, MN 55455.

In a variety of laboratory animals as well as humans, pregnancy has been associated with an activation of a maternal opioid system(s) and with a concomitant elevation in the threshold for maternal responsiveness to aversive stimuli. This analgesia is mediated via the activation of spinal opiate receptors and does not require an intact peripheral opioid system(s). The recently developed kappa-selective opioid antagonist, nor-binaltorphimine (nor-BNI), significantly reduces the threshold for reflexive jumping in response to electric foot shock when administered to the lumbar intrathecal (i.t.) space of pregnant rats (day 20 of gestation). In contrast, i.t. nor-BNI when administered to nonpregnant rats as well as systemic (intraperitoneal) administration of an intrathecally effective dose of nor-BNI to pregnant rats is without effect on the jump thresholds. These data indicate that the kappa type of opiate receptor mediates, at least in part, the analgesia observed during gestation thus providing an important physiological function for this receptor type.

191.11

KAPPA OPIOID RECEPTORS ACTIVATION COUNTERACTS URINE RETENTION DUE TO INTRA SPINALCORD INJECTION OF COLCHICINE IN RATS. M. Baraldi and P. Zanoli*. Chair of Pharmacology and Pharmacognosy, Modena University, School of Pharmacy, 41100 Modena, Italy.

Continence and urination require a good coordination between the inhibitory sympathetic influence and the parasympathetic bladder excitatory activity. This coordination is controlled by intra and supraspinal impulses. We have documented that the intraspinalcord (i.s.c.) injection of low doses (2.5-10 ug/rat) of colchicine (C) in rats induces in a dose related fashion an irreversible urine retention due to inability of bladder to void. Supraspinal influence activated by i.s.c. injected C was excluded by the demonstration that the toxin remains at the site of injection. The notion that μ and δ opioid receptor agonists inhibit bladder motility prompted us to study the levels of endogenous opioids and the characteristics of opioid receptors in the spinal cord of normal rats and rats with C-induced urine retention. Here we report that 72 hs after the i.s.c. injection of C we found a significant increase (0.15 vs 0.08 ng/mg prot.) of Met-Enkephalin (M-Enk) in the lumbar region of the spinal cord which was parallelled by a decreased affinity of δ receptors labelled by ^{3}H-DADLE and which was thought to be responsible of urine retention throught a spinal action. It is noteworthy however that the C-induced urinary retention was minimized by the systemic chronic injection of the kappa receptor agonist bremazocine. In conclusion our observation seems to suggest that the spinal mechanism(s) which regulates bladder motility might be modulated in an opposite direction by M-Enk and dynorphin.

191.12

MULTIPLE OPIOID MODULATION OF PROLACTIN RELEASE IN THE RAT: SUBCHRONIC TOLERANCE STUDIES. S. Iyengar, H. S. Kim, P. Callahan and P. K. Wood. Ciba Geigy Corp., Summit, NJ 07901 and R. W. Johnson Medical School, Piscataway, NJ 08854.

Opioid modulation of prolactin release was evaluated using opiate drugs and opioid peptides in subchronic tolerance studies. The mu opiate agonist morphine (MS) and several kappa opiate agonists including U50488H (U50), potently increased prolactin release in a dose-dependent, antagonist reversible manner. Opiate antagonists naloxone and WIN 4441-3 potently inhibited prolactin release in opiate-naive rats, implicating endogenous opioid peptides in modulating prolactin release. B-endorphin (END), dynorphin (DYN) and the specific enkephalin analogue DPDPE also caused prolactin release with END being the most potent of all compounds tested. MS, U50, END and DYN were then injected into animals made subchronically tolerant to either MS, U50 or END, (Iyengar et al, Brain. Res., 1987, 435: 220). Animals exhibited no cross tolerance with respect to the effects of MS and U50, implying action at independent receptors. The effect of DYN was supressed in U50-tolerant rats, indicating action at kappa opioid sites. The effect of END did not show cross-tolerance to either U50 or MS while the effect of MS was completely inhibited in END-tolerant rats. Thus, while some of the effects of END may be mediated through mu opioid sites, they may also be mediated via another site, possibly the putative "epsilon" opioid receptor site. These studies also implicate independent kappa opioid receptor sites in modulating prolactin release.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: POSTURE AND MOVEMENT V

192.1

MOTOR STRATEGIES FOR THROWING A HEAVY WEIGHT. P.R. Burgess and J.W. Woodbury, Dept. of Physiol., Univ of Utah School of Medicine, Salt Lake City, UT 84108.

A volunteer faced a force transducer mounted waist high on a horizontal track and placed his right hand on the transducer. The transducer was attached via a cable and a pulley to a load weight (LW) exerting 155 Newtons (35 lb). The task was to lift and accelerate the LW by "throwing" the carriage from right to left. Force (F), position (x) and velocity (v) were measured. During hard throws, F rose rapidly until F exceeded LW, then rose more slowly with an upward concavity to a 50% higher peak, and then fell sharply. Peak F's ranged from 225-275 Newtons; peak v's from 160-190 cm/s; x's at release from 23-33 cm; and duration from 0.65-0.95 sec. Peak v varied less than duration; shorter durations (correlated with smaller x's at release) were compensated by faster F buildup. For constant muscle activation, the F-v relation of muscle requires that F decreases as v increases. Conclusions: (1) F-v effects within the muscle appear to be compensated by muscle activation that increases faster than v increases. (2) The throw is terminated when velocity reaches a predetermined value. (3) The concave upward F vs. t curve reduces the amount of energy "wasted" in shortening the muscle against its internal viscosity.

TWO STRATEGIES OF SINGLE JOINT HUMAN ELBOW MOVEMENT: THE SPEED-INSENSITIVE STRATEGY. G.L.Gottlieb, D.M.Corcos & G.C.Agarwal. Rush-Presbyterian St. Luke's Medical Center, Chicago, IL, 60612.

We propose organizing principles for the control of single joint human movements in which tasks are performed by one or a combination of two strategies. These are Speed-Insensitive and Speed-Sensitive strategies.

The tasks were to make elbow flexions with different inertial loads or to targets at different distances. Movement speed was altered by both variations of the task. In this experimental paradigm, subjects used a Speed-Insensitive strategy.

Inertial torque, acceleration, velocity, and movement time all highly correlated with the task variable, load or distance. The significant variable with which EMG, integrated over the acceleration phase of the movement remained strongly and positively correlated, was inertial torque.

The rate at which torque was developed to accelerate the movements was invariant over changes in the value of the task variable, as was the agonist EMG, integrated for the first 30 ms of activity.

Two components can be distinguished in the antagonist EMG. The first, of constant latency and amplitude is terminated by the second and larger component at a latency proportional to movement time. The area of the second antagonist component is proportional to the decelerating force which is proportional to both task variables. When target distance varied, this could only be demonstrated by adjusting for the effects of muscle length on force and on the EMG.

A model is proposed in which movements made under a Speed-Insensitive strategy are executed by controlling only the timing of an invariant pattern of activation of the motor neuron pool.

Supported in part by NIH grants AR 33189 and NS 23593

192.3

TWO STRATEGIES OF SINGLE JOINT HUMAN ELBOW MOVEMENT: THE SPEED-SENSITIVE STRATEGY. D.M.Corcos, G.L.Gottlieb, and G.C.Agarwal. Rush-Presbyterian St. Luke's Medical Center, Chicago, IL, 60612.

We propose organizing principles for the control of single joint movements in which tasks are performed by one or a combination of two strategies. These are Speed-Sensitive and Speed-Insensitive strategies.

Subjects made discrete flexions of the elbow from a stationary initial position to a visually defined target at a fixed distance. Movement speed was operationally controlled either by explicit instruction to the subject or by adjusting the size of the target to which the subject moved. Instructions always included the requirement to accurately hit the target. These experimental paradigms cause subjects to use a Speed-Sensitive strategy of movement control.

Inertial torques, accelerations and movement times correlated with speed. The agonist EMG, integrated over the acceleration phase of the movement, was strongly and positively correlated with inertial torque.

When subjects perform tasks which require control of movement speed, they accomplish this by adjusting the rate at which torque is developed by the muscles. This rate is modulated by the way in which the muscles are activated. The rate at which joint torque develops is correlated with the rate at which the agonist EMG rises.

The antagonist EMG shows two components which scale with torque. The first is a coactivation component which has a latency independent of movement dynamics. The second component is a deceleration burst which has a latency of onset proportional to movement time.

A model is proposed in which movements made under a Speed-Sensitive strategy are executed by controlling the intensity of activation delivered to the motor neuron pool. The kinematic effect is to regulate the rate at which torque, and consequently acceleration, increases.

Supported in part by NIH grants AR 33189 and NS 23593

192.4

UPDATING OF ISOMETRIC FORCE TRAJECTORIES: CORRECTIONS FOR UNEXPECTED CHANGES IN TARGET AMPLITUDE. J. Gordon, R. Bermejo, & C. Ghez. Ctr for Neurobiol & Behav, Columbia Univ and NYS Psych Inst, New York, NY 10032.

The purpose of this study was to determine whether human subjects can utilize new visual information to modify the dynamic phase of rapidly rising force impulses aimed to an earlier visual target. This question was addressed by comparing the trajectories of impulses of elbow flexion force to a single target occurring 450 ms before the response (controls) with ones in which a second target step occurred 80–140 ms before response initiation (double steps). Response timing was controlled by having the subjects initiate their responses in synchrony with the last of a series of four regularly spaced tones. In all trials, an initial target step of one of 3 possible amplitudes was presented 450 ms prior to the synchronizing tone, then, unpredictably in half the trials, the target was again stepped to a new randomized level 120 ms before the tone. Subjects were instructed to correct their responses when a second target step occurred. In all subjects, the peak forces of responses to the double steps were significantly influenced by the amplitude of the second target (r^2 = .51 to .65). This was achieved by adjustments in the rise time of the force. Mean time from response onset to peak force ranged from 104 to 127 ms in control trials, while in double step trials it ranged from 109 to 143 ms. The gain of these corrective adjustments (actual correction divided by required correction) varied between .5 and .6, indicating that subjects incompletely compensated for the new target. Corrections were more effective when the second target was larger than the first. As expected from our earlier studies of response scaling when specification is prematurely interrupted (Neurosci Abstr, 10:801, 1984), the correction for the second target step showed a prominent central tendency bias: the amplitudes of corrective adjustments, while appropriate in direction, were stereotyped in their amplitudes. These results contradict the view that rapid responses cannot be corrected during their course. New target information can be used to modify ongoing responses; however, the reduced gain and central tendency bias of corrective adjustments may have obscured their presence in other studies. DISORDERS OF TRAJECTORY FORMATION IN EARLY PARKINSONISM. T. A. Zeffiro and D. L. Claman. Department of Neurology, University of Wisconsin School of Medicine, Madison, WI 53792.

Analysis of motor performance in patients with Parkinsonism (PD) has been utilized to study the role of the basal ganglia in the process of movement planning and execution. Nevertheless, interpretation of these studies has often been limited by difficulties inherent in analyzing movements of great kinematic complexity and the often uncontrolled and confounding effects of antiparkinsonian medications. To draw inferences concerning mechanism from such data, the observed trajectory abnormalities should not be too complex or variable. In an attempt to simplify the problem, we studied the kinematics of visually triggered arm movements in unmedicated patients with early PD.

Hand trajectories of patients with clinically mild to moderate PD were compared to those of an age-matched, healthy control group. All subjects were free of medication for two weeks prior to the experiment. Movements were recorded as the subject, while sitting in total darkness, tracked a visual stimulus on the surface of a 20" x 20" digitizing tablet. The only instructions were to move as quickly and accurately as possible to the target when it became visible. Vision of the target during trial was manipulated as follows: In one condition the target vanished as the movement began (Toff); and in the other the target remained visible throughout the trial (Ton). A minimum of 200 movements were recorded in each condition.

Quantitative trajectory analysis revealed consistent spatial and temporal abnormalities. In the Toff condition, the group with mild PD exhibited normal movement times and peak velocities. Both spatial and temporal properties scaled appropriately with movement size. Although vision of the target (Ton) resulted in normal improvements in accuracy, this increase was accompanied by abnormal scaling and inappropriately large deceleration times. This effect increased in relation to the clinical severity of the PD. In more severe cases, there appeared additional abnormal scaling during acceleration with inappropriately small peak velocities and hypometria (Ton>Toff).

These results suggest that one function of the basal ganglia may be to integrate visual information during the latter part of the trajectory formstion process.

192.6

REPRESENTATION OF SPEECH MOVEMENTS: EVIDENCE OF BASIC MOTOR PROCESSES. V. L. Gracco. Haskins Laboratories, New Haven, CT 06510.

Human motor actions involve the production of numerous movement patterns reflecting various goal-related activities. Speech, for example, involves the production of 44 basic sounds, each of which is unique in terms of acoustic characteristics. However, it is not clear whether the movements associated with each sound are singly represented and conversely whether their coordination is fundamentally different for the basic sound productions. The present study evaluated the similarity of the kinematics and coordination among the multiple movements associated with a class of speech sounds.

Subjects were asked to repeat six speech-like words constructed to allow manipulation of the extent of oral opening prior to the first closing movement. By using all possible combinations of sounds made with both lips and jaw (e.g., p,b,m) it was possible to evaluate the similarity of the geometric form of the velocity profiles and the coordinative timing for this class of speech sounds.

Inspection of the the geometric form of the velocity profiles from the upper and lower lips suggested a scalar relation underlying the different lip sounds regardless of the preceding vowel. Further, although the absolute timing of the coordinative adjustments were different for the different sounds, the relative timing relations were similar. Variation in the degree of oral opening due to different preceding vowels modified the relations among the lip and jaw movements.

The scaling of velocity profiles in the present and previous studies and the systematic timing relations among the multiple articulators suggest that speech movements may be organized around basic movement relations and control actions. Further, while certain aspects of the basic control actions are invariant, certain aspects are context dependent reflecting the multiplicity of processes underlying motor control. Supported by NIH (NS-13617).

TIMING AND MAGNITUDE CHANGES IN PRE-PULL ANKLE TORQUES AND EMG ACTIVITY FOR HANDLE PULLS OF VARIED MAGNITUDE. W.A. Lee, C.F. Michaels* and Y.C. Pai*. Physical Therapy, Northwestern Univ., Chicago IL 60611.

This study describes how pre-pull ankle torques and EMG activity in leg muscles of standing subjects change when the magnitude of the pulling torque is increased. Five well-practiced subjects made 10 abrupt pulls on a fixed handle attached to a load cell located at elbow height, at 5, 10, 20, 40, 60, 80 and 95% of maximum pulling force (MPF). Initial location of the center of pressure and handle force were controlled. Ankle torques associated with shear (anteroposterior: Tsh) and vertical (Tv) ground reaction forces were computed from force platform data. The torque about the ankle joint due to the pull, Tp, was computed from load cell force. EMG activity was recorded from gastrocnemius (GS), tibialis anterior (TA), biceps femoris (BF) and quadriceps (QD) muscles. All variables were sampled at 200Hz. We measured torque and EMG onset times, peak torques, pre-pull impulses due to Tsh and Tv (Ish; Iv) and the impulse due to Tp from the onset to the peak of the pull.

The onset times of Tsh and Tv were correlated with Tp ($r < -.94$); Tv onset always preceded Tsh, and led Tp onset by up to 700ms. Iv and Ish increased with peak Tp, due to both longer durations and higher peaks for Tsh and Tv. Ish had no abrupt changes in magnitude, although subjects appeared to switch to a "hip strategy" for larger pulls. GS onset was correlated with ($r > .96$) and preceded Tv, indicating a causal role in generating Tv and the pull. No other muscle was activated consistently before Tv by all subjects. All subjects activated fewer muscles at low than at high forces. TA, BF, and QD were recruited at various percentages of MPF. All muscles were recruited by 80% of MPF. Thus, continuous changes in pre-pull ankle torques and gradual recruitment of muscles were observed as the magnitude of the pull increased.

192.8

VESTIBULAR AND PROPRIOCEPTIVE INFLUENCES ON POSTURAL STRATEGIES. J.H.J. Allum, F. Honegger* and C.R. Pfaltz*. ORL Dept.,Basel Univ.,Basel,CH.

Human postural strategies responsible for the coordinated activation of leg and trunk muscles during equilibriating movements may be elicited by proprioceptive and/or vestibular inputs. To test the relative influences of these inputs on EMG response strategies support surface rotations and translations with equal (30 deg/s) ankle rotations, but oppositely directed head accelerations were imposed on normals and patients with absent vestibular function. The major response to toe-up rotation consisted of a coactivated stabilising action in tibialis anterior (TA) and quadricepts (QUAD) assisted by activity in paraspinal (PARAS) and trapezius (TRAP). Onset order was TRAP=PARAS, TA=QUAD. Rearward translations elicited the major reaction in soleus (SOL) and hamstring (HAM) muscles, and enhanced responses in PARAS. Onset order was SOL=ABDOM, HAM=TRAP, PARAS. Patient leg muscle responses to rotation were significantly less than normal, whereas those to translation were only altered in latency. These results in normals and patients indicate that vestibular and proprioceptive inputs, other than at the ankle, are responsible for eliciting the correct equilibriating strategy.

192.9

MUSCLE SPINDLES INFLUENCE NOT ONLY THE PLANNING BUT ALSO THE EXECUTION OF ANTAGONISTIC MUSCLE ACTIVITY IN HUMANS. Benoni B. Edin (SPON: J.H. Abbs). Dept of Physiology, University of Umea, S-901 87 Umea, Sweden (Present address: Speech Motor Control Lab, Waisman Center, Univ of Wisconsin, Madison WI 53706).

It has recently been shown that human muscle spindles (MS) become sensitized, i.e. show an enhanced response to subsequent slow stretch, when their parent muscle has been subjected to repeated rapid stretches and then kept at a short length (Edin, B.B. and Vallbo, A.B., J Physiol, 400:0-0, 1988). In contrast, MS become desensitized when kept at a long length after the rapid stretches. This property is conceivably exclusive to MS, and was in the present study exploited to assess the role of MS in planning and executing finger movements.

Passive, slow ramp-and-hold movements were imposed on a metacarpophalangeal joint and subjects reproduced these movements actively. The MS of the finger extensor muscles were either sensitized or desensitized before the imposed movement and either sensitized or desensitized before the active movement. In some experiments, microneurography recordings from muscle spindle primary afferents were obtained.

1. Afferent inputs from MS influence the planning of antagonistic muscle activity: The discharge of MS during muscle stretch is larger when MS are in the sensitized state compared to the desensitized state. As such, discharge of sensitized MS should give the impression of a larger movement then do desensitized MS. With all subjects, the reproduced movements showed significant differences in the predicted direction.

2. Afferent inputs from MS influence the ongoing execution of pre-planned antagonistic muscle activity: If MS of the finger extensor muscles access the motoneurone pool of the flexor muscles via the Ia inhibitory interneurones, then reproduced movement should be smaller when the MS of the extensor muscles are sensitized vs. desensitized. In fact, such differences were found with all subjects.

192.10

CONTRIBUTION OF PROPRIOCEPTION VS. EFFERENCE COPY TO THE CONTROL OF POINTING MOVEMENTS IN MAN. O.Bock*, R.Eckmiller, and K.Holthoff*. Div.of Biocybernetics, Univ.of Düsseldorf, 4000 Düsseldorf, FRG.

Ss. pointed with their right arm at visual targets, sequentially presented on a cylindric screen 45 cm in front of their eyes. The hand grasped a lever, restricting motion of index fingertip to an arc just in front of cylinder, and just below targets. A horizontal panel prevented vision of the arm, but a flag could pop up for visual feedback (VF). The arm was moved actively by Ss. (A), or passively by torque motor (P).

One set of expts. analyzed pointing accuracy when VF was available only at the starting position of each movement. The gain (right arm amplitude / target displacement) was in A around 0.90 for all movements, and averaged in P 0.84 for rightward, and 1.00 for leftward movements, independent of starting position; these direction differences were highly significant ($p<0.01$). Variability (s.d.) was 30% smaller in A vs. P. These findings suggest that efference copy is available to centers for pointing movement control, improving their performance, and that direction-specific control mechanisms are involved (as suggested before from other evidence by Bock et al, Soc Neurosci Abstr 13, 1987, p716).

Another set of expts. analyzed unidirectional pointing sequences with VF only at the first target of sequence. Both in A and P, pointing errors accumulated within sequences; successive errors were closely correlated ($r=0.74$ in A, $r=0.80$ in B). From this we conclude that error accumulation can not be attributed to the open-loop character of efference copy, but rather suggests that amplitude is a major controlled variable of active as well as passive pointing movements.

192.11

CEREBRAL ACTIVITY ASSOCIATED WITH THUMB FLEXION IN MAN. D.H. York, D. Fousek* and S. Dulebohn*. Dept. of Physiology, Sch. of Med., Univ. of Missouri, Columbia, MO 65212.

The present study was undertaken to evaluate whether force is the principle variable which is defined by the motor output for flexion movement of the thumb in man. Studies were undertaken in normal volunteers who had scalp recording electrodes placed over the motor and sensory hand areas. Subjects performed a ballistic thumb flexion-extension movement over a fixed displacement against a known load. Each response was segregated into different files according to the velocity of the thumb flexion movement. In recordings from the sensory hand area, an inverse correlation was observed between the latency of an N3 component and the velocity of thumb flexion, which was consistent over four different loads. An inverse correlation was found between load and the latency of a P1 component recorded from the motor hand area. The latency of P1 varied from 8.8±sd8.3 msec to 44±sd25 msec for loads ranging from 792-300 gms. Increasing the displacement of the thumb flexion from 2-6 cm was observed to cause an increase in amplitude of the wave component immediately following the onset of movement. In summary, scalp recordings obtained from the sensory and motor hand areas of humans during ballistic thumb flexion-extension movements have revealed specific components of brain activity which are correlated with movement variables of load, velocity and displacement. (Supported by NIH NS24960).

CORTICAL TOPOGRAPHY OF THE PREMOTOR AND MOTOR POTENTIALS PRECEDING SELF-PACED VOLUNTARY MOVEMENT IN MAN. I.M. Tarkka* and M. Hallett. (SPON: J. Grafman). NINCDS, NIH, Bethesda, MD 20892.

A series of potentials precede the onset of unilateral voluntary finger movements. The bereitschaftspotential (BP) begins approximately 1000 ms before movement, NS' starts about 400 ms before movement, the premotor positivity (PMP) starts about 80 ms before movement, and the negative motor potential (MP) starts at the peak of the PMP. This study was designed to investigate the detailed topography of these potentials.

29 channels of EEG, one channel of EOG and the first dorsal interosseus EMG in right and left hands were recorded for a 499 ms window. The EEG montage consisted of the International 10-20 System with 10 additional electrodes between frontal and central, and central and parietal electrodes. Healthy subjects were asked to make self-paced, unilateral index finger abductions. The rectified EMG of the moving finger triggered the computer, the recordings were aligned according to the start of the EMG, and topographic maps were generated from averaged waveforms.

NS' peaked at 82.3 ms (S.E. ±9.9 ms). The peak of PMP occurred at 35.6 ms (S.E. ±5.4 ms). The peak of NS' and the peak of PMP were both closer to the onset of movement in the dominant hand. In the topographic maps NS' localized in central and parietal areas with maximal intensity in CZ and PZ with slight contralateral predominance. The PMP was localized in the central area ipsilateral to the finger moved. The MP appeared in a small, well-localized area in the contralateral central region, corresponding to the motor map obtained by Cohen & Hallett (Neurology, in press) using non-invasive electrical stimulation.

HORMONAL CONTROL OF BEHAVIOR IV

SEX DIFFERENCES IN LORDOSIS EFFECTS OF ESTROGEN METABOLITES: IMPLICATIONS FOR RAT BRAIN ESTROGEN RECEPTOR DYNAMICS. R.H. Lustig, C.V. Mobbs, D.W. Pfaff, and J. Fishman , The Rockefeller University, New York, NY 10021.

16α-hydroxyestrone (16OHE1), a metabolite of estradiol (E2) and precursor of estriol (E3), binds to the estrogen receptor (ER) with an affinity of 3% of E2, but is equipotent with E2 in *in vitro* systems, due to covalent binding to the ER via a Heyns rearrangement of an intermediate Schiff base. We used this novel property to assess the dynamics of estrogenic effects on rat reproductive behavior by measuring the lordosis score (LS) to manual stimulation in response to exposure and withdrawal of these steroids. Male and female castrate Fisher rats were implanted with Alset osmotic minipumps to deliver vehicle, or 150 nmol/kg/d E2, 16OHE1, or E3. In both sexes, LS increases with 16OHE1 were delayed versus E2 and E3 for 2-3 days ($p<0.05$), but ultimately reached similar maximal levels within a sex (males: max LS ~1.1; females: max LS ~2.3; range 0-3). Upon pump removal, E2- and E3-stimulated LS fell to control levels within 2-4 days in both sexes. 16OHE1-stimulated LS in females also fell as quickly, but in males, LS remained maximal for 6 days ($p<0.05$) before decreasing to control levels.

These results suggest that: 1) 16OHE1 and E3 are equipotent with E2 in promoting lordosis in both sexes; 2) the onset of LS with 16OHE1 is delayed, consistent with its poor ER affinity; 3) males demonstrate a prolonged action of 16OHE1 relative to E2 and E3, consistent with its non-dissociable binding to the ER; 4) females do not show prolonged action of 16OHE1. Since estrogens are eliminated more slowly in females than in males, two possible explanations for the prolongation of LS in males with 16OHE1 are (a) 16OHE1 may stabilise brain ER only in males, or (b) brain ER turnover may be slower in males than in females.

193.2

CO-MIGRATION ON 2-D GELS OF AN ESTROGEN-INDUCED BRAIN PROTEIN, AN LHRH-INDUCED PITUITARY PROTEIN, AND AN UNCOATING ATPASE/HEAT-SHOCK 70KD PROTEIN. Charles Mobbs, George Fink, Melanie Johnson#, William Welch#, and Donald Pfaff. (SPON: Z. Wenzel) Edinburgh University, Edinburgh, UK, and Cold Spring Harbor Laboratory, Cold Spring Harbor, NY., Rockefeller University, New York, NY 10021.

Estradiol induces a protein (EI70), MW 70Kd and pI 5.9, synthesized in the female rat ventromedial hypothalamus (VMH) and transported to the midbrain central gray, suggesting a role in estrogen-regulated lordosis; we have hypothesized that this protein may be an uncoating ATPase/heat shock protein and may facilitate vesicle release by removing clathrin from coated vesicles (Mobbs et al., J. Neurosci. 8:113-118). Luteinizing hormone releasing hormone (LHRH) facilitates lordosis and primes the release of LH secretory vesicles and induces a 70Kd protein in pituitary (Curtis et al., J. Endo 105:163-168). We now report that 8.5 or 85 nM LHRH incubated with pituitaries in vitro induces a protein with MW 70Kd and pI 5.9 which precisely co-migrates with EI70 on 2-dimensional gels. Furthermore, these proteins co-migrate on 2-D gels with a protein recognized after Western blotting by antibodies to the uncoating ATPase/heat-shock family. Thus the induction of an uncoating ATPase by hormones may facilitate release of secretory or synaptic vesicles.

193.3

SEX DIFFERENCE IN THE REGULATION OF 70KD HYPOTHALAMIC PROTEINS BY ESTROGEN. Isabel Fraile*, Charles Mobbs and Donald Pfaff. Rockefeller University, New York, N.Y.

Estradiol induces a protein (EI70), MW 70Kd and pI 5.9, synthesized in the female rat ventromedial hypothalamus (VMH) and transported to the midbrain central gray, suggesting a role in estrogen-regulated lordosis; another protein (MW 70Kd, pI 5.8) is decreased by estrogen (Mobbs et al., J. Neurosci. 8:113-118). In the present work we investigated the regulation of these proteins in estrogen-treated males and females. Fisher rats were castrated and one week later given s.c. injections of estradiol benzoate or vehicle. VMH proteins were labeled in conscious rats with (^{35}S) Met/Cys targeted to VMH with cannulae using minipumps. Proteins were separated on 2-D gels and quantitated by densitometry, including extensive analyses of linearity and reproducibility. Of fourteen spots analyzed ten were extremely stable, showing no more than 5-10% variation between groups. In females, but not in males, estrogen treatment increased EI70 and decreased its two immediately acidic neighbors. Thus the estrogen regulation of these 70Kd proteins in female rats does not seem to be present in the males. In females estrogen also induced a previously unreported protein (69Kd, pI 5.7) (no estrogen:58+11; estrogen:94+20). This protein responded in the opposite way to estrogen treatment in the males (no estrogen:79+5; estrogen:50+1).

193.4

DO PROGESTERONE TARGET NEURONS PROJECT TO THE MIDBRAIN? L.L. DonCarlos and J.I. Morrell. Inst Animal Behav, Rutgers Univ, Newark, NJ 07102.

Progesterone (P) affects the genome of cells by binding to P-receptors in these target cells. We hypothesize that, in the nervous system, P-target neurons communicate hormonal status to other neuronal populations via axonal projections. We have used steroid hormone autoradiography combined with midbrain injections of the retrograde tracer, Fluorogold (FG), to determine the location and number of P-target neurons that project to the midbrain in rats. Ovx, adx rats were given a large midbrain injection of FG (3 days before sacrifice) and estrogen treatment to induce P receptors. Injections of 250uCi ^{3}H-ORG 2058 (a synthetic progestin) were made IP 1-1.5 hrs before sacrifice which was by perfusion with 4% paraformaldehyde. Autoradiograms were prepared and exposed 8 mo. ^{3}H-ORG-concentrating neurons were detected in the preoptic area and in the ventromedial, lateral, dorsomedial, arcuate and medial tuberal nuclei of the hypothalamus. FG-labeled neurons were observed in the same, and other, cell groups. ^{3}H-ORG-concentrating neurons that project to the midbrain were generally rare. Supported by HD22983 and NS07997.

193.5

ANDROGEN-CONCENTRATING NEURONS OF PREOPTIC, HYPOTHALAMIC, AND LIMBIC REGIONS PROJECT TO THE MIDBRAIN. C.A. Lisciotto* and J.I. Morrell. Inst Animal Behavior, Rutgers Univ, Newark, NJ, 07102.

Projections of preoptic, hypothalamic, and limbic structures to the midbrain are important for androgen-mediated behaviors. Using steroid autoradiography combined with retrograde tracing, we investigated whether androgen-concentrating neurons in the forebrain project to the ventral midbrain. GDX/ADX adult male rats received 0.3 ul injections of fluorogold into the ventral midbrain. Four days later, 3H-testosterone or 3H-dihydrotestosterone (1.2nM/100g BW; SA=148-168 Ci/mmol) was injected iv, 1-1.5hrs prior to sacrifice. Autoradiograms were prepared and exposed for 3-10 months. Androgen-concentrating neurons that also contained retrograde label were detected in the bed nucleus of the stria terminalis and ventromedial nucleus of the hypothalamus, and were abundant in the medial preoptic area and diagonal band of Broca. Androgen-concentrating neurons were also present in the lateral septal, paraventricular, arcuate, and medial amygdaloid nuclei, but none of these contained retrograde label. Projections of androgen-concentrating neurons may be a route by which steroid target sites influence neural circuits relevant for behavior.

193.6

BOTH FATTY ACID AND GLUCOSE METABOLISM MEDIATE THE EFFECTS OF STARVATION ON REPRODUCTION IN HAMSTERS.
J.E. Schneider* and G.N. Wade., Dept. of Psychology and Neuroscience and Behavior Program, Universtiy of Massachusetts, Amherst, MA 01003.

It has been suggested that a minimum or threshold of body fat is required for reproduction in females of many species, including human beings. We have found that the effects of starvation on hamster estrous cycles depend on prior body weight, such that lean hamsters are highly susceptible, while fat hamsters are less susceptible to starvation-induced anestrus.

We hypothesize that the cessation of reproduction is signalled by changes in the overall availability of metabolic fuels, rather than by a critical body weight per se. Eighty-five per cent of female hamsters immediately stopped estrous cycling when treated with both methyl palmoxirate (MP, an inhibitor of fatty acid oxidation) and 2-deoxy-d-glucose (2DG, an inhibitor of glucose utilization) during the first 2 days of the estrous cycle. However, females treated with either MP or 2DG during the same time period continued cycling. Thus, the cessation of reproduction may be signalled by changes in the general availability of metabolic fuels, rather than by one specific fuel.

ELECTROPHYSIOLOGICAL PROPERTIES OF IDENTIFIED SEROTONERGIC NEURONS IN THE LOBSTER. PoKay M. Ma* and Edward A. Kravitz (SPON: M. Segal). Department of Neurobiology, Harvard Medical School, Boston, MA 02115. Injection of serotonin into freely moving lobsters produces a long-lasting postural change that mimics the naturally occurring posture assumed by dominant animals in a hierarchy. We have recently identified two pairs of large serotonergic neurons, one pair in the last thoracic and one in the first abdominal ganglion that may be important in postural circuits. Intracellular recording shows that these cells receive prominent inhibitory inputs, which generate IPSPs of various sizes; EPSPs, on the other hand, are rarely seen. The IPSPs in the left and right cells within a ganglion are synchronized, suggesting that the two cells receive the same inhibitory inputs. These cells are spontaneously active, firing large action potentials at a frequency of about 1 Hz. Following each action potential, the membrane potential increases slowly through a depolarizing ramp until the next firing threshold is reached. The oscillation of membrane potential is probably endogenous, like the pace-making properties of cardiac myocytes. The oscillation is also temperature-dependent: as the temperature is raised, cell firing changes from irregular through steady to bursting. The bursts of pairs of cells within a ganglion are synchronized. Flexor command neurons excite, while extensor commands inhibit, the firing of the serotonergic cells. When cell firing frequency is increased by direct intracellular stimulation, little effect is seen in the motor output. However, when flexor command neurons are activated the motor output is enhanced or diminished by allowing or preventing the serotonergic cell from firing. These physiological properties will be explored in dominant and subordinate lobsters to see if any changes can be correlated with differences in behaviors exhibited by these animals. (supported by NIH and MDA)

193.8

Pattern of ^{14}C-2-Deoxyglucose (2DG) Concentration Associated With Prostaglandin E_2 Administration and Sexual Behavior of the Female Frog, *Rana pipiens*. C. Diakow, W. Woicyk*, D. McEachron, and N.T. Adler. Adelphi U., Garden City, NY, and Drexel U. and U. Penn., Phila., PA 19104.

An indication of receptive behavior in female *R. pipiens* is absence of a vocalization, the release call, during tactile stimulation of the trunk. Prostaglandin E_2 (PGE_2) silences the female. We compared the pattern of 2DG concentrations in brains of 5 females receiving 1μg PGE_2/g with that of 3 vocalizing controls injected with deionized water. There was high activity relative to the rest of the brain in the PGE_2-treated females in the posterior part of the anterior preoptic nucleus, in the dorsal habenula, and in the dorsal tegmental area of the medulla lateral to the pretrigeminal nucleus. These results are consistent with the ideas that the activity of these areas is modified by PGE_2 action and that these structures participate in inhibition of the release call, hence, reproductive behavior of the female frog.

DO GLUCOCORTICOIDS INFLUENCE AUDITORY PERCEPTION IN NORMAL SUBJECTS? G. Fehm-Wolfsdorf, B. Oergel*, D. Nagel*, H. Zenz* and H. L. Fehm*. Depts. of Medical Psychology, HNO and Internal Medicine I, University of Ulm, D-7900 Ulm, F.R.G.

Glucocorticoids have been reported to influence brain functions related to stimulus perception and processing (Henkin R. I. et al, J. Clin. Invest., 46:419, 1967). Moreover, two different types of glucocorticoid receptors have been identified in rat brain, leading to the speculation that specific receptors in hippocampal regions might be involved in behavioral regulation (de Kloet E.R. & Reul J.M.H.M., Psychoneuroendocrinology, 12:83, 1987). We studied differential effects of hydrocortisone and dexamethasone on auditory perception. 15 male volunteers were treated with 50 mg hydrocortisone, 2 mg dexamethasone or placebo in a double-blind cross-over design. Sessions indcluded measurement of stapedial reflex, pure tone audiogram, speech audiogram and brainstem evoked response audiometry. Reflex and audiogram measures as well as brain stem potentials did not differ between treatment conditions. Only performance in speech audiogram was enhanced after glucocorticoid intake with no difference between hydrocortisone and dexamethasone. From our results we conclude that physiological doses of glucocorticoids modulate cortical processing rather than perceptual thresholds.

193.10

HYPERPROLACTINEMIA INHIBITS OPEN FIELD DEFECATION BUT NOT ANDROGEN-DEPENDENT URINE MARKING. Paul C. Doherty Department of Anatomy, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Hyperprolactinemia inhibits open-field defecation. To determine if this effect represents a general decline in marking behavior, four groups of animals (CG, castrated, pituitary-grafted males; CS, castrated, sham-transplanted males; TG, castrated, testosterone-treated pituitary-grafted males; TS, castrated, testosterone-treated sham-transplanted controls) were examined for defecation and urine marking responses to a novel environment. Each animal was placed in a ten gallon aquarium lined with filter paper for 5 min, and the number of fecal boluses and area of urine deposition were measured. Both castration and pituitary grafting inhibited defecation (CG, 0.06 $\pm$ 0.06; CS, 1.31 $\pm$ 0.48; TG, 1.50 $\pm$ 0.64; TS, 2.29 $\pm$ 0.61 boluses). In contrast, while castration led to significant inhibitory effects on urine marking (CG, 10.68 $\pm$ 1.86; CS, 11.80 $\pm$ 1.75; TG, 26.15 $\pm$ 5.15; TS, 30.76 $\pm$ 6.39 cm^2), pituitary grafting had no significant effect. These results suggest that: 1. Inhibitory effects of hyperprolactinemia on open-field defecation are unrelated to androgen-dependent urine marking; 2. Inhibitory effects of hyperprolactinemia on male sexual behavior do not represent a global inhibition of the effects of testosterone on behavior. 193.11

THE OXYTOCIN FRAGMENT PROLYL-LEUCYL-GLYCINAMIDE FACILITATES SEXUAL BEHAVIOR IN THE FEMALE RAT. B. B. Gorzalka*, K. A. Luck* and G. L. L. Lester* (SPON: R. Tees). Dept. of Psychology, Univ. of British Columbia, Vancouver, B.C., V6T 1Y7 Canada

The structure of prolyl-leucyl-glycinamide (PLG) is identical to that of the C-terminal tripeptide of oxytocin. Whether or not PLG is a natural brain metabolite of oxytocin is a matter of controversy. Some investigators have claimed evidence that a hypothalamic peptidase stepwise degrades oxytocin to PLG. Others have been unable to confirm this, and have noted the existence of PLG in non-oxytocinergic neurons. Tyrosine-prolyl-leucyl-glycinamide (TPLG), a biologically active peptide present in the brain, might also function as a precursor to PLG.

In the present series of experiments, we compared the effects of PLG and TPLG with previously observed effects of oxytocin on sexual receptivity. Administration of oxytocin facilitates sexual receptivity in rats provided that they are primed with adequate quantities of both estradiol and progesterone (Gorzalka and Lester, Neuropeptides, 10, 55-65, 1987). In the present study, ovariectomized rats received estradiol and 0, 200, 250 or 300 µg progesterone. Intraperitoneal administration of 10 mg/kg PLG or TPLG significantly facilitated receptivity at the 200 and 250 µg progesterone doses only. Doses of 0.1 mg/kg PLG, 1.0 mg/kg PLG and 1.0 mg/kg TPLG produced similar effects. The progesterone-dependent effects of PLG and TPLG are reminiscent of results with oxytocin.

PERIPHERAL VS. PREOPTIC AROMATIZATION OF ANDROGEN TO ESTROGEN AND ACTIVATION OF MALE SEXUAL BEHAVIOR IN JAPANESE QUAIL. J. T. Watson, M. Abdulnabi*§, S. Wersinger*, M. A. Ottinger§ and E. A. Regan. Field of Neurobiology and Behavior and Dept. of Psychology, Uris Hall, Cornell Univ., Ithaca, NY, 14853, and §Dept. of Poultry Sci., Univ. of Maryland, College Park MD, 20742.

Male-typical copulatory behavior (mounting) can be restored in castrated male Japanese quail (*Coturnix japonica*) with implants of testosterone (T) or estradiol in the preoptic area (POA) (Watson et al., Soc. Neurosci. Abstracts 12: 835, 1986). Three experiments were conducted to determine if aromatization of T to estrogens (E) in the POA is required to activate mounting. In the first experiment, blood samples were drawn every four hours from groups of sexually active male quail (N=78, 92% mounted) housed under a 16L:8D light-dark cycle, and assayed for estradiol concentration (E2). Mean ± S.D. serum E2 was 52.6± 25.8 pg/ml (median=49.7 pg/ml), and no diurnal cycle in E2 was seen. In the second experiment, 51 males were castrated and implanted with Silastic tubes containing estradiol benzoate (EB) designed to produce 5 different levels of serum E2. At 2, 3, and 4 weeks after implantation, quail were tested for sexual behavior and a blood sample was taken. The range of E2 in quail which mounted was 93.5-527.9 pg/ml (median=263 pg/ml). Only 7.4% of implanted males with E2 in the range of intact males mounted, and only 9.5% of intact males had serum E2 ≥ the minimum associated with mounting in implanted males. These results suggest that serum E2 in intact males is insufficient to activate mounting without aromatization in the brain to produce local E levels higher than those provided by serum E2. In the third experiment, castrated males were each given a POA implant of: testosterone propionate (TP) + cholesterol (CH), TP + the aromatization inhibitor 1,4,6-androstatrien-3,17-dione (ATD), EB+ATD, or CH. Birds with implants containing TP or EB mounted (TP+CH: 4/8, TP+ATD: 3/5, EB + ATD: 3/7, CH: 0/6). These data suggest that POA aromatization is not necessary for T activation of mounting, but simultaneous application of TP and ATD may have reduced the effectiveness of ATD as an aromatization inhibitor. In further studies, ATD treatment will precede POA/TP stimulation. NSF BNS-84-12083.

ESTROGEN RECEPTORS IN QUAIL BRAIN: A FUNCTIONAL RELATIONSHIP TO AROMATASE AND AGGRESSIVENESS. B.A. Schlinger* and G.V. Callard. Department of Biology, Boston University, Boston, MA 02215.

Estradiol (E) mediates many of the activational effects of testosterone (T) on masculine reproductive behaviors. Using Japanese quail as an animal model and a newly devised procedure for quantifying aggressiveness, we recently showed that aggression is E-dependent and that individual differences in behavioral intensity are correlated with aromatase in the hypothalamus/preoptic area (HPOA). In this study we characterized estrogen receptors (ER) in quail brain and tested the hypothesis that aromatase governs T-induced responsiveness by regulating the quantity of E available for ER binding. Based on standard binding assays and LH-20 chromatography, quail brain ER was E-specific; of high affinity (Kd=0.88nM) and of limited capacity (Bmax 23-37 fmoles/gm HPOA). The quantitative relationship between aromatization, ER, and aggressiveness was tested in reproductively inactive (non-aggressive) males by treatment with T± the aromatase inhibitor 4-hydroxyandrostenedione (OHA). After five days, T markedly stimulated aggressiveness and elevated aromatase and nuclear ER in HPOA. Simultaneous treatment with OHA blocked T effects on aggressiveness and aromatase, lowered nuclear (occupied) ER but increased cytosolic (empty) ER. Total ER (nuclear + cytosolic) was higher after T-treatment whether or not OHA was administered suggesting androgen per se induces ER in quail brain. These data provide good evidence that activation of aggressiveness by T in quail is dependent on neural production of E and subsequent ER occupancy but also suggests that T increases aromatizing potential and total ER abundance. (Supported by NSF DCB 85-19737)

A NOVEL IN VITRO MODEL OF FOCAL EPILEPSY: FREEZE LESION OF TURTLE VISUAL CORTEX. D. Adams*, M.G. Blanton, and A.R. Kriegstein. (SPON: J. Hotson) Dept. of Neurology, Stanford University, Stanford, CA 94305-5300.

In order to study the cellular changes associated with cortical injury and epileptogenesis we have developed an in vitro model that allows stable, long-term intracellular recordings during the transition from normal to focal epileptic activity. A dry ice cooled brass probe (2 mm diameter) is applied for 45 seconds to an intact slab of turtle cerebral cortex, placed in a recording chamber. Within two hours spontaneous periodic epileptiform discharges emanate from a peri-lesion focus and propagate throughout the cortex. Pyramidal neurons within the area of the focus exhibit abnormal burst discharges coincident with the epileptiform potential. Intracellular recordings reveal a depolarizing envelope accompanied by a conductance increase. In areas that surround the focus, the epileptic discharge often leads to a burst of partial spikes, thought to represent dendritic action potentials (APs) recordable in the pyramidal cell somata. In uninjured areas of cortex, the discharge coincides with summated Cl^--dependent IPSPs in pyramidal cells and repetitive firing of GABAergic nonpyramidal neurons. These data provide evidence for pathological cellular discharge in the region of the focus with recruitment of activity in uninjured cortex consisting of both excitatory and inhibitory PSPs.

DISTRIBUTION OF INCREASED SYNAPTIC ACTIVITY DURING FOCAL AND GENERALIZED EPILEPTIFORM ACTIVITY REVEALED BY PRESYNAPTIC UPTAKE OF FLOURESCENT DYES. A.R. Kriegstein, J.G. Avilla*, and M.G. Blanton. Dept. of Neurology, Stanford University School of Medicine, Stanford, CA 94305.

Because of the possibility of maintaining large portions of the CNS of the pond turtle in vitro, we have begun to study the participation of cortical and subcortical regions in the generation of focal and generalized epilepsy. To complement physiological recording methods, we used a technique for labelling active presynaptic terminals, introduced in studies of snake skeletal muscle by Lichtman et al (Nature 314:357, 1985). After initiation of seizure activity by cortical freeze lesion (see Adams et al, this meeting) or by application of the $GABA_A$ antagonist bicuculline, the tissue was bathed in a 1% solution of sulfarhodamine 101 or flourescein-5-sulfonate (Molecular Probes), followed by a wash and fixation. Well labelled terminals and occasional faintly labelled neurons were seen in both epilepsy paradigms, while no specific labelling was detectable under conditions of normal spontaneous activity or if synaptic transmission was blocked by omitting Ca^{2+} or adding TTX to the bath. In bicuculline, profound terminal labelling was found in dorsomedial (hippocampal) cortex, the medial septum and basal telencephalon, while the freeze lesion focus was surrounded by a ring of increased activity. This technique should be useful in identifying functionally active regions, with subcellular resolution.

SPONTANEOUS HIGH $[K^+]_o$-INDUCED ELECTROGRAPHIC SEIZURES IN HIPPOCAMPAL SLICES ARE SUPPRESSED BY HYPEROSMOTIC MEDIA. S.F.Traynelis and R.Dingledine, Dept. of Pharmacology, The University of North Carolina, Chapel Hill, NC 27514.

Rat hippocampal slices in 8.5 mM $[K^+]_o$ displayed two types of spontaneous epileptiform activity: ~50 ms duration synchronous bursts that arose in CA3 and propagated to the CA1 region, and longer (~50s) electrographic seizures restricted to CA1. An increase in $[K^+]_o$ should induce cell swelling and subsequent reduction in extracellular space (ECS). The resulting tighter cellular pack might exaggerate extracellular ion transients and enhance electric field effects, possibly providing a synchronizing trigger for seizure initiation. We have assessed the contribution of ECS to seizure initiation by osmotic manipulations of ECS. Media made 5-30 mOs hyperosmotic by addition of agents that alter transmembrane osmotic pressures rapidly abolished seizures in 48/56 slices. However, hyperosmotic changes with compounds that access intracellular space were ineffective (21/25 slices). Osmotic manipulations might arrest spontaneous seizures through reduction of required interictal input to CA1. While hyperosmotic manipulations did not alter burst frequency, burst intensity was attenuated in CA3 (~85% control) and CA1 (~70% control). Likewise, excitatory synaptic transmission in CA1 in high $[K^+]_o$ was attenuated (n=3) by hyperosmotic media. This suggests that the volume of ECS is indeed a critical determinant of seizure initiation in this model (supported by NS17771).

REDUCTION BY CNQX, A NON-NMDA RECEPTOR ANTAGONIST, OF EVOKED AND SPONTANEOUS SYNAPTIC POTENTIALS IN RAT HIPPOCAMPAL SLICES. **N.L. Chamberlin and R. Dingledine, Dept. of Pharmacology, Univ. N. Carolina at Chapel Hill; Chapel Hill, N.C. 27599.**

To investigate the role of synaptic excitation in the initiation of spontaneous epileptiform bursts in hippocampal slices perfused with elevated (8.5 mM) $[K^+]_o$, we carried out the following experiments. First, population spikes and field epsps in CA1 and CA3b/c were evoked by stimulating the Schaffer collaterals and dentate granule cells, in normal (3.5 mM) K^+. Synaptic potentials, which were discerned from fiber-volleys by their sensitivity to low (0-.2 mM) Ca^{2+} solutions, were reversibly and greatly reduced by 1-5 μM CNQX (FG 9065). These results suggest that non-NMDA receptors participate in excitatory synaptic transmission in the hippocampus. Second, the effect of CNQX (1-5 μM) was examined on spontaneous interictal field bursts recorded in CA3b/c of hippocampal slices bathed in 8.5 mM K^+. CNQX reversibly reduced burst intensity (58±13% of control, n=8) and frequency (42±15% of control, n=11). Third, intracellular recordings from 3 CA3b/c cells in 8.5 mM K^+ suggested that frequency of spontaneous epsps (≥ 1 mV in amplitude) was reduced by 2 μM CNQX. Therefore, synaptic activation of non-NMDA receptors appears to be required for spontaneous interictal bursting in hippocampal slices bathed in 8.5 mM K^+. CNQX was a gift from T. Honore. Supported by NS-17771.

BRAIN ASPARTATE DECREASES AND GABA INCREASES DURING STATUS EPILEPTICUS IN THE RAT. **D.M. Treiman, N.Y. Walton,* and S. Gunawan.* Neurology and Research Services, VA West Los Angeles Medical Center and Dept. of Neurology, UCLA School of Medicine, Los Angeles, CA.**

We have described a series of predictable EEG changes during generalized convulsive status epilepticus (SE) in both patients and in experimental SE in the rat (Neurology 37;Suppl 1:244, 1987), which allow us to identify early, mid- and late SE by EEG criteria. We measured whole and regional concentrations of selected amino acids (AAs) during the course of SE induced by IP pilocarpine (25 or 30 mg/kg) in rats given 3 mmol/kg LiCl 24 hours earlier. After decapitation, brains were rapidly removed and frozen in acetone and dry ice. Concentrations of aspartate, glutamate, serine, glutamine, glycine, taurine and GABA were determined by HPLC for whole cerebral hemispheres and 14 specific brain regions after homogenization, extraction in 80% ethanol, and reaction with phenylisothiocyanate to form phenylthiocarbamyl derivatives. Glutamate, serine and taurine did not change in whole brain. The table lists levels of the other AAs acids in whole cerebral hemispheres in umol/gram brain wet weight.

Condition\AA	ASP	GLN	GLY	GABA

PHENCYCLIDINE ANALOGS AS ANTICONVULSANTS: NOVEL COMPOUNDS WITH ENHANCED ANTI-SEIZURE ACTIVITY RELATIVE TO MOTOR TOXICITY. M.A. Rogawski, A. Thurkauf, K.C. Rice, A.E. Jacobson, J.M.H. ffrench-Mullen and S. Yamaguchi, Medical Neurology Branch, NINCDS and Section on Drug Design and Synthesis, NIDDK, NIH, Bethesda, MD 20892.

Phencyclidine (PCP) is a powerful anticonvulsant in a wide variety of animal seizure models, however, undesirable side effects (such as ataxia, hallucinations and cognitive impairment) which occur in the same dosage range as seizure protection limit its practical usefulness in the treatment of seizure disorders. In the present study, we compared the anticonvulsant and ataxia-inducing activities of a series of novel PCP analogs in an attempt to obtain drugs that maintain PCP's anticonvulsant activity but are less toxic. Drugs were screened in mice for protection against maximal electroshock (MES) seizures; motor toxicity was determined with the rotorod ataxia test. PCP was equipotent at protecting against seizures (ED_{50}) and in inducing ataxia (TD_{50}) so that its "therapeutic index" (TI=TD_{50}/ED_{50}) equaled 1. Many PCP-related compounds [dexoxadrol, *m*-amino-PCP, (+)-PCMP] had a similar profile with TI~1. However, we found that certain PCP analogs [phenylcyclohexylamine (PCA), *trans*-(R)-3-methyl-PCA, 3,4-dehydro-PCP] maintained PCP's anticonvulsant activity but caused ataxia only at higher doses, so that the TI was enhanced (~2). Moreover, several compounds (*m*-nitro-PCP, 1-phenylcyclopentylamine, 1-phenylcycloheptylamine, 1,1-pentamethylenetetrahydroisoquinoline) exhibited moderately reduced anticonvulsant potency, but these drugs had an even greater diminution in toxicity so that TI's as high as 3-4 were obtained. In comparison, currently used anticonvulsant drugs have TI's of 1.6-8.1.

BRAIN DAMAGE FROM PILOCARPINE-INDUCED SEIZURES IS AMELIORATED BY AN N-METHYL-D-ASPARTATE ANTAGONIST. D.G. Fujikawa. Exp. Neurol. Lab., V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Neurology, UCLA Sch. of Med., Los Angeles, CA 90024.

Pilocarpine (PC)-induced seizures in the rat can be prevented with bilateral intracerebral injections of the N-methyl-D-aspartate (NMDA) antagonist 2-amino-7-phosphonoheptanoic acid (2-APH). However, the mechanisms of neuronal damage in this seizure model are unknown. We injected 2-APH unilaterally into the basolateral amygdala of adult Wistar rats to study the effect on seizure-induced neuronal necrosis.

Bilateral guide cannulae were implanted in the basolateral amygdaloid nuclei. One week later 20 ug (89 nmol) of 2-APH in 1 ul of buffer was injected through one cannula; the other side received buffer alone. Rats were then given 400 mg/kg PC i.p., and after 3 h seizures they received diazepam and phenytoin or phenobarbital i.p.

Brain perfusion-fixation was performed 3 d later. Neurons beneath the cannula tip on the side of 2-APH injection were protected from cell loss (total neurons 164±13 vs. 92±7 contralaterally [mean ± S.E.M.], $p<0.02$, $n=4$), and of the remaining neurons, fewer were necrotic (0.2± 0.2% vs. 21.0±6.6% contralaterally, $p<0.05$). Brain damage from PC seizures may be at least in part NMDA-receptor-mediated. 2-APH is not only an anticonvulsant, it may also protect against brain damage from ongoing seizures.

194.8

AFTERPOTENTIALS OF PENICILLIN-INDUCED SYNCHRONIZED DISCHARGES IN THE MOTOR CORTEX OF THE RAT IN VIVO. O.W. WITTE, S. UHLIG* and E. VALLE*, Neurologische Universitätsklinik, Moorenstr. 5, 4000 Düsseldorf, F.R. Germany

Penicillin-induced synchronized epileptic discharges are followed by de- or hyperpolarizing afterpotentials. In the present series of experiments different types of afterpotentials were separated. The experiments were carried out on the motor cortex of anaesthetized rats using conventional intracellular recording techniques.

Four different types of afterpotentials could be differentiated: 1. A fast afterhyperpolarization which in seven typical experiments had an average duration (100% to 10% decay time, measured from begin of PDS) of 614 ± 96 ms. 2. A fast afterdepolarization (703 ± 103 ms, $n = 9$). 3. A slow afterhyperpolarization (1.9 ± 0.33 s, $n = 6$). 4. A slow afterdepolarization (1.8 ± 0.23 s, $n = 6$).

Afterhyperpolarizations were especially pronounced in neurons with a low resting membrane potential while neurons with a high resting membrane potential showed afterdepolarizations. Intracellular current injection revealed that the fast afterpotentials reversed polarity at −60 to −70 mV while the slow afterpotentials inverted between −80 and −90 mV.

194.9

A GABA-MEDIATED, DEPOLARIZATION INDUCED BY 4-AMINOPYRIDINE (4AP) IN HUMAN NEOCORTICAL AND HIPPOCAMPAL NEURONS MAINTAINED "IN VITRO". M. Avoli, P. Perreault, A. Olivier and J.G. Villemure, MNI, McGill University, Montréal, Que., CANADA

Intracellular recordings were performed in neocortical or hippocampal neurons in slices obtained from human epileptogenic brain tissue excised during surgical treatment of epilepsy. Bath application of 4AP (50 uM) induced spontaneous excitatory and inhibitory post-synaptic potentials which were blocked by Tetrodotoxin (1 uM). Most of the neurons (12/16) also generated in the presence of 4 AP a long-lasting (up to 1.5s) depolarizing potential which: (i) behaved as expected for a synaptic potential during alteration of the resting membrane potential; (ii) prevented the generation of action potentials induced by intracellular depolarizing current pulses and (iii) was blocked by bath application of bicuculline (20 uM). In the presence of bicuculline spontaneous hyperpolarizations, which inverted near the K^+ equilibrium potential, were recorded. It is concluded that like pyramidal or granule cells of the rat hippocampal slice, human neocortical or hippocampal neurons obtained from either spiking or non-spiking areas are capable of generating a 4AP-induced long-lasting depolarization which is mediated through GABA receptors. Supported by the MRC of Canada and FRSQ.

BEHAVIOR AND NEUROCHEMICAL CHANGES 6 MONTHS AFTER KAINIC ACID. H. Baran, H. Lassmann and O. Hornykiewicz. Inst. Biochem. Pharmacol. and Neurol. Inst. Univ. Vienna, Austria.

Behavioral, neurochemical and histopathological changes were investigated in rats 6 months after systemic application of kainic acid (KA; 10 mg/kg, sc). KA induced long lasting generalized seizures up to 6 h after injection. One month later, the animals seemed to have recovered but spontaneous seizures lasting 4-10s occurred once or twice a month thereafter.

Six months after KA injection, significant increases in GAD activity were noted in temporal (62%), parietal (56%), occipital (57%), frontal (39%) and cingulate (37%) cortex and in nucleus caudatus (37%). No significant GAD changes were found in hippocampus, amygdala/pyriform cortex and substantia nigra. CAT activity was normal in all cortical areas, hippocampus and nucleus caudatus but declined significantly (40%) in amygdala/pyriform cortex. Noradrenaline levels remained unchanged in all areas examined. Changes in glutamine levels were restricted to an increase (50%) in the nucleus caudatus and a reduction (30%) in amygdala/pyriform cortex. GABA levels were increased in the hippocampus, nucleus caudatus (70%) and substantia nigra (40%) and decreased in amygdala/p. cortex (40%). Altered GABA-ergic function in the brain 6 months after KA may reflect compensatory responses of GABA neurons to spontaneous seizure activity. (Supported by the Austrian Science Research Fund projects P5647 and S 25/06).

INDUCTION OF C-FOS PROTO-ONCOGENE PRODUCT mRNA BY ELECTROCONVULSIVE SEIZURES (ECS) IN MOUSE BRAIN. [1]P.J. Marangos, T. Nakajima, J.L. Daval and [2]C.H. Gleiter. [1]Gensia Pharmaceuticals, San Diego, CA 92121-1207, Unit on Neurochemistry, BPB, NIMH and [2]NIAAA/LCS, Bethesda, MD 20892.

Recent studies have shown that the c-fos proto-oncogene product is induced in response to chemically-induced seizures. C-fos is a nuclear DNA binding protein that has been shown to be involved in the induction of transcription in certain cell types. In normal brain tissue, it has been postulated that the c-fos proto-oncogene product may be a nuclear response to various membrane events that involve disturbances in membrane calcium fluxes. In this study, mice were exposed to a single ECS (80mA, 0.5s) and the brains were rapidly removed and frozen in liquid nitrogen at various time intervals following the seizure. Extracted total RNA was resolved by electrophoresis, blotted and analyzed for c-fos mRNA using a ^{32}P labeled DNA probe. A rapid, transient, 5-fold expression of c-fos mRNA was observed at 15 minutes post-ECS and returned to baseline values at 240 minutes. Also, at 15 minutes, a 3-fold significant expression of c-fos mRNA was observed in the control animals that were ear-clipped but not shocked. Our results show that c-fos upregulation is observed with ECS and, perhaps more interestingly, that a much more subtle stimulus associated with the stress of ear-clipping is also capable of inducing c-fos.

194.12

SUPPRESSION AND FACILITATION OF EPILEPTIC ACTIVITY IN THE DENERVATED HIPPOCAMPUS BY NEURAL GRAFTS. G. Buzsáki, G. Ponomareff,* F. Bayardo,* and F.H. Gage. Dept. of Neurosciences (M-024), UCSD, La Jolla, CA 92093, USA.

Spontaneous and stimulus-evoked neuronal activity were studied in the subcortically denervated (fimbria-fornix, FF) hippocampus of the freely moving rat. Spontaneous interictal spikes (< 40 ms, 3-8 mV; IIS) were observed in the hippocampus up to the termination of the experiments (8 mo). Depth profile and unit recording experiments revealed that the trigger zone of IIS was the CA3 region. The threshold for inducing afterdischarges was significantly lower, and the seizures lasted longer in FF rats. Cell suspensions prepared from the fetal locus coeruleus region and transplanted into the denervated hippocampus decreased the incidence of IIS and protected against picrotoxin-induced behavioral seizures. In contrast, in rats with fetal hippocampal cell suspensions the incidence of IIS was significantly higher than in FF controls and spontaneous behavioral seizures occurred in half of the rats. We suggest that the subcortically denervated hippocampus is a useful chronic preparation to study the mechanisms of epilepsy, and replacement of the missing transmitters by means of neural grafts may elucidate the nature of seizure-suppressant control of subcortical afferents.

194.13

THE IMPORTANCE OF CORTICOFUGAL CONNECTIONS IN THE DEVELOPMENT OF SEIZURE-DAMAGE AS EVALUATED BY CO-GRAFTS OF SUBSTANTIA NIGRA AND CEREBRAL CORTEX IN OCULO. M Ingvar°, M Eriksdotter-Nilsson°, L Olson (SPON: O. Johansson). Dept Histology and Neurobiology, Karolinska Institute 104 01 Stockholm

Sustained experimental seizure activity causes cell-necrosis in the substantia nigra pars reticulata (SNPR) in the rat. We have shown that depriving the substantia nigra (SN) of its input from the frontal cortex prior to the seizures diminishes the tissue necrosis in the SNPR. We transplanted fetal rat neuronal tissue from either SN-area alone or in combination with frontal cortex to the anterior chamber of the eye in adult rats. After allowing the grafts to mature for 3-5 months the host rats were subjected to 60 min of status epilepticus (controlled ventilation) and allowed to recover for one week. In all animals subjected to seizures, the expected necrosis in the SNPR was seen in situ. In animals with single intraocular transplants of SN the exposure to seizure activity did not affect the transplants as evaluated by immunohistochemistry of glial fibrillary acidic protein (GFA, a marker for astrocytes) and laminin (a marker for blood vessels). In co-transplants the seizure activity caused a total loss of GFA immunofluorescence within a circumscribed area in the nigral portion of the double grafts, while the cortical portion was unaffected. This change was identical to the findings in situ. The corticofugal fibers to the SNPR contain glutamatergic fibers. This study provides further evidence for the importance of glutamatergic input to the SNPR for the development of a necrosis in the SNPR.

GENETIC MODELS I

195.1

ADRENAL CHROMAFFIN TUMORS IN TRANSGENIC MICE. E.E. Baetge, R.R. Behringer*, A. Messing, A. Sved, R.L. Brinster* and R.D. Palmiter*. HHMI Univ. of Wash. Seattle, WA.; Sch. of Vet. Med. Univ. of Wisc. Madison, WI.; Dept. Behav. Neurosci., Univ. of Pittsburgh, Pittsburgh, PA.; Lab. of Reproductive Phys., Univ. of Penn., Philadelphia, PA.

The human gene for phenylethanolamine N-methyltransferase (hPNMT), responsible for the biosynthesis of epinephrine from norepinephrine has been isolated and the complete nucleotide sequence determined. Transgenic mice containing the hPNMT gene resulted in expression of hPNMT mRNA in adrenal gland (Baetge et al. Proc. Natl. Acad. Sci. USA. Vol. 85, No. 11 (June 1988). Transgenic mice expressing a chimeric gene consisting of 2 kb of the hPNMT 5' flanking region fused to the SV40 early region resulted in T-antigen (T-Ag) protein and mRNA expression in adrenals. By 6-8 wks. of age, the adrenals had become enlarged but maintained normal cortical/medullary structure. By 10-12 wks. of age adrenals had grown 200-500 fold, and cortical cells were no longer apparent. Plasma catecholamine levels in control and transgenic animals were similar up to 10 wks. of age at which time dopamine and norepinephrine levels in the transgenic animals increased approximately 10 fold. Blood pressure was normal through 9 wks., but by 10-12 wks. blood pressure increased 68% in the transgenic animals. These animal lines transmit this phenotype in a dominant manner and may serve as a model system for the study of pheochromocytoma in mice.

195.2

DERIVATION OF NEURONAL CELL LINES FROM RETINAL AND ADRENAL TUMORS IN PNMT-SV40 TRANSGENIC MICE. J.P. Hammang, R.R. Behringer*, E.E. Baetge, R.D. Palmiter*, R.L. Brinster*, and A. Messing. Sch. Vet. Med, Univ. Wisc., Madison, WI 53706, Sch. Vet. Med., Univ. Penn., Phila., PA 19104, H.H.M.I., Univ. Wash., Seattle, WA 98195.

A hybrid gene containing 5' flanking sequences from the human phenylethanolamine N-methyltransferase (PNMT) gene fused to the SV40 early region was used to target oncogene expression to epinephrine-synthesizing cells in transgenic mice. We developed three lines of mice carrying the PNMT-SV transgene that express SV40 T-antigen in adrenal medulla and retina. In all three lines, bilateral adrenal pheochromocytomas develop in 100% of the mice by 10-12 weeks of age. A variable percentage of mice in each line also develops retinal tumors. The retinal tumors arise in the inner nuclear layer of the peripheral retina. Ultrastructural examination revealed numerous neurosecretory dense core vesicles in the adrenal medullary tumor cells, but no secretory vesicles or membrane specializations in the retinal tumor cells. Tissue cultures were established from both adrenal and retinal tumors; T-antigen-expressing retinal cells developed a neuronal-like morphology with small cell bodies (10-15 μm diameters) and long neuritic processes. Both adrenal and retinal cultures have now been growing for over 6 passages and T-antigen positive cells continue to proliferate. Clonal cell lines are currently being developed from each tumor. These cell lines may be useful for comparative studies on catecholamine biosynthesis and regulation of PNMT gene expression in neuroendocrine and CNS-derived cells.

195.3

MYELINATION DEFECTS ASSOCIATED WITH EXPRESSION OF SV40 T-ANTIGEN IN SCHWANN CELLS AND OLIGODENDROCYTES OF TRANSGENIC MICE. A. Messing, E.P. Sandgren*, D. Paulson*, R.L. Brinster*, and R.D. Palmiter*. Sch. Vet. Med, Univ. Wisc., Madison, WI 53706, Sch. Vet. Med., Univ. Penn., Phila., PA 19104, H.H.M.I., Univ. Wash., Seattle, WA 98195.

Transgenic mice carrying an SV40-metallothionein growth hormone fusion gene develop a demyelinating-hypomyelinating peripheral neuropathy (Messing et al., Nature, 316:461, 1985). In order to identify the cell types expressing the SV40 T-antigen, we performed immunocytochemical studies. T-antigen was detected in thick sections of nerve by post-embedding staining, and the T-antigen positive cells were identified in serial thin sections by electron microscopy. Sixty-five T-antigen positive cells were evaluated from the sciatic nerves of two transgenic mice: 77% were Schwann cells either associated with myelinated axons, associated with demyelinated or hypomyelinated axons, or free in the endoneurium, while 23% were unidentified or fibroblasts. None of the non-myelinating Schwann cells associated with small diameter axons were T-antigen positive. No T-antigen positive neurons were found in the peripheral or central nervous systems. Expression of T-antigen consistently occured in CNS white matter, where ultrastructural studies showed mild demyelination. We identified the T-antigen positive cells in the CNS as oligodendrocytes by double-immunolabeling for T-antigen and glial fibrillary acidic protein (GFAP) or cyclic nucleotide phosphohydrolase (CNPase). No cells were positive for both T-antigen and GFAP, while many cells were positive for both T-antigen and CNPase. These results show that expression of T-antigen in two myelin-forming cells fails to induce neoplasia but has the similar consequence of hypomyelination or demyelination.

195.4

THE CEREBELLUM IN PURKINJE CELL DEGENERATION* WEAVER (pcd/pcd*wv/wv) DOUBLE MUTANT MICE. B. Ghetti, C.J. Alyea*, L.C. Triarhou, W.C. Low, S.R. Dlouhy* and R.C. Karn*. Depts. of Pathology (Neuropathology), Physiology & Biophysics and Medical Genetics, and Program in Medical Neurobiology, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The aim of this study was to produce pcd/pcd*wv/wv double mutant mice and to analyze their cerebellar cortex. Homozygous pcd females were crossed with wv/+ males. Double carriers (pcd/+*wv/+) were identified in the F1 generation and intercrossed. Five F2 mice, obtained from several litters and aged 19, 27, 36, 74 and 199 days, had a neurological dysfunction that was indistinguishable from the wv condition. Histologically, all of them showed severe gc loss; in addition, the 19, 27 and 36 day-old mice had Pc with a basal polysomal mass, the 27 and 36 day-old animals had numerous Pc clearly undergoing degeneration, and the 74 and 199 day-old mice had only a few cortical macroneurons. Cerebellar slices from the 19 and the 74 day-old mice were processed for immunocytochemistry against 28-kDa Ca-binding protein (CaBP), which is selectively localized to Pc in normal and wv cerebellum, and in pcd before Pc death. The 19 day-old mouse contained CaBP immunoreactive Pc with abnormally oriented dendrites. The cerebellum of the 74 day-old mouse did not contain CaBP immunoreactive cells. These findings suggest that (a) pcd/pcd*wv/wv double mutants are viable and (b) the anatomical phenotype of such mice is an additive expression of the component phenotypes.

THE MAUDSLEY REACTIVE AND NON-REACTIVE STRAINS OF RAT: EVIDENCE FOR POSSIBLE CONTAMINATION IN THE MNR/Har STRAIN. R.L. Commissaris*, G.M. Harrington*, H.J. Altman and H.W. Kunz* (SPON: D.M. Koester). College of Pharmacy & School of Medicine, Wayne State Univ., Detroit, MI 48202, Dept. of Psychology, Univ. Northern Iowa, Cedar Falls, IA and Univ. Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Open field, conditioned suppression of drinking and acoustic startle behaviors were assessed in male and female Maudsley Reactive (MR/Har) and Non-Reactive (MNR/Har, MNRA/Har) rat strains. While MNRA/Har and MR/Har rats exhibited dramatic strain differences in these behaviors, MNR/Har rats behaved more like Reactive than Non-Reactive rats. Histocompatability testing indicated that the MNR/Har strain may have been genetically contaminated. Thus, while comparisons between the MR/Har and MNRA/Har strains remain viable and relatively clear-cut, the usefulness of the MNR/Har strain as an additional resource with which to study behavioral, physiological and genetic determinants of stress and anxiety may have been significantly undermined. These results underscore the importance of continued periodic validation of the integrity of the genetic determinants which underly differences in selectively inbred strains of laboratory animals used for research. (MH #42501-01; protocol conforms with NIH guidelines)

GENETIC AND HORMONAL MODELS OF DEVELOPMENTAL LANGUAGE/READING DISORDERS. P. Tallal, R. Ross* and S. Curtiss*, Dept. of Psychiatry, Univ. CA San Diego, La Jolla, CA 92093.

There is an increased propensity of boys to be afflicted with developmental language disorders and for these disorders to run in families. Family history questionnaires from families of language-impaired (LI) children were analyzed to determine whether data would support any known models of sex-influenced genetic transmission. Results demonstrated that LI children with an affected parent differed from those without an affected parent in sex-ratio among probands and rate of sibling impairment. The expected higher male:female sex-ratio in language-impaired children occurred primarily in families with affected parents. Affected mothers, but not affected fathers, demonstrated this sex-ratio difference among probands as well as a significantly increased frequency of affected offspring compared to non-affected parents. However, results failed to support sex-linkage hypotheses in that male and female probands had equal propensity to have an affected mother or father and also did not differ in rate or sex of affected siblings. An unexpected finding was a significantly altered sex-ratio in siblings of LI children (65 brothers, 35 sisters, ratio = 1.9:1). Analyses demonstrated that, whereas non-affected parents and affected fathers had approximately equal male and female offspring ratios, affected mothers had a 3:1, male:female offspring ratio and a 5:1 ratio of affected offspring. Genetic and hormonal influences that might affect both sex-ratio and neuro-developmental disorders are discussed.

IMPAIRED SPLENIC T-CELL ASSOCIATED RESPONSES IN AN EPILEPSY-PRONE SUBSTRAIN OF BALB/C MICE. Dolina, S.,Tzory, S., Herishanu, Y. and Segal, S., Depts. of Neurology, Microbiology and Immunology, Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva, Israel.

Patients suffering from epilepsy have been recently shown to exhibit various immune disorders. Since conflicting data have been reported and since the possible mechanism underlying these disorders is obscure, it was necessary to test the existence of a possible association between genetical predisposition to epilepsy and immune impairment in a suitable experimental system. For that purpose, we have bred epilepsy-prone substrain (EPS) of Balb/C mice. The animals were selected by their sensitivity to sound-induced convulsions. Immunocytes originating in the spleens of 8-10 week old EPS and appropriate non-EPS control mice (matched for age and sex) were tested for their ability to respond in vitro to T-cell specific polyclonocal mitogens (Con A and PHA) as assessed by the degree of ^{3}H-thymidine incorporation following 72 hrs of incubation in the presence of the appropriate mitogen. The data obtained demonstrate a severe suppression of the mitogenic response in both sexes of EPS, (especially regarding response to PHA), in comparison to control mice. These results strongly suggest the existence of a possible association between genetical predisposition to epilepsy and immune impairment, at least in the T-cell compartment of the murine lymphoid system. These findings may support the long standing hypothesis implicating the CNS as playing a pivotal role in the modulation of the various arms of the immune system.

SENSORY SYSTEMS II

196.1

THE DEVELOPMENT OF ASCENDING SPINAL PATHWAYS IN XENOPUS LAEVIS. H.J.ten Donkelaar, R.de Boer-van Huizen, J.A.M.van der Linden (SPON: European Neuroscience Association). Dept. of Anatomy and Embryology, University of Nijmegen, P.O.Box 9101, 6500 HB Nijmegen, The Netherlands.

The development of ascending spinal pathways has been studied in the clawed toad, Xenopus laevis. From stage 35 (hatching) on HRP was applied at the spinomedullary border. Several populations of spinal neurons with ascending projections at least as far as the spinomedullary border were successively labeled. In early (up to stage 50) ascending spinal projections arise from Rohon-Beard cells and ascending interneuron populations located at the margins of the gray and white matter, i.e. marginal neurons.

Around stage 50 (shorly after the appearance of limb buds) spinal ganglion cells could be labeled from the spinomedullary border. Gradually all spinal ganglia send ipsilaterally ascending afferents to the brain stem. The number of cells of origin of secondary spinal afferents to the brain stem increases during development and their distribution becomes more extensive. A preponderance of contralaterally projecting neurons present during early development, is superseded by the presence of an increasing amount of ipsilaterally projecting spinal neurons, particularly from the dorsal horn. By applying HRP to the dorsal column nuclei, cerebellum, reticular formation, mesencephalon and thalamus, respectively, the development of spinal projections to these structures has been studied.

196.2

EFFECTS OF NEONATAL INFRAORBITAL NERVE SECTION ON TRIGEMINAL BRAINSTEM CELL NUMBER AND DENDRITIC ORIENTATION. T.A. Henderson*, P.D. Kaszubski*, J.A. Yelon* & M.F. Jacquin (SPON: L.C. Massopust). Dept. of Anat. & Neurobiol., St. Louis University School of Medicine, St. Louis MO 63104.

Retrograde tracing and computer-assisted morphometric techniques were used to assess the effects of left infraorbital nerve section at birth upon projection cell # and dendritic polarity in the trigeminal (V) brainstem complex (TBNC) of adult rats. Bilateral HRP injections spanning all of thalamus (N=4), cerebellum (N=4), or upper cervical spinal cord (N=3) labeled significantly fewer cells in left vs right TBNC (ANOVA: $F=18.7$, $df=21$, $p<.01$). In total, the lesion produced 23.0±12.6%, 27.0±8.2%, and 29.7±17.1% fewer labeled V-thalamic, -cerebellar, and -spinal cells, respectively (mean±SD, corrected for split nuclei). Corrected mean # of V-thalamic cells in left vs right subnuclei principalis (P), oralis (O), interpolaris (I) and caudalis (C) were 9956 vs 12838, 1007 vs 1472, 2280 vs 2917, and 362 vs 499, respectively. Mean # of V-cerebellar cells in P,O,I and C were 985 vs 1084, 619 vs 856, 2401 vs 3323, and 95 vs 132. Mean # of V-spinal cells in P,O,I and C were 65 vs 93, 549 vs 770, 286 vs 346, and 263 vs 364. Dendritic tree centers for each projection group were, on average, in the region of somata, and therefore did not differ from normal. Thus, neonatal denervation results in fewer TBNC projection cells, yet the dendrites of surviving cells are not polarized toward regions of spared mandibular or ophthalmic primary afferent inputs. Support: NIH DE07662, DE07734; AOA.

196.3

CERVICAL RECEPTIVE FIELD SUBSTRATE IN TRIGEMINAL BRAINSTEM CELLS DEAFFERENTED AT BIRTH. W. Anzilotti*, N.L. Chiaia, R.W. Rhoades & M.F. Jacquin (SPON: E.R. Shuter). Dept. Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104 & Dept. Anat., Med. Coll. Ohio, Toledo, OH 43699.

In adult rats with infraorbital nerve section at birth, 519 cells were functionally characterized in trigeminal (V) subnucleus interpolaris (SpVi). Of these, 41 (7.9%) had receptive fields (RF) which included V surfaces and ipsilateral areas innervated by cervical primary afferents (ear, neck, arm, forepaw). Such non-V convergence was never seen in 373 normal cells or in 641 V ganglion cells ipsilateral to the lesion. These atypical RF's must therefore reflect post-synaptic reorganization. Anatomical experiments were carried out to assess possible anatomical substrates. 8 cells with cervical RF's were stained with HRP. Although all had dendrites which were unusually polarized towards SpVi regions containing spared mandibular and/or ophthalmic primary afferents, none had dendrites which extended out of SpVi. Bulk HRP injections into deafferented SpVi (N=5) labeled cells in appropriate regions of cortex, as well as 46±20 cells in ipsilateral C1-3 dorsal root ganglia, and 24±8 cells in C4-8 ganglia. In 3 controls, labeled cells occurred only in C1-3 ganglia (32±9). Bulk HRP injections into lower cervical spinal cord produced weak anterograde labeling in deafferented SpVi, but not in normal SpVi. These data indicate that cervical primary afferent sprouting into SpVi may account for cervical RF's in deafferented SpVi. Support: NIH DE07662, DE07734, NSF BNS8515737.

FETAL VISUAL CORTEX TRANSPLANTED TO SOMATOSENSORY REGION OF NEWBORN RATS DEVELOPS BARREL-LIKE FEATURES. B.L. Schlaggar and D.D.M. O'Leary (Spon: S.Goldring), Dept of Neurosurgery & McDonnell Ctr for Studies of Higher Brain Function, Washington Univ Sch Med, St. Louis, MO 63110

"Barrels" are aggregations of granule cells and thalamic afferents characteristic of the primary somatosensory region of parietal cortex of rodents. To determine if the potential to form barrels is unique to parietal cortex, or if other "granular" cortices share in this ability, we have assayed for the presence of barrels in transplants of occipital cortex to the barrel field of rats. Donor fetuses, exposed to ^{3}H-thymidine in utero on E15, had a piece of occipital cortex removed at E18 and placed in a cavity aspirated in the prospective barrel field region of newborns. The host rats were perfused on P12 and brain sections processed for AChE histochemistry which reveals barrel formations in normal cortex (Robertson, 1987, NSL 75:259). The transplants, delineated from Nissl-stained autoradiograms of adjacent sections, develop barrel-like morphologies resembling those seen in normal parietal cortex, although the overall patterns are not identical. We are investigating whether the abnormal pattern is due to disruptions resulting from transplantation, or to inherent differences between occipital and parietal cortex. These results suggest, though, that the ability to develop barrels is not a property exclusive to parietal cortex. (D.O'L. is a McKnight Scholar and a Sloan Fellow.)

A QUANTITATIVE ANALYSIS OF THE EFFECTS OF NEONATAL INFRAORBITAL NERVE TRANSECTION ON TRIGEMINAL PRIMARY AFFERENTS. W.Renehan, R.Rhoades and M.Jacquin. University of Louisville, UMDNJ and St. Louis University

The present report represents a quantitative analysis of 28 individually labeled primary afferents in trigeminal subnucleus interpolaris of rats subjected to neonatal transection of the infraorbital nerve. Data obtained to date suggest that this lesion results in a decrease in the number of boutons/collateral and bouton density for axons reinnervating mystacial vibrissae as well as a decrease in the circularity of mystacial guard hair terminal arbors (pertinent numbers in boldface type below; p<.01, t test).

FUNCTIONAL CONSEQUENCES OF NEONATAL DEAFFERENTATION IN RAT TRIGEMINAL SUBNUCLEUS INTERPOLARIS. M.F. Jacquin. Dept. of Anat. & Neurobiol., St. Louis Univ. Sch. Med., MO 63104.

Single unit recording, electrical stimulation, and receptive field (RF) mapping techniques were used to assess the responses of cells in interpolaris after infraorbital nerve section at birth. Of 904 cells, 385 were from normal adults, 519 were from neonatally lesioned adults. Deafferentation produced 1) A reduction in areas containing cells with infraorbital RF's, and only a minor increase in areas solely responsive to non-infraorbital surfaces. 2) An absence of topography within cells expressing regenerate inputs. 3) A slight increase in mean discharge latency to V ganglion or thalamic shocks. 4) An increased % of cells orthodromically activated by diencephalic or cerebellar shocks. 5) A decreased % of vibrissa local circuit cells, with increased %'s of local circuit nociceptors and non-responsive cells. 6) An increased % of nociceptors, vibrissae, guard hair and/or skin sensitive cells projecting to thalamus and/or cerebellum. 7) An increased % of local circuit cells responsive to >1 whisker, whereas projection cells did not differ from normal in the # of whiskers in their RF. 8) An increased % of cells expressing interdivisional and intermodality convergence, split RF's, spontaneous activity, directional, high velocity and neuroma sensitivity. Although many of these effects can be attributed to altered peripheral projections of axotomized primary afferents, others must reflect central reorganization. 196.7

DISTRIBUTION OF SKIN AFFERENTS IN THE SPINAL CORD AND BRAIN STEM AFTER NERVE SECTION AND REGENERATION: RELATION TO CORTICAL MAPS. S.L. Florence, J.T. Wall, P.E. Garraghty, and J.H. Kaas. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

We compared the fidelity of regeneration of a cut and repaired median nerve to the cortical map of the hand in the same adult macaque monkey (Macaca fascicularis). In normal macaque monkeys, transganglionic transport of an injected tracer from the glabrous skin of a single digit demonstrates discrete and orderly zones of terminations in the spinal cord and cuneate nucleus. For example, in the spinal cord, afferents from D1 normally terminate at C5 and span half a spinal cord segment. In contrast, an injection into digit 1 of a monkey one year after median nerve repair resulted in labeled terminals extending from C4 - C6.5 in regions of the dorsal horn of the spinal cord normally representing skin between the radial forearm and digits 1 - 3. Labeled afferents also distributed over a wider than normal portion of the cuneate nucleus. Thus, many afferents in the cut nerve incorrectly regenerated into the thumb. A detailed microelectrode map of the representation of the hand in the primary somatosensory cortex (area 3b) of the same animal revealed an abnormal organization that included: (1) representations of digits 1 - 3 that were abnormally distributed in the hand map with apparent discontinuities, and (2) recording sites with large or multiple receptive fields. The results indicate that disorderly reinnervation can follow nerve section and repair. While some aspects of the altered cortical map of the hand clearly relate to the peripheral disorder, other aspects may reflect central reorganization.

196.8

ONTOGENY OF AUDITORY BRAINSTEM EVOKED POTENTIALS IN THE MONGOLIAN GERBIL: STIMULUS RATE EFFECTS. N.K. Woolf, H. Gompers-Foster*, and A.F. Ryan. Dept. of Surgery/Otolaryngology, UCSD School of Medicine and VA Medical Center, La Jolla, CA 92093.

The effect of varying stimulus repetition rate on auditory brainstem evoked potential responses (ABR) of mongolian gerbils (*Meriones unguiculutus*) was investigated at 10, 12, 14, 16, 18, 30 and 45-60 days after birth (DAB). This age range included the onset of neonatal hearing through the attainment of mature auditory system characteristics. Developmental trends for ABR, auditory nerve compound action potentials and auditory nerve single unit responses were computed and compared to those for adults.

Click evoked ABR was first observed at 12 DAB, with thresholds exceeding 110 dB SPL (peak). Only 18% of the subjects exhibited ABR at this age and ABR was limited to Peaks I and IV at this time. Between 12 and 30 DAB, ABR thresholds declined approximately 100 dB. Adult threshold, latency, amplitude, waveform morphology and interpeak relationships for the five ABR peaks were not achieved until 30 DAB.

Developmentally, ABR rate adaptation was most pronounced in the youngest subjects. ABR was abolished at 40 clicks per second in neonatal gerbils. For animals 18 DAB or younger, ABR Peak I amplitude declined slower than Peak IV amplitude with increasing stimulus rate. For subjects 30 DAB or older, ABR Peak I amplitude declined faster than Peak IV amplitude with increasing stimulus rate.

The data indicate that the generators of the ABR peaks matured in a hierarchical order, with the peripheral regions of the auditory system reaching maturity before those in the more central regions.

DEVELOPMENT OF THE BARREL PATTERN IN EARLY POSTNATAL MOUSE SOMATOSENSORY CORTEX AS REVEALED BY THE DISTRIBUTION OF MAP2 IMMUNOREACTIVE DENDRITES AND RC2-LABELED RADIAL GLIA. J.E. Crandall, D. Butler and J.P. Misson. Dept. of Developmental Neurobiology, E.K. Shriver Ctr., 200 Trapelo Rd., Waltham, MA 02254

It has been previously reported that certain lectins can reveal a barrel pattern in mouse somatosensory cortex prior to the development of Nissl-stained cells into the characteristic pattern of cell-dense sides and cell-poor hollows (Cooper and Steindler, J. Comp. Neurol. 1986, 249:157). We have investigated the development of two other components of the maturing neuropil, dendrites and radial glia, using monoclonal antibodies selective for each. We have combined immunocytochemical labeling for MAP2 and the antigen detected by RC2 (Misson et al., Neurosci. Abst. 1987, 13:1465) in the same section to discern the relative role of dendrites and glia in early barrel formation. Both dendrites and radial glia appear to be asymmetrically distributed in a barrel-like fashion by postnatal day 4 (P4; the day of birth = P0). There is a higher density of dendrites and radial glia in the barrel walls compared to barrel centers. Thus, during a similar time period in which the distinctive cell pattern of the barrel cortex forms, radially oriented dendrites and radial glia likewise appear to become similarly organized. This arrangement continues to become more distinctive by the end of the first postnatal week. The age at which these distinctive constellations of radial glia and dendrites first emerges remains under investigation.

196.10

DIETARY DETERMINANTS OF RESPONSES FROM REGENERATED TASTE NERVES. David L. Hill. Dept. Psychology, Univ. Virginia, Charlottesville, VA 22903.

Important determinants of functional responses seem to occur as the first generation of taste receptors form in rat (16 days gestation). The following study was designed to mimic the developmental events by exploiting the trophic influence of taste nerves on receptors. Adult rats had the left chorda tympani/lingual nerves surgically cut; the right nerves remained intact. Rats were then placed on a low-salt diet of 0.03% NaCl for the duration of the experiment. Control rats underwent the same surgical and dietary procedure with the exception of nerve sectioning. When neural recordings were begun 120 days following surgery, taste responses to concentration series of NaCl and sodium acetate from the regenerated nerve was approximately 50-60% of that obtained from nerves in control rats, suggesting that responses from newly-formed receptors are abnormal. Responses to NH_4Cl were similar between regenerated nerves and those in control rats. Surprisingly, responses from the right chorda tympani nerve (uncut nerve) were similar to the abnormal regenerated nerve and not like those in control rats. Thus, functional responses from regenerated and intact nerves were attenuated. It is possible that the intact nerve invaded territory originally occupied by the cut nerve, thereby innervating receptors less sensitive to sodium. Current research seeks to characterize such morphological correlates. (Supported by NIH NS24741 & NS01215).

NEURAL PLASTICITY IN ADULT ANIMALS: INDUCED EFFECTS I

197.1

MECHANISMS UNDERLYING SEIZURE-ELICITED ODC INDUCTION IN ADULT RAT HIPPOCAMPUS. Amy Arai*, Kavian Shahi*, Gary Lynch, Michel Baudry and Christine Gall† (SPON: M. Kessler). Center for the Neurobiology of Learning and Memory, and †Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717.

Recurrent limbic seizures result in the rapid induction of ornithine decarboxylase (ODC), the rate-limiting enzyme in polyamine biosynthesis, as well as alterations in the synthesis of several neuroactive peptides in rat hippocampus. In the present study, we examined the involvement of specific neurotransmitter or neuromodulator systems in the seizure-induction of hippocampal ODC.

A small unilateral electrolytic lesion was placed in the dentate gyrus hilus of all experimental rats; this treatment induces bilateral limbic seizures which recur over the period from 1.5 to 10 hrs postlesion. Three groups of hilus lesion (HL) rats were prepared that received either the opiate antagonist naltrexone (2 mg/kg; i.p. every 3 hrs starting at the time of the lesion), the NMDA antagonist D,L-aminophosphoheptanoic acid (AP-7) (75 mg/kg, i.p.), or saline (i.p.). ODC activity was measured in hippocampus and other brain regions at 8 hrs postlesion. In saline injected animals, the HL produced about a 120-fold increase in ODC activity in hippocampus as compared to untreated controls. Repeated administration of naltrexone did not modify the increase in ODC activity elicited by HL. In contrast, AP-7 injection markedly reduced the HL-induced increase in ODC activity.

These results indicate that while opiate receptor stimulation is not critically involved in the seizure-dependent increase in ODC activity, the activation of NMDA receptors might be a necessary step for either this effect or possibly for full seizure expression. Studies with other NMDA receptor antagonists are now in progress to further evaluate this conclusion.

197.2

REGIONAL ANALYSIS OF GENE EXPRESSION IN AMYGDALA-KINDLED RATS. K. Spanknebel*, L. Dawes, C. Applegate, C-A Ohmstede*, N. Sahyoun, R. Neve. The Children's Hospital, Boston, MA 02115; Wellcome Research Laboratories, Research Triangle Park, NC 27709. (SPON: F. Duffy)

Quantitative analysis of RNA from regions of amygdala-kindled rat brains with a variety of cDNA probes provides a means of identifying both the anatomical sites and the molecular basis of the response to kindling. Total RNA was isolated from neocortex, hippocampus, striatum, brainstem and cerebellum of rats each receiving one of four treatments: (1) naive control, (2) seizure induced in a naive animal, (3) amygdala-kindled, or (4) seizure induced in an amygdala-kindled animal. The RNAs were analyzed by Northern and dot blots with cDNA probes for calcium/calmodulin dependent kinase II, G3PD, v-fos, sodium ATPase, GAP-43, GAD, MAP2 and the Alzheimer amyloid precursor. In both kindled and naive animals with recent seizure activity, RNA levels for most genes were elevated compared to naive or kindled animals. This elevation was more pronounced in naive animals induced to seizure; and this pattern was seen in all regions examined but hippocampus. In the hippocampus, expression of all RNAs analyzed was equivalent for all treatments except for that of seizure induced in a kindled animal, in which expression of all genes tested, except for fos, amyloid and G3PD, was reduced several-fold. In situ hybridization will be used to define more precisely the changes in gene expression that we observed.

197.3

RAPID INCREASE IN 4 TRANSCRIPTION FACTOR mRNAs FOLLOWING SEIZURES: TEMPORAL AND ANATOMICAL CHARACTERIZATION. D.W. Saffen*, A.J. Cole, P.F. Worley, B.A. Christy*, K. Ryder* and J.M. Baraban. Depts. of Neuroscience and Molecular Biology, Johns Hopkins Univ., Balto., MD 21205

Transcription factors (TF) are proteins that bind to DNA and regulate gene transcription. mRNA levels for 4 putative TF genes, zif/268, c-jun, jun-B and c-fos increase rapidly in rat brain following pentylenetetrazole (PTZ)- or picrotoxin-induced seizures, becoming maximal by 60- and returning to baseline by 120 minutes after seizures. In situ hybridization shows that mRNA increases are localized to specific neuronal layers in dentate gyrus and entorhinal cortex. By contrast, apomorphine, a dopamine agonist, and p-chloroamphetamine, a serotonin releasing agent cause no detectable changes in mRNA levels in any brain region. Zif/268 encodes a protein with three zinc finger sequences characteristic of a class of TFs. c-Jun encodes the mammalian TF AP-1; jun-B shows extensive homology with c-jun. v-Fos protein stimulates transcription in vivo, and c-fos protein interacts with AP-1. Our observations extend those of Morgan et al. (Science 237:192, 1987) that c-fos mRNA and protein are induced in rat brain following PTZ seizures. TF gene mRNA increases following seizures suggests that specific neuronal populations manifest a complex, highly regulated genomic response to intense stimulation.

197.4

ACTIVATION OF NMDA RECEPTORS INDUCES PROTEOLYSIS OF SPECTRIN IN HIPPOCAMPUS. P. Seubert*, J. Larson*, M. Oliver*, M.W. Jung*, M. Baudry and G. Lynch (SPON: D. Arst). Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

Activation of N-methyl-D-aspartate (NMDA) receptors has been implicated both in the induction of synaptic plasticity and the development of certain neuropathologies. Although the calcium conductance associated with NMDA receptor activation is thought to be crucial to its function, the biochemical events triggered by this calcium flux remain controversial. We have suggested that such calcium influxes are capable of initiating proteolytic events which alter cytoskeletal proteins and thus neuronal structure and function.

To examine this hypothesis directly we have exposed hippocampal slices to NMDA and examined the calcium dependent proteolysis of brain spectrin, a major cytoskeletal protein found in neuronal processes including synaptic regions. Exposure of hippocampal slices to ~50 μM NMDA resulted in the reversible loss of synaptic responses and caused a marked increase in the amount of a 150 kDa spectrin breakdown product (BDP) detected on immunoblots. Fifteen minutes after NMDA application, BDP levels were increased 84% ± 21 (mean ± S.E.M.) over levels prior to treatment, while control slices showed only a 16% ± 13 increase. The inclusion of 200 μM 2-amino-5-phosphonovalerate (AP5) prior to NMDA addition resulted in BDP increase of only 28% ± 12. Depolarization induced by the addition of 50 mM KCl caused only a 17% ± 6 increase. NMDA added to slices maintained in calcium-free medium caused the loss of antidromic responses but no increase in BDP. Thus, the effect is blocked by an NMDA antagonist, not reproduced by KCl depolarization and dependent upon extracellular calcium. The demonstration of NMDA receptor activation coupled to irreversible cytoskeletal alterations supports the hypothesis that this mechanism functions in the biological processes linked to this receptor.

197.5

FUNCTIONAL CHOLINERGIC SUPERSENSITIVITY IN DENERVATED HIPPOCAMPAL PYRAMIDAL NEURONS. D.M. Benson, E.M. Landau, V. Haroutunian and R. Blitzer. Dept. of Psychiatry, Bronx VA Med. Cntr., Bronx, N.Y. 10468.

Acetylcholine excites hippocampal pyramidal cells, causing depolarization and increases in firing rates. The major source of cholinergic input to the hippocampus is from the medial septal nucleus, via the fimbria-fornix (F-F) pathway. We compared the effects of carbachol (CCh), a cholinergic agonist, on normal and denervated hippocampal pyramidal neurons in vitro. Hippocampal slices were prepared from normal adult rats and from rats 3-6 wks following aspirative lesions of the F-F. Slices were superfused with oxygenated artificial CSF at room temperature, and voltage-clamp recordings obtained from CA_1 neurons. CCh (0.5 to 5μM) induced a dose-dependent inward current in all cells tested, which was easily reversible upon washout of the drug. This CCh-induced current was considerably larger in the denervated (n=20) than in the control (n=22) condition, increasing by 105 ± 37%. The differences between the CCh effect on control and denervated cells was significant ($p<.05$) at all doses tested. The apparent K_D for CCh shifted from 2.1μM in control to 0.9 μM in denervated cells. Furthermore, the effect of CCh on the K^+ current, I_{AHP}, was greater in denervated than control cells. CCh (0.5μM) reduced I_{AHP} by 70±6% (n=7) in control but completely reversed the current in all denervated cells tested (n=6). All slices from F-F lesioned rats showed markedly decreased acetylcholinesterase staining compared to controls. Thus, there appears to be a functional supersensitivity to CCh in the denervated hippocampus. Since reports of alterations in receptor numbers following denervation have been inconsistent, this increased sensitivity may involve enhanced coupling, possibly mediated through G-protein activation. (Supported by NIH-NIA Grant #5P50AG05138.)

DEPOLARIZATION BLOCKADE IN NORMAL AND DENERVATED HIPPOCAMPUS INDUCED BY CHOLINERGIC RECEPTOR ACTIVATION. G. Omri, D. M.Benson, R.D. Blitzer and E.M. Landau. (SPON. E. Heyer). Depts. of Psychiatry and Pharmacology, Mt. Sinai School of Medicine and the Bronx VA Medical Center, New York, NY.

The effect of carbachol (CCh) on neuronal firing was investigated intra-cellularly in hippocampal slices. CCh (20 to 25 uM) depolarized the cells and produced a cessation of neuronal firing. During the depolarization phase, slow calcium spikes were often observed. Similar spikes were also seen when CCh was applied in 0.5 uM of tetrodotoxin. The depolarization blockade could be relieved by applying 100 uM of clonidine which repolarized the cells. When firing was induced with depolarizing current pulses the concentration of CCh leading to blockade of firing was much reduced (0.5 uM) as was the concentration of clonidine offering relief from it (1 uM). In rats where the hippocampus was denervated by sectioning the fimbria-fornix, the threshold for depolarization blockade fell dramatically, CCh as low as 0.5 uM causing the cessation of neuronal firing. These findings suggest that depolarization blockade induced by cholinergic agents may play a major role in determining their pharmacological response, especially in the presence of cholinergic denervation.

Novelty Stress Inhibits the Induction of PB Potentiation in the Hippocampus of Awake Rats. D.M. Diamond, M.C. Bennett and G.M. Rose. VAMC and Dept. of Pharmacology, UCHSC, Denver, CO.

In previous work, we demonstrated that electrical stimulation patterned to mimic hippocampal physiological activity reduces the threshold for LTP *in vitro* and *in vivo* (Neurosci. Lett., *69:244*, 1986; J. Neuroscience, in press). This effect, termed primed burst (PB) potentiation, requires only 5 pulses to be induced. In the present study, we analyzed the role of novelty stress as an inhibitor of PB potentiation in the awake rat.

The major finding is that PB potentiation rarely occurred when the subjects were naive to the recording procedures. Over repeated sessions, the incidence of PB potentiation increased to 100% as the animals acclimated to the procedures. Two additional groups were tested to determine whether this effect was specific to acclimation or it resulted from a kindling-like reduction in threshold. In one group, rats were acclimated to the recording procedures without receiving electrical stimulation. PB stimulation then induced potentiation on the first attempt. In a second group, naive rats were stimulated 3 times in their first recording session. PB potentiation did not occur in any of these rats. *Thus, a critical precondition to inducing PB potentiation is acclimation to the environment.* To study the hormonal basis of the effect, naive rats were adrenalectomized and then stimulated. All of these animals showed PB potentiation in the first attempt. These data suggest that adrenal hormones released during novelty stress exert an inhibitory influence on the induction of synaptic plasticity.

EARLY AND SELECTIVE STRESS-INDUCED CHANGES IN SPECIFIC FOREBRAIN PROTEINS. G. Shanker, V. H. Gilad and G.M. Gilad. Dept. of Neurobiology, Coriell Inst. for Med. Res., Camden, NJ, USA.

We sought to identify specific stress-induced changes in proteins of selective forebrain regions. Rats were subjected to immobilization stress and subcellular fractions, prepared from the hippocampus and frontal cortex, were studied by two dimensional gel electrophoresis. Selective prominent changes occurred after 2 hrs of stress: 1) a protein with a molecular weight of 59,000 (59K) was increased in the soluble fraction but decreased in the synaptosomal fraction, only in the hippocampus. The amount of this protein was higher in an inbred rat strain that is hyper-reactive to stress: 2) a drastic decrease in two 63K proteins differing in pI values, was observed in the soluble fraction of the hippocampus, and 3) a 79K protein increased prominently only in the nuclear fraction of hippocampus where it was enriched, and a 68K protein was decreased in nuclei of both hippocampus and frontal cortex. We conclude that rapid and region-selective changes in brain protein metabolism can be induced by acute application of strong stressors. We now seek to examine whether the magnitude and duration of changes in these proteins may reflect a plastic compensatory metabolic response that may be related to the severity of the stress.

REGULATION OF CCK AND NPY IMMUNOREACTIVITY WITHIN THE ADULT RAT OLFACTORY BULB BY PRIMARY AFFERENT INPUT. I.A. Scarisbrick* and C.M. Gall (Spon: M. Nieto-Sampedro). Dept. of Anatomy and Neurobiology, University of California, Irvine, C.A. 92717.

Previous investigations have demonstrated that tyrosine hydroxylase immunoreactivity (TH-I) within olfactory bulb periglomerular and tufted neurons is reduced following olfactory nerve ablation or odor deprivation. The present study addresses the question of whether the regulation of CCK immunoreactivity (CCK-I) within periglomerular and middle tufted neurons, which appear distinct from those containing TH-I, and NPY immunoreactivity (NPY-I) within large neurons and axonal arbors in the deep granule cell layer (GR), are similarly dependent upon primary sensory input.

The avidin-biotin immunocytochemical technique was used to examine CCK-I, TH-I and NPY-I in the main olfactory bulb of adult male Sprague Dawley rats. Animals were sacrificed 3 weeks after unilateral deafferentation by reversible chemical (1.5% Triton X-100) nasal epithelial lesion or following olfactory nerve transection and removal. In a third group, primary sensory input was reduced without afferent degeneration by unilateral nares closure. In each experimental group, CCK-I and TH-I were dramatically reduced within the ipsilateral olfactory bulb while NPY-I appeared normal. There was a dramatic reduction in the number of CCK-I neurons in both the external plexiform and glomerular layers (GL) and a striking loss of CCK-I within processes extending into the GL. In addition, there was a complete loss of CCK-I puncta within the internal plexiform layer. The density of CCK-I elements within the granule cell layer was unaffected. As reported by others, TH-I was absent or greatly reduced within periglomerular and tufted cells following a complete first nerve lesion or odor deprivation.

These findings are consistent with the concept that the regulation of CCK within olfactory bulb periglomerular and middle tufted neurons is dependent on sensory afferent activity whereas that of NPY is not. Studies are currently in progress to determine whether the loss of CCK-I following Trition X-100 is reversible upon olfactory bulb reinnervation and to determine if neuropeptide levels are being regulated at the level of genomic transcription.

SPINAL AFFERENTS REGULATE THE EXPRESSION OF MOLECULES IN SPINAL CORD CELLS. E. Paige,* P. Levitt, M. E. Goldberger. (SPON: E.H. Murphy). Medical College of Pennsylvania. Phila. PA, 19129.

Unilateral deafferentation (dorsal rhizotomy L1-S2) results in a change in input to lamina II and Clarke's nucleus (CN) due to reactive reinnervation. Although there is no net change in terminal number, behavioral impairments occur, some of which are persistent and might be related to post-synaptic changes as well as altered input. Two markers were used to study post-synaptic effects of unilateral deafferentation of cat spinal cord from 12 days to 3 months post-operatively. LAMP (limbic system associated membrane protein) is a cell-surface glycoprotein which, in the spinal cord, is located only postsynaptically, (i.e. on dendrites and somata) on neurons in lamina II and the IML; cytochrome oxidase (CO) is located both pre- and post-synaptically, and not restricted to specific laminae or nuclei in the spinal cord. After chronic deafferentation LAMP is substantially reduced in lamina II but not in the IML; CO is reduced in lamina II, in the large cells of CN (as well as in the neuropil) and in the IML. In contrast, after chronic hemisection at T13, LAMP is depleted in the IML but unchanged in lamina II and CO is not consistently changed. In Clarke's nucleus, decreases in CO were seen first in the neuropil and later in the large neurons. Changes in LAMP immunoreactivity, seen at 12 days, were moderate but became more dramatic through the 3 month post-operative period. Thus levels of production and\or activity of certain cell-surface and metabolic proteins are regulated by specific afferent inputs or patterns of neuronal activity that depend on those inputs.

DISTRIBUTION OF NEUROFILAMENT ANTIGENS FOLLOWING INTRARETINAL LESION IN ADULT HAMSTERS. K.E. Sloan * and J.A. Stevenson. Dept. of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Perikarya of axotomized peripheral neurons accumulate phosphorylated (P) epitopes of neurofilament proteins (NFP) with no apparent increase in the nonphosphorylated epitopes (Rosenfeld et al., J. Neuropathol Exp Neurol 46:269). As axons regenerate, the number of cells containing P-NFP declines. Although somata of retinal ganglion cells (RGCs) also accumulate P- epitopes following a lesion of the optic nerve or tract (Drager and Hofbauer, Nature 309:624), it is unclear whether there is a change in the distribution of NP- epitopes. In addition, it is unknown how the transient and limited regrowth of RGC axons, known to take place within the retina (Goldberg and Frank, Exp Neurol 70:675), affects the NFP content within perikarya. To further characterize the changes in neurofilament content following axotomy, antibodies against P or NP epitopes were used to examine components of RGCs 1-28 days following an intraretinal lesion. At 4-7 days, chromatolytic somata peripheral to the lesion demonstrated increased reactivity to antibodies against NP-NFP with no comparable increase in P-NFP immunoreactivity. Effects of longer survival times are being examined to determine when P epitopes appear and whether the distribution patterns change if axons begin regrowth.

INDUCTION OF NEUROFILAMENT PHOSPHORYLATION IN BOVINE CHROMAFFIN CELLS. N.J. Grant* & B. Demeneix* (SPON : K. Takeda), Centre de Neurochimie & Inst. Physiologie Générale, Univ. Louis Pasteur, 67084 Strasbourg, France

Chromaffin cells from the adrenal medulla can be induced to transdifferentiate from an endocrine to a neuronal phenotype in culture. We have recently described the induction of neurite outgrowth in bovine chromaffin cells by hypophyseal intermediate lobe (IL) cells (FEBS Lett. 226, 337, 1988). In this study, the expression of neurofilaments (NFs) was examined in order to evaluate the neuronal nature of the phenotype displayed by cultured chromaffin cells. Immunofluorescent studies were done using monoclonal antibodies against nonphosphorylated (np) or phosphorylated (p) epitopes of the 200kD NF subunit. Under standard culture conditions, most chromaffin cells did not display a neuronal phenotype and did not express pNFs. However, npNFs were detected in the cell bodies. In contrast, when chromaffin cells were maintained in IL-conditioned medium for 10 days, the npNF form was also observed in neurites of about 25% of the cells with extensions, but there was little or no immunoreactivity for pNFs. By 17 days in conditioned medium, over 50% of the cells with neurites had extensions showing immunoreactivity for both pNFs and npNFs. The pNFs were restricted to neurites. The results suggest that certain soluble factors released by IL-cells can cause chromaffin cells to develop a more typical mature neuronal phenotype as judged by the appearance and phosphorylation of NFs in neuronal processes.

SYNAPTIC PLASTICITY IN THE MATURE CNS INVOLVES INCREASED LEVELS OF GAP-43. L.I. Benowitz, W.R. Rodriguez, W.F. White and R.L. Neve. Depts. of Psychiatry, Neuropathology and Pediatrics, Harvard Medical School; McLean Hospital, Belmont, MA 02178; Children's Hosp., Boston, MA 02115

When the projections to the rat dentate gyrus from the entorhinal cortex are damaged, other neurons sprout axon collaterals and form new functional synapses upon dendritic segments denervated by the lesion (Cotman et al, 1984, Science 225:1287). Using this well-characterized model system, we investigated whether the growth of new synapses in the mature CNS requires an increased expression of the neuron-specific, growth-associated phosphoprotein GAP-43 (equivalent to B-50, F1, pp46, P-57). At times varying from two days to one month after unilateral entorhinal lesions, rats were sacrificed and their brains processed to visualize GAP-43 by immunocytochemistry as described (Benowitz et al, 1988, J. Neurosci. 8:339). As early as two days after surgery, marked increases were seen in the intensity and extent of GAP-43 immunostaining in the segment of the dentate granule cell dendrites in which the projections arising from hippocampal pyramidal neurons are known to be sprouting; this increase persisted for at least a week. Dendritic segments known to receive sprouting septal projections, however, did not show large GAP-43 increases. We are currently using in situ hybridization to determine whether the differences between the sprouting of hippocampal and septal afferents reflect differences in transcription of the GAP-43 gene or changes in turnover at the synapse. **[NS 25830]**

IMMUNOCYTOCHEMICAL LOCALIZATION OF THE GROWTH-ASSOCIATED PROTEIN, GAP-43, IN THE HUMAN CEREBRAL CORTEX. N. I. Perrone-Bizzozero, D. Weiner*, J. Winickoff*, and L.I. Benowitz. Dept. Psychiat., Harvard Med. School, McLean Hospital, Belmont, MA 02178

The presynaptic membrane phosphoprotein, GAP-43, has been implicated in both the development and modulation of neuronal connections. By the use of a monospecific antibody raised against rat GAP-43, we have studied the distribution of the protein in cortical and subcortical areas of the human brain. On Western blots, the antibody reacted with a synaptosomal plasma membrane protein which had a molecular weight and isoelectric point similar to GAP-43 of other species. In postmortem human brain, the densest immunoreactivity was found in associative areas of the neocortex, particularly within layers 1 and 6, in the molecular layer of the dentate gyrus, the caudate-putamen, and the amygdala. In contrast, primary sensory and motor regions of the cortex, portions of dorsal thalamus, and cerebellum showed only light staining. Staining was generally confined to the neuropil, which showed punctate labeling, whereas most neuronal somata and fiber bundles were unreactive. These results are consistent with the distribution of GAP-43 mRNA in the human brain (Neve et al, PNAS 85 [May 1988]) and may reflect regional variations in the potential for functional and/or structural remodeling. FUNCTIONAL SIGNIFICANCE AND LOCALIZATION OF PHOSPHOSITE(S) IN THE NEURON-SPECIFIC PROTEIN B-50/GAP43. L.H. Schrama*, P.N.E. de Graan*, L.V. Dekker*, A.B. Oestreicher*, H. Nielander*, P. Schotman* and W.H. Gispen* (SPON: A.J. Schecter). Div. Mol. Neurobiol., Rudolf Magnus Inst. Pharmacol, Lab. Physiol. Chem., Inst. Molec. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands.

The neuron-specific phosphoprotein B-50/GAP43 is an endogenous substrate of protein kinase C (PKC) in presynaptic terminal membranes. Phosphorylation of purified B-50 by PKC followed by extensive digestion with S. aureus protease V8 (SAP) revealed that all phosphosites are limited to the small neutral 15 kDa peptide. SAP digestion of the full-length cRNA in vitro translation product after labeling with either [^{35}S]-Met or [^{35}S]-Cys yielded a 15 kDa immunoreactive peptide containing all the label incorporated in the undigested protein. This suggests that the phosphosite(s) in B-50 are confined to the N-terminal portion of the molecule. PKC-mediated B-50 phosphorylation was studied by in situ phosphorylation of synaptosomes or hippocampal slices with $^{32}P_i$ followed by quantitative immunoprecipitation. K^+-depolarization induces neurotransmitter release and a concomitant increase in B-50 phosphorylation. Both the release and the increase in B-50 phosphorylation can be inhibited by PKC inhibitors in a dose-dependent manner and by omittance of extracellular Ca^{2+}. The effects of K^+ can be mimicked by Ca^{2+}-ionophore A23187. Our data suggest a role of B-50 phosphorylation in transmitter release.

197.16

REGIONAL DISTRIBUTION OF MAP 2 IN AGING RAT BRAIN. E.M. Grollman* and P.D. Coleman (SPON: I. Shoulson). Department of Neurobiology and Anatomy. University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

When thermostable extracts of fresh mammalian brain are subjected to polyacrylamide gel electrophoresis (PAGE), two high molecular weight bands corresponding to isoforms A and B of microtubule-associated protein 2 (MAP 2) are easily identifiable after Coomassie staining and can readily be quantitated by laser densitometry. Since MAP 2 is a neuron specific molecule, primarily localized to dendrites (Huber and Matus, J. Neurosci. 4:151-60,1984; De Camilli et. al., Neurosci.11:817-46,1984), the amount of MAP 2 present in a given brain region can be taken as a measure of the dendritic compartment in that region.

An issue important to the mammalian CNS is whether dendritic proliferation (or regression) accompanies normal aging. Previous studies on this topic have relied primarily on quantitative morphological analyses to determine changes in dendritic extent with aging in specific neuronal populations. Marked growth in the dendritic tree of olfactory bulb mitral cells of the Sprague-Dawley rat was observed at 27 months of age followed by a precipitous decline (Hinds and McNelly, J. Comp. Neur. 171:345-68,1977). On the other hand, no age related changes in the complexity of the dendritic network was found in either Purkinje cells (Pentney, Neurobiol. Aging 7:241-8,1986) or layer II pyramidal cells of entorhinal cortex (Coleman and Buell, Soc. Neurosci. Abs.,1983) of the F344 rat or in layer IV stellate neurons in the posteromedial barrel subfield of C56Bl/6 mouse somatosensory cortex (Coleman et. al., Neurobiol. Aging 7:101-5,1986).

We have used laser densitometry of Coomassie stained polyacrylamide gels to quantify MAP 2 levels in cerebellum, entorhinal cortex, hippocampus, olfactory bulb, and frontal cortex in the F344 rat at five ages from 3 to 30 months. This technique provides a nonhistologic means of quantitating the dendritic compartment by brain region.

EFFECT OF TESTOSTERONE ON CALCITONIN GENE-RELATED PEPTIDE LIKE IMMUNOREACTIVITY IN THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS. P. Popper and P. E Micevych. Department of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

Changes in the hormonal milieu of an animal induce changes in the molecules expressed by neurons of its central nervous system. The spinal nucleus of the bulbocavernosus (SNB) is a sexually dimorphic nucleus of about 200 androgen accumulating motor neurons in the lumbar segments 5 and 6 of the rat spinal cord. In the present work we have used immunohistochemistry to investigate the change in calcitonin gene-related peptide like immunoreactivity (CGRP-LI) in the motor neurons of the SNB induced by long term castration. Rats were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer, the spinal cord removed, postfixed for 24 hours in the same fixative. 30 um thick serial sections were processed according to the avidin-biotin peroxidase antiperoxidase method using polyclonal antiserum directed against synthetic rat (Tyr)CGRP$_{23-37}$ (gift from Dr Sternini, CURE, UCLA). The nuclei of CGRP-LI containing neurons and unstained neurons from alternate sections were counted. In the intact animals 53+/-7.4 % (n=4) of the SNB neurons had CGRP-LI and in the castrates 80+/-1.7% (n=9, p<0.001). In animals castrated for four weeks and then implanted with testosterone containing silastic capsules for four weeks the percentage of the SNB motor neurons containing CGRP-LI was not significantly different from that in intact animals. These results demonstrate that change in testosterone level regulates the number of SNB motoneurons that express CGRP-LI. Supported by NS23468.

Na^+- AND Ca^{++}-CHANNEL AGONISTS STIMULATE ENDOGENOUS AMINO ACID RELEASE FROM PRIMARY CEREBELLAR NEURONAL CULTURES. G.R. Dutton, K.L. Rogers and R. Philibert Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242.

We have used HPLC to quantify the release of endogenous amino acids from primary cerebellar neuronal cultures in response to Na^+- and Ca^{++}-channel agonists.

Veratridine (50 µM) evoked release of aspartate, glutamate, GABA, taurine, adenosine, alanine, proline and serine. The onset and peak of release of glutamate, aspartate, GABA, alanine, proline and serine coincided with the onset and peak of stimulation, whereas the peak release of taurine and adenosine was delayed relative to maximal stimulation by approximately 5-7 min. Release of all amino acids was completely antagonized by preincubation with 2 µM tetrodotoxin.

The dihydropyridine Ca^{++}-agonist BAY K 8644 (1 µM) markedly augmented the 30 mM K^+-evoked release of glutamate, aspartate, GABA and adenosine, while increasing the release of the other amino acids only to a minor extent. However, the addition of nifedipine (5 µM) to these stimulating conditions decreased the evoked release of all amino acids well below the levels of release elicited by 30 mM K^+ alone.

These findings demonstrate that a wide variety of amino acids are released from cerebellar neurons, voltage-dependent Na^+- and L-type Ca^{++}-channels are functionally coupled to amino acid release in these cultures, and L-type Ca^{++}-channels may differentially regulate the release of amino acids in response to neuronal depolarization. Supported by NS 20632 and MH 15172.

FAST HPLC METHODS FOR "ON LINE" AND "OFF LINE" MONITORING OF ASPARTATE AND GLUTAMATE IN MICRODIALYSIS PERFUSATES: J. Kehr* and U. Ungerstedt* (SPON: D. Ottoson). Dept. Pharmacology, Karolinska Institute, Stockholm, Sweden.

Fully automated reverse phase high-performance liquid chromatography with precolumn o-phthaldialdehyde (OPA) derivatization and flourescence detection has been modified for the rapid scanning of Asp and Glu levels in microdialysis perfusates of the rat striatum. The method applies an autosampler provided with two 6-port valves, where the separation column (60x4 mm Nucleosil C18, 5 um) is installed in the position of the second valve. The robotics program for the injector enables to optimize the run time in such a way, that after the elution of Asp and Glu (80 sec) the second valve is attenuated and the rest of amino acids is flushed out of the column in the opposite direction within 40 sec. Another 30 sec is needed to reequilibrate the column before the next injection. "Off line" method implies automated derivatization procedure by the autosampler, whereas in the "on line" setup the sample from the microdialysis probe and OPA reagent (both delivered at flow rate 2 ul/min by use of a syringe pump) are mixed before being loaded into the valve. The procedure is used for the monitoring of Asp and Glu outflow under different neuropathological states (ischemia, hypoglycemia), in pharmacology (effects of varying concentrations of K^+, Ca2+, Mg2+ ions in the perfusion medium) and in toxicology.

HIGH SENSITIVITY OF NMDA-STIMULATED CALCIUM UPTAKE TO INHIBITION BY ETHANOL IN PRIMARY CULTURES OF CEREBELLAR NEURONS. Carolyn S. Rabe and Boris Tabakoff. Lab of Physiologic and Pharmacologic Studies, NIAAA, Rockville, MD 20852.

Recent work in this laboratory has shown that glutamate-stimulated cGMP accumulation in cultured rat cerebellar cells is quite sensitive to inhibition by ethanol (Hoffman et al., submitted). In an attempt to understand the mechanism underlying the inhibition, we have begun examining the effect of ethanol on $^{45}Ca^{2+}$ uptake into cultured cerebellar cells in response to stimulation with agonists of the various glutamate receptor subtypes. Both NMDA (100 µM, in Mg^{2+}-free buffer) and kainate (100 µM) produce detectable increases in $^{45}Ca^{2+}$ uptake within 10 sec in these cells. The increase stimulated by NMDA is completely inhibited by DL-2-amino-5-phosphonovaleric acid (200 µM). The NMDA-stimulated increase in $^{45}Ca^{2+}$ uptake also is highly sensitive to inhibition by ethanol. Threshold inhibition is observed between 2.5 and 5 mM ethanol. The EC_{50} for inhibition occurs between 10 and 25 mM and maximal inhibition is observed at 100 mM ethanol. Inhibition of NMDA-gated currents by similar concentrations of ethanol in neurons acutely isolated from dorsal root ganglia also has been observed using patch clamp techniques. (D. Lovinger, personal communication). In contrast, kainate stimulated $^{45}Ca^{2+}$ uptake in cerebellar cells is an order of magnitude less sensitive to inhibition by ethanol. Threshold inhibition of kainate-stimulated $^{45}Ca^{2+}$ uptake is observed between 25 and 50 mM ethanol and 100 mM ethanol causes approximately a 30% inhibition of kainate stimulated uptake. The sensitivity of the kainate-stimulated uptake is consistent with values reported for the ability of ethanol to inhibit voltage-dependent $^{45}Ca^{2+}$ uptake in clonal neuronal cultured cells (PNAS 83:6213, 1986). The relatively high sensitivty of NMDA-stimulated Ca^{2+} uptake to inhibition by ethanol suggests that inhibition of NMDA-mediated responses may have an important role in acute ethanol intoxication.

198.4

CHLORPROMAZINE (CPZ) AND IMIPRAMINE (IMI) METABOLITES ARE NMDA ANTAGONISTS Ian J. Reynolds and Richard J. Miller Dept. Pharm. Physiol. Sci. Univ. Chicago, Chicago, IL 60637.

The NMDA-selective subtype of the glutamate receptor consists of an NMDA recognition site coupled to a cation selective ion channel. The activity of the channel is subject to modulation by a variety of agents. Magnesium and zinc decrease channel activity, while glycine enhances the ability of NMDA and glutamate to open the channel. Using [3H] MK801 we have been able to distinguish between the different binding sites which regulate NMDA receptor activity (Reynolds and Miller, 1988, Mol. Pharm. in press). We have recently found that CPZ and IMI derivatives inhibit binding in a zinc-like fashion. In an attempt to develop specific tools to probe the function of the zinc binding site in vivo we have examined the binding activity of several CPZ and IMI metabolites. Mono- and di-desmethyl IMI are more potent than IMI (7, 5 and 25µM respectively), while didesmethyl CPZ is more potent than CPZ (13 and 40µM). Methoxylation of the phenothiazine ring significantly decreases potency, as does sulfoxidation. However 7- and 2-hydroxy derivatives are more potent than the parent compounds. Based on dissociation kinetic assays these compounds appear to be zinc-like. However CPZ and chlorimipramine are more effective zinc-like drugs than their non-halogenated counterparts. Several of the modifications to the structure of CPZ and IMI that increase the potency at the NMDA receptor are associated with a decrease in their activity at catecholamine uptake sites, dopamine and muscarinic receptors suggesting that it may be possible to separate the respective actions and develop a specific ligand for the zinc binding site of the NMDA receptor.

198.5

COMPARISON OF REGIONAL ^{14}C-2-DEOXYGLUCOSE (2-DG) UPTAKE IN RAT BRAIN FOLLOWING PARENTAL ADMINISTRATION OF EITHER D-2-AMINO-5-PHOSPHOHEPTANOATE (APH) OR KETAMINE. J.E. Mathisen[1]*, S.M. Rothman[1], P.C. Contreras[2] and R.K.Deuel[1]. [1]Department of Pediatrics and Neurology, Washington University School of Medicine, St. Louis, MO 63110. [2]Searle Research and Development, Chesterfield, MO 63198.

Several investigators, using the 2DG method, have observed striking increases in the cerebral metabolic activity in limbic structures following the administration of ketamine, a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist (Crosby et al., 1982). This has raised the question of whether the excitatory effects are mediated entirely by the NMDA receptor. We compared the regional uptake of ^{14}C-2-DG using standard quantitative autoradiographic techniques in 21 loci following the intravenous administration of either the competitive NMDA antagonist APH (600 mg/Kg) or ketamine (20 mg/Kg).

The APH animals had lower global mean cerebral gray matter activity (.207 ± .054 µCi/gm) compared to ketamine animals (.467 ± .238 µCi/gm) ($p < 0.10$). The APH group showed higher relative 2DG uptakes in lateral geniculate and superior colliculus ($p < 0.05$) and sensory motor cortex ($p < 0.01$), while ketamine animals had higher uptake in the anterior thalamus ($p < 0.01$). The lower global gray matter activity in the APH group suggests that increased activity with noncompetitive NMDA antagonists must represent action at a site different from the NMDA receptor complex.

198.6

GUANYLATE CYCLASE ACTIVATION BY EXCITATORY AMINO ACIDS AND ATRIAL NATRIURETIC PEPTIDE IN RAT CEREBELLAR GRANULE CELLS IN PRIMARY CULTURE. A. Novelli, M.A. Vigano'*, R.C. Henneberry* and A. Borsellino*. Lab. Mol. Neurobiology, NIH, Bethesda,MD 20892 ,USA and Internatl. School for Advanced Studies, Trieste 34014,Italy.

Excitatory Amino Acids (EAA) and Atrial Natriuretic Peptide (ANP) have both the capability to increase intracellular concentrations of cGMP in cerebellar granule cells in primary culture (Novelli, A. and Henneberry, R.C., Dev. Brain Res., 34:307,1987). We now present evidences for an interaction between EAA receptors and ANP receptors. In the presence of 1mM Mg^{++},Glutamate (GLU) did inhibit,in a dose-dependent manner, up to 40% of the ANP mediated increase of intracellular cGMP levels. This inhibition of ANP action by GLU was non-competitive and appeared to occur at the proximity of the receptor for ANP. ANP elevation of cGMP levels was not affected by D-(-)-2-Amino-5-PhosphonoValeric acid (APV), a specific glutamate antagonist.In Mg^{++}free conditions, GLU dose-dependent stimulation of cGMP increase was not modified by the presence of 10^{-7}M ANP,a maximal concentration for ANP-stimulated cGMP production. Furthermore no additive effect in the elevation of cGMP levels by GLU and ANP was detectable at concentrations of GLU that were unable to inhibit ANP effect. In the absence of Mg^{++}, GLU induced elevation of cGMP levels was Ca^{++} dependent and a similar increase in intracellular cGMP concentration was achieved using the Ca^{++} ionophore A23187. This receptor-independent, Ca^{++}-mediated stimulation of cGMP synthesis was also not additive to the stimulation of cGMP synthesis by ANP. We suggest that Glu receptor and ANP receptor are closely associated and may be coupled to the same guanylate cyclase molecules.

PCP-LIKE METABOLIC EFFECTS OF THE NMDA-CHANNEL BLOCKING AGENT, MK-801. P.Kazckovsky*, W.E.Hoffmann, and M.F.Piercey, (Spon. P.Ho), The Upjohn Company, Kalamazoo, MI 49001.

MK-801, an NMDA ion channel blocker, has neurocytoprotective and anticonvulsant effects in animals (Iversen et al., Pharmacol. Biochem. Behav. 28:127, 1987). Since PCP is an NMDA-channel blocker, MK-801 may be psychotomimetic. 2-Deoxyglucose (2-DG) autoradiography shows that PCP psychotomimetic effects are elicited in limbic areas, especially Papez' circuit and dopamine (DA) areas (Piercey and Ray, Pharmacol. Biochem. Behav. 28:136, 1987). In the present experiments, rats were injected with 1 mg/kg i.p. MK-801 15 min prior to 2-DG injection using a standard protocol (Sokoloff et al., J. Neurochem. 28:897, 1977). Like PCP, MK-801 produced dramatic increases in metabolism in DA areas (caudate, glob. pall., n. accumbens, olf. tub.) and in Papez' circuit (mamm. body, ant. thal., ent. cortex, mol. layer of hipp). MK-801 produced PCP-like columns in sensorimotor cortex and, like PCP, inhibited metabolism in l. habenula and inf. coll.

CYSTEINE: RELEASE UPON DEPOLARIZATION OF RAT BRAIN SLICES AND EFFECT ON EXCITATORY AMINO ACID RELEASE H.J. Keller*, K.Q. Do*, M. Zollinger*, +K.H. Winterhalter* and M. Cuénod. Brain Research Institute, Univ. Zürich, CH-8029 Zürich and +Laboratory for Biochemistry I, ETH-Zentrum, CH-8092 Zürich, Switzerland.

We performed a screening of potential neuroactive substances by selecting compounds that are released from rat brain slices upon depolarization (50 mM K^+) in a Ca^{2+}-dependent manner. Lyophilized superfusates were derivatized with 9-fluorenylmethyl-succinimidyl-carbonate (FMOC-ONSu) and analyzed by reversed-phase HPLC combined with fluorescence detection. An HPLC peak, which was increased after depolarization, was identified as cysteine (Cys) by fast-atom bombardment mass spectrometry. In order to improve Cys quantification and to minimize further the oxidation of Cys, superfusates were cooled to 0°C and immediately reacted with N-ethylmaleimide. The two HPLC peaks corresponding to the diastereomeres produced by that reaction were summed up. Potassium-stimulated Ca^{2+}-dependent efflux of Cys was highly significant ($p<0.01$) in cortex (33 pmol · mg protein^{-1} · min^{-1}), meso-diencephalon (24), and striatum (18), significant ($p<0.05$) in cerebellum (13), whereas it was not significant ($p>0.05$) in hippocampus and pons-medulla. Moreover in neocortical slices Cys (10-500 µM) increased in a dose-dependent manner both the basal efflux and the efflux induced by 25 mM K^+ of aspartate and glutamate. This suggests that Cys could be released from a synaptic compartment and could modulate excitatory amino acid release.

SOURCES OF PRESUMPTIVE GLUTAMERGIC/ASPARTERGIC AFFERENTS TO THE RAT MESIAL PREFRONTAL CORTEX. K.M. Carnes & J.L. Price. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Small injections of a combined solution of 3H-D-aspartate (3H-D-Asp) and wheat germ agglutinin-horseradish peroxidase (WGA-HRP) were placed in the rat mesial prefrontal cortex in order to compare the pattern of presumptive glutamergic/aspartergic afferents with the overall pattern of afferents to this region. The afferents labeled by 3H-D-Asp were in general a subset of those labeled by WGA-HRP.

Cells retrogradely labeled by an injection of 3H-D-Asp into the prelimbic and anterior cingulate cortical areas were primarily found in the dorsal peduncular, infralimbic, insular and perirhinal cortical areas, the parataenial, mediodorsal, ventromedial (principal division) and intralaminar/midline thalamic nuclei, the amygdaloid complex, and the claustrum. In the contralateral hemisphere, labeled cells were found in the mesial prefrontal and agranular insular cortices.

Fewer neurons were retrogradely labeled by 3H-D-Asp than by WGA-HRP in all of the regions except the claustrum, and the parataenial and ventromedial thalamic nuclei. In addition, neurons in the dorsal peduncular cortex were labeled only with 3H-D-Asp. Except for an occasional cell, neurons along the lateral edge of cingulate cortex, and in the anterior olfactory nucleus (pars medialis), the magnocellular basal forebrain (MNBF), the hypothalamus, the hippocampal formation, and the brainstem were labeled by WGA-HRP but not by 3H-D-Asp.

Supported by NIH NS09518 and ADRC AG05681. KMC was also supported by NIH GM07200, Medical Scientist.

EXCITATORY AMINO ACID-EVOKED RELEASE OF ENDOGENOUS ADENOSINE FROM RAT CORTICAL SLICES K. Hoehn and T.D. White, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4H7

Adenosine may have a protective role in the CNS in situations of excess excitatory neurotransmission due to its ability to inhibit the release of neurotransmitters and decrease firing of central neurons. We have studied excitatory amino acid-evoked release of adenosine in vitro by a continuous superfusion method. Slices were superfused at 0.75ml/min and samples collected at 2.5 min intervals. Glutamate released adenosine in a dose dependent manner. Whereas K^+-evoked release was decreased by about 50% in the absence of Ca^{2+}, glutamate -evoked release was not decreased. Exposure to the specific glutamate receptor agonists, NMDA, kainate, and quisqualate at 100 and 500 µM also released adenosine. Kainate-evoked release was diminished by about 40% by 1mM γ-D-glutamyl-glycine. 500µM NMDA-evoked release was blocked by 1mM DL-APV. 1mM APV also decreased 1.5mM glutamate-evoked release by about 50%, suggesting that NMDA receptors are involved in glutamate-evoked adenosine release. During ischemia or seizures, adenosine may be released to act as an endogenous inhibitory modulator to dampen the firing of neurons.

RELEASE OF [^{3}H]NOREPINEPHRINE (NE) FROM HIPPOCAMPAL SLICES BY N-METHYL-D-ASPARTATE: COMPARISON OF THE INHIBITION BY MK-801 AND Mg^{2+}. C.J. Schmidt* and V.L. Taylor* (SPON: R.J. Dinerstein). Merrell Dow Res. Inst., 2110 E. Galbraith Road, Cincinnati, OH 45215

[^{3}H]NE release from rat hippocampal slices was studied as a functional response to activation of the NMDA receptor. NMDA-induced [^{3}H]NE release was inhibited by the competitive NMDA antagonist, CPP, and was completely blocked by 1.15 mM Mg^{2+}. Predepolarization with 10 mM K^+ or 50 μM kainic acid eliminated this effect of Mg^{2+}. Concentration-response curves for MK-801 and Mg^{2+} yielded IC_{50} values of approximately 35 nM and 35 μM, respectively. Using consecutive pulses of NMDA, MK-801 demonstrated use-dependency in that the degree of inhibition increased with time. In contrast, the degree of inhibition by Mg^{2+} was constant. Kinetic analysis of MK-801-induced inhibition indicated an uncompetitive mechanism while inhibition by Mg^{2+} was noncompetitive. The inhibition of [^{3}H]NE release by MK-801 was a cumulative process which persisted even after removal of the drug. The effect of Mg^{2+} was immediately reversed upon its removal from the media. The results are consistent with both MK-801 and Mg^{2+} inhibiting NMDA receptor-mediated events at a site distinct from the receptor. The voltage sensitivity of Mg^{2+} and the agonist-dependency of MK-801 are consistent with this site(s) being at the cation channel gated by NMDA. Differences in use-dependency, kinetic mechanism and reversibility suggest the two antagonists may act at different sites within the channel.

TRANS-2-CARBOXY-3-PYRROLIDINE ACETIC ACID (CPAA), A NOVEL AGONIST AT NMDA-TYPE RECEPTORS. C. Tsai, J. A. Schneider* and J. Lehmann. Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

Although 2-carboxy-3-pyrrolidine acetic acid analogs are associated with activity as agonists at kainate-type receptors, some compounds in this series possess activity at the NMDA-type receptor. For instance, beta-kainate has been found by some workers to be an antagonist of NMDA-type receptors. Here we report that CPAA is an agonist at NMDA-type receptors.

CPAA evoked the release of [^{3}H]acetylcholine (ACh) from striatal slices with the same efficacy as N-methyl-D-aspartate (NMDA), and an EC_{50} of 20.0 μM, compared to an EC_{50} of 45.8 μM for NMDA. CPAA-evoked [^{3}H]ACh release was inhibited by tiletamine (IC_{50} = 0.53 μM), MK-801 (IC_{50} = 0.12 μM), and $MgCl_2$ (IC_{50} = 26 μM). CPAA produced a tachyphylaxis when applied continuously for 18 min or more, and a cross-tachyphylaxis to NMDA. Similarly, NMDA generated a cross-tachyphylaxis to CPAA. All of these data suggest that CPAA is an agonist at NMDA-type receptors.

198.13

4-PHOSPHONOPROPYLPIPERIDINE-2-CARBOXYLIC ACID (PPPC), AN ANTAGONIST OF THE N-METHYL-D-ASPARTATE (NMDA)-SENSITIVE GLUTAMATE RECEPTORS. D. T. Wong, P. G. Threlkeld*, P. L. Ornstein* and J. W. Chambers*. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

PPPC exhibits high affinity for the NMDA receptors labeled with ^{3}H-CPP in rat hippocampal membranes which have been treated with 1% Triton. The IC_{50} value of PPPC to inhibit ^{3}H-CPP binding is 66 nM, and is about equally potent as the known NMDA antagonists: 91 nM for d-AP5 and 67 nM for CPP. The Hill coefficients for the compounds are not significantly different from unity. Recently, specific ^{3}H-MK801 binding has been described and is functionally linked to the NMDA-sensitive glutamate receptors in vitro (A. C. Foster and E. H. F. Wong, Br. J. Pharmacol. 91:403, 1987). Glutamate (10 μM) and in combination with glycine (30 μM) significantly increased the affinity of ^{3}H-MK801 binding in membranes of forebrain by lowering the dissociation constant from 53.5 to 29.5 and 20.4 nM, respectively, but without changing the density of binding sites (3 pmole/mg protein). On the other hand, PPPC, d-AP5 and CPP inhibited ^{3}H-MK801 binding with IC_{50} values of 2.3, 1.4 and 2.5 μM, respectively. Thus, PPPC behaves like an NMDA receptor antagonist. The relative potencies of PPPC homologs will be described.

IONIC AND RECEPTOR MECHANISMS INVOLVED IN GLUTAMATE-STIMULATION OF DOPAMINE NEURONS IN CULTURE H. Mount, S. Welner, J. Diorio, R. Quirion and P. Boksa. Depts. Pharmacology and Psychiatry, Douglas Hospital Res. Ctr., McGill Univ., Verdun, Quebec, Canada H4H 1R3.

We have previously shown glutamate (GLU) stimulated Ca^{2+}-dependent, Na^+-independent release of [^{3}H]dopamine ([^{3}H]DA) from rat dissociated mesencephalic cells in culture (Mount et al. 1987, Soc. for Neurosci.). We now report that GLU-stimulated [^{3}H]DA release from these cells was not inhibited by tetrodotoxin, Zn^{2+}, lidocaine, or Co^{2+}, indicating that Na^+ or Ca^{2+} action potentials are not necessary for release. This suggests that GLU stimulates DA release directly from dendrites or nerve terminals of DA neurons. N-methyl-D-aspartate (NMDA), quisqualate (QUIS) and kainate, the preferred agonists for 3 GLU receptor subtypes also stimulated [^{3}H]DA release. A specific NMDA antagonist, d,l-APV (100 μM) completely inhibited NMDA-stimulated release, but not QUIS or kainate responses. GLU-stimulated release was inhibited by a broad spectrum antagonist (cis-2,3-PDA), but not by 100 μM d,l-APV, suggesting that GLU acts via non-NMDA receptors. The endogenous amino acid transmitters, homocysteate, aspartate, also stimulated [^{3}H]DA release; this release was inhibited by 100 μM d,l-APV suggesting that these amino acids interact with NMDA receptors. Thus, both NMDA and non-NMDA preferring GLU receptor subtypes may mediate stimulation of DA release from these cells.

ACTIVATION OF GLUTAMATE RECEPTORS INCREASES INTRACELLULAR FREE ARACHIDONATE IN PRIMARY CULTURES OF CEREBELLAR GRANULE CELLS. E. Aronica*, P.L. Canonico and F. Nicoletti* (SPON: P. Strocchi). Institute of Pharmacology, Catania Univ. Sch. of Med., Catania, Italy.

Cerebellar neurons in primary culture express specific classes of ionotropic and metabolotropic excitatory amino acid receptors, associated with Ca^{2+} influx and inositol phospholipid hydrolysis, respectively. Cultures were prelabeled for 16 h with ^{3}H-arachidonic acid (1 uCi/ml). Glutamate (100 uM) produced a small and transient increase in free ^{3}H-arachidonate, and a consistent reduction of ^{3}H-arachidonate-labeled phospholipids. Glutamate stimulated also the formation of unidentified arachidonate metabolites. When cultures were incubated in the presence of cyclo- and lipoxygenase inhibitors (indomethacin and NDGA, 10 uM), glutamate significantly increased (by about 35-45%) intracellular levels of ^{3}H-arachidonate after a 5 min-incubation. The incorporation of ^{3}H-arachidonate into membranal phospholipids was not reduced, suggesting that, in the presence of inhibitors of arachidonic acid metabolism, the released ^{3}H-arachidonate is rapidly recycled back into phospholipids. These results indicate that activation of glutamate receptors stimulates arachidonate release and metabolism in neurons.

TRANSMEMBRANE SIGNALLING AT QUISQUALATE RECEPTOR IN CULTURED NEURONS. A.Ambrosini* and J.Meldolesi* (SPON: F.Clementi). Dept.Pharmacol.,S.Raffaele Inst., CNR Ctr.Cytoph., Milano, ITALY.

In neurons, excitatory amino acids activate membrane phosphoinositides hydrolysis mainly via receptors (R) of the quisqualate (Q) subtype. Experiments in neuronal primary cultures from striatum and hippocampus revealed: 1. an Ins-1,4,5P_3 increase detected as soon as 15 sec after Q (10 μM) addition, with accumulation of total inositol phosphates proceeding for up to 10-15 min; 2. 80% inhibition of these Q-induced responses in cells pretreated for 3 hr with pertussis toxin (PTx). This result demonstrates that transmembrane signalling at QR is mediated by a PTx-sensitive G protein; 3. an even larger (90%) inhibition by short (3min) pretreatment with phorbol dibutirate (PDBu,100nM), suggesting a negative feed-back role of protein kinase C in the modulation of QR. These effects of Q were compared with those induced by carbachol (0.5mM), working through the activation of a muscarinic (M) R. MR responses were unaffected by PTx and inhibited by only 40-50% by PDBu. Thus, the generation of the same intracellular signal at two distinct R types occurs by different coupling mechanisms, and is differently regulated in the same in the same neuronal preparation.

198.17

POLYAMINE SPIDER VENOM COMPONENTS AS EXCITATORY AMINO ACID ANTAGONISTS IN THE RAT CNS. M. J. Pagnozzi*, N. A. Saccomano*, M. F. Gullak*, R. A. Volkmann* and E. E. Mena, (SPON: L. S. Reynolds). Departments of Neuroscience and Medicinal Chemistry, Central Research Division, Pfizer, Inc., Groton, CT 06340.

Spiders paralyze or kill their prey by injecting venoms which have potent actions on invertebrate physiological systems. Polyamine compounds recently isolated from the venoms of the *Argiope aurantia* (Arg-659 and Arg-636) and *Joro* spider (JSTX) potently block excitatory transmission at invertebrate neuromuscular junctions. Since glutamate is the neurotransmitter at these synapses, we examined the effects of these compounds on glutamergic activity in the rat CNS.

The venom components blocked both NMDA-induced (100 μM) and Kainic acid-induced (100 μM) elevation of cGMP in newborn rat cerebellum (IC50's of 10, 50 and 120 μM vs. NMDA and 30, 80 and 250 μM vs. KA for Arg 659, Arg-636 and JSTX respectively). Arg 659, Arg-636 and JSTX also inhibited NMDA-stimulated release of norepinephrine from rat hippocampal slices with IC50's of 1, 32 and 50 μM, respectively. Thus these compounds are functional antagonists at both NMDA and non-NMDA glutamate receptors. Arg-659, Arg-636 and JSTX also inhibited [^{3}H]TCP binding (IC50's of 15, 25 and >100 μM, respectively). The venom components, however, enhanced [^{3}H]Glycine binding. Arg-659 increased [^{3}H]Glycine binding to 285% of control values at 32 μM. The results of this study indicate that the polyamine spider venom components are glutamate antagonists at mammalian synapses. However, the characteristics of this antagonism are inconsistent with either the competitive or noncompetitive type.

198.18

COMPARISON OF MLV-6976 AND NMDA ANTAGONISTS IN THE RAT CORTICAL WEDGE. L. J. Robichaud, T. Malone* and P. A. Boxer. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

A novel oxazolidinone derivative (MLV-6976) has been reported to be a centrally acting muscle relaxant, with non-competitive glutamate blockade proposed as a mechanism of action. In the rat cortical wedge model, we compared the actions of MLV-6976 with the competitive NMDA antagonist CPP and the non-competitive NMDA antagonist MK-801. Wedges were placed in chambers with fluids separately bathing the cortex and white matter, allowing differential DC recordings of membrane potentials in Mg++ free Krebs buffer. MLV-6976 (100 μM) had no effect on the spontaneous epileptiform discharge rate. CPP (3μM) reversibly blocked the discharge rate, while MK-801 (235 nM) irreversibly reduced the rate. Repeatable depolarizations induced by NMDA (10-30 μM) in the presence of tetrodotoxin (0.5 μM) were compared before and after a test agent. CPP (10 μM, 15 min) and MK-801 (235 nM, 120 min) completely inhibited responses to NMDA. MLV-6976 (10-100 μM, 30 or 120 min) failed to inhibit depolarizations induced by NMDA, kainate or KCl. Cortical wedges previously depolarized by NMDA (30 μM) were hyperpolarized by MLV-6976 in a dose-dependent manner. Our data show no evidence that MLV-6976 is an NMDA or kainate antagonist. The mechanism of the hyperpolarization by MLV-6976 remains to be explored.

198.19

GLUTAMINASE-LIKE IMMUNOREACTIVE NEURONS IN RAT LOWER BRAINSTEM. T. Kaneko*, H. Akiyama and N. Mizuno. Dept. of Anatomy (1st Div.), Faculty of Medicine, Kyoto Univ., Kyoto 606, Japan.

Identification of glutamatergic neurons in the lower brainstem of the rat was made immunohistochemically by using a monoclonal antibody MAb-120 raised against phosphate-activated glutaminase (PAG; J. Neurosci. 7:302, 1987). Many brainstem neurons were labeled for PAG. Neuronal cell bodies with the most intense immunoreactivity were densely distributed in the precerebellar nuclei sending the mossy fibers to the cerebellum; in the pontine nuclei, pontine tegmental reticular nucleus of Bechterew, lateral reticular nucleus, and external cuneate nucleus. In the cerebellum, PAG-labeled possible axon terminals were seen in the deep nuclei as well as in the granule cell layer. These findings suggest that many brainstem neurons sending mossy fibers to the cerebellum are glutamatergic. Neuronal cell bodies intensely labeled for PAG were also scattered in the main sensory and spinal trigeminal nuclei, medial and superior vestibular nuclei, regions around the superior olive, posterior ventral cochlear nucleus, paracochlear glial substance, prepositus hypoglossal nucleus, and pontine and medullary reticular formation.

198.20

DEVELOPMENTAL INDUCTION OF GLUTAMINASE IN PRIMARY CULTURES OF CEREBELLAR GRANULE CELLS. C. Banner*, J.W. Thomas, A. Novelli, H.H. Smith*, R.C. Henneberry*, and E. Freese. Laboratory of Molecular Biology, NINCDS, National Institutes of Health, Bethesda, MD 20892

We have used a recently isolated glutaminase cDNA probe (Banner et al., Mol. Brain Res., in press) to examine glutaminase mRNA levels in differentiating granule cell cultures. Between days 3 and 8 after plating neonatal rat cerebellar granule neurons, glutaminase mRNA levels increased over 3-fold relative to total RNA, poly(A$^+$) RNA, and two other mRNAs. Glutaminase protein levels increased over 50% between days 3 and 8 and over 100% by day 10. The total amount of glutamate per cell did not change during this period. Glutaminase induction paralleled the development of calcium-stimulated glutamate release, and the formation of synapses and synaptic vesicles. These results suggest that neuronal glutaminase is involved in the synthesis of a neurotransmitter pool of glutamate.

EXCITATORY AMINO ACIDS V

199.1

PURIFICATION AND CHARACTERIZATION OF THE GLUTAMATE RECEPTOR FROM THE NEMATODE CAENORHABDITIS ELEGANS. Susan Pietrzak Rohrer* (SPON: M. Cascieri). Merck Sharp & Dohme Research Laboratories, Rahway, N.J. 07065

The C. elegans glutamate receptor originally described by Schaeffer et al. (1988, J. Neurochemistry), has been solubilized and purified to homogeneity. In the course of stabilizing the glutamate binding activity of C. elegans membrane preparations, an endogenous ligand, capable of displacing glutamate in the filter binding assay, was discovered. This ligand was removed from tissue by dialysis through tubing with a MW cutoff of 3500. The ligand in the dialysate was lyophilized to dryness, passed over a Sephadex G-25 gel filtration column and recovered as a single active peak absorbing at 206 nM. The membrane bound glutamate receptor was solubilized in 30 mM octyl-B-glucoside. The soluble receptor-ligand complex can be assayed by trapping on glass fiber filters pretreated with 0.3% polyethyleneimine or it can be precipitated from solution with 10% polyethylene glycol and then trapped on glass fiber filters. The K_d for glutamate binding to the soluble receptor is of the same order of magnitude as that for the membrane bound receptor. The soluble receptor has been purified by a combination of ion exchange, hydrophobic, and gel filtration high pressure liquid chromatography (HPLC).

THE PHENCYCLIDINE ANALOG, [^{3}H]TCP, LABELS TWO BINDING SITES IN GUINEA PIG BRAIN DISTINGUISHED BY (+)-MK801. **K.C. Rice[1], M.V. Matteon[1]*, A.E. Jacobson[1],* J.A. Monn[1]*, A.A. Reid[2] and R.B. Rothman[2]. [1]Section on Drug Design and Synthesis, NIDDK and [2]Unit on Receptor Studies, LCS, NIMH, Bethesda, MD 20892.**

Recent studies suggest that NMDA excitatory amino acid receptors and phencyclidine (PCP) receptors coexist in a receptor complex. In this study we begin to test the hypothesis that not all PCP receptors are associated with the NMDA receptor. One prediction of this hypothesis is that [^{3}H]TCP should label two binding sites distinguished by MK801, a potent ligand at the PCP receptor, and in humans, a drug generally devoid of the psychotomimetic effects generally associated with the ingestion of PCP. This clinical observation suggests that MK801 may "mark" the PCP receptor associated with the NMDA receptor.

Large batches of frozen membranes were prepared from 20 to 40 frozen guinea pig brain (including cerebellum). Incubations with [^{3}H]TCP and test drugs proceeded for 2 to 4 hr at 0° C in 5 mM TRIS buffer as described (Neuropeptides 10:261-264, 1987). Using these assay conditions, neither glutamate (100 uM) nor the NMDA antagonist CPP (10 uM), had any effect on binding. To characterize [^{3}H]TCP binding sites, binding surfaces were fit to a one or two site binding model using nonlinear least squares curve fitting methods. The results indicated that the data were best fit by a two site binding model with the following parameter estimates:

	Units	Site 1	Site 2
Bmax	(fmol/mg protein)	428±82	433±52
TCP	(Kd, nM)	47±9	15±1.2
PCP	(Kd, nM)	55±11	102±11
(-)Cyclazocine	(Kd, nM)	566±104	38±4
Dexoxadrol	(Kd, nM)	383±108	5.2±0.6
(+)-MK801	(Kd, nM)	854±750	6.6±2.2

These data demonstrate the existence of two PCP binding sites distinguished by MK801, consistent with the prediction of the hypothesis. Additional studies will test other aspects of the hypothesis.

199.3

TRANSIENT INCREASED DENSITY OF NMDA BINDING SITES IN THE IMMATURE HUMAN AND RAT HIPPOCAMPUS.
E. Tremblay*, A. Represa*, M.P. Roisin*, C. Marlangue and Y. Ben-Ari. INSERM U-29. 123 Bd Port-Royal. Paris 14. FRANCE

Recent studies performed in the visual system suggest a preferential involvement of NMDA receptors in developmental plasticity. In the present report, we have examined the developmental changes in the density of NMDA binding sites in the hippocampus.

Human - Using quantitative autoradiography, we found a highly significant postnatal reduction in ^{3}H Glut. binding sites. Most of this reduction is due to NMDA subtypes of receptors. Thus, in CA1 the density of these sites was of 103 ± 8, 105 ± 3, 41 ± 6 at E (embryonic age) 23-27 weeks E40 weeks and adults respectively. A similar reduction was found in CA3 and the fascia dentata.

Rat - With membrane preparation, a highly significant reduction in NMDA binding sites was found post nataly. This was not associated with a change in affinity. With quantitative autoradiography a 50 % reduction of NMDA sites occured between P8 and P12 in CA1. There is therefore an abrupt transient increase in the density of NMDA binding sites in developping human and rat hippocampus. A parallel report from this laboratory shows the presence of spontaneous recurrent giant epep in hippocampal neurons before, but not after P8. These giant epsps are readily blocked by specific NMDA receptors in immature hippocampal synapses (Coradetti et al. ENA meeting).

199.4

GLUTAMATE IN THE SYMPATHETIC INTERMEDIOLATERAL NUCLEUS OF THE RAT THORACIC SPINAL CORD: SOURCES AND ULTRASTRUCTURAL CHARACTERIZATION *J. Callaway*, S. Morrison, T.A. Milner, P. Petrusz, A. Rustioni and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 and Dept. of Anat. and Physiol., Univ. North Carolina at Chapel Hill, Chapel Hill, NC 27514

Stimulation in the medullary nucleus reticularis rostroventrolateralis (RVL) produces an excitation of sympathetic preganglionic neurons (SPNs) in the spinal intermediolateral nucleus (IML) that is blocked by iontophoresis of the glutamate blocker, kynurenate (Soc. Neurosci. Abstr. 13:808, 1987). To identify the anatomic substrate for these results, a polyclonal antiserum against hemocyanin-conjugated glutamate (J. Neurosci.7:1887-1901, 1987) was localized in the IML using the peroxidase-antiperoxidase method. By light microscopy, glutamate-like immunoreactivity (Glu-LI) was observed in cells and varicose processes within the IML which were unevenly distributed throughout the rostrocaudal extent of the thoracic cord. Glu-LI in the IML was eliminated after preabsorption of the antiserum with low concentrations of bovine serum albumin(BSA)-conjugated glutamate but not with BSA-conjugated aspartate. Six days following T3 spinal transection, Glu-LI in the IML was greatly reduced caudal but remained unchanged rostral to the transection. By electron microscopy, Glu-LI was found in perikarya, dendrites, axons and axon terminals in the IML. The amount of Glu-LI in perikarya and dendrites varied, however, depending on fixation conditions. Terminals with Glu-LI (0.2-1.5μm) contained numerous small clear and 1-3 large dense core vesicles. Out of 89 terminals, 80 were synaptically associated with labeled or unlabeled perikarya and dendrites. Synaptic junctions on perikarya were rare (1%) whereas, those on proximal (large) dendrites were more numerous (13%) and included asymmetric as well as symmetric contacts. However, the majority of terminals with Glu-LI formed asymmetric junctions on distal (small) dendrites (81%) and dendritic spines (5%). These data indicate that glutamate, possibly released by a descending spinal pathway, could play a significant role as an excitatory (asymmetric synapses) transmitter regulating the discharge of SPNs in the IML. (Supported by NIH grants HL 18974 and NS22721.)

AMPA BINDS TO A SUBSET OF QUISQUALATE-SENSITIVE GLUTAMATE BINDING SITES. J. J. Cha, E. Ø. Nielsen*, T. Honoré*, J. B. Penney, and A. B. Young. Neuroscience Program and Department of Neurology, Univ. Michigan, Ann Arbor, MI 48104-1687.

Calcium (Ca^{2+}) and chloride (Cl^-) ions stimulated [^{3}H]glutamate ([^{3}H]Glu) binding to quisqualate (QA) - sensitive [^{3}H]Glu binding sites in rat brain fourfold, as measured by quantitative autoradiography, whereas potassium thiocyanate (KSCN) had no additional effect. In contrast, Ca^{2+} and Cl^- had little effect on the binding of [^{3}H]AMPA, but 100 mM KSCN stimulated binding fourfold. In the absence of KSCN, AMPA displaced little [^{3}H]Glu binding from QA-sensitive binding sites but displaced up to 40% of [^{3}H]Glu binding in the presence of KSCN. The regional distributions in brain of QA-sensitive [^{3}H]Glu binding sites and [^{3}H]AMPA binding sites correlated highly (r = 0.94), suggesting that these binding sites are the same or closely related. Given the differential effects of ions on [^{3}H]AMPA and QA-sensitive [^{3}H]Glu binding and AMPA's limited ability to displace [^{3}H]Glu from QA-sensitive sites, the results suggest that AMPA binds to a subclass of QA-sensitive [^{3}H]Glu binding sites that are highly influenced by ionic environment or that QA-sensitive binding sites exist in several states. Supported by NIH NRSA 5T32 and UHPHS grant NS 19613.

SOLUBILISATION AND CHARACTERISATION OF QUISQUALATE A RECEPTOR FROM CHICK BRAIN J.M. Henley* and E.A. Barnard*, (spon. S. Simasko) MRC Molecular Neurobiology Unit, MRC Centre, Hills Road, Cambridge CB2 2QH, U.K.

The binding of the quisqualate receptor selective agonist [^{3}H]AMPA (α-amino-3-hydroxy-5-methylisoxazole-propionate) to 1-day old chick brain membrane homogenates in the presence of 100 mM KSCN revealed a single class of specific high affinity [^{3}H]AMPA binding sites with a B_{max} of 1.3 pmol/mg protein and a Kd of 51 nM. Solubilisation of viable binding sites was optimal with the anionic detergent sodium cholate. The affinity of the solubilised binding sites for [^{3}H]AMPA in the presence of KSCN was increased (Kd = 21 nM) and the B_{max} was 0.9 pmol/mg protein. The pharmacology of the solubilised and membrane bound receptors was similar with quisqualate ≃ AMPA > CNQX DNQX > L-glutamate being the most potent competitive ligands for [^{3}H]AMPA displacement. The dissociation rate of [^{3}H]AMPA from solubilised binding sites was 0.013 min^{-1} and the kinetically determined Kd was 20 nM. [^{3}H]AMPA binding activity was not enriched by ion exchange chromatography but an approximately 25 fold increase in the specific [^{3}H]AMPA binding per mg protein was obtained using wheat germ lectin chromatography. The results demonstrate the solubilisation of a stable, viable, quisqualate receptor and suggest that chick brain may provide a useful system for further characterisation and eventual purification of this glutamate receptor subtype.

GLUTAMATE RECEPTORS ARE TRANSPORTED BIDIRECTIONALLY IN RAT VAGAL AFFERENT NEURONS. P.M. Beart*, D. Lodge*, S. Lewis*, A. Verberne*, B. Jarrott*, R. Summers*† and M. Cincotta* (SPON: A.W. Goodwin). Univ. of Melbourne, Clin. Pharm., Austin Hosp., Heidelberg VIC 3084 and †Dept. of Pharmacol. Parkville VIC 3052, AUSTRALIA.

Receptors for a variety of transmitters are synthesized in perikarya of neurons of the nodose ganglion (NG) and axonally transported in vagus nerve (X). Since L-glutamate (GLU) may be a transmitter of baroreceptor afferents and NG neurons are excitotoxin-sensitive (Verberne, A.J.M. et al., Eur. J. Pharmacol., 139: 365, 1987), we examined GLU receptor dynamics in NG/X system. Sprague-Dawley rats, anaesthetized with amylobarbitone-methohexitone, had their left NG exposed and X singly or doubly ligatured. Controls received sham ligations or operations. At 24 h postsurgery, rats were re-anaesthetized and each NG/X removed. Longitudinal (10 μm), slide-mounted sections were processed for receptor autoradiography using [^{3}H]GLU. In ligated and control NG, binding was identical and punctate. Binding in X was only found after ligation, both proximal and distal to ligature. Double ligation of peripheral X confirmed this finding. GLU receptors also accumulated after ligation of central X. Colchicine prevented receptor accumulation. All receptor subtypes were present (kainate >50%) and NG contained single population of sites (Kd 130 nM, Bmax 0.6 nM.μg^{-1} protein). GLU receptors are localized in NG and undergo bidirectional flow in peripheral and central X.

ONTOGENY OF EXCITATORY AMINO ACID RECEPTOR SUBTYPES IN RAT BRAIN
T.R. Insel, L.P. Miller, A. E. Johnson, R. Gelhard*. Lab. of Clin. Sci., NIMH, Poolesville, MD 20837; Vet. Adm. Med. Ctr., Wash D.C. 20422

Recent evidence implicates excitatory amino acids (EAA) in experience-dependent changes (e.g. imprinting, olfactory learning, formation of ocular dominance columns) during neural development. To investigate possible sites of EAA action in development, the ontogeny of various glutamate receptor subtypes was examined in rat brain using *in vitro* receptor autoradiography. Slide-mounted 12μ sections from rats at ages 1,7,14,21,28 days, and adult were incubated with ^{3}H-glutamate ± NMDA to label NMDA receptors, ^{3}H-AMPA ± AMPA to label quisqualate receptors, and ^{3}H-kainic acid ± kainic acid to label kainate receptors. Computer-based image analysis using ^{3}H standards was performed on 30 brain regions. The three receptor subtypes showed slightly different developmental profiles. For each of the subtypes, binding appeared to increase gradually with age, peaking at age 21-28 days in most areas, then decreasing to adult levels. In addition, local patterns of markedly increased binding were seen for ^{3}H-AMPA binding in CA3 (days 1-14) and ^{3}H-kainic acid binding in the reticular nucleus of the thalamus (day 7). These regions of transient "overshoot" of EAA receptors may represent sites where EAAs have a specific role restricted to development. Whether EAA receptors are involved in the normal eliminative processes characterizing post-natal neuronal differentiation remains to be determined.

IMMUNOAFFINITY PURIFICATION OF KAINATE BINDING PROTEIN IN PIGEON CEREBELLUM. A. U. Klein* and P. Streit. Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland.

Kainic acid, an agonist at a certain type of excitatory amino acid receptor, binds in the pigeon cerebellum to a low affinity site which is located in the molecular layer (Henke, H. et al., Brain Res., 219:95-105, 1981) and which can be solubilized by Triton X-100 (Dilber, A. et al., Soc.Neurosci.Abstr. 9:260, 1983). To raise monoclonal antibodies (mAb) with crude solubilized preparations against this binding site, a procedure involving partial immunosuppression (Matthew, W. D. and Patterson, P. H. in: Cold Spring Harbor Symposia on Quantitative Biology, Vol.48, pp.625-631, 1983) had to be used. A mAb (mAb 15A4) precipitating kainate binding activity was detected. Immunoaffinity-precipitated by mAb 15A4, this activity appeared as a single peak with M_r = 220,000 in gel filtration FPLC and as a single band with M_r = 50,000 in SDS-PAGE under reducing conditions. Polyclonal antibodies to purified material and mAb 15A4 labeled selectively as yet unidentified elements in the molecular layer of pigeon and chicken cerbellar cortex. In the pigeon an analogous distribution of labeling had been observed in autoradiographic studies with tritiated kainate (Henke et al., 1981).

QUANTITATIVE AUTORADIOGRAPHY OF [3H]GLYCINE BINDING TO THE GLYCINE RECEPTOR ASSOCIATED WITH THE NMDA RECEPTOR OPERATED CHANNEL. J.W.McDonald, J.B. Penney, M.V. Johnston, and A.B. Young, MSTP and Neuroscience Programs and Department of Neurology and Pediatrics, University of Michigan, Ann Arbor, MI. 48104

Glycine potentiates NMDA responses and enhances [3H]TCP, [3H]MK-801, and NMDA receptor binding in vitro suggesting that there is a glycine binding site associated with the NMDA receptor operated channel. We have developed an in vitro autoradiographic method for visualizing this glycine binding site. Kinetic studies were performed at 4°C in 50 mM Tris-citrate, pH=7.4, containing 100nM [3H]glycine using 20 um adult rat brain sections. [3H]Glycine binding was saturable and reversible with a K_d of 75-88 nM. Binding equilibrium was reached within 10-15 min. Under these conditions specific binding represented >90% of total binding. The relative distribution of [3H]glycine binding was highly correlated with that of NMDA receptor binding (r=0.94), MK-801 binding (r=0.97), and TCP binding (r=0.89); CA_1 > dentate > cingulate cortex > parietal cortex (I,II) > thalamus > striatum > cerebellar granule layer > inferior colliculus. [3H]Glycine binding was insensitive to the inhibitory glycine receptor antagonist, strychnine. Binding was not altered by most competitive (NMDA, glutamate, CPP) or non-competitive (MK-801, TCP) NMDA receptor agonists and antagonists. In general, D- rather than L-amino acids were more effective inhibitors of [3H]glycine binding with the exception that L-valine was more potent than D-valine. Kynurinic acid and DL-APV were potent inhibitors of [3H]glycine binding. These data suggest that some of the reported competitive NMDA antagonists may actually reduce NMDA responses by blocking the glycine site and preventing glycine receptor mediated enhancement of NMDA responses.

Supported by USPHS grant NS 19613 and MSTP grant 5 T32 6M07863-07

199.11

QUANTITATIVE AUTORADIOGRAPHY OF [3H]MK-801 BINDING IN RAT BRAIN. S. Sakurai, J.J. Cha, J.B. Penney, & A.B. Young Neuroscience Program and Department of Neurology, University of Michigan, Ann Arbor, MI 48104 - 1687.

MK-801 is a non-competitive antagonist of the NMDA receptor. We have developed a quantitative autoradiographic binding assay for [3H]MK-801. Kinetic experiments were performed at room temperature on 20 µm sections of adult rat brain in 5.0 nM [3H]MK-801 (29.4 Ci/mmol) in Tris-Acetate. The sections were apposed to tritium-sensitive film and exposed for 3 weeks. The binding of [3H]MK-801 was reversible and saturable with a K_d of 1-2 nM as determined by kinetic experiments. The $t_{1/2}$ of association was approximately 50 min. Under these conditions specific binding was greater than 95% of total binding. The relative distribution of [3H]MK-801 binding was: CA1 > dentate gyrus > outer cortex > striatum > cerebellum. The regional distribution of [3H]MK-801 was highly correlated with the distribution of TCP binding sites (r = 0.96) and NMDA receptors (r = 0.96). [3H]MK-801 binding was inhibited by TCP, while NMDA enhanced binding in all areas examined. The NMDA stimulation of [3H]MK-801 binding was inhibited by the competitive NMDA receptor antagonist CPP. In addition, CPP inhibited binding in the absence of NMDA. Finally, glycine stimulated [3H]MK-801 binding in all areas examined. Supported by NS 19613, NIH NRSA 5T32 and a Merck Faculty Development Award (to ABY).

IN VIVO [3H]-MK 801 BINDING IN THE RAT: ANOMALOUS RESULTS OF BLOCKING STUDIES. B.J. Ciliax, J.B. Penney, and A.B. Young, Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

[3H]-MK 801 binds to the high affinity phencylidine (PCP) site, which is coupled to the NMDA receptor and closely matches the anatomical distribution of the NMDA receptor. In vivo [3H]-MK 801 binding was used to investigate this ligand's potential to image the NMDA/PCP receptor complex for ultimate use in PET.

Binding of [3H]-MK 801 after i.v. injection in control animals was heterogeneous and high in cortex, CA1 of hippocampus, and thalamus. The binding distribution was very similar to that seen in in vitro binding assays with [3H]-MK 801 or [3H]-TCP. Surprisingly, a predose of 5 mg/kg cold MK 801 (given from 0 to 240 min prior to the [3H]) *increased* the amount of in vivo [3H]-MK 801 binding. The anatomical distribution of [3H]-MK 801 binding in vivo after cold MK 801 pretreatment was very similar to that in the control animals, but the laminar binding seen in CA1 of the hippocampus and other brain regions was no longer as distinct. These data suggest that the adminstration of the cold drug somehow activated the system to allow for more binding, possibly by recruitment of cryptic sites or feedback activation of the use-dependent PCP site.

Supported by USPHS grant NS 15655, the ADRDA, and a Merck Faculty Development Award.

PHOTOAFFINITY LABELING AND BINDING STUDIES REVEAL TWO TYPES OF PHENCYCLIDINE (PCP) RECEPTORS IN THE NCB-20 CELL LINE. R. Haring, R.S. Zukin and S.R. Zukin. Depts. of Psychiatry and Neuroscience, Albert Einstein Coll. Med., Bronx, NY 10461

It has recently been shown that [3H]N-(1-[2-thienyl]cyclohexyl)piperidine ([3H]TCP) binds to both PCP-type and to non-PCP-σ type sites on membranes of cultured NCB-20 cells (Kushner *et al.*, submitted for publication). The PCP-type site was shown to be coupled to NMDA receptors. However, its pharmacological selectivity differed somewhat from that established for the brain PCP receptor. We addressed the question of whether PCP receptors of NCB-20 cells are structurally congruent with the brain receptors by comparing their polypeptide compositions using the photolabile PCP derivative [3H]azido-phencyclidine ([3H]AZ-PCP). The IC50 values for AZ-PCP displacement of [3H]TCP binding and for TCP displacement of [3H]AZ-PCP binding in the cell membranes were similar. The pharmacological selectivity of [3H]AZ-PCP binding was similar to that which has been reported for [3H]TCP binding. We concluded that [3H]AZ-PCP is suitable for labeling of the PCP receptors to NCB-20 cells. Competition binding curves for AZ-PCP, dexoxadrol and MK-801 were shallow with Hill coefficient <1. Computer-assisted analysis of MK-801 displacement curves suggested a biphasic mode of inhibition with the apparent K_i values of 13 nM and 2.3 µM for the high (10-15% of sites) and low affinity (85-90% of sites) components, respectively. Photoaffinity labeling was carried out, essentially as described before (Haring et al, Biochem. 26: 5854, 1987). We found that each of the five polypeptides previously shown following labeling of rat brain membranes were present in the membranes from NCB-20 cells (M_r 90,000, 68,000, 49,000, 40,000 and 33,000). Addition of MK-801 (10^{-5}M) to the incubation mixture inhibited the labeling mainly of M_r 90,000 and 68,000 polypeptides with less effect upon M_r 33000. The σ ligand (+)3-(3-hydroxyphenyl)-N-(1-propyl)piperidine (+)3-PPP (10^{-5}M) was found to inhibit [3H]AZ-PCP labeling mainly of M_r 49,000 and 33,000 bands. These results indicate the existence of PCP receptors in NCB-20 cells which have the same polypeptide composition as the brain receptors. One population of sites appears to be linked to the NMDA receptor channel. Our findings indicate that the polypeptides of M_r 90,000 and 68,000 previously identified in rat brain as components of the high-affinity PCP binding sites might be associated with the PCP-NMDA receptor-channel complex. Our results also support the presence of low affinity sites. These may be responsible for the anomalies in the ligand selectivity pattern and relatively low affinity shown by [3H]TCP sites in the cells. Supported in part by grants to SRZ (PHS DA-03383; Ritter Foundation), RSZ (PHS DA-04439, 00069) and RH (Camp David Institute).

ASPARTATE IMMUNOREACTIVITY IN CORTICOFUGAL NEURONS IN RATS. R. Giuffrida* and A. Rustioni. Dept. Cell Biology and Anatomy, Univ. North Carolina at Chapel Hill, Chapel Hill, NC 27599.

We have previously reported that 50 to 60% of corticofugal neurons are immunoreactive for an antiserum for glutamate (Glu). We have now explored the possibility that corticofugal neurons immunonegative for glutamate (Glu) are immunopositive for an antiserum for aspartate (Asp) raised in rabbits, like the Glu-antiserum, against the amino acid conjugated to hemocyanin by glutaraldehyde. A retrograde tracer was injected in the motor cortex, or ventral thalamic nuclei, or cervical spinal cord of rats. Two to 3 days later these were perfused with carbodiimide and paraformaldehyde and sections of the sensorimotor cortex were processed for immunocytochemistry. In the regions with highest density of retrogradely labeled neurons, 50 to 60% of these were Asp-immunopositive. The percentage of immunopositive corticofugal neurons increased to over 90% when the same section was processed for both Glu- and Asp-antisera suggesting that a large fraction of these neurons are immunoreactive for either one amino acid but not for both. High levels of Glu and Asp may be present in a fraction of neurons which may release both amino acids or a substance closely related to these.

Supported by USPHS grant NS 12440.

GLUTAMATE-IMMUNOREACTIVE SYNAPTIC TERMINALS OF PRIMARY AFFERENTS TO THE CUNEATE NUCLEUS OF RATS. S. De Biasi and A. Rustioni (SPON: M. Fabri) Dept. Cell Biology and Anatomy, Univ. North Carolina, Chapel Hill, NC 27599.

Glutamate (Glu) meets several criteria as neurotransmitter in dorsal root ganglia (DRG) neurons; only recently has this been tested by immunocytochemistry. Up to 70% of DRG neurons in rats are labeled with an antiserum against Glu conjugated to hemocyanin. We have investigated whether synaptic endings of DRG neurons in the cuneate nucleus are immunopositive for the same Glu antiserum. Rats were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde. Sections were reacted for pre-embedding immunocytochemistry or processed for post-embedding immunogold staining. With both methods: a) terminals with the same morphological features are labeled; b) labeled terminals co-exist with unlabeled ones in the same section; c) terminals with flat vesicles are not labeled. The origin of labeled terminals from DRG neurons is demonstrated in rats with injections of an anterograde tracer. Primary afferent, Glu+ terminals have a scalloped profile, light cytoplasm, and contain many mitochondria and small agranular vesicles homogeneous in size. They contact many profiles some also containing vesicles.

The results support the hypothesis that primary afferent terminals in the dorsal column nuclei release Glu as synaptic transmitter.

COLCHICINE INJECTION PRODUCES A RAPID DECREASE IN GLUTAMATE RECEPTOR BINDING IN RAT HIPPOCAMPUS. Yuzo Nakagawa* and Michel Baudry. Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

Colchicine injection has been widely used to produce selective neuronal death especially in the hippocampal formation where, at low doses, it results in the elimination of dentate granule cells while at higher doses it also eliminates CA_1 pyramidal neurons. Several subtypes of glutamate receptors have been defined and can be labeled by appropriate ligands, i.e., ^{3}H-glutamate and ^{3}H-AMPA for the NMDA and quisqualate receptors respectively. In the present study, we determined the effects of colchicine injection on these two types of receptors in both the dentate gyrus and in CA_1.

Unilateral injection of colchicine (15 µg) in the dorsal hippocampus did not produce any change in ^{3}H-glutamate and ^{3}H-AMPA binding in the dentate gyrus or CA_1 contralateral to the injection site. However, it produced a progressive decrease in the binding of both ligands in both subfields of the injected hippocampus. The changes in binding as a function of time after the injection could be fitted with an exponential function, and the half-life of the binding sites were calculated to be about 7 days for ^{3}H-AMPA and 9 days for ^{3}H-glutamate in the dentate gyrus. Similar values were found in CA_1 although the changes in binding were delayed by about 2 days as compared to the dentate gyrus. Kinetic analysis of the binding at equilibrium were performed 7 days after the injection and indicated that the changes in binding were due to changes in the maximum number of sites but not in affinity for the ligands.

These results indicate that the sites labeled with ^{3}H-glutamate and ^{3}H-AMPA are localized mainly postsynaptically and on neuronal structures. The exponential decay of the receptor binding suggests that the number of glutamate receptors reflects directly the number of surviving neurons in the hippocampal formation.

Supported by grant BNS 12156 from NSF.

AUTORADIOGRAPHIC VISUALIZATION OF NON-NMDA RECEPTORS USING ^{3}H-CNQX: PHARMACOLOGICAL CHARACTERIZATION AND COMPARISON WITH ^{3}H-AMPA BINDING SITES IN RAT BRAIN. E.Ø. Nielsen*, J. Drejer* and T. Honoré* (SPON: L.H.Jensen) Ferrosan Research Division, DK-2860 Soeborg, Denmark.

^{3}H-CNQX (6-nitro-7-cyanoquinoxaline-2,3-dion) selectively labels the non-NMDA receptors in rat brain. ^{3}H-CNQX binding is highest in CA-1, dentate gyrus and CA-3 of hippocampus followed by cortex and molecular layer of the cerebellum. Apparently, ^{3}H-CNQX binds to a single population of sites with a K_D of 67 nM and B_{max} 3.56 pmol/mg protein (molecular layer of cerebellum). Displacement of ^{3}H-CNQX binding by AMPA revealed a biphasic inhibition curve. Quisqualate, glutamate and kainate had high affinity for ^{3}H-CNQX sites whereas NMDA was without significant activity at 100 µM. Equilibrium studies of ^{3}H-AMPA binding in the presence of SCN^- gave two binding sites with K_D = 9 and 278 nM and B_{max} = 0.15 and 1.54 pmol/mg protein, respectively. The finding that ^{3}H-AMPA binding gave biphasic Scatchard plots and AMPA gave biphasic inhibition of ^{3}H-CNQX suggest that the linear Scatchard plot of ^{3}H-CNQX binding is in accordance with CNQX having the same affinity to the two conformational states of the quisqualate receptor (Honoré and Drejer, J. Neurochem. in press, 1988). The regional distribution of non-NMDA receptors labelled with ^{3}H-AMPA and ^{3}H-CNQX showed a good correlation with the distribution of quisqualate-sensitive ^{3}H-glutamate binding.

FULL-LENGTH HUMAN GLUTAMATE DEHYDROGENASE cDNA: MITOCHONDRIAL TARGETTING PRESEQUENCE AND ALTERNATE POLYADENYLATION. Y. Nakatani*, M. Schneider*, C. Banner*, B. Lee*, H. Smith*, and E. Freese (SPON: M. Martin). Laboratory of Molecular Biology, NINCDS, NIH, Bethesda, MD 20892

A genetic defect in a glutamate dehydrogenase (GDH) "isozyme" has been suggested to occur in some patients with certain neurodegenerative disorders. Two or more forms of GDH have been previously reported to exist in brain and liver tissue. By hybridization with one human brain GDH cDNA, we have isolated and sequenced part or all of three GDH cDNAs from human brain, three from human liver, and two from fibroblasts. The identical DNA sequence was found in all cases. Several other GDH cDNAs did not differ from these by restriction mapping or oligonucleotide hybridization analysis. We conclude that the same GDH gene is expressed in all three tissues, and that if GDH "isozymes" occurred in these individuals, they probably had a post-translational origin. Two different GDH mRNAs resulted from polyadenylation at two sites on a single transcript. The full-length GDH cDNA encoded an N-terminal amino acid sequence resembling the previously described sequences that enable protein translocation into the mitochondrial matrix. Isolated rat liver mitochondria actually imported and processed the precursor protein which could be synthesized in vitro from the GDH cDNA.

199.19

EFFECTS OF GUANINE NUCLEOTIDES ON GLUTAMATE STIMULATED [^{3}H]TCP BINDING TO RAT BRAIN SYNAPTIC PLASMA MEMBRANES. R.P. Compton, W.F. Hood and J.B. Monahan. CNS Diseases Research, G.D. Searle & Co., Chesterfield, MO 63198.

GTP (along with its non-hydrolyzable analogs 5'-guanylylimidodiphosphate and 5'-guanylylmethylenediphosphate) and GDP inhibit the binding of [^{3}H]1-(1-(2-thienyl)cyclohexyl)piperidine ([^{3}H]TCP) to the N-methyl-D-aspartate (NMDA) receptor coupled phencyclidine recognition site in rat forebrain synaptic plasma membranes. GMP, cyclic GMP and guanosine are significantly less potent. NMDA receptor agonists, which increase the affinity of [^{3}H]TCP for its recognition site, were examined for their effects on the GTP inhibition of [^{3}H]TCP binding. The inclusion of 1µM glutamate in the [^{3}H]TCP assay results in a parallel shift in the inhibition curves of phencyclidine analogs (eg. MK-801) toward higher potencies while no effect on Zn^{+2} induced inhibition is observed. Glutamate induced a rightward shift (lower potency) in the GTP dose-response curve (IC_{50}'s= 34µM and 235µM, respectively) in a manner similar to that seen with the competitive NMDA antagonist, D-2-amino-7-phosphonoheptanoate. These results are consistent with our previous findings that GTP (IC_{50}=28µM) and its analogs competitively inhibit NMDA-sensitive L-[^{3}H]glutamate binding and support the hypothesis that guanine nucleotides may be endogenous antagonists of NMDA receptor function.

199.20

PCP AND SIGMA RECEPTORS: DIFFERENTIAL EFFECTS OF CATIONS AND pH ON LIGAND AFFINITY. Z.W. YANG, G.A. PALEOS, AND J.C. BYRD. Developmental Neurobiology Program, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213

Phencyclidine (PCP) and benzomorphans bind to at least two sites in the CNS - the PCP receptor, and the Sigma receptor. Using ligands selective for each of these receptors ([^{3}H]TCP and [^{3}H] (+) PPP, respectively) we have compared the binding characteristics of these radioligands for the two receptors. Both ligands achieve equilibrium by 60 min at 21°C. (+) PPP also achieves equilibrium by 120 min at 4°C, but TCP is far from equilibrium under these conditions. TCP shows a pH optimum of 8.0, while (+) PPP has an optimum at pH 9.5. Binding of (+) PPP at pH 9.5 is substantially reduced by both heating and protease digestion. Tris buffer decreases TCP binding by 25% at 5 mM, and 75% at 20 mM. In contrast (+) PPP binding is maximal in 10 mM tris, but decreases 40% in 50 mM Tris. Binding of both TCP and (+) PPP is inhibited by sodium (IC_{50} for TCP = 3 mM; IC_{50} for (+) PPP = 30 mM). 1 mM Ca^{++} virtually abolishes TCP binding, while (+) PPP binding is inhibited 50% by 2 mM Ca^{++}. Other divalent cations (Zn^{++}, Mn^{++}, Ca^{++}, Mg^{++}) also cause marked decreases in TCP and (+) PPP binding. Ca^{++} reduces TCP and (+) PPP binding by different mechanisms. Ca^{++} causes a 2-4 fold increase in the K_d of TCP, but reduces the B_{max} of (+) PPP by 45%. The rank order of potency of several benzomorphans in displacing [^{3}H] (+) PPP is essentially the same at both pH 8.0 and 9.5. However, the stereoselectivity of these compounds is greatly reduced at the higher pH, due largely to a selective decrease in the affinity of the (+) isomer for the Sigma receptor.

199.21

MONOCLONAL ANTIBODIES IDENTIFY A KAINIC ACID RECEPTOR D.R. Hampson, K.D. Wheaton*, C.J.Dechene*,and R.J. Wenthold NIH, NINCDS, Lab of Neuro-otolaryngology, Bethesda, MD 20892

Monoclonal antibodies were produced in Balb/C mice after subcutaneous or intraperitoneal immunizations with a kainic acid receptor isolated from frog (Rana pipiens) brain using ion exchange and ligand affinity chromatography. Ligand affinity chromatography was carried out using the high affinity kainic acid analog, domoic acid (Hampson and Wenthold, JBC 263:2500,1988). Primary screening was done by dot blotting using the affinity purified receptor as antigen. Additional screening assays consisted of western blotting and an indirect immunoprecipitation assay using a solubilized receptor preparation (Hampson, et al., J. Neurochem.49:1209,1987) and antibody-coated microspheres. Hybridoma cloning was via limiting dilution (2X) using hybridoma cloning factor as a feeder cell replacement.

A large number of positive clones were detected in the dot blot assay. Of these, several were capable of immunoprecipitating solubilized kainic acid receptors. The range of immunoprecipitation was from 20% to greater than 80% of the solubilized receptors. For the western blots, crude brain membranes, crude solubilized preparations, and affinity purified receptors were used. Several of the antibodies that reacted on the dot blot and in the immunoprecipitation assay also reacted strongly with a band of M_r=48,000 on western blots. This band corresponds to that observed on silver stained gels of the affinity purified preparations. A number of the monoclonal antibodies displayed a unique pattern of staining on tissue sections that corresponded to the pattern of ^{3}H-KA binding on autoradiograms.

199.22

COMPARISON OF AMINOPHOSPHONOBUTYRIC ACID (AP4)-SENSITIVE EXCITATORY AMINO ACID RECEPTORS MEASURED BY [^{3}H]N-ACETYLASPARTYLGLUTAMATE ([^{3}H]NAAG) BINDING AND IBOTENATE (IBO)-STIMULATED PHOSPHOINOSITIDE HYDROLYSIS. B.G. Johnson * and D.D. Schoepp, Lilly Research Laboratories, Indianapolis, IN 46285.

The binding of [^{3}H]NAAG to brain membranes and the activation phosphoinositide hydrolysis by IBO in brain slices are biochemical parameters which have been previously shown to be selectively inhibited by D,L-AP4. In this study we have further examined if the binding of [^{3}H]NAAG and stimulation of phosphoinositide hydrolysis by IBO are indexing the same or different populations of AP4-sensitive sites in brain. The L-isomer of AP4 selectively inhibited IBO-stimulated phosphoinositide hydrolysis and was 20-times more potent than the D-isomer in competing for [^{3}H]NAAG binding. Likewise, L-serine-O-phosphate, but not D-serine-O-phosphate, selectively inhibits both IBO-stimulated phosphoinositide hydrolysis and [^{3}H]NAAG binding. D,L-aminoproprionic acid (D,L-AP3) was also found to be a relatively potent inhibitor of IBO-stimulated phosphosinositide hydrolysis (IC50% = 113 $\pm$ 11μM). However, at similar concentrations D,L-AP3 does not inhibit [^{3}H]NAAG binding, and concentrations of NAAG up to 1000μM did not stimulate phosphoinositide hydrolysis. Although both assays are sensitive to L-AP4 inhibition they appear to represent disparate excitatory amino acid sites in brain.

AGE-DEPENDENT LOSS OF NMDA RECEPTORS IN RODENT BRAIN. D.T. Monaghan, K.J. Anderson, C. Peterson and C.W. Cotman, Depts. Surgery and Psychobiology, Univ. California, Irvine, CA 92717.

NMDA receptors play a key role in neuronal plasticity as well as excitotoxic mechanisms. The aged nervous system is selectively vulnerable to excitotoxic insults. In this study we have examined the status of the NMDA receptor complex in the aged rodent CNS. Quantitative *in vitro* autoradiographic techniques were used to estimate the density of NMDA receptors in aged (24-26 month-old Fisher 344), middle-aged (4-6 month-old) and infant (14 day-old) rodent brains. [^{3}H] L-glutamate was used to examine the agonist-preferring NMDA recognition sites, [^{3}H] (3-((±)2-carboxypiperazin-4-yl) propyl-1-phosphonic acid (CPP) to examine the antagonist-preferring NMDA sites, and [^{3}H] glycine to examine the glycine allosteric regulation site. For each of these ligands there was a significant reduction of binding to the NMDA receptor complex in select regions of the rat brain. Areas that were especially vulnerable included the striatum, entorhinal cortex and subiculum. It may be significant that the brain regions showing the greatest loss of NMDA receptor binding are known to be sensitive to age-dependent neuropathologies. Loss of striatal neurons occurs in Huntington's disease while Alzheimer's disease is associated with a loss of entorhinal and subicular neurons. Since NMDA receptors have been implicated in the loss of striatal neurons in Huntington's disease, it is tempting to speculate that the loss of NMDA receptors during normal aging may be acting to protect brain regions especially vulnerable to excitotoxic insults.

EFFECTS OF NOVEL ANTAGONISTS AND KINDLING ON NMDA-SENSITIVE ^{3}H-GLUTAMATE BINDING. S.M. Jones, *L.D. Snell and K.M. Johnson, Dept. Pharmacol. & Toxicol., Univ. Texas Med. Br., Galveston, TX 77550.

Buffy coat membranes were prepared from rat cortex according to the method of Kishimoto et al (1981). ^{3}H-glutamate bound with a K_D of 37.2 nM and B_{max} of 2.7 pmol/mg protein. Binding was displaced by NMDA as well as the NMDA antagonists 2-aminophosphonovalerate (APV) and 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) with IC_{50}'s of 2.6μM, 1.1μM, and 0.9μM, respectively. In contrast, kainic acid and α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) had little effect. We feel that this membrane preparation is suitable for screening compounds which act at the NMDA receptor. The NOVA Pharmaceutical Company compounds NPC 12626 (4,5 cyclohexyl-aminophosphonoheptanoate) displaced binding with an IC_{50} of 4.8 μM. This compound also shifted NMDA-enhanced ^{3}H-TCP binding to the right in a competitive fashion. In contrast, 4,5 benzo-aminophosphonoheptanoate (NPC 451) was 100-fold less potent at the NMDA receptor. ^{3}H-glutamate binding was also examined in tissue from amygdaloid-kindled rats three to five weeks following the last stimulation. Preliminary experiments reveal no differences in K_D or B_{max} of ^{3}H-glutamate binding between cortex, hippocampus or amygdala of kindled rats and that of implanted controls. Supported by DA-02073 and NOVA Pharmaceutical Company.

SYNTHESIS, CHARACTERIZATION AND USE OF (+)[^{3}H]MK801 AND SOME DERIVATIVES. J.F.W. Keana*#, M. Scherz*#, P. Barmettler*#, Y. Kitahara*#, M. Quarum*@,M.S.Sonders*@ and E. Weber@ (SPON: C. Russell). #Department of Chemistry, University of Oregon, Eugene, OR 97403 and @Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

MK801 is the most potent and selective ligand recognized to date for the high affinity PCP binding site, and like PCP, blocks cation flux through the NMDA-preferring glutamate receptor. In order to biochemically characterize and ultimately purify the PCP/NMDA receptor, we have synthesized a high specific radioactivity (+)[^{3}H]MK801 and a photoaffinity derivative of it, as well as several nonradioactive congeners.

(+)MK801 was synthesized, N-trifluoroacetylated and then brominated, predominantly yielding a tribrominated derivative. The N-protecting group was removed, the material was converted to the HCl salt and subjected to a catalytic halogen-tritium exchange reaction. Subsequent purification by reverse phase HPLC gave pure (+)[^{3}H]MK801 with a specific activity of 97 Ci/mmol. In radioreceptor assays using guinea pig brain membranes the radioligand displayed a K_d of 2 nM, B_{max} of 1.3 pmol/mg protein and pharmacological profile quite similar to that of [^{3}H]TCP.

Further data will be presented on the use of (+)[^{3}H]MK-801 in solubilizing the PCP/NMDA receptors and on the synthesis and characterization of other derivatives including a photoaffinity analogue of MK801.

199.26

THE LOW AFFINITY STATE OF THE PHENCYCLIDINE (PCP) RECEPTOR: SIMILARITY TO THAT LABELED BY [^{3}H]DEXTROMETHORPHAN? Matthew A. Sills, Michael Williams and Pat S. Loo, * Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

Considerable evidence has accumulated for the existence of an N-methyl-D-aspartate (NMDA)/PCP receptor complex. Previously, multiple states of the PCP receptor were demonstrated (Loo et al., Mol. Pharmacol. 32:820) and compounds such as PCP, MK-801 and dexoxadrol were found to be selective for the high affinity state of this receptor. The present study examined the ability of a series of compounds to inhibit [^{3}H]TCP binding, including the anti-ischemic agents dextromethorphan and trihexyphenidyl, as well as several antipsychotics and antihistaminics. Each compound produced a shallow inhibition curve of [^{3}H]TCP binding in the absence of Mg^{2+} and L-glutamate. In the presence of Mg^{2+} and L-GLU, steep inhibition curves were generated. In contrast to PCP, these compounds were less potent under these conditions, indicating selectivity for the low affinity state of the PCP receptor. A significant ($p < 0.05$) correlation was noted between the activity of these compounds at the low affinity state of the PCP receptor and their ability to inhibit [^{3}H]dextromethorphan binding (Craviso and Musacchio, Mol. Pharmacol. 23:629). These results indicate that [^{3}H]dextromethorphan labels the low affinity state of the PCP receptor and suggests that the two states of the PCP receptor may have functionally distinct roles in the NMDA/PCP receptor complex.

ELECTRON MICROSCOPIC FEATURES OF TENSOR TYMPANI MOTONEURONS IN THE RAT. K.M. Spangler, C.A. Miller* and G.T. Schneider* Dept. Anat., Creighton Univ. Sch. Med., Omaha, NE, 68178.

Computer aided morphometry was performed on examples of electron micrographs of tensor tympani (TT) motoneurons and their synaptic terminals. The results revealed medium sized multipolar motoneurons which received a modest covering of their somata and proximal dendrites with synaptic terminals. The observed synaptic terminals were of four types based on size and shape of the vesicles and the nature of the synaptic density. The most prevalent type of ending contained medium sized synaptic vesicles which were mostly round (length/width ratio<1.25). Occasional dense-cored vesicles were seen in this type of terminal. A second type of ending had vesicles which were slightly larger and more oval in shape (1.25< l/w ratio <1.5). Two other types of endings were rarely seen, one with small round vesicles (max. vesicle size 30-35 nm.) and another type with vesicles which were mostly flat (1/w ratio > 1.5). These findings indicate that TT neurons receive synaptic inputs from several different, as yet unidentified, sources.

DIFFERENT TYPES OF MOSSY FIBER TERMINALS IN THE GUINEA PIG COCHLEAR NUCLEI. M.E. Dunn*, D.E. Vetter, A.S. Berrebi, H.M. Krider* and E. Mugnaini. Lab. of Neuromorphology,U154 and Biotechnology Image Applications Facility, U131, The University of Connecticut, Storrs, CT 06268.

In the cochlear nuclei, there is a mossy fiber-granule cell system, similar to that in the cerebellar cortex, that provides a pathway for the activation of neurons with dendrites situated in the molecular layer of the dorsal cochlear nucleus. It becomes important, therefore, to establish the sources of mossy fibers. Their terminals form the central elements of glomeruli, structurally analagous to those in the cerebellar cortex. By standard electron microscopy, we have identified at least four types of mossy fiber terminals which differ in parameters of internal structure such as features of mitochondrial profiles, density and size of synaptic vesicles, and percentage of dense core vesicles. Some of these parameters were determined visually, while others were measured with the aid of a video-microscopy, computer-assisted image analysis system (Olympus CUE-4- Gould). The experimental animal for this study was the adult NIH-strain guinea pig, but the heterogeneity of cochlear mossy fibers was also recognized in mouse, rat, and cat.

This work was supported by NINCDS NRSA Postdoctoral Fellowship NS-08175 (A.S.B.) and PHS grant NS-09904 (E.M.).

ULTRASTRUCTURE OF THE BAT LATERAL SUPERIOR OLIVE L.K. Owen*, J.M. Zook and R.A. DiCaprio. Dept. of Zoological & Biomedical Sciences and Basic Sciences, COM, Ohio Univ., Athens, OH 54701

The normal ultrastructure of the lateral superior olive (LSO) was examined with the electron microscope in two echolocating bat species: Eptesicus fuscus and Pteronotus parnellii. In general, ultrastructural features of the LSO in both species resemble those seen in other mammals. Synaptic terminals containing large, flattened vesicles form the principal contacts upon the somatic surface of LSO fusiform cells. Synaptic terminals with large, round vesicles contact both the large, proximal dendrites and small, distal dendrites of these cells.

In further experiments, axons of principal cells of the medial nucleus of the trapezoid body were filled intracellularly with horseradish peroxidase (HRP) in an in vitro tissue slice preparation of the brainstem of these two bat species. Preliminary ultrastructural examination of the terminal field of these labeled axons in the LSO suggests that the medial nucleus of the trapezoid body is the source of the synaptic terminals containing flattened vesicles.

ULTRASTRUCTURAL STUDIES OF SYNAPTIC TERMINALS IN THE RAT MEDIAL SUPERIOR OLIVARY NUCLEUS. M.A. Casey. Dept. of Cell Biol. and Anat., University of Alabama at Birmingham, Birmingham, AL 35294.

Neurons in the medial superior olivary nucleus (MSO) are binaurally innervated via projections from the left and right ventral cochlear nuclei. The ultrastructure of the cat MSO has been well characterized (Clark, 1969; Lindsey, 1975; Schwartz, 1980; Kiss and Majorossy, 1983), but the ultrastructure of the rat MSO has not been described prior to the present study. In rats only about 36% of the perikaryal surface is apposed to synaptic endings, while in cats the percent coverage is about 84% (Schwartz, 1980). The vast majority of axosomatic synaptic termials in the rat MSO contain pleomorphic synaptic vesicles and exhibit symmetrical membrane specializations (Type 2 terminals), while in cats, terminals containing large spherical vesicles and asymmetrical synapses (Type 1 terminals) predominate on the soma. Type 1 terminals are predominant on dendrites in the neuropil of the MSO in cats and rats. Type 3 terminals, containing densely packed small spherical vesicles, form less than 5% of the axosomatic terminal population in the rat MSO.

While the synaptology of the lateral superior olivary nucleus (LSO) is essentially the same in the rat and cat (Cant, 1984; Casey, 1986), the arrangement of axosomatic synaptic terminals in the MSO differs markedly in the two species. (Supported by NIH grant AG06188)

200.5

ULTRASTRUCTURAL CHARACTERIZATION OF GABA AND GLYCINE IMMUNO-REACTIVE SYNAPSES IN THE GUINEA PIG SUPERIOR OLIVARY COMPLEX. R.H. Helfert, J.M. Bonneau,* R.J. Wenthold, + and R.A. Altschuler. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109, and +Lab. of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20892

Immunoperoxidase immunocytochemistry was performed on aldehyde-fixed semi-thin sections to assess the distribution of GABA and glycine (GLY) in four major superior olivary complex (SOC) nuclei: the lateral superior olive (LSO), medial superior olive (MSO), medial trapezoid nucleus (MTN) and superior paraolivary nucleus (SPN). The fine structure of the immunoreactive (IR) synapses was evaluated using colloidal gold immuno-electron microscopy.

There was little variability in the morphology of GLY IR synapses among the SOC nuclei. They contained pleomorphic "flat" vesicles and possessed punctate symmetrical membrane specializations separated by a 20 nm synaptic cleft. Light microscopic evaluation showed that most of the somal surface (>65%) of the LSO principal neurons, and the SPN radial neurons, was apposed to GLY IR puncta. These puncta were also seen, to a lesser extent, on the proximal dendrites of these cells. Most perikarya in the MSO central cell band possessed GLY IR puncta on >50% of their surface and on >35% of the surface of their proximal dendrites. Small numbers of GLY IR puncta were observed scattered on MTN somata.

GABA IR synapses were found, in small numbers, on most neurons in the SOC. Unlike the GLY IR synapses, variations in the morphology of GABA IR snyapses were observed. In the LSO, all GABA IR presynaptic terminals were packed with pleomorphic "oval" vesicles and were ~1.25 µm in diameter. These terminals were also identified on the somata and dendrites of neurons in the MSO and MTN. A second type of GABA IR terminal was observed less frequently on MSO dendrites; they were smaller (~1µm wide by 0.75 µm in elevation) and contained very few pleomorphic vesicles. A third type of GABA IR synapse, containing a few dense core vesicles in addition to the electron-lucent pleomorphic "oval" vesicles, was encountered on small caliber dendrites in the SPN. This type is similar, morphologically, to a class of synapses contacting neurons of both the lateral and medial olivocochlear system (R.H. Helfert, I.R. Schwartz, and A.F. Ryan, J. Neurosci., in press).

These data suggest that there may be at least three sources of GABAergic input to the SOC nuclei. Whether or not this is the case for glycinergic input remains to be seen.

STRUCTURE OF SYNAPTIC CALYCES AND THEIR POST-SYNAPTIC TARGETS IN THE VENTRAL NUCLEUS OF THE LATERAL LEMNISCUS IN THE GUINEA PIG. B. R. Schofield and N. B. Cant Dept. Anatomy, Duke Univ., Durham, NC 27710

We have used the light and electron microscopes to examine synaptic calyces in the ventral nucleus of the lateral lemniscus (VNLL) in the pigmented guinea pig, Cavia cobaya. Calyces as well as many smaller axon terminals are labelled by anterograde transport after injections of Fast Blue into the contralateral cochlear nucleus. Each calyx arises from a large axon that splits into numerous tendrils that encircle a neuronal cell body.

In the electron microscope, calyces are characterized by their large size (spanning up to 9 um) and round synaptic vesicles. They usually contact somas, which also synapse with smaller terminals. Some of these smaller terminals contain round vesicles and may be branches of the calyx; others contain pleomorphic or flat vesicles.

The structure of calyces in the VNLL is similar to that of endbulbs in the anteroventral cochlear nucleus and calyces in the medial nucleus of the trapezoid body, where these terminals ensure fast, secure synaptic transmission. Since virtually every cell in VNLL projects to the inferior colliculus (IC) (e.g., Adams'79, J. Comp. Neurol. 183:519-538), calyces in the VNLL probably participate in fast disynaptic pathways to the IC.

Supported by NIH Grants NS14655 and MH15177.

THALAMOCORTICAL SYNAPSES WITH GOLGI-IMPREGNATED, GABAERGIC AND PEPTIDERGIC NEURONS IN MONKEY AUDITORY CORTEX. A. Keller, E. L. White and P. B. Cipolloni. Dept. Morphol., Fac. Health Sci., Ben Gurion Univ., Beer Sheva, ISRAEL; and Depts. of Anat. and Neurol., Boston Univ. School of Medicine, Boston, MA 02118.

Thalamocortical inputs to identified neurons in the auditory cortex of the monkey were examined. Bipolar electrodes were inserted into the medial geniculate nucleus (MGN), and electrolytic lesions were placed in the electrophysiologically-identified MGN to label thalamocortical axon terminals, by lesion-induced degeneration. Four days later, the animals were perfused with aldehydes, and blocks of tissue containing the primary auditory cortex (area KA) were Golgi-impregnated. The blocks were then cut at 120µm, and the sections gold-toned and embedded in plastic. Labeled nonpyramidal neurons were drawn and photographed with a light microscope, and then thin sectioned and processed for electron microscopy. The selected neurons were studied in serial thin sections to determine the distribution of thalamocortical synapses they received. A postembedding immunocytochemical procedure was employed to label the somata belonging to the selected neurons, using antisera to GABA, somatostatin, and choleocystokinin (CCK). All of the nonpyramidal neurons were immunoreactive for GABA. Two of the GABA-immunoreactive neurons were also CCK - positive, and one stained with the antiserum to somatostatin. In no instance were GABAergic cells immunoreactive for both peptides. Supported by BSF grant #8600041/1 , and the Institute for Neurologic Research, Inc.

DISTRIBUTION OF VIMENTIN IN THE GUINEA-PIG COCHLEA. **E.C. Oesterle[1]*, V.J. Sarthy[2], and E.W Rubel. (SPON: R.A. Code). Depts. of Otolaryngology[1] and Ophthalmology[2], Univ. of Washington, Seattle, WA 98195.**

The hypothesis that proteins known to occur in glial cells of the CNS may be present in inner-ear supporting cells was investigated. The main rationale was to determine if vimentin, an intermediate filament protein present normally in certain types of CNS glia, could be used as a marker to identify particular cell types in the auditory end organ. The distribution of vimentin was explored in cochleae of adolescent and adult guinea pigs at the light microscope level using monoclonal antibodies directed against vimentin. Immunocytochemical localization using indirect immunofluorescence and avidin-biotin-peroxidase methods labels a variety of structures in the cochlea. Within the organ of Corti staining is observed in Deiters' cells, one type of supporting cell in the end organ. Immunoreactivity is also observed in the following inner-ear structures: fibroblasts in the spiral ligament, external sulcus cells, some Claudius cells, tympanic border cells, cells lining the perilymphatic surface of Reissner's membrane, satellite-cell processes in the habenular opening, Schwann-cell processes surrounding the cell bodies and peripheral processes of spiral ganglion cells, and areas of the spiral limbus. Results demonstrate that vimentin may be a useful marker for the identification of Deiters' cells from other end-organ cells. (Supported by NIH Grant NS24522 and the Deafness Research Foundation).

COMPARATIVE AMINO ACID LEVELS IN THE HEARING ORGANS OF RAYS, CHICKENS AND MAMMALS. G.M. Bryant, G.G. Ceasar* and R.P. Bobbin. Kresge Hearing Research Lab., LSU Medical Center, New Orleans, LA 70112.

With the advent of immunocytochemical techniques, there are numerous reports on the presence of putative neurotransmitters in heretofore unsuspected locations. For example, Fex et al. (Brain Res. 366:106, 1986) have found GABA immunostaining in a small number of efferent endings in the upper turns of the cochlea and Usami et al. (Hearing Res. 30:19, 1987) reported GABA-like immunoreactivity in the cytoplasm of hair cells of the basilar papilla of the chicken. In an effort to relate the histological findings to biochemical levels, we tested the hypothesis that the amount of GABA in the guinea pig cochlea is small in comparison to that found in the chick basilar papilla. Whole tissue homogenates were analyzed by gradient-elution, reverse-phase HPLC which allowed the determination of endogenous levels of GABA plus 12 other amino acids. The results show that the guinea pig cochlea has 5 times as much GABA as the chick basilar papilla on a per ug protein basis.

200.10

RELEASE OF ENKEPHALINS AND DYNORPHINS AT A MULTITRANSMITTER SYNAPSE IN THE COCHLEA. D.W. Hoffman, R.D. Edkins*, and K.L. Jones-King*. Neurochemistry Lab., Dept. of Psychiatry and Pharmacology, Dartmouth Medical School, Hanover, NH 03756.

The mammalian cochlea is innervated by efferent fibers which arise in the brainstem. These fibers comprise two systems which separately innervate the eighth nerve dendrites under inner hair cells, and the bases of the outer hair cells themselves. The efferent fibers appear to be cholinergic, but the fibers under inner hair cells also contain enkephalins and dynorphins. We use the cochlea as an in situ perfusion chamber to study neurochemical interactions of the neurotransmitters and neuromodulators co-localized in the efferent nerve terminals in the cochlea. Met- and leu-enkephalin, dynorphin B and ACh have all been shown to be released in cochlear perfusate by high potassium or veratridine. Peptides are measured by HPLC-RIA, and ACh by radioenzymatic assay. We are currently assaying the effects of neuropeptides and ACh on each others' release processes.

IDENTIFICATION OF A PROTEIN PRIMARILY LOCALIZED TO THE COCHLEAR NUCLEUS. L. Winsky, and D.M. Jacobowitz, Lab. of Clinical Science, NIMH, Bethesda, MD 20892.

In a previous report (Winsky et al., 1987 Soc. Neurosci. Abs. 250.14), large differences were found in the content of several proteins within the auditory system of rabbits. The present study was aimed at providing a similar comparison of proteins within the central auditory system of guinea pigs. Micropunch samples were obtained from the ventral and dorsal cochlear nuclei as well as the lateral superior olive, nucleus of the lateral lemniscus, inferior colliculus, medial geniculate and auditory cortex. Proteins were separated using two-dimensional gel electrophoresis and were visualized by a silver stain method. Results indicated one protein which was consistently greater in amounts in both the dorsal and ventral cochlear nuclei as compared with other regions examined. Protein separation using more discrete micropunches of the dorsal cochlear nucleus (DCN) suggested that this protein is found predominantly within the principle cell layer of the DCN with much less in the molecular/granule cell region. Finally, preliminary findings suggested that the amounts of this protein may decrease following destruction of the cochlea.

The MW (29 kD), pI (5.2) and appearance of this protein on gels was similar to a cochlear-specific protein identified in both rabbits and rats. Possibly, this protein could be associated with either direct projections from the cochlea via the auditory nerve or cell types which are intrinsic to the cochlear nuclei.

CALBINDIN LABELS AUDITORY NUCLEI IN THE MUSTACHED BAT. M.L. Zettel, C.E. Carr[1], W.W. Wilson & W.E. O'Neill. Depts. of Physiology, and Neurobiology and Anatomy[1], Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Echolocation places a premium on processing rapid acoustic events, which might correlate with fast recovery in auditory neurons. One proposed function of Calbindin is that of an intraneuronal calcium buffering system, which could enhance temporal coding. We therefore used antibodies against calbindin to examine the auditory pathways in the mustached bat. The primary antibody was a rabbit anti-monkey cerebellar serum monospecific for 28 kD CaBP (courtesy Dr. K. Baimbridge), and the secondary was a biotinylated protein A (Dr. R. Sloviter).

Calbindin D-28k prominently stained auditory nuclei. In Cochlear Nucleus (CN), Anteroventral CN showed staining in spherical cells of the anterior group as well as multipolar cells of the medial group. Posteroventral CN had extensive neuropilar and light somatic labeling throughout while Dorsal CN had label only in lateral superficial cells. Lateral Lemniscus had strong somatic labeling in all nuclei, with stained neuropil and a striking cellular banding pattern in both divisions of Ventral nucleus. The Sup. Olives and Trapezoid Bodies stained darkly and uniformly. Labeled cells were scattered throughout Central Nucleus of Inferior Colliculus except for Medial division, where many cells were darkly stained. Medial Geniculate had darkly labeled neuropil and somata in Dorsal division and to a lesser extent in Medial division. Supported by NSF BNS-8617152 to WEO.

GABA AND GLYCINE IMMUNOREACTIVITY OF DESCENDING AND COMMISSURAL INPUTS TO THE COCHLEAR NUCLEUS IN GUINEA PIG.

E.-M. Ostapoff, C. Staatz-Benson, D.K. Morest, S.J. Potashner, and R.L. Saint Marie. Department of Anatomy and Center for Neurological Sciences, University of Connecticut Health Center, Farmington, CT 06032.

Retrograde transport of HRP from the cochlear nucleus was combined with pre-embedding immunocytochemistry to determine which inputs might use GABA or glycine as a neurotransmitter. Nearly all of the neurons immunoreactive (+) for GABA or glycine and projecting to the cochlear nucleus were from periolivary regions of the superior olivary complex. Most GABA+ projection neurons were seen in the ventral trapezoid nucleus, bilaterally. Most glycine+ projection neurons were seen in the lateral trapezoid nucleus, ipsilaterally, and in the ventral trapezoid nucleus, bilaterally. Most commissural neurons in the contralateral cochlear nucleus were glycine+, a few were GABA+. Although there were many GABA+ neurons in the inferior colliculus, GABA+ neurons projecting to the cochlear nucleus were rare. Glycine+ neurons were not detected in the inferior colliculus.

The results suggest that some of the projections to the cochlear nucleus in guinea pig may use GABA or glycine as a neurotransmitter. These include projections from the superior olivary complex and the contralateral cochlear nucleus.

TARGETS AND DISTRIBUTION OF THE CARTWHEEL CELL AXON IN THE GUINEA PIG DORSAL COCHLEAR NUCLEUS.

A. S. Berrebi and E. Mugnaini. Laboratory of Neuromorphology, U-154, The University of Connecticut, Storrs, CT 06268.

We have previously shown that PEP-19, a neuron-specific calcium binding polypeptide, represents an excellent immunocytochemical marker for dorsal cochlear nucleus (DCoN) cartwheel neurons. In guinea pig hindbrain, only cerebellar Purkinje neurons and DCoN cartwheel neurons are densely stained with a rabbit antiserum (gift of Dr. J. I. Morgan). The deeper branches of the cartwheel cell axons demarcate layer 3 of DCoN. By electron microscopic pre-embedding immunocytochemistry, we have found that cartwheel neurons have two primary targets in the superficial layers of DCoN: 1) cells of the same class and 2) the cell bodies and basal dendrites of fusiform cells, the only projection neurons of the superficial layers (which project to the central nucleus of the inferior colliculus). Thus, cartwheel neurons, the most numerous of the inhibitory local-circuit neurons, must be largely responsible for modulation of fusiform cell output. These findings were obtained in adult NIH-strain guinea pigs, but similar observations have been made in mouse and rat.

LOCALIZATION OF THE GABAA/BENZODIAZEPINE RECEPTOR COMPLEX IN THE GUINEA PIG COCHLEAR NUCLEUS: LM & EM IMMUNOCYTOCHEMICAL STUDIES.

J.M. Juiz*, R.H. Helfert, R.J. Wenthold and R.A. Altschuler. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109, LNO, NIH, Bethesda, MD

Immunocytochemical studies using antibodies to GABA and GAD as well as pharmacological, biochemical and receptor binding studies all suggest that the inhibitory amino acid GABA is a major transmitter in the cochlear nucleus. Recent studies showing co-containment of GABA and glycine immunostaining in cells and terminals in the cochlear nucleus as well as GABA and GAD immunostaining terminals apposed by glycine receptor immunoreactivity (Wenthold et al. 1987, Oberdorfer et al. 1988) have raised questions about localization of the GABA receptor complex. As a part of studies to characterize GABAergic synapses in the cochlear nucleus and their relationship to GABA and glycine receptors we have used recently developed monoclonal antibodies to the GABAA/Benzodiazepine receptor complex (deBlas et al. 1988) to study the distribution of this complex in the guinea pig cochlear nucleus at the light and electron microscopic level. Immunoperoxidase and immunofluorescence techniques were used on free-floating and cryostat sections respectively for light microscopic evaluation of the cochlear nucleus, pre-embedding immunoperoxidase and immunogold techniques were used for the ultrastructural evaluation.

GABA receptor complex immunoreactive staining was seen at the light microscopic level in all divisions of the cochlear nucleus with a general distribution similar to that of GABA immunoreactive terminals but with heavier distribution in the granule cell cap. An intracellular cytoplasmic labeling was seen in many small cells and fusiform cells in the dorsal cochlear nucleus. At the ultrastructural level most labeling was associated with the active zone of axo-somatic and axo-dendritic synapses, usually post-synaptic to terminals containing oval/pleomorphic vesicles. A significant amount of cytoplasmic immunostaining was evident, both in dendrites and soma. At some synapses pre-synaptic label was also seen opposite the post-synaptic label. This would suggest that a major synaptic action of GABA is post-synaptic but that at some synapses there may also be a pre-synaptic, perhaps feed-back function.

RELEASE OF AMINO ACIDS IN THE GUINEA PIG COCHLEAR NUCLEUS AFTER ABLATION OF THE INFERIOR COLLICULUS.

M. Bergman and S. J. Potashner. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032

This study determined if projections from the inferior colliculus (IC) to the cochlear nucleus (CN) might use amino acid transmitters. Surgical ablation removed approximately 84% of the left IC without damage to other auditory structures in the brain stem. Five days after the ablation, the electrically-evoked calcium-dependent release of [3H]-D-aspartate and [14C]-GABA from the anteroventral, posteroventral, and dorsal CN were unaffected. The release of [14C]-glycine was depressed by 47% in the anteroventral CN bilaterally, but not in the other CN subdivisions. These findings suggest that fibers projecting from the IC to the CN probably do not use glutamate, aspartate or GABA as transmitters. Similarly, collicular projections to the dorsal and posteroventral CN probably do not use glycine as a transmitter. However, glycine might be a transmitter of some collicular fibers projecting to the anteroventral CN. (Supported by NS 19036 from NINCDS).

CALBINDIN IMMUNOSTAINING OF THE AUDITORY BRAINSTEM,

J. C. Adams, M. Thomasset,* E. Mugnaini and S. Christakos*. ENT Dept., Med. Univ. S.C.; INSERM U.120., Le Vesinet, France; Lab. of Neuromorphology, Univ. Conn., Storrs, CT 06268; Dept. Biochem. N.J. Medical School, Newark, N.J.

Immunostaining in the auditory brainstem of rat and cat using antisera to calbindin shows some staining in all nuclei. The number of cell classes that stain is limited and much about relations of cell classes can be learned from the staining patterns. In the ventral cochlear nucleus a small number of cells in the region of the nerve root are stained. In the dorsal cochlear nucleus the cartwheel cells are stained. Various sized terminals are stained throughout the cochlear nucleus. In the olivary complex all principal cells of the medial nucleus of the trapezoid body are densely stained, as are some cells in the lateral superior olive and in the lateral trapezoid nucleus. Dense pericellular terminals are stained in principal olivary nuclei and in limited periolivary regions. Stained cells are present in the lemniscal nuclei. Many stained cells are present in extracentral portions of the inferior colliculus, the sagulum, and brachium of the inferior colliculus. Large numbers of cells are stained throughout the medial geniculate body. Overall immunostaining in rat and cat is in register but there are exceptions. The most obvious is that some neurons in the dorsal nucleus of the lateral lemniscus stain in rat but not in cat.

200.18

TRANSPORT OF 3H-GLYCINE TO THE SUPERIOR OLIVARY COMPLEX FROM THE COCHLEAR NUCLEUS IN THE GUINEA PIG.

C. Staatz-Benson and S. J. Potashner, Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Glycine may be a transmitter of some descending fibers synapsing in the mammalian cochlear nucleus. Possible sources of descending projections to the cochlear nucleus were identified using retrograde labelling with horseradish peroxidase (HRP). HRP (20% w/v) with 1% peroxidase labelled wheat germ agglutinin was injected into the guinea pig cochlear nucleus. After 24 hours labelled neuronal cell bodies were found bilaterally in all the periolivary nuclei, in the inferior colliculus and in the contralateral cochlear nucleus.

Retrograde labelling with 3H-glycine was used to determine which of these structures provide glycinergic projections to the cochlear nucleus. 3H-Glycine (0.3-0.8 ul; 53 Ci/mmol; 19-380 uM) was injected into the guinea pig cochlear nucleus. After 6-48 hours retrogradely labelled neuronal cell bodies were found ipsilaterally in the ventral and lateral nuclei of the trapezoid body, the dorsal and anterolateral periolivary areas, and the vestibular nuclei. These results suggest that some of the glycinergic synaptic endings in the cochlear nucleus may be contributed by fibers projecting from the ipsilateral periolivary area. (Supported by grant NS 19036 from NIH-NINCDS.)

DISTRIBUTION OF CHOLINE ACETYLTRANSFERASE ACTIVITY IN THE TRAPEZOID BODY OF THE RAT. D.A. Godfrey, L. Carlson*, J.A. Parli* and C.D. Ross. Dept. of Physiology, Oral Roberts University, Tulsa, OK 74171

Since our previous studies suggested that centrifugal cholinergic innervation reaches the rat cochlear nucleus via the trapezoid body, the distribution of choline acetyltransferase (ChAT) enzyme activity was mapped within this tract in 5 albino rats. ChAT catalyzes the synthesis of acetylcholine and is a reliable marker for cholinergic neurons. ChAT activity was measured for contiguous pieces microdissected from freeze-dried sections. A detailed map for one of the rats was based on 31 transverse sections spaced at 60 μm intervals. Adjacent sections histochemically stained for acetylcholinesterase activity were used to identify pieces containing facial nerve root or parasympathetic fibers which cross through the trapezoid body. The rostral and middle parts of the trapezoid body contained higher ChAT activity than the caudal part. At each rostro-caudal level ChAT activity laterally in the trapezoid body was higher in its ventrolateral portion than in its dorsomedial portion, but farther medially the ChAT activity was often higher dorsally than ventrally. These results are consistent with cholinergic fibers mostly entering the trapezoid body in its middle and rostral parts, from a more dorsal location at a point just medial to where it courses under the spinal trigeminal tract, and moving superficially as they move laterally to enter the cochlear nucleus. (Supported by NIH grant NS17176).

MULTIPLE CELL TYPES HAVE GABA IMMUNOREACTIVITY IN THE INFERIOR COLLICULUS OF THE CAT. D.L. Oliver, S.C. Nuding, and G. Beckius*. Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Neurons in the central nucleus of the inferior colliculus were analyzed after immunocytochemical localization of GABA (Wenthold et al., 1987, Brain Res. 380: 7-18). Several types of immunoreactive cells can be distinguished by the size and orientation of their somata and by the visible portions of the proximal dendrites. For example, small cells in one sample have average diameters of 17-18 μm (range 12-20 μm), while medium-sized cells have average diameters of 24-26 μm (range 20-32 μm). Some labeled neurons have somata and proximal dendrites oriented parallel to the fibrodendritic laminae of the central nucleus. These may be disc-shaped neurons. Other neurons have cell bodies and proximal dendrites oriented orthogonal to the laminae and may be stellate cells.

The results suggest that many of the small disc-shaped and stellate cells in the central nucleus may use GABA as a neurotransmitter. Small cells represent only 10-15% of the cells in the central nucleus but about half of the present sample. The medium-sized immunoreactive cells could be special types of stellate and disc-shaped neurons.

(Sponsored by grant R01 NS18391 from NINCDS.)

201.2

RETROGRADE TRANSPORT OF 3H-GLYCINE FROM INFERIOR COLLICULUS TO NUCLEI OF THE LATERAL LEMNISCUS AND SUPERIOR OLIVE. R.L. Saint Marie, R.A. Baker, and D.K. Morest. Department of Anatomy and Center for Neurological Sciences, Univ. of Connecticut Health Center, Farmington, CT 06032.

Retrograde transport of ^{3}H-glycine was used to identify possible sources of glycinergic inputs to the inferior colliculus in chinchilla and guinea pig. Radiolabeled cells were found only ipsilaterally after survival times up to 26 hours. Cells in the ventral nucleus of the lateral lemniscus, the lateral superior olive, and the dorsomedial periolivary nucleus were heavily labeled after survival times as short as 6 hours. Cells in other periolivary nuclei were less heavily labeled.

Retrograde transport of HRP from the inferior colliculus in each of the cases confirmed additional projections that did not accumulate glycine. These included contralateral projections from the inferior colliculus, dorsal nucleus of the lateral lemniscus, lateral superior olive, periolivary nuclei, and cochlear nucleus, and ipsilateral projections from the medial superior olive and cochlear nucleus.

The results suggest that some of the uncrossed inputs to the inferior colliculus from nuclei of the superior olivary complex and lateral lemniscus may use glycine as a neurotransmitter, whereas crossed inputs from these regions and inputs from the medial superior olive and cochlear nucleus probably do not.

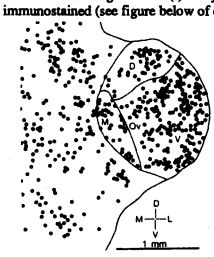
201.3

GLUTAMATE IS A MAJOR TRANSMITTER IN THE RAT MEDIAL GENICULATE BODY. J. M. Popowits*, D.T. Larue, and J.A. Winer (SPON: J.J. Wenstrup). Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The relative simplicity of the rat medial geniculate body is a model system for the study of neurotransmitters. Few neurons (~1%) are GABAergic (J.A. Winer and D.T. Larue, *J. Comp. Neurol.* [in press]), and most of the others appear to project to the cortex (J.A. Winer and D.T. Larue, *J. Comp. Neurol.* 257:282-315 [1987]). However, the thalamocortical transmitter is unknown, and its identity is the goal of this study.

Anesthetized adult rats were perfused at 4°C with Krebs-Ringer's, followed by carbodiimide-glutaraldehyde, then glutaraldehyde or glutaraldehyde-paraformaldehyde. Vibratomed sections were immunostained using the avidin-biotin technique (S.M. Hsu et al., *J. Histochem. Cytochem.* 29:1349-1353 [1981]) and a monoclonal antibody to a glutamate-keyhole limpet hemocyanin conjugate (see J.E. Madl et al., *J. Histochem. Cytochem.* 34:317-326 [1986]) at a 1:20,000 dilution. Controls processed without the primary antibody showed no specific immunostaining.

The main findings are that (i) many neurons in each auditory thalamic subdivision are immunostained (see figure below of cell plots), including their primary dendrites;



(ii) there are regional differences in the intensity of immunostaining, with the darkest cells in the medial division, the palest in the dorsal division, and the ventral division intermediate; (iii) glutamatergic neurons include the largest medial geniculate cells; (iv) interspersed among, and in the same focal plane as the glutamatergic neurons, are many glutamate-negative neurons. Other transmitters besides GABA and glutamate may be present in the medial geniculate complex.

This research was supported by United States Public Health Service Grant RO1 NS16832-08. We thank Drs. A.J. Beitz and J.E. Madl for the generous gift of monoclonal antibody.

201.4

THE GABAERGIC NEURONAL ORGANIZATION OF LAYER I IN RAT AUDITORY CORTEX. D.T. Larue and J.A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The neurons and puncta (axon terminals) immunostained for glutamic acid decarboxylase (GAD) were studied in layer I of rat area 41. Male rats were perfused with zinc salicylate/formalin (after E. Mugnaini and A.-L. Dahl, *J. Histochem. Cytochem.* 31:1435-1438 [1983]) and 25-50 μm-thick frozen or Vibratome sections were immunostained with GAD-1440 (W.H. Oertel et al., *Neuroscience* 6:2689-2700 [1981]) and the avidin-biotin immunoperoxidase technique (S.M. Hsu et al., *J. Histochem. Cytochem.* 29:1349-1353 [1981]).

More than 90% of layer I cells were GAD positive (GAD+) in semi-thin (1 μm-thick) sections cut from pre-reacted tissue. Members of each of the four types of neurons identified in Golgi material were represented. The mean somatic area of GAD+ neurons (59±21 μm^2) indicates that small and medium-sized cells predominate. Some cells have dendrites immunostained for almost 100 μm, well past their secondary branch points. Control sections incubated in pre-immune serum showed no specific staining.

Clusters of 3 to 9 GAD+ cells/100 μm of cortex are common, usually separated by cell-poor intervals of 100 μm or more. Indeed, most GABAergic neurons are within dendritic proximity to each other. GAD+ cells were twice as numerous in the lower half of layer I compared to the superficial half. Puncta were also non-uniformly distributed, being densest in the upper and lower parts of the layer and sparser in the middle.

Since layer I receives thalamic (D.K. Ryugo and H.P. Killackey, *Brain Res.* 82:173-177 [1974]), callosal (D.W. Vaughan, *Brain Res.* 260:181-189 [1983]), and intrinsic (A. Sousa-Pinto et al., *Brain Res.* 95:443-458 [1975]) input, and extrathalamic axons immunoreactive for serotonin, choline acetyltransferase, tyrosine hydroxylase, and dopamine-β-hydroxylase (M.J. Campbell et al., *J. Comp. Neurol.* 261:209-220 [1987]), the largely GABAergic neuronal population could serve as a common pathway for these diverse influences.

This research was supported by United States Public Health Service Grant RO1 NS16832-08. We thank Drs. D.E. Schmechel and E. Mugnaini for their generous gift of antiserum and technical advice.

WELL-DEVELOPED BRAINSTEM AUDITORY NUCLEI IN MANATEES TRICHECHUS MANATUS. J. I. Johnson, Anat. Dept., Mich. State U., E. Lansing, MI 48824; R. L. Reep, Dept. Neurosci., U. Fla., Gainesville, FL 32610; R. C. Switzer III, Depts. Pathol., Med. Biol., U. Tenn., Knoxville, TN 37920; J. A. W. Kirsch, Dept. Zool., and W. I. Welker, Dept. Neurophysiol., U. Wis.-Mad., Madison, WI 53706

Sections through brain stems of 5 manatees, in 3 planes, with Nissl, myelin or cytochrome oxidase stains show: Cochlear nuclei as in other auditorily specialized mammals -- the anteroventrals are large, as are the posteroventrals which hang outside the brain stem along the 8th nerve, capped by the rudimentary dorsals. The superior olives show prominent small-celled lateral nuclei, linear medial nuclei bounded by cell free regions, and large-celled nuclei of the trapezoid body. The nuclei of the lateral lemniscus are particularly massive with distinctive subnuclei. The large inferior colliculi resemble those of other audition-oriented species. (Supported by NSF grant BSR 85-03687.)

CENTRAL PROJECTIONS OF INDIVIDUAL AUDITORY NERVE FIBERS IN THE ALLIGATOR LIZARD (*GERRHONOTUS MULTICARINATUS*).

M.R. Szpir, S. Sento and D.K. Ryugo. Department of Anatomy and Cellular Biology, Harvard Medical School, Boston, MA 02115; Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA 02114; and Center for Hearing Sciences, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The auditory ganglion cells of the alligator lizard give rise to two types of peripheral fibers: tectorial fibers which contact hair cells covered by a tectorial membrane, and free-standing fibers which contact hair cells without a tectorial membrane. We examined the central projections of these ganglion cells after they were labelled with intracellular and extracellular injections of horseradish peroxidase. The tissue was processed with diaminobenzidine which produced a continuous labelling of the axons and terminals, enabling the correlation of the peripheral and central targets of the ganglion cells. Cells whose peripheral processes contact tectorial hair cells project to all three divisions of the cochlear nucleus: N. magnocellularis lateralis (NML), N. magnocellularis medialis (NMM), and the lateral part of N. angularis (NA). Cells whose peripheral processes contact free-standing hair cells project primarily to the medial part of NA, but a few cells also project a single, thin branch to NML. The cells contacting free-standing hair cells do not project to NMM. Tectorial fibers have a greater mean axonal diameter, form a greater number of terminal swellings, and make proportionally more somatic contacts. Electrophysiological studies have shown that tectorial fibers are tuned to low frequencies (100-800 Hz), whereas free-standing fibers are tuned to high frequencies (900-4000 Hz; Weiss, T.F. et al., *Brain Res.* 115:71-90, 1976). Thus, our anatomical results reveal that the different divisions of the cochlear nucleus are associated with particular frequency ranges, and suggest that these frequency ranges are processed differently in the brain. (Supported by NIH grants NS13126, NS20156, and an Albert J. Ryan fellowship to MRS).

201.7

"Holes" in the Gerbil Auditory System Do Not Cause Major Changes in Neuronal Populations in the PVCN. I.R. Schwartz & R. Karnofsky*, Div. Otolaryngology, Yale School of Med., New Haven, CT 06510

To assess possible changes in neuronal populations, size and number of neurons and "holes" (micro-cystic structures first described in the gerbil by Ostapoff et al, ARO Absts. 10:209, 1987) were measured in the posterior ventral cochlear nucleus (PVCN) of gerbils aged 3 & 12 months (M). The 3M gerbil is a fully mature adult & holes are sparse; 12M gerbils are still reproductively active and have attained less than 1/3 of their normal life span, but holes are prominent.

Serial slices (150-250μ) of mixed aldehyde fixed brains were osmicated, uranyl block stained and embedded in Epon. Number and size of neurons (only nucleus containing profiles) and holes were digitized from camera lucida drawings of 1μ plastic sections of the faces of serial transverse slices of the brainstem. Total PVCN volumes were estimated by summing the area occupied by PVCN and multiplying by the slice thickness. Three PVCNs at each age were measured.

Neither the number of neurons/section (3M-132.7±20.8, 12M-144.4±27.2), the % of total area occupied by neurons (3M-8.70±1.8, 12M-7.65±1.85) or total PVCN volumes were significantly different between the two ages. Holes occupy ≈3% of the 3M PVCN (3.17±1.42); ≈9% (8.70±1.84) at 12M. Holes/section at 3M=24.3±9.0; at 12M=64.4±24.2). Since variability within groups and the small sample size could have obscured small differences in neuron numbers and PVCN volume, additional material is being measured.

The absence of major changes in neuronal populations in the presence of substantial increases in the number and volume of holes suggests that hole formation is not directly related to any particular neuronal perikaryal population. Rather, it may be a dynamic process not necessarily resulting in cell loss.

201.8

AXONAL PROJECTIONS OF PHA-L-LABELED NEURONS IN THE MEDIAL NUCLEUS OF THE TRAPEZOID BODY. S.C. Bledsoe, Jr., P.Pandya*, R.A. Altschuler, and R.H. Helfert, Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109.

The medial nucleus of the trapezoid body, (MNTB) is a major relay nucleus in the superior olivary complex and is thought to be an important component in the processing of binaural input. Several studies have described the projection of MNTB neurons in the cat (Morest *et al, 1968;* Spangler *et al, 1985;* Glendenning *et al, 1985*); however, a detailed description of the projection of this nucleus is lacking in the guinea pig, which has been the subject of numerous biochemical, physiological, and immunocytochemical studies.

In this study, the anterograde neuronal tracer *Phaseolus vulgaris* leucoagglutinin (PHA-L) was iontophoresed into the guinea pig MNTB to study the distribution of the terminal arborizations of its neurons. PHA-L offers advantages over other conventional tracers to elucidate axonal projections, such as the discrete deposition of tracer within a well-defined area (normally <1 mm in diameter), and the small numbers of neurons labeled which allows for greater ease in delineating the projection patterns of individual neurons.

The projection of the guinea pig MNTB appeared to be entirely ipsilateral. There also appeared to be a topographical organization to this nucleus which was preserved in many, if not all, of the nuclei it projected to. Labeled axons were seen terminating within the MNTB. Labeled neurons in the MNTB produced terminal aborizations with beaded expansions and terminal boutons which surrounded the perikarya and/or proximal dendrites in the following nuclei: lateral superior olive, medial superior olive, superior paraolivary nucleus, lateral nucleus of the trapezoid body, ventral nucleus of the lateral lemniscus, dorsal nucleus of the lateral lemniscus.

Further evaluation correlating these results with those we are obtaining from immunocytochemical studies is in progress.

Supported by NS 05785, NS 07106 and a grant from the Deafness Research Foundation.

201.9

PRESERVATION OF FIBERS OF PASSAGE FOLLOWING KAINIC ACID LESIONS OF THE SUPERIOR OLIVARY COMPLEX IN THE FERRET: AN HRP ANALYSIS. B.J. Rooney*, G.L. Kavanagh*, and J.B. Kelly (SPON: Z. Wollberg). Laboratory of Sensory Neuroscience, Carleton University, Ottawa, Canada, K1S 5B6.

Previous studies have shown that microinjections of kainic acid (KA) into the superior olivary complex (SOC) destroy cell bodies but leave fibers of passage intact (Kavanagh and Kelly, 1986; Masterton et al., 1979). Behavioural and electrophysiological studies of the effects of these lesions provide an analysis of the function of the SOC that is not possible with traditional surgical methods. In this study we present further anatomical data on the effectiveness of KA for making auditory brainstem lesions. Animals were anesthetized with pentobarbital sodium and KA (5 nmoles/ul Locke's solution) was injected into the SOC through a micropipette. After periods of up to one year animals were again anesthetized and multiple injections of HRP were made into the central nucleus of the inferior colliculus. Forty-eight to seventy-two hrs later animals were sacrificed and the brains processed with TMB. Destruction of the SOC was verified in Nissl strained material by gliosis and the absence of nerve cells. In cases with unilateral lesions, the contralateral SOC showed heavy HRP labelling, while no labelling was evident at the lesion site. The fibers of passage were shown to be intact by retrograde labelling of neurons within the cochlear nucleus. Our results, besides demonstrating that the SOC is sensitive to the excitotoxicity of KA, also indicate its utility in studies investigating the effects of auditory brainstem lesions by avoiding the disruption of fibers of passage.

201.10

A DISTRIBUTED NEURAL NETWORK FOR CALL DETECTION IN THE FROG'S THALAMUS. **J.E. YOCHIM*, J.C. HALL* AND A.S. FENG (SPON: D. Green). Dept. Physiol. & Biophys. Univ. of Illinois, Urbana, IL 61801.**

We are conducting ongoing studies addressing issues concerning the neural basis of call recognition in the frog's auditory system. Recently, we reported that time and frequency cues are processed independently in the frog's thalamus with separate neural channels for each. Specifically, neurons in the posterior and central thalamic nucleus were shown to be selective for the spectral and temporal features of the species vocalizations, respectively. But, are these the only thalamic structures involved in call detection? We have addressed this question by recording acoustically evoked potentials (AEPs) from thalamic efferent targets of the posterior nucleus: the Nucleus of Bellonci (NB) and the ventrolateral thalamic nucleus (dorsal (VLd) and ventral (VLv) divisions). We found that responses to tone combinations (350 and 1,700 Hz) were larger (by 10 – 210%) than the sum of responses to individual tones. These findings were consistent with those reported for the posterior nucleus indicating an ordinal, functional relationship between these structures. This was supported by results of HRP tracing studies which revealed reciprocal connections between the posterior, but not central, thalamic nucleus and the NB, VLd, and VLv. This further supports the concept of parallel processing in the thalamus regarding time and frequency cues; the processing of spectral components is distributed widely (i.e., NB, VLd, VLv and the posterior nucleus) whereas temporal processing occurs principally within the central nucleus. In conclusion, our data suggest that the call detection system within the thalamus is represented by a distributed neural network rather than a localized population of neurons.

201.11

PROJECTIONS OF THE CAT MEDIAL GENICULATE BODY TO THE PRIMARY AUDITORY CORTEX (AI). B.A. Peterson and J.A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The laminar distribution of axons from the cat medial geniculate body in primary auditory cortex (AI) was examined as part of a study of the connections of AI. Adult, pentobarbital-anesthetized cats received stereotaxic injections of .10-.20 µl of HRP (30%) or HRP/WGA (5%) aimed at the ventral division. The animal was reanesthetized and perfused 48 h later, and sections were cut from the inferior colliculus through the somatic sensory cortex. Laminar cortical subdivisions and architectonic borders were identified in DAB-reacted, Nissl counterstained sections. Many inferior colliculus neurons were retrogradely labeled, especially in the central nucleus.

The main results are (i) that the ventral division projects heavily to layers IV and IIIb in AI; (ii) that the projection is a continuous band throughout the rostro-caudal axis of AI; (iii) that thalamocortical input may involve retrogradely labeled corticothalamic layer V pyramidal cell apical dendrites ascending into layer IV (see J.A. Winer and B.A. Peterson, this volume); a similar pattern occurs among layer V cells projecting to the inferior colliculus (K.D. Games and J.A. Winer, *Hearing Res.* [in press]); and (iv) that a smaller projection to layer IIIa may reflect anterograde transneuronal transport.

The high density of thalamocortical input to, and diverse neuronal composition of, layers IIIb and IV is consistent with the idea that, in AI as well as the primary visual cortex, a variety of neurons might be postsynaptic to thalamic input.

This research was supported by United States Public Health Service Grant RO1 NS16832-08. We are grateful to J.M. Popowits for technical assistance.

201.12

ORIGINS OF AUDITORY CORTICOTHALAMIC PROJECTIONS ONTO THE CAT MEDIAL GENICULATE BODY. J.A. Winer and B.A. Peterson. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We identified the layers from which auditory corticothalamic projections arise, characterized the spatial distribution of these neurons, and reconciled the main types of projection neurons with the cells seen in studies of neuronal architecture from Golgi preparations, plastic-embedded material, or immunostained sections.

Corticothalamic cells arise (in decreasing numbers) from layers VI, Vb, and Va. The layer VI projection is particularly heavy and continuous through the dorsal-ventral extent of AI, and it may extend into adjoining, non-primary fields. While far fewer layer Vb neurons are labeled, this projection is still substantial. These cells are larger and more obviously pyramidal than layer VI neurons. Finally, in the upper part of layer Va, solitary, labeled pyramidal cells were often separated by 100-200 µm intervals devoid of such somata or of anterogradely transported material. The thick, HRP-filled apical dendrites of these cells project into layer IV. A gap of up to 150 µm devoid of labeling separated the retrogradely labeled profiles in layers Va and Vb.

The primary conclusions are (i) that the auditory corticothalamic projection involves all of layer VI, and the lower and upper quarters (but not the middle half) of layer V; (ii) that the projection is continuous in layers VI and Vb and discontinuous in layer Va; (iii) that more than one type of pyramidal neuron projects to the medial geniculate body; and (iv) that robustly labeled pyramidal neurons, whose apical dendrites ascend into layer IV, may be a thalamic recipient (see B.A. Peterson and J.A. Winer, this volume).

201.13

INTRINSIC CONNECTIONS OF CAT PRIMARY AUDITORY CORTEX , M.N. Wallace, H.D. Schwark and E.G. Jones. Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Small injections of horseradish peroxidase (HRP) and the anterogradely transported lectin extracted from Phaseolus vulgaris (PHA-L) were made at different depths of the AI cortex. The HRP was injected iontophoretically using currents of 1-2 uA for 1-2 hours and after a survival time of 3-5 days activity was demonstrated using cobalt intensified diaminobenzidine. The PHA-L was injected using a current of 5 uA for 15-20 min. and pipette tips of less than 20 um. Larger tips mainly produced retrograde labelling.

The organization of intrinsic axons was demonstrated with PHA-L and labelled fibers were mainly found in two or three short bands. One band was centered on the injection site and contained clusters of denser terminal labelling at intervals of about 500 um. The other band or bands lay at a distance of 1-1.5 mm. and were roughly parallel to the principal band. The bands of labelling extended through all six layers of the cortex and were oriented obliquely to the coronal plane. Clusters of retrogradely labelled cells were observed at distances of 1-4mm. Most pyramidal cells were densely covered in spines and some cells also appeared to have spines on the axon hillock. However in the case of a few intensely labelled pyramidal cells there was no evidence of any spines. The proximal dendrites were completely smooth and the fine distal branches had a beaded appearance. Supported by NIH Grant NS 25674.

201.14

DESCENDING CORTICAL AUDITORY PATHWAYS IN A PRIMATE. R.E. Hunter,* A.M. Thompson and G.C. Thompson. Dept. of Otorhinolaryngology & Communicative Sciences and Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030.

The anterograde tracers HRP and PHA-L were utilized to elucidate descending pathways from auditory cortex of the lesser bush baby (Galago senegalensis). To determine the maximum extent of the descending projections, large pressure injections of HRP were made into auditory cortex of one animal. Subsequently, to demonstrate the distinct components of those projections and to label their terminal endings, PHA-L was iontophoretically injected into auditory cortex of 3 animals.

Upon light microscopic examination of brain sections from the HRP case (detected with TMB and BDHC), retrogradely labeled cell bodies were observed in the ipsilateral medial geniculate body (MG) and nucleus limitans and in contralateral auditory cortex (layers I and II). Anterogradely labeled terminals were observed in ipsilateral MG and the external, pericentral, and dorsomedial central nucleus of the inferior colliculus (IC).

Examination of the PHA-L cases (detected using immunohistochemical techniques) revealed labeled fibers and terminal-like varicosities in nucleus limitans, ventral division of MG, and the external, pericentral, and dorsomedial regions of IC. Localized regions of labeled terminals were uniquely related to the location of the injection site indicating a specific and finely organized projection system descending to auditory targets.

201.15

RESPONSES OF PERIPHERAL AMPHIBIAN NERVE (*XENOPUS LAEVIS*) TO ELECTRICAL STIMULATION. P.M. Backoff*, B.M. Clopton* and S.C. Bledsoe.(SPON: D. Anderson). Kresge Hearing Research Inst., U. of Mich., Ann Arbor, MI 48109

Responses to direct electrical stimulation were recorded from nerve fibers in the lateral line of the amphibian *Xenopus laevis*. Spontaneous activity had been eliminated by severing the nerve at the stitch, allowing an unambiguous determination of the response threshold to continuous electrical sinusoids. Threshold and suprathreshold spike counts were obtained, and spike time patterns(PSTH) collected to determine the temporal limits for the responses as a function of frequency. The frequency response (threshold tuning curve) of the fibers was very similar to that reported for mammalian auditory nerve fibers, with maximum sensitivity between 73 and 171 Hz for the sinusoids. Dynamic ranges, measured from spike count as a function of stimulus intensity at any particular frequency, varied between fibers, but were generally small, reaching saturation within 1 to 4 dB above threshold. Neuronal responses were strongly phaselocked to all the stimulating frequencies from 49-1221 Hz at very low stimulus levels. (Supported by NIH Grant NS21440)

EFFERENT PROJECTIONS FROM THE OCULOMOTOR REGION OF THE MACAQUE FASTIGIAL NUCLEUS, AS STUDIED BY ANTEROGRADE TRANSPORT OF HRP. S. Sugita, H.Noda, Y. Ikeda* and J. Paallysaho*. Dept. Visual Sci. Indiana Univ. Bloomington, IN 47405.

Efferent pathways from the tail of fastigial nucleus, which receive projections from vermal lobules VIc and VII, were studied. HRP injection site was determined by distribution of retrogradely labeled Purkinje cells. In one of 3 monkeys, in which effective sites were confined to caudal fastigial nucleus, labeled Purkinje cells were found only in the ipsilateral oculomotor vermis.

The majority of fibers from the fastigial oculomotor region crossed the midline and changed the direction to ventrolateral and entered the uncinate fasciculus. After reaching the brachium conjunctivum, most fibers crossed over it and entered the brainstem nuclei; such as LVN, IVN, MVN, PPRF in an area anterior to the abducens N, and RF immediately ventral to IVN. Some fibers advanced also to the lateral part of RF ventral to LVN. Clear terminals were found in the medial portion of the NRTP. Some crossed fibers terminated also in the superior colliculus and thalamic VPL nucleus. Uncrossed fastigial fibers (30 %) were traced to the four ipsilateral VN via the juxtarestiform body, and clear terminals were found only in LVN. There were retrogradely labeled neurons in the N. prepositus hypoglossi but no labeled terminals were identified in the nucleus.

CONVERGENCE OF TERMINAL ZONES OF THE CEREBELLOPONTINE SYSTEM WITH OTHER AFFERENT PROJECTIONS TO THE BASILAR PONTINE NUCLEI OF THE RAT. H.S. Lee, S.A. Azizi, and G.A. Mihailoff, Dept. of Cell Biology and Anatomy, Univ. of Texas Southwestern Medical Center, Dallas, TX 75235

The role of the basilar pontine nuclei (BPN) as an important connecting link between the cerebral cortex and the cerebellum has been widely accepted. Moreover the cerebellum, via projections from the deep nuclei to the BPN, has the opportunity to influence the activity of pontine neurons and thus modify in some way a portion of the mossy fiber input to the cerebellar cortex. The present anatomical studies were undertaken to analyse the overlap between cerebellopontine (CBP) terminal zones with other pontine afferents in the rat BPN. Although previous reports identified some degree of overlap between terminal zones of CBP and corticopontine projections in the opossum, the rat, and the cat by comparing the right and left sides of a rostro-caudal series of BPN sections, the present study employed two different anterograde tracers, *i.e.*, PHA-L injection into the deep nuclei and WGA-HRP injection into other pontine afferent sources such as the sensorimotor, visual, or auditory cortex, or the superior colliculus, thus permitting a more precise visualisation of the overlap between CBP terminals and other pontine afferents in the same BPN section. Moreover, overlap between the terminal zones of CBP afferents and the projections of various sensorimotor regions was localised within discrete portions of the medial, ventral, and lateral BPN. On the other hand, in the lateral BPN, inputs from visual cortex, auditory cortex, or the superior colliculus exhibited the same terminal areas as those from the deep cerebellar nuclei. Preliminary single-unit recording indicates that some basilar pontine neurons receive convergent cerebral cortical and deep nuclear input, while ultrastructural studies are in progress to confirm that single BPN neurons are contacted by synaptic boutons from both of these afferent systems. IS THERE A RECIPROCAL CONNECTION BETWEEN RED NUCLEUS AND INTERPOSED CEREBELLAR NUCLEI IN RABBIT? M.E. Rosenfield and J.W. Moore. Dept. of Psychology, Univ. of Mass., Amherst, MA 01003.

Dry WGA-HRP (Sigma L3892, formerly L9008) was implanted by pipette into the right cerebellar interpositus (IP) nucleus in six albino rabbits (method of Mori, J, et al, *Brain Res Bull*, 6:19, 1981) and left *in situ* for 43-52 hours before sacrifice by pentobarbital overdose. Animals were perfused transcardially (descending aorta clamped) with approximately 2 L of .9% saline followed by equal volumes of 10% formalin and 12% sucrose solution at 4 degrees C. Brains were blocked immediately on extraction (saving only the brain stem and cerebellum), placed in 30% sucrose in .1 M phosphate buffer (pH=7.2), and stored for 24 hours at 4 degrees C for 24 h. Brain stem and cerebellum were embedded in gelatin; frozen sections were cut transversely at 60 μ, mounted on subbed slides, and reacted with tetramethylbenzidine (TMB). Brightfield and darkfield microscopic examination of sections revealed fiber and terminal labeling of contralateral red nucleus (RN) but virtually no retrograde cell labeling. Retrograde cell labeling was observed in cerebellar cortex (Purkinje cells) and/or inferior olivary nuclei in all cases. With identical methods, two animals had WGA-HRP implanted into the left RN. These cases showed substantial retrograde labeling of cells in right IP nucleus but no evidence of terminal labeling (as distinct from cut fibers of passage). These findings are in accord with a study of reciprocal IP-RN connections in cat by Walberg and Dietrichs (*Brain Res*, 397:73, 1986) which also used the Mori et al procedure of implanting WGA-HRP. The evident absence of a RN-IP projection is relevant for studies of neural circuits underlying classical conditioning of the rabbit nictitating response (Yeo, C H, et al, *Exp Brain Res*, 60:114, 1985).

ANATOMICAL ANALYSIS OF CEREBELLAR-OLIVARY PROJECTIONS IN THE RABBIT. C. Weiss, G. Tocco *, J. K. Thompson and R.F. Thompson. Dept. Psychol. Univ. Southern California., Los Angeles, CA. 90089-1061.

The cerebellum is critical for eyeblink conditioning and feedback to the inferior olive (IO) is likely to be important in shaping an appropriate conditioned response. Reciprocating pathways from the cerebellum to the IO have been demonstrated in both the cat and rat. One is an indirect projection via the red nucleus (RN) and dorsal column nuclei, another is a direct projection between the dentate/interpositus region and the IO. We are currently examining these two pathways in the rabbit which is a widely used subject in classical conditioning paradigms.

We injected the dentate/interpositus region with either 1% wheat germ agglutinated horseradish peroxidase (WGA-HRP, 100 nl) or 2.5% Phaseolous Leucoagglutinin (PHA-L , +5 uA, 10 min, 7 sec duty cycle). After a two day survival period rabbits injected with WGA-HRP were prepared and processed for visualization of the HRP using tetramethylbenzidine (TMB) as a chromogen. Following a two week survival period rabbits injected with PHA-L were prepared and processed for immunohistochemistry using a biotinylated secondary antibody, a peroxidase labelled avidin-biotin complex, and diaminobenzidine (DAB) as a chromogen. In other rabbits we injected either 3% Fluorogold (FG) or 1% WGA-HRP into the RN or IO to retrogradely label the cells which provide these two pathways.

Anterogradely labelled fibers from the dentate/interpositus region were observed to provide a massive input to the contralateral RN and also to return caudally and provide input to the IO. In addition, retrogradely labelled cells were found throughout the dentate/interpositus region following injections of either the RN or IO with either FG or WGA-HRP.

Details of these projections as well as results of double labelling experiments following injections of both the RN and IO on the same side, but with different labels, will be presented.

CEREBELLAR PROJECTION FIELDS OF SPINAL CORD SEGMENTS IN THE RAT. P. S. Klinkachorn and J. L. Culberson, Department of Anatomy, WVU Health Sci. Center, Morgantown, WV 26506.

Despite the fact that both deep and cutaneous peripheral receptors influence activity of spatially defined cerebellar regions, the structural substrates mediating this somatotopy remain unclear. By injecting specific spinal segments with HRP-WGA solution, it is possible to label axons arising in these segments and to chart their cerebellar targets. Spinocerebellar tracts from all spinal segments studied reach anterior lobe and lobule VIII of posterior lobe; they generate a series of parasagittal bands across the mediolateral width of the lobules. Thoracic segments generate the densest projections to anterior lobe; these are heaviest to medial bands in lobules II-III and to lateral areas in IV-V. Less dense but well defined bands are labeled by lumbar and sacral injections. Projections from cervical segments are more diffuse and less dense than those from other levels. While differences in segmental projection patterns are seen, it is difficult to see how these differences correlate with somatotopic maps of the cerebellar cortex. (Supported by grants from WVU Med. Corp. and NIH RR05433).

THE LATERAL RETICULAR NUCLEUS OF THE RAT: PROJECTION TO THE CEREBELLUM. A COMPUTER RECONSTRUCTION STUDY. S.A. Azizi, A.J. Painchaud*, S. Askari*, D.J. Woodward. Dept. of Cell Biology, U. T. Southwestern Medical Ctr., Dallas, TX 75235

Ongoing investigation in our laboratory has involved the organization of the brainstem nuclear projections to the cerebellum. This study was undertaken to determine the detailed projections of the lateral reticular nucleus [LRN] to the cerebellar cortex in the rat. Small quantities of (.01 to .2μl) of HRP-WGA were pressure-injected into discrete areas of the cerebellar cortex in 130 rats. The sensitive chromogen, tetramethyl benzidine, was used to visualize labelled neurons.

Results of this investigation demonstrated that the point-to-point, nucleotopic projection system observed in the olivocerebellar and pontocerebellar systems does not exist in the reticulocerebellar system [RCS]. However, the RCS does exhibit discrete patterns in the density of labelling. Neurons in the parvicellular and subtrigeminal regions of the LRN project heavily to the anterior lobe and intermediate zones of the posterior lobe of the cerebellum [CB]. CB posterior midvermal lobules VI & VII receive sparse projections. Neurons in the magnocellular region of the LRN project mainly to the lateral hemispheres of CB, although a contribution to vermal anterior and posterior lobes was noted. These projections are bilateral.

Thus, in comparison to olivary and pontine projections, which originate and distribute in distinct patterns in the cerebellar cortex, axons of LRN seem to influence broader areas of cerebellar cortical circuitry. *Supported by NIDA 2338 and the Biological Humanics Foundation*

SOMATIC AFFERENT TERMINATION ON SPINES IN THE CAT MEDIAL ACCESSORY OLIVE. H.H. Molinari and K.A. Starr*. Department of Anatomy, Albany Medical College, Albany, N.Y. 12208.

In the caudal half of the medial accessory olive (cMAO), spines constitute the primary target of afferents from the gracile nucleus (Molinari and Sluyters, 1987). The present study examined the other major source for cMAO of ascending somatic information from the hindlimb, the lumbosacral spinal cord, and found a similar preferential termination on dendritic spines. The somatic terminals in cMAO were labeled, as in Molinari (Exp. Brain Res., 1987), by anterograde transport of wheat germ agglutinin-horseradish peroxidase and visualized for EM with tetramethylbenzidine.

Spines in cMAO vary widely in size and shape. Although somatic afferents sometimes synapsed on the stalks of these spines, the vast majority synapsed on spine heads. The spine heads participated in either spine clusters or glomeruli but to date none have been shown to form gap junctions (gap junctions between other elements have been observed). Thus, these data raise the possibility that in cMAO the spines influenced by somatic afferents may not be involved in electrotonic coupling. The alternative explanation that the site of coupling is some distance from the somatic synapse is presently under investigation.

GABAERGIC COMPONENTS OF THE MAMMALIAN IO. B.J. Nelson, E. Mugnaini, J.C. Adams, N.H. Barmack. Lab of Neuromorph, U Connecticut, Storrs, CT 06268; Med U South Carolina, Charleston, SC 29425; NSI, 1120 NW 20th, Portland, OR 97209

The cytoarchitecture and climbing fiber topography of the IO is generally conserved across mammalian species, but the homology of afferent projections is less clear. Immunocytochemical detection of GAD, a marker for GABAergic neurons, was used to compare the distribution of GABAergic nerve terminals and cell bodies in the IO of rat, rabbit, cat, rhesus monkey and human. Frozen sections obtained from zinc-aldehyde fixed brainstems were immunoreacted with the GAD antiserum of Oertel et al. (1981) by the PAP method. The IO of each species contained an extremely high density of GABAergic boutons, but regional variations of intensity were apparent, and may indicate different afferent sources. The heterogeneous pattern of GAD immunostaining was strikingly similar for all species. Staining differences between some regions, such as the beta nucleus and the rostral MAO, were due to differences in GABAergic bouton size. The distribution of GABAergic somata within the IO was determined for each species, since they are a potential source of GABAergic boutons. A low density of small GAD-positive neurons was present in the IO of all species, and no distinctive phylogenetic progression in their number was observed. Therefore, the vast majority of GABAergic boutons in the IO of all the species investigated must have extraolivary origins. [Supported by PHS grant NS-09904.]

TOPOGRAPHICAL ORGANIZATION OF INFERIOR OLIVARY PROJECTIONS TO DEEP CEREBELLAR NUCLEI IN MACAQUE. Y. Ikeda*, S. Sugita, H. Noda and Y. Paallysaho*. Dept. Visual Sci., Indiana Univ., Bloomington, IN 47405.

Origins of IO projections to caudal fastigial nucleus (FN) and posterior interposed nucleus (PIN) were studied by retrograde HRP. Effective site in each monkey was determined by mapping retrogradely labeled Purkinje cells (P-cells). When HRP was localized in the fastigial oculomotor region, as evidenced by labeled P-cells confined in lobules VIc and VII, retrogradely labeled IO neurons were found in subnuclei b and lateral part of c of MAO, but caudal end of MAO was free of labeled IO cells. Labeled IO neurons were located also in caudal DAO. When HRP was placed in the ventral part of caudal FN, with labeled P-cells distributed in lobules VI, VII, VIII and IX, labeled IO neurons were located more caudally in MAO, including a large portion of subnucleus c. When HRP covered caudal half of FN, indicated by labeled P-cells distributed in lobules V - IX, labeled IO neurons were found in the caudal half of MAO and a few neurons scattered also in caudal DAO. When HRP was in medial PIN, with positive P-cell distribution in vermal lobule IV - IX and paravermal lobule IV - VIII, labeled IO neurons were found in subnucleus c, central MAO and caudal DAO. When HRP was injected in lateral PIN, with P-cells in paravermal lobules II - IX, labeled IO neurons were found in rostral halves of MAO and DAO.

THE DISTRIBUTION AND ORIGIN OF SEROTONINERGIC AFFERENTS TO THE CAT'S CEREBELLUM. G.A. Bishop, S. Dibert* and R.H. Ho. Dept. of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210

Serotonin (5HT) has been shown to have a heterogeneous lobular and laminar distribution in the cerebellum of the rat and opossum (Bishop & Ho, Brain Res.331:195, 1985; Bishop et al., JCN 235:301, 1985). In the present study the PAP technique was used to determine the distribution of 5HT in the cat; these data are compared to those found in other species. The origin of 5HT to the cat's cerebellum was determined using a double labeling technique. In the cat, 5HT afferents form a beaded plexus of fibers, morphologically distinct from mossy fibers, that is confined to the granule cell and Purkinje cell layers. This differs from the distribution of 5HT in the rat, in which it is present in the molecular layer, in some folia. However, this pattern of laminar distribution is identical to that seen in the opossum. As in other species, there is not a uniform lobular distribution. All lobules contain 5HT except lobule X in which only scant labeling is present. The densest distribution of 5HT is to the bases of most folia; fewer fibers are seen at their apices. The cells of origin of this beaded plexus of 5HT fibers are located in the reticular formation; few double labeled cells are present within any of the raphe nuclei. These data indicate that: 1) the laminar and lobular distribution of 5HT is unique from that described in other species; 2) there are neurons in the cat's reticular formation whose axons terminate within the cerebellum as a beaded plexus of fibers; these double labeled reticular cells intermingle with retrogradely labeled cells that are not serotoninergic; and 3) 5HT may not influence cerebellar circuits uniformly based on its differential lobular and laminar distribution. (Funded by NIH 18028 and the Roessler Foundation).

COEXISTENCE OF CORTICOTROPIN RELEASING FACTOR AND ENKEPHALIN IN CEREBELLAR AFFERENT SYSTEMS. Sharon Cummings and James S. King. Dept. of Anatomy and Neuroscience Program. Ohio State University, Columbus, OH

The distributions of corticotropin releasing factor (CRF)- and enkephalin (ENK)-containing climbing fibers and mossy fibers were found to be coextensive within several regions of the cerebellum of adult and pouch young opossums. In order to determine if CRF and ENK coexist within the overlapping populations, single, 15um sections of opossum cerebellum were incubated simultaneously with primary antisera to CRF and ENK generated in different species, and processed for fluorescence immunohistochemistry. Within the vermis and hemispheres of 70mm pouch young animals, CRF and ENK were found to coexist in climbing fibers in the mid stage of differentiation and in developing mossy fiber rosettes. Each peptide is also found alone in each developing fiber type. Within the vermis of adult animals, climbing fibers are immunoreactive for CRF, or demonstrate colocalization of CRF and ENK. Mossy fibers within the adult vermis are immunoreactive for CRF alone, for ENK alone, or demonstrate colocalization of CRF and ENK. CRF and ENK also coexist in beaded fibers within the deep cerebellar nuclei. It has been reported that CRF and ENK coexist within cell bodies of the inferior olivary complex, the origin of climbing fibers (Cummings and King, Anat. Rec. 220:27A, 1988). Examination of alternate 5um serial sections of brainstem tissue from opossums pretreated with colchicine and processed for CRF or ENK peroxidase immunohistochemistry also revealed that these peptides are coexistent within the lateral reticular nucleus, a source of mossy fibers. These findings support the concept of chemical heterogeneity within the two major afferent systems to the cerebellum. (NS-08798)

202.12

TEMPORAL EXPRESSION OF CHOLECYSTOKININ-LIKE IMMUNOREACTIVITY IN THE ANTERIOR LOBE OF THE DEVELOPING CEREBELLUM. J. S. King, R. H. Ho and G. A. Bishop Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210.

Cholecystokinin (CCK)-like immunoreactivity is present in mossy fiber rosettes throughout the adult cerebellum (King et al, '86, Neurosci. Abstr. 12:461). In the present study we employed the PAP method to localize CCK in the developing opossum cerebellum. Immunoreactive CCK fibers are present by postnatal day (PD) 7. By PD 11 transversely oriented fibers are evident primarily in medial areas of the cerebellar plate. At PD 25 four sagittal bands of punctate immunoreactivity are present in the anterior lobe vermis. By PD 60 only two sagittal bands of CCK positive elements remain in lobules IV and V. These bands contain immature mossy fiber rosettes and focal areas of punctate immunoreactivity which circumscribe the somata of Purkinje cells. In lobules II and III four bands of immature mossy fiber rosettes are present. By PD 70 the punctate staining in sagittal bands seen at PD 60 is diminished. Purkinje cells in lobules IV and V are circumscribed by CCK fibers that resemble the capuchin stage of climbing fiber development. Mossy fiber rosettes are found throughout the anterior lobe at this age. By PD 80 CCK climbing fibers are rare in the anterior lobe, and the adult pattern of mossy fiber distribution is present. These data indicate that: 1) CCK is expressed in cerebellar afferents later in development than serotonin (Bishop et al, '85, Anat. & Embryol. 171:545) or enkephalin (Walker et al, '87, Neurosci. Abstr. 13:1262); 2) the time course for the development of mossy fiber rosettes is not uniform in the anterior lobe; and 3) there are transient climbing fibers in the anterior lobe that do not mature beyond the capuchin stage of development. (Supported by NS-08798).

IONTOPHORETIC EFFECTS OF SIGMA LIGANDS ON RUBRAL NEURONS. R.R. Matsumoto and J.M. Walker. Department of Psychology, Brown University, Providence, RI 02912.

High concentrations of sigma receptors are found in the red nucleus (RN), an area involved in posture and movement. Microinjection of sigma ligands into the RN of rats has been shown to produce abnormal postural changes (dystonia). DTG has marked effects while (+)-pentazocine has similar, but weaker actions. (+)-3PPP produces mixed effects. In this study, the responses of rubral neurons to iontophoretic applications of DTG, (+)-pentazocine and (+)-3PPP were investigated in the rat.

DTG had consistent inhibitory effects on rubral neurons. Dose-dependent inhibitions were observed in cells with constant spike amplitudes. Similar effects were seen with (+)-pentazocine although a smaller percentage of cells responded with inhibitions. (+)-3PPP produced mixed effects: both inhibitions and slight excitations were observed.

These data suggest that sigma receptors may be associated with abnormal postural changes resulting from inhibition of RN activity. The data also suggest that the sigma ligand, (+)-3PPP, may have complex actions, a finding that is consistent with the reports of other investigators.

202.14

MULTIPLE INNERVATION OF PURKINJE CELLS BY CLIMBING FIBERS AND OLIVOCEREBELLAR INTERLOBAR BRANCHING. A. Rosina*, L. Provini* and S.Morara* (SPON: European Neuroscience Association)Ist. Fisiol. Centri Nervosi CNR and Ist. Fisiol. Gen. Chim.Biol., Fac.Farmacia, 20131 Milano,Italy.

A neonatal stage of multiple innervation of Purkinje (Pk) cells by climbing fibers (Crepel et al.,J.Neurobiol.7,567, 1976) precedes the one-to-one relationship typical of the adult mammal. The regression of the redundant synaptic contacts is not due to cell death but to retraction of axon collaterals by the inferior olive (IO) neurons. A likely candidate for the redundant neonatal connectivity is an increased rostro-caudal interlobar collateralization which is known to be related to the functional somatotopy (Rosina and Provini, Brain Res. 289, 45, 1983).

The interlobar branching pattern of the olivocerebellar fibers was analyzed in neonatal kittens by applying retrograde fluorescent techniques. It was found that interlobar branches are indeed more numerous - by a factor of about 2 in terms of doubly projecting neurons - in the first postnatal week. Moreover, the somatotopic distribution of IO axon collaterals present in the adult is not yet settled:it is proposed that the retraction of the redundant IO interlobar collaterals contributes to the somatotopic refinement.

202.15

VISUAL INPUT TO THE CEREBELLUM OF MACAQUES. M. Glickstein, B. Mercier, and J. Baizer. Dept of Anatomy, University College London, Gower Street, London WC1 England.

The cerebellum plays a major role in the visual guidance of movement. What are the anatomical pathways by which visual information is relayed to the cerebellum? The pontine nuclei are known to receive an input from extrastriate visual areas and the superior colliculus, and axons of pontine cells relay visual information to the cerebellar cortex as mossy fibres. In the present experiments we studied the distribution of efferent projections to the pons following small injections of wheatgerm agglutinated horseradish peroxidase (WGA HRP) or tritiated amino acids into extra striate cortex or the superior colliculus. Each of the injections resulted in multiple patchy terminal fields, largely non-overlapping, principally within the dorsolateral quadrant of the pontine nuclei. Injection of WGA HRP into the flocculus/paraflocculus resulted in retrogradely labelled cells in the same region of the pontine nuclei. The evidence suggests that visual information is distributed widely on the cerebellar cortex, but as in rats and cats, the dorsal paraflocculus is a major target of pontine visual cells in monkeys.

202.16

NUCLEOCORTICAL CLIMBING FIBER DEMONSTRATED BY PHA-L METHOD IN THE CAT. F. Murakami and W.-J. Song*, Dept. of Biophysical Eng., Fac. of Eng. Sci., Osaka University, Toyonaka 560, JAPAN

It has been generally accepted that cerebellar nuclei neurons send mossy fibers to the cerebellar cortex. This is mainly based upon the observations that injection of tritiated amino acids into the cerebellar nuclei failed to label fibers in the molecular layer. We injected PHA-L into the interpositus nucleus of the cat and found labelled climbing fibers in the cerebeller cortex. PHA-L was injected iontophoretically into the interpositus nucleus of the kitten and adult cat using glass micropipettes with diameters of 15 μm - 35 μm. Survival times ranged from 5 - 14 days, the cerebellum was cut at 70 μm and processed for immunohistochemistry. Labelled axons were seen to course the white matter towards the cortex. Terminal-like axons were seen both in the granular and the molecular layer. The former often formed rosette-like structure and the latter exhibited tree-like structure with extensive varicosities. Injection of PHA-L into the white matter did not result in labelling of axons in the cerebellar cortex. These results suggest that interposed nucleus is the second source of climbing fiber.

202.17

ZEBRIN II: A NOVEL ANTIGENIC MARKER OF CEREBELLAR COMPARTMENTATION IN FISH AND RAT. Gino Brochu (a), Len Maler (b), and Richard Hawkes (a): a) Department of Biochemistry and Laboratory of Neurobiology, Laval University, Québec, P.Q. b) Department of Anatomy, University of Ottawa, Ottawa, Ont.

Monoclonal antibodies (mabs) have revealed an elaborate topographical organization in the mammalian cerebellar cortex. To extend these studies to lower vertebrates, adult Balb/c mice were immunized with an homogenate from the cerebellum of the weakly electric fish *Apteronotus leptorhynchus*, lymphocyte hybridomas were constructed by conventional methods, and secreted mabs were screened by peroxidase immunocytochemistry on frozen sections of rat cerebellum. One mab recognized a novel polypeptide, zebrin II. On Western blots of rat cerebellar proteins mab zebrin II recognizes a single band at apparent M.W. 36 Kd. Immunocytochemistry of adult cerebellar cortex reveals that zebrin II distinguishes between two subsets of Purkinje cells that are arranged in parasagittal bands reminiscent of the organization of cerebellar afferent axons. The zebrin II bands are co-extensive with antigenic bands of Purkinje cells stained by using mabQ113 (anti-zebrin I).

Selective staining of a subset of Purkinje cells is also seen in *Apteronotus*. Immnunoreactivity was confined exclusively to a subset of Purkinje cells located in the corpus cerebelli, the eminentia granularis (EGa) and the ventromedial part of the valvula. Purkinje cells in other regions are unreactive. Western blotting shows a single antigenic polypeptide apparently identical to that in the rat. Purkinje cells are completely labelled, including their dendrites and axons. As previously suspected Purkinje cells of the corpus and valvula cerebelli project locally to nearby eurydendroid cells. Purkinje cells of EGa project down to the acousticolateral region terminating primarily in the dorsal nucleus.

Given that it is confined to Purkinje cell subsets both in fish and rat, zebrin II may prove a valuable marker of cerebellar compartmentation throughout the vertebrates, and a useful probe for developmental and comparative studies.

202.18

TRANSIENT EXPRESSION OF ENKEPHALIN-LIKE IMMUNOREACTIVITY IN CLIMBING FIBERS OF THE DEVELOPING CEREBELLUM. J. J. Walker, R. H. Ho and J. S. King. Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210

In the adult opossum's cerebellum, enkephalin (ENK) immunoreactive climbing fibers are confined primarily to vermal folia and the flocculus (King et al., '86, J. Neurocytol. 15:545). However, during development, ENK climbing fibers have a more widespread distribution in the cerebellar cortex (Walker et al., '87, Neurosci. Abstr. 13:1262). In the present report we used the PAP technique to study the transient expression of ENK in developing climbing fibers of the lateral cerebellar folia between postnatal day (PD) 18 and 83. Between PD 18 and PD 68 immunoreactive climbing fibers have reached the mid stage of development and distribute extensively in the paramedian lobule, parafloccullus, hemispheric parts of lobule IV and V, lobus simplex and crus I and II. By PD 77 climbing fibers have reached the molecular layer and show a marked decrease in the intensity of immunostaining. They are evident only in restricted foci of Crus I, the parafloccullus and the medial part of the paramedian lobule although they appear less mature when compared to those in vermal regions. By PD 83, when the adult pattern of distribution is reached, only those fibers in the paramedian lobule and parafloccullus persist while the remainder of the lateral folia are populated by fine beaded axons which distribute along the granule cell-Purkinje cell border. These data indicate that ENK is expressed in developing climbing fibers but not mossy fibers during a prolonged period of development coincident with the major stages of Purkinje cell maturation. We hypothesize that this transient expression suggests a developmental role for this peptide in early stages of cerebellar ontogeny. (Supported by NS-08798)

203.1

ACTH PEPTIDES INCREASE ENDPLATE PARAMETERS DURING PERIPHERAL NERVE REGENERATION. L.A. Zuccarelli and F.L.Strand. Center for Neural Science, New York University, Washington Square,New York 1003.

We have shown that ACTH and its fragments accelerate peroneal nerve regeneration, improving qualitative and quantitative aspects of reinnervation of rat extensor digitorum longus (EDL) muscle 1,[2].These peptides also increase terminal branching and endplate area of the developing neuromuscular junction (nmj) [3,4]. Here we investigate the morphological response of the regenerating nmj to ACTH 4-10 and MSH (ACTH1-13):length of terminal branching, perimeter and area as determined by light microscopy and digitizing morphometry. Crush denervation is performed under 8% chloral hydrate (0.6ml/0.1kg IP) with a Dumont #5 forceps producing a 1mm wide lesion 10mm from nerve exit from the spinal cord. Peptide treatment (10 ug/rat/48 h IP) is from time of denervation to day of sacrifice (15 or 21 days after crush). The EDL is fixed in situ and prepared for light microscopy with a combined silver-cholinesterase stain. Both peptides cause significant increases in terminal branching, while MSH also increases area and perimeter as compared to saline controls.Thus both the regenerating and the developing nmj show remarkable plasticity in terms of their response to ACTH peptides. 1.Strand,F.L.& T.T.Kung(1980)Peptides 1:135-138; 2.Saint-Come C. & F.L. 203.2

IMMUNOCYTOCHEMICAL CHANGES IN RAT SPINAL CORD LESIONS. C.P. Barrett*, L. Guth*, and E. Roberts (SPON. T.H. Oh) Dept. Anat., U. MD Sch. Med., Balt., MD and City of Hope Med. Ctr. Duarte, CA

After compression-induced axotomy of the rat spinal cord, regenerating axons enter the lesion along regrowing capillaries, ependymal cells, and astrocytes. This model thus allows us to test drugs that might enhance spinal cord regeneration. We crushed the cords of rats for 1 sec and inserted a subdural polyethylene tube through which we infused isotonic solutions of triethanolamine (TREA, 0.2 ml, 0.1 M, pH 7.2) alone or TREA with dehydroepiandosterone (DHEA, 0.2 ml, 0.1 M, pH 7.2) or vehicle (physiological saline, 0.2 ml, pH 7.2) at four hour intervals for two days. Two weeks postoperatively, the spinal cord was examined histologically and immunocytochemically. At two weeks histological staining revealed no discernible differences between the responses of animals treated with TREA alone and those treated with TREA/DHEA. When compared with saline controls, both treatments revealed decreased cellular infiltration and a more uniformly arranged ingrowth of ependymal cells, astrocytes and capillaries. The drug treatments also increased the phosphorylated neurofilament (PNF) reactivity of neurites and of the laminin around blood vessels. The PNF-stained neurites were especially prominent along the basal lamina of the newly formed blood vessels. These findings further support previous observations (i) that regenerating CNS neurons grow along reconstituted vascular, ependymal, and astrocytic elements and (ii) that the ingrowth of neurites and synthesis of laminin can be enhanced by treatment with simple chemical agents. Supported by NIH grant NS-21460.

NEURITE OUTGROWTH FROM RAT CORTICAL NEURONS ON ONE MICRON DIAMETER COLLAGEN FIBERS. E. Wong[1], A. Rizvi[1]*, D. Christiansen[1]*, D. Dickerman[3]*, R. Hahn[1]*, G. Zazanis[2]* H. Geller[3] and F. Silver[1]*. [1]Biomaterials Ctr., [2]Dept. of Neurosurg., [3]Dept. of Pharm., UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854.

Cortical neurons from fetal rats were grown on 1 um wide collagen fibers in an effort to develop an in vitro model for the study of CNS nerve regeneration. Fifty um thick collagen fibers were placed onto cover glasses. These fibers were cross-linked and then etched using collagenase. Some of the cover glasses containing the cross-linked and etched collagen fibers were subsequently stained with Sirius Red dye. On these cover glasses, one um wide collagen fibers were detected by their birefringence under polarized light. Cortical tissues from fetal rats were dissected aseptically from an etherized Sprague-Dawley rat at day 15 of gestation. These tissues were enzymatically dissociated into individual cells. These cells were allowed to grow on the 1 um wide collagen fibers in Dulbecco's Modified Eagles Medium with antibiotics at 37°C with 5% CO_2. Neurons were found to preferentially attach and send out processes along the long axes of these fibers. This result suggests the possibility of transecting neuronal axons on collagen fibers using microsurgical techniques.

Support was provided by a fellowship from the New Jersey Center for Advanced Biotechnology and Medicine.

EXTENSIVE NEURITE REGENERATION ON RAT AND HUMAN CNS TISSUE SECTIONS IN VITRO K.A. Crutcher. Department of Neurosurgery, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Embryonic sympathetic or sensory neurons have been reported to exhibit little or no regeneration when grown on mature CNS tissue sections but extensive outgrowth on PNS or embryonic CNS tissue (Carbonetto et al., '87; Sandrock and Matthew, '87). However, the CNS areas that were studied (optic nerve, spinal cord and cerebellum) contain predominantly myelinated fiber tracts. Since mature CNS white matter is a non-permissive substrate for neurite elongation (Caroni and Schwab, '88), CNS regions lacking myelin were tested for neurite growth-promoting ability. Fresh frozen coronal sections of adult rat brain or human temporal cortex were thaw-mounted directly onto 35 mm tissue culture plates. Chick sympathetic or dorsal root ganglia (E9) were then placed on the tissue sections and grown in F-12 with 5% horse serum. In some cases, NGF was added to the medium. Neurite outgrowth was assessed 2-3 days later. Explants consistently attached to tissue sections but did not attach to the untreated tissue culture plastic unless NGF was present. Extensive neurite outgrowth (enhanced by NGF) was observed on gray matter, e.g., hippocampal formation, cortex, amygdala, and hypothalamus whereas no growth was observed on white matter e.g., corpus callosum, stria medullaris, fimbria and internal capsule. In fact, explants which attached in areas where both white and gray matter were encountered avoided the white matter tracts but extended neurites well otherwise. These results support the hypothesis that CNS white matter is a non-permissive substrate for axonal growth but also show that mature CNS gray matter is a suitable substrate, at least in vitro. (Supported by NIH # NS-17131.)

APPLIED D.C. ELECTRIC FIELDS IN THE DAMAGED RODENT OPTIC NERVE B.J. Albala*, B.H. Hallas and M.F. Zanakis. American BioInterface Corporation, New York, NY and New York College of Osteopathic Medicine, Old Westbury, NY.

Earlier studies have suggested that damaged optic axons of the rat can regenerate in the presence of applied D.C. electrical fields (Soc. Neurosci. abstract 383.4, 1987). In order to more fully characterize the response to such treatment, the visual system was studied using HRP. In blinded experiments, adult rats received a unilateral crush of the optic nerve, 1mm behind the orbit. The nerves were then implanted with a galvanic nerve cuff (TRAXON®) delivering 2-14μA to the tissue. The cathode was oriented 3mm distal to the lesion site, while the anode was oriented 0.5mm rostral. Control animals received similar devices, but they were rendered inactive (not delivering current). After 4 weeks, all animals were intraocularly injected with HRP, and then sacrificed 2 days later for histological examination of the visual system. The results showed that in all but one of the electric field-treated animals, HRP was present in the optic nerve distal to the lesion as well as in the contralateral optic tract. Often, the lateral geniculate nucleus and the tectum also demonstrated some, although slight HRP transport. In contrast, none of the control animals demonstrated presence of HRP distal to the lesion site. These and other ongoing experiments support the use of electric fields to promote repair of the damaged CNS.

203.6

PARTIAL RECOVERY FROM SPINAL CORD INJURY FOLLOWING APPLICATION OF D.C. ELECTRIC FIELDS IN THE RAT. M.F. Zanakis and M.J. Politis. American BioInterface Corporation, New York, NY and Spinal Cord Research Laboratory, Shaugnessy Hospital Research Center, University of British Columbia, Vancouver, BC.

Previous studies have shown that partial recovery of function can occur following the application of weak D.C. electrical fields to the damaged spinal cord. The present study examined short-term behavioral and histological alterations following contusion lesions of the spinal cord. In blinded procedures, adult rat spinal cords were contused using the weight drop method. DC stimulators (TRAXON®) were applied to the dorsal portion of the cord, orienting the cathode rostral to the lesion. Control animals received either a stimulator with the cathode oriented caudally, or an inactive one. All animals were tested weekly on an inclined plane for sensori-motor function. After 3 weeks, all animals were sacrificed and the dorsal funiculi rostral to the lesion were assessed for numbers of axons. The results showed that the cathode rostral treated animals performed statistically significantly better on the inclined plane at 3 weeks than controls. These animals also exhibited a statistically significantly greater number of axons rostral to the lesion site. Whether such treatment has an effect on growth or regeneration in the spinal cord is now being studied. Other experiments are presently assessing the effect of a delay in the electric field treatment. Investigations of increased vascular perfusion to the damaged region are currently being pursued.

STIMULATION OF NERVE REGENERATION IN VITRO AND IN VIVO USING PULSED ELECTROMAGNETIC FIELDS. BF Sisken, M Kanje*, G Lundborg*, E Herbst*, R Zienowicz*, M Orgel* and W Kurtz*. Center Biomed. Engineer., Dept. of Anatomy & Neurobiol., University of Kentucky, Lexington, KY 40506; Dept. of Zoophysiology and Dept. Orthop. Surg., Univ. of Lund, S-22362 Lund, Sweden, and Univ. of Mass./ Hershire Med. Ctr., Pittsfield, MA 01201 and Dietic Res., NY 10033.

Cultures of dorsal root ganglia from chick embryos were exposed to a 20 ms magnetic pulse, repeating at 2 Hz with an amplitude of 0.4 G. Cultures exposed for 2 hrs/day for 2 days exhibited neuritic growth scores 30-35% higher than controls. Reducing the pulse duration to 5 ms while maintaining the same electrical parameters eliminated the growth enhancement. In a crushed sciatic nerve model, rats were placed in a pulsed magnetic field (20 ms, amplitude of 3.0 G, repetition rate of 2 Hz) for 6 days, 4 hrs/day produced a 22% increase in the rate of axonal sprouting relative to controls. In a transected sciatic nerve model, nerves repaired immediately after transection and treated for 4 hours per day for 5 days gave the clinical impression of reduced neuroma formation. Gait analyses of animals with transected and repaired nerves were conducted at 35, 75, 105 and 140 per days. Animals treated immediately after transection and repair did not show a long-term gain relative to controls. However, animals whose repair was delayed for 5 days and then treated showed a sustained improvement in gait 15-20% above controls. Our results demonstrate that pulsed magnetic field treatment with the appropriate clinical regimen could become a treatment modality for various nerve injuries.

203.8

LAMININ EXPRESSION IN KAINATE LESIONED LATERAL GENICULATE NUCLEUS SUGGESTS POTENTIAL FOR REGENERATION. G. Nilaver, C.K. Meshul, L.M. Lund* and W.R. Woodward. Depts. of Neurology and Biochemistry, Oregon Health Sciences Univ. and VA Medical Center, Portland, OR 97201.

Kainate lesions in rat dorsal lateral geniculate nucleus (dLGN) eliminate geniculate neurons but spare retinal and cortical axon terminals. Light microscopic immunohistochemistry with a monoclonal anti-human laminin exhibited specific punctate staining arranged in a laminar array in the lesioned dLGN. Capillary endothelium and olfactory bulb glia were the only other CNS structures showing specific labelling. Electron microscopic examination of immunostained lesioned dLGN demonstrated specific reaction product over plasma membranes and rough endoplasmic reticulum of astrocytes, consistent with reports of laminin expression within reactive astrocytes following kainate lesions (Liesi, EMBO J: 1984, 1985). Laminin reactivity was also noted in basal lamina of endothelial cells. Plasma membranes of unmyelinated axon terminal profiles and microtubules in unmyelinated, but not myelinated, axons were also labelled. While the precise origin of laminin immunoreactivity in unmyelinated axons of lesioned dLGN is unclear, its presence suggests these terminals may be capable of forming synaptic contacts if provided with appropriate targets.

CELL SURFACE INHIBITORS OF NEURITE GROWTH ON DIFFERENTIATED OLIGODENDROCYTES: APPEARANCE AFTER NERVE FIBER GROWTH AND BEFORE MYELINATION. P. Caroni and M.E. Schwab. Brain Research Institute, University of Zurich, Switzerland.

Differentiated oligodendrocytes and myelin in vitro are non-permissive substrates for neurite growth and fibroblast spreading, due to 35kD and to 250kD membrane-bound inhibitory proteins. Inhibitory activity is specifically blocked by monoclonal antibody IN-1, which binds to both inhibitors and to the surface of differentiated oligodendrocytes (Caroni and Schwab, Neuron 1, 85-96, 1988). We have determined the time course of appearance of IN-1-sensitive inhibitory activity and of inhibitory oligodendrocytes in the rat. In the spinal cord, inhibitory activity was absent at E16, was substantial at birth, and reached near to adult levels at P10. An analogous schedule was found in the optic nerve and no inhibitory activity was found outside the CNS or in CNS areas devoided of oligodendrocytes, e.g. in the retina. Our data are consistent with the following model: 1.) inhibitory activity in the CNS is due to differentiating (and to differentiated) oligodendrocytes, 2.) inhibitory oligodendrocytes appear when a fiber tract has completed its growth phase and before the formation of compact myelin.

MONOCLONAL ANTIBODY ENHANCES PROCESS REGENERATION OF ADULT PRIMATE RETINA IN VITRO. *M.R. Burrous and P.R. MacLeish* Laboratory of Neurobiology, Rockefeller University, New York, New York 10021

We have produced a monoclonal antibody, MR-1, directed against monkey retinal membranes which binds fixed, frozen sections of retina, and the membranes of living, dissociated retinal cells. Papain-dissociated retina from adult macaque monkey was cultured on coverslips treated with MR-1 or other substrates and maintained in L-15 medium supplemented with 10% FCS and 0.7% methocel. Immediately after plating, a variety of retinal cell types could be distinguished including photoreceptor cells with outer segments and pedicles, Muller cells, and a variety of neurons with truncated processes. Within hours, cells retracted their processes and began to show differential adhesion to substrates. After 48 hours, cells plated on conventional substrates (e.g., polylysine, laminin, collagen) showed moderate adhesion at best and rare process outgrowth. However, cells plated on MR-1 showed improved adhesion and many more cells had extended processes several microns long. After 7 days, the difference in cultures was striking. Virtually no neuronal cells were seen growing directly on conventional substrates, although the proliferating subpopulation of flat, non-neuronal cells formed the substrate for the small number of remaining neurons. In contrast, MR-1 supported the marked enhancement of process outgrowth of a large proportion of the initially-plated retinal neurons. Several distinct neuronal cell types could be identified, the vast majority of which stained with neuron-specific enolase. A much smaller population of cells stained positively with an anti-GABA antiserum. Whole cell patch-clamp recordings showed the presence of voltage- and time-dependent conductances; fast inward currents or action potentials were observed in most cells, while a minority showed a slowly developing outward current. Given the variety of cell size and morphology, and of electrophysiological properties, it is likely that several of the major sub-types of retinal cells are present in our cultures. This system allows an exploration of the cellular and molecular biology of adult mammalian CNS regeneration. Supported by EY-05201, The Klingenstein Fund, and the Javits Center Award.

203.11

INO ANTIBODY INHIBITS RETINAL REGENERATION IN RANA TADPOLES. T. Nagy and T.A. Reh, Dept. Med. Physiology, Univ. Calgary, Calgary, Alberta, T2N 1N4.

Previously, in Rana tadpoles, we demonstrated a role for the retinal pigment epithelium (RPE) in retinal regeneration via transdifferentiation to retinal neurons. Further, we demonstrated a strong association of the RPE cells with the vascular membrane prior to the onset of transdifferentiation, suggesting a role for this membrane in transdifferentiations. We have subsequently demonstrated that the extracellular matrix (ECM) component laminin is capable of inducing RPE transdifferentiation in vitro. Therefore, the vascular membrane (VM) may potentially influence transdifferentiation via its ECM. To examine this possibility we injected the INO (inhibitor of neurite outgrowth) monoclonal antibody, which recognizes the laminin-heparin sulfate proteoglycan complex, into regenerating Rana tadpole eyes. While 31 out of 32 eyes injected with control antibodies exhibited normal regeneration, only 12 out of 22 eyes regenerated normally when injected with INO. Those eyes exhibiting abnormal regeneration appear stalled at stages at, or prior to, association with the VM. These results indicate that laminin is essential for retinal regeneration in vivo. 203.12

EXTRACELLULAR MATRIX AND RETINAL PIGMENT EPITHELIUM (RPE) DIFFERENTIATION IN RAT EYE DEVELOPMENT. E. Espinoza-Hoffer* and T.A. Reh (SPON: R. Gellman). Dept. Med. Physiology, Univ. Calgary, Calgary, Alberta T2N 4N1, Canada.

In amphibians, laminin can induce transdifferentiation of RPE cells into neurons (Reh and Nagy, Nature 330:68, 1987). We have tested whether the same observation applies to the mammalian retina, using two protocols. In an initial series (46 cultures) we isolated RPE cells from fetal (14-18 days of gestation) or postnatal rat (1-13 days old). Single-cell suspensions were subcultured in either matrigel, laminin, fibronectin or collagen for up to 21 days. In contrast to the amphibian, there was no evidence of RPE transdifferentiation into neurons on any of these substrates.

Since an essential factor needed for transdifferentiation could be missing from the single-cell cultures we also examined the role of matrigel in whole-eye cultures. Eyes were taken from rat embryos (13-15 days of gestation). The mesenchyme was removed and the eyes were placed in 3D matrigel culture. Two or four days later the eyes were processed and analyzed in plastic sections stained with toluidine blue.

In contrast to control eyes, RPE layer cells in treated eyes began to progressively resemble the neuroepithelial cells of the retina. This result was observed in all eight series of experiments where the mesenchyme was removed. Thus, if the extracellular matrix comes in contact with the RPE cell layer, it can influence the differentiation state of RPE cells in the whole developing mammalian eye.

EXOGENOUS NERVE GROWTH FACTOR ENHANCES THE REGENERATION OF RAT SCIATIC NERVE. **A Derby*, W. Engleman*, G. Neises*, S. Rapp* and D. Roufa. G.D.Searle/CNSDR, St. Louis,MO 63198 and **Dept. of Biology, Univ. of Mo.-St. Louis, MO 63121.
Functional recovery of injured nerves is influenced by both soluble factors and structural elements present in the neurons' environment. The study reported here was aimed at evaluating the effect of pharmacological doses of NGF on sciatic nerve regeneration. A small section of adult rat sciatic nerve was removed and the nerve endings are inserted into a 10mm section of silastic tubing. The tube was prefilled with either 60µg NGF or Cytochrome C and neuronal regeneration within the tube was followed histologically. In NGF treated animals, regenerates fixed 2-4 weeks after surgery exhibit greater numbers of myelinated and unmyelinated fibers as determined by quantitative analysis performed at the light and electron microscopic levels. During this period, there is a 60-80% increase in the number of myelinated fibers, and at two weeks there is an eleven fold increase in the number of unmyelinated axons in the regenerates. These effects on neuronal regeneration appear to part of a more general enhancement in cytoarchitecture that is observed in the regenerate. This observation suggests that in addition to its neurotrophic functions NGF may also affect non-neuronal cells (i.e., fibroblasts, schwann cells and macrophages) that are participating in this regenerative process. These cells are involved in reconstructing the environment that is needed for axonal regeneration and supply neurotrophic substances.

203.14

INVOLVEMENT OF LAMININ IN NERVE REGENERATION IN VIVO. B. Toyota*, S.Carbonetto and S.David, (SPON: D.G. Lawrence). Neurosci. Unit, Mont.Gen.Hosp.Res.Inst. and McGill Univ. 1650 Cedar Avenue, Montreal, Canada.
Laminin (LAM), a major glycoprotein of basement membranes, can promote neurite outgrowth in vitro. We used collagen (COL) tubes as regeneration chambers to study the influence of (i) LAM, and (ii) a monoclonal antibody (mAb) 3A3 (Turner et al. J. Cell Biol. 105:137a, 1987), against a LAM/COL receptor,on nerve regeneration.

COL tubes (2cm; American Biomaterials) with distal ends sealed, were sutured to the proximal stump of transected sciatic nerves in adult SD rats, which were divided into 3 groups. Group I: COL tubes soaked in LAM/PBS and filled with PBS (n=4). Group II: COL tubes soaked in LAM/PBS (370µg/ml) and filled with PBS (n=4). Group III: COL tubes soaked in LAM/PBS (370µg/ml) and filled with mAb 3A3 (2mg/ml) (n=4). At 8 day intervals the tubes were reinjected: groups I & II with PBS and group III with mAb 3A3 (2mg/ml). After 25 days, longitudinal sections were labeled with anti-neurofilament antibodies by immunofluorescence and the length of axon growth measured.

The average length of axonal regeneration from the proximal stump was: Group I = 3.6 mm ± 0.3; Group II = 4.4 mm ± 0.6; Group III = 2.9 mm ± 0.5. These results suggest: (i) that exogenous LAM enhances nerve regeneration in vivo by 20% over COL alone, and (ii) this effect is mediated, in part, by the LAM/COL receptor recognized by the mAb 3A3.

MECHANICALLY PRODUCED PARTIAL BLOCK OF AXONAL TRANSPORT IN REGENERATING AXONS. R.E. Snyder*, R.S. Smith, and H. Chan*. Department of Applied Sciences in Medicine and Department of Surgery, University of Alberta, Edmonton, Canada T6G 2G3.

We describe studies in which the method of removal of the perineural sheath from a regenerating sciatic nerve exerted a profound influence upon the axonal transport of protein and organelles at and distal to the junction between parent and daughter axons.

Sciatic nerves of *Xenopus laevis* were crushed at mid-thigh and allowed to regenerate for 21-27 d. The axonal transport of a pulse of ^{35}S-methionine labelled protein was examined in an *in vitro* dorsal root ganglion-sciatic nerve preparation using a position-sensitive detector and liquid scintillation analysis. The perineural sheath was removed from some preparations. The transport of vesicles and other organelles was detected in individual axons by computer-enhanced microscopy.

Nerves with intact perineural sheaths, or in which the sheath was slit longitudinally, or was removed following longitudinal slitting exhibited radiolabel transport characterized by a uniform 2-5 times increase in the deposition of label in the daughter axons and junctional region compared to the parent nerve. In contrast, removal of the sheath by eversion without pre-slitting resulted in deposition in the junctional region of 70 ± 7% (±SEM) of the label that entered the region and a monotonically decreasing deposition of label in the daughter axons. Computer-enhanced microscopy of similar preparations showed bidirectional transport of organelles in both the parent and daughter axons. Individual axons showed a mean loss of anterograde organelle traffic of 73.5 ± 8.1% (±SEM) across the parent-daughter axon junction and a gain in retrograde traffic of 299 ± 67%.

Ultrastructural features of the junction did not depend upon the method of removal of the sheath. No structural damage was detected in the axolemma or the cytoskeleton. Membrane-bounded organelles and 10 nm granules were concentrated in the junctional region. We conclude that a mechanically-produced deficit that partially blocks axonal transport in individual regenerating nerve fibers can occur at the junction of parent and daughter axons. (This work was supported by the MRC.)

REGENERATION: NERVE GUIDES

204.1

THE INFLUENCE OF ANGIOGENESIS ON RECONNECTION PRIOR TO AXONAL ELONGATION. K. Harman and J.C. de la Torre. Dept. Anatomy, Univ. Ottawa.

Before regenerating axons of transected rat sciatic nerve cross a 3mm gap, a tissue bridge (t.b.) reconnects the proximal and distal stumps. Using Long Evans Hooded rats, a polyethylene nerve guide model was used to study possible influences of: i) nerve cell bodies/target tissue, ii) extrinsic or iii) intrinsic factors on t.b. formation. Three groups, TRIPLE TRANSECTION, LIGATION and FILTER, were studied at three or nine days. Group TRIPLE TRANSECTION tested influences i) and ii). The sciatic nerve was cut in three places; the middle, proximally and distally. The nerve tissue was isolated from extrinsic factors with petroleum jelly or heat-sealed plastic discs. The petroleum jelly preparations produced a t.b. reconnection, but the heat-sealed ones did not. To test influence iii), nerve trunks in Group LIGATION were ligated proximally or distally and then transected. The nerve stumps reconnected and a network of blood vessels was observed in the t.b. In Group FILTER a 0.45 um nylon filter provided access to oxygen and other nutrients, but intrinsic cells did not produce a t.b. Nerve cell bodies, target tissue, intrinsic cells and diffusible extrinsic factors did not appear to influence t.b. formation. Our results indicate that revascularization of the nerve stumps was essential in forming the tissue bridge preceding axonal elongation.

204.2

EXTENSION OF CRITICAL AGE FOR RETINAL AXON REGENERATION BY POLYMER BRIDGES CONDITIONED IN NEONATAL CORTEX. L.S.Carman*, G.E.Schneider and I.V.Yannas*. Depts. Brain & Cognitive Sciences, and Material Sciences and Engineering, M.I.T., Cambridge, MA, 02139. (Spon.: C.M. Oman)

Axons of the hamster optic tract, transected rostral to the superior colliculus (SC), regenerate and reinnervate SC only if the lesion is made on or before postnatal day 3 (P3; P0=day of birth). Such transections after P3 result in a small amount of sprouting proximal to the lesion but axons fail to re-grow across the lesion site. We examined the effect of an artificial bridge, conditioned by temporary implantation in neonatal hamster neocortex, on regeneration of retinal axons transected after P3.

Conditioning of the bridge was based on a technique of Silver & Ogawa ('83) for harvesting astrocytes (GFAP+): a porous biodegradeable collagen-glycosaminoglycan polymer (Yannas et al.,'87) was implanted into the neocortex of P4 hamsters. In all cases the conditioned bridge was harvested on P6 or P7. Host animals received unilateral transection of the brachium of the SC at P6, P9, P14, or P21: A gap (0.5mm wide)was made in the tract by aspiration, and the conditioned implant was transplanted into it. After a 2-week survival, the contralateral eye was injected with HRP. Brains were cut and processed for visualization of the label.

Large bundles of regenerating axons grew on or through the polymer in animals with a transection on P6, and in several cases, reinnervated the SC. In control cases with non-conditioned implants, no regeneration was seen. For transections in older animals, we have not yet found SC reinnervation. Thus, conditioned polymer bridges can extend the age at which hamster retinofugal axons can regenerate. [Supported by NIH grants EY00126, EY02621. Procedures complied with NIH Publ. No. 85-23, 1985.]

204.3

INTRACEREBRAL IMPLANTATION OF SYNTHETIC POLYMER /BIOPOLYMER MATRICES. S. Woerly, R. Marchand, C. Lavallée* and R. Guidoin*. Lab. Neurobiol., Hôp. Enfant-Jésus, Centre de rech. Sci. & génie des macromol., Univ. Laval, Lab. Biomat., Hôp. St-François d'Assise, Québec.

In the past, we implanted collagen hydrogels into artificially made brain cavities as (1) tissue substitutes and (2) scaffolding substrates for neural grafts. In the present study, we designed semi-synthetic hydrogels that combine the adhesive surface properties of collagen with the mechanical stability of synthetic polymers. Micro- and macroporous hydrogels of poly (2- hydroxyethyl methacrylate) (P-HEMA) and poly (glyceryl methacrylate) (P-GMA) were prepared and coated with collagen. The porosity and surface homogeneity of hydrogels were analyzed by scanning electron microscopy (S.E.M.), and samples were implanted into the parietal cortex of adult rats. After 3 months, the implants and the surrounding tissue were taken out for histology and SEM. Macroscopically, all implants were accepted and well-tolerated. Microscopic investigations revealed that, macroporous P-GMA hydrogels with good surface homogeneity were intensely cellularized with the deposition of basal lamina (B.L.) revealed by the Jone's periodic acid methenamine silver method, S.E.M., and of collagen of type I and III by the picrosirius- polarization method. The deposition of B.L. followed the geometric pattern of the inner surfaces of the hydrogels. There was no or little encapsulation of implants, the interfaces showed a fusion between the hydrogels and the host tissue, and the beginning of tissue ingrowth. The tissue reactivity to P-HEMA hydrogels was very mild only. The use of biocompatible, porous, synthetic matrices could be the basis of a reconstructive brain surgery, involving (1) permanent, chemically inert tissue substitute (2) a lattice-surface network coated with B.L. components as potential guiding substrates for regeneration. (Supported by MRC and FRSQ).

204.4

REGENERATION CAPACITY OF THE PROXIMAL NERVE STUMP IN THE ABSENCE OF DISTAL NERVE STUMP EXAMINED IN AN IN VIVO WINDOW CHAMBER. **M.F. Humphrey, W.I. Levy, W.D. Dietrich, J. Mora. Departments of Neurological Surgery and Neurology. University of Miami School of Medicine, Miami, Florida 33136.**

We have recently described the growth characteristics of the peroneal branch of the rat sciatic nerve across a 5mm gap within a thin, glass walled, chamber which allows repeated visualization of the contents. In this study, only the proximal nerve stump was sutured into the chamber. The distal nerve stumpwas resected and the opening plugged. In each case blood vessels,axons and associated cellular elements grew into the chamber for several millimeters. The ingrowth structure was similar to that found when the distal nerve stump was also present. The mean growth rate of 0.30 ± 0.1mm/day was also similar to that in the presence of a distal stump. By 15-20 days myelination of axons occurred within the 2mm closest to the proximal entrance. Subsequently, however, the proximal growth progressively withdrew from the chamber leaving it empty by 25-30 days. This suggests that in some circumstances, the proximal nerve stump can actively regenerate for 2-3 weeks without the presence of a distal nerve stump or a ready made substrate for growth. However, maintenance of this growth does not occur.

204.5

A COMPARISON OF SALINE AND MATRIGEL AS SUBSTRATES FOR PERIPHERAL NERVE REGENERATION IN AN IN VIVO WINDOW CHAMBER. **Walter J. Levy, Martin F. Humphrey, Dalton Dietrich. Department of Neurological Surgery and Neurology, University of Miami School of Medicine, Miami, Florida 33136.**

The efficacy of Matrigel (a basal lamina extract) as a substrate for peripheral nerve growth was assessed in a chronic in vivo chamber implant. A comparison of the regeneration rate and morphology of peroneal nerve growth in Sprague Dawley rats (250g) was made between chambers prefilled with Matrigel or saline. The chamber consists of two coverslips 5mm square separated by a coverslip spacer, making a 70-120um space. It is sealed at its edges by silicone elastomer except for two 1mm ports on opposite sides, which have silicone sleeves attached. The chamber is implanted in the sectioned peroneal of the sciatic nerve, and the stump sewn in at each port. The nerve regenerates as a thin strand through the chamber, and the rate of regeneration was measured by reanesthetizing the animal, re-opening the wound, and examining the chamber under an operating microscope. Forty chambers were studied for up to 100 days. The growth rates were 0.32mm/day (saline) and 0.48mm/day (matrigel). These rates were not significantly different (p>0.05,t-test). Matrigel appears to be a suitable substrate for growth, however, this offers no clear advantage over a saline filled gap.

204.6

PERIPHERAL NERVE REGENERATION THROUGH SEMI-PERMEABLE BLIND-ENDED TUBES: EFFECT OF THE MOLECULAR WEIGHT CUT-OFF. C. Rampone *, V. Guénard *, R.F. Valentini *, P. Aebischer * (SPON: M. Epstein). Artificial Organ Laboratory, Brown University, Providence, RI 02912.

In contrast to impermeable tubes, the use of semi-permeable blind-ended tubes allow peripheral nerve regeneration in the absence of a distal nerve stump, suggesting that factors produced by the external wound environment can support regeneration (Aebischer et al. Brain Res., 456, 1988). By varying the molecular weight cut-off of the tubular membrane it may be possible to assess the relative contribution of wound healing molecules on peripheral nerve regeneration. Asymmetric polysulfone tubular membranes with a molecular weight cut-off of 10 and 100 kilodaltons (KD) were capped at one end with a compatible polymer glue. The proximal nerve stump of a transected hamster sciatic nerve was secured 2 mm within a 10 mm long tube; the distal nerve stump was fully resected and discarded. Cohorts of 6 animals were implanted for 4 weeks. Upon retrieval, all tubes contained tissue cables extending to the distal cap. The cables present at the midpoint of the 10 KD tubes were significantly smaller than those regenerated in the 100 KD tubes. The cables regenerated in the 10 KD tubes were composed of granulomatous tissue devoid of myelinated axons. In contrast, 5 out of 6 100 KD tubes showed nerve cables containing myelinated axons. These results suggest that humoral factors from the external wound healing environment with molecular weights greater than 10 KD are able to support peripheral nerve regeneration in the absence of a distal nerve stump.

FUNCTIONAL RECOVERY FOLLOWING RAT SCIATIC NERVE REGENERATION THROUGH COLLAGEN NERVE GUIDE TUBES: COMPARISON OF DIRECT ANASTOMOSIS, NERVE GRAFT, AND ENTUBULATION REPAIR. **S.J. Archibald* and R. Madison. Department of Neuropathology and Neuroscience, Harvard Medical School and Children's Hospital, Boston, MA. 02115.**

Although numerous natural and synthetic materials have been utilized to effect peripheral nerve regeneration, the preferred standard method to repair human peripheral nerves is either direct anastomosis or the use of autologous peripheral nerve grafts. The present study indicates that in terms of physiological recovery of muscle EMG activity, nerve guide tubes fabricated from Bovine Type I collagen (American Biomaterials Co., Plainsboro, N.J.) are as effective as the standard nerve graft or direct anastomosis to repair transected rat sciatic nerve.

Under deep anesthesia 40 adult male Long Evans rats (N=10 in each group) received transection of the sciatic nerve at mid-thigh level, and repair by: A) direct anastomosis, B) 4mm section of nerve reversed and rotated 180°, C) 6mm porous tube (4mm nerve gap) of standard Type I collagen, and D) 6mm porous tube (4mm nerve gap) of highly purified Type I collagen. At 4 and 12 weeks postoperatively (N=5 for each group at each time), the sciatic nerve was reexposed, stimulated, and averaged evoked EMG recordings (N=64) were made from the gastrocnemius muscle. At 4 weeks group A (575±340 uV, mean ±S.D.) was significantly different (p<.001) from groups B (68±45 uV), C (0.18±.4 uV), and D (12±10 uV). At 12 weeks there was no significant difference among the groups, with EMGs ranging from 6-10 mV. Supported by NS22404 to R.M.

PRIMATE PERIPHERAL NERVE REPAIR BY ENTUBULATION: AN ELECTROPHYSIOLOGICAL STUDY. **C. Krarup*, S.J. Archibald*, R. L. Sidman, A. Sabra*, and R. Madison (SPON: M. Moore). Harvard Medical School, Children's Hospital, Boston, MA.**

In recent years there has been increasing interest in the development of a prosthetic nerve guide as an alternative method to repair peripheral nerves. This study follows the time course of regeneration after implantation of a polylactate nerve guide tube (Allied-Signal, Inc.).

The median or ulnar nerve was sectioned at the wrist in two monkeys (Macaca Fasicularis), the proximal and distal stumps were inserted into each end of an empty nerve guide and were sutured in place with two 10/0 sutures leaving a gap of 5mm between the nerve stumps. Motor (MAP) and sensory (SAP) nerve conduction studies were performed over a period of 19 months. The MAP from the APB/ADQ muscles were first detected at 55-56 days after section with latencies of 18 and 28 msec (vs control side of 1.3-1.2 msec), and amplitudes of 0.1-0.2 mV (vs control side of 20-30 mV). Over the subsequent 17 months the latencies recovered to 130% and the amplitudes to 50% of the control.

The amplitude of the SAP recovered to 15-25% and the conduction velocity to 65-85% of contralateral control. The SAP remained dispersed with late components conducting at 6 m/sec. After regeneration SAP could be evoked in both animals by discrete tactile stimulation of the appropriate finger pad, suggesting functional reinnervation of sensory nerve receptors. The results demonstrate that following this type of entubulation repair, motor and sensory fibers reach significant levels of functional recovery following reinnervation of specific groups of appropriate target organs. Supported by NS22404 to RM.

ADSORBED HUMORAL FACTORS ALLOW PERIPHERAL NERVE REGENERATION THROUGH IMPERMEABLE BLIND-ENDED TUBES. V. Guénard *, M. Goddard *, M. Liu, P. Aebischer *. Artificial Organ Laboratory, Brown University, Providence, RI 02912.

Nerve guidance channels are useful tools to study the effect of humoral factors on nerve regeneration. We investigated the influence of acidic fibroblast growth factor (a-FGF) and ∂1-acid glycoprotein (∂1-GP), a wound healing protein, on the regeneration of rat sciatic nerves. Blind-ended impermeable silicone elastomer (SE) channels were used since they exclude from the regenerating environment humoral factors derived from the distal nerve stump and the surgical wound. The lumens of capped SE tubes were separated into 2 compartments by a 10 mm-long strip of nitrocellulose (NC) paper. The channels were soaked prior to implantation in sterile physiologic saline or DMEM with either a-FGF or ∂1-GP. The proximal nerve stump of a transected rat sciatic nerve was positioned 2 mm within a 12 mm long tube; the distal stump was fully resected and discarded. Cohorts of 6 animals were implanted for 3 weeks. Upon retrieval, all tubes contained tissue strips adhering to both sides of the NC paper and extending for an average of 5 mm. Saline filled tubes were composed mainly of blood cells, fibrin and circumferential cells, whereas a-FGF or ∂1-GP filled tubes were composed of nerve cables all containing myelinated and unmyelinated axons. Three mm distal to the proximal stump the number of myelinated axons present in the ∂1-GP channels was significantly higher than that in the a-FGF channels (2584±897 vs 790±225). These results indicate that adsorbed humoral factors are able to induce peripheral nerve regeneration in the absence of a distal nerve stump. We surmise that factors secreted by the healing wound play a significant role in peripheral nerve regeneration.

EFFECTS OF DIFFERENT TYPES OF SURGICAL INTERVENTION ON NERVE REGENERATION K.L. Gibson*, L. Remsen*, G. Strain, and J.K. Daniloff. Louisiana State University School of Veterinary Medicine, Baton Rouge, LA 70803

Functional restitution following peripheral nerve repair is far from optimal. Entubulization repair, or the implantation of nerve cuffs, has been used both experimentally and clinically. Nerve cuffs have been shown to be effective conduits for nerve regeneration across small gaps. These cuffs provide mechanical support, decrease the amount of implanted suture material required, decrease adhesions, and act as guidance channels for regenerating axons. However, no substance has yet emerged as the material of choice for this procedure. Therefore, the purpose of this investigation was to compare several different types of implants. Specifically, absorbable and non-absorbable materials were compared to delineate which substance is optimal for nerve entubulization.

Nerve cuffs composed of silicone, marlex, or vicryl were implanted to span 0.5 cm gaps in the ischiatic nerve of adult Sprague-Dawley rats. Nerve regeneration through these implants was compared to repair of the same size gap by homogenic nerve grafts. Evaluations of functional return after 10, 24, and 90 days included comparative analyses of walking tracks, electromyography, histopathology, morphometry, and a radiochemical assay of choline acetyltransferase activity. INFLUENCE OF GLUCOSE ON RECOVERY OF RAT HIPPOCAMPAL SLICES FROM ANOXIA. E.L. Roberts, Jr*. and T.J. Sick (SPON: D.M. Easton). Dept. of Neurology, Univ. of Miami School of Med., Miami, FL 33101.

Glucose improves recovery of synaptic transmission *in vitro* following anoxia in rat hippocampal slices (Schurr, A., *et al., Brain Research*, 421:135, 1987). The mechanisms of this recovery were studied in more detail in the CA1 region of the rat hippocampal slice. Extracellular K^+ activity (K^+o) and field potentials were recorded from stratum pyramidale stimulated orthodromically via Schaffer collaterals. Slices were exposed to normoxia (95% O_2 - 5% CO_2) and to physiological solutions containing 5-20 mM glucose, made anoxic (95% N_2 - 5% CO_2), and returned to normoxia. Increasing concentrations of glucose delayed the onset of anoxic depolarization (AD) (sudden loss of ion homeostasis) and improved recovery of synaptic transmission when anoxia duration was kept constant. However, when the duration of AD was kept constant (total duration of anoxia allowed to vary), apparent $Na^+ - K^+$ pump activity (K^+o undershoot) following anoxia was increased by elevation of glucose, but recovery of synaptic transmission was not improved. Thus, glucose improved recovery of both synaptic transmission and ion homeostasis by delaying the onset of AD. However, recovery of ion homeostasis and synaptic transmission following AD were not equally affected by glucose, suggesting that different recovery mechanisms are involved. (Supported by PHS grants NS05820, NS14325, and HL38657)

SYNERGISTIC EFFECTS OF ARACHIDONIC ACID AND GLUTAMATE ON THE INJURY OF ASTROCYTES IN CULTURE. A.C.H. Yu,* P.H. Chan (Sponsor: R.A. Fishman), Dept. of Neurology, University of California, San Francisco, CA 94143

Arachidonic acid (20:4) and extracellular glutamate (glu) contents increased significantly following cerebral ischemia. We have hypothesized that these factors play an important role in the pathogenesis of cellular edema, particularly the astrocytic swelling. One possible mechanism is that 20:4 inhibits the re-uptake of glu in cultured astrocytes and thereby exerts a synergistic effect in inducing astrocytic swelling (Yu et al, J Neurochem 47:1181, 1986). We now further study the effect of 20:4 and/or glu by measuring intracellular water space of cultured astrocytes (IWS; measured by 14C-0-methyl-glucose), lactate dehydrogenase (LDH) efflux and formation of malondialdehyde (MDA). After 4 hrs of exposure, 20:4 (0.2 mM) increased the IWS from 3.5 to 9 uL /mg protein, medium LDH from trace to 300 U/L and MDA content from 0.59 to 3 nmol/mg protein. These effects were time and dose related. Other polyunsaturated fatty acids like docosahexaenoic acid but not saturated fatty acids induced similar changes. Four hrs glu (1mM) incubation increased astrocytic IWS to 11-12 uL/mg protein and the effect was also dose and time dependent. However, 1mM glu alone did not induce release of LDH and formation of MDA in the culture. 20:4 (0.1mM) + glu (1mM) increased the IWS to 17 uL/mg protein in 4 hrs, hastened the LDH efflux, but did not further enhance the MDA formation induced by 20:4 alone. Results suggest that in the presence of glu, the injurious effects of 20:4 were enhanced. Our data indicated that 20:4 and glu injured astrocytes synergistically. (Supported by NS-14543, NS-25372)

205.3

THE EFFECT OF GABAERGIC TRANSMISSION ON ANOXIC DAMAGE TO THE HIPPOCAMPAL SLICE. I.S.Kass, A.E.Abramowicz*, G.Chambers*, J.E.Cottrell*. Anesthesiology Dept., State University of New York, Health Science Center, Brooklyn, N.Y. 11203

We have investigated the mechanism of anoxic damage using the in vitro hippocampus as a model system. Midazolam (1 uM) did not affect the size of the evoked response recorded from the CA1 pyramidal cells before anoxia and did not protect these cells against anoxic damage. A much higher dose of Midazolam (100 uM), which exceeds the amount needed to activate the benzodiazepine receptor, increased the size of the evoked response by 40 ± 8 % over its predrug level. The response in the CA1 region recovered to 27 ± 7 % of its preanoxic level after 5 minutes of anoxia with Midazolam (100 uM) pretreatment. This was significantly different from untreated anoxic slices which showed no recovery (0 ± 0 %). GABA (10 mM), an inhibitory transmitter in the hippocampus, blocked the evoked population spike in the CA1 region. GABA did not protect against anoxic damage (0 ± 0 %) in spite of its blockade of neuronal activity. We found that tissue treated with GABA has lower ATP levels at the end of 5 minutes of anoxia than untreated tissue (1.21 ± .07 vs 1.82 ± .13 nM ATP/mg dry wt). Our results indicate that blocking neuronal activity is not sufficient to protect against anoxic damage.

205.4

POSSIBLE DOPAMINERGIC ACTIONS OF MK-801. D. Corbett. Fac. of Medicine and Dept. of Psychology, Memorial Univ. of Newfoundland, St. John's, NF, CANADA A1B 3V6.

The NMDA antagonists, MK-801, ketamine and phencyclidine protect against cerebral ischemic damage. These latter two compounds are also drugs of abuse. Since many of the behavioral effects of MK-801 are similar to those of ketamine and phencyclidine the abuse potential of this compound was assessed in a brain stimulation reward (BSR) paradigm. Drugs that enhance DA synaptic transmission (e.g. amphetamine) facilitate BSR whereas drugs that impede DA synaptic transmission (e.g. neuroleptics) attenuate BSR.

MK-801 produced a significant facilitation at hypothalamic and cortical BSR electrode sites. This facilitation was blocked by concurrent administration of a DA antagonist. A rotational model was also used to investigate DA effects of MK-801. MK-801 induced an ipsilateral rotation similar to that produced by amphetamine.

These results suggest that MK-801 has DA actions and therefore abuse potential. Excessive DA activity may also contribute to ischemic damage in some brain areas. Such properties may limit the clinical usefulness of MK-801.

205.5

DOPAMINE D-1 BUT NOT D-2 RECEPTORS ARE SELECTIVELY VULNERABLE TO TRANSIENT ISCHEMIA IN THE RAT STRIATUM. M.Y.-T. Globus, D.C. Mash, W.D. Dietrich, R. Busto*, I. Valdes*, and M.D. Ginsberg. Cerebral Vascular Disease Research Center, Department of Neurology, University of Miami, School of Medicine, Miami, FL, 33101.

We have previously demonstrated that dopamine (DA) release during ischemia is involved in the development of ischemic damage in the striatum (Globus et al, Neurosci. Lett. 80:251-256, 1987). Striatal density and distribution of DA D-1 and D-2 receptors was measured autoradiographically 3 and 14 days after 20 min of transient ischemia produced by 4-vessel occlusion in the rat. Adjacent sections were processed for D-1 and D-2 receptors and stained with hematoxylin and eosin for ischemic cell evaluation. D-1 and D-2 receptors were labelled using a saturating concentration of [^{3}H]-SCH 23390, and [^{3}H]-spiroperidol respectively. In control animals the densities of D-1 and D-2 receptors in the dorsolateral striatum were 323 ± 67 and 212 ± 16 fmol/mg tissue, respectively. After 3 days of recirculation, in the presence of ischemic cell damage, no significant changes were detected in the receptor density (D-1 = 242 ± 73, D-2 = 182 ± 45). However, after 14 days of reperfusion the density of D-1 receptors was markedly reduced (40 ± 56) while D-2 receptors were not affected (210 ± 43). The distribution of the D-1 receptor drop-out correlated with the location of the ischemic area. In contrast to the dorsolateral region, no changes were detected in the mediovcntral striatum. These results indicate that striatal neuronal components with D-1 receptors are selectively vulnerable to transient ischemia.

205.6

REDUCTION OF EXTRACELLULAR GLUTAMATE RELEASE DURING ISCHEMIA DOES NOT AMELIORATE ISCHEMIC STRIATAL DAMAGE. R. Busto*, M.Y.-T. Globus, W.D. Dietrich, I. Valdés*, E. Martinez*, B.D. Watson*, and M.D. Ginsberg (SPON: W. J. Weiner). Cerebral Vascular Disease Research Center, Univ. of Miami Sch. of Med., Miami, FL, 33101.

Several lines of evidence suggest that glutamate (Glu) release is involved in the development of ischemic neuronal damage in the hippocampus. However, its involvement in striatal ischemic injury is uncertain. In the present study we examined the effect of a corticostriatal pathway lesion on extracellular release of Glu and on the evolution of histopathological changes in the striatum. Two weeks after photochemically induced unilateral decortication, rats were subjected to 20 min of global ischemia produced by 2-vessel occlusion combined with systemic hypotension (50 mmHg). In one group of animals, striatal extracellular sampling was performed by a microdialysis probe while a separate group was processed for histopathological evaluation after 3 days of recirculation. A 50% reduction in Glu release was observed, during ischemia and early recirculation, on the denervated striatum as compared to the nonlesioned side. However, the degree of ischemic cell damage was similar on both sides. The number of ischemic cells per high power field (mean ± S.D.) in the denervated and non-denervated dorsolateral striata were 45.5 ± 14.7 and 47.3 ± 19.5 respectively. These results suggest that a 50% reduction in striatal extracellular Glu release during ischemia does not alter the final histopathological outcome. It is possible that another injury mechanism may prevail.

205.7

THE EFFECT OF FOCAL CEREBRAL ISCHAEMIA ON GLUTAMATE AND DIHYDROPYRIDINE BINDING SITES IN THE RAT. M.C. Wallace and J. McCulloch, (Spon. S.E. Blackshaw). Wellcome Surgical Institute, University of Glasgow, Glasgow, G61 1QH, Scotland.

Excitatory amino acids and calcium entry into neurones have been implicated in the pathophysiology of cerebral ischaemia. The temporal profile of glutamate and calcium entry blocker binding has been examined in focal cerebral ischaemia in the rat.

Sprague-Dawley rats (n=20) underwent middle cerebral artery occlusion under anaesthesia. Animals were sacrificed at 6, 12 and 24 hours and in-vitro binding with ^{3}H-glutamate (200 nM) and ^{3}H-nitrendipine (0.4 nM) was assessed with quantitative autoradiography. There was an apparent decrease in ^{3}H-nitrendipine binding in the ischaemic cortex and caudate, with marked enhancement of dihydropyridine binding along the margin of the ischaemic area. However, these changes in binding were reflected in both total and non-specific binding. No significant changes in ^{3}H-glutamate binding were detected up to 24 hours after focal ischaemia.

Thus, recognition sites of glutamate and dihydropyridine binding sites are robust, and remain largely unchanged at 24 hours after ischaemia. The interpretation of changes in receptors must be made with consideration given to the effects of tissue quenching of tritiated labelled ligands. Supported by the Wellcome Trust, MCW is an MRC Fellow (Can).

205.8

OPIATE RECEPTOR SUBTYPE BINDING IN GERBIL HIPPOCAMPUS ALTERED BY FOREBRAIN ISCHEMIA. D.C. Perry[1] & L.P.Miller*[2]. [1]Dept. Pharmacology, George Washington Med. Center, Wash. D.C. 20037, & [2]Vet. Adm. Med. Ctr., Wash. D.C. 20422

Although present theories suggest involvement of excitatory amino acids in the specific cell pathology seen after transient forebrain ischemia, endogenous opioids may also play a role. To test for the involvement of opiate receptor subtypes in hippocampal ischemic damage, we used quantitative in vitro autoradiography to measure opiate binding in ischemic gerbils. Ischemia was induced in 10-14 week old female gerbils by bilateral clamping of the common carotid arteries for 10 min under halothane anesthesia. Seven days post-ischemia brains were removed and frozen coronal sections were cut through several hippocampal regions. Autoradiography was done for mu binding (3H-DHM and 3H-DAGO), kappa binding (3H-bremazocine) and lambda binding (3H-naloxone + 300 nM diprenorphine; Eur. J. Pharmacol. 129:147, 1986). Quantitation was done with a Loats/Amersham RAS1000. No changes in mu binding were detected in the hippocampus with either ligand. Kappa binding was significantly lower over the pyramidal layer in CA1 & CA3 (20.5% decrease, $p<0.001$), but not in dentate gyrus. Lambda binding over the mossy fibers was strikingly higher in ischemic animals (65.3% increase; $p<0.01$). These results suggest that dynorphin released from mossy fibers may play a role in ischemia-related neurological damage. Supported by DA04191.

205.9

PARALLEL PATTERNS OF HYPERSENSITIVITY TO NMA TOXICITY AND HYPOBARIC/ISCHEMIC DAMAGE IN DEVELOPING RAT BRAIN. C. Ikonomidou*, J. Mosinger, K. Shahid Salles, J. Labruyere* and J. W. Olney (SPON: M.S. Shahid Salles). Dept. of Psychiatry, Washington University Sch. of Med., St. Louis, MO 63110.

Accumulating evidence implicates the endogenous excitotoxins, glutamate (Glu) and aspartate, in hypoxic/ischemic brain damage. For example, we have found that hypobaric/ ischemic (H/I) conditions cause a form of acute cytopathology in the 10 day old rat brain which is indistinguishable from that induced by exogenous Glu and is blocked by MK-801, a potent and selective antagonist of the N-methyl aspartate (NMA) receptor (the most prevalent sub-type of Glu receptor in brain). Here we have studied, at various postnatal ages, the sensitivity of rat CNS neurons to H/I conditions or to the neurotoxic effects of NMA injected directly into brain.

In the early postnatal period (days 1 to 10), unilateral injection of small doses (6-15 nmol) of NMA into the striatum or neocortex caused a surprisingly severe and widespread excitotoxic reaction affecting many neuronal groups bilaterally. Sensitivity to this fulminating type of reaction increased in the very early period (days 2-6), reaching peak intensity at days 6-8. From days 10 to adulthood, it required progressively higher doses (e.g., 50 nmol at 60 days) to produce significant damage and the damage was confined to the injection site. We found that the period of peak sensitivity to H/I damage also occurred at days 6-8 with progressively diminishing sensitivity being evident with increasing age. The cell populations most sensitive to NMA toxicity in the 2 to 10 day period closely correlated with those most vulnerable to H/I degeneration in this period.

Since the kainic acid (KA) receptor is considered the second most prevalent Glu receptor in brain, its potential complicity in H/I brain damage warrants consideration. In the present study we have corroborated findings from other laboratories that KA is relatively non toxic when injected into the striatum of the 6 day old rat in doses which would produce severe widespread damage in adult rat brain.

Here we show that rat CNS neurons in the early neonatal period are exceedingly sensitive to either H/I degeneration or the direct toxic effects of NMA (but not KA) and that the period of peak sensitivity to the two toxic phenomena coincides. This suggests the interesting possibility that there may be a developmental phase in human ontogenesis when the NMA receptor-ionophore complex is peculiarly hypersensitive and CNS neurons are correspondingly hypervulnerable to hypoxic/ischemic damage. CYCLOHEXYLADENOSINE (CHA) REDUCES THE DOWN-REGULATION OF ADENOSINE A1 RECEPTORS, G-PROTEIN AND ADENYLATE CYCLASE (AC) FOLLOWING ISCHEMIA IN THE GERBIL HIPPOCAMPUS. J.L. Daval, P.J. Marangos, J. Deckert, D.J. Redmond*, S.L. Cohan*, and D.K.J.E. Von Lubitz*. Unit on Neurochemistry, BPB, NIMH, Bethesda, MD 20892.

Transient ischemia produces selective neuronal damage in specific brain areas such as hippocampus. In the CA1 subfield, the pyramidal cells undergo a "delayed neuronal death" within a few days after recirculation. It has been proposed that postanoxic hyperexcitability and synaptic release of glutamate are involved in this process. Adenosine is a neuromodulator in hippocampus formation. Adenosine A1 receptors are believed to mediate the action of adenosine via an inhibition of AC activity. Previous studies have shown a decrease in adenosine A1 receptors after transient brain ischemia in gerbils. In the present quantitative autoradiographic study, the effects of a single IP administration of CHA (2mg/kg) were investigated in gerbil hippocampus 1, 3 or 6 days following a 20 min episode of ischemia induced by occlusion of the carotid arteries. [^{3}H]CHA, [^{3}H]Gpp(NH)p and [^{3}H]forskolin were used to label adenosine A1 receptors, G-protein and AC respectively in brain sections. The data showed a down-regulation of adenosine A1 receptors associated with a decrease in G-protein and AC after ischemia, especially in the CA1 subfield, while CHA treatment considerably reduced the effects of ischemia. CHA might protect the brain by reinforcing the neuromodulatory action of adenosine

205.11

COOLING GREATLY REDUCES EFFECTS OF ANOXIA IN RAT HIPPOCAMPAL NEURONS. M.E. Morris*, K. Krnjević, J. Leblond. *Pharmacology Department, University of Ottawa; Anaesthesia Research Dept., McGill University, Montréal, Canada.

When compared with slices kept at 33.5°, slices at 23-24° show some sharp differences in membrane properties, recorded in the CA1 pyramidal layer: input resistances are higher, action potentials longer, and Ca currents more difficult to elicit. Of particular interest is a much greater resistance to anoxia. In contrast to the near 50% decrease in resistance, marked hyperpolarization and loss of excitability typically evoked by 2-4 min periods of anoxia at 33.5°, there is a much smaller resistance fall (by 15.6 ± 4.0% (n=12)) and no consistent hyperpolarization at 23°; moreover, the characteristic post-anoxic hyperpolarization is inconspicuous or even replaced by depolarization. Moreover, at 23° anoxia as a rule fails to generate either slow steady increases of $[K]_o$ or the dramatic rise - associated with spreading depression-like changes in potential and resistance - that are commonly seen at the higher temperatures.

CARDIOVASCULAR REGULATION IV

206.1

MICROINJECTION OF ATRIAL NATRIURETIC FACTOR (ANF) INTO THE SOLITARY NUCLEUS (NTS) FACILITATES THE BARORECEPTOR REFLEX INDUCED BY STIMULATION OF THE AORTIC DEPRESSOR NERVE (ADN) IN THE ANESTHETIZED RAT D.J. McKitrick* and F.R. Calaresu Dept. of Physiology, University of Western Ontario, London, Ontario, Canada. N6A 5C1

As microinjection of ANF into the rat NTS is known to elicit a depressor response (Am. J. Physiol., in press), we tested the hypothesis that there may be a synergistic action on arterial pressure (AP) of subthreshold stimulation of the ADN and microinjection of subthreshold amounts of ANF into the NTS. In 19 Wistar rats under urethan anesthesia, electrical stimulation (0.5 ms duration, 40 Hz, 10-100 μA, for 10 s) which did not change AP or heart rate (HR) was applied to the ADN, and volumes (2-11 nL) of 10^{-7}M ANF, which did not influence AP or HR, were microinjected into the middle third of the rostrocaudal extent of the ipsilateral NTS. When subthreshold intensities of electrical stimulation and subthreshold amounts of ANF were delivered simultaneously, decreases in AP (-13.4 ± 2.9 mmHg, n=15) and HR (-29.4 ± 7.0 bpm, n=15) were observed. These results indicate that ANF and baroreceptor fibers affect the function of a common pool of neurons involved in the baroreceptor reflex. (Supported by the Medical Research Council of Canada)

206.2

D2 RECEPTORS IN THE POSTERIOR REGION OF THE NUCLEUS TRACTUS SOLITARIUS MEDIATE THE CENTRAL PRESSOR ACTION OF QUINPIROLE (LY171555). R.H. Yang*, Y.F. Chen, J. M. Wyss, S. Oparil (SPON: S. King). Hypertension Program, University of Alabama at Birmingham, Birmingham, AL.

We have previously shown that injections of quinpirole into the 4th ventricle produces a greater pressor response of a more rapid onset than similar injections into the lateral ventricle in conscious Sprague-Dawley (S-D) rats, suggesting a site of action in brainstem. The present study was designed to determine the neurons in the brainstem which mediates this pressor response. Microinjections of quinpirole (5 μg) into the posterior region of nucleus tractus solitarius (P-NTS) caused a consistent increase in BP (Max Δ=12.4±1.1mmHg) with a rapid onset (26 sec) in decerebrate S-D rats, while microinjections into the anterior region of NTS, area postrema, C_1/A_1 regions, raphe obscurus nucleus, locus coeruleus or the regions which are 0.5mm lateral, superior or inferior to P-NTS produced little response. The pressor response induced by bilateral microinjections of quinpirole into P-NTS was not different from that of unilateral microinjection. The pressor response to quinpirole in P-NTS was abolished by pretreatment with metaclopramide (5 mg/kg, i.v. 10 min before), a DA D2 antagonist that crosses the blood brain barrier. Taken together, these data demonstrate that D2 receptors in the P-NTS mediate the central pressor action to quinpirole.

206.3

PICROTOXIN BLOCKS TIME-DEPENDENT INHIBITION OF PERIPHERAL AFFERENT INPUT TO NUCLEUS TRACTUS SOLITARIUS (NTS) NEURONS. B.D. Miller*, R.B. Felder, Dept. of Int. Med. and CV Ctr, Univ. of Iowa, Iowa City, IA 52242.

Recent studies have shown that the responsiveness of NTS neurons to peripheral afferent input is markedly diminished following an appropriately timed conditioning stimulus (CS) to the same or another afferent source. We examined the influence of the γ-aminobutyric acid (GABA) antagonist picrotoxin (PIC) on these time-dependent inhibitory interactions. In an *in vitro* rat brain slice, we made extracellular recordings from 5 medial NTS neurons activated by electrical stimulation of ipsilateral solitary tract (ST). For each unit, we determined the number of action potential responses to a test stimulus (2-8 V; .3 ms;.3-1 hz; 50 stimuli) and the manner in which these responses were modified by a prior CS (2-8 V,.3 ms) applied to the same ST at 50-350 ms intervals. The conditioning paradigm was repeated after adding PIC (10-25 μM) to the perfusate. With perfusate alone, the CS reduced the number of test-evoked responses (expressed as % control, mean±SE) to 77±11% at 350 ms, 60±9% at 250 ms, 33±9% at 150 ms, 26±10% at 100 ms, and 24±7% at 50 ms. With PIC, these values were 96±5% at 350 ms, 91±9% at 250 ms, 88±10% at 150 ms, 75±17% at 100 ms, and 71±17% at 50 ms. PIC significantly ($p<0.05$) blocked the inhibitory influence of the CS at intervals ranging from 50-250 ms. The data suggest that time-dependent inhibitory interactions in NTS are mediated at least in part by GABA receptors.

PRESSOR RESPONSES TO STIMULATION OF THE NTS IN ANESTHETIZED CAT. S.C. Robertson*, R.B. Felder and W.T. Talman (SPON: R. Lim). Lab of Neurobiology, VAMC and Univ. of Iowa, Iowa City, IA 52242.

Classic studies in the decerebrate cat demonstrated a predominantly depressor effect with electrical stimulation of the nucleus tractus solitarius (NTS). We sought to determine the effects on arterial pressure (AP), heart rate (HR), and renal sympathetic nerve activity (RSA) of electrical stimulation of the NTS and to compare the effects with those elicited by microinjections of glutamate (GLU-20 mM) or glycine (GLY-400 mM) into the NTS of fourteen paralyzed, ventilated anesthetized (chloralose) cats. In 36 of 45 sites in the NTS, electrical stimulation elicited pressor responses with variable changes in HR. At 43 of the 45 sites GLU also increased AP and usually (31/45) HR. At 22 sites GLU and GLY each increased AP. Independent of the AP response GLU tended to increase HR when injected medially and decrease HR when injected laterally. The direction of changes in RSA correlated with the direction of change in HR. In 3 unanesthetized, decerebrate cats electrical stimulation of dorsal NTS consistently decreased AP while more ventral stimulation increased AP. These data suggest that chloralose anesthesia modifies the cardiovascular response to stimulation of the NTS. The NTS pressor response is mediated by local neurons. Support: HL32205, HL14388, and NS24621.

NMDA RECEPTORS AND THE BARORECEPTOR REFLEX. N. Kogo*, J. Graff*, P.A. Grieve*, and W.T. Talman. Lab of Neurobiology, VAMC and Univ. of Iowa, Iowa City, Iowa 52242.

We have previously shown that blockade of the response to N-methyl-D-aspartate (NMDA) and kainate (KA) in the nucleus tractus solitarius (NTS) also blocks the baroreceptor reflex. We have now sought to study the role of NMDA receptors in the baroreceptor reflex. Twenty-one anesthetized rats were instrumented for recording arterial pressure (AP) and heart rate (HR) and in some for stimulating the aortic depressor nerve (ADN) and recording single units in the NTS. Microinjections of 2-amino--5-phosphonovalerate (APV) or vehicle were made into the NTS unilaterally before the injection of NMDA or KA or bilaterally before testing the reflex bradycardic responses to pressor doses of phenylephrine. The decrease in AP (41.5 ± 3.7 mmHg, mean ± SEM) elicited by NMDA (3 pmol) was reduced to an insignificant change (4.7 ± 2.1) by the microinjection of 10 mM APV at the same site. In contrast, APV did not affect the depressor response elicited by KA. The bilateral injection of APV led to an 85% reduction in the bradycardic response to equivalent increases of AP before and after APV. APV transiently blocked the orthodromic single unit responses to electrical stimulation of the ADN. These data suggest that the NMDA receptor is integral to the baroreceptor reflex in the NTS and that NMDA blockade abolishes the baroreceptor reflex. Supported by HL32205, HL14388, and VA Merit Review Tab 18.

206.6

DEPRESSOR RESPONSES TO CHOLINERGIC AGONISTS IN THE NUCLEUS TRACTUS SOLITARIUS (NTS) ARE MEDIATED BY M_2 MUSCARINIC RECEPTORS. J. Murugaian*, K. Sundaram* and H.N. Sapru (SPON: J. McArdle). Section of Neurosurgery, UMDNJ - New Jersey Medical School, Newark, NJ 07103.

Microinjections (0.2-2 nmol/site) of an M_2 muscarinic receptor agonist (cis-methyldioxolane; CD) into the intermediate portion of NTS decreased BP (23-52 mmHg) and HR (16-50 beats/min). These effects were produced by the reduction of sympathetic nerve activity. AFDX-116 (a specific blocker for M_2 receptors) when microinjected (0.8 nmol/site) into the same sites prevented the depressor and bradycardic responses induced by CD. Pirenzepine (a specific blocker for M_1 receptors), when microinjected (1.5 nmol/site) into the NTS failed to block the effects of CD. The M_1 receptor agonist (McN-A343; 3 nmol/site) failed to evoke any response from the NTS. These results indicate that muscarinic receptors of M_2 type are present in the intermediate portion of NTS and activation of these receptors by cholinergic agonists results in depressor and bradycardic responses. Support: NIH (HL 24347) and AHA (NJ).

206.7

SYSTEMIC GLUTAMATE DESTROYS SOME TYROSINE HYDROXYLASE AND SEROTONIN IMMUNOREACTIVE NEURONS IN AREA POSTREMA OF SHR. D.K. Hartle and C.F. Phelix*. Cardiovascular Laboratories, Univ. of Ga., Coll. of Pharmacy, Athens, GA 30602.

Neurons within the area postrema (AP) are outside the blood-brain barrier. High doses of systemic glutamate (G) (9 mg/ g, s.c.) produce neuroexcitotoxicity in a significant fraction of total AP neurons in adult rats. Of the circumventricular organs, AP is uniquely susceptible to toxicity at this dose of G. Immunocytochemical localization of tyrosine hydroxylase (TH) and serotonin (5HT) in 20 µm brain sections throughout the extent of the AP was done separately in groups of SHR and WKY rats treated with G, isosmotic saline or glycinate (pH 7.4). Degenerating neurons were consistently observed 4, 6, and 8 hr after G administration. Degenerating elements were eliminated by 24 hr after G. Light microscopic examination revealed that a significant fraction of neurons killed by systemic G were TH or 5HT immunoreactive (IR). Quantitative localization of these populations was performed by video image analyses. Both density and total number of these neurons decreased after G treatment. EM examination verified degenerating TH and 5HT-IR neurons and dendrites in AP, but not within NTS, of G-treated rats. Isosmotic saline and glycinate treatments produced no AP somal or dendritic necrosis. The potential role of susceptible AP neurons in the antihypertensive effect of G treatment in SHR vs. WKY will be discussed. NIH 1 RO1-HL37705-02 (DKH).

206.8

CARDIOVASCULAR ROLES OF TACHYKININ PEPTIDES IN THE NUCLEUS TRACTUS SOLITARIUS OF RATS

Y. TAKANO, A. NAGASHIMA, Y. HIGUCHI and H. KAMIYA.
Dept. Pharmacol., Fac. Pharmaceutical Sci. Fukuoka Univ. Fukuoka 814-01, Japan.

The primary afferent fibers of the glossopharyngeal and vagal nerves transmit baro- and chemoreceptor signals to the nucleus tractus solitarius(NTS). In addition, our previous studies have demonstrated high levels of substance P like immunoreactivity(SP-LI) and neurokinin A like immunoreactivity(NKA-LI) in the NTS (Brain Res.,369,1986). In the present study, we have examined the cardiovascular responses of NKA, SP and related peptides microinjected into the NTS of rats.

Male Wistar rats were anesthetized with urethane (1.0g/kg,i.p.), and artificially ventilated through a tracheal cannula with a respirator. Since saline-vehicle (0.1µl) injected into the NTS caused hypotension and bradycardia (Brain Res.,422,1987), tachykinin peptides were dissolved in artificial cerebrospinal fluid (ACSF) in this study. Microinjection of NKA (10ng and 100ng/0.1µl) into the caudal area of the NTS caused rapidly hypotension and bradycardia. The lower dose of SP (1ng/0.1µl) caused rapidly hypotension and bradycardia, whereas the higher dose of SP (100ng/0.1µl) resulted in increase in heart rate and blood pressure. These results indicate that NKA as well as SP may be involved in the baroreceptor reflex in the NTS.

206.9

CAPILLARY DENSITY AND GLUCOSE METABOLISM IN BARORECEPTOR SUBNUCLEI OF RAT NTS. P.M. Gross, J.J. Pang* and S. Shaver. Neurosurg. Res. Unit, Queen's Univ., Kingston, Ont. K7L 3N6

Caudal to obex, the nucleus of the solitary tract (NTS) is composed of several discrete subnuclei forming synaptic sites for afferent fibers from peripheral chemoreceptors and baroreceptors. Relationships intrinsic to reflex activity in NTS have been identified previously, e.g., subnuclear cytoarchitecture, neural connections, histochemistry, and impulse interactions. We describe other features supporting these processes within caudal NTS (obex -0.2 to -0.4 mm) of adult albino rats by analyses of capillary density (CD) and tissue glucose metabolism (GM), measures closely interrelated. Image processing was applied both to micrographic prints (x240) of coronal NTS sections to assess CD and [^{14}C]deoxyglucose film autoradiographs to measure GM. CDs in n. commissuralis, n. medialis and dorsal strip varied between 297 and 440/mm^2. Values for GM were between .55±.03 and .73±.04 umol/g/min. Mapping correlations between CD, GM and distribution of peptides and catecholamines in NTS subnuclei gives further insight to factors supporting autonomic regulation within the dorsal medulla oblongata.

206.10

METABOLIC ACTIVATION OF EFFERENT PATHWAYS FROM THE RAT AREA POSTREMA. D.S. Wainman*, S.W. Shaver, A.V. Ferguson and P.M. Gross (SPON: M. Caudarella) Neurosurg. Res. Unit and Dept. Physiol., Queen's Univ., Kingston, Ont. K7L 3N6

Specific medullary and pontine sites receive innervation from area postrema (AP) neurons. We examined the metabolic responsiveness of these projections by applying the [^{14}C]deoxyglucose method in anesthetized, ventilated (N_2O-O_2-halothane) albino rats during electrical stimulation (ES, 200 uA, 15 Hz) of the dorsomedial AP. ES provoked an abrupt 20% decrease in arterial pressure and bradycardia, both of which were sustained over time. Rates of glucose metabolism (umol/g/min; control values in parentheses) were doubled by ES in rostral or caudal subregions of AP more than 0.1 mm from the electrode (0.61) and in several subnuclei of NTS (mean = 0.61). DMN of the vagus nerve (0.56), n. ambiguus/A1 noradrenergic region (0.63), locus coeruleus (0.88), and lateral parabrachial nuclei (0.56) were also activated (+27-71%). The results indicate that AP neurons can influence the function of numerous brainstem structures within their efferent trajectories and implicate roles for the AP in regulation of autonomic reflexes.

206.11

CARDIOVASCULAR RESPONSES ELICITED FOLLOWING OPIOID RECEPTOR ACTIVATION IN THE AREA POSTREMA OF ANESTHETIZED RAT.

A.H. Hassen, E.P. Broudy* and J. Nemitz. West Virginia School of Osteopathic Medicine, Lewisburg, WV 24901.

Previous studies have described the cardiovascular responses elicited following selective activation of different opioid receptor types in the nucleus of Tractus Solitarius and the Dorsal Motor nucleus of the Vagus,two components of the dorsal vagal complex, in the anesthetized rat. Mu, kappa or delta receptor activation evoked qualitatively different patterns of cardiac and pressor responses. We have now examined the responses elicited following opioid receptor activation in the third component of the dorsal vagal complex, the circumventricular Area Postrema.

Male Sprague-Dawley rats were anesthetized with urethane (1.6 gm, ip), and prepared for recording of blood pressure and heart rate. The hindbrain was exposed in order to permit the stereotaxic placement of a pulled glass capillary (40-50 um diameter) into the Area Postrema. Mean arterial pressure and heart rate were monitored prior to a single injection (10 nl) of either the saline vehicle, glutamate, a mu-agonist (DAGO), a kappa-agonist (U50,488), or a delta-agonist (D-Pen). Tachycardia and pressor responses were elicited by the mu-agonist, whereas the delta- and kappa-agonists produced transient decreases in heart rate and blood pressure. Glutamate elicited small, transient biphasic changes in blood pressure and heart rate. These data suggest that different opioid receptor types in the area postrema can selectively modulate cardiovascular function. Supported by WVSOM.

DIFFUSION OF ^{3}H-OPIOID AND LATEX MICROSPHERES IN RAT AREA POSTREMA. J.W. Nemitz and A.H. Hassen.

Depts. of Anat. and Physiol., WV Sch. of Osteopathic Med., Lewisburg, WV 25901.

Male Sprague-Dawley rats were anesthetized with urethane, paralyzed, ventilated, placed in a stereotaxic frame, and the dorsal hindbrain was exposed. Single microinjections (300 pmol/10 nl) of either ^{3}H-D-Ala^{2}, MePhe^{4}, Gly-ol^{5} enkephalin solution (^{3}H-DAGO, a mu-opioid agonist) or cold DAGO in a 5% suspension of latex microspheres, were delivered to the area postrema (AP) or gracile nucleus (Gn). Blood pressure, heart rate and temp. were monitored throughout the experiment. Animals were sacrificed with pentobarbital, brains were removed and frozen on dry ice. Serial sections were cut in a cryostat and mounted on slides. The ^{3}H-labelled material was processed using standard autoradiography. All slides were stained and analyzed for distribution of the injected labels. Injections of ^{3}H-DAGO into the AP resulted in a bilateral distribution into the dorsal vagal complex; this was in contrast to the microsphere injections into the AP which remained within the AP. Injections into the AP of either ^{3}H-DAGO or DAGO mixed with microspheres resulted in cardiovascular responses (see abstract by Hassen et al.). Labelling of the AP with ^{3}H-DAGO also occurred after injection into the adjacent Gn, but no marking of the AP resulted from latex microsphere injections into the Gn. The injections into the Gn did not result in observed cardiovascular responses. These data provide evidence for selective diffusion of solutions into and out of the AP after microinjection. Supported by WVSOM.

THE EFFECTS OF CHEMICAL LESION OF THE AREA POSTREMA ON ARTERIAL BAROREFLEX RESPONSE TO PHENYLEPHRINE AND VASOPRESSIN. M. Hay*, B.F. Cox* and V.S. Bishop. Dept. of Pharm., The Univ. of TX Hlth. Sci. Ctr., San Antonio, Texas 78284-7764.

Previous studies have shown that electrolytic lesions of the area postrema abolishes the enhanced baroreflex inhibition of renal sympathetic nerve activity and heart rate (HR). The purpose of this study was to determine if similar effects could be produced by chemical lesions of the area postrema with kainic acid. The area postrema was lesioned with micropressure applications of kainic acid (1 ng/nl) in a series of 5, 15 nl injections given over 20 minutes. In control animals, infusion of arginine-vasopressin (AVP) resulted in a much greater fall in HR for any given change in mean arterial pressure (MAP) as compared to phenylephrine (PE) infusions. A 10 mmHg rise in MAP with PE produced an average 26 beat/min fall in HR whereas a 10 mmHg rise in MAP with AVP produced an average 56 beat/min fall. Lesions of the area postrema with kainic acid shifted the MAP - HR relationship obtained with AVP infusions to approximate the relationship obtained with PE infusions. These data suggest that discreet chemical lesions of the area postrema normalizes MAP - HR responses evoked with AVP and PE, thus further supporting the role of the area postrema in vasopressin modulation of cardiovascular regulation. (Supported by NIH Grants 12415 and 36080).

EVIDENCE FOR THE INVOLVEMENT OF SEROTONIN IN CENTRAL CONTROL OF CARDIAC VAGAL MOTONEURONES IN THE CAT.

D. Jordan, P.N. Izzo* and A.G. Ramage*. Departments of Physiology and Pharmacology, Royal Free Hospital Medical School, Rowland Hill Street, LONDON NW3 2PF, England.

5-HT$_{1A}$ agonists (e.g. 8-OH-DPAT) given i.v. cause vagally mediated bradycardia (Ramage, A.G. & Fozard, J.R. Eur. J. Pharmac., 138:179, 1987). The present experiments were carried out to investigate the possibility that 5-HT-containing nerve terminals can directly affect cardiac vagal motoneurones (CVM's) located in the nucleus ambiguus (NA). Horseradish peroxidase (HRP) was applied to identified cardiac branches of the vagus nerve and after 48-72 hours recovery the animals were killed, the brain fixed and the medulla sectioned (70μm). The sections were processed to reveal both retrogradely transported HRP and for 5-HT immunoreactivity using the PAP method. Electron microscopic examination of the material revealed 5-HT-immunoreactive boutons forming synaptic contacts with retrogradely labelled CVM's in the NA. In parallel experiments, microinjections of 5-HT or 8-OH-DPAT into this region evoked falls in heart rate of up to 37 beats/min in addition to reducing both renal and phrenic nerve activities. These results support our hypothesis that central 5HT-containing pathways are involved in vagal control of the heart.

BARORECEPTOR MODULATION OF HYPOGLOSSAL MOTONEURONES.

P.N. Izzo*, D. Jordan, D.J. Withington-Wray*, & K.M. Spyer. Department of Physiology, Royal Free Hospital Medical School, Rowland Hill Street, LONDON NW3 2PF, England.

Investigation of the physiological characteristics, morphology and precise localization of neurones in the dorsal medulla involved in cardiovascular control have been carried out in the cat using intracellular recording and labelling techniques. One clearly distinguishable group of neurones exhibiting baroreceptor modulation have been identified as a sub-population of hypoglossal motoneurones. Nine hypoglossal neurones, characterized on the basis of antidromic activation and/or intracellular labelling with HRP have been examined. All of these neurones were spontaneously active: the activity in three of them showing respiratory rhythm. Further analysis of their ongoing activity revealed pulse related activity in six of them, three of which were activated by carotid sinus nerve stimulation. One of these neurones, which showed an epsp-ipsp sequence of response to the carotid sinus nerve stimulation, was further characterized by natural stimulation of the carotid sinus baroreceptors, which inhibited the ongoing activity in this neurone.

These studies have identified an influence of the baroreceptor reflex on the activity of hypoglossal motoneurones.

FRONTAL-PARIETAL (F-P) CORTEX RECEIVES AN EFFERENT COPY OF SYMPATHETIC NERVE DISCHARGE (SND). Z.-S. Huang*, K.J. Varner, S.M. Barman and G.L. Gebber. (SPON: T.M. Brody). Dept. Pharmacol., Mich. State Univ., E. Lansing, MI 48824.

We studied the relationship between F-P cortical activity and inferior cardiac SND in chloralose-anesthetized cats. Cross-correlation analysis revealed that the 2- to 6-Hz rhythmic components in cortical activity and SND were temporally related in 10 of 17 baroreceptor-denervated cats. SND lagged cortical activity by 50±20 ms and the value of the crosscorrelation function at this lag was 0.4±0.1. In contrast to baroreceptor-denervated preparations, cortical activity and SND were not related in cats with intact baroreceptor nerves. Since electrical stimulation of F-P cortex increased SND (20-200 μA threshold current; response onset latency, 64±2 ms), the possibility arose that F-P cortex contributes to basal SND in baroreceptor-denervated cats. This possibility was tested by performing a F-P lobotomy bilaterally 1-2 mm behind the apex of the ansate sulcus. F-P lobotomy failed to significantly affect SND and blood pressure, or the reduction in SND and blood pressure produced by subsequent midbrain transection. Thus, the temporal relationship between cortical activity and SND does not reflect a tonic influence of the F-P cortex on SND. Rather, it appears that F-P cortex receives an efferent copy from the generator of 2- to 6-Hz SND. What the F-P cortex does with the efferent copy of SND remains to be determined. (Supported by NIH grant HL33266.)

PREFRONTAL STIMULUS-PRODUCED HYPOTENSION IS BLOCKED BY BRAINSTEM LIDOCAINE INJECTIONS. S.G.P. Hardy, D.E. Holmes*, and S.M. Mack*. Dept. of Anatomy, Univ. of Miss. Med. Ctr., Jackson, MS 39216.

Electrical stimulation of the prefrontal cortex (PFC) typically causes hypotension in the urethane-anesthetized rat. It has been suggested that PFC projections descending through the ipsilateral crus cerebri and terminating upon the contralateral nucleus tractus solitarius (NTS) may mediate the stimulus-produced hypotension (SPH) (van der Kooy, D., et al., J. Comp. Neurol., 224:1-24, 1984). To test this hypothesis, microinjections (0.5ul) of 4% lidocaine were made into various levels of this pathway in anesthetized rats. The area of functional blockade resulting from similar injections has been reported to typically be 0.9 mm in diameter (Sandkuhler, J., et al., Exp. Brain Res., 68:168-178, 1987). In our study it was observed that injections made into the ipsilateral crus cerebri or into the vicinity of the contralateral NTS resulted in the attenuation or complete blockade of SPH. Similar injections made into the superior colliculus, periaqueductal gray and various sites within the reticular formation failed to attenuate SPH. The results of this study support the concept that prefrontal SPH is mediated by prefrontal projections to the NTS.

206.18

CENTRAL H1-BLOCKADE ABOLISHES PRESSOR RESPONSE TO INTRAVENOUS HYPERTONIC SALINE INFUSION. V. Schaumloffel* and S.L. Bealer (SPON: L. Share). Department of Physiology and Biophys., Univ. Tenn., Memphis, TN 38163.

Peripheral infusion of hypertonic saline results in increased mean arterial pressure (MAP), mediated partially by release of vasopressin. Central administration of histamine (HA) results in increased MAP, bradycardia, and vasopressin secretion in the conscious rat. Therefore, we observed the effect of central histaminergic blockade on the cardiovascular response to hypertonic saline infusion. Rats were implanted with lateral ventricular cannulae and catheters in the femoral vein and artery. After recovery, conscious animals received an intracerebroventricular injection of saline (VEH), H1-antagonist promethazine (PMZ), or H2-antagonist cimetidine (CMT), followed by a 30-minute intravenous infusion of 2.5 M or 0.17 M NaCl (10 μl/100 g/min). MAP was continuously recorded.

Isotonic saline infusion had no effect on MAP in any group. However, after a 30-minute hypertonic saline infusion, MAP was significantly elevated in VEH- (20.5 ± 3.8 mm Hg, n=6) and CMT- (15 ± 3.5 mm Hg, n=6) treated animals but not in animals pretreated with PMZ (0 ± 2.2 mm Hg, n=6). These data support the hypothesis that H1 receptors mediate pressor responses to hyperosmotic stimulus.

206.19

CIRCULATORY INSTABILITY MODIFIES BRAINSTEM CATECHOL METABOLIC BASELINE ACTIVITY. JY. GILLON*, L. QUINTIN, B. MILNE*, M. GHIGNONE, G. CHOUVET* and B. RENAUD. Neuropharmacologie, Univ. C BERNARD and CNRS, 69008, LYON, FRANCE.

The cardiovascular, circulatory and metabolic conditions of anaesthetized rats (S-D, 400g) were assessed for 12h, when managed A) conventionnally (CM, n= 9, chloral, spontaneous ventilation, no correction of acid-base balance, no volume infusion) B) under optimized management (OM, n= 7, chloralose, mechanical ventilation, O2= 40%, PetCO2= 40 mmHg, control of acid-base equilibrium, 7 ml/kg/h of a dextran-saline-bicarbonate solution). Voltammetric recordings of a catechol oxidation current (CA.OC) in the caudal ventrolateral medulla (VLM) allowed monitoring of the variations of the catecholamine metabolism under the CM and OM conditions. The CM group experienced i) a decline in mean arterial pressure (MAP), central venous pressure (CVP) and cardiac output 3 to 6 h after induction of anaesthesia, ii) severe metabolic acidosis, iii) progressive increase of CA.OC and iv) death before the end of the study in 6 rats. Deterioration of a rodent preparation was previously reported (Andrade et al., Brain Res., 1982, 242, 125; Guyenet et al., Brain Res., 1984, 303, 31). In the OM group, MAP, CVP, and blood gases remained stable for 12 h and CA.OC was recorded as a stable signal (n= 6). Similar results were obtained in OM rats, anaesthetized with halothane and infused with Ringer's lactate solution. It is concluded that baseline activity of VLM cardiovascular structures may be easier to assess in a thoroughly stable circulatory and metabolic preparation.

206.20

PERIPHERALLY ADMINISTERED γ-MSH CAN HAVE A CENTRAL SITE OF ACTION FOR ITS CARDIOVASCULAR EFFECTS. M.F. Callahan, K.A. Gruber* and S.L. Eskridge-Sloop*. Wake Forest University Medical Center, Winston-Salem, NC 27103.

I.V. administration of γ-MSH produces a pressor response which is partially dependent on the forebrain AV3V region and central vasopressin pathways. We previously showed that a pressor response could be elicited by lateral (icv) or fourth ventricular (ivt) injection of γ-MSH. The current studies examined whether icv injections produce pressor responses similar to iv injections and whether injection into the carotid circulation would produce greater pressor responses than iv administration.

ICV administration of 10 ug of the peptide produces a peak pressor response of 53±10 mmHg at 91±12 sec, while ivt administration results in a 65±6 mmHg pressor response at 54±16 sec. The pressor response following icv doses is associated with a tachycardia response while that following ivt administration results in no change in heart rate. In preliminary experiments, we observed that the icv pressor response is attenuated by ivt vasopressin antagonist.

Finally, 0.5 and 1.0 ug of γ-MSH elicited a pressor response (35±2 and 46±4 mmHg) when infused intra-carotid. Jugular infusions of the peptide produced a significant pressor response (40±4 mmHg) only at a 5.0 ug dose.

These studies suggest that γ-MSH produces greater pressor and tachycardia responses when given either directly into the CNS or into the cerebral circulation.

PHARMACOLOGY OF SYNAPTIC TRANSMISSION I

207.1

THE EFFECTS OF IRREVERSIBLE ACETYLCHOLINESTERASE INHIBITORS ON SYNAPTIC TRANSMISSION IN THE SYMPATHETIC GANGLIA OF THE BULLFROG, Rana catesbieana. J.F. Fiekers and T.J. Heppner*. Dept. Anat. and Neurobiol., Univ. of Vermont Coll. Med., Burlington, VT 05405.

The effects of soman, sarin, and VX were examined on synaptic transmission through the isolated 9th and 10th sympathetic ganglia of the bullfrog using extracellular and intracellular recording techniques. Each agent produced a frequency-dependent reduction in the amplitude of the compound action potential (CAP). At 30 Hz, the CAP amplitude was reduced to 28% of control. This effect was use-dependent with the amplitude of the second train reduced to >15% of control values with each agent. Agent application induced an initial depression in CAP amplitude which corresponded with the amplitude and frequency of spontaneous depolarizing afterpotentials (APs). These extracellular APs (1) occurred ~18msec after the initial CAP component (2) had an amplitude ~35% of the fast component, (3) were not the result of C fiber activation and (4) were irreversible with washing. Intracellular action potentials elicited by orthodromic stimulation demonstrated a frequency-dependent sustained membrane depolarization (1) that failed to return to resting levels within 5 minutes and (2) frequently abolished action potential generation. This work was supported in part by the US Army Medical Research and Development Command, Contract No. DAMD17-86-C-6031.

207.2

SOMAN INCREASES EXCITABILITY OF SYMPATHETIC GANGLION NEURONS OF THE BULLFROG. T.J. Heppner* and J.F. Fiekers (SPON: J. Held). Dept. Anat. and Neurobiol., Univ. of Vermont Coll. Med., Burlington, VT 05405.

The effects of soman were examined on B cell neurons in the 9th and 10th ganglion isolated from the paravertebral sympathetic chains of the bullfrog Rana catesbeiana. Application of soman produced an increase in spontaneous spiking and in the number of spikes during depolarizing step pulses. Intracellular recordings following soman exposure demonstrated (1) a depolarization of ~6.0mV (2) a 49.3% decrease in membrane resistance and (3) a 33% decrease in the duration of the hyperpolarizing afterpotential (HAP). The soman-induced depolarization and the change in membrane resistance were partially reversed by nicotinic and muscarinic receptor blockade and also by current clamping the membrane potential. Receptor blockade prevented the soman-induced shortening of the HAP. Single electrode voltage clamp measurements demonstrated that soman reduced the HAP current amplitude ~50%. These studies demonstrate that soman has multiple actions on ganglion cells which lead to an increase in ganglion cell excitability due to a combination of membrane potential depolarization and a decrease in the duration of the HAP.
This work was supported in part by the US Army Medical Research and Development Command, Contract No. DAMD17-86-C-6031.

207.3

EFFECT OF M_2 MUSCARINIC RECEPTOR ANTAGONISTS, AF-DX 116 AND GALLAMINE, ON MEMBRANE PROPERTIES OF SYMPATHETIC NEURONS. C. A. Yarosh, A. C. Olito* and J. H. Ashe. University of California, Riverside, CA 92521.

The effect of AF-DX 116 and gallamine on membrane electrical properties of sympathetic neurons was examined in rabbit superior cervical ganglion (SCG). AF-DX 116 and gallamine preferentially bind to the M_2(cardiac) muscarinic subtype(Hammer et al., Life Sci.,38,1986), and selectively antagonize the s-IPSP but not the s-EPSP recorded from SCG (Ashe and Yarosh, Neuropharmacol., 23, 1984; Yarosh et al., JPET, 245, 1988). Using intracellular recording techniques, it was demonstrated, in the present study, that superfusion of ganglia with AF-DX 116 (300-1000nM) was without effect on membrane potential (V_m) or membrane input resistance (R_i). In contrast, gallamine (5-35 μM) produced a dose-dependent depolarization that was sustained in the presence of gallamine. Peak depolarization was about 19.0 ± 0.8mV ($\bar{X}$±S.E.; n=34). Furthermore, superfusion with gallamine resulted in an increase in R_i observed with manual voltage clamp. The effects of gallamine were reversible when ganglia were superfused in gallamine-free Krebs-Ringer solution. The effects of gallamine were not diminished by superfusion of ganglia with d-Tubocurarine(35-70 μM) or quiniclinidyl benzilate (100 nM). These observations suggest that gallamine, but not AF-DX 116, may also produce non-cholinergic receptor mediated action(s) on ganglion neurons.

BINDING OF THE HIGHLY POTENT NICOTINIC AGONIST, ISOARECOLONE METHIODIDE, AND 19 OF ITS ANALOGUES AT NICOTINIC AND MUSCARINIC RECEPTORS. C.E. Spivak, J.A. Waters* and R.S. Aronstam. NIDA, Addiction Res. Ctr., Baltimore, MD 21224, NIDDKD, Bethesda, MD 20205, and Dept. Pharmacol. Toxicol., Med. Coll. Georgia, Augusta, GA 30912.

Isoarecolone methiodide (ISO) was previously shown to be among the most potent agonists tested at the frog neuromuscular junction (Spivak et al., Eur. J. Pharmacol. 120:127, 1986). Since nicotinic receptors from different sources vary in their selectivity, ISO as well as 19 additional congeners were studied in binding assays.

Competition studies on electric organ membranes from Torpedo nobiliana using [^{125}I]-alpha bungarotoxin yielded K_i values that correlated strongly (Spearman's correlation coefficient -0.91) with potency of the agonists at the frog neuromuscular junction. Activation of the ion channel by the agonists, as indicated by the enhanced binding of [^{3}H]-perhydrohistrionicotoxin, confirmed the preeminent activity of ISO. Competition studies at muscarinic receptors from rat brains, using [^{3}H]N-methylscopolamine, revealed that ISO was nearly as potent as carbamylcholine. This agent, therefore, appears to be a general, cholinergic agonist. By contrast, 1-methyl-4-acetylpiperazine methiodide, while nearly as active as ISO at the nicotinic receptor, was very weak at muscarinic receptors.

207.5

CHANGE IN ANTICHOLINESTERASE ACTIVITY OF PHYSOSTIGMINE AND PYRIDOSTIGMINE BY STRUCTURAL MODIFICATION. R. Ray and O.E. Clark*. US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.

Several synthetic physostigmine and pyridostigmine derivatives were studied for their structure-activity relationship in inhibiting acetylcholinesterase (AChE) in electric eel (purified) and in rat brain homogenate. These compounds were (-)-physostigmine salicylate (1), and (+)-physostigmine salicylate (2); decarbamylated physostigmine derivatives, (-)-eseroline sulfate (3), and (+)-eseroline sulfate (4); and pyridostigmine bromide (5), and its reduced tertiary derivative tetrahydropyridostigmine bromide (6). The concentration-response relationship of the AChE inhibition by these compounds was determined using an automated colorimetric microtiterplate AChE assay (Ray, R. and Clark, O.E., the FASEB J., 2(5): A1541, 1988). For both sources of AChE, the relative anti-AChE potencies of the carbamylating groups of compounds were in the order of 1 > 2; and 5 > 6; for the reversible inhibitors, 3 > 4. The (-)-optical isomers were more potent than the (+)- optical isomers, as expected, for all enantiomers tested. These results show that the anti-AChE potencies of the physostigmine and pyridostigmine derivatives used in this study depend on the structures of these derivatives, and that their relative potencies are similar for both eel and mammalian brain AChE.

207.6

EFFECT OF MAGNESIUM ON FREQUENCY-DEPENDENT CONTRACTION IN INDIRECTLY STIMULATED FROG SKELETAL MUSCLE. R.S. Manalis and B. Pickelheimer*. Dept. Biol. Sci., Indiana Univ.-Purdue Univ., Fort Wayne, IN 46805.

Sciatic nerve/sartorius muscle preparations from the frog (Rana pipiens) were used to study the effect of high-Mg/low-Ca Ringer on frequency-dependent contraction. Control measurements were obtained from preparations bathed in normal Ringer. A series of four trains of suprathreshold stimuli was applied every 5 min. The duration of each train was 4 sec; the interval between trains was 30 sec. The stimulus frequency within each train was constant and was increased sequentially from .5 Hz (first) to 15 Hz (fourth). Contraction ratios were determined from isometric tensions measured at a given frequency divided by those obtained at .5 Hz. At 15 Hz, the control ratio was 2.56± .33. In the presence of 1.25 mM Mg/1.0 mM Ca-Ringer, this ratio increased to 8.54± 2.70 (n=9). Mg did not alter the frequency-dependency of directly stimulated muscle. Therefore, inferences about transmitter release can be made from a population of neuromuscular synapses by measuring muscle tension from preparations bathed in high-Mg/low-Ca Ringer's solution. (Supported by NSF grant BNS-8609047.)

Alterations of endplate currents by Tetram (an irreversible anticholinesterase agent). E.G. Henderson, D.J. Post*, M.R. Burkard*, and C.A. Pappas*. Dept. of Pharmacology, University of Connecticut Health Center, Farmington, CT. 06032

We have previously shown that 217AO (the tertiary methylamine analog of echothiophate) an irreversible organophosphate acetylcholinesterase inhibitor decreases endplate current (e.p.c.) decay and interrupts the voltage dependence of decay in transected frog cutaneous pectoris muscles (Henderson et al. Fed. Proc. 42, 991, 1983). In contrast Tetram (a tertiary ethylamine analog of echothiophate) slows e.p.c. decay and increases e.p.c. amplitude without significantly altering the voltage dependence of e.p.c. decay. After Tetram is removed from the preparation e.p.c. decay remains normal but e.p.c. amplitude is less than control. At the concentrations used (10^{-8} - 10^{-5} M) these drugs have no affect on either [^{125}I]-α-Bungarotoxin or [^{3}H] phencylidine binding to torpedo electric organ membranes. Thus they are not acting on the receptor recognition site or on the traditional acetylcholine receptor channel blocking site. Further evidence for this is obtained from single channel currents in chick myotubes where they do not act as agonists and in cutaneous pectoris muscle where, at much higher concentrations, they do not depolarize endplates previously treated with MSF. Supported by ES04189.

COMPARATIVE EFFECTS OF ACUTE IN VIVO AND IN VITRO EXPOSURE TO THE PARALYTIC AGENT DITHIOBIURET. J.M. Spitsbergen* and W.D. Atchison. Dept. Pharm./Tox., Mich. State Univ., E. Lansing, MI 48824.

Chronic treatment of rats with dithiobiuret (DTB) causes a delayed onset muscle weakness associated with decreased quantal release of ACh. Acute administration of DTB at doses far in excess of those needed to cause paralysis when given chronically does not cause muscle weakness. The objective of this study was to determine to what extent acute in vivo and in vitro administration of DTB mimicked effects of chronic DTB treatment on neuromuscular transmission. EPPs and MEPPs were recorded from rat hemidiaphragms. In vivo experiments used diaphragms taken from rats 1 hr after acute treatment with 25 mg/kg DTB, ip. In vitro experiments used diaphragms from untreated rats exposed by bath application to a DTB concentration (1.85 mM) approximating that in rats after an acute dose. One hr after injection EPP and MEPP amplitude, and MEPP frequency were decreased, and MEPP and EPP rise and decay times were prolonged. Bath application of DTB initially increased MEPP amplitude and frequency and EPP amplitude. With continued treatment, all three variables were reduced. EPPs were abolished after approximately 10 min exposure to DTB. Rise and decay times for MEPPs and EPPs were also prolonged significantly compared to pretreatment values. These experiments suggest that acute in vivo and in vitro exposure to DTB causes both pre- and postsynaptic effects and that these effects are similar to those seen in rats paralyzed following chronic DTB treatment. (Supported by NIH grant NS20683.)

207.9

INTERACTION OF PREDNISOLONE, CHOLINE, AND VESAMICOL (AH5183) ON NEUROMUSCULAR TRANSMISSION. D.F.Wilson* and P.Zhong* (SPON: R.G.Sherman) Zoology Department, Miami Univ., Oxford, OH 45056.

The interactions of prednisolone, choline,and vesamicol on spontaneous transmitter release were examined in an attempt to identify the mechanism of action of prednisolone on neuromuscular transmission. Intracellular recording techniques were used to monitor miniature end-plate potentials (MEPPs) in the isolated rat diaphragm-phrenic nerve preparation. The preparation was bathed in saline containing 10 mM K^+ to enhance transmitter synthesis and vesicle turnover. It is known that prednisolone (10 μM) enhances the amplitude of the MEPPs, enhances ACh release, and increases the size of the synaptic vesicles. There are at least four mechanisms that could explain these actions a) enhances choline uptake b) enhances the supply of acetyl-CoA, c) enhances the ACh uptake mechanism of the vesicles d) directly enhances ACh synthesis. We examined two of these hypotheses. In choline free bathing medium, 10 μM prednisolone enhanced the amplitude of the MEPPs by 29% . Choline concentrations of 0.1, 1.0 and 30 μM had no effect on the MEPPs in the presence or absence of prednisolone. Vesamicol in low concentration (0.5 μM) depressed the MEPP amplitude by 24% and blocked the action of prednisolone. We conclude that prednisolone does not directly influence ACh uptake into the vesicles or choline uptake into the nerve terminal . We suggest that prednsiolone may stimulate ACh synthesis via stimulating choline acetyltransferase activity or enhance the supply of acetyl-CoA. (Supported by NIH grant NS-23195).

207.10

"L" TYPE OF CALCIUM CHANNEL IN NERVE TERMINAL IS ASSOCIATED WITH TRANSMITTER RELEASE. C.A. Lindgren & J.W. Moore & A.H. Sostman*. Dept. of Physiology, Duke University Medical Center, Durham, N.C. 27710

Fox, Nowycky & Tsien (1987, *J. Physiol. 394*, 149) demonstrated the *coexistence* of three types of calcium channel, called L, N, and T, in neurons from chick dorsal root ganglia (DRG) and showed that it was possible to distinguish between them on the basis of their sensitivity to various pharmacological agents (see Table). This raised the issue of which (if any) of these types of calcium channels is responsible for transmitter release at a neuromuscular junction (NMJ).

We asked this question in presynaptic motor nerve terminals on the ceratomandibularis muscle in the lizard, *Anolis carolinensis*, and have found a single calcium channel which is best characterized as an "L" type. Using focal, extracellular electrodes we measured both end-plate current (EPC) and presynaptic calcium current (I_{Ca}) while applying the inorganic and organic calcium channel blockers and activators used by Fox *et. al.* (1987). The results are summarized on the right below:

	DRG NEURONS			LIZARD NMJ	
	L	T	N	I_{Ca}	EPC
BLOCKERS:					
Cadmium	Yes	No	Yes	Yes	Yes
Nickel	No	Yes	No	No	No
Omega Conus Toxin	Yes	No (weak)	Yes	Yes	Yes
Nifedipine	Yes	No	No	Yes	Yes
ACTIVATOR:					
Bay K 8644	Yes	No	No	—	Yes

207.11

INCREASED EXPRESSION OF TYPE II CALCIUM/CALMODULIN-DEPENDENT KINASE AND VOLTAGE-SENSITIVE CALCIUM CHANNELS DURING DIFFERENTIATION OF NEUROBLASTOMA/GLIOMA CELLS. C.M. Beaman-Hall*, R.D. Veenstra* and M.L. Vallano. Dept. of Pharmacology, SUNY/Health Sci. Ctr., Syracuse, NY 13210.

A type II calcium/calmodulin-dependent protein kinase (CaM kinase) was characterized in a neuroblastoma/glioma cell line (108CC15/NG108-15) using biochemical and immunochemical techniques. Under specific culture conditions the cells "differentiate", a process characterized by elaboration of long neurites, ability to form synapses and secrete ACh, and development of electrical excitability. Since CaM kinase utilizes Ca^{2+} as a second messenger and has been implicated in a variety of depolarization-dependent synaptic events, we compared the expression of CaM kinase and voltage-sensitive Ca^{2+} channels in NG108 cells in the undifferentiated and differentiated states. A 2-5 fold increase in the amount and specific activity of CaM kinase in differentiated cells was observed compared to control cells. Whole-cell voltage-clamp recordings revealed a small (200-300pA), rapidly inactivating N-type Ca^{2+} current in undifferentiated cells which increased 8-10 fold during the first 48 hours of differentiation. Expression of a second inward current with properties similar to the L-type Ca^{2+} channel also emerged during differentiation. Depolarization-dependent, Ca^{2+}-dependent phosphorylation of several potentially important substrate proteins for CaM kinase was also observed in differentiated cells. (Supported by NSF Grant 8602617).

207.12

A ROLE FOR PROTEIN KINASE C ACTIVATION IN THE RELEASE OF EXCITATORY AND INHIBITORY TRANSMITTERS FROM THE ISOLATED RODENT OESOPHAGUS. C.R. Triggle*, S. Will* and D. Bieger (SPON: P. Redfern) Division of Basic Medical Sciences, Memorial University of Newfoundland, St. John's, NF, Canada, A1B 3V6

High concentration of protein kinase C (PKC) in neuronal tissue is suggestive of a function in regulating neuronal activity and several studies have indeed linked activation of PKC to enhanced neurotransmitter release. In this investigation, we have studied the effects of phorbol esters, the diterpine mezerein and the synthetic diacylglycerol, 1-oleoyl-2-acetylglycerol (OAG), on tetrodotoxin-sensitive contractions and relaxations elicited by field stimulation of the isolated inner smooth muscle component of the rat oesophagus. Our results show that low concentrations (20-200 nM) of the active phorbol ester, phorbol 12, 13 dibutyrate (TPA), and the non phorbol ester mezerein enhance both contractions and, in the presence of active tone, relaxations elicited by field stimulation. The inactive phorbol ester, phorbol 12-myristate-13-acetate 4-O-methyl ether, even at 10 μM, was without action on these parameters, whereas OAG, at 5 μM, mimicked the actions of TPA and mezerein. The effects elicited by the assumed activation of PKC could not entirely be explained by post-synaptic effects thus suggesting PKC activation leads to an enhanced release of both excitatory and inhibitory neurotransmitters. Supported by the MRC (MA 9141).

207.13

THE EFFECT OF LITHIUM ION ON PROTEIN KINASE C (PKC) TRANSLOCATION AND ITS RELATION TO SEROTONIN (5-HT) RELEASE IN CORTICAL BRAIN SLICES H-Y Wang and E. Friedman Medical College of Pennsylvania, Philadelphia, PA 19129

Activation of Ca^{++}-, phospholipid-dependent PKC by phorbol esters induces its translocation from cytosol to membrane. PKC stimulation also potentiates K^+-induced serotonin release. Li, especially following long-term administration was found to (1) affect 5-HT release, (2) interfere with PI hydrolysis, and (3) alter membrane lipid metabolism. The effect of Li on PKC activity was, therefore, investigated.

PMA (Phorbol 12-myristate, 13-acetate) or PDBu but not 4 α-PDD increases K^+-induced 5-HT release and to a smaller extent spontaneous [^{3}H]5-HT efflux in a dose-dependent manner (Wang and Friedman, Eur. J. Pharmacol., 141, 15-21, 1987). This effect was obviated by 2-4 mM LiCl in vitro. Furthermore, 3 but not 1 week of Li treatment suppressed PMA-induced facilitation of 5-HT release. In vitro Li affected neither PKC distribution nor PKC activity at concentrations of 1-4 mM. However, Li blocked PMA-induced PKC translocation at therapeutic concentrations both in vitro and in vivo. This Li-evoked inhibition of PKC translocation may be responsible for the reduction in PMA-induced potentiation of 5-HT release and its therapeutic effectiveness.

207.14

EFFECT OF CHRONIC ANTIDEPRESSANT TREATMENT ON PROTEIN PHOSPHORYLATION IN RAT CEREBRAL CORTEX. N. Brunello, D. Tinelli*, J. Perez* and G. Racagni. Center of Neuropharmacology, Univ. of Milan, Italy.

Chronic antidepressant administration is associated with a number of adaptative changes in monoaminergic system. In the present study the pattern of protein phosphorylation in the soluble and microtubule fraction of rat cerebral cortex was investigated after chronic desipramine administration. This experiment demonstrated a higher incorporation of ^{32}P in the protein band of apparent M.W. 280 KD in basal conditions. ^{32}P incorporation, was determined in the presence of cAMP thus demonstrating that the 280 KD protein is effectively phosphorylated by an endogenous cAMP-PK. The high molecular weight and the cAMP dependent protein kinase phosphorylation could suggest that this protein may represent a microtubule associated protein. Since one important step in the phosphorylation system is the regulation of PK, we have studied the soluble cAMP-PK after chronic DMI treatment. The enzyme was partially purified on DEAE cellulose column. After elution with a linear gradient of NaCl the peaks I and II were subjected to a SDS-PAGE electrophoresis (10%). In these conditions an increase in the protein band of apparent M.W. 56 KD following DMI administration was observed. The elution profiles and the molecular weight could suggest that this protein band is the regulatory subunit of cAMP-PK. An acute administration of DMI did not induce any modification indicating that changes in the phosphorylation pattern could be related to the biochemical modifications induced by a chronic treatment with tricyclic antidepressants.

207.15

INHIBITORY SYNAPTIC POTENTIALS IN DORSAL RAPHE: ACTION OF COCAINE Z.Z. Pan*, W.F. Colmers & J.T. Williams. Vollum Institute, Oregon Health Science University, Portland, OR 97201.

Intracellular recordings were made from rat dorsal raphe neurons in slice preparations. Focal electrical stimulation was used to evoke synaptic potentials which consisted of a depolarization (DSP) that was made up of two components (GABA and excitatory amino acid) followed by a hyperpolarizing potential (IPSP). The IPSPs were blocked by spiperone and were increased in amplitude and duration by cocaine (300 nM). With higher concentrations of cocaine (1-10 μM), the duration was further prolonged but the amplitude declined progressively. The IPSP was also studied following blockade of the DSP with antagonists at $GABA_A$ and excitatory amino acid receptors. In these experiments, cocaine depressed the amplitude of the IPSP, even at 300 nM. The cocaine induced increase in IPSP duration was not different from control. These results suggest that the time course of 5-HT mediated synaptic potentials is dependent on a cocaine sensitive reuptake mechanism. Cocaine also seems to cause presynaptic inhibition of 5-HT release in this preparation; an effect which is also sensitive to excitatory input onto the 5-HT neurons.

MOTOR CORTICAL UNIT ACTIVITY PRE AND POST LATERAL COLUMN LESION IN THE BEHAVING MONKEY. S.A. Sahrmann, M.H. Clare, E.B. Montgomery, W.M. Landau. Dept of Neurology, Washington Univ Sch of Medicine, St. Louis, MO 63110

A macaque was trained to perform 4 mirror image isometric ankle tasks triggered and guided by light signals: (1) from rest to large (L) plantarflexion (PL), hold for a random period, rapidly reverse into large dorsiflexion (DO) and return to rest; (2) the mirror image task; (3) small (S) PL with a random hold and relax to rest; and (4) its mirror image S DO. Units were recorded from hindlimb area 4 (M1). The mean of 250 msec intervals of the 4 rest periods was used for resting frequency (RF). A 50% change from RF in the mean of a 100 msec period was considered significant. Preliminary analysis of 99 of 284 related units indicated the RF was increased after complete unilateral section of the lateral spinal column at T10 (47 units, pre 15.8; 52 units, post 23.6). Forty-six percent of pre and 33% of post-lesion units were tonic, maintained activity during hold. Unidirectional (UD) units, those with increased activity with only PL or DO action, were found in equal numbers as bidirectional (BD) units. BD units had a greater peak frequency (PF) for one direction but also increased with movement in the opposite direction. Two times more PL UD pre and post lesion and BD pre units were recorded than DO units but BD PL were less than BD DO units post-lesion. Eighty-four percent DO units participated in all 3 DO task opportunities, both pre and post-lesion. Only 26% pre and 46% post PL units responded to the 3 PL opportunities. The PF for L and for S tasks was the same for DO pre and post lesion and for PL post. The PF for pre lesion PL units was 2 times greater for L than for S tasks.

208.2

INTERHEMISPHERIC ASYMMETRY IN THE AREA 4 REPRESENTATION OF MOVEMENTS IS CORRELATED WITH HAND PREFERENCE. R.J. Nudo, W.M. Jenkins, and M.M. Merzenich, Department of Neurobiology & Anatomy, University of Texas Health Science Center, Houston, TX 77225 and Coleman Laboratory, University of California at San Francisco, San Francisco, CA 94143.

We have found large interhemispheric differences in the representations of distal forelimb movements in primary motor cortex of the squirrel monkey. These differences appear to be related to hand preference in a reaching task. Hand preference was determined using a modified Klüver board. Each animal's hand preference became stable after only limited exposure to the task and remained so when retested over four months later. In each animal, standard intracortical microstimulation techniques were used to map the primary motor cortex of both hemispheres. At each site, the movement obtained with just-suprathreshold stimulation was determined. For brevity, only major classes of movement are described here (e.g., "digit" includes thumb extension, digit 2-5 flexion, etc.). Representations of movements of the digits, wrist, elbow and shoulder were studied in parallel rows of penetrations, about 200 µm apart, then the borders separating these movements were defined. In the primary motor cortex contralateral to the preferred hand, the total digit and wrist area was larger, the total boundary length between digit and wrist regions was longer, and the number of discrete digit and wrist regions was greater compared with the ipsilateral cortex. Indices of complexity ,which normalized absolute areas, also were greater contralateral to the preferred hand. Other features of representational maps, such as relative proportion of digit and wrist area, were approximately the same in the two hemispheres. Large interhemispheric differences are present in the representation of movements in primary motor cortex. These map differences may underlie behavioral asymmetries.

CHARACTERISTICS OF THE FUNCTIONAL ORGANIZATION OF MOTOR CORTEX (MI) HAND REGION IN THE ALERT MONKEY T.M.J.Wannier*, M.A.Maier* and M.-C. Hepp-Reymond Brain Research Institute,8029 Zurich, Switzerland

To investigate the properties and topographical distribution of neurons related to isometric force, 4 monkeys were trained to generate in the precision grip 2 successive step-and-hold force increases. Single cell activity was recorded in MI hand region during the task and in response to somatic and occasionally visual stimulation. The neurons related to force were classified according to their firing patterns (phasic, phasic-tonic, tonic, decreasing, mixed). Two-dimensional reconstructions of the recording sites were made. The convexity contained a greater proportion of decreasing neurons, and some neurons active during ipsilateral finger movements. Most neurons responded to stimulation of deep rather than cutaneous receptors, without clear gradient towards the convexity. A few cells were also activated by stimuli moving across the monkey's visual field. Microstimulation often elicited more complex movements in the convexity than in the bank.

In conclusion, somatic and visual inputs to MI neurons suggest complex sensorimotor integrations. Further, dissimilar properties have been disclosed for the cell populations located in the bank and convexity of the precentral gyrus.

208.4

PINNA MOVEMENTS ELICITED BY MICROSTIMULATION IN THE PREFRONTAL CORTEX OF MONKEYS. D. Burman, C.J. Bruce, and G.S. Russo. Sect. Neuroanatomy, Yale Univ. School Medicine, New Haven, CT 06510.

The position of the pinnae (external ears) were studied in conjunction with microstimulation of cortex in and near the frontal eye fields (FEF) region of the rhesus monkey's prefrontal cortex. Pinnae movements were observed visually and measured via search coils acutely mounted on both the left and right ears. Eye movements were simultaneously observed via a search coil in one eye.

Movements of one or both ears were consistently elicited by microstimulation (thresholds 10-50µA) within a discrete cortical region. At most sites the elicited movement served to direct one or both ears contralaterally, with the contralateral ear usually moving back and the ipsilateral ear either stationary or moving foward to a lesser degree. Ear movement latencies ranged from 40-70 ms. The movement usually continued for the duration of stimulation (25-250 ms). Ear movements of 2-5° were common at threshold and increasing the stimulation current could increase the amplitude to 10° or more.

The cortical zone from which ear movements were obtained at low current thresholds lay between the superior limb of the arcuate sulcus and the posterior portion of the principal sulcus. This is very near the the FEF zone where large amplitude saccadic eye movements are obtained; however, the ear and eye fields appear to be separate as we did not observe eye and ear movements together at a single site. Ear movements were elicited from superficial cortex of the prearcuate gyrus or lip of the arcuate sulcus whereas saccadic eye movements were elicited deeper (in the anterior bank of the arcuate sulcus) and posterior to the ear movement area.

These data suggest that this frontal ear movement area serves primarily to position the pinnae to better monitor sounds from contralateral space, just as FEF stimulation contralaterally directs the eyes. Moreover, we recently discovered that monkeys consistently direct their pinnae towards their direction of gaze. Together, these studies indicate that the primate's FEF, together with this neighboring pinna movement area, constitute a cortical system for orienting both the eyes and ears.

DISTRIBUTION OF THRESHOLD CURRENTS FOR MOVEMENT IN BABOON MOTOR CORTEX: FACE AND FORELIMB REPRESENTATION. D.D. Samulack, C. Chau*, R.W. Dykes, [1]R.S. Waters and P.A. McKinley. Depts. of Physiology, Physical and Occupational Therapy, Neurology and Neurosurgery, McGill Univ., Montreal, PQ, H3G 1Y5 and [1]Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, TN 38163.

Thresholds (TH) for motor responses of the digits, wrist, face and tongue were analyzed in the motor cortex of 4 female baboons using intracortical microstimulation. Distribution of TH currents for eliciting movement was analyzed with respect to body part, cortical layers and white matter. Results indicated that while all body parts had TH values <5μA, the overall distribution was different. 16% of THs were <5μA for face and tongue. However, 55% of tongue THs were evenly distributed between 5-25μA, while only 44% of face THs were <20μA; primarily <5μA. Only 6% of THs were <5μA in wrist and digits. 41% of the digit THs were <20μA and these were evenly distributed. In contrast, 50% of wrist THs were <20μA; distribution was bimodal with peaks at 20μA(16%) and 50μA(15%). Overall TH averages were lowest in layers V and VI (14μA), and highest in layer I and the white matter (34μA). However, THs <5μA were consistently recorded in the white matter.

EFFECTS ON MUSCLE ACTIVITY FROM MICROSTIMULI APPLIED TO PRIMARY SOMATOSENSORY CORTEX (SI) DURING VOLUNTARY MOVEMENT IN THE MONKEY. G.L. Widener and P.D. Cheney. Department of Physiology, University of Kansas Medical Center, Kansas City, KS 66103

Projections from SI cortical areas, particularly 3a and 2, to motor cortex suggest that SI may exert a direct and potentially powerful control over corticospinal output to motoneurons. To test the strength of the linkage from SI to motoneurons, we applied microstimuli to areas 3a, 3b, 1 and 2 in three monkeys trained to make wrist movements alternating between flexion and extension position zones. Microstimuli were delivered as individual pulses (S-ICMS) and as short trains 330 Hz (R-ICMS). Individual stimuli or stimulus trains were used as triggers for computing averages of on-going emg activity from 12 forearm flexor and extensor muscles. Effects from stimulus sites in areas 3a, 3b, 1 and 2 were compared to those from sites of corticomotoneuronal (CM) cells in area 4. All CM cell sites yielded effects on muscle activity with S-ICMS at 20 μA. In contrast, the same stimulation applied to areas 3a, 3b, 1 and 2 yielded effects at only 11%, 0%, 4% and 3% of the sites respectively. Effects from area 3a were predominantly inhibitory, whereas effects from other SI areas were more equally mixed. These results suggest that the linkage between SI cortical areas and motoneurons is weak and unlikely to be directly involved in the generation of muscle activity. Supported by NSF grant BNS-8216608.

208.7

RECEPTIVE FIELD AND DISCHARGE PROPERTIES OF PRIMARY SOMATOSENSORY CORTICAL UNITS DURING ACTIVE TACTILE DISCRIMINATION IN THE MONKEY. S.A. Ageranioti and C.E. Chapman, Université de Montréal, Montréal, CANADA

This study examined the receptive field (RF) and discharge properties of neurones in primary somatosensory cortex of 2 monkeys trained to perform an active scanning movement of the digits over either a smooth or a textured surface. Recordings were made from 92 neurones in the cortical hand area which were classified as receiving input from the glabrous skin of either a single digit (sd, n=16) or multiple digits (md, n=76).

Overall, 37% of the units were unmodulated in the task (26 md, 8 sd), with 18 of these being spontaneously active. Sixty three percent of the cells were modulated in the task, with 48 showing an increase (41 md, 7 sd) and 10 a decrease (9 md, 1 sd). Sd and md units had similar discharge patterns and the relative magnitude of their responses during the task were largely similar. Thus, units with apparently similar RF properties failed to show the same discharge in this task. The absence of any marked difference between units with md and sd RFs would argue against the former units having a special integrative role in the processing of tactile inputs from the glabrous skin of the hand. Supported by the Canadian MRC and the FRSQ.

208.8

THE TOPOGRAPHICAL MODULATION OF SOMATOSENSORY TRANSMISSION TO SI CORTEX PRODUCED BY MICROSTIMULATION OF MI CORTEX IN THE MONKEY. W. Jiang, C.E. Chapman and Y. Lamarre, Université de Montréal, Montréal, Québec, Canada H3C 3J7

Sensory transmission to primary somatosensory cortex (SI) is modulated during voluntary movement. The purpose of this study was to determine the topography, if any, of the modulation of the somatosensory inputs to SI cortex produced by intracortical microstimulation (ICMS) in primary motor cortex (MI) of the awake monkey.

ICMS (train of 11 pulses at 330 Hz, 0.2 ms pulse width) was applied to low threshold ($<14\ \mu A$) sites in MI and cutaneous evoked potentials (20 ms airpuff) were recorded in the adjacent SI arm/trunk representation.

The data of 31 experiments (2 macaque monkeys) showed that ICMS (1-1.5 x threshold) either inhibited the evoked potential in SI or had no effect. Inhibitory effects were observed when the SI receptive field was distal to, or overlapped, the muscle activated by ICMS. Cutaneous inputs from receptive fields proximal to the target muscle were not modulated by ICMS. The results indicate that motor cortex modulates sensory inputs in a topographical manner so as to suppress inputs from the limb segments distal to the moving part. Supported by the MRC of Canada and the FRSQ.

SINGLE UNIT ACTIVITY IN THE FRONTAL CORTEX OF MONKEYS PERFORMING A DELAYED LOCALIZATION TASK. E. Vaadia*, H. Bergman* E. Margalit* and M. Abeles* (SPON: A. Mitz). The Hebrew University, Hadassah Medical School, P.O.B. 1172, Jerusalem, 91010, ISRAEL.

In a previous study it was demonstrated that the activity of some neurons in the frontal cortex is related to active localization behavior. The present study was designed to distinguish neuronal activities related to sensory-perceptual processing from processing related to the preparation of movements. Monkeys were trained to perform two paradigms of a delayed response task: In a "localizing" paradigm two brief stimuli (auditory and visual "spatial cues") were presented successively from two different locations. After delay, a non-spatial cue instructed the monkey to select one of the two locations and touch it. In the second paradigm, the same stimuli were presented. However, the reinforced response was a movement to a predetermined, fixed location. Task related neurons were activated in relation to the spatial cues (88/201), between the onset of the non-spatial cue and the initiation of the movement (68/201) and during the movement (73/201). Some neurons had two or more components of activity. Many neurons showed some degree of spatial tuning (65/88) and paradigm dependency (109/201). The findings indicate that neuronal activities in premotor and prefrontal areas are involved in both stimulus-related perceptual processing and in the preparation of movements. Further, a single unit may be involved in both aspects of task performance.

208.10

SIMULTANEOUS RECORDING OF SINGLE UNITS IN THE FRONTAL CORTEX OF BEHAVING MONKEYS. H. Bergman*, M. Abeles*, E. Ahissar*, Y. Lavner* and E. Vaadia* (SPON:M.H. Goldstein).The Hebrew university, Hadassah medical school, P.O.B 1172, Jerusalem, 91010 Israel.

The activity of several (up to 11) neurons was recorded simultaneously by 6 microelectrodes. Recordings were made in the frontal cortex of Rhesus monkeys during performance of a behavioral task. The electrodes were inserted into the cortex in a straight line (65 penetrations) or a circular arrangement (40 penetrations). The functional properties among "adjacent" neurons" (detected by the same electrode) and "non adjacent neurons" (detected by different electrodes) were analyzed during several phases of task performance. The coactivation of neuron-pairs was examined by crosscorrelograms. Modulations of single unit activity were examined by Peri-Event Time Histograms (PETH) and by time-interval histograms.

The crosscorrelogram analysis indicated that many of the neurons pairs were co-activated even when the neurons were located 2mm apart (60% of the adjacent neuron-pairs and 30% of the non-adjacent pairs). However, the PETH analysis indicated that adjacent neurons could maintain distinctly different task related activity. These data support the view that while neurons in a small cortical area may be coactivated as a functional group to perform specific task, different groups may coexist within each small cortical area.

EEG AMPLIFIER AND FILTERS FOR DETECTING ALPHA AND BETA WAVES IN MONKEYS AND HUMANS. P.E. Volpe*, R.S. Remmel, (Spon:S. Roy), Biomedical Engineering, Boston Univ., and S. Schein, Massachesetts Eye and Ear Infirmary, Boston, M..

Our study with paralyzed monkeys requires an EEG instrument to determine states of alertness and anesthesia. A paralyzed monkey shows no reflexes for checking anesthesia. Alpha waves (approx. 5-10 Hz) indicate adequate anesthesia; beta waves (approx. 10-20 Hz) indicate stress and the need for more anesthetic.

The EEG from two scalp electrodes are input to a differential preamplifier having a common mode rejection of 100 dB. Motorola JFET LF356H operational amplifiers have very low noise for these 10-50 uV signals. Gain is adjustable between 3,000 and 300,000. Fourth order Butterworth filters have cutoff frequencies for alpha (4.97-10.6 Hz) and beta (10.6-22.7 Hz) waves. The lowpass filter with cutoff frequency f_c = 22.7 Hz is 6th order to attenuate 60 Hz noise; this Butterworth filter has gain

$$(1 + (f/f_c)^{12})^{-\frac{1}{2}}$$

This drops off as f^{-6} at high frequencies. Signals can be displayed on two channels of an oscilloscope or polygraph.

Noise and signals outside of a filter's bandwidth were sharply attenuated due to the multiple order of the filters. The instrument cost $300 for parts. Results with monkeys and humans will be reported.

AN IMPLANTED MICROWIRE TECHNIQUE FOR CHRONIC RECORDING IN THE CAT PERICRUCIATE CORTEX. C.L.Palmer, Institute of Physiology, Fribourg University, Switzerland.

One aspect of developing a reliable technique of recording with chronically implanted microelectrodes is that it can provide new insights into the functional micro-organization of the cortex. A technique is described in which lengths of 25ud. teflon insulated Pt/Ir wire are inserted into the pericruciate cortex for chronic single unit recording. The method was developed using 7 cats. In the last 2 cats from a total of 19 electrodes, 13 recorded single unit activity. The yield declined with time due to electrode movement, not electrode deterioration as their impedance measurements were constant.

The longest time a unit could be recorded from was two days, the unit was identified from the latency and threshold at which it was antidromically invaded from pyramidal tract (PT) stimulation. This occurred within the first 30 days after implantation and after 80 days of implantation suggesting that the electrodes were moving in the brain at a con constant rate.

Field potential recordings from PT and cutaneous stimulation were used to monitor electrode movement. The initial negative component of the cutaneous field potential had a longer latency and inverted to a positive potential as the electrode tip moved to superficial regions of the grey matter. The time course and sequence at which this occurred suggested that the electrode tip did not always move in a predictable manner which could be reconstructed from a histological examination of the electrode tract it left at the time of postmortem.

The power of the technique ie the nonselectivity of its recordings, the high yield, its recording stability, and its ability to obtain simultaneous recordings from different cortical regions.

CHARACTERISTICS OF RHYTHMICAL JAW MOVEMENTS (RJMS) ELICITED FROM CORTICAL MASTICATORY AREA (CMA) IN AWAKE PRIMATES. C.-S. Huang[+], H. Hiraba*, G.M. Murray and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6; [+]Chang Gung Mem. Hosp., Taipei, Taiwan.

We have recently described the topographical organization of three patterns of RJMs that we could induce by intracortical microstimulation (ICMS) within the lateral precentral cerebral cortex (CMA). This study describes the temporal features of the RJMs and associated EMG activity evoked by ICMS (0.2 ms pulses, 50 Hz, 3 s train, ≤ 60 μA) of CMA in 3 awake monkeys (Macaca fascicularis). We confirmed that the 3 patterns of RJMs were vertical RJMs, contralaterally directed RJMs, and ipsilaterally directed RJMs (RJMi). The mean (±SD) cycle times of the 3 RJM patterns ranged from 0.94±0.2 to 1.24±0.19 s, and the amplitude of opening ranged from 3-9 mm. Digastric and genioglossus EMG activity occurred in all 3 patterns, but masseter activity was prominent only in RJMi in which it often partly overlapped digastric and genioglossus activity. Digastric showed the first increase in activity (mean onset latency 0.39±0.08 s);this was often preceded by a period of inhibition. These features showed many similarities with natural chewing parameters recorded in the same animals and support the view that CMA is involved in the production and control of primate masticatory movements. Supported by Canadian MRC.

208.14

DISCHARGE PROPERTIES OF SINGLE NEURONES WITHIN PRIMATE TONGUE MOTOR CORTEX DURING TRAINED MOTOR TASKS. G.M. Murray, L.-D. Lin, C.-S. Huang and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

The tongue motor cortex (MI) has been implicated in the control of tongue movements. This study's aim was to see if tongue MI neurones increase their activity in advance of tongue movement during a trained tongue protrusion task and to compare this activity with that during a trained biting task. Extracellular recordings were made in an awake monkey from tongue MI (defined by intracortical microstimulation; ICMS ≤ 20 μA) in which 120 neurones were found to alter their activity during tongue movements. We studied 37 of them during the monkey's trained tongue task, and also tested them for an orofacial mechanosensitive afferent input; some were also studied during the biting task. ICMS at the recording sites of the 37 neurones evoked tongue movements, and an orofacial input was identified in 28 of which 23 had a mechanoreceptive field localized to the tongue. 34 of the neurones increased their activity during the tongue task, and 9 of these showed a marked increase in activity up to 100 ms in advance of EMG evidence of the commencement of tongue movement. 4 of the 9 were also studied during the biting task but showed little change in activity during this task. These data suggest that some tongue MI neurones may preferentially drive tongue movements and support the view that tongue MI is a major component of the control system for tongue movements. Supported by Canadian MRC.

208.15

NEURONAL ACTIVITY IN FACIAL PRIMARY SOMATOSENSORY CORTEX (SI) DURING INGESTION AND MASTICATION IN AWAKE CATS. H.Hiraba*,T.Yoshida* and R.Sumino* (SPON:A.Mori). Dept. of Physiol., Sch. of Dent., Nihon Univ., 1-8-13 Kanda-surugadai, Chiyoda-ku, Tokyo 101, Japan

We investigated the function of the facial SI neurons in relation to spontaneous ingestion and mastication in awake cats. Cats rested comfortably in a box and the head was rigidly mounted by means of two metal bolts and embedded in a dental acrylic crown. The cats were trained to accept oro-facial natural stimulation, and ingest and masticate food (milk, fish flake, salami) without struggling. EMG electrodes were surgically implanted into the masseteric and the digastric muscles. Jaw movement was monitored in the vertical and horizontal axis by a photodiode transducer system. Single neuronal activities were recorded in left prefrontal cortex using a glass-coated Pt-Ir microelectrode. Receptive fields and submodality preferences of neurons were examined with hand-held probes, brushes and other tools.

Approximately one third of the neurons in the oro-facial area of SI were related to ingestion and mastication. Almost all were found in areas 3a and 3b, and few in areas 1 and 2. Area 3b which responded to simple light mechanical stimuli to the perioral hair showed the rhythmical firing when the lower lip touched the upper one during mastication. Neurons with their receptive field in intraoral organs fired in sustained bursts during mastication. Some neurons in area 3b showed increased activity prior to ingestion (about 400ms), which were not related to mastication. Area 3a neurons responded to pressure or tapping of muscles or periodontium. Most neurons in area 3a showed decreased firing at the time of ingestion and sustained bursts during mastication. (The Sato Scholarship of Nihon University School of Dentistry)

ANDROGEN RECEPTORS IN HUMAN TEMPORAL CORTEX. A. Sarrieau, J. Mitchell, and M.J. Meaney. Douglas Hospital Research Ctr., Dept. Psychiatry, McGill Univ., H4H 1R3 Canada.

This work describes the presence of androgen receptor sites in human temporal cortex obtained from 5 adult epileptic patients. Using an in vitro, exchange assay with soluble fractions, with ^{3}H 5a-dihydrotestosterone (5a-DHT) as radioligand with cold 5a-DHT as competitor, we found an apparent K_d of 1.5±0.3 nM with a B_{max} of 50.9±9.1 femtomoles/mg protein. The order of potency of various unlabeled steroids to compete for ^{3}H 5aDHT binding was as follows: 5a-DHT=testosterone>estradiol= androstanedione>progesterone≈5BDHT. This pharmacological profile for the androgen receptor in human brain is virtually identical to that reported in monkey and rat. These data provide evidence for an intracellular mechanism by which circulating androgens might regulate neuronal function in the human cortex. (Supported by grants from the Natural Sciences and Engineering Research Council to MJM).

PROLONGED SUPPRESSION OF ANDROGENS AND ANDROGEN-DEPENDENT TISSUES WITH A BRAIN-ENHANCED DELIVERY SYSTEM FOR ESTRADIOL. W.R. Anderson, J.W. Simpkins, M.E. Brewster* and N. Bodor*. Center for Drug Design and Delivery, Univ. of Florida, Gainesville, FL 32610.

We have developed a brain-enhanced delivery system for estradiol based upon an interconvertible dihydropyridine ⇌ pyridinium salt carrier. The aim of this study was to evaluate the effects of a single 1.0 mg/kg BW dose of estradiol chemical delivery system (E2-CDS) versus an equimolar dose of estradiol benzoate (E2-BZ) on weights of ventral prostate, seminal vesicles and serum hormones in gonadally-intact Sprague-Dawley rats. The single injection of E2-CDS reduced prostate weight by 52% on day 7 and weights remained suppressed to day 21 while E2-BZ was ineffective. Seminal vesicle weights were suppressed on day 1, were maximally reduced by 40% on day 7 and were less than controls for 21 days after E2-CDS treatment. Serum testosterone levels were suppressed with E2-CDS for 1 to 21 days and DHEA concentrations were reduced with both forms of E2 at 1 week only. Serum LH levels were diminished at 24 h with E2-CDS and E2-BZ. Serum estradiol was elevated for 1 week by E2-CDS and for 24 h by E2-BZ while prolactin levels and anterior pituitary weights were increased for 2 weeks with E2-CDS. These data suggest that the brain-enhanced delivery of estradiol causes chronic suppression of serum androgens and reduction in weights of androgen-dependent tissues. (Supported by grants HD 22540, GM 27167 and Pharmatec, Inc.)

BETHANECHOL-INDUCED INCREASE IN HYPOTHALAMIC ESTROGEN RECEPTOR BINDING IS RELATED TO CAPACITY FOR LORDOSIS BEHAVIOR. A.H. Lauber and R.E. Whalen, Dept. of Psychology, Univ. of Calif., Riverside, Ca 92521

Previously, we demonstrated that bethanechol, a muscarinic cholinergic agonist, increased the concentration of soluble estrogen binding sites by 30-35% in female rat hypothalamus but had no effect on males (Brain Res. 443). This study was designed to investigate the relationship between modulation of estrogen binding sites and a sexually differentiated function. Female rats were given high or low doses of testosterone neonatally. In adulthood, high androgen females were "male-like" in responsiveness to estrogen as they were anovulatory and failed to display lordosis. Low androgen females were anovulatory but showed high levels of lordosis. Bethanechol (30 mg/kg) or saline was given 30 min prior to in vitro receptor assays. Amount of estrogen binding by hypothalamic cytosols from drug-treated high androgen females did not differ from levels in saline-treated high androgen controls ($p > .05$). However, bethanechol induced a significant increase in estrogen binding by preparations from low androgen females compared to saline-treated low androgen controls ($p < .01$). These findings suggest that the capacity for drug-induced modulation of estrogen binding sites may be related to the ability to display estrogen-dependent lordosis behavior.

ESTRADIOL-INDUCED PROGESTIN RECEPTOR-IMMUNOREACTIVITY IS FOUND ONLY IN ESTROGEN RECEPTOR-IMMUNOREACTIVE CELLS IN GUINEA PIG BRAIN. J.D. Blaustein and J. Turcotte*. Neuroscience and Behavior Program and Psychology Department, Univ. of Mass., Amherst, MA 01003

A double-antibody, flourescent immunocytochemical technique was developed to determine if progestin receptors are induced in the same cells in the hypothalamus and preoptic area that contain estrogen receptors. As has been reported previously, priming ovariectomized guinea pigs with estradiol caused a large increase in the concentration of progestin receptor-immunoreactive cells in discrete regions of the hypothalamus and preoptic area, in particular, the arcuate nucleus, ventrolateral hypothalamus, periventricular preoptic area, and medial preoptic nucleus and area. Estrogen receptor-immunoreactive (ER-IR) cells were observed in high concentration in each of these areas, as well as in areas in which no PR-IR cells have been observed, such as the amygdala. PR-IR was never observed in the absence of ER-IR. In some areas such as the arcuate nucleus and ventrolateral hypothalamus, most highly-flourescent ER-IR cells also contained PR-IR, while in the amygdala no PR-IR was observed despite a high concentration of ER-IR cells. These results demonstrate that, in the brain as in other tissues, progestin receptors are induced in estrogen receptor-containing cells. (Supported by NS 19327 and RCDA NS 00970 from the NIH)

IN VIVO DOPAMINE (DA) RELEASE FROM THE CAUDATE NUCLEUS (CN) OF CONSCIOUS FEMALE RATS IN RESPONSE TO L-DOPA INFUSION IS INCREASED BY PROGESTERONE (P). D. Dluzen and V. Ramirez. Physiology & Biophysics, Univ. Illinois, Urbana, Il. 61801.

The in vivo release of DA following a direct infusion of L-DOPA into the CN of ovariectomized rats implanted with a push-pull cannula was examined under 3 hormonal conditions: 1)Estradiol Benzoate(EB)-4d sc EB(5µg/d); 2)EB+P+ 4-6h-EB+P(1.25 mg) at 4-6h pre-perfusion and 3)EB+P+24h-perfusion at 24h post-P. Perfusate samples(6-8 µl/min) were collected at 15 min intervals and assayed for DA using HPLC-EC. Following a one h(4 interval) basal collection period L-DOPA was directly infused through the push side of the cannula in 3 increasing doses(10^{-6},10^{-5} & 10^{-4} M) at intervals 5,9 and 14. For each of the 3 doses tested the EB+P+4-6h animals demonstrated a statistically significant increase in DA release following L-DOPA infusion compared to the EB and EB+P+24h groups. Areas under L-DOPA stimulated release curves(pg/75 min, $\bar{X}$+SEM, N=5) were:

	10^{-6}	10^{-5}	10^{-4}
EB -	337±67	4960±1460	12077±2214
EB+P+4-6h -	1296±397	10830±3585	22853±8733
EB+P+24h -	510±170	5253±1139	9986±374

While all 3 hormonal conditions show a dose-response release of DA to L-DOPA, overall release is double for EB+P+ 4-6h animals indicating that P initially exerts a positive modulatory influence upon DA release from the CN in response to L-DOPA infusions in freely behaving rats.

NORADRENERGIC TERMINALS MAY MEDIATE THE STIMULATORY EFFECT OF PREGNANOLONE ON LHRH RELEASE IN VITRO FROM RAT HYPOTHALAMI. O.K.Park and V.D.Ramirez, Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801

We have previously demonstrated that pregnanolone (0.01 ng/ml) when infused in a pulsatile mode stimulated LHRH release from rat hypothalami superfused in vitro. Since NE activates the LHRH neural apparatus, we examined in the present study whether noradrenergic neurons mediate the stimulatory effect of 5β,3β pregnanolone on LHRH release. Hypothalamic fragments from adult OVX+E_2 rats were superfused with a modified KRP medium in the absence or in the presence of 10^{-6}M TTX. Perfusate samples were collected at 10 min intervals and assayed either for LHRH (RIA) or monoamines-NE, Epi, DOPAC, DA and 5-HIAA (HPLC-EC). After 1 h control period of superfusion, 5β,3β pregnanolone (0.01 ng/ml) was administered in a pulsatile mode. Pregnanolone stimulated LHRH release in the absence of TTX, but not in the presence of TTX, indicating that pregnanolone does not directly affect LHRH nerve terminals. In addition, pregnanolone selectively ($p<0.005$) stimulated NE release from hypothalamic fragments superfused in vitro. This stimulation was also obtained even in the presence of TTX, indicating that pregnanolone directly affects noradrenergic nerve terminals. Taken together, these results suggest that pregnanolone stimulates LHRH release in vitro from hypothalamic fragments by activating noradrenergic neurotransmission.

PROGESTERONE RECEPTOR VIABILITY IN HYPOTHALAMIC SLICES CORRELATES TO INCUBATION OXYGENATION. RR Yeoman, LE White, JN Miller*, Ob/Gyn, Neurol, Anes; Univ South Alabama, Mobile, 36688

In vitro results may differ disturbingly from in vivo, and oxygenation may be a factor considering increased diffusional distances. In this study progesterone receptors and chamber media pO_2 were measured. Artificial CSF flowed (50 ul/min) from a reservoir through 3' of 1/8" vinyl tubing to superfuse the tissue. 400 um slices of estradiol primed rat hypothalami were incubated at 34° for 150 min. Control tissue assayed immediately after sacrifice had 54.7±15.9 fM/mg protein (mean ± SE). Neither air bubbled to tissue chamber nor 95%O_2/5%CO_2 bubbled to media reservoir maintained receptors (pO_2=162±6.4 and 178.8±3.9 Torr respectively). Alternately, 95%O_2/5%CO_2 bubbled to the chamber maintained receptors (68.9±13.1 fM/mg; pO_2=429.5± Torr). Additional oxygenation to the media reservoir and increased flow rate (500 ul/min) further elevated the chamber pO_2 (539±13.3 Torr) and sustained the receptors (41.9±4.5 fM/mg). In conclusion, adequate oxygenation appears necessary for maintaining progesterone receptors in brain slices and thus may be relevant to interpreting effects observed in vitro.

PROGESTERONE CONJUGATED TO BOVINE SERUM ALBUMIN BINDS BRAIN SYNAPTOSOMAL MEMBRANES. P.C.KE and V.D.RAMIREZ. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801

Neurophysiological studies have demonstrated a rapid action of progesterone (P_4) in the rat brain. Recently, we reported a LHRH releasing action from in vitro hypothalami of P_4 bound thru specific carbons to bovine serum albumin (BSA). The data suggested specific binding of the complex P_4-BSA to hypothalamic membranes. To investigate this possibility and extend our previous results, the binding to crude brain synaptosomal membranes of P_4 conjugated to BSA was studied. P_4-11-BSA (BSA conjugated at position 11 of the P_4 molecule) labeled with I^{125} to approximately 700 Ci/mmol specific activity was used as probe.

The binding reached saturation after 30 minutes of incubation. BSA conjugated at position 3 of the P_4 molecule (P_4-3-BSA), at position 11 (P_4-11-BSA), and BSA conjugated at position 21 of 11-deoxycorticosterone (DOC-BSA) were used for competition displacement studies. The order of the binding affinity in cerebullum was P_4-3-BSA (ED_{50} about 50 nM) > DOC-BSA (ED_{50} about 0.8 μM) > P_4-11-BSA (ED_{50} about 6 μM). Specific binding was showed in cerebral cortex, brain stem, corpus striatum and hypothalamus, but not in uterus. BSA did not have specific binding at all.

These results indicate that there is a plasma membrane binding site for P_4-BSA conjugate in rat brain. Because of the lack of specific binding for BSA, the binding site must be specific for progesterone. The order of the binding affinity among these three conjugated steroids demonstrated that the side chain and C ring of the P_4 moiety are important for binding. This agree well with our previous result demonstrating that only P_4-3-BSA had the capacity to stimulate LHRH release from rat hypothalami in vitro.

AN AUTORADIOGRAPHIC STUDY OF ESTRADIOL-INDUCED PROGESTIN RECEPTORS IN THE FEMALE SYRIAN HAMSTER BRAIN. Sarah W. Newman and Robert L. Meisel. Dept. of Anatomy and Cell Biology, Univ. of Michigan Medical School, Ann Arbor, MI 48109 and Dept. of Psychological Sciences, Purdue Univ., West Lafayette, IN 47907.

Estradiol treatment can stimulate the synthesis of progestin receptors in cells of the central nervous system, yet this receptor induction is evident only in a limited subset of the regions in which progestin receptors can be measured biochemically. In this study, we compared the autoradiographic pattern of progestin uptake (3H-ORG 2058) in the brains of estradiol-treated (10 ug estradiol benzoate/day for 2 days, N=4) or untreated (2 injections of oil, N=2) ovariectomized female Syrian hamsters.

In two females consistent labelling was found in cells in the medial preoptic area, particularly in the periventricular preoptic, arcuate nucleus, lateral edge of the ventromedial nucleus of the hypothalamus, and ventral premammillary nucleus. These findings are consistent with prior reports. In addition, we found a band of labelled cells along the base of the brain, lateral to the arcuate nucleus, perhaps corresponding to the caudal extension of the retrochiasmatic area. Of the remaining two estradiol-treated females, one had only a few labelled cells in these regions, and the other did not have any detectable label. No labelled cells were found in any region in females not treated with estradiol. Supported by NIH grants NS20269 (to SWN) and HD21478 (to RLM).

209.10

INTERMITTENT INFUSION OF PROGESTINS INTO THE HYPOTHALAMUS OF FEMALE RABBITS USING PUSH-PULL CANNULAE STIMULATES LHRH RELEASE IN VIVO. W. W. Lin and V. D. Ramirez, Department of Physiology and Biophysics, University of Illinois, Urbana, Illinois 61801.

Previously we have reported that intermittent infusion of progesterone (P_4, 10ng/ml), 5β-pregnane-3β-ol-20-one (0.001 ng/ml), and 20-α-hydroxypregn-4-en-3-one (20-α-OH-P, 10 ng/ml) into the hypothalamus of conscious unrestrained does stimulate LHRH release in vivo. In order to further investigate these phenomena, in the present studies, pulses of P_4 and 20-α-OH-P at various doses and another P_4 metabolite, 5α-pregnane-3α-ol-20-one (3α-5α-P), were infused into the hypothalamus of does using push-pull cannulae. Six does were perfused with modified KRP for 60-160 min followed by six pulses of a steroid (10 min on, 30 min off). P_4 was tested in one doe at 0.001, 0.01, 0.1, and 1 ng/ml while 20-α-OH-P was tested at 1 ng/ml (n=3) and 3α-5α-P was tested at 0.001 ng/ml (n=4). Pulses of P_4 were found to increase mean LHRH levels at 0.01, 0.1 and 1 ng/ml, but not at 0.001 ng/ml. 20-α-OH-P effectively increased mean LHRH levels in two does, but not in a third doe. 3α-5α-P was not effective in stimulating LHRH release at 0.001 ng/ml in three does although there was an increase in mean LHRH release in a fourth doe. Overall, these results indicate that P_4 is a very potent stimulator of LHRH release over a wide range of doses and P_4 metabolites are also effective at selective doses.

209.11

IN VIVO α_1 ADRENERGIC STIMULATION OF LHRH RELEASE FROM THE FEMALE RAT HYPOTHALAMUS USING PUSH-PULL CANNULAE. J.F. Gitzen, and V.D. Ramirez, Neural and Behavioral Biology Program and Dept. of Physiology and Biophysics, University of Illinois, Urbana, Il. 61801.

We have previously demonstrated that the in vitro pulsatile administration of the α_1 adrenergic agonist Methoxamine (MTX) stimulates the release of LHRH from superfused female rat medial basal hypothalami (MBH) (Endo. Soc.Abst., 1985, #945).

To establish that LHRH release is also stimulated in vivo by α_1 activation we utilized the push-pull cannula (PPC). PPC were implanted in the MBH of OVX rats. Experimental (N=5) and control (N=3) EB primed rats were initially perfused with modified KRP for two hours. KRP containing 10^{-4}M MTX or control KRP was substituted for the initial 20 minutes of the subsequent two hours. Effluent was collected every 10 min.

In both groups LHRH release showed moderate levels of pulsatility during the first two hrs. In all cases immediately following MTX infusion there was a robust spike of LHRH release. This was confirmed by PULSAR analysis. Total LHRH release during the pre MTX hour (.047±.007pg/min) increased significantly in the MTX treatment hour (.100± .019 pg/min). The pulsatility of control animals remained relatively constant; demonstrating a decrease rather than increase in total LHRH release over the corresponding two hours (.106±.013 v/s 0.070±.008pg/min). This in vivo observation confirms that the activation of rat MBH α_1 adrenergic receptors stimulates the release of LHRH.

209.12

LHRH PEPTIDE AND GENE EXPRESSION IN ORGANOTYPIC CULTURES GROWN IN THE PRESENCE OR ABSENCE OF SERUM: EFFECT OF TETRODOTOXIN. S. Wray and H. Gainer, LNC, NINCDS, Bethesda, MD 20892

Large numbers of luteinizing hormone releasing hormone (LHRH) neurons express their peptide hormone in slice explant roller cultures. These cultures are models for studying LHRH gene expression in a controlled environment. LHRH cells were characterized after 18 days *in vitro* by immunocytochemistry and *in situ* hybridization histochemistry (Wray et al., Soc. Neurosci. Abst., 13, 301.3, 1987). Large variations in steady state LHRH mRNA levels in neurons in the same culture slice were found. This could have been due either to different responses to biologically active agents in the serum containing media (SCM) and/or variations in spontaneous synaptic or electrical activity among LHRH cells in single culture slices. To address the influence of these factors on LHRH peptide and gene expression in culture, immunocytochemical and *in situ* hybridization histochemical studies were carried out in serum free media (SFM) or SCM in the presence or absence of tetrodotoxin (TTX).

400 micron brain slices from postnatal rats were plated on coverslips and grown in SCM (25% horse serum) for 12 days, and then divided into 2 groups: 1/2 were placed in SFM and the other 1/2 maintained in SCM. After 2 days, TTX (10^{-6}M) was added to 1/2 of the cultures in each group. On day 18, cultures were processed for either immunocytochemistry or *in situ* hybridization histochemistry. The number and distribution of immunopositive LHRH cells was maintained in SFM in the presence or absence of TTX. Although the addition of TTX did not change the intensity of LHRH immunopositive cells, secretion appeared to be inhibited since the intensity and extent of immunopositive fibers increased. We are currently examining whether the absence of serum and/or the presence of TTX differentially affected the mRNA level of LHRH cells in these slice explant roller cultures.

INVOLVEMENT OF ENDOGENOUS OPIOID PEPTIDES IN LHRH ULTRASHORT LOOP FEEDBACK IN THE SHEEP. A.M. Naylor, D.W.F. Porter* and D.W. Lincoln*. MRC Reproductive Biology Unit, Centre for Reproductive Biology, 37 Chalmers St., Edinburgh, Scotland, U.K. EH3 9EW.

In the ovariectomized ewe, intracerebroventricular administration of LHRH causes a sustained and receptor-mediated inhibition of pulsatile LH release. Currently, the mechanism involved in this suppression is unknown but does not involve a desensitization of the pituitary gland to LHRH. Endogenous opioid peptides (EOP) have been implicated in the inhibitory control of LH secretion by modulating the hypothalamic release of LHRH. In addition, EOPs mediate the inhibitory effect of CRF on the LHRH pulse generator. The following studies were undertaken to determine whether opioid peptides are involved in LHRH ultrashort loop feedback using the opioid antagonist, naloxone.

At least 3 months prior to experimentation, Blackface ewes were ovariectomized and implanted (under halothane anesthesia) with cannulae directed towards the third ventricle. Plasma LH was measured in 10 min blood samples taken over an 11h period. Intracerebroventricular injections of LHRH were made twice at 4h and 5.5h whilst naloxone was injected intravenously (iv) 4h, 5.5h, 7h and 8.5h into the 11h sampling period.

Injection of LHRH (21pmoles in 50µl saline) into the third ventricle caused a marked inhibition of LH secretion. Pulse frequency and mean LH levels were reduced significantly when compared to the saline control (50µl). In contrast, iv naloxone (4 x 25mg, 1.5h apart) elevated mean LH levels. When LHRH was injected centrally along with iv naloxone, the inhibitory effect of LHRH persisted despite the ability of naloxone to stimulate LH release on its own.

In conclusion, these data suggest that EOPs are unlikely to mediate the LHRH-induced central suppression of LH release. Secondly, in the long term ovariectomized ewe, EOPs exert a tonic inhibitory influence on LH secretion.

CHANGES IN PRO-OPIOMELANOCORTIN GENE EXPRESSION IN THE ARCUATE NUCLEUS DURING PUBERTY IN THE MALE RAT. J.N. Wiemann*, D.K. Clifton* and R.A. Steiner (SPON: J.C. Slimp). Depts. of Ob-Gyn. and Physiol. & Biophys., Univ. of Wash., Seattle, WA 98195.

It has been proposed that during prepubertal life, high levels of endogenous opioid peptide (EOP) activity restrain gonadotropin secretion and that this activity diminishes over the course of puberty, permitting adult gonadotropin secretion to become fully manifest. The arcuate nucleus contains many POMC neurons, some of which could be involved in this process. We tested the hypothesis that POMC gene expression diminishes over pubertal development in the male rat by measuring and comparing POMC mRNA levels in prepubertal (25 day old) and adult (75 day old) animals. Twenty micron coronal slices were taken throughout the arcuate nucleus and prepared for *in situ* hybridization with an ^{35}S-labeled RNA probe complementary to mouse POMC mRNA. Sections (12/animal) were matched anatomically and read blindly. POMC mRNA content in the arcuate nucleus was estimated by counting silver grains over individual cells. These results show that over the course of pubertal development, neurons in the arcuate nucleus of the hypothalamus appear to increase, not decrease, their POMC message content.

Group	Grains/cell (Mean±S.E.M.)	n
Prepubertal	119±10	6
Adult	167±12	7

Conclusion: Diminishing EOP activity is unlikely to account for rising gonadotropin secretion during puberty; more likely, the higher level of POMC message observed in the adult brain is a consequence, rather than a cause, of pubertal maturation.

209.15

SEX DIFFERENCES IN BEHAVIORAL AND ENDOCRINOLOGICAL RESPONSES TO A CONTROLLABLE STRESSOR APPLIED REPEATEDLY. L.K. Takahashi, J.A. Vanden Burgt,* C.M. Barksdale,* and N.H. Kalin. Psychiatry Dept., Univ. Wisconsin Medical School, and VA Hospital, Madison, WI 53705.

We are examining differences between the sexes in response to controllable stressors applied acutely and repeatedly. Adult rats are able to control the termination of tail shocks by turning a wheel. Each session consists of 80 shocks (0.5 mA, 1 shock per min). Male and female rats rapidly learn to turn the wheel to control termination of tail shock in one shock session. Females, however, terminate shock more rapidly than males ($p < .01$) and have significantly higher plasma ACTH concentrations ($p < .01$). Both sexes display a significant increase in the latency to terminate shock ($p < .01$) over the course of six repeated shock sessions administered at 2- to 3-day intervals. This increase in latency to terminate shock is not reversed by naloxone and persists even after a 1-week recovery period. Because significant sex differences in response to the stressor were found, the role of gonadal hormones was investigated. Males gonadectomized during adulthood exhibit latencies to terminate shock similar to those of intact females, whereas gonadectomy increases the latency to terminate shock in females ($p < .05$). In summary, repeated exposure to a controllable stressor results in behavioral alterations that are influenced by gonadal hormones.

209.16

GENOTYPIC INFLUENCES ON REPRODUCTIVE CYCLES OF INBRED FEMALE MICE. S.P. Lerner*, R.B. Mitchell*, and C.E. Finch. (SPON: G. Miljanich). Andrus Gerontology Center and Department of Biological Sciences, USC, Los Angeles, CA 90089-0191.

Genetic influences on female reproductive cycles were found in histocompatibility-congenic strains of mice differing at the H-2 locus. Estrous cycle characteristics were specifically associated with individual H-2 haplotypes, regardless of the background strain into which these haplotypes have been incorporated. Estrous cycles of virgin mice of six strains were monitored between 4 and 7 months of age. Four congenic strains on the C57BL/10 background (C57BL/10SnJ H-2^b, "B10"; B10.BR/SgSnJ H-2^k, "B10.BR"; B10.D2/nSnJ H-2^d, "B10.D2"; B10.A(2R)/SgSnJ H-2^{h2}, B10.A(2R)), and two congenic strains on the C3H background were used (C3H/HeJ H-2^k, "C3H"; C3H.SW/SnJ H-2^b, "C3H.SW"). Estrous cycles were categorized by length: 4, 5, 6, or 7-14 days. As previously observed, B10 mice displayed predominantly 5-day cycles ($p<0.01$), while B10.BR mice displayed predominantly 4-day estrous cycles ($p<0.01$; Lerner, et al., Bioi Reprod, in press). C3H mice (H-2^k) also showed predominantly 4-day cycles ($p<0.01$), while their histocompatibility-congenic partner strain, C3H.SW (H-2^b) displayed a codominance of 4- and 5-day cycles; a pattern indistinguishable from C57BL/6J mice (H-2^b). B10.D2 mice showed mostly 4-day estrous cycles ($p<0.01$). Most interestingly, B10.A(2R) mice, which have either the k or d haplotype at all loci of the H-2 region, except the D locus, where there is the b haplotype, show a predominance of 5-day cycles. These findings both confirm and extend the observation of influences of genetic differences on estrous cycles of mice. The factor(s) responsible for the observed differences in estrous cycle lengths may be localized to one region of the H-2 complex. (Supported by grant AG-004419)

MAPPING OF PROLACTIN BINDING SITES IN RING DOVE BRAIN BY QUANTITATIVE AUTORADIOGRAPHY. J.D. Buntin and J.F. Fechner, Department of Biological Sciences, Univ. of Wisconsin-Milwaukee, Milwaukee, WI 53201.

Ring dove brain membranes contain specific binding sites for ovine prolactin (oPRL) which could conceivably mediate PRL-induced gonadal suppression and hyperphagia (Gen. Comp. Endocr. 65:243, 1987). In order to localize these sites, specific binding (SB) of [^{125}I]oPRL was examined in 34 ring dove brain regions in males (n=6) and females (n=6) by quantitative autoradiography. Slide-mounted sections (20µm) were incubated with [^{125}I]oPRL (75pM) plus unlabelled oPRL (85nM) or [^{125}I]oPRL alone. Sections were then exposed with ^{125}I standards (Amersham) to Kodak XAR-5 film for 7-10 days. Autoradiographs were analyzed by computerized video densitometry. A sex x region effect was observed ($p<.02$), with SB in the preoptic area (POA) being higher in males than in females ($p<.02$). Mean SB levels exceeding 2 standard deviations above zero were detected in the POA and choroid plexus in both sexes, and in several hypothalamic nuclei: periventricular (males), supraoptic and tuberal (females), and ventromedial (both sexes). Lower levels of SB were seen in several other brain regions. Densitometric results were corroborated by binding studies on tissue homogenates in three brain areas. These results suggest the existence of PRL-sensitive cells in brain regions regulating gonadal and ingestive activity. (Supported by NSF DCB 8303026)

INCREASES IN CGRP IMMUNOREACTIVITY IN LAMINAE I AND II FOLLOWING CHRONIC SPARED ROOT DEAFFERENTATION ARE DUE TO AN INCREASE IN TERMINAL NUMBER NOT TERMINAL SIZE. D.L. McNeill*, R.E. Coggeshall, S.M. Carlton and C.E. Hulsebosch. Marine Biomed. Inst. and Dept. of Anat. and Neurosci., Univ. of Texas Med. Br., Galveston, TX 77550.

At the light microscopic level, CGRP immunoreactivity is increased in laminae I and II of the rat dorsal horn following chronic versus acute spared root deafferentation. Preliminary results at the EM level, indicate that the number of CGRP immunoreactive terminals is increased by approximately 75% on the chronic versus acute spared root side. However, no significant difference was observed in the areas of CGRP immunoreactive terminals (chronic = 5.5 + 2.7 μm^2, acute = 5.4 + 2.0 μm^2). In addition, no significant difference was observed between the areas of laminae I and II on the acute and chronic sides. We therefore suggest that the increase in CGRP immunoreactivity in the chronically spared segment is due to terminal sprouting rather than an enlargement of terminal or laminar area. Studies are in progress to determine if there is a concomitant increase in the number of synapses per CGRP immunoreactive terminal. CHRONIC DEPOLARIZATION BY EXTERNAL POTASSIUM PROMOTES SYNAPSES BETWEEN RETINA AND MUSCLE IN CULTURE. J. M. Thompson and D. J. Tepper*. Department of Cell and Structural Biology, School of Life Sciences and College of Medicine, University of Illinois, Urbana, IL 61801.

In tissue culture, cholinergic retinal neurons will form synapses on myotubes as detected by intracellular electrophysiology (Puro et al., P.N.A.S., 74:4977, 1977; Ruffolo et al., P.N.A.S., 75:2281, 1978; Thompson et al., Int. J. Devel. Neurosci., 1:25, 1985). However, these retina-muscle synapses terminate within one week.

In the present experiment, cultures of 8-day chick embryo retinal neurons and rat myotubes were grown in medium containing 5.4 mM or 38 mM KCl (38 mM KCl produces a 20 mV depolarization in myotubes). Growth of retina-muscle cocultures in chronic depolarizing conditions prolongs the retina-muscle synaptic contacts. At 5 days in vitro, 42.5% muscles remained innervated when grown in 38 mM KCl, compared to 9% in controls. The increase in number of retina-muscle synapses in high KCl containing medium is not due to increased survival of myotubes or retinal neurons, or to increased retinal neurite extension. Chronic depolarization may be increasing retina-muscle synapses by blocking action potentials in both nerve and muscle through inactivation of sodium channels. Thus, inactivity reduces the elimination of normally transient retina-muscle synapses.

210.3

EXPRESSION AND DISTRIBUTION OF SYNAPTIC VESICLE PROTEIN SVP65 IN CULTURED DORSAL ROOT GANGLION NEURONS. J.J. Lah* and R.W. Burry (SPON: J.M. Palmer). Dept. of Anatomy, The Ohio State Univ., Columbus, OH 43210.

Rat dorsal root ganglion (DRG) neurons do not form synapses on one another in culture, and thus present unique opportunities for experimental manipulation and analysis of synaptogenesis. In characterizing this culture system, we have studied the expression and distribution of a synapse-specific protein, svp65 (Matthew et al., J. Cell Biol., 91:257). This antigen appears to be ubiquitously present in neuronal cell types, and, while its function is unknown, its expression in regions of forming and mature synapses is well established.

When DRG cultures were probed for expression of this protein, it appeared to be present in some axons but not in others. Since DRG neurons do not form synapses, the observed expression of svp65 by these cells is somewhat paradoxical. Studies with cultured rat cerebellar neurons have shown that these neurons will form presynaptic specializations on polylysine coated surfaces. When DRG neurons are presented with polylysine coated beads, presynaptic terminals form at some of the bead-axon contacts. Furthermore, electron microscopic immunocytochemistry experiments indicate that the ability to form presynaptic specializations may be restricted to axons possessing the svp65 antigen.

210.4

POLYLYSINE COATED CULTURE DISHES STIMULATE LONG TERM AXONAL OUTGROWTH AND SYNAPSE FORMATION WITHOUT INCREASED IN NEURONAL SURVIVAL Richard W. Burry and Diane M. Hayes*, Dept. of Anat., Neurosci. Res. Lab., College of Med., The Ohio State Univ., Columbus, OH.

Polylysine has been used in cell culture systems to enhance neuronal survival by a mechanism that is thought to involve increased cell adhesion. Polylysine coated beads have been used to stimulate development of presynaptic and postsynaptic specialization in cultured cells. We report here on experiments which attempt to differentiate between the two effects of polylysine on cultured neurons. Cell cultures of the rat cerebellum were plated in dishes pretreated with a solution of polylysine, or with no pretreatment. In the first several days, comparisons showed similar numbers of surviving neurons, similar onset of neuritic outgrowth and similar onset of synaptic vesicle antigen p65 expression. In cultures grown on polylysine, at 10 days or longer, there was a marked stimulation of neurite outgrowth and many large growth cones were seen. Electron microscopy showed numerous presynaptic terminals in contact with the polylysine coated culture dish. Immunocytochemistry of cultures on polylysine showed p65 at high levels in the axons and growth cones.

The long term effect of polylysine in neuronal cultures are the result of a metabolic change in the neurons as evidenced by increased axonal outgrowth, antigen accumulation and presynaptic terminal formation.

Heparin and heparan sulphate inhibit nerve-induced ACh receptor accumulation. Y. Kidokoro and Y. Hirano.* Jerry Lewis Center, UCLA School of Medicine, Los Angeles, CA 90024

In Xenopus nerve-muscle cultures, it has been demonstrated that ACh receptors migrate in the membrane to the nerve contact area during junction formation and that "diffusion trapping" is the major mechanism for nerve-induced receptor accumulation (Kidokoro et al., 1986). A crucial remaining question is how the nerve induces the trap for randomly diffusing ACh receptors. In this study, we examined the effect of various glycosaminoglycans in the culture medium on the nerve-induced receptor accumulation and found that heparin and heparan sulphate partially inhibited nerve-induced receptor accumulation, but similar molecules, chondroitin sulphate type A and type C did not. By chemical modification of heparin we also showed the N-sulphate residues and a large molecular weight molecule are essential for this inhibitory effect. Heparin did not affect ACh receptor clustering (hot spot formation) in myocytes cultured without nerve. By changing the time and duration of heparin applicaton we found that heparin was effective in inhibiting nerve-induced receptor accumulation only when it was present in the culture medium during the period that neurites are actively forming contact with muscle membrane.

ACCUMULATION OF EXTRACELLULAR MATRIX COMPONENTS AT AGRIN-INDUCED "SYNAPTIC" PATCHES ON MYOTUBES IN CULTURE. R.M. Nitkin and T.C. Rothschild*. Dept of Biol Sci, Rutgers Univ, Newark, NJ 07102

We have been examining the mechanism by which agrin, an extracellular matrix factor isolated from the *Torpedo* electric organ, induces dense accumulations of acetylcholine receptors (AChRs) and other synaptic components on chick myotubes in culture (J. Cell Biol. 99:615 and 105:2471). Agrin is related to molecules that are localized at neuromuscular junctions in vivo (Nature 315:571).

Here we report on the role of laminin, heparin sulfate proteoglycan (HSPG), fibronectin and type IV collagen in agrin-induced synaptic differentiation. Matrix components were visualized with fluorescein immunohistochemistry, while "synaptic" patches (AChR accumulations) were identified by rhodamine-bungarotoxin. Under these conditions, AChR clustering can be detected within 2-3 hours of agrin treatment, reaching maximal levels by ~ 8 hours.

The distributions of laminin and HSPG were markedly affected by agrin treatment. Untreated myotubes generally had a meshwork across the cell surface. After a few hours of agrin treatment, laminin and HSPG appeared in patches. Half to three-quarters of the AChR patches showed coincidence with laminin, and a similar amount showed coincidence with HSPG. However, laminin and HSPG patching (which require ~ 18 and ~ 22 hrs to reach maxima) occurs more slowly that of AChR so it is unlikely either matrix component serves to initiate synaptic organization.

Myotubes displayed limited amounts of fibronectin and type IV collagen; some cells had wisps while others had a more uniform distribution. In contrast to that of other matrix components above, fibronectin and collagen distributions were not affected by agrin treatment.

In summary, we find that agrin causes laminin and HSPG (but not fibronectin nor collagen) to accumulate at synapse-like sites on cultured myotubes in parallel (but not preceding) AChR accumulations.

210.7

ACCUMULATION OF A_{12} ASYMMETRIC AChE IN AGRIN-INDUCED SPECIALIZATIONS. B. G. Wallace. Dept. Neurobiology, Stanford University School of Medicine, Stanford CA 94305.

Agrin, a protein extracted from the electric organ of Torpedo californica, induces the formation of specializations on the surface of cultured chick myotubes at which several components of the postsynaptic apparatus, including acetylcholinesterase (AChE), accumulate. Our previous results suggest that motoneurons release molecules similar to agrin that induce the formation of the postsynaptic apparatus on developing myotubes. Although several molecular forms of AChE are found in muscle, it is the A_{12} asymmetric form that accumulates at synaptic sites, where it is localized in the synaptic basal lamina. It is of interest, therefore, to determine if agrin induces the accumulation of A_{12} asymmetric AChE.

We found that chick muscle cultures grown in medium without horse serum and embryo extract contained A_{12} AChE, as well as globular forms. Incubating cultures overnight with agrin did not change the level of AChE, the rate of AChE synthesis, accumulation, and release, or the relative proportions of the different molecular forms. By selectively inactivating intracellular AChE and extracting globular forms with detergent, we found that agrin-induced specializations contained both globular and asymmetric forms of AChE and that agrin caused A_{12} AChE to accumulate on the myotube surface in association with extracellular matrix material, as occurs at developing neuromuscular junctions. (Supported by MDA and NIH Grant NS14506).

LOCALIZATION OF ACETYLCHOLINE RECEPTOR mRNA BY IN SITU HYBRIDIZATION IN CULTURED MYOTUBES TREATED WITH A RECEPTOR-INDUCING FACTOR. D.A. Harris, D.L. Falls, and G.D. Fischbach. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110.

42-kD ARIA (AChR-inducing activity) from chick brain stimulates insertion of acetylcholine receptors (AChRs) into the surface of chick myotubes, and selectively increases the amount of mRNA encoding the α-subunit of the receptor. To assess the effect of ARIA on individual myotubes in culture, we have performed in situ hybridization of fixed embryonic myotubes with a 600-nucleotide ^{35}S-labeled cRNA probe for α-subunit mRNA. To reduce nonspecific hybridization, we found it essential to include 0.3M dithiothreitol or β-mercaptoethanol in the hybridization solution and washes, and to wash at high stringency (50% formamide, 0.3M NaCl, 65° C).

A grain density above background could be detected in control myotubes only during the first 2-3 days after plating, when mononucleated cells were fusing and Northern blot analysis indicated that α-mRNA levels were highest. In contrast, 4-day myotubes that had been treated for the previous 24 hrs with a partially purified preparation of ARIA displayed discrete accumulations of grains, which were consistently located near clusters of nuclei. Significantly, not all nuclear clusters were associated with high grain density. Quantitative fluorescence measurements of cells labeled with an anti-receptor monoclonal antibody indicated a correlation between surface receptor density (averaged over 100 um^2) and the local α-mRNA concentration.

Our results raise the possibility that ARIA differentially regulates expression of α-mRNA by individual nuclei, and that surface accumulations of AChRs may result from localized synthesis of receptor messenger.

210.9

QUANTAL ANALYSIS OF SYNAPTIC TRANSMISSION AT A DEVELOPING NEUROMUSCULAR JUNCTION. M. Laser* and M-m. Poo (SPON: J. Rothlein). Section of Molecular Neurobiology, Yale University School of Medicine. 333 Cedar St., New Haven, CT.06510

During the first few hours of synaptogenesis between Xenopus spinal neuron and myotomal muscle cells, the amplitudes of the evoked synaptic currents in physiologic saline show substantial stimulus to stimulus fluctuation suggesting a quantal mechanism with varying numbers of quata released per stimulus. Intrinsic limitations such as the poor viability of the synapse in low Ca^{2+}, the low numbers of trials due to synaptic fatigue, and the absence of a defined amplitude of spontaneous events prevented conventional approaches of quantal analysis. A new method of quantal analysis was developed. The procedure involves the following steps: A series of quantal sizes are chosen. For each quantal size the evoked histogram is quantized and its' mean quantal content is calculated. Theoretical Poisson, binomial or Gaussian distributions with the same mean and normalization are constructed. The fit of each theoretical distribution with the quantized evoked amplitude histogram is assessed by calculating the mean relative variance (MRV) between the two. The quantal size and choice of statistics which yielded the smallest MRV are the likely to be correct if the MRV shows a sharp minimum. The analysis showed that the evoked responses at this developing synapse are best described by Poisson statistics with a single defined quantal size. However, this quantal size is significantly larger than the amplitude of the majority of spontaneous synaptic currents. There was a minor peak in the spontaneous event histogram which corresponded with the predicted quantal size suggesting that only a small subpopulation of the spontaneous events were related to the quantal unit underlying the evoked response during this early phase of synaptogenesis.

210.10

THE CAPACITY OF NON-GROWTH-CONE PORTIONS OF NEURITES TO TRIGGER THE DEVELOPMENT OF A POSTSYNAPTIC SPECIALIZATION. E. Rodriguez-Marin* and M.W. Cohen. Dept. of Physiol., McGill Univ., Montreal, Quebec.

Does the capacity of neurons to induce postsynaptic specializations reside exclusively in their growth cones? To test this possibility spinal cord and myotomal muscle cells from Xenopus embryos were co-cultured at low density (day 0). One day later (d 1), newly-added muscle cells were manipulated to contact neurites which either (A) had not or (B) already had contacted other muscle cells more distally. The neurites belonged to single neurons which were free of contact from all other neurons. The next day (d 2) all muscle cells contacted by the test neurons were examined for neurite associated receptor patches (NARPs) after fluorescent staining of the AChRs.

Even though Type A contacts were less than 1-day-old and were never traversed by a nerve growth cone they had NARPs along ~15% of their length. A similar value was obtained for contacts formed by chance due to new neuritic growth between d 1 and d 2. By contrast, Type B contacts rarely exhibited any NARPs at all. These observations indicate that pre-existing portions of neurite can trigger clustering of AChRs as effectively as nerve growth cones, as long as the neurite has not established contact with other muscle cells more distally. Once neurite-muscle contact is established, the portion of neurite proximal to the contact loses its triggering capacity.

210.11

LOCALIZATION OF GAD TO PRESYNAPTIC SITES CORRESPONDS TO THE ONSET OF INHIBITORY SYNAPTIC TRANSMISSION IN VITRO. J.M. Dubinsky, S.M. Rothman and D.I. Gottlieb. Departments of Pediatric Neurology and Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Mo. 63110.

The development of central inhibitory interneurons has been studied in tissue culture preparations of neonatal rat striatum. Glutamic acid decarboxylase (GAD; Chang and Gottlieb 1988), GABA (Wenthold et al., 1986) and synapsin I (DeCamilli et al., 1983) were identified at different times after plating by immunocytochemistry. At all days in vitro (div) 76% ±6.1% (n=24) of all neurons stained for GAD. This is consistent with the 50-90% seen in vivo. Initially GAD immunoreativity was confined to a weak labeling of neuronal somas, each containing an excentric patch of brighter stain. By 4 div, GAD label appeared uniformly in some processes. By 8-11 div, GAD staining became punctate within processes and almost disappeared from the somas. Similarly, synapsin I immunoreactivity was uniform in neuronal somas and processes initially but became punctate within the neurites after a week. Double labeling with GAD and synapsin I showed an exact coincidence of all GAD puncta with synapsin I puncta. In contrast, immunoreactivity to GABA was quite weak initially, but became uniform in neurites and somas by 11 div. Neuronal responses to pressure applied GABA were recorded using whole cell voltage clamp. GABA conductances normalized to cell capacitance did not change over 30 div. However, spontaneous and evoked inhibitory synaptic activity could only be detected after 8 div. Since postsynaptic responses remained stable, the late onset of inhibitory transmission may be attributable to the slower development of the mature pattern of presynaptic synthetic enzyme.

A MODEL FOR SPATIAL CONSTRAINTS DURING DEVELOPMENTAL SYNAPTIC REDUNDANCY. J. Mariani and G. Waysand*. Inst. Neurosciences (UA CNRS 1199), Univ. P & M Curie, and Lab. Phys. Solides, Univ. P. VII, Paris 75005 France.

Transient redundancy of synaptic contacts seems to be a general feature of the development of the nervous system, the subsequent elimination of synapses leading to the adult connectivity (see review in Mariani and Delhaye-Bouchaud 1987). Until now, little attention has been paid to factors that introduce an upper limit to the synaptic redundancy, i.e. to the maximum number of axons converging on a given target cell. In this study we consider synaptogenesis as a problem of disordered media. We propose that the maximum of synaptic redundancy can be described, at least formally, as the whole set of contacts in an isostatic random stacking of non-penetrating hard spheres. Geometrical contraints in this model impose, on average, 3.5 contacts per sphere. For all the documented cases of synaptic redundancy, the ratio of the transient maximum to adulthood final connectivity is always simply related to this 3.5 value predicted by the model. When several axons innervate a target cell in the adult stage, a rigourous partition of synapses appears which could be interpreted as the existence of some hidden organisation below the macroscopic disorder.

DEVELOPMENT OF CGRP IMMUNOREACTIVITY IN RELATIONSHIP TO THE FORMATION OF NMJ IN XENOPUS MYOTOMAL MUSCLE. H.B. Peng, Q. Chen, S. De Biasi, and D.-L. Zhu. Dept. of Cell Biology & Anatomy, Univ. of North Carolina, Chapel Hill, NC 27599.

Calcitonin gene-related peptide (CGRP) has recently been localized at the neuromuscular junction (NMJ). To understand the role of this peptide in postsynaptic differentiation, we examined its appearance at developing NMJs in the myotomal muscle of Xenopus larvae. Tadpole tails were double-labeled with fluorescent α-bungarotoxin and a monoclonal antibody against the 65 kD synaptic vesicle antigen (SV48) or a polyclonal antibody against human CGRP. AChR clusters as shown by the toxin staining began to appear at the rostral NMJs as early as stage 22 (24 hr) and were detectable at all myotomes at stage 40 (66 hr). On the other hand, CGRP first appeared at the most rostral NMJs at stage 32 (40 hr) and became detectable in all myotomes at stage 42 (80 hr). Preabsorption of antibody solution with 2.6 nM synthetic human CGRP abolished the staining. The onset of CGRP immunoreactivity closely paralleled that of SV48 and, at mature NMJs, both kinds of staining coincided precisely in all the myotomes. Thus, CGRP was localized within the nerve terminals concomitantly with the clustering of synaptic vesicles. Since AChR clusters develop prior to the presynaptic CGRP localization, this peptide is unlikely to participate in signaling the postsynaptic development.

210.14

THE INFLUENCE OF INNERVATION ON BEAD-INDUCED ACH RECEPTOR CLUSTERS. W. Rochlin* and H.B. Peng (SPON: R. Glasser) Dept. of Cell Biology and Anatomy, Univ. of North Carolina, Chapel Hill, NC 27599.

Previously, innervation of cultured Xenopus myocytes was shown to disperse pre-existing aneural receptor patches and prevent their formation. However, neurites from different neurons can induce clustering of ACh receptors on the same myocytes. Thus, the global influence of the nerve depends on the nature of the clustering stimulus. To characterize this global influence, we examined the ability of innervation to disperse pre-existing bead-associated receptor patches (BARPs) and to inhibit the formation of BARPs. When myocyte cultures were treated for 1 day with beads and then for 1-1.5 days with dissociated neural tube cells, the percentage of beads with BARPs was decreased on cells with nerve-associated receptor patches (NARPs) in all 5 trials, but the difference was significant in only 3 of these trials. Similarly, when the treatments were reversed, there was a decreased percentage of BARPs in all five experiments, and a significant difference in 3 of these experiments. BARPs appeared to be less frequent at beads close to a NARP. We conclude that innervation reduces, but does not eliminate, the survival and formation of BARPs. This effect is variable, and depends in part on bead-NARP distance.

INDUCTION OF TYROSINE HYDROXYLASE mRNA IN CULTURED RAT CORTEX BY A MUSCLE-DERIVED FACTOR(S). *L. Lyandvert*, M. Evinger, D.J. Reis and L. Iacovitti (SPON: I.R. Katz).* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

We have previously reported that a soluble muscle-derived factor(s) induces a dramatic 10-20 fold increase in the number of cultured cortical neurons which can express the catecholamine (CA) enzyme tyrosine hydroxylase (TH). Since this induction occurs without change in neuronal survival, it was concluded that muscle contains a "differentiation" factor(s) which promotes TH expression in a previously undetected class of cultured cortical neurons. In this study we sought to determine whether such enhanced TH expression occurred only at the protein level or instead required an increase in the steady state levels of TH mRNA. To do so, the cortices of embryonic day 13 rat were dissociated and grown in culture on control media or media supplemented with 10-14 mg/ml of soluble muscle fraction (prepared by homogenization and high speed centrifugation of cultured L6 muscle cells). Cultures were harvested at 2 days *in vitro* and TH mRNA levels were quantitated by Northern blot analyses using a TH cRNA probe (380 ntd). On Northern blots, levels of a single mRNA band of 1900 bases was increased in those cultures maintained on the muscle factor(s) as compared to controls. In addition, supplementation of the culture with this factor(s) resulted in an increase in the amount of 60 kD protein which could be precipitated with TH antibodies following *in vitro* translation. We conclude that the muscle-induced increase in TH containing cortical neurons found in culture is accompanied by increases in the cortical levels of TH mRNA, suggesting that the effects of this factor(s) may be mediated at the level of the TH gene.

211.2

A SOLUBLE MUSCLE FACTOR(S) INDUCES TYROSINE HYDROXYLASE ACTIVITY IN CULTURED SUBSTANTIA NIGRA NEURONS. *L. Iacovitti, M. Evinger and D.J. Reis* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

In our previous studies, we found that a soluble muscle-derived factor(s) will greatly induce the differentiation of catecholamine (CA) traits in cultured rat cortex, increasing both the number of tyrosine hydroxylase (TH)-containing cortical neurons and their levels of TH enzyme activity. In this study, we sought to establish whether this muscle factor(s) also increases TH expression in other brain CA neurons. Cells from the substantia nigra of embryonic day 14 rats were dissociated and plated in culture on control media or media supplemented with the cytosolic fraction of cultured L6 muscle cells (final concentration: 10-14 mg protein/ml). After 7 days *in vitro*, cultured cells were harvested for radioenzymatic assay of TH activity and Northern analysis of TH mRNA. Sister cultures were processed for immunocytochemistry and the number of TH- immunoreactive neurons determined. In contrast with cortex, supplementation of substantia nigra neurons with muscle factor(s), resulted in a 35-50% decline in the number of TH-immunoreactive cells. Although surviving TH neurons appeared healthy, their morphology was distinctly different from that of nigral neurons grown on control media; TH stained neuritic processes were more numerous, shorter and less varicose than in controls. Moreover, the levels of TH enzyme activity (calculated per TH neuron) were dramatically increased 33-fold in nigra cultures grown with muscle factor(s) (76.5 fmol/TH neuron/hr) as compared with control (2.3 fmol/TH neuron/hr). Northern analysis with a TH cRNA probe revealed an increase in the levels of 1900 ntd mRNA in these muscle-supplemented cultures. In addition, the amount of 60 kD protein immunoprecipitated with TH antibodies following *in vitro* translation was also significantly elevated following the addition of muscle factor(s). Although the survival of TH neurons is decreased in supplemented cultures, the results of these studies indicate that, in surviving dopamine neurons, the expression of TH mRNA and TH enzyme activity is greatly induced by the addition of soluble muscle factor(s). The similarity of cortical and nigral responses to muscle suggests a common factor may be mediating these effects.

NORADRENERGIC SYNAPSES REMAIN FOLLOWING TARGET NEURON DEGENERATION IN A HYPERINNERVATED MOTOR NUCLEUS. Y.P. Shao* and J. Sutin. Dept. of Anatomy & Cell Biology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Axotomy of motor neurons results in synapse retraction of about 50% of the afferent terminals ending on the soma and proximal dendrites. Neonatal 6-OHDA treatment leads to a marked, permanent noradrenergic hyperinnervation of the trigeminal motor nucleus (MoV) in rodents. The super-nummary NE terminals displace other synaptic endings on the motor neuron soma (Hemmendinger & Moore, J. Comp. Neurol., 1986, 250: 462-68). The injection of the toxic lectin Ricin communis into the masseter nerve leads to the degeneration of virtually all masseter sub-nucleus motor neurons and results in an extensive proliferation of glial cells which express β-adrenergic receptors. Since MoV contains only motor neurons, we determined if the increased NE synapses produced by neonatal 6-OHDA treatment survive after complete removal of target neurons. NE levels were measured by HPLC in tissue punches from control and Ricin-treated animals and by catecholamine histochemistry. No major differences in NE levels were found after elimination of target neurons. Supported by NIH-NINCDS grant #NS 14778.

SEPTAL EXTRACTS REGULATE G_4 ACETYLCHOLINESTERASE ISOFORM SYNTHESIS IN MOUSE HIPPOCAMPAL CULTURES. K. Schegg,* J. Peacock, P. Hering,* and K. Futamachi.* Reno VA Medical Center, University of Nevada School of Medicine, Reno, NV 89520.

Mouse hippocampal (HIPP) neurons in cell culture produce most of their acetylcholinesterase (AChE) in the globular monomeric (G_1) isoform whereas cultured mouse septal (SEP) neurons predominantly synthesize globular tetrameric (G_4) isoform (Schegg et al, 1986). Addition of SEP to HIPP cells in coculture appears to induce a modification of isoform synthesis in HIPP neurons such that G_4 is the predominant isoform. In order to determine if SEP indeed regulates AChE isoform composition in HIPP neurons, we have searched for a soluble factor released by SEP neurons. Exposure of HIPP cultures to media conditioned by growth on SEP or SEP-HIPP cocultures is ineffective. Extracts were prepared from mouse SEP & HIPP (ages embryonic day 18 to postnatal day 59); each have at least a small positive effect in increasing the relative percentage of G_4. However, extracts from postnatal day 10 of SEP cause a major increase in G_4 such that the isoforms shift from the HIPP to the SEP pattern. Total AChE activity is not increased in treated cultures. The isoform-shifting effect can not be mimicked by adding nerve growth factor, epidermal growth factor, or carbachol to cultures. Thus these data support a positive regulatory effect of SEP on AChE isoform compositions in HIPP.

211.5

ACTIVATION OF EXCITATORY AMINO ACID RECEPTORS ENHANCES PROTEIN SYNTHESIS IN BRAIN STEM AUDITORY NEURONS OF THE CHICK. R. L. Hyson* and E.W Rubel. Department of Otolaryngology, University of Washington, Seattle, WA 98195.

Elimination of excitatory afferent input to second-order auditory neurons in nucleus magnocellularis (NM) of the chick results in a rapid and dramatic decrease in protein synthesis in NM neurons, followed by cell atrophy and cell death (Born, D.E. & Rubel E.W, J. Neurosci., 8:901, 1988). Similarly, using an in vitro slice preparation of the brain stem auditory system of the chick, we have shown that orthodromically activated NM neurons display greater protein synthesis than unstimulated neurons. Here we show that the enhanced protein synthesis appears to be the result of an excitatory amino acid released from auditory nerve terminals: 1) this enhancement is not observed when synaptic transmission is blocked by maintaining the slice in a low calcium, high magnesium medium, and 2) it is not observed when orthodromic activation of NM neurons is blocked by the general excitatory amino acid receptor antagonist, kynurenic acid (5mM). This receptor-mediated increase in protein synthesis also appears to be independent of those events involved in the generation of action potentials since antidromic activation of the NM neurons does not increase protein synthesis. These results suggest that in addition to their traditional role in synaptic transmission, excitatory amino acids may also serve to transneuronally regulate the metabolic activity of young neurons. (Supported by PHS grants NS 24518 and NS 07906.)

211.6

EFFECT OF BASIC FIBROBLAST GROWTH FACTOR (FGF) ON SECRETION OF PROLACTIN (PRL) AS ASSESSED BY THE REVERSE HEMOLYTIC PLAQUE ASSAY (RHPA). G.H. Larson*, M.A. Sortino, R.A. Koos*, P.M. Wise (SPON: I.R. Cohen-Becker). Dept. of Physiology, Univ. of Maryland, School of Medicine, Baltimore, MD, 21201.

Although particularly high concentrations of FGF are produced by folliculo-stellate cells of the anterior pituitary gland, its precise function is controversial. Co-incubation of folliculo-stellate cells with anterior pituitary cell aggregates suppressed secretogoque-induced secretion of PRL, whereas co-incubation of FGF and anterior pituitary cells in long term cell cultures stimulated secretion of PRL. Therefore, we utilized the RHPA to assess the acute effect of FGF on secretion of PRL from individual lactotrophs. Rats were ovariectomized and 1 week later implanted with estradiol (180 µg/ml). After 3 days of exposure to estradiol, rats were decapitated and medial portions of the anterior pituitaries were removed and prepared for use in the RHPA. Pituitary cells were incubated with various doses (0.055-3.000 µM) of FGF for different lengths of time (30-240 minutes). FGF inhibited secretion of PRL in a dose dependent manner with the greatest inhibition (42.2%) observed at the 3 µM dose of FGF. Maximal inhibition was observed by 30 minutes at all doses of FGF. Thus, the acute effect of FGF is to inhibit secretion of PRL, suggesting that the interaction between FGF and lactotrophs is complex.

211.7

EFFECTS OF LONG-TERM RETINAL BLOCKADE WITHOUT DENERVATION ON VISUAL SYSTEM GLUCOSE METABOLISM IN THE HOODED RAT. G.A. Thurlow and R.M. Cooper. Psychology Dept., University of Calgary, Calgary, Alberta, Canada, T2N 1N4.

As assessed by the 2-deoxyglucose (2-DG) technique, both eye enucleation and retinal receptor elimination initiate a sequence of metabolic depression and "recovery" in cortical and subcortical visual centers in the hooded rat. Denervation and loss of retinal input occur in each procedure. To determine whether denervation (loss of trophic factors) or loss of retinal activity was sufficient to initiate the sequence of metabolic changes, tetrodotoxin (TTX) was monocularly injected every 48 h to silence retinal ganglion cells, and glucose uptake was determined after times ranging from 24 h to 2 mos. In all visual areas, TTX resulted in an initial metabolic depression, but unlike eye enucleation or receptor loss, only slight metabolic recovery occurred during the TTX administration; and within animal comparisons after bilateral TTX injections 24 h prior to 2-DG showed only a slight metabolic elevation on the long-term-TTX side. Enucleation reinstated the original depression levels. We conclude that, because denervation, direct or indirect, is critical to the metabolic increase, and because inactivity without denervation does not result in a similar increase, the "recovery" of metabolic levels must be an indication of physiological changes which occur as a direct result of loss of a trophic factor.

211.8

NGF AND NICOTINIC ACH RECEPTOR EXPRESSION ON RAT NODOSE NEURONS IN CULTURE. Allan Mandelzys and Ellis Cooper, *Dept. of Physiol. McGill University. Montreal, Que. H3G 1Y6.*

The nodose ganglion contains sensory neurons that innervate visceral tissues, such as, the heart, the lungs, the liver. Most nodose neurons from newborn rats, however, when grown in tissue culture without other cell types, express funtional nicotinic ACh receptors, and some form cholinergic synapses with one another. In this study, we have examined the role of NGF on the expression of ACh receptors by nodose neurons in culture. We find that NGF has little influence on the growth and survival of these neurons when grown in culture without other cell types for 3-4 weeks. At later times, however, small differences between +NGF and -NGF cultures were apparent: neurons with NGF grew to be about 10% larger in diameter than those grown without NGF and their neurite outgrowth was qualitatively greater. Although the effect of NGF on growth was small, most neurons, independent of whether grown with or without NGF, expressed high affinity NGF receptors as measured by I NGF binding. To test whether these NGF receptors are involved in the expression of functional nicotinic receptors, we measured the proportion of neurons expressing ACh receptors in sister cultures grown for 3 weeks either in the presence or absence of NGF. We found that over 60% (327/534 in 12 cultures) of neurons grown with NGF expressed ACh receptors, whereas, less than 12% (54/473 in 10 cultures) of neurons grown without NGF expressed ACh receptors. Futhermore, in preliminary experiments where we removed NGF from cultures at times when the neurons are acquiring ACh-sensitivity (the first 4 to 10 days in culture), we found that 2 days later these cultures had significantly fewer ACh-sensitive neurons compared to sister cultures that contained NGF throughout. In summary, this study suggests that activation of NGF receptors is a necessary step for nicotinic ACh receptor expression by nodose neurons, independent of NGF's action on neuronal growth.

211.9

THE EFFECT OF ELIMINATING AFFERENT IMPULSE ACTIVITY ON THE MORPHOGENESIS OF THE AMPHIBIAN MAUTHNER CELL. L.A. Goodman and P.G. Model, Dept. Neurosci., Albert Einstein Col. Med., Bronx, NY 10461.

Afferent innervation affects the properties of target neurons. For example, in the developing amphibian, the formation of extra vestibular (nVIII) contacts on the Mauthner cell (M-cell) enhances dendritic branching, while deprivation reduces it (Goodman and Model, *J. Neurosci., 8*:776, 1988). The mechanism underlying the interaction between afferent fibers and developing dendritic branches is not known; neural activity may be an essential component of the stimulating effect. In the developing axolotl *(Ambystoma mexicanum)*, we have examined the role of afferent impulse activity in the regulation of M-cell dendritic branching by interrupting neural activity while preserving nVIII contacts. In the medulla of the axolotl, M-cells occur as a pair of large, uniquely identifiable neurons at the level of entry of nVIII. Each cell receives synapses from the ipsilateral nerve; the terminals are restricted to a highly branched region of the M-cell lateral dendrite. We varied the amount of nVIII innervation as well as eliminated afferent impulse activity. First, a vestibular primordium was taken from a donor embryo and unilaterally implanted in a host embryo rostral to the *in situ* one: the experimental M-cell was deprived of nVIII input in the donor embryo while it was superinnervated in the host. Second, TTX-producing newt *(Taricha torosa)* embryos were surgically joined to axolotl embryos producing immobilization of the *Ambystoma* twin. Sodium channel blockade by TTX presumably eliminated action potential propagation allowing M-cell development in the absence of incoming impulse activity. Reconstruction of the M-cells in 18 mm donor larvae revealed that the dendritic branching pattern of "control" cells is normal and that of deprived cells is reduced. The preliminary data indicate that neural activity is not essential to transsynaptic stimulation of dendritic growth by afferent innervation. POSTNATAL MOTONEURONS SURVIVE LONG-TERM SEPARATION FROM THEIR TARGET. L.L. Crews* and D.J. Wigston (SPON: J. Manning) Emory Univ. Dept. of Physiology, Atlanta GA 30322

The survival of embryonic motoneurons is thought to depend on the acquisition of a peripheral trophic substance but it is somewhat uncertain whether this reliance persists after birth. To address this, we labeled motoneurons in postnatal mice then examined them up to six weeks after disrupting their peripheral connections. The biceps motoneurons were bilaterally labeled with Fluorogold before unilateral limb amputation, nerve transection or crush. The mice were fully anesthetized for all surgery.

Motoneurons retained their typical size and morphology after nerve crush, perhaps because the sheath surrounding the injured axons remained intact. However, following amputation or transection many of the prelabeled cells (10-80%, depending on age and survival time) were severely atrophied. The area of the atrophied somata was less than 10% that of control motoneurons. The remaining labeled cells on the injured side were, on average, 60% as large as their uninjured counterparts.

The number of labeled cell bodies on the injured side was equal to the number of labeled cells on the control side, indicating that few, if any, motoneurons died. It is unlikely that Fluorogold had been transferred from dying motoneurons to glia: the atrophied cells were not recognized by a polyclonal antiserum directed against GFAP from spinal cord astrocytes.

We conclude that when target access is compromised by amputation or axotomy, motoneurons do not die but rather persist in a protracted state of atrophy. The most intriguing implication of these results is that it may be possible to rescue these atrophied motoneurons.

211.11

EXPRESSION OF A SYNAPTIC VESICLE PROTEIN AFTER DEAFFERENTATION OF THE SUPERIOR CERVICAL GANGLION IN RATS DIFFERS WITH AGE. K. F. Greif and K. N. Flaherty*. Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

We have demonstrated previously that changes in the levels of a synaptic vesicle-specific protein (p65) in response to deafferentation of the superior cervical ganglion (SCG) differ in neonatal and adult rats. The time course of the shift in response has been investigated. Sprague-Dawley rats aged 1, 7, 14, and 28 d had bilateral deafferentation of the SCG. Similar surgery was conducted in 11 and 22-24 month old F344 rats, to study the response in aged animals. All surgical procedures were conducted using general anesthesia. At selected times after surgery, animals were killed and levels of p65 were determined using indirect radioimmunoassay. Antigen levels were measured in the SCG and in two SCG targets, the iris and pineal.

Results demonstrate that the shift from the neonatal to adult patterns in the SCG occurs during the first postnatal week. In neonatal animals, deafferentation produces a block in normal postnatal increases in p65 in the SCG. In animals deafferented at 7 d or older, a transient increase in p65 is observed. In the SCG of aged rats, responses resemble those in young adults, although the rate of response is slowed and magnitude increased. Patterns of response in target tissues suggest that development proceeds in a target-specific manner. These findings suggest that a critical developmental stage for SCG responsiveness to transsynaptic influences occurs during the first week of life. Studies in aged animals indicate that while the aged SCG retains the ability to respond to changes in neural activity, elements of patterns of response are altered.

FACTORS GOVERNING THE ABILITY OF ASTROCYTES TO PROMOTE NEURONAL SURVIVAL AND PROCESS OUTGROWTH IN DISSOCIATED HYPOTHALAMIC CULTURES. D. S. F. Ling, D. Dickerman, R. E. Petroski, J. P. Grierson and H. M. Geller. Dept of Pharmacology, U.M.D.N.J. - Robert Wood Johnson Medical School and The Graduate School, Rutgers University, 675 Hoes Lane, Piscataway, NJ 08854.

The existence of glial-derived attachment and trophic factors is now well recognized and some of these are believed to play an important role in neuronal survival and process outgrowth. However, large variations in neuronal survival and growth on such monolayers has led us to investigate possible reasons for this heterogeneity. Astrocytes obtained from the newborn rat cerebral cortex were grown in flasks and are then plated (without prior passage) at various densities onto polylysine-coated glass coverslips and were allowed to form a confluent monolayer. Neurons obtained from fetal rat (E17) hypothalami were plated onto these monolayers and maintained in Dulbecco's-modified Eagle's medium with 10% fetal calf serum. Neuronal survival and process outgrowth were assessed and cultures were immunocytochemically examined for markers of glial and neuronal specific proteins as well as for extracellular matrix molecules. Our observations suggest that the competence of glial cells to promote neuronal growth is not reflected by the expression of GFAP or NCAM. Nor does the presence of laminin and fibronectin in the extracellular matrix seem to be of particular importance. Instead, neuronal attachment and process outgrowth appear to be related to glial cell density, such that low astrocyte density promotes neuronal survival. Supported by NIH NS25168 and a grant from the UMDNJ Foundation.

211.13

THE POSTNATAL ENRICHMENT OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) IS PRESERVED IN TRIGEMINAL GANGLION NEURONS THAT MAINTAIN A PROJECTION TO THE CEREBRAL ARTERIES. K. Horgan, T. P. O'Connor and D. van der Kooy (spon: J. A. Connolly), Dept. of Anatomy, University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

The adult trigeminal ganglion's sensory projection to the cerebral arteries is enriched in the neurotransmitter CGRP. We asked if this CGRP enrichment is present in the arterial projection from the neonatal ganglion or if it is due to selective survival of a small number of CGRP containing neurons in the face of massive postnatal cell death and axon retraction in the overall arterial projection. Two populations of ganglion cells were retrogradely labelled from adult or neonatal flourescent tracer applications to the middle cerebral artery; the population that maintains an artery collateral postnatally and the composite population that either maintains or retracts an artery collateral postnatally. In the composite population, CGRP was present in 20.7±1.4% of retrogradely labelled cells at postnatal day (PND)5 and in 13.1±1.4% of labelled cells at PND90. In the population specifically maintaining an artery collateral, CGRP was present in 20.7±1.4% of labelled cells at PND5, and in 25.5±1.8% of labelled cells at PND90.Thus the CGRP enrichment is present in the neonatal arterial projection and there is a small increase in the proportion of CGRP positive cells by PND90 amongst the cells specifically maintaining artery collaterals. However, CGRP enrichment appears to be lost by the cells which retract artery collaterals. The presence of adult trigeminal ganglion projections to the forehead skin with low CGRP levels permits a test of this idea. In neonatal rats a significant number of single trigeminal cells have axon collaterals to both the cerebral arteries and the forehead. By PND90 almost all of these cells specifically retract their artery collaterals. A developmental decrease in CGRP positive cells amongst the population specifically retracting an artery collateral but retaining a forehead projection (identified by retrograde double labelling), will support the idea that arterial projections maintain enriched trigeminal CGRP levels.

SCHWANN CELL-NEURONAL INTERACTIONS INVOLVE NGF. B.A. Urschel and C.E. Hulsebosch. Dept. of Anat. & Neurosci. and Marine Biomed. Inst., Univ. of Tex. Med. Br., Galveston, TX 77550.

In an attempt to gain insight into the functions of Nerve Growth Factor (NGF), we suppressed the endogenous levels of NGF with antibodies. We were interested in the effects produced by the inactivation of NGF on both centrally and peripherally projecting fibers. Newborn rats were given subcutaneous injections (3 µl/gm body weight) of rabbit antibodies to purified mouse β-NGF (ANTI-NGF) daily for a period of one month. The relation of myelin thickness to fiber diameter of myelinated axons in T7-T11 dorsal and ventral roots and peripheral nerves was analyzed in the ANTI-NGF animals and in normal littermates (CONTROL). The results of the analysis are shown below as means ± standard error (n = 100).

Myelin thickness in:	ANTI-NGF	CONTROL
DORSAL ROOTS	.34µm ± .03µm	.59µm ± .02µm
VENTRAL ROOTS	.71µm ± .02µm	.81µm ± .02µm

Myelin thickness was significantly thinner in the dorsal and ventral roots ($p < 0.005$ and $p < 0.002$ respectively) of those animals treated with ANTI-NGF as compared to their untreated littermates. These results indicate that Schwann cell-neuronal interactions are altered by the inactivation of NGF. The peripheral nerve study will be presented. (Supported by SCRF, NIH grants NS11255 and NS25450, Hall Foundation and Bristol-Meyers).

SOMATOSTATIN EXPRESSION IN CULTURED CILIARY GANGLION NEURONS

JAMES COULOMBE AND RAE NISHI,
DEPT. OF CELL BIOLOGY AND ANATOMY,
OREGON HEALTH SCIENCES UNIVERSITY, PORTLAND OREGON.

The avian ciliary ganglion contains two distinct neuronal cell types: ciliary neurons which innervate striated muscle of the eye's iris and ciliary body, and choroid neurons which innervate the vascular smooth muscle of the choroidal coat. Although much is known about the differences between ciliary and choroid neurons, how these differences arise has not previously been addressed. Recently, the neuropeptide somatostatin has been found within the choroid neurons *(Epstein et al 1988, Neuroscience in press)*. We are interested in how expression of this neuropeptide is controlled during development. We have found that a substantial proportion of ciliary ganglion neurons express somatostatin immunoreactivity when cocultured with dissociated cells from the choroid layer. In contrast, no somatostatin is detectable in ciliary ganglion cells cultured alone or when cocultured with striated muscle. This observation is consistent with the hypothesis that somatostatin expression depends upon an interaction with vascular smooth muscle target cells. Such interactions may be important for regulating the neuronal traits which differ between choroid and ciliary neurons.

211.16

GROWTH OF EMBRYONIC HEART CULTURED IN OCULO IS ALTERED BY SYMPATHETIC INNERVATION AND EPINEPHRINE STIMULATION. D.C. Tucker and C.H. Gautier . Department of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL 35294

Control of embryonic rat heart growth and beating rate by sympathetic innervation and by circulating catecholamines was studied by grafting hearts into the anterior eye chamber of adult host rats. Embryonic hearts grafted into sympathetically denervated eye chambers have a faster intrinsic beating rate and are smaller than embryonic hearts grafted into unmanipulated eye chambers (Tucker & Gist, 1986).

To study the interaction of sympathetic innervation and circulating epinephrine, host rats were prepared by unilateral superior cervical ganglionectomy (SCGx) and bilateral adrenal medullectomy (Medx). Grafts into unmanipulated eye chambers grew equally well in Medx and sham-operated hosts (2.23 + .41 vs 2.40 + .51 mm^2). Grafts into sympathetically denervated eye chambers attained a larger size in Medx than sham-operated hosts (1.48 + .27 vs. 0.86 + .09 mm^2). Grafts cultured in hosts sympathectomized as infants also grew less well if the adrenal medulla was intact than if hosts were Medx before grafting (1.43 + .25 vs 2.58 + .43 mm^2 for atria grafts and 0.9 + .02 vs 2.83 + .55 mm^2 for ventricle grafts). These data suggest that embryonic heart growth may be inhibited by circulating epinephrine stimulation and promoted by sympathetic innervation.

GROWTH OF RETINAL EXPLANTS ON WHEAT GERM LECTIN AND LAMININ IN THE PRESENCE OF TAURINE. L. Lima*, P. Matus* and B. Drujan*. (SPON: H. Vanegas). Lab. of Neurochemistry, Instituto Venezolano de Investigaciones Científicas, Caracas, Venezuela.

The extracellular matrix plays important roles in controlling cell growth and organization of tissues. Minimal requirements for regeneration in vitro are substrate-related. Retinal explants from goldfish (Carassius auratus) were plated 10-14 days after crush of the optic nerve in Leibovitz medium. The plates were previously coated with poly-L-lysine (PLL, 0.1 mg/ml), as control for growth, or with wheat germ lectin (WG, 0.1-0.2 mg/ml), and laminin (LAM, 5-10 µg/ml). Attachment of explants was 80, 66 and 71% on PLL, WG, and LAM respectively. Taurine stimulates growth from explants on PLL in a concentration-dependant manner, but was much less effective in the rest of substrates used. After 5 days in culture taurine increases nerve growth index (NGI) in 225% on PLL. Explants on LAM started to grow at 7-8 days, by 10 days the NGI increases in 33% in the presence of taurine. Similar results from explants plated on concanavalin A, lentil and peanut lectins were previously reported. Fibers were of 6 µm on PLL and LAM, and 4 µm on WG. Clockwise directionality was only observed on PLL. These results demonstrate the dependance of extracellular matrix for the stimulation produced by taurine, and suggest a better interaction with polycation surface than with glycosides residues.

211.18

IDENTIFICATION OF GROWTH-RELATED OPIOID PEPTIDES USING NEUROTUMOR CELLS IN CULTURE. P.J. McLaughlin and I.S. Zagon. Dept. Anatomy, Penn. State Univ. College of Medicine, Hershey, PA 17033.

Tumorigenic events are regulated by endogenous opioid systems (i.e., opioids and receptors). To determine which opioid peptide(s) is (are) involved with growth, S20Y neuroblastoma (NB) cells were used in an assay system that studied growth in the presence of peptides representative of the three opioid precursor molecules: prodynorphin, proenkephalin A, and POMC, as well as a variety of exogenous opioids and non-opioid compounds. The pentapeptide, methionine enkephalin (ME), was the most active growth inhibitory agent, followed by slightly modified peptides (e.g., leucine enkephalin). Further examination indicated that ME had a dose-response effect that was naloxone reversible and stereospecific. Studies of thymidine incorporation and mitosis revealed a significant reduction in labeling and mitotic indexes in ME treated cultures relative to controls. RIA demonstrated that tumor cells produced a variety of peptides, including ME. Opioid receptors, including those for ME were also detected. These studies indicate that ME is a potent and natural trophic factor in growth, support the thesis that a target of opioid action is cell proliferation, and reinforce evidence that opioids and receptors function in an autocrine fashion to regulate growth. Support by NIH grants NS-20500 and NS-20623.

EXOGENOUS POLYAMINES. EFFECTS ON DEVELOPMENT AND PROTECTIVE EFFECTS AGAINST NEURONAL DEGENERATION. G.M. Gilad and V.H. Gilad. Dept. of Neurobiology, Coriell Inst. for Med. Res., Camden, NJ, USA.

Treatment of rats with exogenous polyamines (PA) for a limited time period after peripheral nerve injury can accelerate regeneration and functional recovery. Similar PA treatment can reduce programmed neuronal death as well as axotomy-induced death of sympathetic neurons in development. While the cellular site and mechanism of PA action is still unknown the basic working hypothesis is that when cells in general have an increased demand for PA, as evidenced by increased PA biosynthesis, they also develop a high affinity uptake system for extracellular PA; and, that this is a relatively short lasting event. Results of preliminary experiments are in support of this notion: 1) PA treatment during the first 12 days after birth can lead to earlier eye opening and earlier appearance of righting reflex, and, 2) similar treatment can prevent the monosodium glutamate-induced neuronal degeneration in the developing retina. PA may exert their effects directly on the reactive cells and/or indirectly through enhancing the effects of growth factors which are produced by other cells.

ALCOHOL, BARBITURATES AND BENZODIAZEPINES

PENTOBARBITAL PRODUCES TEMPERATURE-INDEPENDENT AND DEPENDENT CHANGES IN VISUAL EVOKED POTENTIALS OF RATS. B.E. Hetzler and L.K. Norris*. Psych. Dept. Lawrence Univ., Appleton, WI 54912

Flash evoked potentials (FEPs) have often been used to assess the effects of drugs on the nervous system, but few studies have examined pattern reversal evoked potentials (PREPs). Even in the case of FEPs, secondary influences of altered body temperature are often unknown. The present study examined FEPs, PREPs and body temperature in hooded rats following i.p. injections of saline, and of 15 and 30 mg/kg pentobarbital. Rats were tested in standard (23°C) and warm (31°C) environments. The 30 mg/kg dose produced hypothermia of 2.6°C at 23°C, but not at 31°C. Early components of FEPs were generally increased in amplitude by the 15 mg/kg dose, and decreased by the 30 mg/kg dose at 23°C. At 31°C, the 30 mg/kg dose no longer decreased early component amplitude. Late FEP components were decreased in amplitude at both ambient temperatures. The main PREP components N1P1 and P1N3 showed an amplitude increase at 15 mg/kg, but not at 30 mg/kg, at both temperatures. However, PREP component N2P2 was reduced by the 30 mg/kg dose only at 23°C. The 30 mg/kg dose increased FEP and PREP latencies at both temperatures, but the increases were roughly twice as large at 23°C. These data show that pentobarbital produces amplitude and latency changes in both FEPs and PREPs independent of hypothermia, and that some of the drug-induced effects are enhanced by hypothermia. The results also help explain differences in PREPs recorded previously in awake versus anesthesized rats.

212.2

EFFECTS OF PENTOBARBITAL ON FACILITATED AND SPONTANEOUS TRANSMITTER RELEASE IN CRAYFISH. B.D. Winegar and G.D. Bittner. Department of Zoology and Institute for Neurological Sciences, University of Texas, Austin, TX 78712.

The effects of pentobarbital (PB) on evoked excitatory post-synaptic potentials (EPSPs) and spontaneous miniature EPSPs (MEPSPs) were studied in central opener muscle fibers in the chelipeds of crayfish (Procambarus clarkii). Facilitated EPSPs evoked by 10 Hz stimuli were significantly decreased by 2 min exposure to 10^{-3} M PB $F(5,35)=3.89$, $p<0.01$. Non-facilitated transmitter release evoked by 1 Hz stimuli appeared to be unaffected by 10^{-7} to 10^{-3} M PB. PB at 10^{-4} M and 10^{-3} M significantly reduced the ratio of EPSP amplitudes at 10 Hz to those at 1 Hz (a measure of facilitation). EPSP time constants of decay (a post-synaptic measure) were unaffected by PB. MEPSP frequency was reduced by about 50% immediately upon addition of 10^{-4} M PB to the saline bath, while MEPSP amplitudes and their constants were unchanged. These results suggest that PB has a presynaptic action to depress facilitated and spontaneous transmitter release at excitatory synapses in crayfish opener muscle fibers.

FUNCTIONAL TOLERANCE TO THE ANXIOLYTIC EFFECT OF PHENOBARBITAL IN RATS. J.A. Richter, P.V. Hanford* and R.H.B. Sample*. Depts. of Pharmacology Psychiatry and Pathology, Indiana Univ. Sch. of Med. and Psychology, I.U.P.U.I., Indianapolis, IN 46223.

Functional tolerance develops to some but not necessarily all effects of the barbiturates. We wished to determine if functional tolerance develops to the anxiolytic effect of barbiturates which can be demonstrated in the Geller-Seifter conflict procedure.

Rats were reduced to 85% of their free-feeding weight and trained to lever press in a Skinner box for a reward of sweetened, condensed milk. Final performance was stabilized on a VI 1' schedule. Superimposed on the VI 1' schedule were periodic 2 min segments during which the subjects received 0.5 mA shocks for every fifth response (FR 5) and a non-contingent shock at the end of those segments. The rats received 73 days of twice daily i.p. injections of saline or sodium phenobarbital (NaPheB). NaPheB doses increased from 50 mg/kg at 8 am and 75 mg/kg at 5 pm to 80 mg/kg and 90 mg/kg respectively by day 22. For the final test for tolerance, we reduced the prior afternoon dose by half and injected all rats with 35 mg/kg in the am before testing. The two groups then exhibited equal anxiolytic effects but brain PheB levels determined by HPLC were 36% higher in the group given chronic PheB (37.0 ± 2.02 vs 27.2 ± 0.36 ug/g; mean ± SEM, N=6, 6). By this measure, functional tolerance was demonstrated to the anxiolytic effect. Grant RO1 DA00796.

212.4

BEHAVIORAL CONVULSIONS AND LONG-DURATION BURSTING ELICITED BY BRAIN REGIONAL INFUSIONS OF PENTOBARBITAL (PB). J.L. Lewis and F.S. LaBella. Dept. of Pharmacology, University of Manitoba, Winnipeg, Manitoba

Although PB is considered to be a CNS depressant, site-specific excitatory responses have been reported both in vitro and in vivo after peripheral administration, and in single neurons after iontophoresis. We have reported that general anesthesia induced by administration of β-endorphin is mediated by sites in or adjacent to the inferior third (I3V) and fourth (4V) ventricles. To assess the effect of PB at these sites, we administered either .004mM or .012mM PB into either the I3V or 4V of rats. The lower dose produced hyperresponsiveness and hyperactivity at either site. Animals infused in the I3V showed early ataxia. At the higher dose, infusions into the 4V consistently produced convulsions comprised of barrel rotations, flailing, forelimb clonus, and tonic extension accompanied by EEG sharp waves. Tactile stimulation precipitated convulsions for up to 40 min. Postictal depression and ataxia persisted up to 3 hr. I3 infusions resulted in hyperactivity followed by ataxia and flaccidity. In contrast to 4V animals, these animals showed EEG bursting which was still evident after seven days. At these doses, PB can induce excitation and convulsions in regions mediating anesthesia by other agents. (Work supported by the MRC of Canada.)

THE FACE TO FACE TEST FOR ANXIOLYTICS: A SOCIAL INTERACTION TEST IN MICE. P.J.K.D.Schreur. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

The face to face test in mice is a quicker and less expensive adaptation of Sandra File's social interaction test in rats (File and Hyde, 1978; File, 1980). Male CF-1 mice (Charles River, 19-29g, 8 pairs per dose) were injected s.c. 30 min before testing. Pairs of mice from different home cages were placed together into a tiny plastic cage (7" x 5-1/2") with an opaque lid. Duration of face to face interaction was measured visually for 3 min. Groups were compared by Wilcoxon's rank sum (two-tailed).

Face to face interaction was increased by diazepam, chlordiazepoxide HCl, alprazolam, flurazepam HCl, buspirone HCl, gepirone HCl, ipsapirone HCl, 8-OH-DPAT (8-hydroxy-dipropylaminotetralin HBr), and a high dose of sodium pentobarbital. For some of these, high doses were less effective than lower doses. RO 15-1788, RO 16-6028, and RO 17-1812 had no significant anxiolytic effect in this test; in fact, RO 15-1788 and RO 16-6028 actually decreased the amount of face to face interaction without causing noticeable sedation (an anxiogenic effect?). In addition, RO 15-1788 also antagonized the anxiolytic effect of diazepam. Chlorpromazine HCl did not significantly increase face to face interaction; in fact, high (sedative) doses eliminated it. d-Amphetamine sulfate had no effect at all in this test. In conclusion, the face to face test in mice is a sensitive predictor for anxiolytic activity of classical benzodiazepine anxiolytics and the 5-HT1a agonists buspirone and 8-OH-DPAT.

212.6

EFFECTS OF SCOPOLAMINE ON PASSIVE AVOIDANCE IN OFFSPRING OF DIAZEPAM-TREATED MALE MICE. A. Márquez-Orozco*, M.C. Márquez-Orozco, M.* Ramos-Avila* and R.A. Prado-Alcalá. Embryol. Dept. and Physiol. Dept., Med. Sch, Natl. Univ. of México, P.O.B. 70250, México, D.F., México 04510.

To assess the effects of scopolamine (SCOP) on retention of passive avoidance in offspring of diazepam-treated male mice (DZP-T), male CD-1 mice were given diazepam (2.7 mg/kg, i.p.) daily during six weeks. Nine weeks later they were mated with females. Two months after birth, the litters were trained to avoid a footshock that was given in a passive-avoidance conditioning box. Retention of the task was tested 5 and 8 days later. A group of litters of untreated parents (UT) was also studied. Each of these two groups had four subgroups: SCOP-treated males, SCOP-treated females, Saline (SAL)-treated males and SAL-treated females (10/group). The SCOP and SAL i.p. injections were given within 1 min after training. There were significant differences in retention among groups only during the second retention test: the DZP-T-SCOP groups had lower retention than the DZP-T-SAL and the UT-SAL animals; the male UT-SCOP animals performed worse than its UT-SAL countepart, but the UT-SCOP females did not differ from the UT-SAL females. These results suggest that SCOP interacts with the effects of diazepam to produce deficits in long-term memory, and that the male mice are more affected by SCOP than females.

212.7

COMPETITION FOR SUCROSE-PELLETS IN TRIADS OF RATS: EFFECTS OF ACUTE AND SUBCHRONIC ADMINISTRATION OF CHLORDIAZEPOXIDE. C.Gentsch*, M.Lichtsteiner* and H.Feer* (SPON: A. Enz). Psychiatric University Clinic, CH-4025 Basel (Switzerland).

Within triads of male Wistar rats, clear and stable rank-orders have been discerned, based on each individual's competition-score for a limited number of sucrose-pellets (Gentsch et al. Behav.Brain Res.27:37,1988). Being interested in pharmacological manipulations which enable poor-performing rats to overcome their typical abstention from competition, we compared, in parallel, the effects of chlordiazepoxide (CDZ) in poor-performing (P) and high-performing (H) rats. After a single dose (0.1-20mg/kg,ip.,-1h), CDZ did not improve the P-rats' competition-rates but temporarily attenuated the competition-scores in H-rats (to 70 and 5% of the mean pre-drug levels at 6.7 and 20mg/kg, respectively). Subchronic treatment (5mg/kg for 5 consecutive days) produced, on the first day, no effect in P-rats and an attenuated mean competition-score in H-rats. On subsequent days, H-rats recuperated almost completely and, within that period, CDZ increased the P-rats' mean scores to 13,19 and 14 on days 3,4,5, respectively (as compared to a mean pre-drug level of 4). Following drug-withdrawal, both H- and P-rats re-attained their previous levels of competition. Thus, within the present "social experimental set-up" CDZ can, indeed, influence P-rats. However, these rats need to become tolerant to the drug's sedative effects (as apparent in H-rats), prior to being disinhibited (caused by CDZ's anxiolytic efficacy).

DIAZEPAM IMPROVES PERFORMANCE OF MAUDSLEY REACTIVE RATS IN A SHUTTLEBOX ESCAPE TASK. S. L. Cottingham and J. N. Crawley. Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

The Maudsley Reactive (MR) and Non-reactive (MNR) rat strains have been selected for their high (MR) and low (MNR) levels of "emotionality" when placed in a novel environment. In addition, NIH MR ratshave performance deficits in a shuttlebox escape task compared to MNR rats whose performance is comparable to Sprague-Dawley rats. In MR rats, latency to complete the escape task increases over the testing period. We therefore hypothesized that the shuttlebox deficit may be due to the stressful nature of the task in MR rats that have been bred for hyperemotionality.

The present study was undertaken to determine whether an anxiolytic drug could reverse the deficit that MR rats, but not MNR rats, show in the escape task. Rats were removed from the home cage and administered diazepam (DZP,1.25 mg/kg i.p.) or vehicle. 25 minutes later rats were placed in the shuttlebox and allowed to habituate for 5 minutes. The task consisted of 5 FR1 (one crossing) and 25 FR2 (two crossings) in which an 80 dB, 2.8 kHz tone was presented 5 seconds before shock onset. An animal was considered to have failed the task if the average latency over the 25 FR2 trials to perform the task was more than 15 seconds from the shock oriset.

The average latency for DZP-treated MR animals (n = 7) was 12.7±1.1 sec, compared with 17.6±2.2 sec for vehicle-treated animals (n = 13). 0/7 of the DZP-treated MR rats failed, as compared to 4/13 vehicle animals. The difference between the vehicle-treated group and the MR population response was not statistically signifcant but the average latency of DZP-treated MR rats was less than that of the MR population (t test, $p < .05$). There was no difference between vehicle and DZP-treated MNR rats, all of which learned the task.

These results suggest that anxiolytics partially reverse the performance deficit in MR rats, in this presumably stressful learning paradigm.

SWIMMING BEHAVIORAL ALTERATIONS INDUCED BY PRENATAL ADMINISTRATION OF DIAZEPAM. M.C. Márquez-Orozco*, A. Márquez-Orozco* and I. Zarco de Coronado. Embryol. Dept. and Physiol. Dept., Med. Sch. Natl. Univ. of México, P.O.B. 70250, México 04510. (SPON: J.A. Roig)

In a great number of studies it has been reported that benzodiazepines exposition during pregnancy causes morphological changes in almost all visceral and somatic structures, in newborn mice. Also, the central nervous system showed long lasting alterations specially in the cerebellum, mesencephalon, striatum and cortex. In order to detect how these alterations affect the postnatal somatic development swimming behavior was evaluated. Female mice CD-1, received a daily dose of diazepam (2.7 mg/kg b.wt., i.p.), from the 6th to 17th day of gestation. Gestation term remained unchanged. Control mice received 0.09% saline solution. After birth the pups were separated from their mothers and each litter was reduced to n=8 and transfered to a foster mother for nursing. From 5th to 12th day pups were placed for 15 to 30 sec in a swimming pool (40x30x25 cm) filled up to 15 cm deep (35°C). All the experimental animals exhibited hypotonia, fatigue, dyspnea and it was neccesary to apply reanimation techniques. They showed slow evolution in maduration of swimming behavior characteristics such as lifting the nose, maintaining straight direction and coordination of movements. These alterations were attributed to a deficient neuronal differentiation.

INTERACTIONS OF ETHANOL AND RO 15-4513 ON LOCOMOTOR ACTIVITY AND INTRACRANIAL SELF-STIMULATION IN RATS. **G.J. Schaefer and R.P. Michael, Dept. Psychiatry, Emory Univ., School of Medicine, Ga Mental Hlth. Inst. 1256 Briarcliff Rd, Atlanta, GA 30306.**

The behavioral effects of Ro 15-4513 alone and in combination with ethanol were evaluated. In the first study, rats (n=10) were habituated to an activity apparatus (Digiscan RXY) for 30 minutes. They were then administered either vehicle or Ro 15-4513 (0.1,0.3,1.0,3.0 mg/kg), and locomotor activity changes were recorded for the next hour. Increases in activity were observed at the 1.0 and 3.0 mg/kg doses. In a second study, rats (n=10) were tested similarly in an activity apparatus, but were administered either vehicle, ethanol (0.1,0.3,1.0,1.7 g/kg), or combinations of ethanol and 1.0 mg/kg Ro 15-4513. The combinations of Ro 15-4513 and ethanol produced increases in activity compared to those of ethanol alone at all ethanol doses. In a third study, rats (n=6) were implanted with stimulating electrodes aimed at the medial forebrain bundle and trained to lever-press for brain self-stimulation on a fixed ratio 15 schedule of reward. Animals were then tested with vehicle, ethanol (0.1,0.3.0.56,1.0,1.7 g/kg) or combinations of ethanol and 1.0 mg/kg Ro 15-4513. Ethanol alone produced a modest increase in lever-pressing at 0.3 g/kg, followed by a graded decrease at higher doses. Ro 15-4513 alone produced a large decrease to about 30% of vehicle scores. When combined with ethanol, Ro 15-4513 produced marked decreases in response rates at all ethanol dose-levels (< 20% of vehicle scores). The data showed that Ro 15-4513 has behavioral actions of its own, which are both antagonistic and synergistic to those of ethanol. (Supported by Georgia Dept. Human Resources and Emory Univ. Research Council).

212.11

THE EFFECTS OF RO15-4513 ON SMALL AND MODERATE DOSES OF ETHANOL IN A LOCOMOTOR ACTIVITY PARADIGM. T.K. McKean* and W.M. Bourn. Dept. of Pharmacology and Toxicology, Northeast Louisiana University, Monroe, LA 71209-0400.

The imidazobenzodiazepine Ro15-4513 has been reported to antagonize some of the acute effects of ethanol administration in a number of paradigms. The present experiments were designed to test the ability of Ro15-4513 to reverse the locomotor effects of ethanol in rats.

The effects of Ro15-4513 (1 or 10mg/kg ip) were investigated in Sprague-Dawley rats pretreated with small or moderate doses of ethanol (0.25 or 1.5g/kg ip). Ethanol, as a 25% w/v solution, was administered 10 minutes prior to Ro15-4513 (suspended in deionized water and 1% tween 80).

Ro15-4513, in a dose-dependent manner, blocked an increase in locomotor activity produced by the low dose of ethanol. However, Ro15-4513 alone produced a reduction in locomotor activity, suggesting that the ethanol "antagonism" could simply result from an additive effect of the two drugs. Ethanol alone at the higher dose reduced locomotor activity. The latter was attenuated by the low dose of Ro15-4513.

The results of this study are somewhat supportive of the hypothesis that Ro15-4513 is capable of antagonizing some of the effects of ethanol. However, the intrinsic mild behavioral effects may be partly responsible for reported ethanol antagonist actions.

212.12

EFFECT OF RO15-4513 ON ACUTE ETHANOL-INDUCED CHANGES IN INTOXICATION SCORE, AMBULATORY ACTIVITY AND MONOAMINE METABOLITE LEVELS. M. Gongwer*, J.M. Murphy and W.J. McBride. Inst. Psych. Res., Indiana Univ. Sch. Med., Indianapolis, IN 46223.

This study investigated whether the GABA-benzodiazepine (GABA-BZD) receptor complex is involved in the ethanol-induced (2.5 g/kg body wt, i.p.) increases in the levels of 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA) in the anterior striatum (ASTR) and nucleus accumbens (ACC) of adult male Wistar rats (N=7 per group). This dose of ethanol (E) produced distinct signs of intoxication and significantly reduced spontaneous motor activity by 35%; administration of 10 mg/kg RO15-4513 restored ambulatory activity to control values and significantly reduced the degree of intoxication. In the ACC, the levels of DOPAC, HVA and 5-HIAA were increased by 69, 115 and 19%, respectively, one hour after E. Similar increases were observed in the ASTR. RO15-4513 did not alter the E-induced increases in these metabolite levels in either region. The behavioral data are consistent with the GABA-BZD-Cl^- receptor complex being a site of action of E, but the biochemical data indicate that activation by E of the DA and 5-HT neurons projecting to the ACC and ASTR is not mediated by this complex. (AA-03243, AA-07462).

212.13

ETHANOL INTOXICATION AND BENZODIAZEPINE ANTAGONISTS: DOSE RESPONSE EFFECTS OF RO15-4513 AND FG7142. **P. J. Syapin, B. L. Jones*, A. Sartorius*, K. W. Gee*, and R. L. Alkana. USC, Schs. of Med. and Pharm., L.A., CA 90033.**

The antagonism of ethanol hypnosis by the benzodiazepine (BZ) antagonist/partial inverse agonist Ro15-4513 is a BZ receptor mediated action (Brain Res. Bull. 19 603, 1988). To further characterize this effect, the dose-response curve for Ro15-4513 antagonism of ethanol hypnosis was determined. For comparison, the BZ antagonist/inverse agonist FG7142 was also studied. Male C57BL/6J mice were first given ethanol (3.6 g/kg i.p.) and ten minutes later were injected with either Ro15-4513 (1, 5, 10, or 20 mg/kg), FG7142 (20, 40, or 60 mg/kg), or their respective vehicles. Ro15-4513 dose-dependently antagonized hypnotic effects of ethanol. Each dose caused a significant increased in the wake-up blood ethanol concentration (BEC) and reduction in the duration of hypnosis. In contrast, the effects of FG7142 on ethanol-induced hypnosis were not systematic. The lowest FG7142 dose significantly increased the wake-up BEC without altering the duration of hypnosis, while the highest dose significantly increased the duration of hypnosis, with no change in wake-up BEC. The dose-response characteristics of Ro15-4513 and FG7142 as antagonist of ethanol hypnosis appear to be different, suggesting differences in their underlying mechanisms of antagonism. **(Supported by NIAAA Grant AA03972 and BRSG SO7 RR05792)**

212.14

RO15-4513 INDUCED DECREASE IN VOLUNTARY ETHANOL INTAKE IN RATS: EVIDENCE FOR NON-SPECIFICITY. B.R. Smith*, R. Segal* and Z. Amit., Ctr. Stud. Behav. Neurobiology, Dept. Psychol., Concordia Univ., Montreal, Que., CANADA.

The present paper examined the effect of the partial benzodiazepine inverse agonist, RO15-4513 and the GABA antagonist picrotoxin on voluntary ethanol intake in rats. It has been reported that RO15-4513 blocked ethanol induced physical intoxication (Suzdak et al., Science, 234:1243, 1986) and decreased operant responding for oral access to ethanol (Samson et al., Pharm. Biochem. Behav., 27:517, 1987). Rats were exposed to an ascending series of ethanol solutions presented in a free choice along with water and were later maintained in this paradigm at 9% v/v ethanol and water. Both, RO15-4513 (3 mg/kg, IP) and picrotoxin (2 mg/kg, IP) decreased voluntary ethanol consumption as measured by g/kg intake of ethanol. However, unlike picrotoxin treatment, this decrease produced by RO15-4513 was not accompanied by a reduction in preference for ethanol over water. The absence of a corresponding shift in preference is often indicative of a general reduction in fluid intake and RO15-4513 was seen to decrease general fluid intake. Picrotoxin did not alter fluid consumption. The present findings indicate that GABA ergic mechanisms may play some role in the regulation of voluntary ethanol intake. However, RO15-4513's effect on ethanol consumption may not represent a specific interaction with ethanol, but may rather reflect some general nonspecific action which decreases intake of fluids.

212.15

ROLE OF BENZODIAZEPINE (BZ) RECEPTORS IN TREATMENT BUT NOT ETIOLOGY OF ETHANOL-WITHDRAWAL ANXIETY. C.M. Harris, D. Benjamin,* I.S. Elkhayat,* S. Bhadra* and H. Lal. Dept. Pharmacol., Texas Col. Osteopath. Med., Ft.Worth, TX 76107.

Ethanol withdrawal produces a stimulus (Lal et al., Fed. Proc. 46:1301, 1987) similar to the anxiogenic pentylenetetrazol (PTZ). To assess the role of BZ receptors in modulating the withdrawal stimulus, rats were trained with food reward in a two-lever choice task to discriminate between PTZ (20 mg/kg, ip) and saline (1 ml/kg, ip), then given chronic ethanol (11-13 g/kg/day) in the diet for 4-6 days, and tested for lever selection after injection of test drugs at 12-20 hr after a last dose (3 g/kg, po) of ethanol. After saline (1 ml/kg, ip), rats selected the PTZ lever. PTZ lever selection was reduced by CGS 9896 (20 mg/kg, po; $p < 0.005$). Zopiclone (2.5 - 10 mg/kg, ip) and midazolam (0.64 - 2.5 mg/kg, ip) each reduced the PTZ lever selection dose-dependently. In contrast, flumazenil (10 - 40 mg/kg, ip) had no effect during this period of peak withdrawal or a day later when half of the rats select the PTZ lever after saline. Thus the PTZ-like withdrawal stimulus was blocked by anxiolytics acting at the BZ receptor but was not affected by a receptor antagonist. These data suggest that if ethanol-withdrawal anxiety is produced by endocoids acting at the GABA-BZ-TBPS receptor-chloride ionophore complex, they act at a site different from the BZ receptor.

Supported by Grant AA06890 from NIAAA.

212.16

ANTAGONISM OF THE ATAXIC EFFECTS OF ETHANOL BY DRUGS ACTING AT BENZODIAZEPINE RECEPTORS, THE PICROTOXIN SITE, AND BY ALPHA-2 RECEPTOR ANTAGONISTS. R.G. Lister, M.J. Durcan and M. Linnoila. Laboratory of Clinical Studies, NIAAA, DICBR, Bethesda, MD 20892.

The ability of benzodiazepine (BDZ) receptor partial inverse agonists (Ro 15-4513, FG 7142 and Ro 15-3505), of drugs acting at the picrotoxin site of the BDZ/GABA receptor complex (pentylenetetrazole (PTZ) and Ro 5-3663) and of alpha-2 receptor antagonists (atipamezole and idazoxan) to antagonize the ataxic effects of ethanol was investigated. NIH Swiss mice were injected with ethanol (2.4 g/kg) and 5 min later their ataxia was rated. The mice then received the various drug treatments, and ataxia was again rated for a further 20 min by an observer ignorant of the treatment each mouse had received. Ro 15-4513 (3 mg/kg), PTZ (20 and 25 mg/kg), Ro 5-3663 (4 mg/kg), atipamezole (1 and 3 mg/kg) and idazoxan (1 mg/kg) all significantly attenuated the ataxic effects of ethanol. In contrast Ro 15-3505 (1.5 mg/kg) and FG 7142 (20-40 mg/kg) failed to alter ethanol-induced ataxia. Further FG 7142 (20-40 mg/kg) reversed the antagonism of ethanol's effect by Ro 15-4513.

A comparison of these results with those obtained from other behavioral paradigms suggests that ethanol's ataxic effect is mediated by a mechanism different from that underlying its other behavioral actions (e.g. its anxiolytic and anticonvulsant effects).

212.17

THE BENZODIAZEPINE INVERSE AGONIST RO15-4513 EXACERBATES, BUT DOES NOT PRECIPITATE, ETHANOL WITHDRAWAL IN C3H MICE. H.C. Becker and R.F. Anton. VA Medical Center and Department of Psychiatry, Medical University of South Carolina, Charleston, SC 29403.

RO15-4513, an imidazobenzodiazepine that has been reported to antagonize several behavioral and biochemical actions of ethanol, was given to C3H mice at various times during withdrawal from chronic (72 hours) continuous exposure to ethanol vapor. The ethanol withdrawal response was scored for ambulatory behavior and convulsions (spontaneous as well as handling- and audiogenic-induced seizures). When administered immediately following chronic ethanol exposure, RO15-4513 (6 or 12 mg/kg) did not influence the withdrawal response. However, when given at subsequent times (3, 5, and 8 hours post-ethanol withdrawal), RO15-4513 significantly increased the severity of the withdrawal response in ethanol-exposed mice. Moreover, this exacerbation was completely reversed by pretreatment with the benzodiazepine receptor antagonist RO15-1788. RO15-4513 did not significantly influence the behavior of controls. Thus, these data indicate that the benzodiazepine inverse agonist, RO15-4513, is capable of exacerbating, but not precipitating ethanol withdrawal. Supported by the Veterans Administration and NIAAA.

212.18

FG-7142, A BENZODIAZEPINE PARTIAL INVERSE AGONIST, ANTAGONIZES ETHANOL-INDUCED DEPRESSIONS OF ELECTROPHYSIOLOGICAL ACTIVITY IN CEREBELLAR PURKINJE NEURONS. C.G. van Horne*, J.T. Harlan*, and M.R. Palmer. Univ. Colo. Hlth. Sci. Ctr., Denver Colorado.

It has been hypothesized that effects of ethanol may be mediated through a GABA receptor mechanism. It has been reported that the behavioral, biochemical, and electrophysiological effects of ethanol are antagonized by the benzodiazepine (BDZ) derivative, RO15-4513, a partial inverse agonist at the BDZ/GABA receptor complex. Our goal was to determine whether this antagonism was a unique property of Ro15-4513 or whether it could be attributed to partial inverse agonists in general. Both systemic and local applications of ethanol are known to cause a depression in the electrophysiological activity of cerebellar Purkinje neurons (CPNs). We therefore recorded the extracellular electrophysiological activity of CPNs through a multibarreled microelectrode and then compared pressure ejected local applications of ethanol (750 mM.) that caused repeatable and consistent depressions in baseline activity (between 30 and 70%) before and after the local application of FG-7142 (200 uM, pH 5.5-6.0), a BDZ partial inverse agonist. We found that FG-7142 application significantly antagonized ($p < 0.001$, paired t-test) the electrophysiological depressant effects of locally applied ethanol in 15 out of 17 neurons studied. Complete antagonism was observed in 47% of the FG-7142 sensitive neurons and a greater than 90% antagonism was seen in all but 3 sensitive cells. In comparison to our previous studies with Ro15-4513, FG-7142 was less potent but had a greater efficacy than Ro15-4513 in antagonizing ethanol. We therefore conclude that FG-7142 can antagonize the electrophysiological depressant effects of locally applied ethanol, and that this antagonism is not unique to Ro15-4513 but may be a property of partial inverse agonists in general. Grant support: AA05915 and AA03527.

ETHANOL-INDUCED DEPRESSIONS OF HUMAN CORTICAL NEURONS ARE ANTAGONIZED BY Ro15-4513: EVIDENCE FROM INTRACELLULAR TRANSPLANTS IN ATHYMIC RATS. A-C. Granholm[1], M. Eriksdotter-Nilsson[2], J. Stromberg[2], Philip Stieg[2], L. Olson, A. Seiger[3], M. Bygdeman[4], B. Hoffer[4] and M. Palmer[4]. [1]Department of Pharmacology, University of Colorado HSC, Denver, CO 80262, USA, [2]Dept. of Histology, Karolinska Institute, Stockholm, Sweden, [3]Dept. of Neurological Surgery, Univ. of Miami School of Medicine.

Human fetal tissue from the cerebral cortex was collected following elective abortions in the eigth to eleventh week of gestation using procedures approved by the Ethical Committee of the Karolinska Hospital conforming to USPHS guidelines. The human cortical tissue was transplanted to the anterior eye chamber of athymic nude rats. The cortical transplants increased significantly in size in oculo and became vascularized from the host iris. Different classes of neurons were identified with immunohistochemistry. Extracellular recording of single unit activity was performed in 9 transplants after 3-7 months in oculo. Single action potentials showed a more immature waveform in younger transplants, with long durations and very slow spontaneous discharges. Firing rates ranged from 0.5 to 6.0 Hz. Superfusion with known concentrations of ethanol elicited predominantly inhibitions of baseline firing rates, with occasional excitations at low concentrations (1-10mM). The transplants could be divided into two groups with respect to neuronal ethanol sensitivity, with EC50s of 28.9 mM (n=13) and 2.70 mM (n=4) respectively. Superfusion with Ro15-4513 caused a significant antagonism of ethanol-induced inhibitions. This antagonism lasted for 1.5-2 hours, whereafter the response to ethanol returned to control levels. In conclusion, ethanol elicits dose-dependent inhibitions of discharge in transplanted human cortical cells. This inhibition is antagonized by Ro15-4513.

212.20

RO15-4513 PREFERENTIALLY REVERSES ANTICONVULSANT EFFECTS OF ETHANOL IN RATS. S.K. Kulkarni* and M.K. Ticku (spon. R. Huffman), Dept. of Pharmacology, Univ. of Tx. Hlth. Sci. Ctr., San Antonio, TX 78284-7764.

RO15-4513, a novel imidazobenzodiazepine, is reported to antagonize the acute intoxicating effects of ethanol in rodents. In the present study the reversal by RO15-4513 (1-4 mg/kg, ip) of ethanol (2 g/kg, ip) protective effect against bicuculline (8 mg/kg) and picrotoxin (10 mg/kg) induced convulsions were studied in rats. Modification of onset of myoclonic jerks, duration of tonic extensors and mortality rate and time were recorded. Pretreatment with RO15-4513 (4 mg/kg), reversed the anticonvulsant effect of ethanol against bicuculline-induced tonic extensor phase and mortality (87%), a response sensitive to reversal by RO15-1788 (10 mg/kg). It reversed picrotoxin-induced mortality only upto 50%. As compared to ethanol it only partially reversed the protective effect of pentobarbital. The tonic extensor phase was not reversed. On the other hand FG-7142, another inverse agonist had least effect on the tonic extensor phase while it reversed ethanol protection against onset and mortality due to bicuculline-induced convulsions. FG-7142 failed to reverse the anticonvulsant effect of ethanol against picrotoxin. Both RO15-4513 and FG-7142 possessed proconvulsant effects against bicuculline but not against picrotoxin. These observations suggest that RO15-4513 preferentially reverses ethanol effects as compared to other inverse agonist.

212.21

[^{3}H]Ro 15-4513 BINDING TO CULTURED CEREBELLAR GRANULE CELLS. K. Nieminen, E.R. Korpi and O. Malminen*. Research Laboratories of the Finnish State Alcohol Company, Alko Ltd., POB 350, SF-00101 Helsinki, Finland.

The imidazobenzodiazepine Ro 15-4513 has been reported to block the anticonflict and intoxicating effects of ethanol in vivo as well as to antagonize ethanol-stimulated GABA-receptor mediated uptake of $^{36}Cl^-$ (Suzdak et al., Science 234: 1243-1247, 1986). Ro 15-4513 has not, however, proven to be an efficient alcohol antagonist in all studies (Hellevuo and Korpi, Pharmacol. Biochem. Behav. 30: in press). Pharmacologically, this controversial agent is classified as a partial inverse agonist of the benzodiazepine receptor. In addition to binding displaceable by traditional benzodiazepine agonists, such as diazepam, also diazepam-insensitive (d-is) binding of Ro 15-4513 has recently been reported (Sieghart et al., J. Neurochem. 48: 46-52, 1987).

We studied the properties of [^{3}H]Ro 15-4513 binding to intact granule cells from neonatal rat cerebellum. In cultured cells 7 d.i.v. about 60 % of the specific binding was diazepam-insensitive. Ro 15-1788 and βCCE displaced all specific binding with IC_{50} values near 100 nM and 1 μM, resp. Ethanol (30-300 mM) decreased the binding in the absence of diazepam, but not in the presence of it (10 μM).

The results suggest that Ro 15-4513 binds to two populations of sites in granule cells from the rat cerebellum; of these the binding displaceable by diazepam is sensitive to ethanol.

DRUGS OF ABUSE I

213.1

A DOSE-RESPONSE STUDY OF AMPHETAMINE-INDUCED LOCOMOTOR STEREOTYPY IN RATS. K. Mueller, P. Kunko*, D. Whiteside* and C. Haskett*. Dept. of Psychology, Texas Christian Univ., Fort Worth, TX 76129

We have recently proposed a new statistic ($\hat{\gamma}$) that quantifies the tendency of amphetamine-treated rats to exhibit repetitive patterns of locomotion in an open field. In our initial studies we found that higher doses of amphetamine (3.5 to 6.5 mg/kg) increased locomotor stereotypy (as measured by $\hat{\gamma}$) by producing repetitive trips around the perimeter of the open field.

In this experiment we injected rats (n=12 per group) with saline, 1.0, 2.0, 3.0, and 4.0 mg/kg amphetamine (subcutaneously) after the rats had been in the open field for 20 min. Each rat was immediately returned to the open field; its path through the open field was recorded.

Saline-treated rats tended to sleep during most of the observation period. The greatest locomotor stereotypy was produced by 2 mg/kg amphetamine; it was not unusual for some rats to repeat the same pattern of locomotion for 20 min. or more. Rats given higher doses of amphetamine exhibited locomotor stereotypy prior to exhibiting focused stereotypy (characterized by absence of locomotions and intense sniffing/biting of a restricted area of the open field).

We conclude that locomotor stereotypy is an important component of the behavioral effects of amphetamine in rats.

213.2

ENDOCRINE, IMMUNE AND NEUROCHEMICAL CHANGES IN RATS DURING WITHDRAWAL FROM CHRONIC AMPHETAMINE (AMPH) INTOXICATION. N.R. Swerdlow (1), R. Hauger (1), M. Irwin (1) K.T. Britton (1), G.F. Koob (2) and L. Pulvirenti (2), (1) Dept. Psychiatry, UCSD Sch. of Med., San Diego, CA 92093; (2) Preclin. Neurosci., RISC, La Jolla, CA 92037

Following cessation of chronic AMPH use or administration, both humans and infrahumans exhibit behavioral changes. Withdrawal from AMPH in humans is accompanied by symptoms similar to major depression, with disturbances in sleep, concentration and mood, including suicidality. Little is known regarding the neural substrates underlying the affective consequences of AMPH withdrawal.

In the current study, male Wistar rats (n=68) were treated with d-amphetamine sulfate (AMPH; 7.5 mg/kg i.p.) or saline (SAL) twice daily for 10 d. Withdrawal from this regimen of AMPH has been shown to disrupt responding for intracranial electrical brain stimulation in rats. One, 5, and 10 days following the final dose of AMPH, animals were challenged with either SAL or physostigmine (PHY; 0.1 mg/kg sc). PHY challenge has previously been shown to stimulate a "supersensitive" increase in plasma ACTH in depressed humans and dopamine-depleted rats. 20 min following PHY injection, animals were sacrificed. Trunk blood was collected and analyzed for levels of ACTH, prolactin and corticosterone. Pituitaries were collected and CRF receptors were assayed for K_D and Bmax. Brains were dissected and assayed for catecholamines in striatal and mesolimbic regions using HPLC. Spleens were collected and assayed for N_K cell activity.

Our findings indicate significant effects of AMPH withdrawal on neuroendocrine, neurochemical and immunological indices. AMPH withdrawal in rats provides information critical for understanding neural substrates of affective changes that accompany cessation of chronic AMPH use in humans.

213.3

IN VITRO REACTIVATION OF CENTRAL TRYPTOPHAN HYDROXYLASE AFTER IN VIVO INACTIVATION BY AMPHETAMINES. D.M. Stone*, G.R. Hanson and J.W. Gibb (SPON: W. Stevens) Dept. of Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112.

Within 1 h of systemic administration to rats, methamphetamine (METH) and several of its structural analogues, including 3,4-methylenedioxymethamphetamine (MDMA) and p-chloroamphetamine (PCA), induce a pronounced decrease in the activity of central tryptophan hydroxylase (TPH), the rate-limiting enzyme for serotonin biosynthesis. The mechanism of this effect currently remains unknown; however, it appears not to be a direct effect of the parent compound, since amphetamines have no inhibitory action on TPH activity in vitro (Sanders-Bush et al., *Biochem. Pharmacol.* 21:1501, 1972; Schmidt and Taylor, *Biochem. Pharmacol.* 36:4095, 1987). We have recently discovered that cortical TPH activity from MDMA-treated rats, which was reduced to < 60% of control 3 h after a 10 mg/kg dose, could be completely reactivated to control enzyme activity by a 20-h preincubation in vitro (25°C) under strong reducing conditions (5 mM dithiothreitol, 50 μM Fe^{+2}, N_2 atmosphere). Cortical TPH previously inactivated by METH or PCA could be similarly reactivated. However, enzyme activity which was decreased 30 days after multiple MDMA doses could not be reactivated, suggesting irreversible inactivation had occurred by this time. These results suggest that the in vivo activity of TPH may be regulated by the oxidation/reduction status of key sulfhydryl groups within the enzyme molecule, and that amphetamines inactivate TPH by inducing oxidation of these groups (formation of protein disulfides), most likely indirectly via an oxidized metabolite or liberation of a reactive endogenous species. The kinetics of enzyme reactivation will be presented. (Supported by USPHS grants DA 00869 and DA 04222).

REGIONAL EFFECTS OF ALPHA-BENZYL-N-METHYLPHENETHYLAMINE (ABNMP) ON DOPAMINE AND SEROTONIN METABOLISM IN RAT BRAIN. V. Jackson-Lewis, M. Katz*, C.R. Clark*, S. Fahn and J.L. Cadet. Columbia University, New York, New York 10032

Illicit synthesis of drugs of abuse often results in compounds that are neurotoxic. Alpha-Benzyl-N-Methylphenethylamine (ABNMP), a methamphetamine analog, is such a compound. We investigated the acute effects of this drug on Dopamine (DA) and Serotonin (5-HT) metabolism in rat brain.

Male rats were treated with ABNMP (5-20mg/kg i.p.) and decapitated 30 mins. later. Another group of rats were treated with ABNMP (20mg/kg i.p.) and sacrificed at varying times up to 8 hrs after drug. Brain regions were dissected out on ice and tissues were frozen at -80°C until assayed. ABNMP (10-20mg/kg) caused decreases in DA in the striatum (25-35%) and in the nucleus accumbens (NAc) (25-30%). DOPAC and HVA were increased in these brain areas.

ABNMP (5-20mg/kg) decreased 5-HT (17-26%) and 5-HIAA (16-23%) in striatum, but had no effect on NAc 5-HT. 5-HIAA, in NAc, was slightly elevated.

ABNMP (20mg/kg) caused a peak decrease in striatal DA at 60 mins. which was still present 8 hrs. later. NAc DA was less affected; there was a small decrease in 5-HT in the striatum but not in the NAc.

Results suggest that ABNMP may affect the DA and 5-HT systems in rat brain.

213.5

NEUROBIOLOGICAL COMPONENTS OF THE DISCRIMINATIVE STIMULUS PROPERTIES OF d-AMPHETAMINE. C. Bimle*, C. Co* and S.I. Dworkin (SPON: L.A. Bittenger). Dept. of Psychiatry, LSU School of Med., Shreveport, LA 71130

Rats were trained to discriminate d-amphetamine (1.0 mg/kg IP) from saline using a standard two lever procedure. The subjects were then tested using a modified drug-titration procedure. A descending range of doses from 1.0 to .17 mg/kg and saline were tested for discriminative stimulus properties. The dose tested with individual rats was decreased during successive sessions until the rat choose the saline lever after a drug injection and was increased until the subject again choose the drug lever. Following the determination of this threshold dose, the rats were lesioned with 6-OHDA or its vehicle. The animals were then tested again using the dose-titration procedure.

The procedure resulted in generalization gradients similar to those previously reported. The 6-OHDA lesion resulted in a moderate depletion of dopamine in the nucleus accumbens and a small but significant attenuation of the discriminative stimulus properties of d-amphetamine. These changes were not as large as those previously reported for cocaine discrimination. Thus, it appears that destruction of the dopaminergic input into the accumbens only moderately alters the discriminative stimulus properties of d-amphetamine. Research Supported By USPHS Grant DA-03631.

EFFECTS OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) ON BRAIN AND HEART BIOGENIC AMINES IN MICE. T.D. Steele* D.E. Nichols, and G.K.W. Yim. (SPON: C.O. Rutledge) Dept. of Pharmacol. and Toxicol., and Med. Chem. and Pharmacognosy, Purdue University, W. Lafayette, IN 47907.

The effects of acute and chronic administration of (±)-MDMA on brain and cardiac neurotransmitter and metabolite levels were assessed in male CF-1 mice. Acute treatment with the highest dose of MDMA (40 mg/kg) transiently decreased norepinephrine (NE) levels in the brain and heart. Only the cardiac depletion was blocked by desipramine pretreatment. In contrast to reported effects in rats, brain levels of serotonin and dopamine were elevated 3 hrs post-MDMA but were normal 6 and 24 hrs post-treatment. Levels of 5-HIAA, DOPAC and HVA were significantly lowered 3 hrs post-MDMA and gradually returned to control values. A regimen consisting of four daily doses of MDMA caused a significant decrease only in amine metabolite levels one week following the last treatment, which suggests an alteration in amine turnover possibly due to drug effects on monoamine oxidase. This effect may represent one biochemical difference contributing to the species variation in the response of biogenic amine systems to MDMA. (Supported in part by USPHS BRSG RR05586)

213.7

EFFECTS OF METHYLENEDIOXYMETAMPHETAMINE (MDMA, "ECSTASY") ON THE FIRING RATES OF SEROTONERGIC, DOPAMINERGIC, AND NORADRENERGIC NEURONS IN THE RAT. J.T.Lum, J.R.Palmer, and M.F.Piercey. The Upjohn Company, Kalamazoo, MI 49001.

MDMA is a non-hallucinogenic drug of abuse with an ability to reduce anxiety, increase sociability, and aid psychotherapy in human subjects. It releases dopamine (DA) and 5-HT, although higher concentrations destroy 5-HT terminals (Science 239:864, 1987). To further understand MDMA's psychotropic effects, we measured i.v. MDMA effects on firing rates of 5-HT neurons in dorsal raphe, noradrenaline (NE) neurons in locus coeruleus, and DA neurons in substantia nigra pars compacta. MDMA depressed firing rates of all 5-HT neurons, but potencies varied widely. There was a high-sensitivity group (MDMA ED50 = approximately 100 ug/kg) and a low-sensitivity group (MDMA ED50 = approximately 2000 ug/kg). Neither spiperone, a 5-HT1A autoreceptor antagonist (Lum and Piercey, Neurosci. Abs. 13:1649, 1987), nor the 5-HT2 antagonist LY53837 reliably reversed MDMA effects in either group. NE neurons were also depressed (ED50 = 670 ug/kg); piperoxan, an alpha-2 antagonist, only partially reversed these effects. MDMA in doses up to 3000 ug/kg did not affect firing rates of DA neurons. MDMA's psychotropic effects may be due to a unique interaction with NE cells and a highly sensitive subpopulation of 5-HT cells. Effects may reflect feedback control following enhanced transmitter release from terminals in post-synaptic targets.

213.8

MDMA AND MDE MEDIATE SUPRASPINAL BUT NOT SPINALLY MEDIATED ANALGESIA: EVIDENCE FOR POSSIBLE 5-HT INVOLVEMENT. J.W. Boja, T. Crisp and M.D. Schechter, Dept. of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272

Serotonin (5-HT) has been shown to facilitate the reflexive response to pain and inhibit ascending nociceptive transmission (Zemlan et al., 1983). The "designer" drugs MDMA and MDE have both been reported to release 5-HT. Additionally, the analgesic properties of MDMA have been demonstrated in the mouse. In order to test the analgesic properties of MDMA, and the related drug MDE, male rats were tested utilizing the hot-plate test that measures supraspinal mediated analgesia, whereas the tail-flick procedure was used to measure spinally-mediated analgesia. MDMA (3.0 and 6.0 mg/kg, i.p.) significantly elevated hot plate latencies in a dose-dependent manner. MDE (8.0 mg/kg, i.p.) produced analgesia using the hot plate test. However, neither MDMA nor MDE elevated tail-flick latencies in rats. In fact, a hypersensitive response of this measure was seen following administration of 6.0 mg/kg MDMA. These results suggest that the analgesic effects of MDMA are mediated via the release of 5-HT. Funded by grant DA 04181.

213.9

SIGMA RECEPTORS: A PUTATIVE SITE OF ACTION OF MDMA (3,4-METHYLENEDIOXYMETHAMPHETAMINE) AND RELATED ANALOGS M. Yousif*, G. Battaglia, E.B. De Souza and R.A. Glennon* NIDA Addiction Res. Cntr., Baltimore MD 21224 and Dept. Medicinal Chemistry, MCV/VCU, Richmond, VA 23298

Sigma receptors are believed to mediate some of the effects of PCP and benzomorphan opiates. We report here that some of the psychotomimetc effects of the "designer" drug MDMA, and related analogs (MDE and MDP), may likewise be mediated by brain sigma receptors. MDMA, MDE and MDP exhibited high affinity (Ki= 0.2-3uM) for sigma receptors; these drugs were 7, 28, and 84-fold more potent, respectively, than MDA at this site. In contrast, the affinities of MDA were similar to those of MDMA (< 2-fold difference) at each of 20 other receptors and recognition sites in brain. All of the analogs exhibited low affinity for PCP receptors (Ki > 100uM) with MDA, MDMA, MDE and MDP being 11, 115, 454 and 484-fold more potent, respectively, at sigma receptors compared to PCP sites. The selectivity exhibited by these drugs contrasts with drugs such as PCP and benzomorphan opiates which interact with both sigma and PCP receptors. The data from the present study suggest that some of the psychotomimetic effects of MDMA, MDE and MDP may be due to selective high affinity interactions with brain sigma receptors. The finding that these compounds are more potent than MDA at sigma receptors may explain some of the differences in behavioral and/or subjective effects that have been reported between MDA and drugs such as MDMA and MDE.

213.10

SIGMA OPIATES: IDENTIFICATION OF A PRIMARY PHARMACOPHORE AND THE DESIGN OF HIGH-AFFINITY SIGMA-SELECTIVE LIGANDS. R. A. Glennon,* G. Battaglia,(+) J.D.Smith,* A. Ismaiel* and J. Herndon*. Dept Medicinal Chemistry, MCV/VCU, Richmond VA 23298 and (+)Addiction Research Center, Baltimore MD 21224 (SPON: L.S.Harris)

Few classes of agents bind at σ receptors with high affinity; of those that do, selectivity is generally low and structure-activity relationships are poorly understood. Perhaps the best studied agents are the "sigma opiates" (e.g. NANM, cyclazocine, pentazocine). We have begun an investigation of the structure-affinity relationships (SAFIR) of the σ opiates and have identified what we believe to be a primary pharmacophore: PAP. Although PAP itself binds with relatively low affinity, amine-substituted derivatives bind with a significantly higher affinity. For example, for R(-)PPAP, a derivative of PAP, Ki = 6 nM for [3H]haloperidol-labeled σ sites (rat cerebellum). SAFIR studies reveal that aromatic substitution also plays a significant role. These studies led to the design and synthesis of, e.g., (±)C2-PAP which binds with moderate affinity (Ki = 290 nM) and (±)C2-PPAP, one of the highest affinity agents yet reported for these sites (Ki = 0.5 nM). In addition, unlike many of the σ opiates, these agents display a fairly low affinity (Ki > 10,000 nM) for [3H]TCP-labeled PCP sites. Additional SAFIR studies with PAP analogs promise to provide new high-affinity, site-selective sigma ligands.

213.11

THE DETERMINATION OF PHENCYCLIDINE (PCP) AND RELATED COMPOUNDS BY HPLC-EC. C. Stephen*, C.J. Drebing*, W. Phillips*, R. Freedman and G.A. Gerhardt. Depts. Psychiatry and Pharmacology, Univ. of Colo. Hlth. Sci. Ctr., Denver, CO 80262.

We have developed a new rapid and sensitive method for the measurement of PCP, its metabolites, and cocaine using high performnace liquid chromatography coupled with electrochemical detection (HPLC-EC). PCP and related species are separated on a cyano bonded phase column (Beckman, 4.6 mm X 7.5 cm, 3 micron); the mobile phase is a pH 6.5 citrate-phosphate buffer containing 2.0 g/l NaCl with 20% acetonitrile. All eluting species are detected with a dual-carbon electrochemical detector (ESA 5011 Cell; electrode #1 set at 0.65 volts and #2 set at 0.80 volts). Species are detected at the second electrode and methyl-PCP is used as an internal standard. The detection limit of the assay is currently less than 1 nanogram per injection with a total separation time of less than 10 minutes. We are currently applying this method to studies of PCP metabolism and excretion in CSF, plasma and postmortem brain tissue samples from rodents.

213.12

DOSE DEPENDENT BEHAVIORAL EFFECTS OF N-ALLYLNORMETAZOCINE (SKF10,047) ISOMERS IN A PRIMATE SOCIAL COLONY. D.J. McGinness*, R.F. Schlemmer, Jr., N.L. Katz & J.M. Davis, Univ. of Illinois at Chicago & Ill. State Psychiatric Institute, Chicago, IL 60612

(±)N-Allylnormetazocine (NAN) is a potent psychotomimetic in humans. Although this activity is usually attributed to its sigma agonist property, binding studies suggest that (+)NAN is a preferential sigma agonist, while (-)NAN is a mu antagonist and kappa opiate receptor agonist. The present study compared the behavioral effects of the isomers & racemate of NAN in a primate social colony. Following determination of normal colony behavior, 4 members of a stable Stumptail macaque social colony received 5 acute doses of (±)NAN, (+)NAN, & (-)NAN, 0.1-3.0 mg/kg, in a cross-over design. Each dose was given i.m. 15 min. prior to a 60 min. observation session conducted by a "blind" observer. All forms of NAN decreased initiated social interactions, grooming, locomotion & checking (visual scanning); and increased total resting time. Interestingly, (-)NAN was consistently more potent than (+)NAN. NAN failed to induce most of the behavioral changes induced by dopamine agonist psychotomimetics in this species, but instead induced changes more consistent with phencyclidine (PCP). The results of this study suggest that the mu antagonist and kappa agonist activity should not be disregarded when considering the clinical effects of the "sigma agonist" (±)NAN.

213.13

DO DEXOXADROL AND PHENCYCLIDINE PRODUCE DIFFERENT DISCRIMINATIVE STIMULI? D.A. Bennett, P.S. Bernard, C.L. Amrick and J. Lehmann. Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

Dexoxadrol (DEX) is a dissociative anesthetic for which discriminative stimuli have not been reported. In the following investigation, the discriminative stimuli of DEX were compared with those of phencyclidine (PCP). In generalization experiments, the representative dissociative anesthetics PCP, DEX and ketamine generalized to both cues. Two other compounds, dextrorphan (DT) and dextromethorphan (DM), were assessed for both generalization to and antagonism of the cues. Both compounds generalized to PCP discriminative stimuli but only DT generalized to DEX discriminative stimuli. In antagonism studies, DT did not block either the PCP or DEX cue, while DM produced dose-dependent antagonism of the DEX cue, with a maximum of only 22% antagonism of the PCP cue. These data suggest a qualitative difference between DEX and PCP discriminative stimuli. Dissociative anesthetics are know to produce some effects characteristic of psychosis. As such, an antagonist of these effects may have potential antipsychotic properties. It has been difficult to block PCP-induced behaviors. If the DEX cue is sensitive to compounds that antagonize the effects produced by dissociative anesthetics, it suggests that this assay might identify compounds with potential antipsychotic activity.

213.14

ANTIPUNISHMENT EFFECTS OF PHENCYCLIDINE AND PCP-LIKE COMPOUNDS. J.H. Porter, J.L. Wiley and R.L. Balster*. Depts. of Psychology and Pharmacology, Virginia Commonwealth Univ., Richmond, VA 23284.

Antianxiety drugs such as chlordiazepoxide (CDP) have been shown to increase punished responding in animals. The present study examined the antipunishment effects of phencyclidine (PCP) and related compounds in a Geller-Seifter (1960) Conflict test. Twenty male rats (80% BW) were trained to respond under a multiple fixed interval 60-sec (food only) fixed ratio 1 (food + shock) schedule of reinforcement. Significant increases in punished responding were produced by CDP (5 and 10 mg/kg), PCP (2 mg/kg), N-allylnormetazocine (10 mg/kg), etoxadrol (8 mg/kg), and (-)-B-cyclazocine (1 mg/kg). Morphine and (-)-a-cyclazocine did not produce any significant changes in punished responding, but both produced significant decreases in unpunished responding. Also, it was found that naltexone (1 mg/kg) did not block the antipunishment effect of (-)-B-cyclazocine. These results demonstrate that PCP and related compounds produce increases in punished responding, and that this effect does not appear to be related to the opiate properties of these compounds. The abuse of PCP and related compounds may be in part related to the antianxiety properties of some of these drugs. (Research supported by NIDA grant DA-01442)

213.15

IN VIVO BRAIN MICRODIALYSIS STUDY OF PHENCYCLIDINE ON PRESYNAPTIC DOPAMINE EFFLUX IN RAT CAUDATE NUCLEUS. J. Chen* and E.L. Gardner. Depts of Neuroscience and Psychiatry, Albert Einstein College of Medicine, New York, NY 10461.

Phencyclidine (PCP) is a potent CNS-acting drug with major abuse potential and the ability to induce psychosis claimed to mimic naturally occurring schizophrenia. Due to the postulated role of brain dopamine (DA) systems in mediating the rewarding properties of abused drugs (Spyraki, C., et al., *Psychopharmacology*, 79:278, 1983) and in the neuropathology of schizophrenia (Creese, I., et al., *Science*, 192:481, 1976), PCP has been suggested to affect brain DA systems. Gerhardt et al. (*J.Pharmacol.Exp.Ther.*, 241:714, 1987) showed PCP to mimic the action of the DA reuptake blocker nomifensine on *in vivo* electrochemical potentials presumed to represent DA in rat caudate. We studied PCP's effect on presynaptic DA efflux using *in vivo* brain microdialysis coupled with high performance liquid chromatography (HPLC), thus permitting precise biochemical identification of neurotransmitter efflux. Rats were implanted with microdialysis probes in the caudate, and dialysis experiments carried out as described by Zetterström et al. (*J.Neurochem.*,41:1769, 1983). 5 mg/kg PCP significantly raised basal DA efflux and robustly elevated K^+-stimulated DA efflux; these effects lasted up to 2 hrs and correlated with PCP-induced behavioral stereotypy. 10 mg/kg PCP produced more pronounced effects. We conclude that PCP has strong DA agonist effects and suggest these relate to its abuse potential and induction of psychosis.

213.16

DISRUPTION OF CENTRAL SEROTONERGIC FUNCTION BLOCKS THE ACTIVATION OF A_{10} BUT NOT A_9 DOPAMINE NEURONS BY PHENCYCLIDINE (PCP). A.Ceci* and E.D.French (SPON: F. Porreca Dept.Pharmacol., Univ.Arizona, Coll.Med., Tucson, AZ 85724

PCP's psychotomimetic effects have been suggested to involve the activation of the A_{10} mesocorticolimbic dopamine neurons. Since these cells receive a prominent serotonergic (5-HT) input from the dorsal raphe nucleus (DRN), the role played by this transmitter in PCP's A_{10} effects was investigated.

Single-unit extracellular recordings from A_{10} and A_9 neurons, identified according to well-established electrophysiological criteria, were made in chloral hydrate anesthetized rats. From these recordings cumulative dose-response curves for PCP were made: (1) 7-days following radiofrequency lesion of the DRN; (2) 2 hr after the administration of the selective 5-HT_2 antagonist, ritanserin (5 mg/kg, i.p.); and (3) 24 hr after the 2nd injection of the 5-HT depletor, p-chloroamphetamine (PCA) (10 mg/kg/day, i.p.). In controls, PCP increased the firing rate of A_{10} neurons by$\sim$50%. However, after all 3 treatments, this effect of PCP was virtually eliminated (+11% after DRN lesion, -7% after ritanserin and +12% after PCA). In contrast, the maximum activation of A_9 neurons by PCP ($\sim$+44%) was not attenuated following DRN lesion (+44%) or ritanserin (+48%) pretreatment. Also, none of the treatments significantly affected spontaneous firing rates.

These findings suggest that DRN 5-HT neurons play a pivotal role in PCP's stimulation of the mesocorticolimbic dopaminergic system, presumably through activation of 5-HT_2 receptors, and as such may be fundamentally involved in PCP's psychotomimetic actions.

THE EFFECT OF PHENCYCLIDINE ON DOPAMINE RELEASE IN THE CAUDATE-PUTAMEN OF THE RAT. X.Y. Xuan*, D. Chapman*, R.A. Gazzara, and S. Howard. (Sponsor: P. Lomax) MRRC, BRI, Department of Pharmacology, UCLA, Los Angeles, CA 90024.

Phencyclidine (PCP) has multiple pharmacological effects including: a psychotomimetic; a dissociative anesthetic; and a sympathomimetic. In these studies we used in vivo microdialysis to examine the effect of PCP on the extracellular levels of dopamine (DA) and its metabolites, dihydroxyphenylacetic acid (DOPAC), and homovanillic acid (HVA) in the caudate-putamen of the rat. The dose-related effects of PCP (1, 10 and 20 mg/kg i.p.) in the urethane-anesthetized animal will be compared with the effects found in the unanesthetized preparation. Microdialysis samples were collected every 10 minutes and levels of DA, DOPAC, and HVA were measured using HPLC-EC. In the anesthetized preparation, PCP produced a dose-dependent increase in DA that was followed in time by an increase in both DOPAC and HVA. These preliminary data suggest that in the anesthetized preparation, PCP facilitates release of DA but does not inhibit uptake. Supported by USPHS Grant DA 03020.

213.18

BEHAVIORAL COMPARISON OF THE EFFECTS OF PHENCYCLIDINE, KETAMINE AND N-ETHYL-PHENYLCYCLOHEXYLAMINE IN THE CAT. *L.M. Hiraide*, S. Howard, D. Chapman* and M.S. Levine (SPON: M.K. Shellenberger). MRRC, UCLA, Los Angeles, CA 90024.*

This study compared the behavioral effects of phencyclidine (PCP), ketamine (KET) and an N-substituted analog of PCP, N-ethyl-phenylcyclohexylamine (PCE). KET has low binding properties to the PCP receptor while PCE has been demonstrated behaviorally and in binding studies in the rat to be a potent agonist of PCP. Experiments were performed on 15 adult cats. Each animal received 4 dosages of only one compound (0.1, 0.5, 1.0 and 2.0 mg/kg). There were 5 animals in each group. Behavior was assessed from 10 min pre-injection to 5 hr post-injection. Saline was administered to each cat on alternate weeks as a control. All compounds produced dose-related behavioral changes in postural integrity, locomotor activity, and stereotypic head movements. Responses produced by PCP and PCE were similar at all dosages. Overall the effects of PCE began with a shorter latency and outlasted those of PCP. The most intense and long-lasting effects occurred at the highest dose for both PCP and PCE. These results support previous data obtained in rats which have shown KET to be less behaviorally potent than PCP. Although in binding studies PCE has been reported to be six times more potent than PCP, the behavioral effects of these two compounds were similar in the cat. Supported by USPHS Grant DA03017.

213.19

EFFECTS OF PHENCYCLIDINE ON DOPAMINE IN THE CAUDATE NUCLEUS OF THE AWAKE CAT. D. Chapman*, R.A. Gazzara, X.Y. Xuan* S. Howard. MRRC, BRI and Department of Pharmacology, UCLA Los Angeles, CA 90024.

Phencyclidine (PCP) has been shown to inhibit the uptake of dopamine and at higher doses to release dopamine in vitro. Microdialysis was performed on chronically prepared awake restrained cats to evaluate the neurochemical basis of the behavioral effects of PCP. Cats adapted to restraint were each given 0.1,0.5,1.0, and 2.0 mg/kg PCP. Samples were collected every ten minutes using a microdialysis probe located in the caudate nucleus. Samples were analysed for dopamine, dihydroxyphenylacetic acid (DOPAC), and homovanillia acid (HVA) using HPLC-EC. PCP produced an increase in the extracellular concentration of dopamine, while the metabolites DOPAC and HVA decreased. These findings are consistent with earlier observations that demonstrate an inhibition of striatal dopamine uptake and a facilitation of release. The results of this study suggest that the neurochemical effects of PCP on striatal dopamine may be correlated with its behavioral effects in the cat. Supported USPHS Grant DA03020.

MONOAMINES AND BEHAVIOR II

214.1

POST-STRESS CHANGES IN RAT BRAIN MONOAMINES AND THEIR FREE AND CONJUGATED METABOLITES USING HPLC WITH SERIAL OXIDATIVE-REDUCTIVE ELECTROCHEMICAL DETECTION

W.W. Woodmansee, P.H. Desan, L.H. Silbert*, T.K. Smock and S.F. Maier, Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309

Exposure to various forms of stressful stimuli have been shown to induce behavioral and neurochemical changes. We examined the duration of monoamine alterations in the rat brain following a tailshock stressor. HPLC coupled with serial oxidative-reductive electrochemical detection was employed to measure norepinephrine (NE), dopamine (DA), and serotonin (5HT) and their respective metabolites (free MHPG, free DHPG, DOPAC, and 5HIAA) in the anterior cortex, cerebellum, hippocampus (structures whose chief noradrenergic input arises from the dorsal NE system), and hypothalamus (a region with a major innervation from the ventral NE system). Samples were collected from nonshocked controls and .5, 2, 6, and 24 hours following the termination of the stressor. Total (free and sulfated) MHPG and DHPG content was determined in cortex samples by enzymatic deconjugation prior to analysis. Stress was not found to alter DA and 5HT levels in any of the regions examined, but NE was dramatically reduced in the hypothalamus and hippocampus. Hypothalamic NE remained depleted for at least 24 hours. There were transient increases in 5HIAA and DOPAC in all regions examined, and transient increases in MHPG in all areas except the hypothalamus, suggesting an activation of all three monoaminergic systems. Hypothalamic MHPG and DHPG were significantly reduced up to 24 hours following stress. Large accumulations of free and sulfated MHPG were observed in the cortex, whereas significant increases in DHPG were evident in the conjugated, but not in the free form. Thus, stress, as employed in this laboratory to produce behavioral deficits, alters monoaminergic functioning in the rat brain that may persist for 24 hours. Supported by NSF grants BNS 85-07451 and BNS 85-20622.

214.2

THE EFFECT OF STRESS ON THE RELEASE OF ELECTROACTIVE SPECIES IN THE THALAMUS OF FREELY MOVING RATS. K.J.Renner*, L.Pazos* and R.N.Adams. (SPON: A.Oke) Dept. of Chemistry, University of Kansas, Lawrence, KS 66045.

The effects of shake-induced stress on the release of electroactive species was chronoamperometrically monitored in the ventral thalamic nuclear region. Male rats were bilaterally implanted with electrochemically pretreated, Nafion-coated carbon fiber electrodes and allowed to recover overnight. Chronoamperometric measurements, +0.12V vs Ag/AgCl, were taken at 15 sec intervals. In vitro, the Nafion-coated electrodes were minimally sensitive to ascorbic acid, serotonin, 5-hydroxyindole acetic acid and had low sensitivity to 3,4-dihydroxyphenyl acetic acid.

In vivo evaluation of electrode response to systemic drug administration showed that the baseline current decreased after α-methyl-p-tyrosine (αmpt) and FLA-63. Increases in the baseline current were observed following treatments with pargyline, yohimbine and yohimbine-injected 2 hr post-pargyline. These results suggest that an electrochemical signal, primarily due to norepinephrine (NE) release, can be monitored in thalamic regions.

Chronoamperometric responses to 2 min periods of the shake-stress were long lasting (ca. 20 min), reproducible and small in magnitude (ca. 200 nM). The signals were blocked by the administration of αmpt and FLA-63. These studies provide in vivo evidence suggesting that stressful sensory input to the thalamus is accompanied by the release of NE. (Supported by NSF).

214.3

ANGIOTENSIN AND DRINKING INDUCE DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS. D. S. Blander*, G. P. Mark, L. Hernandez and B. G. Hoebel (SPON. M. Lampert). Dept. Psychol., Princeton Univ., Princeton, NJ 08544

Angiotensin II can induce drinking when administered intracerebroventricularly (ICV). This experiment measured dopamine (DA) release in the nucleus accumbens (NAC) using microdialysis following ICV injections of angiotensin II or saline. Male, Sprague-Dawley rats were implanted with stainless steel cannulas in the third ventricle and guide shafts aimed at the posterior medial NAC. At least 1 week after surgery a microdialysis probe (0.2 mm x 2 mm tip) was inserted into the NAC and brain dialysate was analyzed every 20 min, for 1 hr prior to and 2 hr after ICV injections of either angiotensin II (100 ng/5 ul) or saline vehicle. One group (N=15) was tested with angiotensin or saline, and a second group was given angiotensin plus water to drink for 20 min. Angiotensin alone caused a small (25%) but statistically reliable increase in extracellular DA, and this effect dissipated 40 min post-injection. In contrast, with ICV angiotensin plus water to drink, NAC dopamine increased 70% above baseline, reaching a peak 40 min after injection. Extracellular DA remained elevated in these subjects for an additional 40 min. These results implicate dopaminergic involvement in reward-related behaviors [1,2] and suggest that DA may be released differentially in the accumbens depending on whether an animal is motivated (e.g. angiotensin alone) or rewarded (angiotensin plus water consumption).

214.4

EXTRACELLULAR DOPAMINE INCREASES IN THE NUCLEUS ACCUMBENS FOLLOWING REHYDRATION OR SODIUM REPLETION IN RATS. V. C. Chang*, G. P. Mark, L. Hernandez and B. G. Hoebel, Dept. Psychol., Princeton Univ., Princeton, NJ 08544

Studies have suggested dopaminergic involvement in rewarded behaviors such as food or fluid consumption [1,2]. The role of dopamine (DA) in salt and water intake was examined in this study using *in vivo* microdialysis in the nucleus accumbens (NAC). Male, Sprague-Dawley rats were implanted with stainless steel guide shafts ending dorsal to the posterior-medial NAC. One group (N=4) of animals was sodium deprived by combining diuretic, furosemide injections with a sodium-deficient diet. Another group (N=5) was deprived of water for 20 hr prior to testing. On the day of the experiment, a microdialysis probe (0.2 mm OD by 2 mm tip) was inserted into the NAC, and brain dialysate was analyzed at 20 min intervals for 1 hr before and 2 hr after giving 2% saline to salt-deprived animals or distilled water to water-deprived animals. Extracellular levels of DA increased significantly in both cases: 200% of baseline during saline drinking and 140% during water drinking. In both cases the increase was maintained for at least 1 hr following intake. These results suggest that dopamine in the nucleus accumbens is involved in rehydration and sodium repletion.

214.5

EFFECTS OF DRINKING ON DOPAMINE, DOPAC AND HVA LEVELS IN THE RAT AS MEASURED BY IN VIVO DIALYSIS. K.E. Sabol and C.R. Freed, Univ. of Colo. Health Sci. Ctr., Denver, CO 80262.

This experiment was designed to determine whether water drinking results in changes in the release of dopamine (DA) and its metabolites using the in vivo dialysis technique. DA, DOPAC and HVA were measured in water deprived rats for a 220 min period on 2 separate days. Dialysis cannulae were located in either n. accumbens (NA) (n=5) or lateral anterior striatum (LAS) (n=5). For each rat, one day was designated a baseline session and no intervention was imposed. In the second session, the rat was given access to water for 24 min in the middle of the session. Consumption of approximately 15 ml of water caused increases of 30% for DOPAC and 24% for HVA in NA, and 24% for DOPAC and 27% for HVA in LAS. There were no changes in DA. In another experiment, the volume of water delivered was restricted to 0.05 ml of water every 30 sec. This fixed time paradigm was associated with equivalent motor activity though rats consumed only 16% of the water they received while free drinking. Preliminary results from the fixed time experiment showed increases in DOPAC and HVA even with the reduced water consumption. Changes in DA metabolites therefore appear unrelated to the amount of water consumed. Measures of overall activity made in both experiments suggest that changes in DA metabolites are instead related to motor activity induced by the drinking paradigms.

214.6

'IN VIVO' VOLTAMMETRIC RELEASE OF STRIATAL DOPAMINE (DA) IN INBRED MOUSE STRAINS. M.K. Sanghera;F. Crespi*+;K.Martin*+& C.A.Marsden*+. Dept Psychiat, UT Southwestern Med Ctr, Dallas, TX 75235; Dept Physiol, Univ Nottm Med Sch,UK+.

BALB/c and CBA mice differ in the spontaneous and drug-induced behaviors that are thought to to be mediated by DA mechanisms. In this study to sought to determine if this could be due to differences in the release of DA from terminals in the striatum. Carbon fiber electrodes (CFE) were implanted in the striatum of both strains (N=12) under chloral hydrate. Animals were pretreated with pargyline HCl (150 mg/kg,ip) and 3 hrs later K^+-stimulated DA release was measured using differential pulse voltammetry. The infusion of 2 µl of KCl from a Hamilton syringe inserted close to the CFE resulted in the immediate appearance of the DA Peak at +80 mV in both strains. In Balb/c this peak was 3.5x larger than in the CBA. The height of the peak corresponded to an 'in vitro' DA value of 24.5 ±7.6 µM for BALB/c and 7±2 µM for CBA. This DA release could be evoked every 10-15 mins with similar magnitude only in the BALB/c. Striatal DA after pargyline, measured with HPLC-ECD, was not different in the strains suggesting that in the BALB/c more DA may be present and released from the readily releasable pool than in CBA.

214.7

AMPHETAMINE SENSITIZATION IN THE NUCLEUS ACCUMBENS STUDIED WITH *IN VIVO* MICRODIALYSIS. Terry E. Robinson. Dept. of Psychology, The University of Michigan, Ann Arbor MI 48109.

The repeated use of amphetamine (AMPH) produces a hypersensitivity to the motor stimulant and psychotogenic effects of AMPH that can persist for months to years after the cessation of drug use. This suggests that AMPH may produce very long-lasting changes in those neural systems that mediate the motor stimulant and psychotogenic effects of AMPH. The present study was designed to explore the neurobiological basis of this sensitization phenomenon by studying rats that were pretreated with an escalating dose regimen of AMPH (from 1 to 10 mg/kg over 5 weeks). This regimen mimics the pattern of drug use associated with the development of AMPH psychosis. It was found that this treatment was not neurotoxic, because 25-30 days after the last pretreatment injection the postmortem tissue concentrations of dopamine (DA), serotonin and their metabolites were normal, and the animals showed relatively normal levels of spontaneous motor activity across the day-night cycle. However, AMPH pretreatment produced robust behavioral sensitization. Animals showed a marked hypersensitivity to the motor stimulant effects of an AMPH challenge, even after 15-21 days of withdrawal. Most importantly, this behavioral hypersensitivity to AMPH was accompanied by significantly elevated extracellular concentrations of DA in the nucleus accumbens, as indicated by *in vivo* microdialysis in freely-moving animals. In contrast, AMPH pretreatment had no effect on the basal extracellular concentrations of DA. It is suggested that the sensitization produced by chronic AMPH use may be due to enduring changes in the releasability of DA, and may represent an example of neural plasticity common to other forms of behavioral adaptation.

ELECTROPHYSIOLOGICAL ACTIONS OF SELECTIVE SIGMA RECEPTOR AGONISTS AND ANTAGONISTS ON MIDBRAIN DOPAMINE NEURONS. G.F. Steinfels and S.W. Tam. DuPont Co., Medical Products Department, Wilmington, Delaware 19898 U.S.A.

Receptor binding and autoradiographic studies have demonstrated that sigma and phencyclidine receptors have distinct binding sites and different anatomical distribution in brain. In vivo pharmacological studies, however, have been hampered by the lack of highly selective agonist and antagonist ligands for each site. (+)-Pentazocine, (+)-3PPP, and DTG bind to the sigma receptor but not to the PCP receptor. I.V. administration of these sigma agonists produced a dose dependent decrease in firing rate of A9 dopamine (DA) neurons. In contrast, MK-801, a selective PCP receptor agonist generally increased firing rate. Rimcazole and BMY 14802 are antipsychotic compounds which bind to sigma but not to PCP or DA receptors. I.V. administration of Rimcazole produced either no effect or increased DA neuron firing rate. BMY 14802 more consistently produced an increased firing rate of DA neurons compared to Rimcazole. Further, the rate reducing effects on DA neurons produced by (+)-3PPP were found to be partially or completely reversed following administration of BMY 14802. These data demonstrate different pharmacological properties of selective sigma or PCP receptor agonists on DA neurons. This study also demonstrates that a selective sigma receptor antagonist can antagonize the pharmacological response of a sigma receptor agonist.

214.9

MODULATION OF THE MASSETERIC REFLEX BY ENVIRONMENTAL CONDITIONS. I.L. Stafford and B.L. Jacobs, Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

The masseteric or jaw closure reflex is a monosynaptic brainstem system that receives dense monoaminergic inputs. We have proposed it as a model system for examining functional changes in central neurotransmission. Here we describe the basic methodology and explore changes in the reflex produced by conditions known to physiologically activate NE neurons. The next abstract directly explores the role of NE in mediating these changes. The reflex is elicited in behaving cats by pulse stimulation of MesV delivered every 6 sec for 8 trials at each of 3 current levels. This stimulation monosynaptically activates MoV, causing a masseter muscle contraction, which can be measured on an oscilloscope. Following baseline measures of the reflex amplitude, the reflex was once again elicited while cats were exposed to 15 min of loud white noise (100 db), a dog, or clicks presented at various intervals prior to MesV stimulation. The first two conditions dramatically facilitated the reflex response. The clicks produced reflex facilitation at 100 & 150 msec and suppression at 20 msec. The next study examined whether these effects could be directly attributed to changes in brain NE.

214.10

MODULATION OF THE MASSETERIC REFLEX BY BRAIN NOREPINEPHRINE. B.L. Jacobs and I.L. Stafford, Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ

Two approaches were employed to determined whether NE mediated, at least in part, augmentation of the masseteric reflex produced by environmental conditions known to activate NE neurons (see preceding abstract). In the first, cats were given either the α-adrenergic antagonist prazosin (5 mg/kg i.p.) or the 5-HT antagonist methysergide (0.5 mg/kg i.p.) and then exposed to loud white noise (100 db), a dog, or clicks presented at various intervals prior to elicitation of the reflex. In all cases prazosin blocked the reflex augmentation whereas methysergide was without effect. In the second study, the catecholamine neurotoxin 6-OHDA (4 μg in 1 μl) was employed to produce unilateral NE denervation of the motor component (MoV) of the reflex pathway. One week later, the reflex was elicited bilaterally while the cat was exposed to the aforementioned conditions. The normal augmentation of the reflex produced by these conditions was either blocked or markedly diminished on the denervated side. In both experiments, the suppression produced by the 20 msec click-reflex interval was maintained, indicating that these effects were not non-specific. These data represent the first demonstration that the release of NE, at a specific site and under physiologic conditions, facilitates behavioral output in the intact organism.

214.11

SEROTONERGIC FACILITATION OF THE MASSETERIC REFLEX IN BEHAVING CATS. L.E. Ribeiro-do-Valle, C.W. Metzler*, I.L. Stafford and B.L. Jacobs. Prog. Neurosci., Dept. Psych., Princeton Univ., Princeton, NJ 08544.

Serotonin (5-HT) has been shown to facilitate the activation of spinal and facial motoneurons in anesthetized animals. Preliminary results in our laboratory with awake cats indicate that 5-HT also increases the response of trigeminal motoneurons to their mesencephalic trigeminal nerve (MesV) input. This action of 5-HT was systematically examined in the present work. Cats were prepared as described in the preceding two posters. The amplitude of the electrical response of the masseter muscle (Mas) to stimulation of MesV was recorded before and at various times after injection of 0.125 ug of 5-HT directly into the motor nucleus of the trigeminal nucleus (MoV). We observed a mean increase of 250% in the magnitude of the reflex response, one and five min after 5-HT injection into MoV. The response approached baseline levels in the next 30 to 60 min. Three to six hours after the drug injection, we observed a second increase of 300% in the reflex response. The following day the response was again near baseline levels. The present results indicate that 5-HT has short- and long-latency facilitatory actions upon the trigeminal motoneurons. The short-latency effect may be related to the well known slow depolarization of motoneurons caused by 5-HT, while an intracellular second messenger system may be responsible for the long-latency effect.

214.12

SENSORY-EVOKED PHASIC ACTIVATION OF LOCUS COERULEUS NORADRENERGIC NEURONS IN BEHAVING CATS. E.S. Levine, W.J. Litto, C.A. Fornal, D.A. Morilak, K. Rasmussen and B.L. Jacobs, Prog. Neurosci., Princeton U., Princeton,NJ 08544.

Phasic presentation of noxious and non-noxious sensory stimuli elicits a brief activation of locus coeruleus noradrenergic neurons (LC-NE) in awake animals. In the present study using behaving cats, the tail-flick response to radiant heating of the tail was used to examine LC-NE neuronal responses to a mild, short-lasting noxious stimulus. Heat intensity was adjusted to produce baseline tail-flicks within 3-5 sec. All trials began when the cat was in a quiet waking state based on polygraphic and behavioral criteria. LC-NE neurons consistently showed a phasic activation around the time of the tail-flick. Unit activity was significantly elevated ($\sim$ 300%) during the two sec period centered at the time of the tail-flick compared to a two sec period centered at the time of heat onset. Systemic administration of an analgesic dose of morphine (2.0 mg/kg, i.p.) increased baseline unit activity and tail-flick latency, but did not alter the phasic activation of LC-NE units during the tail-flick. In contrast, a low dose of diazepam (0.125 mg/kg, i.p.) significantly reduced the phasic activation of LC-NE neurons at the time of the tail-flick, but did not significantly alter baseline unit activity or tail-flick latency. We are presently examining LC-NE neuronal responses to noxious and non-noxious stimuli as a function of changes in the level of behavioral arousal.

214.13

EFFECTS OF HYPERGLYCEMIA ON SINGLE UNIT ACTIVITY OF LOCUS COERULEUS NORADRENERGIC (LC-NE) AND DORSAL RAPHE SEROTONERGIC (DRN-5HT) NEURONS IN BEHAVING CATS. W.J. Litto, C.A. Fornal and B.L. Jacobs, Prog. Neurosci., Dept. Psychology, Princeton Univ., Princeton, NJ 08544.

Central noradrenergic and serotonergic neuronal systems have been implicated in the regulation of blood glucose levels through an interaction with feeding, neuroendocrine, and autonomic mechanisms. In this study, the effects of glucose loading on the single unit activity of LC-NE and DRN-5HT neurons were determined in catheterized, behaving cats. Single unit activity was sampled when cats were in a quiet waking state based on polygraphic and behavioral criteria. Single unit activity and blood samples were obtained prior to, and at 5, 15, 30, 45, 60, and 90 min following a bolus injection of dextrose (500 mg/kg, i.v.). Blood glucose levels were increased four-fold over baseline levels (89.4 $\pm$ 6.8 mg/dl; n=8) 5 min after dextrose injection, were significantly elevated for 60 min, and returned to preinjection levels by 90 min. Single unit activity of LC-NE and DRN-5HT neurons was not significantly different from baseline levels at any time following dextrose injection. These data suggest that LC-NE and DRN-5HT neurons are not directly glucose-sensitive, and that changes in their activity are not a component of counterregulatory mechanisms invoked by hyperglycemia.

214.14

SINGLE-UNIT ACTIVITY OF SEROTONERGIC DORSAL RAPHE NEURONS IN RELATION TO THE HYPOTENSIVE ACTION OF 8-HYDROXY-2-(DI-N-PROPYLAMINO)TETRALIN (8-OH-DPAT) IN BEHAVING CATS. C.A. Fornal, W.J. Litto, H. Nagasaki*, L.E. Ribeiro-do-Valle and B.L. Jacobs, Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Central serotonergic neurons are thought to play an important role in blood pressure regulation. Recently, 5-HT_{1A} agonists like 8-OH-DPAT have been shown to decrease mean arterial pressure (MAP), presumably by inhibiting the neuronal activity of serotonergic neurons via a direct action on somatic 5-HT autoreceptors. In this study, the effects of intravenous administration of 8-OH-DPAT (1-100 ug/kg) on MAP and single-unit activity of serotonergic neurons recorded in the dorsal raphe nucleus (DRN) were examined. The lowest dose of 8-OH-DPAT had no effect on MAP, but produced a brief, moderate inhibition of serotonergic DRN unit activity. Larger doses (>5 ug/kg) produced dose-related decreases in MAP within 30 sec that reached a maximum between 2-4 min. The fall in MAP was preceded by a complete suppression of serotonergic DRN unit activity. The maximum decrease in MAP ($\sim$50 mm Hg) was observed following 100 ug/kg, whereas maximum suppression of unit activity was produced by lower doses ($\sim$ 10 ug/kg). The hypotensive action of 8-OH- DPAT was relatively long (>30 min) and usually outlasted the unit suppression. These data support the hypothesis that inhibition of serotonergic neurons may contribute to the hypotensive action of 8-OH-DPAT.

214.15

REPEATED MILD STRESS MAY CAUSE TERMINAL SPROUTING OF LOCUS COERULEUS NEURONS: PHYSIOLOGICAL EVIDENCE. S. Nakamura, T. Sakaguchi* and F. Aoki*. Dept. of Physiology, Fac. of Medicine, Kanazawa Univ., Kanazawa 920, Japan.

Stress has been known to cause a variety of neurochemical changes in the central noradrenergic system. We now report physiological evidence that in repeatedly stressed rats, the number of axon terminals arising in the locus coeruleus (LC), a main nucleus of central noradrenergic neurons, increased in the cerebral cortex. Male Sprague-Dawley rats (8-to-14 weeks of age) were used. For stress treatment, animals restrained in a small cage were bathed up to the neck in warm water (36-37°C) for 10 min daily. The stress groups received stress treatments for either 1 or 2 weeks. The amount of projections of LC neurons to a given brain site was assessed by the physiological measure "projection index" (P-index), which is defined as the percentage of LC neurons activated antidromically from the given brain site. The P-indices for the frontal and occipital cortex and thalamus were determined under urethane anesthesia. The P-indices for each stimulating site did not differ between the control and 1-week stress group, whereas those for the cerebral cortex significantly higher in the 2-week stress than control group. These results suggest that repeated mild stress causes terminal sprouting of LC neurons in the cerebral cortex.

214.16

EFFECTS OF PHENTOLAMINE ON BEHAVIORAL THERMOREGULATION. S. Kent, C. Ricks*, D. Freedman* and E. Satinoff. Dept. of Psychology, Univ. of Illinois, Urbana-Champaign, IL. 61820.

We have shown that phentolamine (PHEN), an α-adrenoceptor antagonist, suppresses REM sleep. This effect was secondary to the drop in body temperature (Tb) which was ambient temperature (Ta) dependent. The present study examines whether the Tb changes reflect an altered thermal setpoint or altered effector capabilities. Five male Long-Evans rats (b.w. 300-500 g) were housed on a 12:12 LD cycle at a Ta of 23±1°C with food and water available ad lib. They had previously been trained to press a bar for warm air in the cold (0-4°C: cold escape) and for cool air in the heat (38-42°C: heat escape). Tb and Ta were monitored by telemetry every 2 minutes and 5 seconds, respectively, for at least 1 hour pre- and 2 hours post-injection (PHEN 10 mg/kg i.p. or an equivalent volume of saline).

Within 15 minutes of a PHEN injection in the cold rats increased the number of cold escapes by over 750%. Ta rose from a range of 2-4°C to 16-18°C within an hour, controls did not increase the Ta. After PHEN Tb dropped 2.5°C within ½ hour and then began to rise. Without access to the bar Tb dropped a mean of 7°C and the animals had to be removed from the cold. There are no differences between treatments in the heat. We conclude that PHEN does not alter thermal setpoint.

EFFECTS OF THE NEUROTOXIN DSP4 ON CATECHOLAMINE LEVELS, ALPHA-TWO ADRENERGIC RECEPTOR BINDING AND STEROID-DEPENDENT REPRODUCTIVE PROCESSES IN THE JAPANESE QUAIL. P. Sante*, G.F. Ball B.S. McEwen, and J. Balthazart. Univ. of Liège, Liège, Belgium and Rockefeller Univ., New York, N.Y. 10021 (SPON: B. Nock).

Several lines of evidence implicate catecholamines (CA) in the regulation of reproductive hormones and behavior. We tested this possibility by administering the noradrenergic neurotoxin DSP4 (50 mg/kg) to castrated and testosterone-treated quail. The efficacy of the neurotoxin was assessed by measuring monoamine levels with high performance liquid chromatography combined with electrochemical detection in selected microdissected brain regions. Significant decreases in norepinephrine (NE) and epinephrine (E) concentrations were detected while dopamine and serotonin were unaffected. Plasma luteinizing hormone (LH) levels were decreased and copulatory activity was increased in DSP4 treated birds confirming a significant role for the noradrenergic system in these processes. The behavioral effect of the drug was only apparent in the T-treated birds and did not affect other androgen dependent behaviors. α-2 Adrenergic receptors as assessed by quantitative autoradiography ([³H]para-aminoclonidine binding) were not affected by the administration of the neurotoxin in any of the areas examined. In that a significant decline of NE and E was observed in most brain regions, this strongly suggest that these α-2 receptors are in general post-synaptic. These receptors are primarily located in steroid sensitive areas which play a major role in the regulation of both copulatory behavior (e.g. preoptic medial nucleus) and LH secretion (e.g. infundibulum). These receptors may mediate many of the effects of NE and E on steroid dependent reproductive processes. Supported by grant # MH41256 to B.M.

NORADRENERGIC AGONISTS AND LHRH STIMULATE MALE REPRODUCTIVE BEHAVIOR IN JAPANESE QUAIL. M.A. Ottinger, L. Cortes-Burgos* and C.S. Rawlings*. Dept. of Poultry Science, University of Maryland, College Park, MD 20742.

Pharmacological agents were given to castrated male Japanese quail to determine if activation of mating behavior would occur with low plasma testosterone. Males were castrated under anesthetic at 2 weeks of age, maintained in controlled environment (photoperiod of 15L:9D), with feed and water available ad libitum. At 8 weeks of age, males had low circulating testosterone and showed no sexual behavior. Phenylephrine and isoproterenol were injected peripherally into 50 castrate males. Both phenylephrine (0.075 mg/kg) and isoproterenol (7.5 mg/kg) stimulated mating behavior in 40% of the males. Testosterone implants were given to stimulate mating behavior in castrates. Propranolol (12.5 mg/kg) administration resulted in a depression of the number of males showing behavior (100% to 10%).

Avian LHRH was administered into the third ventricle (111 ng/1 µl PBS) to castrate males given testosterone implants. The number of mating attempts and completed matings increased significantly at 30 and 60 min., post-injection and then declined by 90 min. These data further support the regulatory role of the noradrenergic system in the expression of reproductive behavior and the modulatory effects of the LHRH system in behavior.

ALPHA-ADRENERGIC FACILITATION OF ROUGH-AND-TUMBLE PLAY IN THE RAT. S.M. Siviy, J. Menendez and D.M. Atrens*. Psychology Dept., Univ. of Sydney, Australia.

Previous research from our laboratory has shown that acute blockade of alpha-1 adrenoceptors with the selective antagonist prazosin reduces rough-and-tumble play in juvenile rats (Soc. Neurosci. Abst., 13:409). The effects of prazosin on play are both pharmacologically and behaviorally specific. Reduced adrenergic activity thus appears to be incompatible with active play in the rat. It follows that increased adrenergic activity should facilitate play. Idazoxan is a specific alpha-2 adrenergic antagonist which results in increased release of forebrain norepinephrine (Brain Res, 426:103-111). Accordingly, the effects of idazoxan on play were assessed. Juvenile rats (29-38 days old) were housed individually and given a daily 5 minute opportunity to play. Rats were injected IP with either the vehicle or one of four doses of idazoxan (1 - 8 mg/kg) 30 minutes prior to a play session. Idazoxan increased pinning, an indicator variable of play in this species, at all doses tested. The largest increase, 56% over vehicle levels, was after 4 mg/kg. Dorsal contacts, an index of play solicitation, were not affected by any of the doses. These data suggest that increased noradrenergic activity at alpha receptors is facilitatory to rough-and-tumble play in the rat. Experiments designed to assess the behavioral specificity of this effect are currently in progress.

EFFECTS OF FOREBRAIN NOREPINEPHRINE DEPLETION ON NEOPHOBIA IN THE RAT. J.D. Steketee and A.C. Swann. Department of Psychiatry and Behavioral Sciences, University of Texas Medical School, Houston, Texas 77030.

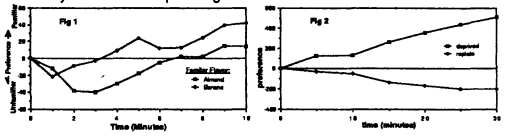
Forebrain NE depletion has been reported to increase (Britton et al. Physiol. Behav. 33:473, 1984) or decrease (Sahakian et al. Neurosci. 10:1405, 1983) neophobia. This may result from differential effects on environmental and food neophobia (Robbins et al. Physiol. Psychol. 13:127, 1986). In order to investigate this possibility we examined environmental and food neophobia in rats after NE depletion by bilateral infusions of 6-OHDA into the dorsal bundle. After a minimum of 2 weeks of post surgical recovery, environmental and/or food neophobia was measured in food deprived rats. Environmental neophobia was measured in a novel open field with familiar food mounted on a centrally placed food pedestal. Food neophobia was measured in a different novel environment with 2 food cups placed in the center, one for familiar rat chow and the other for novel cheddar cheese. Lesioned rats reared less and approached familiar food fewer times than controls showing increased environmental neophobia in lesioned animals. Lesioned animals preferred novel cheese (20/21 chose cheese first, $p<0.0001$) while controls showed no food preference (11/20 chose cheese first). Lesioned animals spent more time eating the novel food ($p<.0001$) while controls spent more time eating the familiar food ($p<.02$). Results of this study support an opposite role for forebrain NE in environmental and food neophobia.

215.1

A ROLE FOR BOTH NEOPHILIA AND POST-INGESTIVE FEEDBACK IN DIET SELECTION BY PROTEIN DEFICIENT RATS. S.C. Heinrichs*, B.O. Moore and J.A. Deutsch*(SPON:R. Boynton) Psychology Dept., UCSD, C-009,CA 92093.

A new method allows second by second monitoring of responses made by protein deficient rats to obtain either a protein diet or a non-protein, carbohydrate alternative. If fed an experimental diet lacking in protein for at least 4 days, animals eat more of at least seven protein alternatives in a 30 minute meal (Moore, See Abstract). Pregnant dams fed inadequate amounts of protein also prefer a new protein alternative. On the other hand, if control or pregnant dams are protein replete, they choose more of the carbohydrate.

These results indicate preference for a novel flavor (neophilia) since 1) each group prefers a novel alternative depending on experimental diet and protein need, 2) the preferred choice occurs within 1 minute's time, insufficient for post-ingestive consequences, and 3) the two choice responses are concurrent, again avoiding a post-ingestive contingency. However, if the novel flavor cue is inert rather than nutritive (e.g. almond extract), an initial neophilia decays rapidly in protein deprived animals and is reversed within minutes (Fig 1). In contrast, protein deprivation produces a consistent preference for protein continuing over 30 minutes (Fig 2). Thus, evidence will be presented for a compound protein selection strategy in which neophilia persists only if beneficial post-ingestive feedback is available.



215.2

DIET-INDUCED ELEVATIONS IN BODY WEIGHT AND FAT DEPOSITION ASSOCIATED WITH CHRONIC REDUCTIONS IN SYSTOLIC BLOOD PRESSURE BUT INCREASED BLOOD PRESSURE RESPONSIVENESS IN SHR RATS. R. J. Contreras. Dept. of Psychology, University of Alabama, Birmingham, AL 35294.

Interest is in the contribution of diet and patterns of consumption in influencing blood pressure and blood pressure responsiveness in Spontaneously Hypertensive Rats (SHR). Male 60-day old SHR rats were maintained on an unrestricted diet of either (1) Agway Prolab Chow pellets; (2) high fat mash and sweetened milk (HF/M); or (3) alternate 2-week periods of HF/M and Agway pellets. Body weight and caloric intake were measured weekly as were systolic blood pressure and heart rate using tail plethysmography under light ether anesthesia. After 16-weeks, mean arterial pressure (MAP) and heart rate (HR) responses to the pressor effects of bolus intravenous infusions of phenlyephrine hydrochloride (50, 100, 200, 400 ng/100 g BW) were obtained from the femoral artery of urethane-anesthetized rats.

The consumption of the HF/M diet resulted in significant elevations in body weight and in terminal brown fat pad, white fat pad, and heart organ weights. In addition, HF/M feeding resulted in significantly faster heart rates; for rats on the alternate feeding regimen, HR was elevated during HF/M feeding and reduced during pellet feeding. However, the indirect blood pressure levels of the two groups fed the HF/M diet tended to be lower than those of the pellet-fed group. Despite these chronic reductions in indirect blood pressure, the rats fed the HF/M diet were significantly more responsive to the pressor effects of intravenous phenylephrine.

215.3

SATURATED FAT DIETS DECREASE CARBOHYDRATE AND INCREASE PROTEIN SELECTION IN RATS. C.D. McGee* and C.E. Greenwood (SPON: N. Scott) Department of Nutritional Sciences, University of Toronto, Toronto, Ontario, Canada M5S 1A8.

Rats consuming 20% (w/w) lard diets select less carbohydrate (CHO) and more protein (PRO) than rats fed 20% (w/w) soybean oil (SBO) diets (Pharm Biochem Beh 27:1). To ensure this effect was not specific to fat source, male Wistar rats were stabilized to 20% (w/w) SBO or beef tallow (TAL) diets containing 24% PRO and 48% CHO for 2 weeks. During self-selection from 2 diets with the fat previously fed but different PRO and CHO composition (5% PRO, 67% CHO and 55% PRO, 17% CHO), TAL fed rats selected more PRO (119±9 vs 62±3 g/14 d, mean±SEM, TAL and SBO respectively) and less CHO (98±12 vs 170±6 g/14 d) than SBO fed rats. A second study was conducted to rule out the possibility that differences were due to taste preference. When rats selected from diets with identical PRO and CHO composition but differing in sources of dietary fat, there was a slight preference for TAL at all PRO levels. When rats selected between diets described in experiment 1 from first exposure, TAL fed rats selected significantly more PRO and less CHO than SBO fed rats during the last 2 weeks but not the first 2 weeks, suggesting physiological adaptation must occur prior to expressing selection differences. These results confirm that rats fed high saturated fat diets select more PRO and less CHO than rats fed high polyunsaturated fatty acids. Further, these data suggest this difference is not due to taste preference. (MRC)

I.V. FAT- AND WATER-SOLUBLE NUTRIENTS AFFECT FOOD INTAKE DIFFERENTLY. E.K. Walls and H.S. Koopmans, (SPON: C. Riphagen) Dept. of Medical Physiology, Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1

Nutrients infused directly into the bloodstream bypass the usual absorptive mechanisms of the gut. To assess the effect of gut signals on daily food intake, two different types of i.v. nutrients were infused during 17.5 hours of feeding. In the first experiment (n = 5), food intake during 6 days of saline infusion was 80.0 ± 2.7 kcal and the rats gained 1.4 ± 0.8 gms/day. Thereafter, a solution of 25% dextrose and 4.25% amino acids (Travasol) was infused i.v. at levels of 27 and 54 kcal/day for two consecutive four day periods during night-time feeding. During the infusion periods, the rats reduced their food intake by 20.7 ± 1.7 and 40.0 ± 2.4 kcal per day, respectively, and gained weight at a rate of 3.5 ± 1.2 gm/day. Thus, oral intake was reduced by an amount that was equivalent to 75% of the total i.v. calories infused ($p<.05$), showing that gut signals play a small but significant role in limiting food intake. In the second study with fat infusion (n = 4), the rats ate 63.5 ± 2.0 kcal during 6 days of saline infusion and their body weight was stable. When infused i.v. with 40 kcal of a fat emulsion (Intralipid), the rats showed a significant ($p<.01$) but smaller reduction, 12.1 ± 1.1 kcal/day, in oral food intake and gained 3.0 ± 0.8 gm/day. Their reduction in food intake was only 30% of the fat calories infused. The results show that gut signals play a major role in the control of daily food intake, particularly for dietary fats.

EFFECT OF PROTEIN AND CARBOHYDRATE BREAKFASTS ON PLASMA TRYPTOPHAN RATIO IN MALES. K.L. Teff and S.N. Young, Dept. of Psychiatry, McGill Univ., Montreal, Canada H3A 1A1.

To enter the brain, TRP must compete with other large neutral amino acids for uptake across the blood-brain barrier. The plasma ratio of TRP to the sum of the competing amino acids (TRP/NAA) has been used as an indicator of tryptophan availability to the brain. Protein and carbohydrate have opposite effects on brain TRP. Protein tends to lower brain TRP while carbohydrate increases it. We have looked at the effect of breakfasts containing varying amounts of protein and carbohydrate on the plasma tryptophan ratio in normal human males. Isocaloric breakfasts were given in the form of a chocolate pudding that contained either 0, 4, 8 or 12% protein with carbohydrate as the remaining macronutrient. An additional treatment consisting of a Danish pastry and coffee was given to determine the effect of a typical breakfast on the TRP/NAA ratio.

We found that only the 0% protein treatment (pure carbohydrate) significantly increased the TRP/NAA. The addition of even 4% protein was sufficient to inhibit the rise in the ratio. As all normal meals contain 4% or more carbohydrate, there are no normal meals which are "carbohydrate meals" as far as the TRP/NAA ratio is concerned. We conclude that behavioral changes observed after intake of meals high in carbohydrate in humans are not mediated by increases in the TRP/NAA ratio.

Threonine (Thr) injection into the prepyriform cortex increases the intake of thr imbalanced diet. J.L.Beverly*, D.W.Gietzen, P.M.B.Leung and Q.R.Rogers. Dept. Physiol. Sci. and Food Intake Lab, Univ. California, Davis, CA 95616.

An intact prepyriform cortex (PPC) is essential for the normal reduction of food intake observed 2 hrs after feeding rats a thr imbalanced diet. More recently the concentration of thr in the PPC of rats fed a thr imbalanced diet (IMB) was found to be significantly reduced by 2.5 hr of feeding IMB. In two trials thr or buffered aCSF (vehicle) were injected bilaterally into the PPC of rats and the effect on intake of a thr basal diet (BASAL) or IMB measured. Bilateral chronic guide cannulae were implanted 3 mm above the PPC of male Sprague-Dawley rats which were then fed BASAL for 10-14 days. Rats were anesthetized with Metofane 30 min. prior to the onset of dark cycle and 2.0 nmoles (Trial 1) or 2.2 nmoles (Trial 2) thr or vehicle injected (1 ul/5 min) into the PPC. Although the reduction in 24 hr intake of IMB was not completely attenuated intakes of IMB by rats receiving thr were greater than by rats receiving vehicle. 24 hr intakes of IMB by rats receiving thr were 151% of vehicle rats in Trial 1 ($p<.01$) and 138% of vehicle rats in Trial 2 ($p<.05$). The differences in intake were not apparent in either trial until at least 2 hr of feeding. These results indicate that increasing thr content in the PPC partially alleviates the reduction in intake of a thr imbalanced diet. Supported by NIH Grants AM-07355, DK-13252 and USDA Grant CRCR-1-2418.

EFFECT OF DIETARY PROTEIN ON POST-MEAL GLUCOSE, INSULIN AND TRYPTOPHAN AVAILABILITY IN RATS. L. Thibault, G. Bergeron* and A.G. Roberge. Sch. of Dietetics and Human Nutrition, McGill Univ., Montreal; Lab. Neurochemistry & Nutrition, Laval Univ., Quebec, Canada.

An inverse relationship between the dietary protein/carbohydrate ratio and the fasting serum tryptophan level and a direct relationship between the former and the fasting brain tryptophan level and 5-HT turnover in limbic structures was previously observed in rats fed single casein diets (Thibault & Roberge,J.Amer.Coll.Nutr.In Press,1988).Selection of nutrients from a dietary choice is a fundamental characteristic of behavior in animals and in man.Adult male Sprague-Dawley rats were allowed to choose for a 8 h daily period and for 16 consecutive days between pairs of diets containing either 0 and 60% casein or 0 and 60% soya. On day-16, diets were removed after the 8 h feeding period and arterial and veinous blood samples were collected under anesthesia at intervals of 30, 60 and 90 min after the end of eating.The total food intakes were similar in casein and soya fed rats whereas a significantly higher food intake of the 60% soya diet was observed when data were compared to the 60% casein diet.The post-meal arterioveinous glucose,insulin and tryptophan differences were assessed and the results obtained suggested: 1)a higher glucose utilization in casein fed rats than in soya fed rats within 30 min after eating, and 2)▲-insulin values at 30 and 60 min post-meal and arterial and veinous tryptophan levels at all the post-meal intervals significantly higher in soya fed rats than in casein fed rats. These results suggested that the protein/carbohydrate selection is regulated differently according to the type of dietary protein and that the preference for selecting protein with soya is possibly mediated by an increased tryptophan availability related to a high insulin secretion but paralleled by a glucose utilization that is similar to the one observed with casein. Supported by NSERC of Canada.

NUTRIENT COMPOSITION: EFFECTS ON TEMPORAL PATTERNS OF FEEDING. G. Brennan*, G. Shor-Posner, C. Ian*, R. Jasaitis*, P. Eyih*, K. Madhu*, & S. F. Leibowitz. (SPON: J. Brudny) The Rockefeller University, New York, NY 10021

Evidence suggests that some foods may be more effective than others in their capacity to promote satiety. To examine this further, we have utilized computerized techniques to investigate the influence of pure nutrients (fat, protein, and carbohydrate) upon nocturnal patterns of feeding in 30 adult male Sprague-Dawley rats.

Microstructural analyses have revealed that the nutrient content of a meal produces different effects upon some, but not all, standard meal parameters. The latency to initiate eating, rate, and feeding duration were similar for all meal compositions. However, a first meal of the dark period composed primarily of protein resulted in a reliably ($p<.05$) longer intermeal interval (83 min) than was associated with a carbohydrate (40 min) or fat (41 min) meal. This effect was unrelated to the size of the meal, as the protein-rich meal (11 Kcal) was similar in size to the carbohydrate-rich meal (10 Kcal) and significantly smaller than a fat-predominant meal (18 Kcal, $p<.05$). Thus, protein appears to be more effective than carbohydrate and fat in producing satiety in rats.

215.9

EFFECT OF CONTROL (C), HIGH FAT (HF) AND HIGH SUCROSE (HS) DIETS ON WEIGHT GAIN IN LIGHT AND HEAVY RATS. J.H. Carlton and J.L. Howard. Wellcome Res Labs, Res Tri Park, NC 27709.

Study of food intake and body weight is complicated by the fact that rats of similar age, sex and strain display a wide range of body weight, a range that increases across the life span. Regarded as inconvenient variability, little has been done to characterize this phenomenon.

Three weight-matched sets of 10-wk old, female, Sprague Dawley rats were fed ad lib one of the following diets: C - Wayne Lab Ration (WLR); HF - ground WLR, vegetable oil, cream and cheese; or HS - ground WLR, sweetened non-fat milk and cookies. After 12 wks, rats had maintained their initial rank order of body weight within groups, HF and HS were equal in mean weight gain and both had gained 40% more than C. Based on final body weights, the lighter (L) and heavier (H) rats in each dietary group were selected for comparison. For all groups, L rats had weighed initially more than 90% of what H rats weighed. After 6 wks on C, L rats gained only 38% of what H rats did; on HF and HS, L rats gained 60% of what H rats did. These weight difference ratios were maintained at 12 wks. During wk 12, HS mean caloric intake was 68% above C, HF 107% above C. In C, H rats consumed significantly more calories than did L rats. In HF and HS, H rats maintained elevated weights without consuming more calories than did L rats. Data on metabolism will be presented. In summary, body weight varies widely in ad lib C-fed rats. HF or HS diets increase body weight and reduce divergence between L and H rats.

215.10

GLUCOSE AND FRUCTOSE SUPPRESS THE EXCITATORY EFFECT OF CONDITIONED CUES ON MEAL INITIATION. M. Bedard and H.P. Weingarten. Dept. of Psychology, McMaster University, Hamilton, Ontario, L8S 4K1 Canada.

Since feeding behavior is under multifactorial control, the appropriate analysis of meal initiation requires examination of the interaction of factors involved in this behavior. External stimuli (CS+'s) conditioned to food reliably elicit large meals (Weingarten, 1983). We examined the ability of various factors to block conditioned meal initiation. This strategy analyzes the interaction between excitatory and inhibitory influences on meal initiation and provides insight into mechanisms involved in suppressing eating during the intermeal interval. Caloric preloads, administered intragastrically 15 min before onset of the CS+, suppressed meal initiation in a dose-dependent manner. Further data helped specify the mechanism by which nutrient in the gut suppressed meal initiation. Specifically, both glucose and fructose injected ip suppressed meal initiation and reduced meal size by as much as 59%. Although the exact nature of the inhibitory signal gating the excitatory influence on meal initiation is unclear, our results are congenial with the speculation of others that this event is postabsorptive and that the liver plays a key part in this process.

215.11

EFFECT OF LOCUS CAERULEUS (LC) LESIONS ON FOOD INTAKE RESPONSES AND DIETARY CHOICE OF RATS FED DIETS CONTAINING PROTEIN IN EXCESS. P.M.B. Leung, D.W. Gietzen and Q.R. Rogers. Department of Physiological Sciences, University of California, School of Veterinary Medicine, Davis, CA 95616.

Bilateral electrolytic lesions were placed in LC of adult Sprague Dawley rats (7.4 to 7.8 mm posterior to bregma, ±0.7 mm from sagittal suture and 6.0 mm from dura). Rats with LC lesions were fed the 6% casein diet (LP) pre- and post operatively and showed mild transient hyperphagia during recovery. Following equilibration with LP, animal with lesions and intact controls (INT) were fed a 75% casein diet (HP) for 19 days before reequilibration with LP. Then rats with lesions and INT were offered, in sequence, choices between LP and HP (28 days), LP and 36% casein diet (MP) (21 days) or LP and 15% casein diet (NP) (13 days). Rats with LC lesions and INT showed similar marked initial food intake (FI) depression (39.1±2.8% and 39.6±5.7% of their respective baseline intake of 23.4±0.7g and 22.9±0.6g) and slow adaptation when fed HP. During LP and HP choice, PE% (protein calories as % of total caloric intake) selected were 11.6%, 16.2% and 16.6% for rats with lesions and 10.7%, 20.6% and 12.3% for INT on the 1st, 15th and 28th day respectively. For LP and MP choice, PE% selected on 1st, 14th and 21st day were respectively 24.0%, 18.6% and 22.0% for lesioned rats and 23.1%, 18.5% and 24.5% for INT. During LP and NP choice, PE% selected were 12.6%, 12.8% and 11.7% for lesioned rats and 12.1%, 13.3% and 11.0% for INT on the 1st, 7th and 13th day respectively. Results indicate that LC does not appear to be involved in the control of FI of rats fed diets containing protein in excess. (Supported by NIH grant DK13252).

215.12

GUSTATORY NEURAL RESPONSES TO POLYSACCHARIDE AND STARCH IN THE RAT B.K. Giza*, R.F. Antonucci*, A. Sclafani and T.R. Scott (SPON: K. Campbell). Dept. Psychol. and Inst. Neurosci., Univ. Delaware, Newark, DE 19716

Polycose and amylopectin are highly palatable to the rat. The tastes however, do not generalize well to that of sucrose or of the other prototypical stimuli--NaCl, HCl and quinine--in behavioral tests. We used these chemicals in addition to a standard array of taste stimuli during recordings from 63 single neurons in the NTS of anesthetized rats to determine their neural effectiveness and relative taste qualities. Amylopectin (2%) elicited only a few spikes, always at stimulus onset; Polycose, at 0.1 M, evoked a burst of activity followed by a moderate tonic response. The time courses of both responses were similar to the phasic-tonic sequence of non-sweet stimuli. The profile of activity evoked by Polycose across neurons was most similar to those elicited by Na-Li salts and by quinine; it showed moderate similarity to the patterns representing HCl and MSG, and modest correlations with the patterns for sugars. The results of behavioral studies have led to the suggestion that Polycose represents a unique taste quality. Our electrophysiological data align Polycose with all non-sweet chemicals and, to a lesser extent, with sugars as well, implying a complex quality. The basis for its highly appetitive nature is not apparent from the neural response Polycose evokes.

Supported by research grant DK30964 from the NIH.

215.13

CAPSAICIN-SENSITIVE NEURONS MEDIATE FEEDING INDUCED BY DECREASED FATTY ACID UTILIZATION BUT NOT BY GLUCOPRIVATION. S. Ritter, J. Taylor* and S. Stone*, Dept. of VCAPP, Washington State Univ., Pullman, WA 99164

Surgical lesions and capsaicin, a toxin that destroys small unmyelinated sensory neurons, were used to evaluate the participation of visceral sensory neurons in glucoprivic and lipoprivic feeding. Rats were maintained on a fat supplemented diet and feeding was measured after systemic blockade of fatty acid or glucose utilization with mercaptoacetate (MA) or 2-deoxy-D-glucose (2DG), respectively. Capsaicin abolished MA feeding, but not 2DG feeding. Area postrema/nucleus of the solitary tract (AP/NTS) lesions abolished both MA- and 2DG-induced feeding. Hepatic vagotomy did not impair responses to either challenge. Low suprathreshold doses of 2DG and MA given simultaneously were additive in their effects on feeding in controls and hepatic vagotomized rats. Capsaicin-treated rats ate the same amount after 2DG plus MA as after 2DG alone. AP/NTS lesioned rats did not eat in the combined drug test. Thus, glucoprivic and lipoprivic feeding are mediated by chemically and anatomically distinct receptors. Glucoprivic feeding requires neurons in the AP/NTS region, but is not vagally-mediated. Lipoprivic feeding requires sensory neurons that project to the AP/NTS, but not those in the hepatic vagal branch. Additivity of MA and 2DG in stimulating feeding requires participation of both receptor populations.

215.14

INCREASE IN BODY WEIGHT AND SWIMMING DEFICIT FOLLOWING INTRAPERITONEAL CAPSAICIN IN NEONATAL RATS. I.A. Coronado-Zarco* and I. Zarco de Coronado. Physiol. Dept. Med. Sch. Natl. Univ. of Mexico. P.O. Box 70250. 04510 México, D.F.

Capsaicin was administered in order to elucidate the participation of unmyelinated sensory somatic or visceral neurons on the regulation of food intake as revelead by the control of body weight or the motor swimming hability during the postnatal development.

On the 5th. postnatal day rats received capsaicin or vehicle intraperitoneal injection. From day 7 to 22 experimental animals showed increase in gnawing activity and body weight. The swimming behavior observed maintained inmature characteristics for longer time than control animals. Hypophysis was found bigger in the trated rats. These findings suggest that capsaicin damages afferent pathways, alter food intake and swimming activity by acting at a neuroendocrine level.

215.15

THE EFFECT OF CHRONIC DEXAMETHASONE-21-ACETATE TREATMENT ON MEAL SIZE, MEAL FREQUENCY AND MACRONUTRIENT SELF-SELECTION IN RATS. P.S. Grigson*, D.F. Johnson*, K. Ackroff*, G.H. Collier* and C.F. Flaherty. Psychology Department, Rutgers University, New Brunswick, NJ 08903.

Chronic treatment with dexamethasone (a synthetic glucocorticoid) leads to suppressed levels of circulating corticosteroids, elevated blood glucose and a dramatic loss in bodyweight (Bryson, unpublished dissertation, U. of Cal. 1981). We examined the effects of chronic dexamethasone-21-acetate (dex) treatment on bodyweight, food intake and macronutrient selection in two experiments. Experiment 1, which examined the effects of dex (.5 mg/kg, ip) on 24 hour intake in two animals, replicated the decrease in bodyweight and suggested it was at least in part due to a decrease in food intake --owing to both a decrease in meal frequency and meal size. Experiment 2, which examined macronutrient self-selection, indicated that chronic dex treatment (.5 and 1.0 mg/kg, ip) led to a decrease in total kcals which was due entirely to a decrease in the consumption of fat, with no change in carbohydrate consumption and an elevation in protein intake.

215.16

SHIFTS IN RATS' PREFERENCES FOR SUGAR AND POLYSACCHARIDE SOLUTIONS. K. Ackroff* and A. Sclafani (SPON: I. Abramov). Dept. of Psychology, Brooklyn College and Graduate School, CUNY, Brooklyn, NY 11210.

In 2-bottle preference tests (24 hr/day), rats initially prefer a 32% sucrose solution to an isocaloric 32% hydrolyzed starch (Polycose) solution. However, over days, the animals reverse their preference and drink more Polycose than sucrose (Sclafani et al., 1987). We conducted several experiments to determine the role of taste and postingestive factors in this preference shift. Adult female rats were given ad lib access to chow and two carbohydrate solutions. At 4% and 8% concentrations sucrose was persistently preferred to Polycose, but at 32% a shift to Polycose was observed. Rats also persistently preferred saccharin-sweetened Polycose to plain Polycose. These data suggest that taste factors alone do not account for the preference shift effect. When given iso-osmotic solutions of 32% sucrose and 16% Polycose + 16% glucose rats rapidly switched their preference from sucrose to the mixed solution. Rats also show a preference shift in 32% glucose vs. 32% Polycose tests. These data indicate that neither the osmotic effects nor the unique metabolic effects of sucrose are responsible for the preference shift. In the above studies, the Polycose preference was lost after an 8-day break but reappeared with additional testing. This negates a simple learning explanation of the preference reversal effect. The shift phenomenon appears to represent a complex interaction of the taste and postingestive actions of carbohydrates.

215.17

POLYSACCHARIDE AND SUGAR TASTE PREFERENCES IN MONKEYS. A. Sclafani and G. Sunderland*. Dept. of Psychology, Brooklyn College and Dept. of Psychiatry, SUNY-Health Science Center, Brooklyn, NY 11210.

Rats are very attracted to the taste of starch-derived polysaccharides (e.g., Polycose), whereas humans are not attracted to Polycose. The present experiment compared the taste preferences of nonhuman primates to Polycose, sucrose, and maltose. Maltose was of interest because to rats maltose appears to have a Polycose-like rather than sucrose-like taste.

Adult male squirrel monkeys (n=9) and bonnet macaques (n=6) were given 24 hr/day saccharide vs. water preference tests. The saccharides included Polycose, sucrose and maltose (.01, .05, .10 and .20 or .50 M). Chow was ad lib.

Squirrel monkeys displayed stronger preferences for sucrose (61.6% to 78.2% of total intake) than for Polycose (49.8% to 69.3%) or maltose (53.9% to 61.4%). The bonnet macaques, on the other hand, displayed equivalent preferences for Polycose (63.9% to 91.8%), maltose (75.1% to 95.6%) and sucrose (64.5% to 100%). In addition, the bonnet macaques showed greater preferences for Polycose and maltose than did the squirrel monkeys. Sucrose preferences did not reliably differ between species. These different taste preference profiles are consistent with the natural diets of squirrel monkeys (frugivores) and bonnet macaques (omnivores). The results suggest, but do not establish, that bonnet macaques, like rats, have taste receptors for polysaccharides whereas squirrel monkeys, like humans, lack such receptors.

GLUCOCORTICOIDS POTENTIATE THE DIPSOGENIC ACTION OF ANGIOTENSIN II. R. Ganesan* and C. Sumners [Spon: W.W. Dawson] Dept. of Physiology, Univ. of Fla., Coll. of Medicine, Gainesville, FL 32610.

Previous studies from this laboratory have indicated that long-term peripheral infusions of the mineralocorticoid, deoxycorticosterone acetate, enhanced the drinking response to peripherally- and centrally-administered angiotensin II (AII). We have now found that the synthetic glucocorticoid, dexamethasone, can similarly potentiate A II-induced drinking in rats. In addition, we obtained this effect using a single injection of the steroid. Initial studies indicated that a 750 μg/kg intraperitoneal dose of dexamethasone caused a reduction in body weight and inhibited feeding for up to 48h after the injection. An enhancement of AII-induced drinking was observed when the glucocorticoid was given 3h or 6h prior to the dipsogen (200 μg/kg, sc). However, when subjects were tested 24h after the administration of the steroid, the amount of water consumed was no different from controls. Subsequently we confirmed that a subcutaneous injection of the steroid was equally effective, and that the magnitude of its action on AII drinking was dose-dependent (100 μg-1600 μg/kg). Dexamethasone also potentiated drinking to intracerebroventricular (icv) AII (2.5 ng), but it had no effect on icv carbachol-induced drinking. This result renders less likely the possibility that dexamethasone has a general stimulatory effect on all drinking. A notable point is that dexamethasone not only increased drinking to AII but also lengthened its duration up to 2h after the icv injection. Recent work has uncovered interactions between several different aspects of the angiotensin system and glucocorticoids, but further examination is required to pinpoint the exact locus of interaction in this instance. (Supported by NIH grant HL-36645).

RELATIVE CONTRIBUTIONS OF HIGH AND LOW AFFINITY CORTICOSTEROID RECEPTORS TO LONG TERM REGULATION OF FEEDING, METABOLIC EFFICIENCY, AND ADIPOSITY. L. Devenport, T. Thomas, A. Sundstrom*, and A. Knehans*. Department of Psychology, University of Oklahoma, Norman, OK 73019.

Relatively pure or mixed Type 1 or 2 corticosteroid receptor agonists exhibited variations in their effectiveness across time and regional tissues. Young adrenalectomized male rats were infused for 4 weeks with doses of dexamethasone (DEX, Type 2 agonist), aldosterone (ALDO, Type 1), DEX+ALDO, or corticosterone (B, dose-dependent mixed agonist). ALDO's anabolic and appetite-stimulating effects were undiminished across the 28 d. In contrast, DEX's strong catabolic action subsided during the first 14 d. Declines either ceased (high dose) or weight began increasing (other doses) during the last two weeks. Carcass analysis indicated that the abatement of Type 2 effects were unevenly distributed. Infusion of B at lower doses mirrored the ALDO results. Higher doses at first produced a net catabolic (Type 2) effect but as it waned, Type 1 effects were unmasked. Body composition analysis revealed that high dose B rats were locally obesified, and in other regions, wasted. The particular distribution was a joint product of the uneven remission of Type 2 effects, and the unremitting Type 1 activity. This Cushing's pattern was mimicked by combined DEX+ALDO infusion. The results closely match the reported patterns of receptor autoregulation and pituitary modulation of ligand capacity, and are probably best understood in those terms.

215.20

ROLE OF THE SYMPATHETIC NERVES IN THE ACTION OF ESTRADIOL ON WHITE ADIPOSE TISSUE. S. Lazzarini* and G. Wade. (SPON: A. Barto). Neuroscience and Behavior Program and Psychology Department, Univ. of Massachusetts, Amherst, MA 01003.

Estrogens have both central and peripheral effects on body weight in rats. Ovariectomy (OVX) induces weight gain, primarily by increasing fat stores, an effect which can be reversed by estradiol replacement. Sympathetic activity also regulates the mobilization of free fatty acids in vivo. Furthermore, estrogens potentiate catecholamine-induced lipolysis in vitro. The present experiments were designed to determine whether sympathetic nerves mediate estrogen-induced lipolysis by influencing adipose tissue cytosol estrogen receptor (CER) concentration. Rats were OVX and 3 weeks later, the retroperitoneal fat pads (RTRO) were unilaterally denervated. After 14 days of EB treatment (2 ug/day), the denervated pad lost 23% less weight than the innervated pad. There was no effect of denervation in the oil treated animals. Measurement of fat pad CER concentration in the oil treated groups revealed no differences between intact and denervated fat pads. These data suggest that the sympathetic nerves play a role in estrogen-induced reductions in fat pad weight but not via changes in adipose tissue CER.

KNEFIRFamide, A NOVEL FMRFamide-LIKE NEUROPEPTIDE FROM THE NEMATODE ASCARIS SUUM. C. Cowden* and A.O.W. Stretton. Dept. of Zoology, Univ. of Wisconsin, Madison, WI 53706.

Several FMRFamide-like peptides have been extracted from Ascaris heads where they are found in neurons but not in muscle or hypodermis (Cowden et al., 1987 Amer. Zool. 27:127A). The first of these to be purified and sequenced is the heptapeptide KNEFIRFamide. An acid methanol extract from 10,000 Ascaris heads was fractionated on C18 cartridges with acetonitrile (ACN)-TFA. The first and second steps of HPLC used a C18 column eluted with gradients of butanol-TFA and ACN-TFA. The next step was HPLC gel filtration in ACN-TFA and the final step was an isocratic elution from a C18 column with ACN-HFBA. Fractions were monitored with an RIA. A liquid phase sequenator was used to determine the amino acid sequence (U.W. Biotechnology Center). This Ascaris peptide is different from all known FMRFamide-like peptides. Synthetic peptide co-elutes with Ascaris peptide. Its physiological role in the Ascaris motornervous system is now being studied (Davis et al., this meeting).
Supported by NIH postdoctoral award #5 F32 NS07954-02 and NIH grant #AI 20355.

216.2

ELECTROPHYSIOLOGICAL EFFECTS OF KNEFIRFamide, A PEPTIDE FROM THE NEMATODE ASCARIS SUUM. R.E. Davis*, C. Cowden*, and A.O.W. Stretton. (SPON: H.M. Sobkowicz). Dept. of Zoology, University of Wisconsin - Madison, Madison, WI 53706.

The heptapeptide, KNEFIRFamide, has been isolated from Ascaris (Cowden and Stretton, this meeting). The physiological effects of synthetic KNEFIRFamide on the Ascaris motornervous sytem were investigated using intracellular recording techniques. The peptide had a dramatic effect on the electrical properties of ventral inhibitory motorneurons: slow potentials, whether spontaneous or induced by depolarization, were rapidly and reversibly blocked by nanomolar concentrations. Neuromuscular transmission was not effected. No effects on the electrical properties of dorsal excitatory motorneurons (which do not exhibit slow potentials) or their synapses were observed.
Supported by NIH grant #AI 15429.

216.3

EFFECTS OF FMRFamide ON INTACT AND ISOLATED LONGITUDINAL MUSCLE CELLS OF THE MEDICINAL LEECH. B.J. Norris and R.L. Calabrese. Dept. of Biology. Emory Univ. Atlanta, GA 30322

The neuropeptide Phe-Met-Arg-Phe-NH_2 (FMRFamide), when bath-applied onto longitudinal muscle of the medicinal leech, causes a tonic contraction and occasionally triggers a weak myogenic rhythm (Norris and Calabrese, J Comp Neurol, 266:95, 1985). In intact muscle cells, under current clamp, FMRFamide causes a depolarization which is initially accompanied by a conductance increase. This increase is followed within seconds by a conductance decrease, that has little effect on membrane potential. Depolarization persists as long as FMRFamide is present, even after the conductance decrease has appeared, but terminates quickly when FMRFamide is removed. The conductance decrease, however, can last for many minutes after FMRFamide is removed. Using isolated cells, we will attempt to identify the ions involved in both conductance changes. This work is supported by NIH grant no. NS24072-04 to RLC.

216.4

STRUCTURE-ACTIVITY RELATIONS OF FMRFamide-RELATED PEPTIDES (FaRPs) ON CRUSTACEAN HEART. K.G. Krajniak* and M.J. Greenberg. The Whitney Laboratory, Univ. of Florida, St. Augustine, FL 32086.

The FaRPs were first discovered in molluscs, but members of this peptide family have now been identified and sequenced in crustaceans and insects. The crustacean FaRPs are cardioexcitatory, and we have therefore compared their activities with those of the molluscan peptides, and with related analogs, on isolated, perfused hearts of the blue crab, Callinectes sapidus. All peptides studied caused dose-dependent increases in rate, amplitude, or both. Two known crustacean peptides, TNRNFLRFa and SDRNFLRFa [a = amide], had the lowest thresholds: 10^{-9}-10^{-8} M. Three of the heptapeptide FaRPs (SDPFLRFa, NDPFLRFa, pQDPFLRFa) characteristic of the pulmonate molluscs are also N-terminally extended analogs of FLRFa, but they are (like FLRFa and its tetrapeptide analogs, FMRFa and FIRFa) 1000-fold less potent than the crustacean peptides: threshold was 10^{-6} to 10^{-5} M. RNFLRFa and pQNFIRFa are shorter than the crustacean FaRPs, but they have the Asn residue in the same position and are only about ten-fold less active; threshold was 10^{-8}-10^{-7} M. The insect FaRP, leucomyosuppressin (pQDVDHVFLRFa) had a very high threshold (10^{-5} M) on the crab heart. Neither YGGFLRF nor FLRF were active (up to 10^{-4} M), although their amidated analogs were. Therefore, FaRP receptors of crustacean hearts seem to require an amidated peptide with the minimum sequence: NFXRF-NH_2 (X is L, M, or I).

216.5

TOWARD THE GENETIC BASIS OF THE FMRFamide-RELATED PEPTIDES (FaRPs) IN MOLLUSCS. T.R. Nuttall*, D.A. Price and M.J. Greenberg. The Whitney Laboratory, Univ. of Florida, St. Augustine, FL 32086.

A survey of molluscan FaRPs has revealed that the phyletic distribution of the peptides is not uniform; in particular, a set of heptapeptide analogs of FLRFamide is restricted to the Pulmonata. The gene encoding FMRFamide in the opisthobranch Aplysia californica includes no heptapeptide sequences, but the 5' region of the gene does code for 1 copy of FLRFamide and 1 of a long peptide with the C-terminal sequence -GYLRFamide. Duplication and subsequent mutation of this region could have given rise to a heptapeptide gene. The distribution of FMRFamide-like genes in molluscs was examined by Southern blotting; a fragment of a FMRFamide cDNA from Aplysia was the probe. Under low stringency conditions (i.e., 50-56°C, 1xSSC, 0.1%-0.5%SDS), hybridization signals were detected by autoradiography in all gastropod subclasses and in bivalves. A well-defined hybridization signal was detected in both the Eco RI and Pst I digests of DNA from Veronicella floridana, a systellommatophoran pulmonate; DNA fragments of approximately 4 Kb (Eco RI digest) and 2.5 Kb (Pst I digest) occurred at low stringency (56°C, 1xSSC, 0.5% SDS). A restricted DNA library is being made. Since the Systellommatophora diverged from the main pulmonate line close to the time of the opisthobranch/pulmonate split and heptapeptide FaRPs have been detected in Veronicella, examination of this species should provide clues to the evolution of the FaRPs.

216.6

PROCTOLIN IN THE CNS OF LYMANTRIA DISPAR AND OTHER LEPIDOPTERA. N.T. Davis* and H. Keshishian (Spon: W. Chapple). Dept. Physiol. Neurobiol., Univ. Ct, Storrs, CT 06268.

The neuropeptide proctolin has important functions in many arthropods, but it is reported to be absent in Lepidoptera. Its occurrence in these insects was reinvestigated and a proctolin-like substance was recovered from ganglia of Lymantria dispar. The substance has the same chromatographic retention time as proctolin, enzymatic degradation indicates that it is a peptide, it is bound by proctolin antisera, and, thus it is indistinguishable from authentic proctolin.

A small number of proctolin-like immunoreactive (PLI) neurons was stained in the larval CNS of L. dispar, Manduca sexta, Trichoplusia ni, Galleria mellonella, and Vanessa cardu, and included a median cluster of A-neurons of the brain, paired neurons of the frontal ganglion, an anteriomedial and ventromedial cluster of neurons in the subesophageal ganglion, paired lateral neurons in the thoracic ganglia, and dorsomedial neurons in the abdominal ganglia. Also varicose PLI axons were found in the corpora cardiaca, perivisceral organs, and transverse nerves. In L. dispar, PLI neurons were found in the corpora cardiaca and on the transverse nerves. The A-neurons are a subset of median neurosecretory cells of the pars intercerebralis, and these and PLI neurons of the subesophageal ganglion project into the retrocerebral complex. PLI neurons of the transverse nerves and the thoracic neurons project into the perivisceral organs.

STATE-DEPENDENT MODULATION OF THE CRAB PYLORIC RHYTHM BY MODULATORY PROCTOLIN-CONTAINING NEURONS. M.P. Nusbaum and E. Marder. Dept. Biol. Brandeis Univ., Waltham, MA 02254.

Stimulation of the two modulatory proctolin-containing neurons (MPNs) initiates or enhances the pyloric rhythm of the crab stomatogastric ganglion. Simultaneous recordings of both MPNs indicate that the two MPNs have similar effects and appear electrically coupled. The MPNs have state-dependent excitatory effects on the pyloric cycle frequency. In rhythmic preparations, MPN stimulation causes larger increases in the cycle frequency of slow rhythms than of fast ones because MPN stimulation causes maximal pyloric cycle frequencies of approximately 1 Hz. This ceiling effect occurs at the same cycle frequency as the maximal effect attained by bath-applied proctolin on the lobster pyloric rhythm (Hooper & Marder, J. Neurosci. 7:2097-2112). MPN continues to enhance the impulse activity of its pyloric network targets, however, even when it causes little or no increase in cycle frequency. MPN causes both small amplitude (<1 mV) postsynaptic potentials and long lasting depolarizations in the LP and IC neurons. We are studying these two MPN effects to determine: 1) whether they are both caused by proctolin or whether the MPN's also release a second neuroactive substance, and 2) how each contributes to MPNs state-dependent effects on the activity of the intact pyloric network. Supported by NRSA NS-07446 (MPN) and NS-17813.

216.8

PROCTOLINERGIC MODULATION OF NEUROMUSCULAR TRANSMISSION AT AN OVIPOSITOR MUSCLE OF *LOCUSTA MIGRATORIA*. J.H. Belanger and I. Orchard. Dept. of Zoology, Univ. of Toronto, Toronto, ON, Canada M5S 1A1.

The only behaviour for which the muscles of the locust ovipositor are used appears to be egg-laying. These muscles have associated with them 0.68 to 1.97 pmol proctolin/muscle (Belanger and Orchard, *Neurosci. Abs.* 13:235, 1987). The opener muscles of the ovipositor of laying females appear to be modulated by proctolin.

At low proctolin concentrations (10^{-10} M), neurally-evoked contractions of the muscle are enhanced three- to fourfold above controls. There is no significant change in the resting potential of the fibres or the input resistance of the fibre membrane, nor is there a significant change in tonus.

At higher doses (10^{-8} M), a slow (0.3 - 0.5 Hz) myogenic rhythm appears, superimposed upon a large increase in tonus. These are accompanied by a large (30 mV) depolarization, and an enhancement of neurally-evoked contractions by up to 300X.

We are currently investigating the physiological relevance of this modulation, as well as the possibility that the ovipositor muscles of non-laying females are not (as) sensitive to proctolin.

ACTIVATION OF CRAYFISH SWIMMERET RHYTHM IS ASSOCIATED WITH RELEASE OF A PROCTOLIN-LIKE SUBSTANCE. L.D. Acevedo, M.E. Adams,+ W.M. Hall+ and B. Mulloney. Zoology Dept., University of California, Davis, CA 95616 and +Entomology Dept., University of California, Riverside, CA 92521-0137.

Excitatory command neurons activate the swimmeret rhythm in the crayfish, *Pacifastacus leniusculus* (Wiersma and Ikeda, 1964). The neuropeptide proctolin mimics stimulation of these neurons (Mulloney et al., 1987). To determine whether proctolin is the transmitter used by these command neurons, we measured proctolin-like bioactivity (PLB) in the abdominal ganglia, looked for proctolin-like immunoreactivity (PLI) in appropriate areas of each ganglion, and quantified release of PLB following command neuron stimulation.

We used a locust leg bioassay (O'Shea and Adams, 1981) to determine if PLB exists in the abdominal ganglia. All ganglia contained PLB, with an average of 10 pmol per ganglion. Depolarization of the abdominal ganglia with high-potassium saline released about 1% of the total PLB.

Immunohistochemical staining of the abdominal nervous system revealed PLI in the Lateral Neuropil, which contains most of the swimmeret circuitry. Several pairs of axons in the interganglionic connectives showed PLI; some of these axons sent branches into each Lateral Neuropil.

Stimulation of axon bundles containing excitatory command neurons resulted in release of PLB. In some cases, release of PLB was associated with command activation of the swimmeret rhythm. The released PLB was 4% of that releasable by high-potassium depolarization.

Supported by NSF grant BNS 84-06931 and NIH grant NS 21194 to B. Mulloney.

216.10

ISOLATION AND CHARACTERIZATION OF A PIGMENT DISPERSING HORMONE FROM THE SHRIMP, PENAEUS AZTECUS. J. M. Phillips*, K. R. Rao, J. P. Riehm*, W. T. Morgan.*† Dept. of Biology, Univ. of West Florida, Pensacola, FL 32514. †Dept. of Biochemistry and Molecular Biology, Louisiana State Univ., Med. Center, New Orleans, LA 70112.

Utilizing the methods employed for isolation of pigment dispersing hormone (PDH) from Uca (Rao et al., 1985), we have purified and characterized an analog of β-PDH from lyophilized eyestalks of Penaeus. After initial extraction and liquid partition, the PDH was purified by gel filtration, cation-exchange chromatography, partition chromatography, and reversed-phase HPLC. Automated gas-phase sequencing and identification of C-terminal amide established the sequence as NSELINSLLGIPKVMNDAamide, and we confirmed this sequence by chemical synthesis.

Penaeus PDH differs from β-PDH (NSELINSILGLPKVMNDAamide; Uca/Cancer PDH) at positions 8 and 11. When tested for melanophore pigment dispersion, these peptides were nearly equipotent. In the crabs Uca and Cancer, β-PDH is the major form of pigment dispersing hormone. Similarly, the β-PDH analog characterized here is the major form present in the brown shrimp Penaeus; in contrast, α-PDH is the major form of PDH in the eyestalks of the prawn, Pandalus (Fernlund, 1971, 1976).

Supported by NSF Grant DCB-8711403.

216.11

SUBSTANCE P IS NOT AN EFFERENT NEUROTRANSMITTER IN THE *LIMULUS* EYE. H.K. Lehman, T.J. Lewandowski* J.K. Johnson and S.C. Chamberlain. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

Immunoreactive Substance P (ir-Subst P) has been widely reported from *Limulus polyphemus*. Immunocytochemical investigations have detected the presence of ir-Subst P in the brain and retina (Chamberlain and Engbretson, J. Comp. Neurol. 208: 304-315). Ir-Subst P has also been detected by radioimmunoassay in *Limulus* retinal extracts and was proposed to be an efferent neurotransmitter (Mancillias and Brown, J. Neurosci. 4: 832-846). We report here that indeed ir-Subst P is found in the *Limulus* retina, but isolated ir-Subst P does not play a role in modulating visual function as an efferent neurotransmitter.

Brain and retinal extracts were extracted with boiling acetic acid and the residue was passed through a column of Sephadex G-25. Five ml fractions were collected and tested for 1) bioactivity that increases the ERG amplitude of *Limulus* and 2) ir-Subst P by radioimmunoassay. Three bioactive peaks elute from the Sephadex column, in .6, 1.0 and 1.2 column volumes; ir-Subst P elutes from the column in the void volume (0.1 column volumes). The binding curves of isolated ir-Subst P and synthetic Subst P are similar. Ir-Subst P elutes as single peak from reverse phase HPLC, but does not coelute with authentic Substance P.

Ir-Subst P has also been studied with immunocytochemical techniques. At the light microscopic level, ir-Subst P fibers penetrate the retina and run between the ommatidia to the level of the corneal epidermis. Ir-Subst P is not contained within the efferent fibers. Moreover, ir-Subst P is absent in fibers innervating photoreceptors not derived from epidermis. We are in the process of confirming these results at the ultrastructural level.

We conclude that an ir-Subst P molecule exists in the *Limulus* retina, but does not have the proper physiological actions or anatomical localization to be considered an efferent neurotransmitter, but may be part of a more general epidermal innervation.

This work has been supported by the NIH.

216.12

MONOCLONAL ANTIBODIES RAISED TO DROSOPHILA EMBRYOS RECOGNIZE NEURAL ANTIGENS IN THE MARINE SNAIL BULLA GOULDIANA. B. Ibrahim*, V. Bedian* and M.H. Roberts (SPON: R. Konopka), Department of Biology, Clarkson University, Potsdam, NY 13676

We have attempted to map the positions of immunohistochemically identifiable neurons in the CNS of the marine snail Bulla gouldiana, as a prelude to studies of the neurophysiological control of rhythmic behavior by central circadian pacemakers.

Using the avidin-biotin (ABC) technique, we find that monoclonal antibodies raised against Drosophila embryos recognize a number of neural antigens in the Bulla CNS. Out of thirty-five antisera screened, we find seven that stain cells in the Bulla nervous system. Five of the antisera recognize neuron nuclei, with the staining appearing uniform over the entire nucleus. Two of the antisera recognize the cytoplasm: one stains all cells in a non-uniform pattern; the staining is dense near the nucleus and decreases toward the periphery. The other cytoplasmic antigen, recognized by antibody E2F8.E5, is found exclusively in a small number of neurons in the pleural and pallial ganglia.

These results, particularly with antibody E2F8.E5, illustrate the utility of using immunohistochemistry with novel antisera as a method of identifying unique neurons in the molluscan nervous system. Current work is aimed at identifying the antigens recognized by these antisera.

216.13

FUNCTIONAL CONNECTIONS EXIST BETWEEN CONTRALATERAL BAG CELL CLUSTERS WITHIN THE HEAD GANGLIA OF APLYSIA. S. B. Shope and J. E. Blankenship, Marine Biomedical Institute, Univ. of Tex. Medical Branch, Galveston, TX 77550.

The bag cells of the marine mollusc Aplysia californica form two clusters of about 400 cells each on the rostral border of the abdominal ganglion. Bag cells discharge synchronously due to electrical coupling both within and between clusters. In recent experiments we removed the intact central nervous system from the animal and lesioned the abdominal ganglion longitudinally, separating the left and right bag cell clusters. In 6 of 6 experiments, electrical stimulation of one bag cell cluster resulted in a discharge in the other bag cell cluster. The effect depended only upon an intact pathway between each half of the abdominal ganglion through the pleural and cerebral ganglia. This suggests that there is a functional connection between the bag cells within the head ganglia. We are unable to determine if the connection is electrical or chemical. No obvious synchrony was noted between the clusters, however, any synchrony induced by electrical coupling in the head ganglia may be overridden by stronger electrical coupling within each cluster. Supported by NINCDS NS23169 and NSF BBS 8711368.

COMPARISON OF POTENCIES AND EFFICACIES OF ALPHA BAG CELL PEPTIDE ANALOGUES ON VOLTAGE CLAMPED NEURONS OF APLYSIA. M. K. Rock, S. B. Shope, and J. E. Blankenship. Marine Biomedical Institute, Univ of Tex Medical Branch, Galveston, TX 77550.

Alpha bag cell peptide (αBCP) is synthesized in the bag cells of the marine mollusc, Aplysia californica as a 9 amino acid peptide (αBCP_{1-9}) but active fragments αBCP_{1-8} and αBCP_{1-7} can be isolated from bag cell releasate as well. αBCP analogues were superfused onto voltage clamped rostral white cells (R3-R13) of the abdominal ganglion at 10^{-9} to 10^{-4} M. Dose-response curves demonstrated that αBCP_{1-8} and αBCP_{1-7} had similar potencies (dissociation constants) but that αBCP_{1-7} was more efficacious, ie, it produced a maximal current about twice that of αBCP_{1-8}. Scatchard and Hill analysis of the αBCP_{1-8} dose-response curve suggests two binding sites each requiring a single molecule for activation. Preliminary results suggest that αBCP_{1-9} is much less potent than the other two analogues. Supported by NINCDS NS 23169 and NSF BBS 8711368.

LOCALIZATION AND ACTIONS OF CATECHOLAMINES IN THE FEEDING SYSTEM OF APLYSIA CALIFORNICA. M.M. Rathouz*, K.P. Cohen* and M.D. Kirk. Dept. of Biology, Boston University, Boston, MA 02215.

The glyoxylic acid histofluorescence technique was used to localize catecholamines in Aplysia buccal ganglia and nerves and the esophagus. We observed high levels of blue-green fluorescence, indicating the presence of catecholamines, in three identifiable cell bodies (two symmetrically paired and one unpaired), and 10 smaller lateral cells (five in each ganglia). The esophageal nerve, the cerebro-buccal connective, and the neuropil of the ganglia contained processes which fluoresced blue-green as well. A plexus of blue-green axons is present in the area where the esophageal nerve joins the esophagus. This net of processes may act as a neurohemal organ releasing catecholamines diffusely in the outer wall of the gut.

Previous biochemical studies found that dopamine is the only catecholamine which accumulates to significant amounts in gastropod molluscs, therefore, we suggest that the blue-green fluorescence is due to dopamine. Our physiological studies show that bath-applied dopamine increases the strength and frequency of contractions in strips of Aplysia esophagus, crop, and gizzard. Actions of dopamine on the esophagus resemble actions of bath-applied acetylcholine. The localization of catecholamines in cells and processes of the buccal system and the actions of dopamine on the digestive apparatus suggest a modulatory role by these neurotransmitters in feeding and digestion. Supported by NIH grant NS24662 to MDK.

216.16

FURTHER LOCALIZATION OF SCPBERGIC NEURONS IN THE BUCCAL GANGLIA OF APLYSIA CALIFORNICA. P.J. Church and M.D. Kirk. Dept. of Biology, Boston University, Boston, MA 02215

The Small Cardioactive Peptide B (SCPB) is present in buccal neurons of Aplysia californica and has profound effects on buccal motor activity. Previous studies have localized SCPB to the identified neurons B1, B2, and B15 and shown its absence in B4/5 and B16. Immunocytochemical studies on juveniles have shown several small dorsal cells and an additional three or four medium to large ventral cells to contain SCPB, but the cells have yet to be characterized.

To determine the functional roles of SCPBergic buccal neurons, we are identifying and physiologically characterizing the remaining buccal neurons with SCPB-like immunoreactivity. Ganglia from 200-300 gram animals were treated either as whole mounts or in 20 um frozen sections. Cell identification was based on size, position, and physiology, and in some cases was combined with lucifer yellow injection for double-label experiments.

Based on cell body position and size, positive staining of the identified neurons B15, B1 and B2 was confirmed in adult animals. In addition, double label experiments show SCPB-like immunoreactivity in B11 and B9, as well as an absence of staining in B3. Consistant staining also appeared in cells on either side of B9 and B3 and a lone cell located on the lateral edge of the ganglia. The neuron medial to B3 appears to be B7. Several (approx. 25) small cells in the dorsal-rostral group stained positive as did at least one cell located peripherally at a branch point of the esophogeal nerve. Numerous processes in the neuropil, buccal nerves, commissural arch, and sheath above the arch also show SCPB-like immunoreactivity. Supported by NIH grant NS24662 to MDK.

216.17

CHARACTERIZATION OF SCP_b IMMUNOREACTIVE CELLS IN THE BUCCAL GANGLION OF *APLYSIA*.

M.W. Miller*, I. Kupfermann, and K.R. Weiss (SPON: S.K. Salzman). Center for Neurobiology and Behavior, Columbia University, Coll. P & S, and NYS Psychiat. Inst., New York, NY 10032.

A cluster of 15 to 30 neurons which exhibits immunoreactivity to the small cardioactive peptide SCP_b was identified on the rostral surface of the buccal ganglion of *Aplysia* (Lloyd et al.,1985). Lucifer yellow injected cells from this group typically have a bipolar appearance, with one process ramifying extensively in the lateral region of the ganglion, and a second process extending toward the buccal commissure. In addition to sending a branch into the contralateral hemiganglion, the axon bifurcates into each branch of the radula nerve.

In preparations exhibiting spontaneous rhythmicity or in which repetitive bursting was produced by radula nerve stimulation (1-2 Hz), the rostral SCP_b immunoreactive ($iSCP_b$) cells were depolarized 10-15 mV in phase with bursting in the identified B4/B5 interneuron pair. This depolarization usually results in synchronous bursting of the $iSCP_b$ cells during the late phase of the B4/B5 burst. Synchrony of $iSCP_b$ cell bursting appears to result from common synaptic inputs and non-rectifying electrotonic connections among members of the cluster (somatic coupling ratio: 0.02-0.04). No dye coupling was noted with 6-carboxyfluorescein or Lucifer Yellow. Firing individual cells did not produce detectable muscle contractions. These cells may serve a sensory function, may be involved with peripheral (Lloyd, et al.,1984; Richmond et al., 1986) or central (Sossin et al., 1987) modulatory actions of SCP_b, or may play a role in a developmental stage of feeding behavior, as suggested by their relative prominence in juvenile specimens (Lloyd et al., 1985).

THE R20 NEURONS, WHICH MODULATE RESPIRATORY PUMPING IN *APLYSIA*, SYNTHESIZE SCP.

A. Alevizos, K.R. Weiss, and J. Koester, Center for Neurobiology & Behavior, NY State Psychiatric Institute, and Department of Physiology and Cellular Biophysics, Columbia University, New York, NY 10032

Respiratory pumping in *Aplysia* consists of transient, synchronous pumping actions of the gill, siphon, mantle shelf and parapodia. This behavior previously has been shown to be driven by a network of about 30 electrically coupled interneurons in the abdominal ganglion, the R25 and the L25 cells. The R20 cells are a pair of electrically coupled interneurons which, when active, can initiate respiratory pumping or increase its spontaneous rate of occurrence. We describe here in more detail the properties of the R20 cells.

The R20 cells, which have somata that are approximately 120-160 µm in diameter, are located on the right caudal edge of the abdominal ganglion, just medial to the branchial nerve. They increase respiratory pumping activity by producing a slow, long-lasting excitation of the endogenous burst mechanism of cells in the R25/L25 network. They also make slow inhibitory connections to the RB cells in the abdominal ganglion and to the gill motoneurons in the branchial ganglion. They are weakly inhibited by cell L10.

The R20 cells stain positively with an anti-serum raised against the molluscan neuropeptide SCP_B. Biochemical purification with HPLC analysis of ^{35}S labeled cells demonstrates that each of R20 cells synthesizes not only SCP_B, but also SCP_A, a closely related molecule that is known to be encoded by the same gene as SCP_B. Both R20 cells also synthesize in abundance identical sets of several other low molecular weight, methionine-containing peptides.

The actions of the R20 cells on the R25/L25 network are mimicked by pharmacological application of SCP_A and SCP_B. However, the actions of the R20 cells on the RB cells are not mimicked by the SCPs: SCP produces excitation while firing the R20 cells produces inhibition. Likewise, firing the R20 cells inhibits the branchial ganglion cells, while bath application of SCP_B causes them to burst (Colebrook and Lukowiak, 1987). Thus the R20 cells probably release SCP_A and SCP_B and at least one other unidentified transmitter.(Supported by grants NS14385 and MH35564).

MONOAMINERGIC AND PEPTIDERGIC MODULATION OF MOLLUSCAN MOTOR FUNCTION.

Haydon,P.G., Zoran, M.J., and Matthews,P.J. Department of Zoology, Iowa State University, Ames, IA 50011.

Serotonin (5-HT) and small cardioactive $peptide_B$ (SCP_B) are known to evoke patterned motor activity in identified neurons (e.g. B19) in the buccal ganglia of *Helisoma*, while FMRFamide has inhibitory effects (Granzow & Kater, 1977; Murphy *et al.*, 1985). This study shows that these neuroactive substances also have potent modulatory effects on the muscle targets of *Helisoma* buccal motoneurons.

In vivo, action potentials in neuron B19 evoke one for one excitatory junction potentials (EJPs) in the supralateral radular tensor (SLT) muscle that are reduced in amplitude by tubocurare. Application of 5-HT and SCP_B (10^{-6}M) has no effect on the amplitude of the EJP but significantly enhances neuron B19-evoked muscle contractions of supralateral radular tensor (SLT) muscle.

To determine whether these modulators act directly on muscle, a neuron-free culture system of single dissociated SLT fibers was established. Collagenase dissociated SLT muscle fibers maintain normal physiological properties including resting membrane potentials, excitatory potential changes in response to applied ACh, and contractile responses to both ACh and depolarizing current injection. Depolarizing potential responses to pressure applications of ACh are unaffected by either 5-HT and SCP_B (10^{-6}M) while FMRFamide (10^{-6}M) reduces the amplitude of the ACh depolarization. Although 5-HT and SCP_B have little effect on ACh-evoked depolarizations they potently enhance the magnitude of ACh-evoked SLT fiber contractions.

These results demonstrate that neuroactive substances in *Helisoma* not only effect the generation of patterned buccal motorneuron activity, but also directly modulate the peripheral targets influenced by this motor activity.

ACETYLCHOLINE INDUCES OUTWARD CURRENT IN THE TAIL SENSORY NEURONS OF APLYSIA.

M. Ichinose*, M. Sawada*, T. Maeno* and D.J. McAdoo. Dept. Physiol. Shimane Medical Univ., Izumo 693, Japan and Marine Biomedical Inst., Univ. of Texas Medical Branch, 200 Univ. Blvd., Galveston, TX 77550

The effects of acetylcholine (ACh) on tail sensory neurons in the pleural ganglion of Aplysia kurodai were characterized by whole-cell patch-clamp. Micro-application of ACh induced an increased conductance outward current. Repeated application at 1-2 min intervals produced little desensitization. The threshold was 10^{-7} M. The reversal potential in normal seawater is close to -80 mV. The reversal potential shifted to -63 mV in 20 mM $[K^+]$ and -33 mV in 50 mM $[K^+]$. Tetraethylammonium (1 mM) reduced the response to 22% of control. The reversal potential did not shift in Cl-deficient seawater. Atropine (1 mM) and d-tubocurarine (1 mM) partially blocked the response. Hexamethonium (1 mM) had no effect. Carbamylcholine induced a smaller outward current (71% of Ach response). Nicotine and muscarine had almost no effect. Arecoline induced a small outward current (12% of ACh response). We conclude that tail sensory neurons have an H type receptor to ACh which opens the K^+ channel.

REGULATION OF AUTONOMIC FUNCTION II

217.1

EFFECTS OF LUMBOSACRAL DEAFFERENTATION ON BRAINSTEM EVOKED MICTURITION IN THE DECEREBRATE CAT.

B. Fedirchuk and S. Shefchyk,Dpt.Med.&Physiol.,Univ.Manitoba, Winnipeg Canada R3E 0W3

The manner in which descending brainstem and segmental pelvic afferent systems interact during voiding has been subject of extensive speculation (de Groat et al., J. Aut. Ner. Sys. 3:135,1982; Floyd et al. J. Physiol. 322;45,1982). The purpose of this study was to determine if electrical stimulation of the pontine micturition facilitatory region could produce adequate detrusor contraction and external urethral sphincter (EUS) relaxation resulting in coordinated voiding in the absence of lumbosacral afferents.

Ten decerebrate male cats were used for the study. Bladder pressure was monitored using a suprapubic catheter inserted into the fundus of the bladder. Electromyographic records from the EUS muscle were also obtained. Lower lumbar and sacral deafferentation was done by cutting the dorsal roots bilaterally from L6-S3 (extending to upper Ca segments). In several cats the dorsal root ganglia of L7, S1 and S3 were also removed. Following deafferentation, no amount of distension of the bladder could produce a reflex void; only overflow leakage was observed. However, the ability for brainstem stimulation to evoke a bladder contraction of a magnitude and duration sufficient to empty the bladder remained. In addition, the reciprocal inhibition of the EUS activity was also observed during this voiding. These results suggest that the pontine micturition facilitatory region is capable of activating neural systems within lower brainstem regions and/or the spinal cord which can coordinate sacral parasympathetic activation and pudendal somatic inhibition independent of sacral segmental sensory pathways. This research is supported by the Medical Research Council of Canada.

217.2

SYMPATHETIC MODULATION OF CHOLINERGIC TRANSMISSION IN VESICAL PARASYMPATHETIC GANGLIA (VPG) OF THE CAT MEDIATED BY $ALPHA_1$ AND $ALPHA_2$ ADRENERGIC RECEPTORS.

W.C. de Groat, J.R. Keast and S. Smerin*. Dept. Pharmacol., Univ. Pittsburgh, Pittsburgh, PA, 15261.

Previous studies have shown that exogenous catecholamines can facilitate and inhibit transmission in cat VPG, in vitro, via α_1 and α_2 adrenergic receptors, respectively. The present experiments revealed that similar responses can be elicited by electrical stimulation (10-30 Hz, 20-40 V, 10-20 sec) of sympathetic pathways in the hypogastric nerves (HGN) in the anesthetized cats. HGN-stimulation or intraarterial (I.A.) injections of norepinephrine (2-10 µg) commonly depressed the postganglionic potentials elicited by preganglionic stimulation, although in some cats the responses consisted of initial inhibition (15-20 sec) followed by facilitation (0.5-2 min). Phenylephrine (5-50 µg I.A.), an α_1 agonist, facilitated transmission or produced an initial inhibition followed by facilitation. Yohimbine (20-50 µg, I.A.), an α_2 antagonist, blocked the inhibitory effects of drugs and HGN-STIM and unmasked or enhanced the facilitatory effects. Prazosin (20 µg), an α_1 antagonist, blocked the facilitatory responses but not the inhibitory responses. It is concluded that adrenergic neurons in VPG can modulate cholinergic transmission via α_1 facilitatory as well as α_2 inhibitory mechanisms.

217.3

OPIOID MODULATION OF BLADDER REFLEXES AT THE LEVEL OF THE PONTINE MICTURITION CENTER (PMC). J.R. Roppolo, H. Noto, B. Mallory and W. C. de Groat. Depts. of Pharmacol., Behav. Neurosci. and Ctr. Neurosci., Univ. of Pittsburgh, PA 15261.

Studies using intracerebroventricular injections of opioid agonists and antagonists have suggested a supraspinal site for opioid modulation of bladder reflexes. The present study was undertaken to determine if the PMC (in the dorsolateral pons) is a site where opioid modulation of micturition occurs.

Opioid agonists and antagonists were microinjected into the PMC of decerebrate cats while recording either isovolumetric rhythmic bladder contractions or cystometrograms (CMG). Both fentanyl (2-15 nM), a mu receptor agonist and DSLET (0.5-5 nM), a delta receptor agonist inhibited bladder contractions or increased the capacity of the bladder as demonstrated by the CMG. These effects could be reversed by naloxone either administered IV (30 to 100 µg/kg) or microinjected into the PMC (500-1000 nM). Microinjections of morphine (10 to 1000 nM) had only weak effects on bladder reflexes. Microinjections of naloxone (100-1000 nM) without prior administration of opioid agonists, increased the duration or frequency of rhythmic bladder contractions or reduced bladder capacity. These studies suggest that enkephalinergic inhibitory mechanisms are important in modulating bladder reflexes at the level of the PMC.

217.4

BRAINSTEM CONTROL OF URINARY BLADDER AND EXTERNAL URETHRAL SPHINCTER IN CAT. H. Noto, J. Roppolo, B. Mallory, M. Kruse and W. de Groat. Depts. of Pharmacology & Behav. Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

The present study examined the pontine control of urinary bladder (UB) and external urethral sphincter (EUS) coordination in decerebrated cats. Electrical stimulation (ES) (50-150 µA, 0.3 ms, 300 ms train at 50 Hz) of the pontine micturition center (PMC, P 1-3, L 1.5-3, H 0- -3) elicited a UB contraction at a latency of 0.4-1.5 sec, but evoked various responses in the EMG of the EUS. ES of the optimum site in the PMC induced an inhibition of the EUS (shortest latency 40-60 ms) which preceded the evoked UB contraction; this mimics the normal micturition pattern. The threshold intensity for EUS inhibition was lower than that for UB excitation, and the inhibition was induced with a full or empty bladder. ES of adjacent areas of the PMC occasionally evoked EUS excitation (0.1-2 sec latency). ES of the lateral reticular formation evoked EUS excitation. ES of the ventral reticular formation applied during a UB contraction inhibited the ongoing contraction and activated the EUS (latency 95-120 ms), whereas application of the same stimulus in the absence of a bladder contraction inhibited the EUS (latency 40-60 ms). These results indicate that the EUS receives inhibitory and excitatory descending inputs from the pons, and suggest that the PMC has an important role in the coordination of the UB and EUS.

217.5

PONTINE CONTROL OF MICTURITION IN THE RAT. M. Kruse, H. Noto, J. Roppolo and W. de Groat. Depts. Pharmacol. & Behav. Neurosci., Univ. Pittsburgh, Pittsburgh, PA 15261.

Micturition in rats differs from that in many other species by exhibiting a coactivation of the urinary bladder (UB) and the external urethral sphincter (EUS). The present study examined the role of the pons in coordinating the activity of these two structures. Short trains of electrical stimulation (50 Hz) in the medial pons (~ B -8.3, L 0.8, H 5-6.5) elicited contractions of the UB and an increase in EUS activity (latency < 1 sec). The EUS responses occurred with a full or empty UB, indicating that the EUS receives a direct descending input from the pons. Continuous stimulation (50 Hz) with intensities at or just below the threshold for inducing UB contractions markedly reduced the UB capacity as measured by cystometrogram (UB capacity decreased by 44±9%, n=5). Similar effects were noted with stimulation in a more lateral area (~ B -8.3, L 2.2, H 5-6.5). Electrical stimulation of regions ~2 mm ventral to these sites evoked short latency EUS activity (100-200 ms); however, continuous stimulation of these ventral areas increased the UB capacity by 62±30% (n=5). These data indicate that the rat's UB and EUS can be coactivated by descending inputs from the pons, and demonstrate that pontine stimulation can elicit responses that mimic physiologic behavior, including modulation of bladder capacity.

217.6

EFFECTS OF DIABETES MELLITUS ON URINARY BLADDER FUNCTION IN THE RAT. A.M. Mackway*, W.D. Steers, J. Ciambotti*, and W.C. de Groat, (SPON: O. Reinmuth). Depts. Pharmacol., Urol., and Behav. Neurosci., Univ. of Pittsburgh, Pittsburgh, PA 15261.

Streptozotocin-induced diabetic male rats (8 wks. duration) underwent cystometrographic (CMG) and electrophysiologic evaluations to determine etiology of bladder dysfunction. Diabetic rats (D, n=6) in comparison to controls (C, n=8) had significantly greater bladder (BL) capacity (D, 3.0+/-0.84 ml vs C, 0.7+/-.4 ml, P<.001), and weight (D, 112.6+/-10.7 mg vs C, 56.1+/-9.0 mg, P<.01). No differences between D and C were found for latencies or thresholds of hypogastric and pelvic nerve-evoked peripheral and central responses in BL nerves. However, alterations in central micturition reflexes were manifested as an absence of spinal reflexes in D rats (present in 38% C) and a lack of facilitation of the supraspinal reflexes by bladder distension in D (seen in 38% C).

These functional and electrophysiological changes in D differ from those observed in the enlarged BL due to outlet obstruction, and are consistent with an underlying autonomic dysfunction induced by diabetes.

INTRATHECAL CLONIDINE INDUCES INHIBITION OF MICTURITION REFLEXES AND SPASTICITY IN SPINAL CORD PATIENTS MADE TOLERANT TO SPINAL MORPHINE. R.M. Herman, D.W. Coombs*, R. Saunders*, M.C. Wainberg*. Catholic Med. Ctr., Manchester, NH 03102, Dartmouth/Hitchcock Med. Ctrs., Hanover, NH 03756.

Intrathecal (i.t.) clonidine (CLO) produces analgesia in patients tolerant to i.t. morphine (MOR). In patients with suprasacral spinal cord lesions (SSCL), an acute injection or chronic infusion of i.t. MOR attenuates spontaneous motor discharges ("spasticity") and hyperactive micturition reflexes, leading to enhanced bladder capacity. This study was undertaken to examine the effect of a bolus injection of i.t. CLO (150 µg) on micturition reflexes and spontaneous motor discharges when administered to 2 patients with SSCL, made tolerant to i.t. MOR by chronic infusion of the substance. Volume-induced micturition reflexes and EMG discharges from the striated ano-urethral sphincters and various lower limb muscles were assessed during medium fill cystometry. Within 30 minutes, i.t. CLO suppressed all vesical reflexes and spontaneous motor contractions prior to depression of blood pressure. The action of CLO potentiated the anti-spasticity action of i.t. MOR; in contrast to the action of i.t. MOR, i.t. CLO reduced peak detrusor pressure and vesico-sphincter dyssynergia. By manipulating the doses of MOR-CLO and the selection of opiate-α_2 adrenergic receptor agonists, functional synergism may be attained. (Partial Support: Spinal Cord Soc., Dartmouth/Hitchcock Med. Ctrs., Catholic Med. Ctr., Good Samaritan Med. Ctr., Phoenix, AZ 85006.

217.8

BED NUCLEUS OF STRIA TERMINALIS INFLUENCE OVER GASTRIC FUNCTION **G.E. Hermann, M.J. McCann and R.C. Rogers, Dept. Physiology, Ohio State Univ.**

Anatomic studies by Ricardo and Koh (1978) had indicated that the bed nucleus of the stria terminalis (BST), paraventricular nucleus of the hypothalamus (PVH), and the central nucleus of the amygdala (CNA) have reciprocal connections with the nucleus of the solitary tract (NST) and the dorsal motor nucleus of the vagus (DMN); nuclei that are involved autonomic control of gastric function. Our previous electrophysiological experiments have demonstrated that both PVH and CNA maintain direct connections with NST and DMN; thus, they are able to modulate the basic circuitry controlling gastric secretion and motility.

Our recent physiological experiments have revealed that brief electrical stimulation of the BST elicits an increase in the contractility and/or tone of the gastric musculature. This increase in gastric activity is mimicked by micropressure injection of glutamate into the same region of the BST and can be abolished following systemic administration of atropine methyl nitrate. Thus, the BST may be another forebrain structure that can modulate the function of the stomach via the dorsal medullary vagal complex.

THYROTROPIN-RELEASING HORMONE (TRH) POTENTIATES THE GASTRIC RESPONSES EVOKED BY DORSAL MEDULLARY SEROTONIN (5HT). M.J. McCann*, G.E. Hermann, & R.C. Rogers, Dept. of Physiology, Ohio State University, Columbus, OH 43210. (Spon: D. Lim).

TRH and 5HT are colocalized in terminals in the dorsal motor nucleus (DMN), thus both may influence the output of this nucleus. We studied this by measuring gastric function after injections of TRH and 5HT into the DMN. Microinjection of 5HT (8pm/4nl) produced a small increase in motility (44%) and tone (367 mg) above baseline, whereas TRH (1nm/1ul) applied to the dorsal medulla evoked large increases in both indices (323% and 908 mg). After baseline levels returned following TRH application, subsequent 5HT injections now evoked large elevations in motility (291%) and tone (817 mg). This potentiation was blocked by a peripheral muscarinic antagonist. These results suggest that TRH augmentation of 5HT-mediated effects on autonomic nuclei may be a significant feature of the alterations in gastric function that accompany stress-related gastric pathology. (Supported by NINCDS-NS24535).

217.10

TRH EFFECTS ON PHYSIOLOGICALLY-IDENTIFIED NEURONS IN THE DORSAL VAGAL COMPLEX: IN VIVO AND IN VITRO STUDIES. R.C. Rogers, M.J. McCann and G.E. Hermann Dept. Physiology, Ohio State Univ.

Recently, our laboratory showed that TRH micropressure injected into the DMN in picomolar amounts significantly increased gastric secretion and motility. Though direct action of TRH on DMN neurons was implied, there has been no electrophysiological data available to support this contention. Evidence for direct action of TRH on dorsal vagal complex neurons in vivo was obtained by pressure injecting TRH (10 to 200 femtomole in 10-200 picoliter pulses) onto single electrophysiologically-identified DMN or NST cells. With in vitro studies, coronal slice preparations were superfused with TRH (10 micromolar). 46% of DMN cells were activated by TRH; none were inhibited. Conversely, 53% of NST neurons were inhibited by TRH; none were excited. These results indicate that central TRH pathways may "command" autonomic changes by suppressing vagal sensory inputs while activating vagal-motor outputs.

INTRACEREBROVENTRICULAR (I.C.V.) ANGIOTENSIN II INCREASES FLUID ABSORPTION FROM RAT ILEUM. D.R. Brown and M.A. Gillespie*. Dept. of Veterinary Biology and Neuroscience Graduate Program, Univ. of Minnesota, St. Paul, MN 55108.

Angiotensin (A) II acts at peripheral and CNS sites to maintain extracellular fluid homeostasis. We examined the actions of A-II, A-III and other peptides on intestinal fluid absorption and mean arterial pressure (MAP) in rats after i.c.v. administration. In urethane-anesthetized rats (275 - 400 g), the carotid artery was cannulated for MAP determination and the jejunum (J) or ileum (I) was isolated and perfused in situ with a modified Ringer-HCO_3 solution containing 5 μCi/L of [^{14}C]polyethylene glycol 4000 as a fluid transport marker. Gut perfusates were collected 15' before and after peptide or saline i.cv. injection. A-II and A-III, but not A-I or angiotensinogen (1 μg/rat) increased net water absorption from I; A-II did not alter J transport. Somatostatin (1 μg) decreased I absorption; bombesin and TRH had no transport-related activity. All peptides ($\leq$ 1 μg) increased MAP. The pressor and proabsorptive actions of A-II were inhibited by the α-adrenoceptor blocker phentolamine (1 mg/kg, i.v.) or the A-II antagonist [Sar^1, Val^5, Ala^8]A-II (5 μg, i.cv.); atropine methylnitrate (0.1 mg/kg, i.v.) inhibited A-II actions on I transport but not MAP. Thus, A-II appears to increase I absorption through actions at CNS sites distinct from those mediating its hypertensive effects.

217.12

GABA RECEPTORS IN THE CENTRAL NERVOUS CONTROL OF GASTRIC FUNCTION: MICROINJECTIONS OF BICUCULLINE. H.-S. Feng,* J. Han,* and F.P. Brooks.* (SPON: J.R. Brobeck). Departments of Medicine and Physiology, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104.

Bicuculline methiodide 250 ng. injected into the dorsal motor nucleus (DMV) of the vagus was reported to increase acid output and gastric contractions in cats (Washabau et al, Gastroenterology 92: 1807, 1987) but 100 ng failed to increase gastric contractions in other experiments (Williford et al, Science 214: 198. 1981). We have made microinjections by micropressure injections of 200 nl. of saline containing 0-1000 ng. of bicuculline into the DMV, NTS and LHA of 29 anesthetized cats. Gastric content was collected from a gastric fistula and gastric contractions recorded with extraluminal force transducers on the antrum and corpus. Gastric content was titrated to pH7 with 0.1N NaOH with an autoburette. The force of antral contractions increased 6x (5.1$\pm$1.1 to 29$\pm$2gm) at 50 ng. bicuculline, but no increase in acid secretion occurred until 100 ng. was injected in either the DMV or NTS. The maximal gastric acid output was 2x greater (1.0$\pm$0.2 vs. 0.58$\pm$0.08mM/15 min)with injection of the NTS than the DMV. The LHA responded to 250-1000 ng. in a dose-related fashion with an increase in force of contractions (5.6$\pm$0.3 to 32$\pm$2gm). These results suggest that GABA receptors exert a more powerful inhibitory control of gastric motility than acid secretion in the DMV and NTS. However, acid secretion is inhibited to greater degree by GABA receptors in the NTS than the DMV. GABA receptors also participate in the tonic inhibition of a vagally mediated gastric motor excitatory pathway from the lateral hypothalamus. (NIH GRANT R01-36693-2)

217.13

AUTONOMIC NERVOUS SYSTEM INVOLVEMENT IN THE EFFECTS OF NPY IN THE PARAVENTRICULAR NUCLEUS ON GASTRIC ACID SECRETION. G.A. Humphreys*, J.S. Davison* and W.L. Veale. Dept. Med. Physiol., University of Calgary.

Interdigestive gastric acid output is suppressed significantly after injection of 200 pmole of NPY into the paraventricular hypothalamic nucleus (PVN) of anesthetized rats (Brain Research, in press). The purpose of these experiments was to characterize the magnitude and duration of this inhibitory response in gastrin stimulated rats and to determine the autonomic pathways which mediate this NPY effect. In gastrin stimulated rats, gastric acid output dropped by 10 $\pm$ 1.4 μeq/10 min 20 minutes after injection of 200 pmole NPY into the PVN and remained significantly lower than saline injected controls for the duration of the 180 min post-injection measurement period. The inhibitory effect of NPY in gastrin stimulated rats was abolished by intravenous injection of atropine and by coeliac ganglionectomy. The inhibitory response in unstimulated rats was abolished by subdiaphragmatic vagotomy, atropine, coeliac ganglionectomy and by phenoxybenzamine treatment. These results demonstrate that NPY inhibits both unstimulated and gastrin stimulated acid output in the anaesthetized rat. The effect is dependent on the integrity of, and may be mediated by, both the sympathetic and parasympathetic branches of the autonomic nervous system.

217.14

CENTRAL ADMINISTRATION OF BOMBESIN, DERMORPHIN, AND SALMON CALCITONIN REDUCES THE SEVERITY OF PAF-INDUCED GASTRIC ULCERS. A. Guglietta, B. J. Irons* and L. H. Lazarus, LMIN, NIEHS, Research Triangle Park, NC 27709.

Platelet Activating Factor (PAF) is a potent ulcerogenic agent that might be important for the formation of some gastric ulcers in humans. In this study we investigated whether the central administration of peptides (bombesin, 500 ng; dermorphin, 100 ng; salmon calcitonin, 250 ng) which suppress gastric acid secretion might influence PAF-induced gastric ulcers. Peptides were injected icv in rats and 1 h later PAF (3.2 μg/kg) was administered iv. Control animals received vehicles icv and iv. One h after PAF injection the animals were sacrificied, stomachs removed and graded macro- and microscopically for gastric lesions according to an arbitrary scale. PAF induced extensive gastric lesions which did not extend to the duodenum. Previous injections of bombesin, dermorphin or salmon calcitonin significantly reduced the severity of PAF-induced gastric ulcer macro- and microscopically. These data indicate that central injection of these peptides might influence the development of some type of gastric ulcer.

217.15

PARAVENTRICULAR NUCLEUS STIMULATION CAUSES GASTRO-DUODENAL ULCERS. A.V.Ferguson, P.Marcus*, J.Spencer*, and J.L.Wallace* (SPON: D.Bakker). Dept.Physiol. Queen's Univ. Kingston, Ont. CANADA. K7L 3N6.

The hypothalamus has long been known to play a role in the regulation of gastrointestinal function presumably through descending neural projections to medullary autonomic centres. In fact the elimination of such control over gastric acid secretion through bilateral vagotomy, has been a surgical procedure widely used for treatment of peptic ulcer for decades. More recent studies involving intracerebroventricular injections of various peptides, lesions in specific regions of the hypothalamus and stimulation in such regions have provided information on the specific hypothalamic nuclei involved in these regulatory control mechanisms.

The present studies have examined the effects of stimulation in the PVN on gastroduodenal ulceration in urethane anaesthetised male Sprague Dawley rats. Electrical stimulation (60 m, 200 uA, 60 Hz) in PVN resulted in damage in both the stomach (1.75±0.29) and duodenum (1.68±0.4) as assessed by histologically derived damage scores. Similar stimulation in immediately adjacent regions was without significant effect on the gastric mucosa. PVN stimulation following bilateral vagotomy resulted in damage scores (stom. 0.23±0.1, duod. 0.06±0.04) which were significantly reduced compared to the PVN stimulated vagi intact group ($p < 0.05$), but were not different to the group stimulated in regions outside the PVN ($p < 0.05$). These data suggest an important role for PVN efferents influencing medullary vagal preganglionic neurons in the development of gastric ulcers.

217.16

ELECTROPHYSIOLOGICAL RESPONSE OF NEURONS IN THE LATERAL HYPOTHALAMUS TO GASTRIC VAGAL INPUT. C.S. Yuan*, W.D. Barber and B.J. Cammarata* (SPON: S. Hsiao). Department of Anatomy, College of Medicine, University of Arizona, Tucson, AZ 85724.

Gastric vagal input from the proximal stomach was electrophysiologically evaluated in neurons in the lateral hypothalamus in anesthetized cats. Gastric vagal branches of the dorsal and ventral vagal trunks, which serve the proximal stomach, were electrically stimulated with paired pulses (0.3 msec duration, 300 uA, 0.5 Hz) to activate neuronal responses in the lateral hypothalamus. The latency of 70 gastric vagally-evoked unitary responses, recorded in the lateral hypothalamus, was 366 ± 39.1 msec with a conduction velocity of < 1 m/sec suggesting that the stimulus was conveyed largely by unmyelinated fibers. The majority of the vagally evoked hypothalamic unitary responses were phasic bursts containing multiple spikes. Twenty-three % of the units in the lateral hypothalamus receiving gastric vagal input showed tonic activity. The vagal effect upon these tonically active hypothalamic units was predominantly inhibitory. Distention of an intragastric balloon also activated units in the region of the hypothalamus where gastric vagally evoked responses were recorded. This study demonstrated that vagal input from the proximal stomach was capable of altering the activity of neurons in the lateral hypothalamus which other studies have implicated in control of food intake. (Supported by USPHS DK 35434).

VAGAL ALIMENTARY AFFERENT PROJECTIONS TO THE FERRET BRAIN STEM USING 2-DEOXY-GLUCOSE. B. Greenwood, J. Wood* and D. Kostreva. Depts of Pharmacology and Anesthesiology. Medical College of Wisconsin and VA Medical Center, Milwaukee, WI.

Previous studies using retrograde labelling of HRP demonstrated that in the ferret vagal afferent fibers project to the medial nucleus of the tractus solitarius (NTS) (Fitzackerly et al, 1987). The aim of this study was to investigate alimentary vagal afferent projections to the ferret brainstem by stimulating alimentary vagal afferent fibers and performing a functional mapping study with 14C-labelled 2 deoxyglucose (2DG). The central cut end of the vagal communicating branch (CB), connecting the dorsal and ventral vagal trunks just below the diaphragm was stimulated for 45 mins at 10Hz, 5mA and 0.5msec, 30sec on and 30 sec off. The right cervical vagus was cut. Prior to stimulation, a single bolus of 14C-2DG (100ug/kg i.v.) was injected and 16 serial blood samples taken for scintillation counting and blood glucose. At the end of the experiment the brain was removed and immediately frozen in isopentane at -40°C. Serial sections were cut at 20um and covered with film. After 12 days the films were developed, scanned and converted to glucose utilization. The sections were also stained with cresyl violet for histological comparisons. Electrical stimulation of vagal afferent fibers within the CB led to a significant increase in glucose utilization in the left medial NTS from 0.2mm caudal to the obex to 1.0mm rostral. Glucose utilization was also increased substantially in the left dorsal motor nucleus of the vagus 0.2mm caudal to the obex to 0.6mm rostral. Identical areas on the right side of the brain did not demonstrate significant changes in glucose utilization. Increased glucose utilization was also apparent in the inferior olive.

DENDRITIC ARCHITECTURE OF MOTONEURONS PROJECTING TO THE UPPER ALIMENTARY TRACT IN RAT: S.M. Altschuler*, X. Bao and R.R. Miselis. (SPON: J. Metzler) Depts. of Animal Biology and Pediatrics and Inst. of Neurological Sciences. Univ. of Pennsylvania, Philadelphia, PA, 19104.

The motor innervation for palatal, pharyngeal, laryngeal, and esophageal muscles involved in swallowing originates primarily within the nucleus ambiguus (NA). The visecerotopic organization of the NA in the rat has been precisely determined (Beiger and Hopkins, JCN 262:546, 1987), but little information concerning the dendritic arborizations of NA motoneurons is available. The neural tracer cholera toxin-horseradish peroxidase (CT-HRP, 0.4%), which is particularly effective at revealing dendrites of retrogradely labeled neurons, was used to determine the extra-nuclear dendritic projections of swallowing motoneurons. CT-HRP was injected into either the soft palate, pharynx, larynx or esophagus. Motoneurons innervating the soft palate, pharynx, larynx, and cervical esophagus were all found to have extensive dendrites that extended into adjacent reticular formation with a distinct pattern for each muscle group. In contrast, the dendrites of motoneurons to lower esophagus were confined to the NA. These extensive dendritic arborizations of NA motoneurons provide a wide ranging target for central afferents that modulate swallowing activity. Support: NIH GM27739, DK01747 and MacArthur Foundation.

ARE THERE SODIUM SENSORS IN THE RAT'S KIDNEY ?. M.P. Rosas-Arellano*, L.P. Solano-Flores* and A. Guevara-Rojas*. (SPON: H.U. Aguilar-Baturoni). Dept. Fisiología, Fac. Medicina, U.N.A.M. México. Apdo. Postal 70250, 04510-México, D.F.

Paradoxical antidiuresis produced by diuretic drugs suggests the existence of kidney tissue sensors which report to a central regulating mechanisms about the changes in the rate of loss or conservation of Na^+ by the organ. For each test, the left kidney of the rat was isolated and placed on a special support. It was perfused with oxigenated Locke's after its artery and vein were cannulated and the urine was collected by means of a ureteral canula. The temperature was kept at 22 °C ±1°. Filaments of the renal nerves were dissected and placed on Ag-AgCl electrodes to conventionally record the afferent impulse discharges. Spontaneous multiunitary afferent activity with a frequency of 1.1 to 4.4 impulses/second was initially recorded. An increase of the frequency from 3.3 to 6.6 impulses/second occured in many units when furosemide was added to the perfusion. On the contrary, cortisol reduced the frequency from 0.03 to 2.2 impulses/second. These responses probably are the sensor's reports about the natriuretic or antinatriuretic action of the drugs.

POSSIBLE MECHANISMS RESPONSIBLE FOR CHANGES IN Na^+ AND K^+ EXCRETION AND DIURESIS WHEN THE β-ADRENERGIC PATHWAYS OF THE SEPTAL AREA ARE STIMULATED. W.A.Saad, L.A.A.Camargo*, L. A. De Luca Jr.*, A.Renzi*, W.Abrão-Saad* and J.V.Menani*. Dep. of Physiology, Fac. of Dentistry, UNESP, Araraquara, 14.800. Dep. of Surgery, Fac. of Medicine, USP, São Paulo, Brazil.

The objective of the present investigation was to study the renal mechanisms that may be mediating the changes in Na^+, K^+ and urine volume induced by stimulation of β_2- adrenergic receptors of the medial septal area (MSA). Holtzman rats bearing a delay cannula directed toward the MSA and anesthetized with pentobarbital sodium were infused with a 3% glucose and 0.25% sucrose solution through the jugular vein so that a constant urine flow could be maintained. Urine was colleted through a catheter introduced into the bladder and mean arterial pressure(MAP) was recorded during a 20-minute control period. At the end of this time,a blood sample was collected. Isoproterenol or salbutamol was then injected centrally and the same procedure was repeated during the next 20 minutes. Injection of isoproterenol or salbutamol into the MSA induced a decrease in glomerular filtration rate (GFR),in filtered Na^+ and in MAP, and an increase in fractional Na^+ reabsorption. These results suggest that the fall in Na^+ excretion produced by activation of β_2-receptors in the MSA may be due to the fall in GFR and in filtered Na^+ and to the increase tubular Na^+ reabsorption.

CENTRAL AND PERIPHERAL NEUROTRANSMITTER ALTERATIONS IN THE BRATTLEBORO (DI) RAT. R. Dawson, Jr. and D.R. Wallace. Dept. of Pharmacodynamics, College of Pharmacy, Univ. of Florida, Gainesville, FL 32610

Vasopressin (AVP) has been implicated as an important modulator of central and peripheral autonomic function. The present study examined the neurochemical consequences of the absence of endogenous AVP by evaluating monoamine and amino acid content in brain regions from DI rats. Catecholamine content was also determined in the heart, adrenals and kidneys of DI rats.

Three month old Long-Evans (LE) control (n=12) and homozygous DI rats (n=12) were utilized in these studies. Monoamine and amino acid levels were measured by HPLC with electrochemical detection. Norepinephrine (NE) content in DI rats was significantly elevated in the spinal cord, anterior hypothalamus, neurointermediate lobe, adrenal gland and kidney. Serotonin was significantly elevated in the spinal cord and anterior hypothalamus of DI rats. ASP, GLN, GLU and GLY were significantly elevated in the spinal cord and GLN and TAU were significantly elevated in the anterior hypothalamus of DI rats. The lack of AVP in DI rats significantly altered monoamine and amino acid neurotransmitters in the anterior hypothalamus and spinal cord. Sympathetically innervated peripheral tissues of DI rats also exhibit significant changes in NE stores. In summary, AVP exerts a significant modulatory effect on neurotransmission in brain regions involved in autonomic and cardiovascular regulation.

NUCLEUS MEDIANUS (NM) STIMULATION DEPRESSES THE ACTIVITY OF SUPRAOPTIC (SON) NEUROSECRETORY NEURONS IN THE RAT. Ralph Nissen* and Leo Renaud (SPON: A.T. Tan), McGill Univ. Centre for Research in Neuroscience, Montreal, Quebec, H3G 1A4.

NM neurons project to the SON. Since both structures participate in hydromineral homeostasis, we utilized a transpharyngeal approach in urethane anesthetized male Long Evans rats to evaluate the influence of SON vasopressin (VP) and oxytocin (OXY)-secreting neurosecretory neurons. Following 1 Hz electrical stimulation (20 µs pulse, 10-50 µA, monopolar) in NM, 54/59 SON VP neurons displayed a transient (50-250 ms) inhibition (latency range 8-15 ms) whereas 20/20 OXY cells demonstrated a brief (13-33 ms) activation followed in 5/20 cells by a depression in activity. However, at 5-10 Hz stimulation all tested OXY cells were inhibited. Chemical activation of NM neurons with 0.2 µl infusions of 2-10 µM glutamate transiently depressed spontaneous firing in 12/15 VP and 2/2 OXY cells tested. Thus, NM appears to depress a majority of SON neurosecretory cells. Supported by FCAR and MRC.

REGIONAL ALTERATIONS IN HEXOKINASE ACTIVITY WITHIN RAT BRAIN DURING DEHYDRATION AND REHYDRATION. T.L. Krukoff and D.H. Vincent*. Dept. of Anatomy & Cell Biology, Faculty of Medicine, U. of Alberta, Edmonton, Canada, T6G 2H7.

Histochemical localization and photodensitometric quantification of the metabolic enzyme, hexokinase (HK), was used to study changes in metabolic activity in rat brain during development of (5 d) and recovery from (7 d) dehydration. In water deprived (WD) rats, HK activity increased after 2 d in the subfornical organ (SFO, 22%), nucleus circularis (NC, 36%), parvo- and magnocellular divisions of paraventricular nucleus (pPVH, 17%; mPVH, 46%), and supraoptic nucleus (SON, 46%). Activity in SFO declined to control levels at 3 d, but then increased. In pPVH, mPVH, and SON, activity was elevated until the end of the experiment. In NC, activity returned to control levels when rats were given water. In salt loaded (2% NaCl in water) rats, changes were like those in WD rats up to 2 d dehydration (SFO, 25%; NC, 20%; pPVH, 16%; mPVH, 38%; SON, 50%). Activity in SFO and pPVH returned to control levels after 3 d dehydration. In mPVH, SON, and NC, activity remained elevated but declined to control levels when salt-free water was provided. Results show that metabolic activity varies during periods of de- and rehydration and that it is necessary to study changes in brain metabolism daily to more fully understand the roles of discrete brain regions in regulation of body fluids. A COMPARISON OF SPINAL SEXUAL REFLEXES IN MALE AND FEMALE RATS. K.E. McKenna and S.K. Chung, *Dept. of Physiology, Northwestern Univ. Medical School, Chicago, IL 60611*

Mature Sprague-Dawley rats were anesthetized with urethane (1.2 g/kg, S.C.) and spinalized at midthoracic levels. Recordings were made from the pudendal and cavernous nerves and from striated perineal muscles. It was determined that the coitus reflex (the neural concomitants of sexual climax) could be elicited in both sexes by mechanical stimulation of the distal urethra. This reflex consists of highly regular, rhythmic bursts of activity in both the pudendal and cavernous nerves, with a period of 1-2 seconds and a total duration of 8-30 seconds. In the male, the bursts give rise to phasic penile erections (with flips and cups) and ejaculation. In the female, there are clonic contractions of the striated sphincters and phasic contractions of the vaginal wall. Anesthesia of the of the urethral mucosa with 1% lidocaine abolished the reflex elicited by mechanical stimulation. The coitus reflex could also be elicited by electrical stimulation of the pudendal sensory branch, which contains the afferent axons innervating the distal urethra. In both sexes, section of efferent nerves or ganglionic and neuromuscular blockade did not abolish the reflex, indicating that peripheral feedback is not essential for the rhythmic behavior. The coitus reflex could not be elicited prior to spinalization, indicating that this spinal pattern generator is under descending inhibitory control. Gonadectomy (> 1 month) did not attenuate or abolish the reflex in either sex.

We conclude that sexual climax is produced by a spinal pattern generator which is very similar in both sexes; is under descending control; is insensitive to gonadal steroids; and is activated by a simple peripheral stimulus of the distal urethra.

URINARY CATECHOLAMINES IN OBESE AND NONOBESE RHESUS MONKEYS. T. Wolden-Hanson*, J.W. Kemnitz, G.A. Davis and D. Hei*. Wisconsin Regional Primate Research Center and Neurosciences Training Program, University of Wisconsin-Madison, WI 53715

A role for the sympathoadrenal system in energy homeostasis has been clearly established, and abnormal activity of the sympathetic nervous system has been implicated in the pathogenesis of obesity. We have begun to evaluate the relation of catecholaminergic function to manifestations of obesity in a nonhuman primate model. Catecholamines were measured in urine of spontaneously obese (OB, n=8) and nonobese (NOB, n=5) rhesus monkeys during successive 2-day periods of *ad libitum* feeding (baseline), food deprivation and refeeding. Total urinary dopamine (DA), norepinephrine (NE) and epinephrine (E) were measured by HPLC with electrochemical detection. Food intake of OB was not significantly different from NOB and all subjects ate more ($\bar{X}$=26%) during the refeeding phase than during the baseline period ($p<.01$).

Averaged across all three periods, OB excreted 128% more DA, 66% more NE and 67% more E than NOB (p's<.03). DA excretion during deprivation was 62% of the baseline value ($p<.001$), while E increased by 12% during deprivation and then decreased to 63% of baseline during refeeding ($p<.01$). NE excretion during refeeding was 17% greater than baseline, but this change did not achieve statistical significance. There was no statistically reliable interaction of groups with feeding conditions for DA, NE or E. In summary, OB had greater catecholamine excretion than NOB but did not differ from NOB in their response to changes in feeding condition. The basis and functional significance of the striking decrease in DA excretion during food deprivation remain to be elucidated. (Supported by NIH grants RR00167 and GM07507.)

BOMBESIN MICROINFUSION INTO THE RAT PARAVENTRICULAR NUCLEUS INCREASES BLOOD GLUCOSE, FREE FATTY ACIDS, AND CORTICOSTERONE IN RATS. M.W. Gunion[1], Y. Taché[2], M.J. Rosenthal[1]*, S. Miller[1]*, B. Butler[1]*, and B. Zibl*. [1]GRECC, Sepulveda VAMC, Sepulveda, CA 91343; [2]CURE, Wadsworth VAMC, Los Angeles, CA 90073.

Bombesin-14 (0, 15, 50, 150 ng/300 nl; 0, 9, 27, 90 pmol) was infused into the hypothalamic paraventricular (PVN) or ventromedial nucleus (VMH), lateral hypothalamus (LH), or caudate nucleus (CN) using unilateral guide cannulae previously implanted under enflurane-methoxyflurane anesthesia. Blood samples (120 ul) were taken from the tail tip 0, 15, 30, 60, 90, and 120 min postinfusion. Infusions into the PVN, but not other sites, produced significant dose-related elevations in serum glucose and corticosterone. All three doses significantly increased glucose at this site; only the highest two significantly elevated corticosterone. Free fatty acids were reliably increased by infusions into all three hypothalamic sites, but not by CN infusions. PVN infusions had larger effects on free fatty acids than did VMN infusions; both were more effective than LH infusions. These results imply that the bombesin binding sites and immunoreactive terminals previously identified in these regions may be involved in the central regulation of circulating metabolic fuel levels and the pituitary-adrenal axis. 217.27

INTRACRANIAL MICROINFUSION OF PANCREASTATIN ELEVATES BLOOD GLUCOSE, FREE FATTY ACIDS, AND CORTICOSTERONE IN RATS. M.J. Rosenthal[1]*, M.W. Gunion[1], K. Tatemoto[2], and J.E. Morley[1] (SPON: H. Raybould). [1]GRECC, Sepulveda VAMC, Sepulveda CA 91343; [2]Dept. Psychiatry & Behavioral Sciences, Stanford University, Stanford CA 94305.

Pancreastatin, a novel peptide recently isolated from porcine pancreas, was infused into the lateral ventricle of acutely anesthetized rats, or into the third ventricle of conscious rats with chronic intracranial cannulae that had previously been implanted under enflurane-methoxyflurane anesthesia, or subcutaneously in conscious rats. Blood samples (120 ul) were taken from the tail tip 0, 15, 30, 60, 90, and 120 min postinfusion in all three experiments. Intraventricular microinfusion of pancreastatin significantly elevated blood glucose, free fatty acid, and corticosterone concentrations in a dose-related manner. None of these effects was seen after subcutaneous injection of the same doses. Centrally administered pancreastatin appears to produce its effects on glucose and free fatty acids through actions in the brain, and either the brain, the median eminence, and/or pituitary for corticosterone. (Supported by NS20660 [MG], AG04793 [MR], DK39188 &MH23861 [KT], NS22397 [JM], and Vet. Adm. research funds [MG, MR, JM].)

CORRELATION BETWEEN PLASMA INSULIN AND ADRENAL TYROSINE HYDROXYLASE ACTIVITY IN LIFELONG DIETARILY RESTRICTED MICE. B.Davis, D. Ingram, E. Bresnahan, T. McNeill, S. Felten and R. Hamill. University of Rochester School of Medicine, Rochester, NY 14642 and Gerontology Research Center, National Institute on Aging, Baltimore, MD 21224.

Neuroendocrine regulation of blood glucose involves a complex interplay between dietary intake, the sympathoadrenal system, the endocrine pancreas and insulin-and glucagon-sensitive peripheral tissues. The present study assessed neuroendocrine changes in the lifelong dietarily restricted mouse, an animal model of increased longevity. Six week old male C57Bl/6J mice were housed 4/cage at the vivarium facility of the Gerontology Research Center, Baltimore, Maryland. Mice were randomly assigned to AL (fed ad libitum every day throughout the experiment) or DR (fed ad libitum on Mon, Wed, and Fri throughout the experiment) groups. At twenty months of age, all mice were killed after 24 hours of access to food. Trunk bood was assayed for glucose, insulin and glucagon. Adrenals were processed for tyrosine hydroxylase (TH) activity. Our results show that plasma glucose levels of AL and DR mice were comparable. However, DR mice had insulin levels which were significantly higher than in the AL group. Adrenal TH activity also was significantly higher in the DR group, and there was a significant positive correlation between plasma insulin levels and adrenal TH activity. These results suggest that lifelong dietary restriction in the mouse has profound effects on the sympathoadrenal system which may modulate hormonal regulation of metabolism in this animal model.

OBSERVATIONS OF EMETIC MECHANISMS IN THE FERRET (Mustela putorius furo). N.L. Strominger, A.P. Knox, A.H. Battles* and D.O. Carpenter. Dept. of Anatomy, Cell Biology and Neurobiology, Albany Medical College, Albany, NY 12208.

Recently the ferret has been used to study mechanisms of emesis. This species has a low emetic threshold to chemotherapeutic agents and radiation. To further study the suitability of the ferret as an animal model, a series of experiments was conducted to determine the ferrets' sensitivity to some commonly used emetic agents. The data were compared with that obtained from other species.

Our findings confirm observations indicating that ferrets are variably responsive to the classic emetic agent apomorphine, a D_2 agonist [Andrews et al., '86; Gylys et al. '88]. Systematic i.v. injections of apomorphine (.005-1.0 mg/kg) in 3 ferrets elicited emesis inconsistently. Dogs invariably vomit after .25 mg/kg of apomorphine; monkeys are unresponsive to high doses. Leu-enkephalin (0.01-1.0 mg/kg) injected i.v. never elicited emesis in the ferrets; it is very potent in dogs. Subcutaneous injections (1mg/kg) of apomorphine in ferrets elicited emesis in some but not all animals. Bilateral subdiaphragmatic vagotomy rendered a ferret refractory to $CuSO_4$ but did not alter sensitivity to subcutaneous apomorphine.

Data suggest that ferrets are less sensitive than dogs to i.v. emetics but more sensitive than monkeys.

PHARMACOLOGY OF THE ACETYLCHOLINE-INDUCED INCREASE IN THE SHORT-CIRCUIT CURRENT ACROSS SWINE TRACHEAL EPITHELIUM. Jerry M. Farley, J. Greg Adderholt* and Terry M. Dwyer. Dept. of Pharmacol. & Toxicol. and Dept. of Physiol. & Biophys., Univ. Miss. Med. Ctr., Jackson, MS 39216.

Mucous gland cells secrete mucus in response to stimulation of muscarinic receptors by acetylcholine (ACh). The mucus must be hydrated after release and in order to accomplish this the surface cells and possibly gland cells secrete water to permit hydration. Secretion of water should involve ion transport into the lumen of the trachea. We have examined this possibility by pharmacological modification the ACh-induced increases in short circuit current measured using the Ussing chamber technique. ACh is most likely stimulating gland cells rather than surface epithelial cells. The increase in short circuit current (I_{sc}) induced by ACh is dose-dependent. Cumulative dose-response curves peak at 10^{-4} M giving a peak I_{sc} of ~18 uA (1.26 cm^2 area). The response to a single dose of ACh (10^{-5} M) causes an increase in I_{sc} which has a fast rising phase and a more slowly developing phase. The fast rising phase can be blocked by the addition of tetraethylammonium (TEA, 10-30 mM) to the serosal solution. TEA also caused a reduction in the resting I_{sc} of 4-10 uA. TEA had no effect when added to the mucosal solution. Bay-K-8644, a calcium channel agonist, applied to the serosal surface appears to cause an increase of about 30% in the I_{sc} induced by ACh. These data are consistent with the existence of potassium channels on the serosal but not mucosal surface of the gland cells. This finding along with earlier findings suggesting that Cl^- channels exist in the mucosal membrane suggests that these cells are involved in water transport. The effects of Bay-K-8644 suggest the possible involvement of calcium channels in the increase in short circuit current. (This work was supported by the Cystic Fibrosis Foundation and the Miss. Lung Assoc.)

PENTOBARBITAL-INDUCED CHANGES IN MEDULLARY RESPIRATORY-RELATED UNIT DISCHARGE PATTERNS AND DIAPHRAGM EMG IN CHRONICALLY INSTRUMENTED GUINEA PIGS. F.-C.T. Chang, R.E. Foster and R. Olaya*. USAMRICD, APG, MD 21010-5425.

Effects of pentobarbital (35 mg/kg) on respiration were studied in guinea pigs chronically instrumented to allow concurrent recording of bulbar respiratory-related unit (RRU) activity, diaphragmatic EMG (DEMG) and ECoG. Recordings were made before and throughout the course of induction of, and recovery from, anesthesia. The most dramatic effects were seen during the development of pentobarbital-induced bradypnea. During that period, and concomitant with discrete alterations in ECoG spectral components, the temporal organization of RRU and DEMG activities underwent spectacular transformations from that of a variable wakefulness pattern (Chang and Foster, Neurosci. Abst., 2:82.7 1986) to a rhythmic pattern characterized by a) invariant periodicity; b) reduced cycle frequency (30-50% of control); c) increased burst duration and spike frequency; d) elevated threshold and diminished response magnitude to alveolar CO_2 loading (ramp, 2.5%/5-min.); and e) diminished T_I/T_E ratio in inspiratory-related units. In conclusion, this study offers, for the first time, direct evidence from functionally and structurally intact preparations that respiratory system components are either inactivated or profoundly altered by anesthesia. The significance of this study, as related to the possibility of different rhythmogenetic control mechanisms underlying sleep and wakefulness respiratory drives, will be discussed.

217.32

TIME OF NIGHT EFFECT ON RESPIRATORY SINUS ARRHYTHMIA IN VICTIMS OF THE SUDDEN INFANT DEATH SYNDROME (SIDS). V.L. Schechtman, R.M. Harper, K.A. Kluge*, A.J. Wilson* and D.P. Southall*. Brain Res. Inst. and Dept. of Anatomy, UCLA, Los Angeles, CA 90024; Dept. of Medical Physics & Clinical Engineering, Sheffield University, Sheffield, England; Cardiothoracic Inst., Brompton Hospital, London.

Respiratory sinus arrhythmia (RSA), variation in heart rate from respiratory sources, is known to be diminished in infants who later succumb to SIDS. Since infants show distinct circadian periodicities in cardiac rate and variability measures after the first month of life, we determined if the reduced RSA in SIDS victims is present throughout the night, or only at particular points during the night. Extent of RSA during quiet sleep (QS), rapid eye movement sleep (REM), and waking (AW) was determined during three time periods (7-11 pm, 11 pm - 3 am, and 3-7 am) in 7 infants 40 to 65 days of age who subsequently died of SIDS and in 21 age-matched control infants. During REM, RSA was diminished in the SIDS victims in all three time periods. During AW, the SIDS victims showed diminished RSA only in the first two periods of the night; from 3-7 am there was no significant difference in extent of RSA. These results confirm previous findings of a disparity in cardiac measures between the 7 pm - 3 am period and the final four hours of the night in SIDS victims, suggesting the possibility of circadian influences operating to differentiate infants at risk for SIDS from other infants. Supported by HD 22695.

INTERACTIONS BETWEEN VERAPAMIL INJECTION TIME AND MORPHINE EFFECTS ON PHYSIOLOGICAL PARAMETERS IN RATS. F. Ford-Rice*, A. Della Puppa*, F. Snyder*, E. Cone* and E.D. London (SPON: W. Pickworth). Neuropharmacology Laboratory, NIDA ARC, Baltimore, MD 21224.

Verapamil, a calcium channel antagonist, has been shown to facilitate morphine-induced analgesia (Benedek, G. and Szikszay, M., Pharmacol. Res. Comm., 16:1009, 1984) while antagonizing morphine-induced respiratory depression in rats (Szikszay, M. et al., J. Pharmacol. Exp. Ther., 238:192, 1986). Respiratory and cardiovascular effects of s.c. doses of verapamil injected simultaneously with and 10, 30 and 60 minutes before morphine were assessed in 64 partially restrained, awake Fischer-344 rats. Morphine alone did not significantly affect mean arterial blood pressure, but did produce hypoxia, hypercapnia, acidosis and marked tachycardia. Morphine, however, when given together with verapamil facilitated verapamil-induced hypotension. Verapamil alone did not affect arterial blood gases, pH, or cardiac rhythm, but verapamil in combination with morphine increased morphine-induced acidosis and greatly attenuated morphine-induced tachycardia. Furthermore, verapamil suppressed morphine-induced hypercapnia only when injected simultaneously with morphine. The present findings support speculation that calcium ions and calcium channel blockade influence opioid activities, but further studies are needed to establish the relevance of regulation of opioid activity by calcium antagonists.

OPIATES, ENDORPHINS AND ENKEPHALINS: ANATOMY AND CHEMISTRY I

218.1

INTERACTIONS OF OPIOID PEPTIDE AND CATECHOLOAMINE NEURONS IN THE RAT HYPOTHALAMUS. M.D. Fitzsimmons, J.A. Olschowka, and G.E. Hoffman[1]. Dept. of Neurobio. and Anat., Univ. of Rochester, Roch NY 14642 [1]Dept of Physio., U. of Pittsburgh, Pgh PA 15261

A great deal of evidence suggests that opiate agonists exert their effect on prolactin secretion by attenuating an inhibitory influence of dopamine neurons in the hypothalamus. Our goal in these experiments was to see if endogenous opioid peptide-containing neurons interact directly with hypothalamic dopamine neurons which regulate prolactin release. Using both light and electron microscopic double-labeling techniques, we have found evidence for direct synaptic interaction between these systems.

The tissue, obtained from Sprague-Dawley rats, was processed by two consecutive immunocytochemical procedures (ABC-Vector Labs). In the first iteration, the primary antibody was directed against a representative of one of the three major opioid peptide families: ACTH (proopiomelanocortin or POMC), Dyn A 1-17 (prodynophin), or mEnk (proenkephalin). The first reaction is distinguished from the second by adding nickel sulfate which produced a blue-black reaction product. The second primary antibody was directed against tyrosine hydroxylase, a marker for catecholamine neurons. Thus, the opioid peptide neurons were labeled blue-black and the dopamine neurons were labeled brown. Some sections, specially prepared for electron microscopy, were cut to 1-2 μm, photographed, reembedded, cut to 70-100 nm, and observed under an electron microscope. The color photographs were used as a reference to determine the chemical nature of electron dense structures.

Light microscopic analysis suggests that neurons from all three opioid peptide families contact dopamine neurons in the hypothalamus (both A12 and A14). Qualitatively, A14 neurons appear to be more frequently contacted than A12. It also appears that prodynorphin and proenkephalin neurons interact more frequently with dopamine neurons than do POMC neurons. Quantitative studies are now underway. Electron microscopic observations have confirmed that apparent contacts correspond to synapses. Supported by NS 23591.

218.2

SUBPOPULATIONS OF HYPOTHALAMIC ENKEPHALIN NEURONS ARE DIFFERENTLY REGULATED BY ADRENERGIC STIMULI. S.R. George, L. Roldan* and D.A. Haas. Departments of Medicine and Pharmacology, University of Toronto, Toronto, ONT M5S 1A8, Canada.

Enkephalin neurons are present in many areas of the hypothalamus and likely subserve a variety of functions there. We have examined the effects of adrenergic manipulation in male rats on Met-enkephalin immunoreactivity in hypothalamus and in neurointermediate pituitary. Met-enkephalin was quantified by sensitive radioimmunoassay. Depletion of hypothalamic catecholamines by reserpine resulted in an increase of Met-enkephalin concentrations in neurointermediate pituitary ($p<0.001$). Treatment with the alpha-adrenergic agonist methoxamine resulted in depletion of Met-enkephalin from neurointermediate pituitary ($p<0.01$) and an augmentation of Met-enkephalin in hypothalamus ($p<0.05$). This increase was shown to be confined to the median eminence ($p<0.01$). Selective depletion of brain noradrenalin/adrenalin by 6-hydroxydopamine, with protection of dopaminergic and serotonergic neurons by benztropine and fluoxetine respectively resulted in a reduction of Met-enkephalin in median eminence only ($p<0.05$). These results suggest that alpha-adrenergic mechanisms have a role in attenuating Met-enkephalin levels in neurointermediate pituitary, and in augmenting Met-enkephalin levels in median eminence. Whether these effects result through alterations of synthesis and/or release of the enkephalins remain to be shown.

218.3

NICOTINE ALTERS MET-ENKEPHALIN NEURON ACTIVITY IN DISCRETE AUTONOMIC NUCLEI. G.R. Van Loon, K. Pierzchala*, L. Marson and M. Palkovits*. VA Medical Center and Univ. of Kentucky, Lexington KY 40511 and Semmelweis Univ., Budapest, Hungary.

Nicotine acts in CNS to regulate autonomic outflow, however the pathways and mechanisms of its action are poorly understood. Endogenous opioids present in autonomic nuclei modulate sympathoadrenal and cardiovascular function. Recent studies suggest an interaction between brain nicotinic receptors and endogenous opioid peptides. We examined the effects of a single systemic injection of nicotine on levels of native and cryptic Met-enkephalin (MENK) in discrete regions of hypothalamus, brain stem and spinal cord. Nicotine decreased native MENK in caudal ventrolateral medulla, intermediolateral column of spinal cord and central amygdala, which may suggest an increase in release of MENK. A decrease of cryptic with no change in native MENK was observed in central grey, indicating increased processing of the larger peptides to the native form. No changes were found in hypothalamic nuclei or NTS in either native or cryptic MENK. These data suggest that nicotinic receptors modulate autonomic function by altering the release of native MENK and/or the synthesis and processing of proenkephalin A.

STRIATAL CONCENTRATION OF THE TRIPEPTIDE, TYR-GLY-GLY, PROVIDES AN INDEX OF ENKEPHALIN RELEASE IN VIVO. A.A. Houdi* and G.R. Van Loon. VA Medical Center and Department of Medicine, University of Kentucky, Lexington, KY 40511.

Enkephalins function putatively as neurotransmitters or neuromodulators in brain. Although considerable is known regarding their localization, mechanisms of biosynthesis, and changes in regional concentration, methods of assessing their turnover rates have not been generally available. Recently, Schwartz, Llorens-Cortes and colleagues have described the use of steady-state levels of Tyr-Gly-Gly (YGG), an extraneuronal metabolite of proenkephalin A-derived peptides, as an index of changes in enkephalin release in vivo. In the present study using a sensitive RIA with antiserum raised in our laboratory, we found regional variation in YGG levels in rat brain, highest in striatum and lowest in cerebral cortex. Inhibition of YGG synthesis by icv treatment with the enkephalinase inhibitor, thiorphan, produced a 50 per cent reduction in rat striatal YGG, whereas aminopeptidase inhibition with bestatin produced a 4-fold increase in striatal YGG. To confirm the use of this index under conditions of altered neuronal activity, we examined the effects on YGG of chronic treatment with haloperidol which is known to increase levels of Met-enkephalin and proenkephalin A mRNA. Haloperidol increased striatal YGG by 45 per cent, an effect consistent with increased enkephalin release.

VARIATION IN ß-ENDORPHIN AND CHOLECYSTOKININ FOLLOWING ARCUATE NUCLEUS LESION OR DEAFFERENTATION. G.J. Lavigne[1,2] and G.P. Mueller[1]. Dept. Physiol., USUHS, Bethesda, MD 20814[1]; Méd. dent. et CRSN, Univ. Montréal, H3C 3J7, Canada[2].

Recent evidence from several laboratories indicates that opioids and cholecystokinin octapeptide (CCK-8) function as natural antagonists in their effects on nociception and other behavior. Little is known, however, about the biochemical mechanisms which underlie these observations. In this study we assessed in rats the influence of brain ß-endorphin (ß-END) denervation on the content of immunoreactive (i) ß-END in the hypothalamus (HYP) and of iCCK in the subcollicular-periaquaductal gray (sc-PAG). Electrolytic lesion (EL, 3 mA, 15 sec) of the HYP arcuate nucleus, the origin of a major proportion of brain ß-END neurons, resulted in a significant reduction ($p<0.01$) in the HYP iß-END by 7 days (from mean control value of 20.1±1.6 (n=10) to 13.5±1.0 fm/mg (n=20)), while sc-PAG iCCK was significatively increased ($p<0.025$ from 63.5±3.4 to 77.8±3.4 fm/mg). However, levels of iCCK in sensory cortex and striatum, sites not well innervated by arcuate ß-END neurons, were unaffected by the lesion. In a different experiment, the same observations were replicated at 7 days; however, nonsignificant trends were observed at 14 and 21 days. HYP deafferentation (Halasz knife) produced a similar pattern of responses, though the magnitude of the effects was greater when compared to those of EL. Although the exact mechanisms through which ß-END and CCK may interact remains to be determined, the present findings provide evidence for a biochemical relationship between these two peptide systems. (G.J.L. supported by the FRSQ, Québec, Canada.)

EFFECT OF HYPERPROLACTINEMIA ON IMMUNOREACTIVE BETA-ENDORPHIN CONCENTRATIONS IN DISCRETE HYPOTHALAMIC REGIONS. L.P. Kapcala and P.M. Wise. Depts. of Medicine and Physiology, U. Maryland, Baltimore, MD 21201

Hyperprolactinemia (hyperPRL) inhibits pulsatile LH secretion. Previous work has suggested that enhanced opioid tone may be a mechanism whereby hyperPRL inhibits gonadotropin secretion. Therefore, we tested whether hyperPRL alters ß-endorphin concentrations in discrete hypothalamic regions. Adult rats were ovariectomized (day 0). Rats were treated with ovine PRL (4 mg/kg, sc, every 8h) or vehicle on days 4-6. Rats were decapitated on day 6. Extracts from discrete hypothalamic regions (medial preoptic nucleus [MPN], paraventricular nucleus [PVN], median eminence [ME] and arcuate nucleus [AN]) were assayed for IR-ß-endorphin.

Mean ± S.E. IR BetaEndorphin (pmole/mg protein)

	MPN	AN	PVN	ME
Control	11.7±1.1	4.7±0.5	3.1±0.6	7.1±0.7
oPRL	6.3±0.7*	5.5±0.3	6.2±1.0*	5.6±0.7

*Significantly different from control ($p < 0.01$)

Conclusion: changes in hypothalamic β-endorphin concentrations may play a role in hyperPRL-induced suppression of pulsatile LH release. (NIH NS23317 [LPK]; HD15955 & AG02224 [PMW])

BETA-ENDORPHIN IMMUNOREACTIVE CELLS IN RATS PRENATALLY EXPOSED TO ETHANOL. R.A. Baker and W.J. Shoemaker. Center for Neurological Sciences and Dept. of Psychiatry, Univ. of Conn Hlth. Center, Farmington, CT 06032.

Previous results have shown significantly increased levels of immunoreactive Beta-Endorphin (B-End) in offspring of rats prenatally exposed to ethanol (Shoemaker et al. 1983). Using pregnant rats fed either an alcohol containing diet, an isocaloric pair-fed control diet or standard chow, we confirmed the increase in B-End levels using RIA. In order to determine whether the alcohol induced increase in peptide level results in a concomitant change in the number of B-End containing cells, we have examined the number of B-End cells in the mediobasal hypothalamus (MBH) with immunocytochemistry. Plotting the number of immunoreactive B-End cells in 40 micron sections, our preliminary evidence indicates a 40% increase in the number of immunoreactive cells: counting every 5th section, we find 8415 cells in control, vs. 11880 cells in prenatal ethanol exposed animals. In rats prenatally exposed to ethanol, mapping of positively stained cells indicates that the rostro-caudal extent of stained cells is similar to control animals, but the major difference is that the ethanol exposed offspring has an increase in stained cells in the dorso-lateral aspect of the MBH.

STIMULATION OF β-ENDORPHIN RELEASE FROM RAT HYPOTHALAMUS *IN VITRO*. D.M. Bronstein and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Cell bodies of neurons containing β-endorphin (βE) and other pro-opiomelanocortin (POMC)-derived peptides are localized primarily in the arcuate nucleus of the mediobasal hypothalamus and project to a variety of brain regions. Little is known about the neural systems that regulate POMC neurons in the arcuate or which neurotransmitters affect βE release from these cells. The goal of this study was to examine the effects of various chemicals on the release of βE-immunoreactive (βE-ir) peptides from hypothalamic tissue *in vitro*. Hypothalamic blocks (ca. 100 mg) were dissected from adult male rats, cut into 4-6 pieces, and incubated in a Krebs-Ringer-Bicarbonate (KRB) buffer at 37°C in O_2/CO_2 (95:5%). Following a 45 min equilibration period, tissue was transferred every 10-15 min to normal KRB media or to KRB containing one of several putative neurotransmitters or secretagogues. After incubation, media were immediately frozen on dry ice for subsequent determination of βE-ir content. When hypothalami were incubated with high concentrations of K^+ (55 mM), 2-3 fold more βE-ir was detected in the media compared to that found in normal KRB media. Corticotropin releasing factor (CRF), 5-hydroxytryptamine (5-HT) and vasopressin each produced dose-dependent (10^{-8}, 10^{-7}, 10^{-6} M) increases in βE-ir release into the media. Dopamine (10^{-6} M) inhibited basal release of βE-ir to virtually non-detectable levels and completely blocked the effects of 55 mM K^+. It is interesting that the same chemicals which stimulate βE-ir release from hypothalamic tissue also are potent secretagogues of βE from corticotrophs of the anterior pituitary gland.

INCREASES IN PRODYNORPHIN PEPTIDES FOLLOWING CHRONIC MORPHINE TREATMENT. K.A. Trujillo, D.M. Bronstein and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109.

The discovery of endogenous opioid peptides and receptors led to early speculations that opiate tolerance and dependence might result from changes in endogenous opioid systems. It was thought that chronic treatment with opioids would lead to a down-regulation of these systems, resulting in decreases in opioid peptides or receptors. Such speculations have recieved little experimental support; chronic treatment with opiate drugs has been found to have little effect on pro-opiomelanocortin or proenkephalin peptides, or on opioid receptors.

In the present studies, we examined the effects of chronic morphine on prodynorphin (PRODYN) peptides in forebrain and midbrain regions of the rat. Animals were implanted subcutaneously with morphine or placebo pellets under ether anesthesia and sacrificed 1, 3 or 7 days after the start of treatment. Dorsal striatum (caudate-putamen), ventral striatum (nucleus accumbens and olfactory tubercle), substantia nigra and ventral tegmental area were obtained and radioimmunoassayed for Dyn A 1-17, Dyn A 1-8, Dyn B, and alpha neo-endorphin. Morphine caused an increase in all four PRODYN peptides at 7 days, averaging 60-70% above placebo in the dorsal striatum, and 20-30% above placebo in ventral striatum. Assays on midbrain tissue have yet to be completed, however preliminary data suggests no consistent changes. These results suggest that PRODYN peptides may be involved in some of the long-term consequences of opiate treatment, including tolerance and dependence. It remains to be determined if the observed changes result from increased synthesis or decreased release of these peptides.

THE ANTIESTROGEN TAMOXIFEN ALTERS THE PITUITARY CONTENT OF DYNORPHINS IN THE FEMALE RAT. S.Spampinato and S. Ferri*. Inst. of Pharmacol., Univ. of Bologna, Bologna, Italy.

In the anterior pituitary(AP), immunoreactive dynorphin (ir-dyn) has been detected within gonadotroph cells and is regulated by ovarian factors(Spampinato et al., Life Sci., 38:403, 1986). In the neurointermediate lobe (NIL), dynorphins are colocalized with vasopressin. In this study, we have employed the antiestrogen tamoxifen (TAM) to obtain further insight into how estrogens regulate the pituitary content of ir-dyn A and ir-dyn B (evaluated by RIA). In intact adult female rats, TAM (50 µg/day, sc injected for 7 days) caused an increase of AP ir-dyn A(0.29±0.05 vs 0.15±0.03 fmol/µg prot, $p<0.01$) and ir-dyn B(0.31±0.06 vs 0.14±0.01, $p<0.01$). Estradiol benzoate(EB, administered for 7 days via sc implants) fully prevented this increment and by itself caused a significant reduction of both peptides. As regards the NIL, the levels of ir-dyn A and ir-dyn B were not changed in rats exposed for 7 days to TAM or EB. Interestingly, a 14-day treatment with TAM markedly reduced either ir-dyn A(2.81±0.47 vs 7.54±1.17, $p<0.01$) than ir-dyn B(5.14±0.32 vs 9.83±0.8, $p<0.01$). Although this effect was not observed in ovariectomized rats, it was not prevented by EB. This study shows that TAM alters AP dynorphins acting as antiestrogen. More complex mechanisms underlie the effects elicited on NIL.

RELEASE OF ENDOGENOUS OPIOIDS DISPLACES [^{3}H]-DIPRENORPHINE FROM RAT HIPPOCAMPUS. J. F. Neumaier, J. N. Wiemann*, and C. Chavkin, Dept. of Pharmacology, Univ. of Washington, Seattle, WA 98195.

Release of endogenous dynorphin and enkephalin peptides was detected by displacement of the opioid antagonist, [^{3}H]-diprenorphine ([^{3}H]-DPN), from rat hippocampal slices. Freshly dissected slices (500 μm) were equilibrated in oxygenated Kreb's bicarbonate buffer in individual culture wells. All wells contained peptidase inhibitors (bestatin, thiorphan, and captopril). Slices were incubated with 1 nM [^{3}H]-DPN for 30 min and then homogenized and counted or frozen for autoradiographic processing. Non-specific binding was determined in the presence of 10 μM naloxone. Depolarization by 50 mM KCl significantly reduced specific [^{3}H]-DPN binding by 30%. 10 μM veratrine induced a similar displacement. The displacement of binding by both KCl and veratrine was calcium dependent and blocked by 10 mM Mg^{++}. The magnitude of the KCl-induced displacement was diminished by ommission of the peptidase inhibitors. KCl-induced displacement of [^{3}H]-DPN binding was transient; addition of KCl 15 min prior to adding [^{3}H]-DPN caused maximal competition. None of the experimental compounds reduced [^{3}H]-DPN binding in membrane homogenate assays. Preliminary autoradiography and densitometric analysis showed that KCl depolarization reduced [^{3}H]-DPN binding in CA3 and the dentate gyrus. These results suggest that depolarization leads to a calcium-dependent release of a peptidase-sensitive material that displaces specific [^{3}H]-DPN binding (presumably dynorphin and enkephalin peptides). Supported by NS-23483 and GM-07266.

DEPOLARIZATION DISPLACES [^{3}H]-DITOLYLGUANIDINE FROM HALOPERIDOL-SENSITIVE SIGMA RECEPTORS IN RAT HIPPOCAMPUS. C. Chavkin and J. F. Neumaier. (SPON: L. Halpern) Dept. of Pharmacol., Univ. of Washington, Seattle, WA 98195.

We examined the effects of ionic conditions and tissue depolarization on sigma receptors by studying [^{3}H]-propyl-3-(3-hydroxyphenyl)-piperidine ([^{3}H]-3-PPP) and [^{3}H]-ditolylguanidine ([^{3}H]-DTG) binding. In rat brain homogenates, binding of 1 nM [^{3}H]-3-PPP was reduced by NaCl with an IC_{50} of 8 mM, whereas [^{3}H]-DTG binding was insensitive to NaCl. LiCl, choline chloride, and KCl did not reduce binding significantly at concentrations below 100 mM. $CaCl_2$ or $MgCl_2$ (10 mM) reduced binding of both radioligands by 30%. Previous physiologic studies demonstrated agonist properties of 3-PPP and antagonist properties of DTG; our current results suggest that sodium sensitivity in binding assays may differentiate agonists from antagonists at the sigma receptor as it does for the μ and ∂ opioid receptors.

Freshly dissected hippocampal slices (500 μm) were equilibrated in oxygenated Kreb's bicarbonate buffer in individual culture wells containing peptidase inhibitors (bestatin, thiorphan, and captopril), incubated in 3 nM [^{3}H]-DTG for 30 min, and then homogenized and counted. Nonspecific binding was defined by 10 μM haloperidol. Depolarization by 10 μM veratridine or 50 mM KCl reduced specific [^{3}H]-DTG binding by 65%. Removal of $CaCl_2$ and the addition of 10 mM $MgCl_2$ blocked the depolarization-induced displacement by 50%. 10 μM tetrodotoxin completely blocked the veratridine effect. The magnitude of the depolarization-induced displacement was diminished by ommission of the peptidase inhibitors. Depolarization either releases an endogenous sigma ligand or directly affects properties of the sigma receptor (e.g. internalization). The calcium-dependence and peptidase-sensitivity of the [^{3}H]-DTG displacement supports the former interpretation. Supported by NS-23483 and GM-07266.

HIPPOCAMPAL TRANSPLANTS EXPRESS ENKEPHALIN BEFORE DYNORPHIN IMMUNOREACTIVITY. J.F. McGinty, P. Tandon and H.A. Tilson. Dept. Anatomy & Cell Biology., East Carolina U. Sch. of Med., Greenville, NC 27858 and Lab of Integrative & Molecular Neuroscience, NIEHS, NIH, Research Triangle Park, NC 27709.

Impaired acquisition of a spatial working memory task after colchicine-induced destruction of dentate granule cells (Walsh et al. Brain Res. 398:23, 1986) is ameliorated by fetal (E17-18) hippocampal cell suspension grafts (Tandon et al. Brain Res. submitted). In this study, we investigated the histochemical organization of the mossy fiber system in similar hippocampal grafts after placement in the dorsal or ventral hippocampus of rats treated 3 weeks previously with an intradentate colchicine or artificial cerebrospinal fluid (ACSF) injection. Four, 6, or 11 weeks after grafting, the rats were perfused; serial sections through the transplant were cut and Nissl-stained, Timm-stained (for zinc), or immunoperoxidase-stained with anti-dynorphin A 1-8 (DYN) or met-enkephalin (ENK) antiserum. There was no difference in the degree of transplant survival in colchicine or ACSF-treated rats. In 1 month old transplants, Timm-stained and ENK-immunoreactive fibers had formed clusters around presumptive pyramidal cells; however, no DYN immunoreactivity (IR) was present in adjacent transplant sections. In 6 and 11 week old transplants, ENK-IR and DYN-IR were present in fiber clusters presumed to be mossy fibers. To support the conclusion that DYN-IR and ENK-IR were present in grafted mossy fibers, in situ hybridization histochemistry is now being used to identify dentate granule cells in the grafts.

CORTICOTROPIN RELEASING-HORMONE (CRH) IN OLD WORLD NONHUMAN PRIMATE HYPOTHALAMUS, PLACENTA AND LATE PREGNANCY PLASMA. A.N.Margioris*, M.Grino* and G.P.Chrousos(SPON: D.Symmes). Developmental Endocrinology Branch, NICHD, NIH, Bethesda, Md, 120892.

CRH is synthesized and secreted by human placenta. We have found that the CRH gene is also expressed in nonhuman primate placentae. In this study we examined the post-translational processing of CRH in Rhesus monkey (Macaca mulatta) placenta and hypothalamus. In gel chromatography of hypothalamic extracts, all IR-CRH eluted in one peak with a Kav corresponding to that of hCRH. Gel filtration of placental extracts showed that the bulk of IR-CRH eluted in two peaks. The first peak coeluted with the high mol wt IR-CRH present in human placental extracts and the second exhibited a Kav between that of the high mol wt CRH and synthetic hCRH. Ion exchange chromatography showed that the IR-CRH present in monkey placental extracts consisted of at least three different forms. IR-CRH was also present in the plasma of pregnant rhesus monkeys the mean concentration of which was 31.3±4.6 pg/mL (n=7); on gel chromatography, the bulk of plasma IR-CRH coeluted with hCRH. In conclusion: The IR-CRH present in nonhuman primate placentae consisted of multiple mol wt forms, while the bulk of IR-CRH in the plasma of pregnant primates and in the hypothalamus of nonpregnant monkeys had the mol wt of synthetic hCRH. These findings suggest that the post-trasnlational modifications of nonhuman primate placental CRH differ from those in hypothalamus but are similar to those described in human placenta.

EXPRESSION OF PREPROENKEPHALIN mRNA BY CULTURED ASTROCYTES AND NEURONS. M.H. Vilijn[2*], P.J.-J. Vaysse[2*], R.S. Zukin[2] and J.A. Kessler[1,2], (SPON: P.G. Model) Departments of Neurology[1] and Neuroscience[2], Albert Einstein College of Medicine, 1300 Morris Park Ave., Bronx, NY 10461, USA.

Astrocytes are the most numerous cell type in the brain and appear to subserve multiple functions. The present study reports that cultured neonatal astrocytes from rat hypothalamus, striatum, frontal cortex, hippocampus and cerebellum contain significant levels of preproenkephalin mRNA (PPE mRNA). Cultured cells were identified as astrocytes on the basis of morphology, expression of immunoreactivity for glial fibrillary acidic protein (GFAP) and absence of immunoreactivity for fibronectin, for galactocerebroside or for the monoclonal antibody A_2B_5. PPE mRNA levels determined by Northern blot analysis were significant in astrocytes cultured from all of the brain areas. Levels of PPE mRNA were significantly higher in hypothalamic astrocytes compared to astrocytes derived from other brain regions and were comparable to levels present in cultured embryonic hypothalamic and striatal neurons. Prodynorphin mRNA was not detectable in cultured astrocytes, although cultured hypothalamic neurons contained substantial levels of this mRNA. Thus, glia do not express all opioid peptide genes during development. These observations suggest that expression of the PPE gene by astrocytes may play a role in development of the brain.

218.16

THE LOCALIZATION OF PRODYNORPHIN AND PROENKEPHALIN mRNAs IN THE RAT ADRENAL GLAND BY *IN SITU* HYBRIDIZATION. R. Day, M. K.-H. Schafer*, J. Douglass*, M.R. Ortega*, S.J. Watson and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109. Vollum Institute for Advanced Biomedical Research, The Oregon Health Sciences University, Portland, Oregon, 97201.

Pro-enkephalin (PE) and pro-dynorphin (PD) are both known to exist in the adrenal gland. The better studied of the two, PE, has been localized by immunocytochemistry and *in situ* hybridization in various species. In the rat adrenal, low levels of peptides and mRNA have made similar studies difficult. Less is known about PD in the rat adrenal. Previous studies have demonstrated high levels of PD mRNA by Northern analysis in the rat adrenal (Civelli et al., 1985, *Proc. Natl. Acad. Sci. USA*, 82, 4291). Our study aims to answer a few basic question about these two mRNAs. How are they distributed in the rat adrenal? Are they co-localized or are there distinct cells which synthesize and process their precursors? Our approach is to use high specific activity ^{35}S labelled cRNA and cDNA probes to PE and PD to visualize their mRNAs by *in situ* hybridization. Our results clearly show a patchy distribution of PE mRNA in the chromaffin cells of the adrenal medulla. PD mRNA, however, is localized mainly in the adrenal cortex. Low levels of PD mRNA are also observed in cells of the medulla. It is not yet known whether these medullary cells are co-localized with PE mRNA. Further studies are underway to elucidate this point.

218.17

THE DISTRIBUTION OF PRODYNORPHIN mRNA THROUGHOUT THE RAT BRAIN: A SEMI-QUANTITATIVE MAPPING STUDY. M.K.-H. Schafer*, J.P. Herman, R. Day, J. Douglass*, H. Loats, H. Akil and S.J. Watson (SPON: H. Akil). Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109, Vollum Institute for Advanced Biomedical Research, The Oregon Health Sciences University, Portland, OR 97201 and LOATS Associates Inc., Westminster, MD 21157.

^{35}S labeled cRNA probes of high specific activity were generated from prodynorphin cDNA subclones. Prodynorphin mRNA was localized in serial frozen sections throughout the rat brain by in situ hybridization. Autoradiograms were analyzed by dark field microscopy and prodynorphin positive neurons mapped according to the coordinate system of Paxinos and Watson. Semi-quantitative analyses of different prodynorphin containing regions were performed using a LOATS image analysis system. We will report the detailed distribution of prodynorphin mRNA in the rat brain and compare it with proenkephalin mRNA in certain brain areas. Furthermore, a quantitative comparison of prodynorphin mRNA content between different neuronal cell types will be made.

218.18

LOCALIZATION AND REGULATION OF RAT KIDNEY ENKEPHALINASE: AN *IN SITU* HYBRIDIZATION ANALYSIS. S. Burke*, L. Hersh, S. Unnithan*, R. Chipkin, M.K.-H. Schafer*, A. Mansour and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, University of Texas Health Sci. Center, Dallas, TX and Shering Corp., Bloomfield, NJ.

Enkephalins can be hydrolyzed into inactive fragments by a variety of peptidases. One of these enzymes, Enkephalinase, hydrolyses the Gly^3Phe^4 amide bond. Enkephalinase has been purified and cDNA clones isolated by Malfroy for both rat brain and kidney. The analysis of these cDNAs indicates that the Enkephalinase enzyme is identical in kidney and brain.

In this study we report the use of a 1.6 Kb clone isolated from a rat kidney lambda gt11 library for localization and regulation of mRNA in rat kidney. Kidney was chosen for initial studies, as Enkephalinase is 100 times more abundant in kidney than in brain. By both immunocytochemistry and *in situ* hybridization we have found the enzyme and message to be mainly localized in the distal tubules. We are studying three types of pharmaceutical manipulations on the rat: Gentamicin (for a general tubular insult), Naltrexone and a Shering compound (SCH 32615; an Enkephalinase inhibitor). Data to date suggests that naltrexone has little or no effect on mRNA levels. Gentamicin treated rats exhibit a 45% increase in mRNA levels over normal saline controls. Studies with the Shering Enkephalinase inhibitor are in progress.

218.19

LOCALIZED LESION OF NEURONS WITH N-METHYL-D-ASPARTATE (NMDA): SUPPORT FOR A NEURONAL LOCALIZATION OF ENDOPEPTIDASE 24.11 (ENKEPHALINASE) IN FOREBRAIN. S. A. Back, M. E. Hargreaves*, J. E. Swett, and C. Gorenstein, Department of Pharmacology, University of California, Irvine CA 92717.

We have previously observed cell bodies in enkephalin-positive regions of the CNS to stain for the enzyme enkephalinase (endopeptidase 24.11, E.C. 3.4.24.11). The sites of enzymatic activity were visualized by a fluorescent histochemical method using nitrosalicyaldehyde to localize a reaction product resulting from sequential enzymatic cleavage of the synthetic peptide substrate, glutaryl-alanyl-alanyl-phenylalanyl-4-methoxy-2-naphthylamide by enkephalinase and exogenous aminopeptidase M. In the present study we sought further support for a neuronal localization of the enzyme. Enkephalinase staining was examined in the CNS of male rats which were either untreated, which received 250 ug of colchicine i.c.v, or which received NMDA 5-7 days prior to sacrifice. Injections of 10 ug of NMDA were made into the nucleus accumbens, the medial caudate putamen, or the globus pallidus. The cellular response to injury was assessed by Nissl stain and by ethidium bromide fluorescent counterstain.

We did not observe a marked difference in the regional distribution of enkephalinase in untreated versus colchicine-treated animals in regions including the nucleus accumbens, ventral pallidum, caudate putamen, globus pallidus, nucleus basalis, and the substantia nigra, compacta and reticulata. There were extensive populations of enkephalinase-positive cell bodies in these regions in untreated animals. Enriched staining in proximal processes and decreased neuropil staining were the major differences observed in response to colchicine. NMDA altered both the amount and distribution of enkephalinase reaction product in the injected regions. The overall intensity of staining was markedly reduced and was largely unassociated with any cellular elements. By contrast, it was often possible to observe normal cellular enkephalinase staining at the periphery of the lesioned areas. The Nissl stain and ethidium bromide counterstain confirmed a marked decrease in neuronal cell bodies and a corresponding increase in glial cells particularly at the injection site. These cellular changes were focal in nature, and no indications of distant morphological damage or decreased enzyme staining in any other CNS regions were detected.

The size and morphology of enkephalinase-stained cell bodies, the lack of alteration in enzyme distribution in response to colchicine, and the pronounced decrease in cellular enkephalinase staining in repsonse to NMDA-induced injury, support the presence of extensive populations of enkephalinase-positive neurons in the forebrain.

MEMBRANE ASSOCIATED PUROMYCIN SENSITIVE RAT BRAIN ENKEPHALIN DEGRADING AMINOPEPTIDASE: ARTIFACT OR REAL?. S. H. Dyer*, K. Orth+*, C.R. Moomaw+*, C.A. Slaughter+* and L.B. Hersh. Depart. of Biochemistry, Univ. of Texas Southwestern Medical Ctr. and Howard Hughes Medical Inst. Dallas, Texas 75235

An enkephalin degrading puromycin sensitive aminopeptidase has been shown to exist in soluble and membrane forms in rat brain. The kinetic properties and molecular weight of these enzyme forms have been found to be the same. In this study the physical properties of the two enzymes were compared. The enzymes exhibit the same subunit and native molecular weight indicating they are monomers of identical size. An antiserum generated against the soluble enzyme exhibits identical cross-reactivity with the membrane enzyme and both enzymes exhibit the same pI and the same mobility on native gels. Identical tryptic maps and N-terminal sequence for the two enzyme forms were obtained.

The membrane enzyme is not released by salt and does not exhibit the latency expected of vesiculated proteins. These results suggest the membrane enzyme may associate with the membrane by non-covalent interactions with integral membrane proteins.

218.21

ISOLATION OF PRO-DYNORPHIN-RELATED END PRODUCTS FROM THE BRAIN OF THE AMPHIBIAN, XENOPUS LAEVIS. R.M. Dores and C.A. Sei. Dept. of Biological Sciences, Univ. of Denver, Denver, CO 80208.

Methanol/HCl extracts of the brain of the amphibian, Xenopus laevis were analyzed for the presence of pro-dynorphin-related end products. Radioimmunoassay analysis coupled with Sephadex G-50 column chromatography and reverse phase HPLC revealed the presence of immunoreactive alpha-neo-endorphin, dynorphin A(1-17) and dynorphin A(1-8). Following HPLC analysis, these peptides eluted with the same retention times as the synthetic mammalian standards. These extracts were also screened for the presence of enkephalin-related peptides. Both met-enkephalin and leu-enkephalin were detected following HPLC analysis. This observation was unexpected since Xenopus pro-enkephalin does not contain a leucine enkephalin sequence (Martens and Herbert, Nature 310:251, 1984). These results would indicate that in this species some pro-dynorphin-related peptides are processed to yield leucine enkephalin as an end product. This study was supported by NIH grant HD23100.

FURTHER CHARACTERIZATION OF AN ENDOGENOUS LIGAND ("SIGMAPHIN") FOR *SIGMA* RECEPTORS IN THE BRAIN. T.-P. Su and D. B. Vaupel*. Neuropharmacology Lab., Addiction Research Center, NIDA, Baltimore, MD 21224.

An endogenous ligand for *sigma* receptors was partially purified from guinea-pig brain extracts using molecular sizing and ion-exchange chromatography. Two systems were used simultaneously to monitor *sigma* activity during purification: a *sigma* receptor binding assay and a relatively specific bioassay using the guinea-pig vas deferens (Vaupel, D.B. and Su, T.-P., Eur. J. Pharmacol., 139:125, 1987). The "sigmaphin" thus identified had an apparent molecular weight of about 485 daltons. Like prototypic *sigma* drugs, sigmaphin potentiated electrically-evoked twitches of the guinea-pig vas deferens in a dose-responsive manner, and the potentiation was inhibited by the putative *sigma* antagonist, haloperidol. The activity of sigmaphin was not affected by pronase treatment or 6N HCl hydrolysis. EDTA did not inactivate sigmaphin. Sigmaphin was resistant to chloroform extraction under acidic, neutral and alkaline conditions. No stainable spot could be detected on TLC plates containing sigmaphin using either ninhydrin, fast blue B or iodoplatinate spray. It is concluded that sigmaphin is nonpeptidic, small, chemically polar and probably contains no nitrogen. Further purification and structural determination of sigmaphin would facilitate our understanding of the possible physiological roles of *sigma* receptors.

218.23

ISOLATION AND IDENTIFICATION OF THEBAINE FROM OVINE BRAIN. H. Kodaira, C.A. Lisek*, I. Jardine*, A. Arimura# and S. Spector. (SPON: R.F. Margolskee). Roche Inst. Molec. Biol., Nutley, NJ 07110. *Mayo Clinic, Rochester Minn. 55905. #Tulane Univ., Herbert Cntr., Belle Chasse, LA 70037

Morphine and codeine have been identified in various mammalian tissues. The increase of these alkaloids following the administration of thebaine or salutaridine and the conversion of reticuline to salutaridine were demonstrated in mammals. Recently we reported on the enzymatic conversion by mammalian tissues of thebaine to morphine and its cofactor requirements (Proc. Natl. Acad. Sci. U.S.A.,85:1267,1988); the pathway was similar to that which exists in the opium poppy. Thus, the enzymes necessary for the biosynthesis of morphine or its intermediates exist in mammalian tissue. Here we report the isolation of thebaine from ovine brain. The intermediate was purified to homogeneity by HPLC with the combination of a radioimmunoassay for thebaine. The immunoreactive material behaved identically to standard thebaine in two HPLC systems, then was confirmed by gas chromatography and mass spectrometry. This is the first identification of the intermediate thebaine in mammalian tissue. The presence of thebaine as well as codeine and morphine in ovine brain provides strong evidence that morphine and codeine in mammalian tissues are of endogenous origin and actually biosynthesized from the precursor.

STAINING AND TRACING TECHNIQUES I

HISTOCHEMICAL DEMONSTRATION OF ACETYLCHOLINESTERASE IN PLASTIC SECTIONS. M.R.Donald, K.S.Jodelis*, and L.R.Williams, CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

Improved morphological preservation and resolution of AChE-expressing structures in rat brain were achieved by processing 10 μm glycol methacrylate plastic sections according to Hedreen et al. (1985). Several modifications were made to the basic methodology reported by van Straaten et al. (1986). Optimal parameters of tissue preparation included: fixation in 4% paraformaldehyde, 0.1% glutaraldehyde with 7% sucrose in 0.1M phosphate buffer, pH 7.2; rinsing with 50 mM NH_4Cl in phosphate buffer containing 2% sucrose; acetone dehydration; vacuum infiltration with LKB Historesin; polymerization at 4°C; overnight incubation in the Hedreen et al., AChE reaction mixture at 37°C using iso-OMPA as the inhibitor of non-specific esterase; and intensification with 2% $(NH_4)_2S$. As well as providing excellent visualization of axonal processes, the method also enabled visualization of cholinergic neurons in serial sections through the basal forebrain using the pharmacohistochemical method of Butcher (1983).

219.2

DOUBLE-LABEL ELECTRON MICROSCOPIC IMMUNOCYTOCHEMISTRY USING TETRAMETHYLBENZIDINE (TMB) AS A CHROMAGEN. Y.Tsai*, R.B. Norgren, Jr.* and M.N. Lehman (SPON: R.R. Cardell). Dept. Anat. & Cell Biol., Univ. Cincinnati Coll. Med., Cincinnati, OH 45267.

A technique developed by Olucha (*J. Neurosci. Meth., 13*:131-138) allows one to use TMB as a chromagen for HRP histochemistry at close to a physiological pH. Although initially developed for tract tracing, we have found that, with some modifications, it can be used reliably for EM immunocytochemistry. We investigated the possibility of using this technique in conjunction with a diaminobenzidine (DAB) protocol to demonstrate the presence of two antigens at the EM level. Adult Suffolk ewes were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde. Vibratome sections were processed for demonstration of the first antigen (TH or NPY) using an avidin-biotin-HRP procedure (Vectastain) with DAB as the chromagen. Sections were then processed for the second antigen (LHRH) as above with the exception that the chromagen used was a TMB-ammonium heptamolybdate (TMB-AHM) solution (pH 6.0). After a 20 min. pre-incubation, hydrogen peroxide was added until blue-green reaction product was observed. Sections were quickly washed in Tris buffer (pH 7.3) and immediately put in a 0.5% DAB-cobalt solution in order to make the TMB-AHM reaction product electron dense and stable at a higher pH. As soon as reaction product turned turned blue-black, sections were transferred to phosphate buffer. Areas of interest were microdissected, osmicated, dehydrated, and embedded in epon. LHRH cell bodies and processes labelled with TMB-AHM could be easily identified by the presence of crystalline rods, and were distinct from granular DAB labelled elements. Good ultrastructural preservation allowed identification of NPY synapses onto LHRH neurons. [Supported by NIH HD21068 to M.N.L.]

219.3

DOUBLE-LABEL CYTOCHEMICAL-AUTORADIOGRAPHIC METHOD FOR ELECTRONMICROSCOPIC (EM) CO-LOCALIZING ACETYLCHOLINE-STERASE (AChE) AND ACETYLCHOLINE RECEPTORS (AChRs) IN THE SAME INNERVATED CULTURED HUMAN MUSCLE FIBER (Inn-CHMF). R.B. Alvarez,* V. Askanas, P. Alhissin,* W.K. Engel. USC Neuromuscular Center, Los Angeles, CA 90017.

In adult human muscle fibers cultured aneurally in monolayer, AChE stain is negative and AChRs are weakly and evenly distributed plasmalemmaly. In CHMFs innervated by fetal rat spinal cord, AChE and AChRs accumulate at newly-formed neuromuscular junctions (NMJs). Without stains for AChE or AChRs, NMJs on Inn-CHMFs are not easily identified by light-microscopy (LM). We have developed a new method that enables LM identification of NMJs on Inn-CHMFs by AChE reaction and subsequent EM studies of AChE and AChRs on the same section, as follows: 1) living cultures are incubated in ^{125}I-alpha-bungarotoxin; 2) after fixation, cultures are stained for AChE; 3) after short osmification and embedding, NMJs are identified by LM, marked and core-drilled out; 4) thin- sections containing AChE-stained NMJs are EM-photographed, then dipped in Ilford L-4 emulsion, and processed for EM-autoradiography (EM-AR); 5) since most of the AChE reaction is lost during EM-AR processing, easily visible grains representing AChRs can be EM-photographed on the same NMJs. This method enables comparative studies of AChE and AChR co-localization at various stages of NMJ formation in tissue-culture.

219.4

IMMUNOHISTOCHEMICAL LABELING OF OPTIC NERVE TISSUE PRINTS ON NITROCELLULOSE PAPER. L.L.Y. Chun* and B.A. Barres (SPON: A. Ames), Department of Neurology and Howard Hughes Medical Institute, Massachusetts General Hospital and Program in Neuroscience, Harvard Medical School, Boston, MA.

Analysis of neural structure can be impeded by the high density of processes and the often poor access of antibodies to cell *surfaces* in fixed tissue sections. We have developed a simple immunohistochemical technique that allows excellent visualization of neural cell bodies, along with fine details of their connectivity.

Pieces of tissue (optic nerve or retina) were briefly incubated in a papain solution and gently blotted on wet nitrocellulose paper. The adherent tissue, which included cells and their processes, was then fixed with 85% methanol or 2% paraformaldehyde. A variety of immunohistochemical methods were used to visualize the antigenic determinants. Staining methods compatible with the technique included standard counterstains, indirect immunofluorescence and immunoenzymatic methods of higher sensitivity utilizing peroxidase/DAB/Ni, alkaline phosphatase (black substrate only), and intensification of DAB with silver. With the immunoenzymatic techniques the final result was visualized by dehydration of the tissue in graded t-butyl alcohol and clearing with xylene (Other solvents dissolved either DAB or the nitrocellulose.). The clearing process also made the nitrocellulose paper transparent for transillumination, and thus compatible with DIC optics. Related techniques have been reported by Seshi (1986) and Cassab and Varner (1987).

We have used this technique to analyze aspects of optic nerve structure. All of the optic nerve glial cell types identified by Raff *et al.* (1983) have been observed as well as the relationships of their processes to axons and to each other. We have also immunohistochemically labelled whole layers of retina obtained by the technique of Shiosaka *et al.* (1984). This technique may be directly applicable to other CNS regions.

219.5

SPECTROPHOTOMETRIC DETERMINATION OF FLUOROCHROME-TO-PROTEIN RATIOS IN IgG CONJUGATED WITH THE BLUE FLUOROCHROME AMINOMETHYLCOUMARIN ACETIC ACID (AMCA). S.Tallaksen-Greene, M.W. Wessendorf, and R. Elde. Department of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455

IgG conjugated with the blue fluorochrome 7-amino-4-methylcoumarin-3-acetic acid (AMCA) has been successfully employed for fluorescence immunocytochemistry. However, AMCA conjugates of IgG sometimes precipitate out of solution. This tendency seems to be related to amount of AMCA-N-hydroxysuccinimide used to conjugate the IgG, suggesting that over-conjugation of the IgG is responsible. To study this phenomenon a simple means of determining the ratio of fluorochrome to protein (f/p ratio) in AMCA conjugates would be useful.

Tryptophan residues in protein cause it to absorb light at 280 nm. Similarly, free AMCA absorbs strongly at 355 nm. Beer's law states that the absorbance of light by a solute in a solution equals its concentration, times the extinction coefficient (E) for the substance at the wavelength employed. The extinction coefficient at 280 nm and 355 nm for free AMCA in pH 7.2 PBS was measured spectrophotometrically at concentrations of 65 μM, 22 μM, and 6.5 μM. The mean value determined for the E_{280} was 3,271. The mean value for the E_{355} was 15,333. Previous reports indicate that the E_{280} for IgG is 210,800 (Handbook of Biochemistry), and that the E_{355} for IgG is negligible. These values suggest the following formula for the f/p ratio of AMCA conjugates of IgG:

$$f/p = 13.7 \times \frac{A_{355}}{A_{280} - (.213) \times A_{355}}$$

m-PHENYLENEDIAMINE: A NOVEL FLUORESCENT NISSL-LIKE STAIN FOR NEUROANATOMY. B.Quinn & E. Weber. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

Although fluorescent techniques are widely used in neuroanatomy, the high specificity of these methods in identifying isolated neurons may impair visualization of surrounding neuronal architecture. Several compounds with distinct spectra have been proposed as fluorescent counterstains (1); and Oriol & Mancilla-Jimenez (2) have reported that p-phenylenediamine, sometimes used as an anti-fading agent for fluorescein, could be used in an oxidized state as a brown nuclear counterstain. We report that an isomer of this compound, m-phenylene-diamine (m-PhD), can provide a Nissl-like counterstain with characteristics different from fluorescent counterstains previously described. 20 mg of m-PhD (Sigma) are dissolved in 900 ul of H_2O, 20 ul of HAc, and 100 ul of glycerol, and heated for 10 min at 50-60° C, developing a light tan color. 50 ul of this solution are applied to slide-mounted sections, rinsed, and sections mounted under Tris- or PO4-buffered glycerol, pH 8. Alternatively, the m-PhD solution is diluted 1:2 in buffered glycerol and used as a coverslipping medium. Either method produced yellow-green staining of neuronal perikarya well visualized with routine fluorescein filters. An excellent counterstain effect was obtained for retrograde tract tracing using 6% rhodamine B isothiocyanate (Sigma) or rhoadamine-labeled antibodies in immunohistochemistry. This m-PhD technique has also been utilized as an effective counterstain to aid intracellular labeling in an *in vitro* slice preparation (see Walker, Graybiel, Baughman, & Arbuthnott, this meeting.)

AB5 MONOCLONAL ANTIBODY- A SPECIFIC MARKER FOR 'PROJECTION NEURONS' IN THE CENTRAL NERVOUS SYSTEM. K.R. Fry and D.M.-K. Lam. CENTER FOR BIOTECHNOLOGY, BAYLOR COLLEGE OF MEDICINE, THE WOODLANDS, TX. 77381.

The AB5 monoclonal antibody (Fry et al, Brain Res. 338:360, 1985) has been determined to be a specific marker for retinal ganglion cells in several mammalian species. The present study was undertaken to determine whether the AB5 antibody also labels neurons in other regions of the central nervous system. An adult cat was anesthetized and perfused with 4% paraformaldehyde. Frozen sections of the brain and spinal cord were immunostained with the AB5 monoclonal antibody and examined at the light microscopic level. Several neuronal cell types were observed to be labelled. In the spinal cord, only the spinal motor neurons and some cells located in the intermediate gray matter were labelled. In the cerebellum, Purkinje cells and neurons of the deep cerebellar nuclei were labelled. The AB5 antibody labelled neurons in most of the major brainstem nuclei. Some AB5-labelled neurons were observed in the diencephalon and in the cerebral cortex, where pyramidal cells were labelled. In all cases, the neurons labelled by the AB5 antibody were neurons which project to other locations within the nervous system, ie. 'projection' neurons. The possible role that this antigen may play in long distance signal transduction remains to be determined. Supported by NIH grants EY06469 (KRF) and EY02608 (DMKL) and USPHS Grant No. RR-05425 (KRF).

FRAGMENT C OF TETANUS TOXIN IS A NON-TOXIC LABEL FOR LIVING NEURONS. E.A. Neale, J. Koh* and W.H. Habig*. Lab. Devel. Neurobiol., NICHD, NIH and Div. Bact. Prod., FDA, Bethesda, MD 20852

Tetanus toxin has been used with radioautography and immunohistochemistry as a neuron-specific marker. A complex of the binding portion of the toxin molecule, Fragment C, with a non-neutralizing monoclonal antibody specific for this fragment, labels the surface of mouse CNS neurons in culture more intensely than tetanus toxin and does not cause the electrophysiologic effects of intact toxin. The complex does not interfere with early morphologic development and can be detected on the cell surface with a fluorescent secondary antiserum. Intense, diffuse fluorescence is observed over the soma and processes of neurons labeled two hours after plating. Twenty-four hours after labeling, fluorescence is less bright and punctate, and redistributed out to the tips of newly extended neurites. Forty-eight hours after labeling, fluorescence no longer can be detected on the neuronal surface. Fixation and detergent treatment prior to secondary antibody reveal small amounts of internalized complex. Newly dissociated cells, labeled in suspension, show a similar redistribution of label over twenty-four hours. The complex persists longer on the surface of older neurons. The Fragment C / monoclonal antibody complex should prove useful as a neuronal probe that can be applied to living cultures.

219.9

RETROGRADE LABELING OF EMBRYONIC MAMMALIAN MOTONEURONS WITH A CARBOCYANINE DYE. E. F. Salazar-Grueso, and R. P. Roos*, Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637.

Several laboratories have reported isolation and purification of avian and mammalian motoneurons by retrograde labeling with fluorescent conjugated lectins (FCL) and subsequent fluorescence activated cell sorting (FACS). Limitations of this approach include: rapid photobleaching of FCL, leakage of FCL and the relative transience of fluorescence in cultures of FCL-labelled cells. Carbocyanine dyes (CD) are hydrophobic fluorochromes that have none of these limitations, and fluorescence persists within labeled cells for weeks (Honig & Hume Soc. Neurosci. 11:98). We have been able to label mammalian embryonic motoneurons with the CD, 3,3'-dioctadecyloxacarbocyanine perchlorate (DiO). Limbs of E12 mouse embryos were injected with DiO in ethanol. After 12-18 hours in a oxygenated balanced salt solution at room temperature, embryos were processed for cryostat sectioning. Fluorescent cells in the spinal cord were confined to the ventral horn. The identity of these cells has been determined to be motoneurons in other experiments employing lectin conjugated horseradish peroxidase as the chromophobe. Future studies of long-term cultures of FACS isolated DiO labeled motoneurons will make immunohistochemical, neurophysiologic, and developmental studies possible. (Supported by a grant from the MDA.)

IDENTIFIED CHOLINERGIC BASALOCORTICAL NEURONS IN TISSUE CULTURE. A.A. Khan and R.W. Baughman. Dept of Neurobiolgy, Harvard Medical School, Boston MA 021115.

The role of cholinergic input from the basal forebrain to cerebral cortex is difficult to study in vivo. Monolayer tissue culture provides a more favorable preparation for investigating the synaptic pharmacology of this system, but it is necessary first to establish a method to identify reliably the cholinergic basalocortical cells. We have achieved this by combining retrograde labelling with immunohistochemical staining for choline acetyltransferase (ChAT). The fluorescent dye 1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (di-I) was injected into primary and secondary visual cortex of 6-7 day-old Long/Evans rat pups. After two days to allow for retrograde transport of the dye to the basalocortical cells, the basal forebrain was dissociated enzymatically (Huettner and Baughman '86) and plated in monolayer tissue culture on feeder layers of glia from the same area. In order to enhance survival of the cholinergic basal forebrain neurons, 7S nerve growth factor was added to the culture medium (Eagle's MEM with 5% rat serum). At times from a few days up to 72 days, large multipolar cells were easily recognizable in the cultures. The majority of these cells were ChAT-positive, indicating that they were cholinergic. Many di-I labelled cells also were present in the cultures. Of the large (> 20 um) di-I labelled cells, over 80% were ChAT-positive. The majority of the ChAT-negative, di-I labelled cells were smaller in size (< 20 um). These results indicate that retrograde labelling from cortex with di-I provides a reliable marker for cholinergic basalocortical cells in tissue culture. Supported by NIH EY03502 and ADRDA II-86-099.

GREEN FLUORESCENT LATEX MICROSPHERES: A NEW RETROGRADE TRACER. L.C. Katz and D.M. Iarovici*. (Lab. of Neurobiology, The Rockefeller University, NY, NY and Yale Univ. School of Med., New Haven, CT).

Fluorescent latex microspheres ("beads") (Katz et al. Nature 310:498,1984) have many advantages over other fluorescent retrograde tracers, including minimal diffusion from injection sites, low cytotoxicity, resistance to fading, and compatibility with all other retrograde tracers and with immunocytochemistry. The currently available "red" beads fluoresce under rhodamine excitation. We have now developed "green beads," which are invisible under rhodamine excitation, but fluoresce a bright green under fluorescein illumination. Except for the fluorochrome, the behavior of the two colors is identical. Green bead injections into rat or cat cortex label cells in local, cortico-cortical, and cortico-thalamic pathways with the distinctive granular cytoplasmic fluorescence characteristic of beads. In double-labelling experiments, small injections (<50 nl) of green and red beads separated by less than 500 μm were completely distinct. Double labelled cells were easily distinguished, since the cytoplasmic granules containing the beads fluoresced different colors. Even weak double labelling is detectable, as only a few grains of each label can easily be distinguished within a labelled cell. This is a clear advantage over other commonly employed double labels, with which weak labelling is difficult to distinguish from other fluorochromes or from autofluorescence. When a mixture of red and green beads was injected, the labels were co-localized . Thus cells do not differentiate between the two labels. However, the green beads seem to label cells somewhat less intensely than the red ones. Under the electron microscope, the retrogradely transportable fraction of both green and red beads consists mainly of 30-60 nm diameter particles. The properties of green and red beads should be extremely useful in understanding local circuits, in situations in which multiple tracers are to be combined with immunocytochemistry, and in developmental studies where long term label retention is important. Supported by the L.P. Markey Charitable Trust (to L.C.K.).

SELECTIVE UPTAKE OF LATEX NANOSPHERES CONTAINING ACTIVE CHROMOPHORES INTO SUBPOPULATIONS OF CULTURED RAT NEOCORTICAL NEURONS. **J.D.Macklis and R.D.Madison. Departments of Neurology and Neuropathology, Harvard Medical School, and Neuroscience, Children's Hospital, Boston, MA 02115**

A novel latex nanosphere delivery system (LNDS) is developed for selective delivery of fluorescent dyes, photoactive agents, and drugs to subpopulations of neurons. Chromophores are incorporated within latex nanospheres of defined size (100-300 nm diameter) and surface properties (charge, protein conjugate). These nanospheres are nontoxic, become concentrated within cell bodies indefinitely, appear to withstand processing for electron microscopy, and allow double or triple labeling studies with ultrastructural analysis on the same cells.

We screened several LNDS samples for uptake into cultured rat neocortical neurons. Neurons were cultured by standard methods and exposed to LNDS samples with various surface properties and proteins. We compared uptake results with those for cultures exposed to commercially available Rhodamine latex microspheres. Uptake of commercially available microspheres is concentration dependent, but nonspecific; neurons, glia, and fibroblasts all accumulate these beads avidly. Some samples of the LNDS undergo low levels of nonspecific uptake that is concentration dependent. Other LNDS samples exhibit selective uptake into neuronal subpopulations, dependant on the surface properties and proteins. These preliminary studies do not attempt to define target subpopulations for the different LNDS samples. We will use such culture studies to guide our future transport studies in vivo. **Supported by a grant from the Whitaker Foundation.**

219.13

RETROGRADE LABELING OF HYPOTHALAMIC PROJECTIONS TO NUCLEUS TRACTUS SOLITARIUS IN THE RAT USING RHODAMINE-LABELED LATEX MICROSPHERES. R. A. Cava*, D. Melancon*, J. A. Weyhenmeyer and D. C. Kuo. College of Medicine, Univ. of Ill., Urbana, IL 61801.

The paraventricular nucleus (PVN) of the hypothalamus has been shown to send projections to the nucleus tractus solitarius (NTS) and vagal motor nucleus (DMX). These descending projections to brainstem autonomic regions have been implicated in the regulation of cardiovascular activity. In the present study we retrogradely labeled hypothalamic neurons by microinjecting (1.5-3.0 μl) rhodamine-coated microspheres (0.02-0.2 μm) into the dorsomedial medulla at the level of the obex. Medial injections resulted in a large number of labeled cells that were clustered in the PVN and scattered throughout the lateral hypothalamus. Injections placed more laterally resulted in a significant decrease in the number of labeled neurons. Adjusted cell counts indicated a larger projection than previously reported using other fluorescent markers. Staining was bilateral with a slight ipsilateral predominance. Further, staining was often visible in dendritic arbors. These findings suggest that rhodamine-coated latex microspheres are superior to other fluorescent dyes for retrograde labeling due to their stronger intensity and resistance to fading. Supported by grants from NSF and AHA-IL.

219.14

SELECTIVE SUPPRESSION OF ENDOGENOUS PEROXIDASE ACTIVITY: APPLICATION FOR ENHANCING APPEARANCE OF HRP-LABELED NEURONS *IN VITRO*. C.B. Metz*, S.P. Schneider and R.E.W. Fyffe* (SPON: E.R. Perl). Department of Physiology, Univ. of N. Carolina, Chapel Hill, NC 27514.

The use of HRP for staining neurons in brain slices is complicated by peroxidase activity in red blood cells (rbc's) distributed throughout the tissue. We have developed a simple procedure that suppresses selectively the peroxidase activity of rbc's in aldehyde fixed sections of the mammalian CNS while enhancing the staining density and uniformity of HRP-injected neurons. These effects are accomplished by washing the sections in ethanol solutions prior to histochemical processing. The procedure is compatible with standard methods for demonstrating HRP; with diaminobenzidine (DAB) as chromogen our protocol is as follows:

1) Incubate sections in a series of 50%, 70%, 50% ethanol solutions for 10, 15 and 10 min, respectively.

2) Wash sections in phosphate buffer for 10 min. Incubate for 30 min in a solution containing 25 mg nickel ammonium sulphate, 20 mg DAB and 7μl of 30% hydrogen peroxide in 100 ml of TRIS-HCl buffer (0.05 M) at pH 7.6.

3) Mount sections, counterstain and coverslip.

Supported by grants NS 25547, NS 14899 and NS 10321 from the NINCDS.

219.15

ENHANCEMENT OF HORSERADISH PEROXIDASE UPTAKE AND/OR TRANSPORT AND ENZYME ACTIVITY BY A RADIOCONTRAST MEDIUM. C.N.R. Henderson and S. Saporta. Dept. of Anat., Coll. of Med., Univ. of South Florida, Tampa, FL 33612

Bilateral, symmetrical injections (0.016 μl each) were made in the somatosensory cortex of five rats. The left cortex received 2% WGA-HRP in deionized water (DI) and the right received 2% WGA-HRP in MD 40 (a 1:0.9 dilution of MD-76 with DI). Twenty-four hours later, each animal was deeply anesthetized and perfused transcardially with saline followed immediately by cold 1% paraformaldehyde-2% glutaraldehyde in 0.1 F phosphate buffer (pH 7.4). Frozen 40 μm coronal sections through the diencephalon were reacted with tetramethyl benzidine (TMB) to demonstrate the presence of HRP.

The amount of anterograde label was consistently greater in the ventrobasal nucleus ipsilateral to the side of the WGA-HRP/MD40 injection, though there was not a clear enhancement of retrograde label. The relative enzymatic activity of the two solutions, as measured by spectrophotometric assay (Worthington Manual, 1972), revealed greater activity in the WGA-HRP/MD40 solution. Control experiments have indicated that the increased amount of anterograde label is probably due to increased uptake and/or transport of WGA-HRP rather than simply an enhancement of HRP enzymatic activity.

219.16

TRANSNEURONAL TRANSPORT OF HERPES SIMPLEX VIRUS IN THE RAT BRAIN. J.H. McLean, M.T. Shipley and D.I. Bernstein*. Dept. of Anatomy and Cell Biol., Univ. of Cincinnati Coll. of Med., Cinti., OH., 45267-0521 and The Gamble Inst., Cinti., OH.

At last year's meeting, we presented evidence that herpes simplex virus type 1 (HSV1) is transported transneuronally in a retrograde direction in the rat olfactory system. Here, we examined the generality of transneuronal label by HSV1 in several additional neural systems. Anaesthetized rats were injected with 50-200nl of 10^5 to 10^9 PFU/ml of HSV1 (McIntyre strain) into the visual cortex, septum, somatosensory cortex or the olfactory bulb. Sites of HSV1 incorporation in the brain were observed by immunocytochemistry.

In all systems studied, multineuronal connections were demonstrated and the number of synapses crossed by the virus was determined, based on known circuitry of the involved systems. For example, in the visual system the virus crossed 2-3 synapses to reach bipolar cells in the retina. In all systems studied the transport was mainly retrograde but, occasionally, label could be attributed to anterograde transport of the virus. Generally, with short survival periods of 2-3 days postinoculation, only neurons incorporated the virus. With longer survival both neurons and glia became infected. Preliminary results also indicate that, at least for serotonergic neurons, the neurotransmitter can also be identified immunocytochemically in infected cells. Because the virus is amplified at each level of synaptic transfer, the strength of the label does not diminish even in neurons located many synapses removed from the injection site and in many neurons the label resembles Golgi impregnation. Supported by NINCDS PO1 23348-01 & AHAF-ADR.

219.17

ANTI-RICIN ANTIBODY PROTECTS FROM SYSTEMIC TOXICITY WITHOUT AFFECTING SUICIDE TRANSPORT. R.G. Wiley and T.N. Oeltmann*. Lab of Experimental Neurology, VAMC, Nashville, TN 37212.

Subepineural injection of the toxic lectin, ricin, is a useful way to selectively destroy neurons projecting through the injected nerve. However, the ricin dose necessary to reliably destroy all neurons projecting through a large, heavily myelinated nerve often causes systemic toxicity and/or death. Systemically administered lactose or anti-ricin antibodies can protect against systemic ricin poisoning. In the present study, we sought to determine if commercially available anti-ricin antibodies given at the time of subepineural ricin injection could protect rats from systemic ricin toxicity without interfering with the suicide transport action of ricin. 24 anesthetized, adult, male Sprague-Dawley or Long Evans hooded rats received subepineural pressure microinjections of ricin into one sciatic nerve (2.7-13.5 ug) or one vagus nerve (0.05-4 ug). Half of the rats received 0.1-0.25 mg of anti-ricin antibody (Vector Labs) subcutaneously within 5 mins of the ricin injection. Animals were observed daily and long term survivors were subsequently reanesthetized, perfused transcardially with aldehyde fixative and examined histologically for evidence of destruction of neurons projecting through the injected nerves. All rats with sciatic nerve injections died unless given antibody. Antibody protected 3 of 4 rats given 6.5 ug and 2 of 2 given 2.7 ug of ricin into the sciatic nerve. In all sciatic experiments, there was extensive destruction of neurons in the ipsilateral L5 and L6 dorsal root ganglia and in the ipsilateral ventral horn of the spinal cord. Antibody did not protect rats injected with 4 ug of ricin into the vagus but this may have been due to the excessively large brainstem lesion in these animals. 4 rats were injected with 0.05 ug of ricin (2 also received antibody) into one vagus nerve to assess the effect of antibody on suicide transport of less than maximally effective ricin doses. In all cases, the subtotal vagal lesions were similar whether or not antibody was given concurrently. These results are interpreted as showing that anti-ricin antibody can protect animals against systemic ricin toxicity without altering the suicide transport activity of the toxin. This strategy should facilitate experiments using ricin to ablate large nerves. (This work supported by the Veterans Administration.)

THE USE OF PHA-L FOR TRACING CONNECTIONS IN THE IMMATURE RAT BRAIN. J. Weber * and D. G. Amaral. The Salk Institute, P. O. Box 85800, San Diego, CA. 92138.

We have attempted to use the lectin anterograde tracer phaseolus vulgaris leucoagglutinin (PHA-L) to study the development of connections in the rat hippocampal formation. A variety of parameters were varied to establish an optimal injection procedure and most of the studies were conducted in animals approximately 24 hours of age. In all cases, a 2.5% solution of PHA-L in phosphate buffered saline (pH 7.2) was injected either by iontophoresis (2-9 uamp, positive current, 7 sec. duty cycle) or by air pressure (5-20 nl) through glass micropipettes; survival times ranged from 6 hours to 3 days.

The associational and commissural connections of the dentate gyrus were clearly labeled in the one-day-old animals as were hippocampal subcortical projections to the septal and mamillary nuclei. As in the adult, selective and intense anterograde labeling of projections was only achieved with iontophoretic injections and currents of approximately 7 uamp proved most successful. In several cases, apparent growth cones could be visualized at the tips of labeled axons. Transport also occurred with the pressure injections though labeled fibers had a fragmented appearance and there was substantial retrograde labeling. Labeling of the contralateral hippocampal formation was achieved with as little as 6 hours survival. While PHA-L is potentially a valuable tracer for developmental studies, our rate of successful injections (≈ 30%) was far lower than in mature animals.

REGIONAL VARIATION IN PROTEIN LEVELS IN RAT BRAIN TISSUE SECTIONS . J.A. MILLER, Merrell Dow Research Institute, Cincinnati, OH, 45215.

Using computerized densitometry the variation in protein levels in rat brain sections (10 um) was examined. The technique uses the dye Coomassie Blue (2.5% w/v in 20 mM HEPES buffer, pH 7.4) to stain protein. The neocortical layers were heterogeneous in their protein concentrations (Table 1). Other brain areas, such as thalamus, hippocampus and cerebellum also showed a distribution of protein concentrations. The highest levels of protein were those seen in layers 2 through 5, corresponding to the regions which contain the greatest density of dendrites. Conversely, layers rich in axonal fibers, layers 1 and 6, are relatively deficient in protein. These variations in tissue protein levels should be considered in receptor autoradiography when measuring receptor density.

Table 1. Protein in rat neocortical sections (n = 3).
Protein concentration (ng protein/mm2) ± SEM

Cortical Layer	Region of Neocortex: Frontal	Frontoparietal	Striate
1	142 ± 9	148 ± 23	139 ± 13
2	381 ± 92	428 ± 99	349 ± 38
3	300 ± 25	282 ± 58	346 ± 50
4	295 ± 33	275 ± 40	311 ± 41
5	246 ± 38	199 ± 16	276 ± 52
6	193 ± 37	143 ± 18	230 ± 37

HIGH RESOLUTION SCANNING AND ANALYSIS FROM MICROSCOPE SLIDES. J.S. McCasland and T.A. Woolsey (SPON: S. Highstein). Division of Experimental Neurology & Neurosurgery and McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

We have developed an automated analysis system for generating high-resolution maps from tissue sections on slides. The method can be used with various combinations of emulsion autoradiography, immunohistochemical stains and other specific markers. Data are collected directly from microscope slides by means of a computer-controlled microscope, image processor, and an integrated software package (J. Voyvodic, Soc. Neurosci. Abstr., 12:390, 1986). Macro image processing functions tailored to specific applications can be user developed and written. The data are reconstructed as a 2-dimensional matrix for analysis by RS/1® software. The software generates density "maps" of grains, stains, etc. (for laser printer or color output) and allows statistical analysis of features within defined anatomical contexts. These maps can be combined or compared for features in the same section and different sections. The method is extremely flexible, and new image processing strategies can be developed and incorporated as needed to extract information of interest. (Supported by NIH 2 P01 NS17763 and McDonnell Center for Studies of Higher Brain Function.)

STAINING AND TRACING TECHNIQUES II

220.1

THREE DIMENSIONAL STRUCTURE OF SELECTIVELY STAINED NEURONS: CONFOCAL LIGHT AND HIGH-VOLTAGE ELECTRON MICROSCOPY. J.N. Turner, D.N. Collins, D.O. Carpenter, J.W. Swann K. Smith, M. Siemens, and D. Szarowski (SPON: M. Evans) Wadsworth Center for Laboratories and Research, New York State Dept. of Health, Albany, NY 12201

Three dimensional (3-D) morphology is critical for correlating structure and function in the CNS. We have developed methods to apply scanning laser confocal light microscopy (SLCM) and high-voltage electron microscopy (HVEM) to 3-D imaging of individual cells and cell components deep (several hundred microns) within thick slices. Unlike conventional light microscopy, SLCM images are not degraded by other labeled structures or unlabeled tissue. HVEM images samples microns thick at high resolution. Our correlation of these images directly compares microanatomy and ultrastructure. Hippocampus and pyriform cortex were imaged using flourescent dyes and gold toned Golgi samples. Cells studied physiologically via intracellular or field microelectrodes were selectively stained for SLCM with lucifer yellow or hydroethidine. The former was used for 3-D imaging of neurons. Photooxidation and osmium provide a correlative stain for HVEM. Hydroethidine was useful for microanatomy and nuclear morphology. SLCM imaging methods were developed for gold toned Golgi samples and correlated to HVEM and conventional electron microscopy. Support: PHS grants RR01219 and RR02984 DRR; NS13809.

220.2

SHAPE CHARACTERISTICS OF NEURONS

W.B.MARKS, T.G.SMITH, G.D.LANGE, W.H.SHERIFF* AND E.A.NEALE
Labs of Neural Control and Neurophysiology and Instrumentation and Computer Section, NINCDS, and Lab. of Developmental Biology, NICHD, NIH, Bethesda, MD 20892.

Mandelbrot (The Fractal Geometry of Nature, W.H. Freeman & Co, NY, 1982) has pointed out that the length L of the borders of natural objects often increases as the length E of the measuring tool decreases, and that the form of the relationship L(E) can be used to characterize the surface or the shape of the object. We have implemented several methods for measuring the outlines of two dimensional objects, using a computer controlled image processor. We have applied these methods to constructed images whose border length satisfies $L(E) = \lambda E^S$, where $-1 < S < 0$ ("fractal" objects), and to the outlines of stained cultured neurons. The methods differ in their sensitivity to branching, their speed, and their generalization to the measurement of surfaces, but they are all forms of smoothing followed by measuring. We give examples of the use of these methods to characterize form, including the measurement of the "fractal dimension" $D = 1 - S$. For objects such as our computer constructed figures, made by processes that act similarly at a range of length scales, the log-log plot of L vs E is straight for several octaves of change in E. For neurons, which are presumably not "self similar" in this way, the plots were also surprisingly straight, so that the roughness or complexity of the shape of neurons can often be characterized by the number D.

220.3

N-DIMENSIONAL CLUSTERS OF NEURONAL SOMATA: A STATISTICAL ANALYSIS. R.D. Rose and R.C. Grimson*. VA Med. Ctr. and Dept. Pharmacol., U. Pitt. Med. Sch., Pgh PA 15240 and Depts. Neurobiol. & Behavior and Community & Preventive Med., SUNY, Stony Brook NY 11794

Neuronal somata often appear physically clustered in histological sections. But are such clusters real or only apparent? We describe a simple and versatile test based on the number of associations between neurons in apparent clusters (those clusters one expects to see due to chance) and the actual number of associations one observes in the microscope. Comparison of these numbers using Chebychev's inequality results in highly conservative answer.

Very briefly, if one considers potential clustering within a labeled subset of cells that is scattered (in N dimensions) among non-labeled cells, the number of expected associations between labeled cells due to chance alone is $\approx yn^2/2x$; where y is the average number of associations per cell, n is the number of labeled cells, and x is the total number of cells. The number of observed associations is compared to this expected value.

Typically, in 1D $y \leq 2$, in 2D $y \leq 6$, in 3D $y \leq 12$, etc. In tissue, n and x can be determined accurately directly (2D) or using recursive translation (3D, Rose and Rohrlich JCN 1988). Furthermore, since our analysis is not dimension limited, higher order associations can also be examined.

220.4

THE M.I.T. "NEUROTRACE" SYSTEM FOR MICROCOMPUTER-AIDED MICROSCOPY. A.Passera*, S.Fulks*, G.E.Schneider, S.Ayres*, S.Jhaveri* and R.S.Erzurumlu. Dept. Brain & Cognitive Sciences, M.I.T., Cambridge, MA, 02139.(Spon.: V.Domesick)

The Neurotrace System has been developed at MIT for use with color graphics-equipped models of the IBM PC, AT, model 80 (and compatibles) and also for the NEC APC3 microcomputer. The graphics and math capabilities of these machines are used by programs for 3-D reconstruction and quantitative analysis of anatomical material. Memory requirements are 640K or more of RAM.

Two modules are currently in use: "AXON" can be used for single- or serial-section 3-D reconstructions of individual axons or cells from Golgi-impregnated tissue or HRP, PHA-L (or equivalent) labelled material. "CELLS" allows a reconstruction, in 2 or 3 dimensions, of the size and/or spatial distribution of cells, axon terminals or other structures. Both software packages have been optimized for ease of data entry, and of viewing and plotting the resulting pictures, by computer-naive users. Plotter files can be used by a customized CAD system for combining drawings and for adding lettering, for creation of publishable figures.

The creative use of various symbols and colors allows representation of various classes of axons, axon branches, cells or terminals in the same drawing. Results can be viewed and plotted at any magnification and orientation. Illustrative examples from our work on the visual system will be presented: optic tract axons traced from ventral thalamus to midbrain, trajectories of groups of retinal axons traced from the embryonic eye through the entire optic nerve, spatial distributions and sizes of retinal ganglion cells backfilled from specific brainstem structures, 3-D reconstructions of the distribution of axon terminal types in the rodent LGBd with accompanying bouton size histograms. [Supported by the Whitaker Foundation, and the InterActions Co., Cambridge, MA]

220.5

NEUROLUCIDA: A PC BASED 3-DIMENSIONAL IMAGING SYSTEM FOR VISUAL AND VIDEO NEURON TRACING. J.R. Glaser and E.M. Glaser. University of Vermont College of Medicine, Burlington, VT 05405.

Image combining microscopy is a method for 3-d tracing of neurons. It uses computer graphic displays that are superimposed by camera lucida on optical images. Computer controlled stage movement in 3 dimensions allows the analysis of large regions of tissue with one half micron spatial precision for position and distance. We have refined this method into a more powerful PC-based version that also works with video images. The new version is based upon Neurolucida (copyright), DOS compatible 'C' software that runs on XT, AT and PS2 type PC computers. While the system works best with a 3-axis computer controlled stage, operation with a manually controlled stage that monitors 3-d position has also been demonstrated. Neurolucida utilizes EGA, VGA, or 'standard' (512x480 pixels) graphics. In the video mode the overlay graphics and the microscopic image are video combined. This permits full use of the tracing features of the original optical system. A frame grabber (Matrox) permits working with stored sequences of dynamic images as well as weakly fluorescent images. An image editor permits immediate correction of an erroneous graphics image by comparing it with the original image. Neurolucida can generate dynamic rotations of stored stick figure images about any selected axis.

220.6

THE USE OF LASER ACTIVATED MICROPROBE MASS ANALYSIS (LAMMA) FOR STUDY OF TRACE METALS IN RAT BRAIN. P. Szerdahelyi*, W. Markesbery*, W.D. Ehmann* and E.J. Kasarskis, Depts. Neurol., Chem., and Path. VA Hosp and Univ. Kentucky, Lexington, KY 40536.

Trace metals, especially zinc and copper, are essential for development of the CNS and the maintenance of synaptic and metabolic processes. A wide variety of analytical and histochemical methods has been developed to anatomically localize and determine the levels of these metals in brain regions. However these methods typically detect only a single element and are plagued by low sensitivity and/or spatial resolution.

The LAMMA technique resolves metal ions in a time-of-flight mass spectrometer which are produced by ionization of a microscopic region of an individual cell. Samples of brain were embedded in Epon and the 0.3 µm thick sections were stained with toluidine blue before analysis with the LAMMA-500 instrument (Leybold, Köln). The high detection efficiency (typically 10^{-18}-10^{-20}g), multielement capability, and high spatial resolution of this technique allowed a semiquantitative analysis of zinc bound to the hippocampal mossy fiber zone (at m/z=64 and 66). Similarly, copper was localized to the Bergman glial cells of the cerebellum (m/z=63 and 65).

220.7

RAPID FIXATION OF IN VITRO BRAIN SLICES USING MICROWAVE IRRADIATION. F.E. Jensen and K.M. Harris, Dept. Neurosci., Children's Hospital, Boston MA 02115.

We have evaluated the use of microwave (MW) irradiation to enhance immersion fixation of rat hippocampal slices. This method produces perfusion quality fixation within seconds of immersion. 400u thick slices were prepared from adult male rats and maintained in vitro for 90 min. Slices were then transferred on nets into mixed aldehydes within a MW oven (700W,2450MHz), irradiated, and then washed immediately in buffer and processed for LM and EM. In order to determine optimal conditions, parameters varied included MW time (7-30sec) producing tissue temperatures of 34-92C, and concentration of glutaraldehyde in the fixative (2.5%,4%, or 6%: paraformaldehyde 2%). These MW fixed slices were compared to within animal control slices immersed in the same concentration of aldehydes for 11 sec to 16 hours. Electron micrographs were taken of area CA1 pyramidal cell bodies and dendrites at 100-125u depth from the slice surface and compared between MW,control slices,and perfusion fixed material. Slices irradiated for 11sec (40-50C) while immersed in fixative containing 6% glutaraldehyde yielded fixation quality comparable to perfusion. Post fixation in aldehydes after MW did not enhance quality. MW fixation to higher temperatures caused disruption of dendritic microtubules. Concentrations of 2.5% and 4% glutaraldehyde resulted in inferior quality at all temperatures of MW fixation. Control slices immersed without MW irradiation revealed markedly inferior fixation. MW enhanced fixation markedly reduces the occurence of dentritic and mitochondrial swelling and other necrotic changes which occur with conventional immersion fixation and should provide more accurate ultrastructural data related to dynamic electrophysiological properties recorded in slice tissue.

221.1

[³H]-BMY 7378: A SELECTIVE, HIGH AFFINITY 5-HT$_{1A}$ LIGAND IN RAT HIPPOCAMPAL AND CORTICAL MEMBRANES. F.D. Yocca[1], L. Oneto[1] and S. Maayani.[2] CNS Research, Bristol-Myers Co., Box 5100, Wallingford, CT, 06492 and Depts. of Anesthesiology and Pharmacology, Mt. Sinai School of Medicine, New York, NY, 10029.

The 5-HT$_{1A}$ receptor and its related binding sites are distributed nonuniformly throughout mammalian brain. Additionally, 5-HT-sensitive [³H]-8-OH-DPAT binding sites are homogenous in hippocampus yet heterogenous in in cortex, as evidenced in membranes from rat brain with respect to the K_d and IC_{50} values of several drugs. Previously, we reported that BMY 7378 demonstrated high affinity, selectivity and low efficacy at 5-HT$_{1A}$ receptors linked negatively to adenyl cyclase (Yocca et al., 1987). We have tritiated BMY 7378 and used it to label apparent homogenous populations of [³H]-5-HT and [³H]-8-OH-DPAT sensitive sites in cortical and hippocampal membranes. The pharmacology of the [³H]-8-OH-DPAT and [³H]-BMY-7378 sites in hippocampus was indistinguishable with respect to IC_{50} values of 5-HT$_{1A}$ agonist and antagonists, GppNHp sensitivity and with respect to the inhibition of forskolin-stimulated adenyl cyclase activity. Similarly, the pharmacology of the 5-HT-sensitive [³H]-BMY 7378 sites in cortical and hippocampal membranes in rat was indistinguishable. These data suggest that [³H]-BMY 7378 selectively labels 5-HT$_{1A}$ sites in brain regions other than hippocampus. (Supported in part by USPH GM 34852).

221.2

EVIDENCE FOR THE EXISTENCE OF PUTATIVE 5-HT$_{1D}$ RECEPTOR BINDING SITES IN HUMAN BRAIN. J. Martial*, M. Dalpé*, C. deMontigny and R. Quirion. (Spon: B. Suranyi-Cadotte) Douglas Hosp. Res. Ctr. and McGill Univ., Montreal, Quebec, Canada H4H 1R3

Multiple serotonin (5-HT) receptor sub-types are present in mammalian brain tissue. In human brain, the existence of 5-HT$_{1A}$ and 5-HT$_{1C}$ receptor sites have been clearly demonstrated while 5-HT$_{1B}$ sites are most likely absent. Very little information is currently available on the presence of 5-HT$_{1D}$ binding sites in human brain. Brain membranes were prepared using control postmortem human brain cortical tissues. Membrane binding assays were usually performed at 25°C for 30 min in 50 mM Tris.HCl containing 10µ M pargyline, 4 mM $CaCl_2$, 0.1% ascorbic acid and various concentrations of [³H]5-HT in presence of saturating concentrations of 5-HT$_{1A}$, 5-HT$_{1B}$ and 5-HT$_{1C}$ blockers to inhibit binding of the ligand to those sites. Under these conditions, [³H]5-HT apparently binds to a remaining single class of high affinity sites in human brain cortex. The ligand selectivity pattern demonstrates that 5-HT > mianserin > 8-OH-DPAT > mesulergine = propranolol in competing for [³H]5-HT sites. This is similar to the ligand selectivity pattern reported by Heuring and Peroutka (J. Neurosci. 7, 894-903, 1987) for the putative 5-HT$_{1D}$ sites present in bovine brain. Thus, it would appear that a similar sub-type of 5-HT$_1$ sites is also found in human brain cortex.

221.3

EFFECT OF GEPIRONE ON RAT CORTICAL AND HIPPOCAMPAL SEROTONIN SYNTHESIS. J. Torrente,* E. Ryan,* and F.D. Yocca. (Spon: M.S. Eison).CNS Research, Bristol-Myers Company, Wallingford, CT, 06492-7660.

Gepirone (G) is a novel anxiolytic/antidepressant candidate which demonstrates selective agonist activity at central 5-HT$_{1A}$ receptors.Evidence for this includes: 1) G displaces [³H]8-OH-DPAT from 5-HT-sensitive binding sites in rat and guinea pig hippocampal homogenates (Yocca et al., 1986); 2) G elicits a partial agonist action on 5-HT$_{1A}$ receptor coupled adenylate cyclase in similar preparations (Yocca and Maayani, 1985; Yocca et al., 1986); 3) G induces the 5-HT behavioral syndrome in rats (Eison et al., 1986); and 4) G inhibits the firing of serotonin containing dorsal raphe neurons after systemic administration (Gehlbach and VanderMaelen, 1985). Acute administration of gepirone (either s.c. or p.o.) decreases serotonin synthesis in both cortex and hippocampus as measured by accumulation of L-5HTP after administration of the decarboxylase inhibitor NSD-1015. Furthermore, at a low dose (1 mg/kg, s.c.; 5 mg/kg,p.o.) gepirone selectively inhibits 5-HT synthesis in rat cortex. This effect is probably not mediated by synthesis controlling terminal 5-HT$_{1B}$ receptors (Galloway et al., 1987) since gepirone lacks affinity for 5-HT$_{1B}$ binding sites, and may be due to a preferential action of G at 5-HT$_{1A}$ somatic auto receptors on 5-HT neurons projecting to the cortex.

221.4

ADENOSINE A_1 AND 5-HT$_{1A}$ RECEPTORS SHARE A COMMON PERTUSSIS TOXIN (PT)-SENSITIVE, G_i-LIKE PROTEIN IN RAT HIPPOCAMPUS: J.M. Zgombick[1], S.G. Beck[1], and S. Maayani[1,2] Depts. of Pharmacology[1] and Anesthesiology[2], Mount Sinai School of Medicine, CUNY, New York, NY 10029.

Adenosine A_1 and 5-HT$_{1A}$ receptors in rat hippocampal preparations share common features including inhibition of forskolin-stimulated adenylate cyclase (FSAC), hyperpolarizations, and high density of their related binding sites. Biochemical and electrophysiological studies were initiated to test the possible sharing of effector mechanisms. Maximal inhibition of FSAC produced by PIA (40%) was greater than 5-HT (30%), but both agonists (1 uM) stimulated [^{35}S]-GTPγS binding approximately 15% above basal. PIA (10 uM) and 5-HT (15 uM) elicted hyperpolarizing responses (7-8 mV) within the same cell which were mediated through enhanced K^+ conductance. The combination of maximal 5-HT and PIA concentrations did not potentiate either the biochemical or electrophysiological responses from that observed with PIA alone. Central administration of PT produced similar reductions in 5-HT- and PIA-mediated inhibition of FSAC and hyperpolarizations. We propose that adenosine A_1 and 5-HT$_{1A}$ receptors may coexist on the same hippocampal pyramidal cells and share a common PT-sensitive, G_i-like transducing protein. [Supported by USPH Grants GM 34852, MH 41917 and Training Grant DA-07135].

221.5

EFFECTS OF INTRANIGRAL SEROTONIN AGONISTS ON STRIATAL DOPAMINE METABOLISM. **S.L. Rubinstein* and K. Gale (SPON: R. McGee). Dept. of Pharmacol. Georgetown Univ. Med. Ctr., Washington, DC 20007.**

Intranigral microinfusion of either serotonin (5-HT, 45 nmoles) or the 5-HT$_{1B}$ selective agonist 1-(m-trifluoromethylphenyl)-piperazine (TFMPP, 10 nmoles) caused an elevation in dopamine (DA) metabolism (30% increase in DOPAC and HVA) in the homolateral striatum of awake, unrestrained rats sacrificed 60 min after microinfusion (Soc. Neurosci. Abstr. 12; 872, 1986). We present here the effects on DA metabolism of the 5-HT$_{1A}$ selective agonist 8-hydroxy-dipropylaminotetralin HBr (8-OH-DPAT) and the 5-HT uptake inhibitor fluoxetine HCl. 8-OH-DPAT (10 nmoles) microinfused into one substantia nigra (SN) did not significantly alter striatal levels of DOPAC, HVA or DA in rats sacrificed 60 min after microinfusion. This suggests that nigrostriatal DA neurons are not influenced by 5-HT$_{1A}$ receptor stimulation in the SN. Fluoxetine HCl (15 nmoles) microinfused into one SN significantly elevated homolateral striatal DOPAC and HVA to 40% above the corresponding values in control rats receiving a saline microinfusion in the SN. This effect of fluoxetine was not reduced by prior depletion of 5-HT via pretreatment with p-chlorophenylalanine (a tryptophan hydroxylase inhibitor), suggesting that the effect of fluoxetine is not dependent upon presynaptic stores of 5-HT in SN.

221.6

A NON-5-HT$_{1A}$, 5-HT$_1$-"LIKE" RECEPTOR MEDIATES INHIBITION OF ADENYLYL CYCLASE IN RAT SUBSTANTIA NIGRA AND NUCLEUS ACCUMBENS. C.D. Mahle, J.M. Zgombick, F.D. Yocca, and S. Maayani. Depts. Anesthesiology and Pharmacology, Mt. Sinai School of Medicine, CUNY, NY, NY 10029 and CNS Research, Bristol Meyers Co., Wallingford, CT 06492.

At least five distinct subtypes of functional 5-HT receptors have been suggested. The spiperone and BMY 7378 sensitive 5-HT$_{1A}$ receptor is negatively linked to adenylyl cyclase (AC). The 5-HT$_{1A}$ and a second 5-HT receptor that are negatively linked to AC were examined in membrane preparations from rat hippocampus, substantia nigra (SN), and nucleus accumbens (NA) using 5-HT, 5-carboxyamidotryptamine (5-CT), spiperone and (+/-) pindolol. 5-CT was a more potent agonist than 5-HT in eliciting the inhibition of AC linked to both the 5-HT$_{1A}$ and the non-5-HT$_{1A}$ receptor.

	E_{max} (%)	EC_{50} (nM):	5-CT	5HT
HIPPOCAMPUS	30		5	50
SUBSTANTIA NIGRA	20		10	50
NUCLEUS ACCUMBENS	10		15	50

While spiperone and pindolol antagonized the response to 5-HT and 5-CT in the hippocampus, (5-HT$_{1A}$ receptor), in SN and NA the 5-HT and 5-CT effect was not antagonized. Futhermore, the forskolin stimulation of AC activity in these regions was insensitive to 8-OH-DPAT, mesulergine, BMY 7378, ketanserin, or ICS 205-930. In SN, 5-HT displaced [³H]-5-HT in a competitive manner (IC_{50} = 10 nM) 5-CT displaced [³H]-5-HT with a slope less than unity (IC_{50} = 7 nM). It is proposed that in the regions examined, (SN and NA) 5-HT and 5-CT inhibit the AC activity via a non 5-HT$_{1A}$ receptor. (USPH grant GM 34852).

221.7

AUTORECEPTOR CONTROL OF SEROTONIN (5HT) SYNTHESIS IN BRAIN SLICES: REVERSAL OF 5HT-1B EFFECTS BY 5TH1-A AGONISTS, M.P. Galloway, C. McIntyre*, E.A.Novak*, B.N. Mathews*, Wayne State Univ. Sch. Med. & Lafayette Clinic, Detroit, MI

We have previously shown that 5HT synthesis in vivo is inhibited by 5HT agonists regardless of their 5HT-1A/1B character. However, using brain slices in vitro, we found that 5HT synthesis is attenuated exclusively by 5HT-1B agonists, 5HT-1A agonists are without effect on 5HT synthesis in isolated nerve terminals. In light of the possible opposing biochemical roles exerted by each receptor subtype, we have studied the combined interaction between 1A and 1B agonists at the 5HT synthesis modulating autoreceptor. In depolarized cortical slices (K^+=30 mM), 5HT synthesis is inhibited concentration dependently by the 5HT-1B agonists TFMPP, mCPP, and RU-24969. In the presence of the 5HT-1A agonist 8-OHDPAT (10 uM), the inhibition afforded by the 5HT-1B agonists (1uM) is almost completely reversed. The effect of 8-OHDPAT was dose dependent in the presence of a fixed concentration of 1B agonist. Related monohydroxylated aminotetralins such as (+)-7- or 5-OH-DPAT (potent dopamine autoreceptor agonists), had little ability to reverse TFMPP thus demonstrating receptor specificity. Although putative inhibition of kinase C by polymixin B (100 uM) partially prevented (70%) the K^+ activation of 5HT synthesis, it did not potentiate TFMPP effects. Apparently, 8-OHDPAT can either exert 5HT-1B antagonist activity or 1A and 1B receptors interact in an opposing fashion.

Support: USPHS MH-41227, DA-4120, State of Michigan.

221.8

SEROTONIN AUTORECEPTORS IN GUINEA PIG CORTEX SLICES RESEMBLE THE 5-HT_{1d} BINDING SITE. J.Schipper and M.T.M.Tulp*. Dept. of Pharmacology, Duphar B.V., P.O.Box 2, 1380 AA, Weesp, The Netherlands

Serotonin (5-HT) release is modulated by presynaptic receptors. In the rat, these 5-HT autoreceptors have been characterized as 5-HT_{1b} binding sites. In pigs and monkeys, the 5-HT autoreceptors have different characteristics (Schipper et al. Soc. Neurosci Abstr 1987, 13: 345). In this study, the pharmacology of the 5-HT autoreceptors in guinea pig brain slices was further evaluated with regard to subtypes of 5-HT binding sites.

Slices of parietal cortex were loaded with [^{3}H]-5-HT, superfused with Krebs-Ringer buffer containing 10 µM fluvoxamine (5-HT uptake inhibitor) and release of 5-HT was induced by 20 mM K^+. The K^+-induced release of [^{3}H]-5-HT was almost completely abolished in the presence of 1 µM 5-HT (pD_2=8.5). Release was also inhibited by the 5-HT agonists RU24969 (pD_2=7.9) TFMPP (pD_2=6.8), 8-OH-DPAT (pD_2=7.1) and 5-methoxytryptamine (pD_2=7.9). The effect of 5-HT could be antagonized by methiotepine (pA_2=8.3), metergoline (pA_2=7.4) and yohimbine (pA_2=7.4). Cyanopindolol (pA_2<6.5), mianserine (pA_2<6) MDL 72222 (pA_2<6) and ketanserine (pA_2<6) were inactive.

In comparison to receptor binding data, these findings indicate that the terminal autoreceptor of the guinea pig does not match with the 5-HT_3, 5-HT_2, 5-HT_{1a}, 5-HT_{1b}, 5-HT_{1c} binding sites. The best correlation ifs found with the 5-HT_{1d} binding sites.

221.9

TRYPTOPHAN HYDROXYLASE ACTIVITY IN BRAIN SLICES AND ITS REGULATION BY SEROTONIN (5-HT) AUTORECEPTORS. L.B.Bosch* and J.Schipper (SPON: L.D.Bradford). Dept. of Pharmacology, Duphar B.V., P.O.Box 2, 1380 AA, Weesp, The Netherlands

Tryptophan hydroxylase (TPH) is the rate-limiting enzyme in the 5-HT biosynthesis. In contrast to modulation of 5-HT release, relatively little is known about the regulation of TPH activity by 5-HT autoreceptors. Therefore we studied the role of 5-HT autoreceptors on TPH activity in brain slices under conditions at which 5-HT release is modulated. Raphe and cortex slices from rat brains were incubated for 60 min at 37°C in an oxygenated Krebs-ringer buffer containing 10µM NSD 1015 and 100µM l-tryptophan. After homogenation in the medium, the total amount of 5-HTP was determined with HPLC. K^+ (20mM)-induced 5-HT release was measured by [^{3}H] overflow from [^{3}H]-5-HT preloaded cortex slices.

K^+ stimulated 5-HT release is inhibited by 5-HT (pD_2=7.8) and other agonists such as TFMPP (pD_2=7.7) and Eltoprazine (pD_2=7.6). Under similar conditions, the TPH activity is not influenced by these 5-HT agonists. Incubation under depolarizing conditions (56 mM K^+) increased TPH activity to 140%. Low Ca^{2+} (0.1 mM) prevented this increase, whereas 5-HT agonists were inactive. The results suggest that TPH activity is not directly influenced by a 5-HT autoreceptor. This is different from the situation with DA autoreceptors which modulate tyrosine hydroxylase activity. The K^+-induced increase of TPH activity suggests that the biosynthesis of 5-HT is mainly under a depolarization induced control.

SEROTONIN STIMULATION OF CYCLIC NUCLEOTIDE PRODUCTION AND CYCLIC NUCLEOTIDE MODULATION OF PHOSPHOINOSITIDE TURNOVER IN PORCINE CHOROID PLEXUS. M.J. Kaufman, B.J. Hoffman and P.R. Hartig. Dept. of Env. Health Sci., The Johns Hopkins Medical Institutions, Balto., MD, 21205.

Maximal production of inositol monophosphate (IP) by the choroid plexus (CP) 5HT_{1c} receptor occurs at 1uM 5HT with an EC_{50} of 46nM. At higher 5HT concentrations (10uM and 100uM) there is a decrease in IP production (25 and 33%). We now report that activation of this receptor leads to accumulation of cGMP. The EC_{50} for this response is similar to that for IP production. Maximal formation of cGMP is several fold above basal levels. We hypothesize that the IP decrease seen at high 5HT levels may be caused by 5HT-stimulated cyclic nucleotide production. Therefore we tested other compounds that are known to elevate CP cyclic nucleotide levels to determine whether they could influence 1uM 5HT-stimulated IP production. Incubation of CP with cAMP elevating agents (2.5uM Isoproterenol, 100uM dBcAMP) did not alter IP production, however, compounds which increase cGMP levels (100uM dBcGMP, 500uM Carbamylcholine, 100uM Sodium Nitroprusside) inhibited IP production by 14-44%. Since cholinergic and atrial natriuretic peptide stimulation of CP have been shown by others to elevate cGMP, these inputs into CP may modulate 5HT function in this tissue. Further, cGMP increases produced by 5HT may negatively modulate the IP elevations produced by 5HT in CP.

221.11

THE BOVINE HIPPOCAMPAL 5-HT_{1A} RECEPTOR -G-PROTEIN INTERACTIONS ARE CONSERVED IN DETERGENT SOLUTION. T.B.Kline*[1], Y.Gold,*[2] L.R.Meyerson,[2] R.Iyengar*[1] (1)Department of Pharmacology, Mt. Sinai School of Medicine, CUNY, NY,NY10029 and (2)Medical Research Division,American Cyanamid Co., Ramapo College, Mahwah, NJ 07430.

Studies on the bovine hippocampal 5-HT_{1A} receptor, solubilized in 50 mM TRIS/10 mM CHAPS/200 mM NaCl, in the absence of agonist, provide evidence for the tight coupling of the receptor with its associated guanine-nucleotide-binding (G)protein(s). Scatchard analysis of [^{3}H] 8-OH DPAT binding shows a single site with K_d = 1.9 nM, B_{max} = 42 fmol/mg protein. The rank order of affinity of WB4101, 5-HT, and 5-$CONH_2$T indicates that a 5-HT_{1A} receptor has been solubilized. The K_{act} values for guanine nucleotides for the converstion of the receptor from a high to a low affinity agonist state are 50-300 nM. Agonist (5-HT, 8-OH DPAT, 5-$CONH_2$T) stimulated [^{35}S]GTPγS binding to G proteins is observed in detergent extracts. The K_{act} of 8-OH DPAT for this allosteric effect (2 nM) indicates that this effect occurs as a consequence of agonist binding to the 5-HT_{1A} receptor. Although guanine-nucleotide sensitivity for other receptors in detergent solutions has been demonstrated, many (although not all) receptors require preexposure to agonist in order to retain the G-protein coupling. In contrast, the bovine hippocampal 5-HT_{1A} receptor-G-protein complex is apparently formed prior to agonist occupancy.(Supported by NIDA grant DA-01875 and NIH grants DK-38761 and CA 44998).

GUANYL NUCLEOTIDE SENSITIVE SEROTONIN 5HT_{1D} RECEPTORS IN HUMAN CORTEX AND CAUDATE. K.HERRICK-DAVIS* and M.Titeler (SPON: M. Miller) Dept. Pharmacol. Toxicol. Albany Medical College, Albany, NY 12208.

Radioligand binding studies in mammalian brain have revealed the presence of multiple serotonin receptors: 5HT_{1A}, 5HT_{1B}, 5HT_{1C}, 5HT_2 and 5HT_3. Recently, evidence has been provided for a new subtype of serotonin receptor, 5HT_{1D}, in bovine, porcine and rat brain. The pharmacology of this site is unique in that it displays high affinity for 5CT, yohimbine, methysergide and ergotamine.

Radioligand binding studies were performed to characterize 5HT_{1D} receptors in human prefrontal cortex and caudate homogenates. 3H-5HT binding, in the presence of pharmacologically blocked 5HT_{1A}, 5HT_{1B}, 5HT_{1C} and 5HT_2 receptors, was specific, saturable, reversible and of high affinity. In both brain regions the majority of 5HT_1 sites were of the 5HT_{1D} subtype. 5HT_{1D} sites in human brain have a similar pharmacology to 5HT_{1D} sites in rat, bovine and porcine brain. Guanyl nucleotides modulated the binding of 3H-5HT to 5HT_{1D} sites, while adenyl nucleotides had no effect. These findings are supportive of the presence of serotonin 5HT_{1D} receptors in human prefrontal cortex and caudate which appear to be coupled to a GTP binding protein.

221.13

DETECTION AND CHARACTERIZATION OF THE NOVEL 5HT1E RECEPTOR IN HUMAN AND OTHER MAMMALIAN BRAIN TISSUES. M. TITELER and K. HERRICK-DAVIS*. Dept. of Pharmacol. Toxicol., Albany Medical College, Albany, NY 12208.

Radioligand binding studies utilizing 3H-5HT and brain tissue homogenates have previously revealed the presence of four $5HT_1$ receptor subtypes. In human cortical tissue homogenates, in the presence of pharmacologically blocked $5HT_{1A}$, $5HT_{1C}$ and $5HT_{1D}$ receptors (there are no detectable $5HT_{1B}$ receptors in human brain tissue), a saturable, high affinity binding site for 3H-5HT was detected. This binding site (termed "$5HT_{1E}$" in keeping with the currently popular 5HT nomenclature system) was pharmacologically distinguished from any of the other six 5HT receptor subtypes by displaying low affinity for ketanserin (a high affinity $5HT_2$ drug), ICS-205-930 (a high affinity $5HT_3$ drug), 8-OH-DPAT (a high affinity $5HT_{1A}$ drug), TFMPP (a high affinity $5HT_{1B}$ drug), mesulergine (a high affinity $5HT_{1C}$ drug) and 5CT (a high affinity $5HT_{1D}$ drug). Preliminary studies indicate this site is present in human, bovine and porcine brain tissue and is sensitive to guanyl nucleotides and insensitive to adenyl nucleotides (indicating a $5HT_{1E}$/GTP binding protein interaction). Detailed radioligand characterization of this novel $5HT_{1E}$ receptor in mammalian brain tissue will be presented.

221.14

HALLUCINOGEN INTERACTIONS WITH RADIOLABELLED HUMAN $5HT_2$ RECEPTORS. S. LEONHARDT*, R.A. LYON, M. TITELER, B.SAZDOT*, J. BARABAN, and R.A. GLENNON*.(SPON: M. DENTINGER). Dept. Pharmacol. Toxicol., Albany Medical College, Albany, New York 11208. Dept. Neurosciences, Johns Hopkins Univ. Med. Ctr., Baltimore, Maryland 21205. Dept. Medicinal Chemistry, Virginia Commonwealth University, Richmond, Virginia 23298

It has been hypothesized that stimulation of brain $5HT_2$ receptors is the mechanism-of-action of LSD and similarly acting hallucinogens. Therefore studies to determine the affinities of the hallucinogens in binding to human cortical $5HT_2$ receptors were undertaken in order to determine whether the affinities for the human $5HT_2$ receptor would match the affinities for the rat $5HT_2$ receptor and would correlate closely with the hallucinogenic potencies in humans. Preliminary data appear to indicate that the hallucinogens interact with the human and rat brain $5HT_2$ receptors with similar affinities, supporting the hypothesis that brain $5HT_2$ stimulation produces the psychoactive properties of these drugs. Autoradiographical studies designed to investigate the interactions of hallucinogens with radiolabelled human $5HT_2$ receptors in slide-mounted tissue sections are being conducted and will be presented.

221.15

SEROTONIN NEURONAL GROWTH FACTOR RELEASED BY ASTROGLIAL 5-HT_1 RECEPTORS. P.M. Whitaker-Azmitia, L. Noreika*, E. Azmitia, Department of Psychiatry SUNY, Stony Brook, NY 11794

We have shown the presence of high affinity serotonin receptors on astroglial cells. The number of sites (B_{max}) is greatest in immature astrocytes, an observation which led us to the hypothesis that these receptors may play a role in brain development.

To test this hypothesis, we treated immature astroglial cultures with 500 nM 5-HT, 8-OH-DPAT, TFMPP or mCPP and collected the media after 4 and 24 hours incubation. The astroglial-conditioned media was then added to cultures of fetal rat serotonergic neurons. Growth of the neurons was assessed by the amount of specific uptake of 50 nM ^{3}H-serotonin in twenty minutes.

Greatest stimulation of growth (139% increase) was observed in cultures containing media from astrocytes treated with 5-HT for 24 hours. The selective 5-HT_{1a} agonist 8-OH-DPAT also stimulated growth (134%). The 5-HT_{1b} agonists, TFMPP and mCPP showed the least effect (115% and 114% respectively).

Media from astroglial cultures, incubated for only 4 hours with the receptor agonists, did not show growth-promoting factors. This suggests that the factor is not a readily available constituent of astroglial cells (for example, glucose), but rather requires time to be produced.

221.16

ESTROGEN ENHANCES SEROTONIN-1A ELECTROPHYSIOLOGICAL RESPONSES IN FEMALE RAT HIPPOCAMPAL SLICES. W.P. Clarke, S.G. Beck and J. Goldfarb. Department of Pharmacology, Mount Sinai School of Medicine, CUNY, New York, NY 10029-6574.

The gonadal steroids are known to modulate several aspects of CNS serotonergic neurotransmission: synthesis, content, turnover and uptake of serotonin (5-HT) as well as 5-HT receptor density. In this study we investigated the effects of estrogen on electrophysiological responses to 5-HT in rat hippocampal slices.

Female Sprague-Dawley rats were anesthetized with ether and ovariectomized. At least two weeks later, rats were treated for 4 to 6 days with estrogen (either injections of 10 µg estradiol benzoate/day sc or implants of silastic capsules [5 mm x .058 in id] containing estradiol, sc). Chronic estrogen treatment enhanced the 5-HT_{1A} induced decrease in CA1 population spike amplitude. The concentration response curves to 5-carboxyamidotryptamine, a 5-HT_{1A} agonist, were shifted to the left approximately 5-fold as compared with control. Chronic estrogen enhanced the 5-HT_{1A} mediated hyperpolarization of CA1 pyramidal cells without affecting 5-HT's reduction of the afterhyperpolarization. The mechanism(s) by which estrogen enhances the sensitivity of 5-HT_{1A} responses is under investigation. Supported by grants DA 01875 and MH 41917.

221.17

SEROTONERGIC PHENYLPIPERAZINES: HYPOTHERMIA OR HYPERTHERMIA RELATED TO AFFINITY FOR 5HT-1A or 5HT-1B BINDING SITES. G.E. Martin, M.K. Scott, W.J. Baldy, R.P. Shank and J.R. Mathiasen. Janssen Research Foundation, Department of Biological Research, Spring House, PA USA.

Previously, we have reported that selected phenylpiperazines (PP) block conditioned avoidance responding in the rat, although they exhibit no affinity for dopamine D-2 receptors. (Martin, et al., Abst. Neuroscience 1987, 13:800). Herein the effect of PP on the rectal temperature of the rat is reported. In general, following administration of ortho-substituted PP, a fall in the rectal temperature of the rat was observed. When substitutions were placed in the meta-position of the phenyl ring, however, hyperthermia was produced concomitant with a shift in selectivity of the PP in binding assays from the 5HT-1A to the 5HT-1B binding site. Hyperthermia evoked by 5HT-1B selective agonists was abolished by pretreatment with the serotonin antagonist metergoline. Metergoline, on the other hand, failed to reduce hypothermia produced by 5-HT-1A agonists. Conversely, the 5HT-1A selective antagonist, (-) propranolol did reverse some of the 5HT-1A agonist induced hypothermia without blocking 5HT-1B-induced rises in rectal temperature. The data suggest activation of 5HT-1A and 5HT-1B binding sites produce opposite effects on the rat's rectal temperature, and reveal meta vs ortho substitution on the phenyl ring is more likely to render a 5-HT-1B selective agent than a similar substitution in the ortho position.

221.18

HALLUCINOGENS DIRECTLY ACTIVATE SEROTONIN 5HT-1c RECEPTORS IN CHOROID PLEXUS. K.D. Burris* and E. Sanders-Bush. Dept. of Pharmacology and Psychiatry, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232.

Central serotonin (5HT) receptors, in particular the 5HT-2 subtype, are believed to be involved in mediating the actions of hallucinogens. Because of similarities between the 5HT-2 and 5HT-1c receptors, the effects of hallucinogens at 5HT-1c receptors were examined in an in-vitro assay of receptor function. Agonist-induced phosphoinositide (PI) hydrolysis was determined in rat choroid plexus by measuring ^{3}H-inositol monophosphate formation in the presence of LiCl. 1-(2,5-dimethoxy-4-phenyl)-2-aminopropane (R,S-DOM) increased PI hydrolysis with an EC_{50} of 0.6 µM and maximum effect that was 70% that produced by 5HT. The R(-) isomer of DOM was 10-fold more potent than the S(+) isomer. D-lysergic acid diethylamide (+ LSD) potently stimulated PI hydrolysis with an EC_{50} of 50 nM and maximum effect 25% of that produced by 5HT. The potent 5HT-1c receptor antagonist, mianserin, was more efficacious than the less potent 5HT-1c antagonist, spiperone, at blocking the effect of both R,S-DOM and (+) LSD. Lisuride and (-) LSD, both nonhallucinogenic congeners of (+) LSD, were pure antagonists of 5HT-1c mediated PI hydrolysis with IC_{50} values of approximately 100 nM and 100 µM respectively. This study demonstrates for the first time that hallucinogens are agonists at 5HT-1c receptors. (Supported by DA05181, MH34007 and GM07628.)

221.19

SEROTONINERGIC MODULATION OF LOCAL INHIBITION IN HIPPOCAMPAL SLICE: MEDIATION BY 5-HT$_{1A}$ RECEPTOR.

S. Springfield, C. Ayala and D. Delma, Dept. of Biology, City College of City Univ. of N.Y., New York, NY 10031.

In previous studies, we demonstrated that serotonin (5-HT) attenuates local inhibition in the hippocampus. We report here that this effect may be mediated through the 5-HT$_{1A}$ receptor.

Rat hippocampal slices were constantly superfused with a bicarbonate-buffered balanced salt solution equilibrated with 95% O_2/5% CO_2 and maintained at 32° C. Evoked population spikes were recorded with a single barreled glass micropipette from the somal layer of CA1 pyramidal neurons. To activate inhibitory interneurons, pairs of stimuli were delivered to either the stratum radiatum or the alveus at 1/30 Hz. When stimuli were presented at short interstimulus intervals (10-40 msec), a reduction in the second population spike occurred. This reduction has been attributed to the action of GABA-mediated inhibition superimposed upon orthodromic excitation.

Superfusion of 0.1 uM 8-hydroxy-2(di-n-propylamine)-tetralin (8-OH-DPAT), a 5-HT$_{1A}$ receptor agonist, mimics the action of 5-HT, while superfusion of 0.1 uM spiroxatrine, a 5-HT$_{1A}$ antagonist, blocks the action of 5-HT on local inhibition. These studies demonstrate that the effect of 5-HT on local inhibition may be mediated through the 5-HT$_{1A}$ receptor. (Supported by NSF grant BNS 86-06419, PSC-CUNY award and MBRS program).

221.20

INHIBITION OF PURKINJE CELL SPONTANEOUS DISCHARGE BY THE 5HT$_{1A}$ SPECIFIC AGONIST 8-OH-DPAT IN THE IN VITRO CEREBELLAR SLICE IS MG^{++} SENSITIVE.

E.J. Darrow, H.K. Strahlendorf, and J.C. Strahlendorf. Depts. of Physiology and Neurology, Texas Tech University Health Sciences Center, School of Medicine, Lubbock, TX.

We have previously shown (Darrow, et al., Soc. Neurosci. Abst. 17: 1652, 1987) that the 5HT$_{1A}$ specific agonist 8-OH-DPAT produces inhibition of Purkinje cell (PC) spontaneous discharge, in the in vitro cerebellar slice preparation. Recent studies by Norman, et al. (Mol. Pharm., 28: 487, 1985) using radioligand binding studies, and by Daval, et al. (J. of Neurosci. 6: 3474, 1986) using autoradiography have shown agonist binding to the 5HT$_{1A}$ receptor subtype is [Mg^{++}] dependent. Our studies examine the effects of low [Mg^{++}], in the perfusion medium, on the inhibition of PC spontaneous discharge by microiontophoretic application of 8-OH-DPAT. In the cerebellar slice preparation, we have seen that lowering the [Mg^{++}] from 1.15 mM to 0.56 mM significantly decreases the inhibition of PC spontaneous firing produced by 8-OH-DPAT. This study gives physiological support to the findings of Norman, et al. and Daval, et al. in that the decreased inhibition caused by lowered [Mg^{++}] appears to be due to a decrease in the binding affinity of 8-OH-DPAT to the 5HT$_{1A}$ receptor subtype. (Research supported in part by the Tarbox Parkinson's Disease Institute, TTUHSC.)

221.21

DIRECT EFFECTS OF SUPERFUSED SEROTONIN ON NEURONS OF DEEP CEREBELLAR NUCLEI.

P.A. Cumming*, J.C. Strahlendorf and H.K. Strahlendorf (SPON: R. Norman). Depts. Physiology and Neurology, Texas Tech University Health Sciences Center, Lubbock,TX 79430.

Based on anatomical studies demonstrating a serotonergic innervation to both the cerebellar cortex and deep cerebellar nuclei (Chan-Palay, V., In: Cerebellar Dentate Nucleus: Organization, Cytology and Transmitters, 1977), as well as our studies characterizing the actions of serotonin (5-HT) on Purkinje cells (Strahlendorf, J.C., et. al., *Exp. Brain Research*, 56: 50, 1984), this study examines the actions of 5-HT on the neurons of the dentate/interpositus nuclei in an in-vitro brain slice. Using an interface chamber with the temperature controlled at 34° C., horizontal slices of Sprague-Dawley rats (350 µm sections) were superfused with various concentrations of 5-HT. Dentate/interpositus cells display a regular firing pattern with a frequency range between 15-80 Hz and an average of 47 Hz (n=19). Seventy-one percent of the cells responded to 5-HT with a decrease in the discharge rate, while 29% exhibited an increase. 5-HT at 10^{-7}, 10^{-6},10^{-5} M produced a dose related decrease in spontaneous firing rate of 34, 47, and 52%, respectively. At these same concentrations of 5-HT, increases of 16, 13, and 33%, respectively, were seen in the cells displaying excitation. The cells within the deep cerebellar nuclei appear to be more sensitive than Purkinje cells in the cerebellar cortex by approximately three orders of magnitude. Collectively, our previous studies and these results further identify a neurotransmitter/modulator role of 5-HT on cerebellar neurophysiology at both the cortical and nuclear levels. Supported by NS19296 (JCS & HKS).

221.22

THE CONTRACTILE EFFECT OF 5-HYDROXYTRYPTAMINE (5-HT) ON CEREBRAL BLOOD VESSELS IS MEDIATED BY HETEROGENEOUS 5-HT RECEPTORS.

E. Hamel and E.T. MacKenzie*. Montreal Neurological Institute, Montréal, Québec H3A 2B4 and *L.E.R.S. 92220 Bagneux, France.

We tested a range of 5-HT agonists and antagonists on the in vitro reactivity of the cat middle cerebral artery and compared their vascular potency with affinity values for the various 5-HT receptor subtypes. 5-Carboxamidotryptamine and RU 24969 (agonists at 5-HT$_{1A-1B}$ subtypes) were, respectively, significantly more potent and as potent as 5-HT itself in eliciting vasoconstriction. α-Methyl-5-HT (5-HT$_{1C-2}$ agonist) and 2-methyl-5-HT(5-HT$_3$ agonist) were 20 and 60 times less potent than 5-HT. All these agonists induced similar maximal responses (E_{AM} varied from 0.83 to 1.20g; that of 5-HT was 1.16±0.09g and the EC_{50} value for 5-HT was 7.9±0.8 x 10^{-8}M). The most selective 5-HT$_{1A}$ agonist, 8-OH-DPAT, was the least potent but induced a significantly more intense vasoconstriction (E_{AM} = 1.84±0.12g; $p<0.01$). Amongst the antagonists tested, 5-HT$_{1A-1B}$ 5-HT$_{1C}$ and 5-HT$_3$ selective drugs such as propranolol-cyanopindolol, mesulergine and MDL 72222 were inactive. In contrast, the 5-HT$_2$ receptor antagonists exerted a non-competitive inhibition of the 5-HT-induced constriction. The order of potency was pizotifen > ritanserin ≥ dihydroergotamine > cyproheptadine ≥ methiothepin > ketanserin ≥ methypergide. The pD_2' values (negative logarithm of the molar concentration of antagonist needed to decrease E_{AM} response by 50%) varied from 8.74±0.14 (pizotifen) to 6.88±0.26 (methypergide).

A 5-HT$_2$ and a 5-HT$_{1B}$-like receptors appear to be involved in this cerebrovascular response to 5-HT. The vascular 5-HT$_{1B}$-like site shares pharmacological similarities with the 5-HT$_{1D}$ subtype recently described.

221.23

ALTERATIONS IN SEROTONIN (5-HT) BINDING SITES AFTER 5,7DIHYDROXYTRYPTAMINE (5,7DHT) TREATMENT IN THE RAT SPINAL CORD.

L.M. Brown, D.L. Smith*, G.M. Williams and D.J. Smith. Depts. of Pharmacol./Tox. and Anes., West Virginia University, Morgantown, WV, 26505.

These studies attempted to confirm the presynaptic distribution of the 5-HT$_{1B}$ binding sites presumed to modulate transmitter release in the rat spinal cord. Experimental rats received desipramine (DMI) (25mg/kg, i.p.) prior to the intrathecal (i.t.) injection of the 5-HT neurotoxin, 5,7DHT (100µg). Paired controls also received DMI and the vehicle (i.t.). At 3,7,10 and 14 days after 5,7DHT, competition binding assays were performed using 2nM ^{3}H-5-HT and Trifluoromethylphenyl piperazine, a drug which interacts with 5-HT$_{1B}$ and 5-HT$_{1A}$ binding sites. Binding capacities and affinities were determined using LIGAND (Munson and Rodbard Anal. Biochem. 106:220,1980).

At three days, 5,7DHT caused a significant decrease (35%) in 5-HT$_{1B}$ binding sites with the affinity of those remaining being higher. The decrease in binding correlated (r=0.71) with the degree of 5-HT depletion. At later time periods, no significant changes were observed in the 5-HT$_{1B}$ binding site perhaps because of adaptive changes and/or gliosis. By day 14 an increase (30%) in the binding capacity of the 5-HT$_{1A}$ site was also observed. These results confirm the presynaptic distribution of the 5-HT$_{1B}$ binding site.

221.24

INHIBITION OF ISOLATION-INDUCED AGGRESSION BY SELECTIVE SEROTONERGIC AGENTS.

S. M. White, R. F. Kucharik* and J. A. Moyer. Wyeth-Ayerst Research, Department of Experimental Therapeutics, Princeton, NJ 08543.

The inhibition of isolation-induced aggressive behavior in male mice has been proposed as a preclinical screen for anxiolytic activity. Benzodiazepines and, more recently, several serotonergic (5-HT1A) partial agonists have been found to reduce aggressive behavior.

CF-1 male mice were individually housed for 3 weeks and then trained to attack a group-housed intruder mouse. Drugs were administered IP 60 min prior to the test and total fighting time during the 3 min test was measured. Debilitation was evaluated by the rotorod/ataxia test.

The 5-HT1A partial agonists, buspirone and SM-3997, were equipotent to diazepam in antagonizing aggression, while ipsapirone and chlordiazepoxide were less potent. Selective 5-HT1A agonists (8-OHDPAT and Wy-48,723) and 5-HT1A antagonists (BMY-7378 and Wy-47,846) had greater potency in inhibiting aggressive behavior than any of the benzodiazepines tested. O-methoxyphenyl-piperazine (oMPP) exhibits 5-HT1A partial agonist/antagonist activity and may be an active metabolite of enciprazine, a non-benzodiazepine anxiolytic. Both were found to inhibit aggressive behavior as potently as lorazepam. Both 5-HT1A partial agonists and antagonists inhibit aggression at non-sedative doses, suggesting a pre/postsynaptic 5-HT or a non-serotonergic mechanism of action.

221.25

5-HT SYNDROME: DIFFERENTIAL EFFECTS OF 5-HT1A SELECTIVE COMPOUNDS. **R. F. Kucharik*, S. M. White, T. H. Andree, and J. A. Moyer. Wyeth-Ayerst Research, Department of Experimental Therapeutics, Princeton, NJ 08543**

The agonist and antagonist properties of serotonin (5-HT) selective compounds were elucidated through their ability to elicit or block the 5-HT syndrome in rats, a post-synaptic 5-HT1A mediated response. Agonist activity was evaluated by quantifying the behavioral response using a four-point ranked intensity scale on each of the six symptoms that characterize the 5-HT syndrome. Antagonist activity was assessed by administering compounds 15 min prior to a subsequent 5-methoxy-N,N-dimethyltryptamine (MeODMT) challenge.

MeODMT, 8-OH-DPAT, Wy-48,723, buspirone and gepirone dose-dependently increased 5-HT syndrome scores. BMY 7378, Wy-47,846, buspirone and gepirone inhibited the syndrome produced by MeODMT. A single test dose of enciprazine was unable to block or elicit the 5-HT syndrome, but its putative metabolite o-methoxyphenylpiperazine (oMPP) produced a profile similar to that of buspirone and gepirone. Binding studies on Wy-48,723, Wy-48,846, and oMPP have demonstrated a high affinity for the 5-HT1A site, whereas enciprazine had low affinity. In the 5-HT syndrome MeODMT, 8-OHDPAT and Wy-48,723 appear to be full agonists. Buspirone, gepirone and oMPP are partial agonists/antagonists, while BMY-7378 and Wy-47,846 may be considered antagonists.

221.26

5HT1A AGONISTS: ASSOCIATION BETWEEN HYPOTHERMIA AND BRAIN FUNCTION AS MEASURED BY THE AUDITORY-EVOKED BRAINSTEM RESPONSE. **R. R. Notvest, L. Sutherland, and J. T. Haskins. Department of Experimental Therapeutics, Wyeth-Ayerst Research Inc., Princeton, NJ 08543-8000**

In a preliminary study we found that 5HT1A agonists increased all peak latencies of the auditory-evoked brainstem response (ABR). Other studies have shown that 5HT1A agonists induce hypothermia (G. M. Goodwin, et al., 1985) and, independently, hypothermia increases the peak latencies of the ABR (Rossi and Britt, 1984). This study more fully examined the effect of 5HT1A agonists on both the ABR and body temperature (BT).

Male SD rats, previously implanted with cortical electrodes, were restrained and placed in sound attenuated chambers. Following baseline recordings, rats received 5 mg/kg ip of either buspirone (n=6), 8OH-DPAT (n=6), Wy-48,723 (n=4) or vehicle (n=6). ABRs and BT were recorded at regular intervals for 4 hrs.

All three 5HT1A agonists significantly decreased BT and increased ABR latency (quantified as a change in Peak IV latency), with the order of potency being Wy-48,723 $\geq$ 8OH-DPAT > buspirone ($p<0.05$). Changes in BT and ABR latency were correlated. The results suggest that 5TH1A-induced changes in the ABR are non-specific effects due to hypothermia.

PRECLINICAL NEUROPHARMACOLOGICAL PROFILE OF WY-48,723, A POTENT SEROTONIN (5-HT_{1A}) AGONIST. T.H. Andree, J.A. Moyer, G. Stack, E.A. Muth and J.T. Haskins. Wyeth-Ayerst Research, CNS Subdivision, Philadelphia, PA 19101

Wy-48,723 (decahydro-3-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-1,5-methano-6,7,9-metheno-2H-pentaleno-[1,2-d]azepine-2,4(3H)-dione, hydrochloride hemihydrate) is a substituted arylpiperazine synthesized for potential anxiolytic/antipsychotic activity. In vitro receptor binding assays reveal high affinity for 5-HT_{1A} sites (Ki=0.3nM) with lower affinity for D_2 (Ki=56nM) and 5-HT_2 (Ki=272nM) binding sites. Wy-48,723 produced less than 40% inhibition of $alpha_1$ (36%), $alpha_2$ (0%), beta (4%) and D_1 (0%) radioligand binding at 1µM drug concentration. Both i.p. and p.o. administration of Wy-48,723 (10 mg/kg) inhibited the ex vivo binding of ^{3}H-8-OHDPAT in hippocampal membranes. Electrophysiologically, Wy-48,723 and buspirone inhibited the firing of dorsal raphe neurons (IC_{50} values=0.008 and 0.03 mg/kg, i.v., respectively), suggesting agonistic activity. In behavioral studies, Wy-48,723 was active in inhibiting apomorphine-induced climbing (ED_{50}=0.4 mg/kg, i,p.) but not stereotyped behavior (inactive at 40 mg/kg). Like buspirone, Wy-48,723 inhibited conditioned avoidance behavior following i.p. administration (AB_{50}s <10 mg/kg), but was inactive in the Geller-Seifter conflict model. In summary, Wy-48,723 has an interesting profile suggesting potential antipsychotic/anxiolytic activity.

221.28

BUSPIRONE PARTIALLY GENERALIZES TO THE STIMULUS EFFECTS OF DPAT USING THE DISCRIMINATED AVERSION PROCEDURE. J.M. Marcoccia* and I. Lucki (SPON: M. Bauer). Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

Rats were trained to discriminate the stimulus effects of the 5-HT_{1A} agonist DPAT (0.4 mg/kg IP) using a new discriminated aversion procedure (Lucki et al., Soc. Neurosci. Abstr., 13:344, 1987). Rats demonstrated the stimulus effects of DPAT with a 2-bottle choice test by a reversal of their ordinary preference for saccharin over tap water. The ability of 3 anxiolytic drugs with high affinity for the 5-HT_{1A} receptor, buspirone, ipsapirone, and gepirone, to substitute for the DPAT stimulus was examined with this method.

Administration of DPAT produced a dose-dependent reduction of the preference for saccharin over tap water in conditioned rats, but did not alter saccharin preference in untrained controls. Buspirone only partially substituted for the effects of DPAT. Gepirone completely substituted for effects of DPAT, whereas the effect of ipsapirone was intermediate between that of gepirone and buspirone. The results suggest that the discriminated aversion method can detect the effects of full and partial 5-HT_{1A}.

This research was supported by USPHS grants MH 36262 and GM 34781.

BMY 7378 BLOCKS BEHAVIORAL RESPONSES PRODUCED BY THE 5-HT_{1A} AGONIST 8-OH-2-(di-n-propylamino)tetralin (DPAT). I. Lucki, D.Z. Press* and J.M. Marcoccia*. Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA 19104.

BMY 7378 was suggested to be a weak partial agonist at the 5-HT_{1A} receptor because of its high binding affinity and low response efficacy in vitro (Yocca et al., Eur. J. Pharmacol., 137:293, 1987). Because of this profile, BMY 7378 was examined at responses produced by systemic administration of the 5-HT_{1A} agonist DPAT in rats.

BMY 7378 alone did not produce signs of the 5-HT behavioral syndrome but pretreatment with BMY 7378 prevented DPAT from producing the syndrome. BMY 7378 alone produced a small (-0.6°C) reduction in body temperature, but pretreatment attenuated the larger (-2.0°C) hypothermic effect of DPAT.

The stimulus effects of DPAT (0.4 mg/kg) were studied using a new discriminated aversion method (Lucki et al., Soc. Neurosci. Abstr., 13:344, 1987). BMY 7378 administered alone produced a small but significant substitution for the stimulus effect of DPAT. However, pretreatment with 1.0 mg/kg BMY 7378 prevented discrimination of the DPAT training stimulus.

When administered in combination with the 5-HT_{1A} agonist DPAT, BMY 7378 prevented many of its behavioral actions. These behavioral results support the characterization of BMY 7378 as a weak partial agonist at the 5-HT_{1A} receptor.

This research was supported by USPHS grants MH 36262 and GM 34781.

221.30

THE DEVELOPMENT OF TOLERANCE FOLLOWING CHRONIC ADMINISTRATION OF 5-METHOXYDIMETHYLTRYPTAMINE. K. A. Brown and M. A. Blackshear. Department of Biological Sciences, Tennessee State University, Nashville, TN 37209-1561.

It has been recently reported that tolerance develops to the induction of serotonin (5-HT) mediated behaviors following chronic administration of 5-HT agonists. The present study examines the effects of repeated administration of 5-methoxydimethyltryptamine (5-MeODMT), a putative selective 5-HT_1A agonist, on three parameters of 5-HT receptor function; food intake, body temperature, and 5-HT binding sites.

Male Sprague-Dawley rats received a single dose (6 mg/kg) or 7 daily doses (3 mg/kg, twice daily) of 5-MeODMT. Body temperature and food intake were measured 30 minutes after acute treatment, or 30 minutes after a challenge dose of 5-MeODMT was given at 48 hours after termination of treatment. Serotonin-2 binding sites were measured at 48 hours after acute or chronic administration of 5-MeODMT.

Food consumption was markedly reduced after a single injection of 5-MeODMT (11 ± .4 saline controls vs 3 ± .74 gms 5-MeODMT), but was unchanged after repeated doses (11.4 ± .4 saline vs 9.2 ± .4 gms 5-MeODMT).

Similarly, body temperature was decrease after acute 5-MeODMT (36.3 ± .11° C controls vs 34.0 ± .3°C 5-MeODMT), but was unaltered following chronic treatment (36.4 ± .2°C control vs 36.0 ± .3°C 5-MeODMT). [^{3}H]-ketanserin binding to 5-HT2 sites in the frontal cortex was not altered by acute or chronic 5-MeODMT treatment. These results suggest that food intake may be mediated by 5-HT_1A receptors and provides supporting evidence of the development of tolerance after chronic stimulation of central 5-HT receptors. (Supported by NIH - ROMI grant# G12RR03033).

221.31

COMPARISON OF THE NOVEL 5-HT_{1A} RECEPTOR RELATED ANXIOLYTICS BUSPIRONE, GEPIRONE, IPSAPIRONE, SM 3997, THEIR METABOLITE 1-PYRIMIDINYLPIPERAZINE AND DIAZEPAM IN ANIMAL MODELS OF ANXIETY.

J.Traber*, T.Schuurman* and U.Benz* (SPON. W.Daunicht), Neurobiology Department, Tropon Pharmaceuticals, Neurather Ring 1, D-5000 Köln 80, F.R.G.

The second generation anxiolytics buspirone, gepirone, ipsapirone and SM 3997, which potently and selectively interact with central 5-HT_{1A} receptors, their common metabolite 1-pyrimidinylpiperazine (1-PP) and diazepam were compared in various rat models of anxiety and in motor function tests. The former included the shock suppressed drinking (SSD), the Geller-Seifter conflict, the conditioned emotional response (CER), the social interaction (SI) and the ultrasonic vocalization (USV) test. All five anxiolytics released punished behavior in the SSD and Geller-Seifter test in the potency rank order diazepem > gepirone = ipsapirone > buspirone > SM 3997 and disinhibited lever pressing in the CER. In the USV paradigm, in which ultrasonic vocalization was elicited by electric footshock, all test compounds mentioned decreased the duration of 22 kHz vocalization. The duration of social interaction between rats in a brightly illuminated test arena was increased by all compounds except SM 3997 and 1-PP. Interestingly, under low light, less stressful conditions only ipsapirone but not the other substances showed prosocial effects. 1-PP was active in a few of the anxiety models its potency being lower than that of the parent compounds. Motor functions in mice were stronger affected by diazepam than by the 5-HT_{1A} receptor related anxiolytics.

The results indicate differences in the efficacy and potency as well as in their activity profile of the serotonergic anxiolytics.

221.32

FUNCTIONAL INTERACTION OF THE NOVEL 5-HT_{1A} RECEPTOR ANXIOLYTICS WITH 5-HT_{1A}- and α-ADRENERGIC RECEPTORS

T.Gläser*, L.A.A.van Rooijen* and J. Traber* (SPON: C.Richter-Landsberg), Neurobiology Department, Tropon Pharmaceuticals, Neurather Ring 1, D-5000 Köln 80, F.R.G.

There is substantial evidence that the 5-HT_{1A} receptor subtype in the brain is involved in mechanisms underlying anxiety. The aim of the present study was to compare on a biochemical level the novel 5-HT_{1A} receptor related anxiolytics buspirone, gepirone, ipsapirone and SM 3997 as well as 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) in respect to their functional interaction with 5-HT_{1A} and α-adrenergic receptors. These compounds bound with high affinity to 5-HT_{1A} receptors in the rank order 8-OH-DPAT > ipsapirone SM 3997 > buspirone > gepirone. 8-OH-DPAT and SM 3997 acted as full agonists on these receptors as measured by inhibition of forscolin-stimulated adenylate cyclase in rat hippocampus. The intrinsic activity of buspirone, gepirone and ipsapirone was considerably lower than that of the full agonists. At higher concentrations ipsapirone, but only marginally buspirone could antagonize the agonist induced inhibition of enzyme activity. Ipsapirone bound with higher affinity than the other 5-HT_{1A} receptor related anxiolytics or 8-OH-DPAT to central α_1- and α_2-adrenergic receptors. Functional in vitro studies revealed ipsapirone to possess antagonistic or agonistic properties on α_1- or α_2-adrenergic receptors, respectively.

The present results indicate differences of the novel anxiolytics in their intrinsic activities on 5-HT_{1A} receptors and in their affinity to α-adrenergic receptors, which might be relevant for their pharmacological profile.

221.33

PHARMACOLOGICAL DIFFERENTIATION OF $5HT_1$ AND $5HT_2$ COMPONENTS OF A SEROTONERGIC SYNDROME IN MICE

B. Dubinsky, R. Ernest and D. A. Shriver. Research Laboratories, Ortho Pharm. Corp., Raritan, NJ 08869.

Administration of 5-hydroxytryptophan (90 mg/kg, iv) to mice 1 hr after serotonin (5-HT) uptake inhibition with zimelidine (12 mg/kg, sc) produces head twitch (TWITCH), body tremors (TREMOR) and abduction of the hindlimbs (ABDUCT). TWITCH and TREMOR are probably mediated by both $5\text{-}HT_1$ and $5\text{-}HT_2$ receptor systems. However, ABDUCT is thought to be mediated by $5\text{-}HT_1$ receptors in the spinal cord. Compounds with relatively selective affinity for $5\text{-}HT_2$ receptors, such as, ritanserin (RIT), pirenperone (PIREN) or cyproheptadine (CYPRO) potently blocked TWITCH (ED_{50}=0.3, 0.3 or 1.0 mg/kg, respectively); and, with the exception of CYPRO, inhibited TREMOR. However, ABDUCT was not inhibited by RIT (ED_{50}>20 mg/kg), PIREN (ED_{50}>3 mg/kg) or CYPRO (ED_{50}>10 mg/kg). In contrast, metergoline, a compound less selective for $5\text{-}HT_2$ vs. $5\text{-}HT_1$ sites, blocked or inhibited all three components of the syndrome at similar doses; TWITCH (ED_{50}=3 mg/kg), TREMOR (ED_{50}=3 mg/kg) and ABDUCT (ED_{50}=12 mg/kg). In conclusion, the syndrome is influenced by various oral treatments in a manner consistent with their putative effect on 5-HT receptors; thus, this method represents a model for the detection of compounds having differential affinities for $5\text{-}HT_1$ or $5\text{-}HT_2$ receptors in mice.

SEROTONIN, HISTAMINE AND OTHER BIOGENIC AMINES V

222.1

FENFLURAMINE NEUROTOXICITY: SELECTIVE DEGENERATION AND RECOVERY OF BRAIN SEROTONIN NEURONS.

J.F. Contrera, G. Battaglia, R. Zaczek and E.B. De Souza Neuroscience Branch, Addiction Research Center, NIDA, Baltimore, MD 21224 and FDA, Rockville, MD 20857.

Fenfluramine, a widely prescribed anorectic agent, has been reported to suppress brain serotonin (5-HT) systems. The present study investigates the neurotoxic effects of fenfluramine (1-24 mg/kg s.c., b.i.d. for 4 days) on rat brain 5-HT neurons with respect to dose-dependence, neuroanatomical specificity and timecourse of recovery. Neurotoxicity was assessed by decreases in 5-HT and 5-HIAA content and decreases in ^{3}H-paroxetine-labeled 5-HT uptake sites. Fenfluramine caused dose-dependent reductions in all serotonergic markers in the cerebral cortex, with maximal decreases (80%) in 5-HT, 5-HIAA, and 5-HT uptake sites observed at 12 and 24 mg/kg. Marked decreases in all 5-HT parameters were also observed in olfactory bulb, striatum, hippocampus, hypothalamus, midbrain, pons-medulla and cerebellum. Recovery of 5-HT uptake sites in cerebral cortex and hippocampus occurred over a protracted period of time. Following 75-80% reductions in 5-HT uptake sites at 18 hours after short-term treatment with fenfluramine, the initial rate of recovery was faster in cortex than in hippocampus; a 20% deficit was present in both brain regions as long as 8 months after drug administration. These data demonstrate that fenfluramine elicits potent, widespread and long-lasting neurodegenerative effects on brain 5-HT neurons.

222.2

FENFLURAMINE SELECTIVELY DESTROYS SEROTONIN TERMINALS IN BRAIN: IMMUNOCYTOCHEMICAL EVIDENCE.

Nathan M. Appel and Errol B. De Souza. Neuroscience Branch, National Institute on Drug Abuse, Addiction Research Center, Baltimore, MD 21224.

Fenfluramine is an amphetamine derivative which is used as an appetite suppressant. In rats fenfluramine treatment decreases brain serotonin (5HT) levels and inhibits high affinity uptake of 5HT. Recent studies in our laboratory have shown that fenfluramine decreases ^{3}H-paroxetine-labeled 5HT uptake sites in cerebral cortex and cerebellum. In view of these data we used immunohistochemistry to assess whether these neurochemical changes were associated with destruction of 5HT-containing neurons.

Male Sprague-Dawley rats were injected with fenfluramine HCl 24 mg/kg sc b.i.d. for 4 days. Twelve-18 h following the final injection rats were treated with tranylcypromine, anesthetized and perfused with buffered paraformaldehyde. Ten and 35 μm brain sections were processed for fluorescence and avidin-biotin-peroxidase complex immunohistochemistry, respectively, using antisera to 5HT or tyrosine hydroxylase (TH).

Fenfluramine treatment caused a profound reduction in fine-caliber 5HT-immunoreactive fibers and terminals visible in frontal, parietal and striate cortex. In cerebellum there was almost total depletion of 5HT-like immunoreactivity in both molecular and granular layers. Remaining 5HT-immunoreactive fibers showed cytopathologic features characteristic of degenerating neurons (i.e. thick, swollen and fragmented appearance). On the other hand 5HT-immunoreactive cell bodies in midbrain nuclei appeared to be spared. TH-like immunoreactivity seemed to be unaffected.

These data suggest that fenfluramine is neurotoxic and that this neurotoxicity is in part expressed by massive destruction of 5HT-containing fibers and terminals.

222.3

RITALIN AND PEMOLINE DO NOT CAUSE MONOAMINE TERMINAL DEGENERATION. R. Zaczek, G. Battaglia, J.F. Contrera and E.B. De Souza (SPON: N. Bernick). NIDA, Addiction Res. Ctr., Baltimore, MD 21224 and FDA, Rockville, MD 20857.

Several amphetamine-like stimulants such as methamphetamine (METH), fenfluramine and methylene-dioxymethamphetamine have been shown to cause monoamine terminal degeneration. We assessed the possible neurotoxic properties of pemoline (PEM)(20 and 60mg/kg) and Ritalin (RIT)(7 and 21mg/kg), two psychostimulants used clinically to treat attention deficit disorder. METH (5 and 15mg/kg) was included in the survey to validate the procedure.

Rats were injected s.c. with drug or vehicle twice daily for 4 days. One day after the last injection the rats were sacrificed, cerebral cortex and striatum were dissectd and analyzed for biogenic amine markers. Cortex was analyzed for norepinephrine (NE), NE transport sites, serotonin (5-HT) and 5-HT transport sites. Striatum was analyzed for dopamine (DA), DA transport sites, 5-HT and 5-HT transport sites.

While METH at the high dose caused significant depletions in all markers measured, neither PEM nor RIT elicited any decrease in monoamine markers.

We conclude that repeated injection of PEM or RIT does not cause a pattern of monoamine terminal damage similar to that observed after repeated injection of METH. Thus, use of PEM or RIT may carry less risk than the use of other amphetamine-like stimulants.

222.4

INCORPORATION OF ^{3}H-METHYLENEDIOXYAMPHETAMINE (MDA) INTO RAT BRAIN SYNAPTOSOMES. Steven Culp*, Robert Zaczek and Errol B. De Souza. Neuroscience Br., NIDA Addiction Res. Ctr., Baltimore, MD 21224.

MDA and its N-methyl derivative MDMA have been proposed as adjuncts to psychotherapy. Recently MDMA has surfaced as an illicit drug of choice. Several studies have demonstrated specific neurodegeneration caused by repeated injection of either MDA or MDMA in rats and monkeys. While attempts to demonstrate specific interactions of ^{3}H-MDMA with brain membranes have been unsuccessful, possible interactions of ^{3}H-MDA have not been studied. We have found that ^{3}H-MDA was incorporated into rat brain synaptosomes; this incorporation could be divided into three pools. ^{3}H-MDA associated with a saturable-non-specific pool which remained after synaptic membranes had been boiled for 15 min. Non-linear curve fitting analysis of ^{3}H-MDA saturation isotherms revealed specific high (Kd = .57μM) and low (Kd = 51μM) affinity components. The low affinity component was abolished by preincubation in hypoosmolar media indicating that it may represent sequestration. Eliminating the low affinity component left a single population of high affinity binding (Kd = 1.2μM). Pharmacologic profiles revealed subtle differences between the high and low affinity sites. While the inhibition profile for the low affinity site was: paroxetine = desipramine > 2,5 methoxy-4-methamphetamine (DOM) = MDA; the profile for the hgh affinity component was paroxetine > desipramine = DOM > MDA. Of the endogenous neurotransmitters used in the inhibition studies, 100uM serotonin inhibited 1.0uM ^{3}H-MDA incorporation by 26%, while neither dopamine nor norepinephrine were effective inhibitors at 100uM. Preliminary studies of ^{3}H-MDMA incorporation into rat brain synaptosomes indicate the presence of a site similar to the low affinity component of ^{3}H-MDA incorporation.

222.5

NEUROANATOMICAL SPECIFICITY OF MDA- AND MDMA-INDUCED DEGENERATION OF SEROTONIN NEURONS IN RAT BRAIN. G. Battaglia, J. Sharkey*, M.J. Kuhar and E.B. De Souza (SPON: A.C. Church). Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224.

It has been demonstrated that the "designer" drugs MDA (3,4-methylenedioxyamphetamine) and MDMA (3,4-methylene-dioxymethamphetamine) cause long-lasting destruction of serotonin (5-HT) terminals in rat brain. We have used in vitro autoradiography of ^{3}H-paroxetine-labeled 5-HT uptake sites to assess whether specific 5-HT pathways may be differentially affected by these drugs. Following treatment with MDA or MDMA (20 mg/kg, b.i.d. for 4 days), marked decreases in 5-HT uptake sites were observed in a number of brain regions known to receive projections of 5-HT neurons. These regions included cerebral cortex, caudate nucleus, hippocampus, nucleus accumbens, olfactory tubercle, superior and inferior colliculi, geniculate nuclei and some thalamic nuclei. Other 5-HT projection areas such as the septal nuclei were not substantially affected. Additional brain areas that were less sensitive to the neurotoxic effects of MDA and MDMA were those containing 5-HT cell bodies (e.g. dorsal and median raphe and pontine nuclei) and 5-HT axons of passage (e.g. indusium griseum and lateral hypothalamus). These data suggest that MDA and MDMA cause preferential degeneration of 5-HT terminals whereas 5-HT perikarya and axons of passage are less affected.

222.6

MDMA SELECTIVELY DESTROYS BRAIN SEROTONIN TERMINALS IN RHESUS MONKEYS. J.N. Johannessen, T.R. Insel, G. Battaglia, M.J. Kuhar and E.B. De Souza. Lab. Clin. Sci., NIMH, Poolesville, MD 20837 and Neurosci. Branch, NIDA Addiction Research Center, Baltimore, MD 21224.

The potential neurotoxic hazard of 3,4-methylenedioxy-methamphetamine (MDMA, "Ecstasy") in humans was assessed by examining the effects of repeated systemic administration of MDMA (2.5 or 10 mg/kg, b.i.d. for 4 days) on selected neurochemical and behavioral measures in rhesus monkeys. Following either dose of MDMA, greater than 50% decreases in CSF concentrations of the serotonin (5-HT) metabolite 5-hydroxyindoleacetic acid (5-HIAA) were noted. By contrast, CSF concentrations of other monoamine metabolites showed little change. Eighteen hours after the last dose of MDMA, concentrations of 5-HT and 5-HIAA, but not dopamine or norepinephrine, were reduced by at least 70% in cerebral cortex, caudate and putamen. Furthermore, at the high dose of MDMA selective destruction of brain 5-HT terminals (decreases in 5-HT uptake sites) was observed; no significant decreases were noted in the densities of dopamine and norepinephrine uptake sites. Behavioral changes following MDMA were consistent with reduced 5-HT transmission in brain. We are currently investigating long-term changes in CSF monoamine metabolite concentrations following MDMA administration. These data demonstrating potent effects of MDMA on various brain 5-HT parameters in rhesus monkeys suggest that high doses may selectively destroy 5-HT terminals in humans.

222.7

[3H]PAROXETINE BINDING IS ASSOCIATED WITH SEROTONIN (5-HT) UPTAKE IN BLOOD PLATELETS OF HEALTHY CONTROLS. **L.J. Iny, M.J. Meaney, P. Desjardins*, R. Quirion & B.E. Suranyi-Cadotte. Douglas Hospital Research Centre, Dept. of Psychiatry, McGill Univ., Verdun, Que. H4H 1R3**

Altered 5-HT uptake is associated with the pathophysiology of various disorders. Recently, paroxetine was found to be a potent, selective inhibitor of 5-HT uptake, and specific sites for [3H]paroxetine have been associated with the 5-HT carrier in rat brain and platelets. Platelet [3H]paroxetine binding could thus be a useful index of changes in the 5-HT uptake system.

We investigated binding and uptake in parallel in blood platelets of healthy volunteers. A single class of high affinity [3H]paroxetine binding sites was observed, with a Bmax of 1416 ± 111 fmol/mg prot. The Vmax of [14C]5-HT uptake was 142 ± 22 fmol/105 platelets/2 min. A significant positive relationship between the two measures was found ($p<.05$). The results provide support for an association between [3H]paroxetine binding and the 5-HT carrier, and also suggest that platelet [3H]paroxetine binding may be a useful marker of the 5-HT uptake site.

222.8

USE OF TETRABENAZINE AS A TOOL TO DISTINGUISH DIRECT FROM INDIRECT 5-HT AGONIST EFFECTS ON 5-HT NEURON ACTIVITY IN VITRO. G.C. Rigdon and C.M. Wang. Dept. Pharmacology, Burroughs Wellcome Co., Research Triangle Park, NC 27709.

5-HT reuptake blockers inhibit the firing of 5-HT neurons in vitro (SFN, 13:1648, 1987). This experiment was designed to determine if this inhibition was the result of direct agonist effects. Single unit recordings were obtained from slices of rat midbrain. The effects of increasing concentrations of the 5-HT uptake blockers, imipramine and fluoxetine and the direct agonist, 8-OHDPAT, on the firing rates of these dorsal raphe neurons were investigated in brain slices treated with and without (TBZ), a compound which depletes neuronal 5-HT. Brain slices were exposed to TBZ (10 uM) for 20-30 min prior to testing and 1 uM during testing. The concentration-response curves of both imipramine and fluoxetine were shifted to the right as was predicted. The IC50 values in untreated brain slices were; imipramine-2.7 ± 0.8 uM, fluoxetine-4.2 ± 2.1, and the IC50 values in TBZ treated slices were; imipramine-7.3 ± .7 uM, fluoxetine->>10 uM (50% inhibition not observed). TBZ treatment did not decrease the potency of the direct agonist, 8-OHDPAT; untreated slice IC50=1.8 ± 1.4 nM, TBZ slice IC50=0.9 ± 0.3 nM. This evidence supports the hypothesis that the inhibition of 5-HT neuron firing by antidepressant drugs in vitro is the not the result of a direct agonist effect.

222.9

EFFECTS OF HIGH-DOSE METHAMPHETAMINE (MA) ADMINISTRATION ON SEROTONIN UPTAKE SITES IN RAT BRAIN MEASURED BY QUANTITATIVE AUTORADIOGRAPHY. **G.B. Kovachich, C.E. Aronson* & D.J. Brunswick, VA Med. Ctr. & Univ. of Pa School of Medicine; Phila., PA 19104.**

High doses of MA cause long-term neurotoxic effects on serotonergic neurons in brain. In the present study the effect of MA on serotonin uptake sites in rat brain was examined by quantitative autoradiography using ^{3}H-cyanoimipramine (0.3nM) (Kovachich et al., Brain Res. in press). Rats were treated with either MA (15 mg free base/Kg N=6) or saline (N=6) given subcutaneously every 6 hrs for 5 doses and were killed 7 or 30 days following the last dose. MA caused large reductions in ^{3}H-cyanoimipramine binding in several brain regions examined both at 7 and 30 days after MA. Seven days after MA, greatest reductions were seen in the superior colliculus, central gray area and entorhinal cortex (53-61%). Reductions of 28-38% were seen in caudate putamen, parietal cortex, hypothalamus and hippocampus. In contrast, no significant effect was noted in the substantia nigra or dorsal raphe n.. Thirty days after MA, greatest reductions were seen in superior colliculus and entorhinal cortex (50-57%). Reductions of 30-36% were seen in parietal cortex, hippocampus and central gray area. Small reductions occurred in substantia nigra (19%) and dorsal raphe n. (14%). No significant reductions were seen in caudate putamen or hypothalamus. These results show that MA causes localized reductions in ^{3}H-cyanoimipramine binding in terminal areas of rat brain. The dorsal raphe n., a serotonin cell body area, is more resistant to the neurotoxic effect of MA. **(Supported by Research Funds from the Veterans Administration).**

222.10

IN VIVO LABELING OF SEROTONIN UPTAKE SITES WITH ^{3}H-PAROXETINE AND EFFECTS OF MDMA. U. Scheffel and P.R. Hartig*. Div. Nuclear Medicine and Dept. Environ. Health Sciences, The Johns Hopkins Medical Inst., Baltimore, MD. 21205.

3H-Paroxetine (^{3}H-P) is a potent and selective serotonin uptake site inhibitor in vitro. The purpose of this study was to characterize the in vivo binding of ^{3}H-P in mice with a view towards the development of a ligand for imaging 5-HT uptake sites in the living human brain.

^{3}H-P showed high uptake in the mouse brain, regional localization in agreement with the known distribution pattern of 5-HT uptake sites, and good regional selectivity. 3H-P in vivo binding to the hypothalamus was inhibited by 5-HT uptake blockers in a dose-dependent manner. There was an excellent correlation (r=0.99) with respect to the potency of these drugs in inhibiting ^{3}H-P binding in vivo vs. inhibition of 5-HT uptake in synaptosomes.

The effect of MDMA on in vivo 3H-P binding to 5-HT uptake sites in mice was studied: At one day after the last MDMA dose (8x 20 mg/kg), an up-regulation of 5-HT uptake sites was observed. There was no late (7 -14 days) neurotoxic effect on 5-HT uptake sites, in agreement with previous results in mice.

The data indicate that ^{3}H-paroxetine is a potent and selective in vivo label of 5-HT uptake sites which can be used to monitor 5-HT uptake site regulation in vivo.

222.11

EFFECTS OF MDMA ON CENTRAL SEROTONERGIC NEURONS IN NON-HUMAN PRIMATES: PERMANENT OR TRANSIENT? G. A. Ricaurte, L. S. Forno, S. G. Wiener, L. E. DeLanney, I. Irwin, J. W. Langston. Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; Pathol. Dept., Vet. Adm. Med. Ctr., Palo Alto, CA 94304; Psychiat. Dept., Stanford Univ., Palo Alto, CA; Inst. Med. Res., San Jose, CA 95128.

The purpose of this study was to determine if the effects of 3,4-methylenedioxymethamphetamine (MDMA) on central serotonergic neurons in non-human primates are reversible. Previous studies indicate that administration of 5 mg/kg of MDMA s.c. twice daily (0900 and 1700 hours) for 4 days to squirrel monkeys results in an 75-86% depletion of regional forebrain serotonin, and in the appearance of abnormal inclusion bodies in nerve cells in the dorsal raphe nucleus (Ricaurte et al., JAMA, in press). These observations were made in monkeys killed two weeks after MDMA administration. We now report that monkeys killed ten, rather than two, weeks after an identical regimen of MDMA have only a 30-47% depletion of regional forebrain serotonin, and no inclusions in the dorsal raphe nucleus. Moreover, these monkeys also show recovery of 5HIAA in CSF over the 10 week period. There was no evidence of cell loss in the midbrain raphe of ten-week survival animals. These findings suggest that serotonergic deficits produced by the aforementioned regimen of MDMA in the monkey are reversible, and that inclusion bodies in the dorsal raphe nucleus do not herald cell death, but more likely reflect reaction of the cell body to axonal injury.

222.12

ELECTRON MICROSCOPIC STUDY OF THE DORSAL RAPHE NUCLEUS IN THE MDMA-TREATED SQUIRREL MONKEY. L. S. Forno, G. A. Ricaurte, L. E. DeLanney, I. Irwin, J. W. Langston. Pathology Dept., Vet. Adm. Med. Ctr., Palo Alto, CA 94304; Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; Inst. for Med. Res., San Jose, CA 95128.

We have recently shown that when 3,4-methylenedioxymethamphetamine (MDMA) is administered systemically to squirrel monkeys, it produces not only damage to serotonin-containing nerve terminals, but also marked changes in nerve cell bodies in the dorsal raphe nucleus (Ricaurte et al., JAMA, in press). Specifically, MDMA induces formation of PAS-positive inclusions in nerve cells of the dorsal, but not median, raphe nucleus. These inclusions were present in three of three six year old monkeys that had received MDMA two weeks previously. Electron microscopic examination of the dorsal raphe nucleus of a one year old monkey administered MDMA two weeks earlier shows loss of cisternae of rough endoplasmic reticulum, constricted, thread-like mitochondria, and an increase in dense bodies with early stages of lipofuscin or ceroid formation. In another young monkey, examined ten weeks after MDMA, no inclusion bodies could be found by light microscopy, and by electron microscopy, only small amounts of lipofuscin were present. These preliminary studies demonstrate an effect of MDMA on the phagolysosomal system, and suggest that nerve cell changes after MDMA may be reversible.

222.13

EVIDENCE FOR A MONOAMINERGIC LINK IN THE NEUROTOXICITY OF METHYLENEDIOXYMETHAMPHETAMINE (MDMA). V.L. Taylor* and C.J. Schmidt* (SPON: P.J. Robinson). Merrell Dow Res. Inst., 2110 E. Galbraith Road, Cincinnati, OH 45215

The psychedelic amphetamine analog, MDMA, is a selective serotonergic neurotoxin when administered to rats in high doses. A single dose of MDMA (20 mg/kg) resulted in a decrease in cortical tryptophan hydroxylase (TPH) activity and 5-HT concentrations for one month post-drug. Pretreatment with the centrally active inhibitor of aromatic l-amino acid decarboxylase, α-monofluoromethyl-dopa (MFMD, 100 mg/kg daily x 3), antagonized the MDMA-induced loss of both cortical TPH activity and transmitter concentrations observed at 1 week. The neurotoxicity of MDMA was also antagonized when rats were pretreated with the tyrosine hydroxylase inhibitor α-methyl-p-tyrosine. To determine if dopamine was involved, unilateral 6-OH-dopamine lesions of the substantia nigra were performed on rats 1 week prior to MDMA administration; serotonergic markers in contralateral and ipsalateral structures then were compared. Although the lesions reduced ipsalateral dopamine to less than 10% of control, striatal 5-HT and cortical TPH activity were reduced to a similar extent on both sides 3 hr after MDMA. Identical results were observed in animals allowed to survive 1 week after MDMA. The results suggest a catecholaminergic link in the serotonergic neurotoxicity of MDMA; however, the anatomical basis for the role of catecholamines is unresolved.

222.14

5-HIAA IN CEREBROSPINAL FLUID REFLECTS DAMAGE OF SEROTONERGIC NEURONS INDUCED BY MDMA IN CNS OF NON-HUMAN PRIMATES. S.G. Wiener, G. A. Ricaurte, L.E. DeLanney, I. Irwin and J.W. Langston. Department of Psychiatry, Stanford University School of Medicine, Stanford, CA 94305; Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21205; Institute for Medical Research, San Jose, CA 95128.

This study assessed the feasibility of using 5-hydroxyindoleacetic acid (5HIAA) in cerebrospinal fluid (CSF) as a marker for serotonergic neurotoxicity induced by (±)3,4-methylenedioxymethamphetamine (MDMA) in non-human primates. Monkeys were administered doses of MDMA known to produce toxic effects on central serotonergic neurons. Two weeks later, the animals were lightly anesthetized with ether and samples of CSF were collected by means of cervical puncture. Later that same day, monkeys were killed for determination of brain and spinal cord serotonin concentrations. Monoamines and their major metabolites were measured using HPLC-EC methods. Monkeys with 80-90% depletions of regional forebrain serotonin and a 42% depletion of cervical cord serotonin had a 60% reduction in CSF 5HIAA, with unchanged homovanillic acid (HVA) or 3-methoxy-4-hydroxyphenethyleneglycol (MHPG). These findings suggest that CSF 5HIAA can be used to index MDMA-induced serotonergic neurotoxicity in non-human primates, and indicate that it may be possible to probe for MDMA-induced neuronal damage in humans by means of CSF 5HIAA analysis.

222.15

EFFECT OF OPTICAL ISOMERS OF 3,4-METHYLENEDIOXY-METHAMPHETAMINE (MDMA) ON STEREOTYPED BEHAVIORS AND NEUROTRANSMITTER RELEASE INTO RAT BRAIN DIALYSATE IN VIVO

M. Hiramatsu[1] [2]*, T. Nabeshima[2], T. Kameyama[2] and A.K. Cho[1]. [1]Dept. of Pharmacol., UCLA Sch. of Med., Los Angeles, CA 90024 and [2]Dept. of Chem. Pharmacol., Meijo Univ., Nagoya 468, Japan (supported by USPHS DA 04206).

MDMA elicits behavioral effects characteristic of both the amphetamine and the hallucinogenic phenylalkylamines. High doses of MDMA were found to cause a dramatic depletion of 5-HT and its metabolite, 5-HIAA and these effects are similar to the 5-HT releaser, p-chloro-amphetamine (PCA). However, little information is available regarding the differences in optical isomers of MDMA on behavioral effects and neurotransmitter release in vivo. When examined within 1 hr S(+)-, R(-)-MDMA and S(+)-MDA produced stereotyped behavioral responses such as sniffing, head-weaving, backpedalling and turning. These responses were similar to those induced by PCA. S(+)-MDMA was more potent than the R(-) enantiomer in eliciting head-weaving, backpedalling and turning behaviors. It is known that MDMA and PCA interact with both the 5-HT- and dopamine-systems by causing an increased efflux or release of these transmitter in vitro. PCA increased both transmitter release and decreased their acidic metabolites in brain dialysates. The differences in transmitter release between S(+)- and R(-)-MDMA will be presented.

222.16

NOVEL METHAMPHETAMINE ANALOG CAUSES LONG-LASTING DEPLETION OF DOPAMINE IN THE RODENT BRAIN.

L. E. DeLanney, G. A. Ricaurte, I. Irwin, J. W. Langston. Inst. for Med. Res., San Jose, CA 95128; Dept. of Neurology, Johns Hopkins Univ. School of Med., Baltimore, MD 21205.

N,N-dimethylamphetamine (N,N-DMA) is an analog of methamphetamine (METH) which has recently surfaced on the illicit drug market in various parts of the United States. This new analog ("designer drug") is synthesized via reduction of N-methylephedrine, a non-restricted analog of ephedrine. The aim of the present study was to evaluate the neurotoxic potential of N,N-DMA, and compare it to that of METH. Mice repeatedly administered various doses (10, 20 and 40 mg/kg) of N,N-DMA and analyzed for brain monoamine content one week later showed a dose-related depletion of dopamine, with the highest dose producing approxiamately a 30% depletion. N,N-DMA did not alter the concentration of serotonin in various regions of the mouse brain. As mice tend to be relatively resistant to the serotonin-depleting effects of amphetamines, the effects of N,N-DMA were also examined in rats. Again, N,N-DMA produced a depletion of dopamine but not serotonin. Compared to METH, N,N-DMA was approximately one fifth as potent at depleting caudate dopamine in both mice and rats. These results suggest that both the dopamine- and serotonin-depleting effects of N,N-DMA are less pronounced than those of METH, and indicate that methylating the nitrogen group of METH attenuates its neurotoxic activity.

222.17

EFFECT OF THE INHIBITION OF DEAMINATION OF 5-HYDROXY-TRYPTAMINE WITHIN SEROTONERGIC NERVE ENDINGS ON THE UPTAKE OF 5-HYDROXYTRYPTAMINE.

R.E. Becker and S.S. SHIM. Dept. of Psychiatry and Pharmacology, Southern Illinois Univ., Springfield, Il 62794-9230.

Km and Vmax of the uptake of 14C 5-hydroxytryptamine (5-HT) into 5-HT synaptosomes were determined in presence and absence of pargyline (100 uM), a monoamine oxidase (MAO) inhibitor. Synaptosomes of rat brain were prepared according to the discontinuous sucrose density gradient method. It was confirmed that the preparation is free of extrasynaptosomal MAO. 14C 5-HT uptake was expressed as the sum of total 14C 5-HIAA formed plus 14C found in synaptosomes minus 14C 5-HIAA in the synaptosomes. In absence of pargyline, Km of 14C 5-HT uptake was o.2 uM, Vmax 29 p mol/mg protein/2 min. In presence of pargyline, Km of 14C 5-HT uptake was 0.059 uM, Vmax 5.9 p mol/mg protein/2 min. From these results, we concluded that the inhibition of 5-HT deamination in 5-HT synaptosomes significantly decreases the maximum capacity of 5-HT synaptosomes for 14C 5-HT uptake without significant change in their affinity for 14C 5-HT. We propose the reduced uptake may result from an increase in the cytoplasmic concentrations of 14C 5-HT in 5-HT synaptosomes following MAO inhibition.

222.18

A DOSE-RESPONSE STUDY OF p-CHLOROAMPHETAMINE (PCA) EFFECTS ON AUDITORY AND TACTILE STARTLE HABITUATION IN RATS AND MICE.

J. Tizzano, R.N. Tamura*, R.L. Bailey*, and J. Buelke-Sam. Toxicology Division, Lilly Research Laboratories., Greenfield, IN 46140.

Davis et al. (1986) suggested that 5-HT may differentially alter startle if it acts primarily in the forebrain or spinal cord, i.e., 5-HT may depress startle via actions in the forebrain but increase startle via actions in the spinal cord. In our laboratory, 5 mg/kg PCA has produced an ca 25% increase in auditory startle in rats during expression of the "5-HT syndrome," but no change in startle following 5-HT depletion 24 hrs later. In this study, auditory and tactile startle was evaluated in groups of 13 male and 13 female CD rats (0, 5, 10, or 20 mg/kg PCA ip), and 8 CD-1 mice (0, 10, or 20 mg/kg PCA ip) before and 15-min and 48-hrs following dosing. Startle testing occurred in SDI chambers and each 50-trial session was made up of alternating 5-trial blocks of auditory (120 dBA noise) and tactile (20 psi air puff) stimuli presented at 8-sec intervals. One-hr activity levels were monitored in these animals prior to and 3-4 days following PCA administration. Across all treatment groups rats, but not mice, showed greater tactile startle than auditory startle amplitudes. Within-session habituation on both auditory and tactile trials was more evident in rats than mice. All PCA-treated rats, but not mice, displayed the characteristic 5-HT syndrome 15-min after dosing. All doses of PCA produced slight increases in auditory and tactile startle 15-min post dosing in male rats and mice, but not in female rats. At 48 hrs, no change in startle elicited via either modality was evident in rats, but a slight (ca 10-15%) dose-related decrease was seen in mice. These data do not suggest that PCA-induced release and depletion of 5-HT differentially alters auditory or tactile startle in this paradigm.

PAIN PATHWAYS: LONG-TERM CHANGES

223.1

ALTERATIONS WITHIN LAMINA I OF THE RAT DORSAL HORN FOLLOWING NEONATAL CAPSAICIN TREATMENT.

S. Saporta and J.A.Jacobson* Dept. of Anatomy, Univ. South Florida Coll. Med. Tampa, FL 33612.

We have been examining the secondary changes that the injection of capsaicin and the subsequent early loss of central C fiber terminations may have on the organization of spinothalamic tract cells. Four adult rats that had previously been injected subcutaneously on postnatal day 2 with capsaicin (50mg/kg), two adult animals injected on postnatal day 2 with vehicle and two uninjected adult animals were deeply anesthetized and perfused with 10% phosphate buffered formalin. Spinal segments C2-C4 and L3-L4 were embedded in plastic, serially sectioned at 2μm and stained with cresyl violet. The number of neuronal somata and the number of neurons per unit area of lamina I were determined from camera lucida drawings and photographs of the dorsal horn of every 15th section. While there was a trend for lamina I of capsaicin treated animals to have fewer neurons, no significant differences were detected at any spinal level in the total number or density of neurons within lamina I between any groups. These data indicate that either the present method was not sufficiently sensitive to detect the death of spinothalamic tract neurons within lamina I or that the previously reported inability to label these neurons following capsaicin treatment is due to the reorganization of their central connections.

223.2

SPINOTHALAMIC TRACT (STT) CELLS SIGNAL THE PAIN AND HYPERALGESIA FOLLOWING INTRADERMAL CAPSAICIN.

D.A. Simone, U.T. Oh*, L.S. Sorkin, J.M. Chung, W.D. Willis and R.H. LaMotte, Marine Biomed.Inst., UTMB, Galveston, TX, 77550 and Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT, 06510.

Intradermal (ID) injection of capsaicin (CAP) produces burning pain, hyperalgesia to heat at the injection site, and mechanical hyperalgesia in a large area surrounding the injection site. In the present study, we examined the effect of ID CAP on responses of identified STT cells. Recordings from single lumbosacral STT cells were made in anesthetized monkeys. Cells were classified according to their responsiveness to graded mechanical stimulation as high threshold (HT) or wide dynamic range (WDR). Responses to a 10 μl injection of vehicle or 100 μg CAP were recorded for 5 min after injection. Four of 5 HT and 9 of 10 WDR cells responded vigorously to ID CAP. At the injection site, the median heat threshold of WDRs was lowered from >50° to 34°C. Mechanical responsiveness of 2 HT and 7 WDR cells to von Frey filaments and to stroking the skin lightly with a cotton swab was enhanced within a radius of >4 cm around the injection site. Vehicle effects were weak or absent. These results correlate with those from psychophysical studies in humans and demonstrate an important role for STT cells in mediating pain and hyperalgesia.

ALTERATIONS IN TRIGEMINAL NUCLEI FOLLOWING APPLICATION OF TOXIC RICIN TO ADULT FELINE DENTAL PULPS. R.C. Canfield*, M.A. Henry, and L.E. Westrum (SPON: D. Farrell). Depts. of Neurol. Surgery, Biol. Structure, Restorative Dent., Univ. of Washington, Seattle, WA 98195.

Previous studies (J. Neurocytol. 16:601, 1987) showed extensive axonal and terminal degeneration of primary afferents in brain stem trigeminal nuclei (TNC) at 6-10 days after intrapulpal application of toxic ricin. We are using light (LM) and electron microscopic (EM) methods to investigate the more chronic effects of ricin application to pulps on TNC. At 20 days survival silver stains show persisting degeneration bilaterally in the same regions as in those from shorter survivals. Although, argyrophilic neurons were not seen in the silver stains, semi-thin sections of EM preparation show "dark neurons" in regions known to receive dental afferents. EM shows dramatically increased glycogen near blood vessels and within glia and altered terminals and dendrites suggesting a response to injury. Electron dense somata and dendrites are seen as are dendrites with abnormal vacuolization. Terminal alterations occur in EM preparations as earlier, but markedly dense ones appear to be reduced. Growth-cone-like profiles, not seen previously, are also seen. The findings show increased degenerative changes in postsynaptic structures and possible new axonal growth. 223.4

MYELINATED AFFERENTS IN AN ACUTELY INJURED NERVE DEVELOP A RESPONSE TO VIBRATORY STIMULI. C. M. Koschorke*, R. A. Meyer, and J. N. Campbell. Dept. Neurosurgery and Applied Physics Lab., The Johns Hopkins University, Baltimore, MD 21205

Recently, we demonstrated that regenerating nerve sprouts in mature neuromas exhibit a neural response to vibratory stimuli over the frequency range of 5 to 100 Hz. In the present study, we sought to determine when this vibratory sensitivity first occurs. In pentobarbital anesthetized monkeys, the sural nerve was acutely crushed, ligated, and transected immediately distal to the ligature. Six small strands were dissected from the parent nerve proximal to the transection site, and action potential activity from myelinated afferents was recorded from these strands for the next 13 hours. A displacement-controlled mechanical stimulator was used to apply sinusoidal stimuli to the transection site. A neural discharge to vibratory stimuli first appeared 6.5 hours after the nerve was transected in 7 A-fibers (5%). By 13 hours after the transection, 22 A-fibers (17%) had developed a response to vibratory stimuli. These results indicate that mechanical sensitivity develops within hours of a nerve injury. This is consistent with the hypothesis that the mechanical-to-electrical transducer, which is responsible for the mechanical sensitivity of normal cutaneous mechanoreceptive afferents, is transported down the nerve fibers and becomes functional in the regenerating membrane.

223.5

Dose related actions of capsaicin on nociceptive afferent fibres of the neonatal rat tail in vitro. **A.Dray, J.Bettaney*, P.Forster* and M.N.Perkins* (SPON:R.M.Lindsay). Sandoz Institute for Medical Research, Gower Place, London, England.**

Capsaicin produces a variety of effects on polymodal nociceptors including activation, desensitization and conducation block. We have studied the relationship between these effects and determined whether they are dependent on extracellular calcium.

In an in vitro preparation of the spinal cord and attached tail isolated from 1-2 day old rats, ventral root (L3-L5) depolarization was used to measure the activation of peripheral fibres by noxious stimuli. During superfusion of the tail with normal calcium (1.26mM) the depolarization produced by a submaximal dose of capsaicin (ED50 = 0.5 uM) was reproducible. Prolonged administration of capsaicin at 0.2 - 2.0 uM produced complete desensitization which was reversible after many hours but the effects of other noxious (heat, bradykinin) and innocuous stimuli were unchanged. Desensitization following 20-50 uM doses was accompanied by impaired responsiveness to other noxious stimuli. Complete removal of calcium did not reduce capsaicin evoked depolarization or desensitization. However in 20mM calcium depolarization by capsaicin was reduced and capsaicin evoked impairment of afferent fibere responsiveness to other stimuli was increased.

These data suggest that capsaicin evoked desensitization and the impairment of C-fibre transmission are separable. In addition external calcium does not play an important role in the activation or desensitization of nociceptors.

223.6

SENSITIVITY OF CULTURED NEONATAL RAT DRG NEURONS TO LOW DOSES OF CAPSAICIN: A PATCH-CLAMP STUDY. M. Alreja,*[1] D. Lo,[2] and R.H. LaMotte[1]. Department of Anesthesiology[1] and Section of Molecular Neurobiology[2], Yale Univ. Sch. of Med., New Haven, CT 06510.

The sensitivity of membrane currents of cultured rat DRG neurons to low doses of capsaicin was tested. Neurons were enzymatically dissociated from 1-7d old rat DRGs and 3-30 days later whole-cell voltage clamp recording was carried out using standard patch-clamp techniques. Early inward and delayed outward currents were produced by step depolarizations from a prepulse of -90 mV. In between trials the cells were maintained at a potential of -70 mV. Steady state inactivation was determined using depolarizing pre-pulse protocols. Capsaicin (54.5 mM stock solution in ethanol) was diluted to its final concentration (100pM-10μM) in the bath solution and applied for 15 sec to 10 min. Capsaicin but not vehicle, decreased and then completely abolished the early inward and delayed outward currents in >80% of the cells. This effect was seen both in small (>20 μm diam.) and large (>28 μm) cells. Some cells were responsive even to the smallest doses. The decline in the currents was more gradual with lower doses. Recovery of the response was not seen with the micromolar doses for up to 90 minutes after capsaicin. An increase in cell size was sometimes observed following capsaicin.

ELECTROPHYSIOLOGICAL PROPERTIES OF ADULT RABBIT TRIGEMINAL NEURONS IN DISSOCIATED CELL CULTURE.
T.K. Baumann and R.H. LaMotte, Dept. of Anesthesiology, Yale University School of Medicine, New Haven, CT 06510

While dorsal root ganglion (DRG) neurons have been studied extensively with intracellular methods, trigeminal neurons have so far received much less attention. Also, the majority of DRG neurons studied in cell culture were derived from newborn animals. We used whole cell patch clamp recording as the first step in the electrophysiological characterization of cultured adult rabbit trigeminal neurons. Neurons with relatively small cell bodies (soma diameters ranging from 24 to 36 μm) were selected. In response to prolonged (80 ms) depolarizing current pulses most fired only one action potential. Fewer fired repetitively, with the frequency of discharge increasing with the strength of the stimulus, reaching 200 Hz when 1 nA of current was injected. Two kinds of neurons were found, based on responses to hyperpolarizing current pulses. One type showed a pronounced time-dependent rectification, whereas the other did not. The latter had action potentials of relatively long duration (>4.5 ms). Thus, adult trigeminal neurons in cell culture display characteristics of in vivo trigeminal neurons studied recently by others.

ELECTROPHYSIOLOGICAL EVIDENCE SHOWING GROWTH OF VENTRAL ROOT AFFERENTS AFTER INJURY TO SCIATIC NERVE IN NEONATAL RATS. K.J. Kim, U.T. Oh*, S.C. Nam* and J.M. Chung. Marine Biomed. Inst. and Depts. of Anat. & Neurosci. and of Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX 77550.

We previously reported that many ventral root (VR) afferent fibers are the third branches of dorsal root (DR) ganglion cells. In this study, we examined the possibility of growth of these processes in the VR after an injury to the peripheral branches.

In 10 anesthetized neonatal rats (1-7 days after the birth), the sciatic nerve on one side was cut at the level of mid-thigh. Ninety to 120 days after surgery, compound action potentials were recorded from the L5 VR while electrically stimulating the DR of the same segment. The size of the C-fiber elicited compound action potentials was compared between the operated and unoperated control sides for 17 pairs. As compared to the control side, the size of compound action potentials recorded in the operated side was increased at least 50% in 9 cases. In 6 pairs, the size was similar, while smaller in the injured side for 2 other pairs. The size of response recorded at the distal site was larger than that at the proximal site in the operated side. This difference, however, was not seen in the control side.

These results suggest that some VR afferents in the rat grow centrally when sciatic nerve is injured in the neonatal stage. (Supported by NIH NS21266 and RCDA NS00995)

223.9

EFFECT OF SCIATIC NERVE TRANSECTION ON THE NUMBER OF UNMYELINATED FIBERS OF THE L5 VENTRAL ROOT IN ADULT RAT. J.W. Leem*, S.C. Nam*, K.J. Kim, K. Chung and J.M. Chung. Marine Biomed. Inst. and Depts. of Anat. & Neurosci. and of Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX 77550

The present study examined the possibility of unmyelinated axonal sprouting into the ventral root (VR) after peripheral nerve injury in the adult rat.

The right sciatic nerve of 5 adult rats was tied and cut at the level of mid-thigh under sodium pentobarbital anesthesia. After 5 months of survival time, the animals were perfused and fixed. Bilateral L5 VRs were removed and divided into three segments along the length of the root. Each segment was processed for electron photomicrography. The number of both myelinated and unmyelinated fibers was counted and compared between the operated and unoperated sides.

In both sides, the number of unmyelinated fibers in the VR was largest at the distal segment and decreased as the spinal cord was approached. There was no significant difference in the number of myelinated fibers between the control and experimental sides at any segment. As compared to the control side, the number of unmyelinated fibers on the experimental side was about 3 times larger in all 3 segments.

These data suggest that there is unmyelinated axonal sprouting in the VR after sciatic nerve injury in adult rats. (Supported by NIH NS21266, NS11255 and RCDA NS00995)

223.10

THE DEAFFERENTATION SYNDROME IN THE RAT: EFFECTS OF BILATERAL PARAFASCICULARIS LESIONING. Mark A. Lyerly, Janice Ovelmen-Levitt, and Blaine S. Nashold, Jr., Div. of Neurosurgery, Duke Univ. Med. Ctr., Durham, NC 27710

A deafferentation syndrome (DS), produced in rats by C5-T2 dorsal root ganglionectomies (DRGs), is expressed as scratching of partially afferented &/or biting (autotomy) of anesthetic limb areas. This objective evidence is used as an experimental model to study chronic dysesthesias &/or pain from deafferentation. This study included behavioral observations of the DS and the effects of bilateral parafascicularis nuclei lesions (PFL) on its expression. A total of 28 male Sprague-Dawley rats were used: 5 underwent PFL without deafferentation (PO); 14, DRGs (DO); and 9, PFLs 5 days prior to a DRG. The PO animals exhibited no autotomy. The DO rats demonstrated early onset, more severe and later onset, less severe biting groups ($p<0.01$ Mann-Whitney U), with 6/14 DO rats biting by the 3rd post-op day (13/14 by day 90), and 9/14 having scores of >5. Among rats having PFLs then DRGs, only 1/9 bit by the 3rd post-deafferentation day (5/9 by day 90), and only 4/9 had scores >5; both a lower % of animals biting and a lower total autotomy score than the DO rats. These results indicate that parafascicularis nuclei may play a role in the development/control of chronic pain; their lesioning apparently decreases both the degree of autotomy and percentage of animals expressing it.

223.11

THE DEAFFERENTATION SYNDROME IN THE RAT: EFFECTS OF FRONTO-PARIETAL CORTICAL LESIONS. J. Ovelmen-Levitt, E. Rossitch, Jr.,* J. Young,* and B. S. Nashold, Jr. (SPON:I. Diamond) Div. Neuros., Duke U. Med. Ctr., Durham, N.C. 27710

Forelimb sensory-motor cortical lesions in the rat have been found to suppress the deafferentation syndrome which follows C5-T2 ganglionectomy-avulsions whether the cortical lesions were made prior to or several days after the dorsal root lesions. The syndrome consists of biting and scratching of the affected limb. The self mutilation was observed daily for 45 days post-ganglionectomy and the degree of this was assigned a score of 0-19. Ten rats received dorsal root lesions only (G/A(0); 5 animals had cortical lesions only (SI(0); 6 rats had craniotomy only before or after dorsal root lesions (CR(1), CR(2); while 13 animals had cortical lesions either preceding (SI(1)) or following (SI(2) the ganglionectomy-avulsions. Only 2 of the 6 SI(1) rats (33%) bit by 45 days post-op, while 100% (10/10) of the G/A(0) rats had bitten by that time. The G/A(0) animals achieved a mean score of 15.2, while the SI(1) rats had a mean score of 2 at 45 days. The SI(2) achieved a mean score of 4.5. Although 85% of SI(2) bit by 45 days, 37% had begun biting before the cortical lesions were made. SI(1) and SI(2) groups of rats are significantly different populations from G/A(0) Mann-Whitney U:$p < .05$. SI(0) animals did not bite. CR(1) and CR(2) were not different from G/A(0). These results indicate that the fronto-parietal neocortex may be involved in the development and/or expression of chronic central pain.

223.12

ALTERATIONS OF THE THALAMIC SOMATO-SENSORY MULTIUNIT RESPONSE BY AN EXPERIMENTAL PERIPHERAL NERVE INJURY IN THE RAT. A. Louveau *, L. Jeaugey * and A.L. Benabid. LMCEC, INSERM U. 318 , Grenoble Univ., 38700 La Tronche, FRANCE

Studies about mechanical lesions of peripheral nerves are of particular interest because of their high frequency in traumatology. We developped an experimental model in the rat to investigate the suffering of the different groups of neural fibers, during the gradual compression of the sciatic nerve. 40 adult OFA rats (190-210 g) were investigated under chloral hydrate anaesthesia (400 mg/kg i.p.), paralysed with Pancuronium Bromide (0.3 mg/kg i.v.), tracheostomized and artificially ventilated. Electrical stimulation (0.5-50 V) was delivered through bipolar hook electrodes to the dissected isolated sciatic nerve. Multiunits responsive to sciatic stimulation were recorded in the VPL nucleus of the Thalamus. Changes in cell activity were studied using post stimulus time histograms (PSTH). Calibrated compression of the sciatic nerve was performed by a weighted piston . The stimulation induced somatosensory VPL response was made of a short latency (15 ms) low threshold (1 V) input carried by Ab fibers (peak 1) and followed, after a 60 ms inhibitory period, by a discharge lasting from 100 to 500 ms (peak 2). This late discharge was thought to be carried by Aδ and C fibers for it was elicited at higher thresholds (up to 50 V), it was selectively suppressed by systemic morphine (10 mg/kg i.v.) and was restored by systemic naloxone(1 mg/kg i.v.).This evoqued pattern in VPL was altered by a gradual compression of the sciatic nerve downstream to the stimulation site. Peak 1 was more sensitive to compression since it was selectively suppressed by a weak compression (50 g). Peak 2 was erased by a 3 to 4 times stronger pressure (150-200 g). Under constant weight, the early inputs suffered faster than the late inputs and recovered later after the release of compression, depending on its duration. These thalamic recordings confirm that the large myelinated fibers are more sensitive to traumatism than the thin unmyelinated fibers and show that the thalamic cells activity reflects these peripheral nerve lesions.

Do Calcium Spikes Account for the Bursts of Action Potentials which occur in Sensory Thalamus of Central Pain Patients? F Lenz, J Dostrovsky, H Kwan, T Hirayama*, R Tasker*, J Gorecki*. Univ. of Toronto, Toronto, Canada.

Previous work has demonstrated abnormal activity in the sensory thalamus of patients with central pain secondary to spinal cord injury (Lenz et al. Pain 31:225). Neurons which had lost their normal sensory input exhibited increased activity and tended to fire in bursts of action potentials. These bursts have now been characterized by application of techniques for the analysis of neuronal firing patterns (25 cells).

Bursts consisted of 3 to 7 action potential (AP) occurring at frequencies of greater than 200 Hz. Within a burst, each interspike interval (ISI) was longer than the preceding one. The duration of the first ISI in a burst was inversely related to the number of APs in the burst. When a single neuron had APs consisting of an initial positive and subsequent negative component, the negative component was larger for the first AP in the burst than for subsequent APs in the burst. This pattern is characteristic of bursts associated with the occurrence of underlying calcium spikes in intracellular studies of thalamic nuclei and suggests that an underlying calcium spike may explain the bursting activity of thalamic neurons in pain patients. If the perception of pain is related to this abnormal activity then the mechanism of bursting suggested by the present results may have significant therapeutic implications.

Sensitization of high threshold mechanoreceptors in the oral cavity of the goat. Friedman*, R. Cooper, B.Y., Ahlquist*, M.L., and Loughner*, B.A. (Spon: C.J. Vierck, Jr.) Departments of Neuroscience, Oral and Maxillofacial Surgery, and Pain Center, University of Florida, Gainesville, Florida, 32610.

Properties of high threshold mechanoreceptors (HTM) of the goat oral cavity were examined.

HTMs in fresh tissue and had relatively high thresholds (.68 nt/mm2), punctate receptive fields and slow conduction velocities (.5-25 m/sec). With repeated stimulation, afferents either fatigue or remain stable in response to slowly accelerating mechanical forces (n=24). Tonic activity could be occasionally observed from units previously quiescent (n=12). This activity fell into two categories: continuous and bursting.

HTMs in carrageenan inflamed tissue had generally lower thresholds (.55 nts/mm2) and much improved dynamic response properties (n=35). Tonic activity of both kinds (see above) could be obtained from either quiescent or driveable afferents (n=23). The success rate of sampling HTMs was greatly improved in inflamed tissue (250%). Similar improvements were apparent for observations of tonic activity. These differences are likely to be due to release or synthesis of endogenous substances.

Studies of afferent chemosensitivity, in fresh tissue, suggested that afferent response properties could be greatly improved by exposure to serotonin (5 ug/ul, i.a.). Both increases in dynamic response properties and transitions to tonically active forms could be observed.

RESPONSES OF T_2-T_7 DORSAL HORN CELLS TO DISTENSION OF INFLAMED AND NORMAL DISTAL ESOPHAGUS IN CAT. **DW Garrison, MJ Chandler and RD Foreman. Depts. Physical Ther. and Physiol., Univ. Okla. HSC, Okla. City, OK 73190.**

Esophageal disease can be associated with an inflamed esophagus. We hypothesized that T_2-T_7 dorsal horn cells would have a lower threshold of activation to distension of inflamed distal esophagus as compared to normal esophagus. In 21 anesthetized vagotomized cats the internal distal esophagus was exposed to a gauze soaked in turpentine for either 1.5 or 3 hr. Histological examination confirmed that inflammation had occurred. The left gray matter of the T_2-T_7 spinal cord was searched with microelectrodes to record activity of dorsal horn cells. Seventeen cells were excited with distension of the distal inflamed esophagus by water injected into the balloon of a Foley catheter. A distension volume of 2.4 $\pm$ 0.3 ml was required to reach threshold for increasing cell activity. In experiments where the distal esophagus was not inflamed, 18 cells required a threshold distension volume of 8.8 $\pm$ 0.8 ml to increase cell activity. The threshold for activating T_2-T_7 dorsal horn cells was significantly less for distension of inflamed esophagus as compared to normal esophagus ($P<0.001$). These data may explain why mechanical events such as swallowing or esophageal spasm are innocuous in normal individuals but may elicit pain in patients with esophageal disease. ADJUVANT-INDUCED INFLAMMATION IS ASSOCIATED WITH INCREASED DYNORPHIN IMMUNOREACTIVITY IN BOTH LOCAL CIRCUIT AND PROJECTION NEURONS IN LUMBAR SPINAL LAMINA I OF THE RAT. R.L. Nahin, J.L.K. Hylden and R. Dubner, Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD., 20892.

Increases in spinal dorsal horn dynorphin (DYN) levels are associated with peripheral inflammation induced by local injections of Complete Freund's Adjuvant (CFA) (Ruda et al., PNAS, 85(1988) 622-626; Iadarola et al., BR, In Press). The present study combined the retrograde transport of Fluorogold with the immunocytochemical identification of DYN A_{1-8} in superficial dorsal horn neurons to examine whether the CFA-induced DYN increase is found in local circuit neurons only or also in projection neurons.

Lamina I projection neurons were retrogradely labeled following injections of Fluorogold (0.1-0.2 μl) into the ponto-mesencephalic parabrachial area. Ten to 14 days after injections, rats were administered colchicine (70 μg) onto the lumbar spinal cord. Twenty-four hours later, the rats were perfused with 4% paraformaldehyde. Some rats received injections (75 μg : s.c.) of CFA into one hindpaw 1 to 5 days prior to colchicine administration. The lumbar spinal cord (L3-6) was cut and processed for standard fluoresence-immunocytochemistry using an antibody against DYN A_{1-8}.

Ipsilateral to CFA injections, the total number of DYN-like immunoreactive (DYN-LI) neurons increased 300% ($p<.01$) in lamina I as compared to the contralateral side. Although this increase consisted of both single-labeled and retrogradely-labeled DYN-LI neurons, the proportional increase was greater (275% vs 1100%; $p<.01$) for retrogradely labeled neurons. Mirroring this, the percentage of retrogradely labeled lamina I DYN-LI neurons rose from 5% of the total lamina I DYN-LI pool in naive animals or contralateral to CFA injections, to 20% ipsilateral to CFA injections. We conclude that CFA-induced inflammation has a differential effect on the increase in the number of local circuit and projection DYN-LI neurons in lumbar spinal lamina I.

224.4

TEMPORAL RELATIONSHIP BETWEEN INCREASES IN C-FOS mRNA AND PREPRODYNORPHIN mRNA IN RAT SPINAL CORD DURING PERIPHERAL INFLAMMATION. G. Draisci*, M.J. Iadarola and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

We have shown previously that peripheral inflammation induces a rapid (within 8 hrs) increase in preprodynorphin mRNA in rat dorsal horn neurons. Recently, Hunt et al (Nature, 328:634,1987) using similar types of stimuli reported an even more rapid increase (within 30 min) in the protein(s) coded by the c-fos proto-oncogene. The somatotopic and laminar location of the dynorphin positive and c-fos positive neurons were very similar suggesting that the two products may be in the same cell and that c-fos may be involved in the transcriptional control of the dynorphin gene. We have examined the time course of increase in the dynorphin mRNA and c-fos mRNA in rat lumbar spinal cord during inflammation induced by intraplantar injection of carrageenan (6mg in 150 ul). Total RNA was isolated from lumbar spinal cord at 0.5,1,2,4,8,and 24 hrs after injection. RNA blots were prepared and hybridized with ^{32}P-labeled probes for rat c-fos (kindly provided by Dr. T. Curran) and rat preprodynorphin (kindly provided by Drs. J. Douglass and O. Civelli). Peak increases in c-fos mRNA were observed between 0.5 and 2 hrs, declined to 1/2 maximal by 4 hrs and were essentially at control levels by 8 hrs. In contrast, the initial increase in dynorphin mRNA was not apparent until 4 hrs and substantial increases (100% over control) were seen by 8 hrs. While progressively greater elevations were observed in dynorphin mRNA at later times, c-fos was not increased (e.g. at 4 days) despite the maintained inflammation and hyperalgesia seen in this model. Thus, the increase in c-fos mRNA is an early event in the present inflammatory model, preceding the increase of dynorphin mRNA. Assuming a similar cellular location, this temporal relationship suggests that the c-fos protein may interact in transcriptional regulation of the dynorphin gene.

POTASSIUM- AND CAPSACICIN-EVOKED RELEASE OF SUBSTANCE P FROM DORSAL AND VENTRAL RAT SPINAL CORD SLICES. R.E. Solomon[1], L.D. Aimone[2], T.L. Yaksh[2] and G.F. Gebhart[1]. [1]Department of Pharmacology, University of Iowa College of Medicine, Iowa City, IA 52242 and [2]Laboratory of Neurosurgical Research, Mayo Clinic, Rochester, MN 55905.

The release of substance P (sP) from superfusates of rat spinal cord *in vitro* was studied. Portions of the lumbar enlargement were dissected into dorsal and ventral halves, sliced into 0.5 x 0.5 mm pieces and perfused with an artificial, HEPES-buffered CSF. Four-min perfusates were collected and, utilizing previously published procedures (J. Physiol. 391: 141), assayed for sP by radioimmunoassay. Elevation of the potassium (K^+) concentration to 10 - 70 mM, or addition of capsaicin (0.01 - 100.0 μM) to the perfusate evoked concentration-dependent release of sP from dorsal spinal cord. Release of sP evoked by 50 mM K^+ was 3-fold greater from dorsal than from ventral spinal cord and was proportional to the dorsal/ventral difference in sP content. In contrast, 10.0 μM capsaicin increased sP release from dorsal spinal cord almost 9-fold over basal levels but did not evoke sP release from ventral spinal cord. Depletion of calcium from the perfusate and addition of EGTA (3.0 mM) abolished sP release evoked by 50 mM K^+ or by 10.0 μM capsaicin from dorsal spinal cord. Preliminary pharmacological experiments indicated that both morphine and clonidine (10^{-4} M) significantly attenuated sP release evoked by 0.1 μM capsaicin from dorsal spinal cord. The results are consistent with the putative role of sP as a nociceptive transmitter of primary afferents. Supported by T32 GM 07069, DA 05329, NS 16541 and DA 02879.

224.6

SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE RAT DORSAL HORN FOLLOWING HINDPAW INJECTION OF ALGESIC AND ANALGESIC AGENTS. L.N. Holland* and B.D. Goldstein (SPON: M.L. Kirby). Department of Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA 30912-2300.

Hindpaw injection of formalin has been shown to increase substance P (SP) levels in the rat dorsal horn (DH). Morphine has also been shown to increase SP levels. Thus, agents of opposing roles in nociception produce similar changes in SP. In order to better characterize these changes, we tested the action of a hindpaw injection of either eugenol, an anesthetic, or bradykinin, an algesic agent, on SP levels in the rat DH.

Urethane anesthetized rats (1200 mg/kg) were injected with either eugenol, bradykinin or formalin in a concentration of 1% into the right hindpaw. After sixty minutes, rats were perfused, the spinal cord removed (L4-L6), and stained immunohistochemically for SP. SP levels were quantified using microdensitometry.

Formalin and eugenol produced higher levels of SP compared to control while bradykinin produced significantly lower levels of SP.

In conjunction with data which show that naloxone blocks formalin induced changes of SP in the rat DH at sixty minutes, these data suggest that formalin injection may not be a good model for nociception.

224.7

NALOXONE BLOCKS THE INCREASE OF SUBSTANCE P IN THE DORSAL HORN DURING A NOCICEPTIVE STIMULUS. K.E. McCarson, B.D. Goldstein. Dept of Pharmacol and Toxicol, Medical College of Georgia, Augusta, GA 30912-2300.

Substance P (SP) found in primary afferent terminals has been proposed as a mediator of nociception. Formalin (FM) injected into the hindpaw of a rat as a nociceptive stimulus has been shown to increase the amount of immunoreactive SP in the dorsal horn. This increase may be due to a blockade of release of SP by enkephalinergic interneurons. Therefore, anesthetized rats were treated with naloxone (NAL) 10 mg/kg or saline (SAL) s.c. either 30 min before or 2 min after the delivery of either a 0.4 ml 5% FM or SAL injection into the plantar aspect of the right hindpaw. After various time intervals, the animal was perfused and the lumbar enlargement removed. SP was quantitated using immunohistochemical staining. SAL caused an increase in SP lasting 20 min while FM produced a biphasic effect with early (0-10 min) and late (20-60 min) increases in SP. NAL pretreatment partially blocked the initial increase in SP due to SAL or FM, but not if NAL was injected 2 min following SAL or FM. The late increase of SP resulting from FM was blocked by NAL only if it was administered prior to the FM. The SP time course resulting from FM is consistent with behavioral and electrophysiological studies. Blockade by NAL suggests an influential role of endogenous opioids in the control of SP levels in the dorsal horn.

EFFECTS OF DIFFUSE NOXIOUS STIMULI AND INFLAMMATORY AGENTS ON TRIGEMINAL MEDULLARY DORSAL HORN NOCICEPTIVE NEURONES IN THE RAT. J.W. Hu*, X. Chen* and B.J. Sessle. Fac. Dentistry, Univ. Toronto, Toronto, Ont. M5G 1G6 Canada.

Single neurones were recorded extracellularly in the medullary dorsal horn (N. caudalis) of anaesthetized, paralyzed rats, and classified as nociceptive-specific (NS, n=35) or wide dynamic range (WDR, n=37) on the basis of their responses to natural and electrical cutaneous stimuli. Diffuse noxious stimuli applied for 30 s outside the orofacial mechanoreceptive field (e.g. to tail, paw) produced a strong inhibition (onset<5 s; duration 40-60 s) of evoked A and C-fibre activity in both WDR and NS neurones. The injection of 2-5 µl of the inflammatory agent mustard oil (5%) into the deep masseter muscle in contrast produced a facilitation (20-75% increase above control activity; latency 1-3 min; duration 10-30 min) of especially C-fibre activity in 50% of the 16 neurones tested; WDR neurones in particular were affected. This facilitatory effect was usually associated with an expansion of the cutaneous mechanoreceptive field of the neurones. Electrical stimulation (1 min, 2 Hz, 2 ms, 5 mA) of XII nerve muscle afferents also produced facilitation of C-fibre activity in the nociceptive neurones. These findings emphasize the marked plasticity and sensitivity of caudalis nociceptive neurones to noxious and inflammatory conditions in sites distant from their mechanoreceptive field. Supported by NIH grant DE04786.

SYMPATHETIC ACTIVATION OF HYPERACTIVE WDR NEURONS FOLLOWING RECEPTIVE FIELD TRAUMA. W.J. Roberts & R.C. Kramis.* R.S. Dow Neurol. Sci. Inst., Good Samaritan Hosp. and Medical Center, Portland, OR 97209.

Mechanoreceptor input to hyperactive wide-dynamic-range (WDR) neurons is thought to cause both the spontaneous pain and the touch evoked pain (allodynia) characteristic of sympathetically maintained pain (Roberts, Pain, 24: 297-311, 1986). We tested this hypothesis by recording extracellularly from spinal neurons in barbiturate anesthetized cats. The responses of WDR neurons to sympathetically evoked afferent activity were recorded before and after trauma (noxious pinch or heating) to the receptive fields.

Brief (1 min) noxious stimulation elevated background WDR activity for tens of minutes. Sympathetic stimulation resulted in even higher rates of activity during the post-trauma period. These findings disclose a persistent trauma-induced hyperactivity in some WDR neurons following brief noxious input and further demonstrate that sympathetic efferent actions can increase the already elevated WDR output, as is hypothesized to occur during chronic sympathetically maintained pain.

DISCHARGES IN SMALL AND LARGE MYELINATED PERIPHERAL FIBERS EVOKED BY FORMALDEHYDE INJECTED IN THEIR CUTANEOUS RECEPTIVE FIELDS. N.E. Saadé, M. Tabbara*, S.F. Atweh and S.J. Jabbur. Fac. of Med., American University of Beirut, Beirut, Lebanon.

We have earlier shown that subcutaneous (sc) injection of formaldehyde (F) solution in the receptive fields of dorsal horn neurons elicited an immediate and continuous discharge in wide-dynamic-range (WDR) neurons and no effect in the low-threshold mechanoreceptive (LTM) neurons (Exp. Neurol., 93, 275, 1986). These differences could have been determined by the responses to F of peripheral nerve terminals. In spinal cats, 31 fiber filaments were isolated from sural or superficial peroneal nerves and their receptive fields (RFs), sensory modalities and conduction velocities (CVs) were determined. The response discharges of each fiber to sc injection of 0.1-0.15 ml of 2.5% F in RF were studied. F effects were categorized as (1) none, (2) short-term (<10 min) excitatory generally followed by complete loss of sensitivity of the RF and (3) long-term (15-80 min) excitatory.

We observed that F injection results in sustained discharges from the majority (11/15) of small myelinated fibers (with CV<30 m/sec), and short-term or no discharges from the majority (15/16) of large myelinated fibers (with CV 30-80 m/sec), which could account for the respective behaviours of WDR and LTM spinal neurons. (Supported from Lebanese N.R. Council and D.T. Sabbagh Fund).

PROLONGED EFFECTS ON CA1 POPULATION SPIKE IN RAT HIPPOCAMPUS PRODUCED BY NOXIOUS STIMULI. S. Khanna* and J. G. Sinclair. Div. of Pharmacol. & Toxicol., Fac. of Pharmaceutical Sciences, Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

There are indications that the hippocampus is involved in nociceptive mechanisms (Prado, & Roberts, Brain Res. 340: 219, 1985; Sinclair, & Lo, Neurosci. Lett. 68: 47,1986; Soulairac, *et al.*, Int. J. Neuropharmacol. 6: 71, 1967). We have investigated the effect of peripheral noxious heat on monosynaptic transmission through region CA1 of the dorsal hippocampus (dH). Experiments were done in rats (250-350 g) lightly anaesthetized with urethane 1.0 g/kg, i.p. Deep anaesthesia during surgery was produced by supplementation with halothane. A submaximal CA1 population spike (PS), evoked by field CA3 stimulation, was recorded. In addition, the contralateral dH electroencephalogram (EEG) was recorded. Noxious heat (50-60°C, 15 sec) applied to the distal 3.0 cm of the tail produced a temperature-dependent depression of the CA1 PS amplitude. While 50°C did not consistently reduce the amplitude of the PS, 55 and 60°C resulted in a mean decrease to 39±14 % of control (n=7) and 17±6 % of control (n=5), respectively. At 55°C the mean recovery time was 8 min following exposure whereas at 60°C the depression lasted 18 min. Qualitatively, a similar response was observed when the distal 2.0 cm of the left hind foot was exposed to noxious heat at 55°C. On repeated exposures of a receptive field to noxious heat, the CA1 depression was markedly attenuated. However, a subsequent application of noxious heat to a different topographical area resulted in a depression of the PS. A noxious stimulus usually changed the EEG activity from an irregular pattern to a 4-6 Hz rhythmic slow wave activity (RSA) which lasted for a short period of time. Interestingly, in the presence of continuous spontaneous RSA, noxious stimuli failed to depress the PS amplitude. These results implicate the hippocampus in nociceptive processing mechanisms. (Supported by the Medical Research Council of Canada and B.C. Health Care Research Foundation).

225.1

MUSCARINE DEPRESSES AN APV-INSENSITIVE FORM OF LTP IN CA3 HIPPOCAMPAL NEURONS. *S.H. Williams & D. Johnston*, Neuroscience Program, Baylor College of Medicine, Houston, Tx 77030.

Long-term potentiation (LTP) of the hippocampal mossy-fiber CA3 pyramidal cell synapse is insensitive to NMDA receptor antagonists such as APV. A previous investigation showed that β-adrenoreceptor agents could modulate LTP at this synapse, agonists produce a potentiation and antagonists block (Hopkins & Johnston, *J.Neurophysiol*, 59 667-687). We report here that cholinergic agonists can also modulate LTP: in contrast to norepinephrine, however, muscarine produces a *depression* of LTP. Transverse hippocampal slices were prepared using standard techniques and incubated in a picrotoxin containing media to block inhibition. Single CA3 neurons were studied under current and voltage clamp. Tetanic stimulation of the mossy fiber input to CA3 neurons (3 episodes of 1s duration, 100Hz), elicited LTP in 13/15 control cells (> 20% increase in epsp or epsc 15 min after tetanus). When 1μM muscarine was present during tetanization only 3/10 cells showed LTP. The current-voltage relationship for the synaptic current showed that muscarine blocks the increase in synaptic conductance (G, normally associated with LTP. These data are summarised below.

	%change normalized to pre-tetanus control (mean ± sem)		
	EPSP	EPSC	G,
Control	+50 ± 9%	+43 ± 11%	+41 ± 2%
+ 1μM muscarine	+ 7 ± 9%	+ 6 ± 6%	+ 5 ± 8%

The bidirectional modulation of LTP by β-adrenergic and muscarinic agonists may be mediated by modulation of calcium channel activity in the postsynaptic membrane. (NIH grants HL31164 & NS11535, and AFSOR 85-0178).

DECREASE IN SYNAPTIC VESICLE CALCIUM DEPOSITS DURING LTP IN THE HIPPOCAMPUS. C.K. Meshul and W.F. Hopkins. V.A. Med Center and Dept. Neurol., Oregon Health Sciences Univ., Portland, OR 97201.

Long-term potentiation (LTP) displays a stringent calcium dependence, and may be due to a long-term increase in transmitter release. We assessed the possibility that LTP is accompanied by changes in the distribution of calcium in the presynaptic terminal. Calcium was localized ultrastructurally within terminals located in stratum radiatum of the CA1 subfield according to the method of Borgers (1981). Rat hippocampal slices were prepared and maintained in vitro using standard techniques. The pEPSP in CA1 was monitored following a stimulus train (100 Hz, 1 sec), and a significant increase in the amplitude of the pEPSP beyond 15 min was called LTP. Control slices were given the same number of stimuli at a frequency that did not result in LTP. The slices were fixed between 15 and 60 min following stimulation and processed for calcium localization. Seventy percent of the presynaptic vesicles from control slices contained calcium deposits, whereas 42% did so from slices that displayed LTP ($p < .05$). The decrease in the percentage of synaptic vesicles containing calcium deposits might suggest that during LTP, vesicular calcium is released into the nerve terminal cytoplasm. Such an increase in free calcium could subserve the long-term increase in transmitter release that may underlie LTP.

EFFECT OF POTASSIUM CONCENTRATION ON CALCIUM INDUCED POTENTIATION IN HIPPOCAMPAL CA1 PYRAMIDAL CELLS. **L. Grover & T. Teyler. Neurobiol. Dept., N.E. Ohio Univ. Coll. Med., Rootstown, OH, 44272.**

Ten min exposure to high extracellular calcium produced potentiation of population spike and EPSP in area CA1 of hippocampus (Turner et al. Neurosci. 7: 1411-6, 1982). We examined effects of high calcium and potassium on EPSPs recorded intracellularly from CA1 pyramidal cells of in vitro rat hippocampus. Baseline responses were obtained during a 10 min period when slices were superfused (0.5 ml/min) with normal medium (3.4 mM potassium, 2.0 mM calcium). Slices were then exposed for 10 min to: (1) high calcium (4.0 mM), (2) high potassium (6.25 mM), or (3) high calcium and potassium. High calcium produced transient potentiation (reversed within 10 min following return to normal medium) in 4 of 5 cells. Mean change in EPSP amplitude ± SEM (all 5 cells) = 12.8 ± 7.5 %. Effects of high potassium (n=4) also reversed quickly upon return to normal medium. Nine of 10 cells exposed to high calcium and potassium showed potentiation; in all but one cell, potentiation persisted for the duration of the recording: up to 60 min following return to normal medium. Change in EPSP for time periods following return to normal medium were: 1-10 min, 39.0 ± 10.7 % (n=10); 11-20 min, 27.9 ± 6.8 % (n=10); >21 min , 21.8 ± 11.3 (n=6). **Supported by ONR 86K0664, NIH DA03755, EPA CR813394.**

HOMO- AND HETEROSYNAPTIC EXPRESSION OF LTP IN HIPPOCAMPAL CA3 NEURONS: SENSITIVITY TO INTRACELLULAR EGTA INJECTIONS

J.E. Bradler* and G. Barrionuevo (SPON: D.M. Barnes) Depts of Behavioral Neuroscience and Psychiatry, and Center for Neuroscience, University of Pittsburgh, Pittsburgh PA 15260

Last year we described the homo- and heterosynaptic expression of LTP in the CA3 region in vitro (Soc. Neurosci. abstr. 13(3): 976, 1987). Recently, we have investigated the sensitivity of homo- and heterosynaptic LTP expression in voltage-clamped CA3 neurons to intracellular EGTA injections (.5 M ; 1.25 nA 450 ms pulses at .5 Hz for 4-5 min). The disappearance of I_{ahp} measured at -62mV in hybrid clamp demonstrated EGTA effectiveness. Following the disappearance of I_{ahp}, 5 trains of 6 pulses at 100 Hz were delivered to one of three stimulation sites: CA1 s. radiatum, the s. granulosum of the dentate gyrus, or the fimbria. An extracellular electrode confirmed the induction of LTP in the CA3 cell population. In 4/4 cells, the mossy fibers (MF) expressed homosynaptic LTP following tetanization of the MF. In 2/2 cells, LTP was heterosynaptically expressed in the fimbria (Fi) and CA1-evoked EPSCs following a MF tetanus. In an additional 2 cells, homosynaptic LTP was expressed in the Fi-evoked EPSC following a Fi tetanus. In one cell, homosynaptic LTP was expressed in the CA1-evoked EPSC. We have not observed the extracellular expression of LTP in the absence of intracellular LTP expression in an EGTA-injected cell. Supported by an RCDA (NS01196) to G.B.

CALCIUM INFLUX THROUGH NMDA-RECEPTOR CHANNELS MODELED IN A HIPPOCAMPAL DENTATE GRANULE CELL. W.R. Holmes and W.B Levy, Math. Research Branch, NIDDK, NIH, Bethesda, MD 20892, and Dept. of Neurosurgery, U. Virginia School of Medicine, Charlottesville, VA 22908.

Calcium influx through NMDA-receptor channels is thought to play a major role in the development of LTP. Calcium influx through channels linked to voltage-dependent NMDA receptors was modeled at a synapse on a dendritic spine on a dentate granule cell. The cell received synaptic inputs on spines at anywhere from 1-117 different dendritic locations. The frequency of synaptic activity was varied from 25-800 Hz while holding the number of active afferents and the number of activations of each afferent constant.

The Ca^{++} influx was dependent on both the frequency of the input and on the number of co-active inputs. With few active inputs Ca^{++} influx was small, and there was little or no increase of Ca^{++} influx with increasing input frequency. However, with larger numbers of co-active inputs (e.g. 39 or 57), increasing input frequency resulted in a steep non-linear transition between low Ca^{++} influx and high Ca^{++} influx. This transition occurred at lower frequencies as the number of active inputs was increased. After this transition, further increases in input frequency or in the number of co-active inputs produced little additional increase in Ca^{++} influx, and in some cases influx decreased.

Parameters related to conductances mediated by non-NMDA receptors could be doubled or halved with only minor effects on total Ca^{++} influx. This was not true for the NMDA mediated conductance. Changes in NMDA receptor affinity, the number of receptors, and to a lesser extent the mean channel open time had a large effect on total Ca^{++} influx. Changes in the amount of neurotransmitter released, the transmitter uptake rate, and changes in extracellular Mg^{++} also had large effects on Ca^{++} influx.

Although the model helps to illuminate the function of the NMDA receptor regarding Ca^{++} influx, the best temporal input patterns for LTP found by Levy and Steward (1983) were not the same ones found for highest Ca^{++} influx in the model. Another conductance or some other factor needs to be added to explain these LTP timing studies. (This work was supported by NS07845 (WRH) and NS15488 and NIMH RSDA K02-MH00622 to WBL.)

225.6

LONG-TERM POTENTIATION IS ACCOMPANIED BY AN INCREASE IN EXTRACELLULAR RELEASE OF ARACHIDONIC ACID. T.V.P. Bliss*, M.P. Clements*, M.L. Errington*, M.A. Lynch* and J.H. Williams*. (SPON: European Neuroscience Association). Div'n. of Neurophysiology and Neuropharmacology, National Institute for Medical Research, Mill Hill, London NW7, U.K.

These experiments are part of an investigation into the possibility that arachidonic acid and/or its lipoxygenase metabolites are the retrograde messenger(s) postulated to carry information from the postsynaptic to the presynaptic side of the synapse to trigger the sustained increase in release of glutamate associated with LTP. We have measured, using HPLC separation and UV/fluorometric detection, the concentrations of arachidonic acid and glutamate in (i) push-pull perfusates from the dentate gyrus following the induction of LTP by tetanic stimulation of the perforant path, and (ii) superfusates from hippocampal slices in which LTP was induced by 15 min exposure to 5mM calcium. In both cases there was a sustained increase in the concentration of glutamate and arachidonic acid in the two hours following the induction of LTP. The phospholipase A_2 and lipoxygenase inhibitor, nordihydroguaiaretic acid, which blocks the induction of both tetanus-induced and calcium-induced LTP (Bliss et al., Pflug. Archiv., 411, Suppl. 1, 229, 1988), also suppressed the increase in release of glutamate and arachidonic acid. Although we do not know the site of release of arachidonic acid, the LTP-associated increase in extracellular release is consistent with the idea that it exerts a messenger and/or trophic role in LTP.

NALOXONE BLOCKS MOSSY FIBER, BUT NOT COMMISSURAL OR HETEROSYNAPTIC LONG-TERM POTENTIATION IN THE HIPPOCAMPAL CA3 REGION IN VIVO. B.E. Derrick and J.L. Martinez, Jr., Dept. of Psych., University of California, Berkeley, CA 94720.

Hippocampal CA3 responses were observed in male Sprague-Dawley rats under pentobarbital anesthesia via stimulation of the mossy fibers and the contralateral CA3 field. Naloxone (NAL, 5 mM, pH 6.8 in Ringer's, 1.0 ul pressure ejected) did not consistently alter field responses given to either pathway during the 10 min following drug application. Two 1-sec, 100 Hz trains, which did not produce afterdischarges, were given to each pathway to induce LTP. NAL blocked the usual increase in the primary mossy fiber population spike (NAL, x = 1.4%, Ringer's, x = 55%). Increases in the commissural spike were unaffected by NAL (x = 72%, Ringer's, x = 55%). NAL also abolished the short-term potentiation in both pathways usually seen post tetanus (PTP). LTP was, however, observed in the later negative components of the mossy fiber response following NAL. Heterosynaptic LTP also was observed in the later components of the commissural response following tetanization of the mossy fibers, and less frequently seen in mossy fiber responses as a result of commissural tetanus. In both cases it was not affected by NAL. These data suggest that (1)heterosynaptic LTP is postsynaptic to the mossy fiber-CA3 synapse, and may be a result of potentiation of a common final recurrent pathway; and (2) our previous studies (Derrick, et al., Neurosci. Abstr, 13, 1987) suggest that opioid peptides do not alter inhibition in the CA3 region, thus opioid peptides may be directly involved in the initiation of mossy fiber LTP, rather than indirectly modulating it via a disinhibitory effect.

Long-term Potentiation (LTP) and c-fos: is there a link?

M Dragunow WC Abraham SE Mason and RLM Faull; Dept of Anatomy, School of Medicine, Auckland University, Auckland; Dept of Psychology, Otago University, Dunedin, New Zealand (SPON: J.M. Wild)

The nuclear "third messenger" c-fos has recently been shown to be massively induced in adult neurons by kindling stimulation (Dragunow and Robertson Nature 329, 414), suggesting that it might be involved in plastic changes associated with seizure activity. In another model of CNS plasticity, LTP, c-fos is not consistently induced in urethane-anaesthetized rats (Douglas,Dragunow and Robertson, in press). In the present series of experiments we investigated the production of c-fos following LTP of the perforant-path-dentate gyrus synapse in unanaesthetized rats. Low-frequency stimulation, or high frequency stimulation in the presence of CPP, urethane or MK801 did not induce c-fos in dentate granule or entorhinal cortical cells. However, in some rats (4/6) stimulated at high frequency there was a slight (an average of three times the contralateral side) induction of c-fos protein in the dentate gyrus, but not the entorhinal cortex. Thus, high frequency stimulation can induce c-fos in some animals but the relationship of c-fos with LTP is unclear.

PATHWAY-SPECIFICITY OF NOREPINEPHRINE-INDUCED LONG-LASTING POTENTIATION (NELLP) IN DENTATE GYRUS OF RAT HIPPOCAMPAL SLICE. D. Dahl, G. Decker, and J.M. Sarvey. Department of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

This laboratory and others have reported NELLP of dentate gyrus granule cells that is manifested as a persistent (> 30 min) increase of the excitatory postsynaptic potential (EPSP) and the population spike evoked by perforant pathway stimulation.

We have differentially stimulated the medial and lateral components of the perforant pathway to the dentate gyrus and confirmed isolation by the distinctive response profiles associated with activation of each afferent. NELLP of the medial perforant pathway-evoked EPSP and population spike was reliably obtained by superfusion of a combination of 1.0 or 10.0 μM NE + 50.0 μM phentolamine, whereas no potentiation was apparent at these concentrations in response to activation of the lateral perforant pathway. An NE concentration of 1.0 μM without phentolamine was not effective in eliciting NELLP, and phentolamine alone had no effect on responses to activation of either pathway. Isoproterenol, however, at a concentration of 1.0 μM, induced the same pathway-specific NELLP of medial perforant pathway-evoked responses as the concurrent administration of NE and phentolamine.

These results indicate that NE acts differentially on entorhinal cortical projections to the dentate gyrus, and that NELLP of the medial perforant pathway can be obtained with NE concentrations as low as 1.0 μM with concurrent administration of phentolamine.

LONG-TERM POTENTIATION IN THE DENTATE GYRUS IS ENHANCED BY STIMULATION OF THE MEDIAN RAPHE NUCLEUS. J.M. Klancnik[1,2], A.G.Phillips,[1], Depts. of Psychology[1], and Physiology[2], University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

The dentate gyrus (DG) receives significant serotonergic projections from the median raphe nucleus (MR), and contains a dense population of serotonergic binding sites. Therefore it is significant that population spikes evoked in the DG perforant path (PP) stimulation can be enhanced during a 90 msec period following a single pulse of stimulation to the MRN. It is well established that population responses in the DG undergo long-term potentiation (LTP) after tetanic stimulation to the PP. However, there is a degree of uncertainty surrounding serotonergic modulation of LTP in the DG. This issue was addressed in the present study which investigated the effects of electrical stimulation of the MR on LTP of the PP-DG population response. Urethane anesthetized adult male Wistar rats were implanted with stimulating electrodes in the MR and PP, and a recording microelectrode in the hilus of the DG. Population responses in the DG were evoked by PP stimulation, at an intensity that produced a half-maximal amplitude population spike. A 100 Hz., 1 sec stimulus train was applied either to the PP alone, or concurrently to the PP and MR. Subsequently, PP-DG responses were evoked and recorded at the rate of 1/min. Concurrent stimulation of the MR and PP produced a significantly greater increase in population spike amplitude and population EPSP slope than was seen after tetanic stimulation of the PP alone, both at one and sixty min. after tetanus. These results suggest a modulatory influence of serotonergic afferents on the processes underlying neuronal plasticity in the DG.

225.11

A CONTEXT DEPENDENCY FOR LONG-TERM POTENTIATION? K-A. Moore and R. J. Racine (SPON: C. Hawryshyn). Dept. of Psychology, McMaster Univ., Hamilton, Ontario, CANADA, L8S 4K1.

It is well known that memory is context-dependent (e.g. state-dependent learning). We have attempted to determine whether long-term potentiation (LTP), a memory model, might also show a context-dependency. If it does, then at least some of this dependency may be determined by interactions that occur at the cellular level. A "cooperativity" effect has been demonstrated for LTP in which co-activation of separate inputs serves to strengthen the LTP produced in one or both inputs. Although the tetanizing trains are applied contiguously, the test pulses have always been restricted to one or the other pathway. We have attempted to reproduce the "context" that is present during tetanization by co-activating the pathways during the test phase as well. We chose the medial septal input to provide a context for perforant path input, because the septal input enhances LTP in the perforant path/granule cell circuit without being altered itself (Robinson, G.B. and Racine, R.J., Brain Res. 1982, 249, 162-166). A compound stimulus, consisting of a brief septal train followed, 70 msec later, by a pulse to the perforant path, was used to trigger the baseline response (with context). Similar trains were then applied 70 msec prior to perforant path trains, after which the test stimuli were reapplied. Results thus far indicate that responses evoked "in context" show a greater LTP effect than those evoked by perforant path pulses alone.

TWO FORMS OF LONG-TERM POTENTIATION IN THE CA3 REGION OF THE RAT HIPPOCAMPUS IN VIVO. M.K. Washington, D.N. Lieberman, B.E. Derrick, & J. L. Martinez, Jr. (SPON: C. BARRIT) Psych Dept., Univ. of Calif., Berkeley, CA 94720

Hippocampal CA3 responses were observed in male Sprague-Dawley rats under pentobarbital (50 mg/kg) or urethane (1.0 g/kg) anesthesia. Mossy fiber (MF) responses were elicited using bipolar nichrome electrodes placed in the stratum lucidum of the CA3 region. Commissural (COM) responses were produced by stimulating the homotopic contralateral CA3 pyramidal layer. Two 1 sec trains of 100 Hz were delivered to either the MF or the COM afferents. Long-term potentation (LTP) of the COM response (N=8) consisted of an increase in both the population spike and the later components (5-15 msec) of the response. Both responses reached maximum at approximately 10 min post-tetanus. COM LTP was decremental, with a half-life of approximately 75 min for the population spike. In contrast, MF potentiation (N=8) consisted of an increase in only the population spike. This increase was gradual, reaching maximum at approximately 45 min and showed no decrement in response over the course of the experiment (>2 hrs). Heterosynaptic LTP was observed in the later components of the commissural response following tetanization of the mossy fibers, but was less frequently seen in mossy fiber responses following commissural tetanus. COM and MF LTP are differentially affected by pharmacological agents (see Derrick, et al., this volume). LTP of the MF response is blocked by urethane but not pentobarbital anesthesia. Urethane does not affect LTP of the COM response, nor does it affect post-tetanic potentiation of COM or MF responses. We currently hypothesize that the non-decremental LTP of the mossy fiber response is dependent on both opioid receptor activation and phosphoinositol turnover.

IS BEHAVIORAL LONG TERM POTENTIATION DUE TO LEARNING OR CHANGES IN MOTOR ACTIVITY? A PRELIMINARY REPORT. E.L. Hargreaves* and D.P. Cain (SPON: R. Steenhuis). Dept. Psychology, U. of Western Ontario, London, Ontario, CANADA N6A 5C2.

In light of the finding that changes in ongoing behavior can affect the hippocampal evoked potential (EP), reports of LTP-like changes in EPs after the acquisition of a learned behavior could be due to changing motor patterns instead of learning. To explore this possibility ten rats were chronically implanted with stimulating and recording electrodes in the perforant-path/Dentate system of the hippocampus and then run through an eight arm radial maze and a one way active avoidance task. Daily recording sessions occurred three hours prior to placement in the learning environment. During the recording session EPs were collected under strict observation of two different homogenous behavioral activities, wheel running and immobility.

Preliminary results indicate consistent differences in EPs collected under the two behavioral states as measured by EPSP slope and pop-spike amplitude. Measures of learning show strong improvements in the behavioral performance of both tasks over time. However, no changes in EPs were observed as a function of acquisition of the tasks, and the EPs in general remained fairly consistent with baseline measures. Further research is now being conducted to confirm that the neural system under study can support a plastic change through the induction of traditional LTP. Supported by Grants from NSERC to D.P.C.

EVIDENCE FOR AN LTP REFRACTORY PERIOD J. Greenberg*, J. Larson*, & G. Lynch. (SPON: J. Turnbull) Center for the Neurobiology of Learning & Memory, University of California, Irvine, CA 92717.

Use of stimulation patterns consisting of brief, high frequency bursts has provided evidence for several postsynaptic events controlling induction of long-term potentiation (LTP) in hippocampus. In particular, burst stimulation given to one set of inputs to a CA1 pyramidal cell induces LTP only if preceded by priming stimulation of the same inputs or a separate set of inputs to the same cell (Larson & Lynch, Science, 232:985, 1986); when several inputs to a primed cell are stimulated in sequential but overlapping order, the degree of LTP induced at the activated synapses depends on their order in the temporal sequence (Larson & Lynch, this meeting). The present experiments provide evidence that burst stimulation in a primed cell is followed by a brief period during which further burst stimulation of a separate input is less effective for LTP induction.

Two stimulating electrodes were positioned to activate separate sets of Schaffer/commissural axons converging on CA1 neurons in the rat hippocampal slice. Dendritic population EPSP's were measured for a 10 min period before and 20 to 30 min following patterned stimulation. This consisted of a priming pulse to both inputs followed by a burst (4 pulses , 100 Hz) to S1 at a delay of 180 msec and to S2 at a delay of 220 msec. The resultant potentiation (% increase in EPSP slope) was 49.1% (±5.9) for S1 and 29.5% (±5.3) for S2. S1 potentiated to a greater degree than S2 in 12 of 17 cases; S2 potentiated more than S1 in only 3 cases. Control experiments in which either S1 or S2 (at the corresponding delays of 180 or 220 msec) were stimulated alone resulted in LTP of 52.2% (±5.7). In the combined pattern then, prior stimulation of S1 reduced the efficiency of the S2 burst by about 40%.

Inspection of the extracellular responses recorded in the apical dendritic field revealed that the responses to the S2 bursts were considerably reduced in magnitude, compared to either the S1 responses or responses to bursts given at the same priming delay without S1 stimulation. We have previously reported that the magnitude of burst responses is highly correlated with the degree of LTP induced by those bursts; therefore, the reduced potentiation at S2 synapses may result from shunting of postsynaptic responses to S2 bursts by currents activated by S1.

DEGREE OF LTP IN CONVERGING INPUTS IS DETERMINED BY THEIR POSITIONS IN A TEMPORAL STIMULATION SEQUENCE. J. Larson* and G. Lynch (SPON: M.-L. Kean). Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

Recent evidence suggests links between the hippocampal theta rhythm and the induction of long-term potentiation (LTP). Short stimulation bursts (mimicking complex-spike discharges) produce maximal LTP when repeated at 5Hz-the theta frequency. This appears to be due to a suppression of subsequent IPSPs by the first burst, allowing enhanced postsynaptic depolarization in response to later bursts and consequent activation of NMDA receptors (Larson & Lynch, *Science* 232:985, 1986; *Brain Res.* 441:111, 1988). The present study examines the effects of asynchronous input activation--such as might occur during a single theta wave -- on LTP induction.

Three stimulation electrodes (S1, S2, S3) were used to activate independent inputs to apical dendrites of field CA1 neurons in rat hippocampal slices. Field EPSPs evoked by single test stimuli to each electrode were monitored for 10 min before and 20-30 min after patterned stimulation as follows: A "priming" pulse was given to each input to suppress IPSPs; then a burst (4 pulses, 100Hz) was given to each electrode at a different delay: 180 msec (S1), 200 msec (S2), and 220 msec (S3). Thus, pulses 3 and 4 of S1 overlapped pulses 1 and 2 of S2; pulses 3 and 4 of S2 overlapped pulses 1 and 2 of S3. The pattern was repeated 10 times at 5 sec intervals. Stimulus intensity was set such that activation of any input separately would not induce LTP. After stimulation of the three inputs together, the degree of LTP induced (% increase in field EPSP) was greatest for S1 (25 ± 3%), intermediate for S2 (17 ± 2%) and least for S3 (8 ± 2%), measured 20 min after patterned stimulation.

Intracellular recordings were made from pyramidal neurons in order to quantify postsynaptic responses during patterned stimulation. The degree of postsynaptic depolarization was greatest during the period of S2 stimulation. Since S1 synapses showed greater LTP than S2 synapses, we conclude that the degree of LTP induced does not depend simply on the degree of depolarization during input activation. Rather the depolarization during and after input activation appears to determine the magnitude of LTP. This is probably a consequence of the unusual kinetics of NMDA receptor-linked ion channels. The relatively weak LTP effects at S3 synapses may also reflect the activation of shunting currents by the earlier inputs.

STABLE DEPRESSION OF POTENTIATED SYNAPTIC RESPONSES IN THE HIPPOCAMPUS INDUCED BY LOW FREQUENCY STIMULATION. U. Staubli and G. Lynch. Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

Reversal of long-term potentiation (LTP) figures prominently in discussions of 1) the possible causes of forgetting and 2) the weakening of synapses as part of learning algorithms in neuronal network models. Results from experiments done in acute animal preparations suggest that depressive mechanisms exist in the hippocampus (Barrionuevo *et al.*, 1980). However, there is no evidence a) that the depression is synaptic in nature as opposed to more global changes of neuronal properties and b) that the depression lasts long enough to be a factor in memory.

To analyze these points, we have carried out a study using chronically implanted rats with two stimulating electrodes and one recording electrode in the Schaffer collateral/commissural system. This allowed us a) to assess the duration of the LTP reversal, b) to verify if the depression is specific to responses evoked by the experimental electrode, and c) to induce LTP again in cases where the previous potentiation remained reversed for at least 24 hrs. We found that repetitive low frequency stimulation (LFS) at 1 Hz (100 sec) induced a specific and lasting (>24 hrs) reversal of LTP in 21 of the 33 animals tested while control responses remained unchanged. No effect was observed when LFS was administered to the unpotentiated pathway. In six animals the potentiation was only temporarily depressed (<15 min) by LFS, and no effect was observed in the remaining animals. In 18 of the animals that showed a lasting depression LTP was re-established and remained stable for at least 24 hrs.

Current studies seek to identify (1) optimal parameters (stimulation pattern and time point of administration) for the reversal effect and (2) physiological characteristics of potentiated vs. unpotentiated responses during low frequency stimulation. The results may have important implications for hypotheses about (a) the substrates of LTP and (b) the mechanisms underlying forgetting.

LONG-TERM POTENTIATION IN AMYGDALA BRAIN SLICES. P. F. Chapman* and T. H. Brown. Division of Neuroscience, Beckman Research Institute, City of Hope, Duarte, CA 91010

The amygdala is a structure with demonstrated importance to affect and learning (Davis, 1986, *Behav. Neuro.*, 100, 814; Mishkin, 1982, *Nature*, 273, 297). Investigations of this structure have generally focussed on the effects of lesions, drugs, or electrically-induced epiliptiform activity on behavior. Due to the complexity of its intrinsic and extrinsic connections, few examinations have been made of the relationship between cellular neurophysiology, and function.

We have used an *in vitro* slice preparation to make intracellular current- and voltage-clamp analyses of long-term potentiation (LTP) in the amygdala of rats. Either coronal or horizontal slices (450 µm) through the amygdala were prepared by isolating a block of tissue from each hemisphere. Glass recording electrodes (50-90 MΩ) were filled with 4M KAc and placed in the lateral or basolateral amygdala. EPSPs and EPSCs were recorded using a single-electrode current- and voltage-clamp device.

Stimulation of the external capsule with 20 µsec constant current pulses produced an EPSP with a latency of 2-3 msec and peak amplitude of 10-15 mV. The corresponding EPSC varied in amplitude between 0.3 and 1.5 nA. Baseline measures were made for each cell by selecting the stimulus intensity that produced EPSPs greater than 5 mV, but at least 10 mV less than the spike threshold for that cell. Test pulses were delivered at a rate of five per minute. After 10 minutes, three trains of pulses were delivered at 300 Hz, each lasting 100 msec, with a five second inter-train interval. Following tetanic stimulation, EPSPs and EPSCs increased between 20 and 150 percent for at least 20 minutes.

The occurrence of LTP in the amygdala slice should facilitate detailed biophysical and pharmacological analysis of the mechanisms that control its induction and expression. Such knowledge may enable tests of the behavioral role of LTP in this structure. *(Supported by the AFOSR).*

Comparative Extracellular Current Flow at Dendrites and Soma of Dentate Gyrus Granule Cells During Long-Term Potentiation. C. Pavlides*, Y.J. Greenstein & J. Winson. The Rockefeller University, 1230 York Ave., NY, NY 10021.

In the study of long-term potentiation (LTP) in the dentate gyrus, the magnitude of the initial slope of the evoked synaptic potential (ESP) in the region of the granule cell layer, is commonly used as a measure of the increase of synaptic efficacy at the site of the perforant path (PP) input. To investigate the viability of this assumption, in rats anesthetized with either Chloropent (N=5) or Urethane (N=5), LTP was induced by tetanic stimulation of the PP and ESPs were measured simultaneously at both the soma and the dendritic site of the PP input.

Decoupling of somal and dendritic ESPs occurred in both groups of animals, the nature of the decoupling depending on the anesthetic used. Thus in animals anesthetized with Urethane the somal (14.5%) increase of the ESP was significantly lower than the dendritic (38.9%) ($P < .001$). In contrast, in animals anesthetized with Chloropent, the somal (23.3%) increase of the ESP was significantly higher than the dendritic (14.9%) ($P < .05$). We conclude that in assessing changes of synaptic efficacy, following the induction of LTP, measurements should be taken at the site of synaptic input.

ASYMMETRY OF ASSOCIATIVE LONG-TERM POTENTIATION (LTP) IN THE HIPPOCAMPUS ACROSS THE CELL BODY OF CA1 PYRAMIDAL CELLS. J. Jester, P.K. Stanton, and T.J. Sejnowski. Dept. of Biophysics, Johns Hopkins University, Baltimore, MD 21218.

Long-term potentiation (LTP), a lasting increase in synaptic strength, occurs in hippocampus following high-frequency stimulation. Further, associative LTP has been shown in pathways receiving a weak stimulus concurrent with a strong stimulus to a converging input. We have investigated the association of inputs using patterned stimuli on the same or opposite sides of the cell bodies of CA1 hippocampal neurons.

Extra- and intracellular recordings were made from 400 μm thick slices of rat hippocampus in an interface chamber at 34°C. The stimulus sites were stratum oriens (SO), which synapses on the basal dendrites, and the Schaffer/commissural (SCH) pathway in stratum radiatum (SR) which synapses on the apical dendrites of CA1 pyramidal cells. The "strong" stimulus pattern (which alone induced LTP) consisted of trains of 10 bursts of 5 stimuli given at 100 Hz, with an interburst interval of 200 msec. The "weak" stimulus pattern (which alone had no effect) was a series of single shocks at 5 Hz which either coincided with or came between bursts to the strong site.

Pairing of the SO site as the strong stimulus and SCH as the weak resulted in no change of the epsp slope (+5.4 ± 4.8%, n=8) 15-60 minutes post-tetanus. However, when strong and weak sites were reversed, the SO site showed significant increases in both the epsp (+62.7 ± 19.9 %, n = 7) and the amplitude of the population (pop) spike (+58.5 ± 15%, n = 7). When the stimulus sites were in SR on opposite sides of the recording site, pairing strong and weak led to an increase of +37.0 ± 11.1 % (n = 10) of the epsp and +65.4 ± 16.0% (n=14) of the pop spike, whereas interleaving weak site shocks and strong site bursts resulted in long-term depression of the pop spike with no change in the epsp. Thus, associative LTP occurs across CA1 cell somata preferrentially when the weak input is in the basal dendrites.

CA3 COMMISSURAL, BUT NOT MOSSY FIBER, SYNAPSES IN HIPPOCAMPUS EXHIBIT ASSOCIATIVE LONG-TERM POTENTIATION (LTP) USING RYTHMICALLY COACTIVE INPUTS. S. Chattarji, P.K. Stanton, and T.J. Sejnowski. Dept. Biophysics, Johns Hopkins Univ., Baltimore, MD 21218.

Long-term potentiation (LTP) is characterized by a persistent increase in synaptic efficacy following brief, high-frequency stimulation of afferent pathways in the hippocampus. There is evidence that weak excitatory inputs that do not exhibit LTP when stimulated alone do elicit LTP when coactivated with stronger inputs. Recent studies suggest that associative LTP can be induced in field CA1 of the hippocampus depending on the phase of rythmically active inputs. The present study evaluates whether associative LTP can be induced using such rythmically coactive inputs in field CA3, where mossy fiber synapses exhibit LTP not involving N-methyl-D-aspartate (NMDA) receptor activation.

Extracellular recordings were made in 400 μm thick rat hippocampal slices in an interface recording chamber at 33°C. Responses of CA3 pyramidal cell somata and apical dendrites were recorded following stimulation of the Commissural/Schaffer (COM) and mossy fiber (MF) afferents. Strong (potentiating) stimuli consisted of trains of 10 bursts of 5 pulses each at a frequency of 100 Hz, with an interburst interval of 200 msec. The weak stimuli, a train of single shocks at 5 Hz, was given either superimposed on the middle of each burst (in phase), or symmetrically between the bursts (out of phase).

A strong tetanus alone induced LTP at both COM and MF synapses, while weak inputs alone produced no change. When the COM side received a weak input in phase with a strong MF tetanus, associative LTP (>30 min) was induced at COM synapses. In contrast, a weak MF stimulus failed to elicit associative LTP when applied in phase with a strong COM input. Furthermore, when the COM side received a weak input out of phase with a strong MF train, a long-term depression (LTD) of COM evoked population spikes was observed. Thus, MF synapses, which lack NMDA receptors, do not exhibit associative LTP. (Supported by Naval Research Grant #N00014-88-K-0198)

LEARNING AND MEMORY: PHYSIOLOGY III

226.1

NMDA-RECEPTOR-MEDIATED ACTIVITY AND LONG-TERM POTENTIATION (LTP) IN RAT NEOCORTEX. L.J. Bindman and K.P.S.J. Murphy*. Dept. of Physiology, University College London, London, WC1E 6BT, U.K.

We have examined the involvement of N-methyl-D-aspartate (NMDA)-receptor-mediated activity in the production and maintenance of LTP in rat neocortex. Both intracellular and field potential recordings were made from slices of neocortex in vitro, bathed in c.s.f. containing 1.1 mM Mg^{++}. D-2-amino-5-phosphono-valerate (D-AP5, 10 to 20μM) was bath applied to block selectively NMDA-receptor-mediated activity. Test shocks were applied to the subcortical white matter at 0.1 Hz.

We found that (1) e.p.s.p.s in layer V neurons did not potentiate over tens of min. although subsequent application of D-AP5 showed there was a significant component due to activation of NMDA-receptors (Aram, J. et al., J. Physiol. (Lond), 394: 117P, 1987). (2) The presence of D-AP5 prevented the induction of LTP in neurons of layers V and VI following conditioning trains, thus extending the observations on cells in layers III and IV (Artola, A. and Singer, W., Nature 330: 649, 1987); (3) Application of D-AP5 after establishment of LTP in layers III, V and VI reversibly reduced its magnitude, showing that NMDA-receptor-mediated activity was also involved in the maintenance of LTP in neocortex.

226.2

BATH APPLICATION OF PROGESTERONE INHIBITS THE INDUCTION OF LONG-TERM POTENTIATION IN AREA CA1 OF THE HIPPOCAMPUS. C.L. Dolorfo* and S. Veraggo. (SPON: L. Denner) Dept. of Biol. Sciences, San Jose State Univ., San Jose, CA 95192.

Long-term potentiation (LTP) is a phenomenon that has been proposed to be involved in both learning and memory and in epilepsy. It has been suggested that certain cognitive abilities, as well as seizure susceptibility in epileptic women, vary during the menstrual cycle. Such effects may be related to fluctuations in progesterone and estrogen levels. In a previous study, we observed that the duration of LTP in hippocampal slices from rats in metestrus (a time when the mean progesterone to estrogen ratio (P/E) is highest) was shorter than that generated in slices from rats in diestrus (when the mean P/E is lowest). Also, the duration of LTP produced in slices from progesterone treated ovariectomized (OVX) rats was shorter than that produced in slices from estradiol treated and untreated OVX rats. These results suggested that progesterone might have an inhibitory effect on the maintenance of LTP. The purpose of the present study was to determine if progesterone has a short-latency effect on LTP. Hippocampal slices from OVX Sprague-Dawley rats were perfused with artificial CSF (ACSF) containing progesterone (40ng/ml). A control population spike was produced in region CA1 (0.2Hz, 0.1ms) and maintained for 20 min before production of LTP (15Hz, 10s--3 trains, 10s intervals) was attempted. LTP could not be generated in progesterone treated slices (n=8; $p<0.001$), but LTP was produced in the control ACSF (n =10; $p<0.001$). These data suggest that progesterone may have a direct, short-latency effect that prevents the induction of LTP. These observations suggest a possible mechanism by which fluctuations in gonadal steroids may modulate cognitive processes and seizure frequency. DANTROLENE BLOCKADE OF LONG-TERM POTENTIATION (LTP) IN THE RAT HIPPOCAMPAL CA1 REGION. A. Obenaus, I. Mody and K.G. Baimbridge. Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5

Previous reports from our laboratory and others have suggested an important role for calcium (Ca^{2+}) in the induction of LTP with a particular emphasis being placed on Ca^{2+} entry through NMDA activated channels. Using Wistar rat hippocampal slices maintained in vitro, we have examined the possible contribution of intracellular Ca^{2+} release in LTP. Dantrolene (DANT) blocks Ca^{2+} release from the sarcoplasmic reticulum of skeletal muscles, and our results indicate that DANT (20μM) also blocks LTP. The blockade is highly dependent upon the time of exposure to the drug; most likely due to slow diffusion of DANT into the hippocampal slices. Total blockade of LTP requires exposures of 2 hours or more. This blockade is unlikely to be via a direct effect on the NMDA receptor (see Mody et al. this vol.). We suggest that intracellular release of Ca^{2+} may contribute to the Ca^{2+}-dependent component of LTP in the rat hippocampus. (Supported by a Canadian MRC Program Grant to KGB.)

APPLICATIONS OF A FREEZING SYSTEM DESIGNED TO CAPTURE CNS DYNAMIC MORPHOLOGY. C.S. Wallace, F.-L. Chang and W.T. Greenough. Neur. & Beh. Biol. Prog., Depts. Psych. & Cell & Struct. Biol., Univ. IL, Champaign, IL 61820.

Previously we have reported the design of an inverted slam freezer (Wallace et al, Soc. Neurosci. Abs., 1987) which brings a mirror freezing surface in contact with a stationary specimen, in contrast to conventional freezers which require that the specimen be mounted in an inverted position prior to freezing. Beginning with this instrument, we have developed a system for studying the morphology of CNS synapses as a function of recent activation history. To keep the tissue in a properly controlled environment prior to freezing, we have designed a detachable chamber that mounts on the inverted slammer. By incorporating stimulating and recording electrodes directly into the freezer's specimen holder we have eliminated the need to transport the tissue prior to freezing. Timing of the stimulation and the freezing can be coordinated, with at least .04 msec precision, by optical sensors. A tangential dentate slice (Chang & Greenough, adjacent) permits rapid freezing of neural circuits lying immediately beneath a natural (pial) surface. It is hoped that this development can provide insights into the morphological correlates of central synaptic function. Supported by ONR, EFA

LONG TERM POTENTIATION IN UPRIGHT TANGENTIAL MOUSE DENTATE SLICES. F.-L. Chang & W.T. Greenough, Col. Med., Neur. Beh. Bio. Prog., Dept. of Psych., & Cell Struct. Bio., Univ. of Illinois, Champaign, IL 61820

One of the most significant drawbacks of transverse hippocampal slices is the loss of fiber projections that run perpendicular to the cut. In 1968, Yamamoto and Kawai (Jap. J. Physiol., 18, 620) described a slice preparation cut from the ventral surface of guinea pig dentate; however, the viable slice thickness allowed only the ventral portion of the hilus to be included, and this was potentially damaged due to proximity to the cut. We took advantage of the small size of the mouse dentate; within a tangential slice, most of the hilus is intact, as are the local interneurons and their projections.

Mouse hippocampus was dissected out and followed by 2 coronal cuts 150 um apart to isolate the mid-segment. A third cut produced a 450 um slice from the ventral surface. After an incubation of 1.5 hours, spontaneous unit activities could be recorded throughout the dentate. LTP was produced successfully via stimulation of the perforant path in over 70% of the slices. Among the successful slices, LTP of population spikes ranged from 20 to 59% (mean: 35%), and lasted for at least 1.5 hours.

This dentate slice, with its 2-D fiber projections and uncut ventral surface, combined with Wallace et al's inverted slam freezer (adjacent) provides an unique opportunity to study CNS plasticity. Funded by EFA & ONR.

BLOCKING CHOLINERGIC FUNCTION WITH ATROPINE FAILS TO ALTER THE ESTABLISHMENT OF LTP IN HIPPOCAMPAL SLICES *IN VITRO*. Y. McQueen* and W. D. Knowles (SPON: C. L. Cherniсky). Cleveland Clinic Foundation, Cleveland, OH 44195.

Cholinergic synaptic function exists in hippocampal slices, and may play a role in memory function. We tested the role of cholinergic function in the establishment of long term potentiation (LTP) in CA1 of the hippocampal slice by applying atropine during tetanization. There was no difference in the potentiation seen with atropine.

Guinea pig hippocampal slices (300-450 μm) were maintained at 35°C in physiological saline (3 mM K^+, 2 mM Ca^{++}, 2 mM Mg^{++}) in an interface chamber. Test stimuli (0.2 Hz) were delivered to the Schaffer collaterals on both the subicular and CA3 side of the recording electrode in CA1 stratum pyramidale. Stimuli amplitudes were adjusted to produce a half-maximal population spike. Two minutes prior to tetanization, atropine methyl nitrate (100 μM in physiological saline) or physiological saline was applied to the surface of the slice as a microdrop. LTP was produced by a 2 sec train of 100 Hz, 100 μs stimuli to one of the stimulating electrodes, randomly chosen. LTP was measured 15 minutes after tetanization. We saw no difference in the amplitude of LTP with atropine or vehicle. We conclude that muscarinic cholinergic function does not influence the establishment of LTP in CA1 pyramidal cells.

COMPARISON OF DENDRITIC AND SOMA-INDUCED DEPOLARIZATION AS CONJUNCTIVE STIMULI FOR PAIRING WITH SYNAPTIC ACTIVATION, GIVING LONG-TERM POTENTIATION IN RAT HIPPOCAMPAL SLICES. Ø. Hvalby*, G.-Y. Hu*, J.-C. Lacaille and P. Andersen* (SPON: A.Njå) Inst. of Neurophysiology, University of Oslo 0162 - Oslo 1, Norway.

Temporal coupling of postsynaptic depolarization with low-frequency synaptic activation induce long-lasting potentiation of synaptic transmission across the radiatum fibre/CA1 hippocampal synapses.

Glutamate was iontophoretically delivered (200-800 ms) at a "hot spot" in the apical dendritic tree, giving a mean depolarization of 9.9 ± 6.0 mV, n=28). A single afferent volley to the same dendritic area was delivered simultaneously, and the conjunction was repeated 10-120 times at 0.2 Hz. In 20 of 28 cells this paradigm caused an improved synaptic transmission in the paired pathway, lasting more than 15 minutes. A separate non-paired pathway to the same cells was unchanged.

In contrast, when the same paradigm was applied for current-induced depolarization of comparable magnitude (12.2 ± 5.9 mV, n=18), no changes in the synaptic transmission was observed. Stronger depolarization, causing the cells to discharge above 50 Hz were effective.

The results suggest that dendritic depolarization is essential for an effective conjunctive effect. Stronger currents may be needed at the soma in order to spread sufficiently far into the dendritic tree.

THETA STIMULATION OF THE LATERAL OLFACTORY TRACT SERVES AS A CUE IN A SUCCESSIVE-CUE OLFACTORY DISCRIMINATION TASK. T.A. Otto, U. Staubli and G. Lynch. Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

Electrical stimulation of the olfactory bulbs or of the lateral olfactory tract (LOT) has been reported to serve effectively as a discriminative stimulus in olfactory learning tasks (Mouly *et al.*, 1985; Roman *et al.*, 1987). The present report provides additional evidence of the efficacy of such stimulation to serve as a learning cue, and further describes a paradigm in which this stimulation activates piriform cortex at the same time as natural odors, permitting a description of the physiological events in a cortical network occurring during learning.

Stimulating electrodes were implanted bilaterally in the LOT and recording electrodes bilaterally in the piriform cortex at levels maximizing the dendritic monosynaptic population EPSP. Following recovery, water-deprived rats were trained to discriminate natural odors in a successive cue, "go, no-go" task. One sec nosepokes into an odor port resulted in the delivery of one of two odors--one 'positive', the other 'negative'. Sessions consisted of discriminating two session-unique odors to a criterion of 18 correct responses in 20 consecutive trials; normal rats generally require no more than 5 or 6 such sessions to reach criterion within the first 20-25 trials.

The first session of training with LOT stimulation required a discrimination between clean air as the 'negative' cue, and clean air plus 2 sec of bursts of 4 pulses at 100Hz delivered at theta frequency (7Hz) to one LOT as the 'positive' cue. The first burst was delivered 200 ms after the onset of clean air ejection; we have recently discovered that the firing of single units in piriform cortex to natural odors in this task is delayed by approx. 200 ms following odor presentation (McCollum *et al.*, 1988). The second session of LOT stimulation training required the subject to discriminate stimulation of one LOT from stimulation of the contralateral LOT. In both cases, subjects display nearly perfect transfer of learning from natural odors to electrical stimulation.

The procedures described herein permit an analysis of the monosynaptic responses accompanying behaviorally relevant and precisely controlled input to cortex, thereby permitting future analyses of the cellular events accompanying learning in a defined cortical network. Preliminary data suggest that synaptic changes in piriform similar to LTP may occur following stimulation training.

EFFECTS OF SCOPOLAMINE AND GLUCOSE ON LONG-TERM POTENTIATION IN DENTATE GYRUS. R.C. Michaelis and P.E. Gold, Department of Psychology, University of Virginia, Charlottesville, VA 22903-2477.

Glucose administration enhances memory in humans. Glucose also antagonizes scopolamine induced amnesia and hyperactivity, and augments physostigmine induced tremors in mice. These interactions between glucose and scopolamine, together with the evidence of cholinergic involvement in memory storage, led us to evaluate the effects of scopolamine and glucose on long term potentiation. Under physiological control in anesthetized rats, bipolar stimulating electrodes were implanted in the perforant path and monopolar recording electrodes were implanted in the hilus of the dentate gyrus. Test pulse amplitude (0.1 msec duration) was adjusted so that the population spike (PS) amplitude was 33-50% of the extracellular EPSP amplitude. High frequency stimulation (10 trains, 20 msec each, 400 Hz, 10 second ITI) resulted in a 356 ± 57% (mean ± sem) increase in the PS amplitude in control animals. Scopolamine (2.0 and 3.0 mg/kg) produced a dose-dependent reduction in the amount of potentiation (218 ± 41% and 165 ± 25%, respectively), without any marked changes in the baseline PS amplitude. Glucose (1000 and 1500 mg/kg) reversed the scopolamine (3 mg/kg) induced deficit in a dose-dependent manner (256 ± 32% and 313 ± 53%, respectively). These glucose doses by themselves had no effect on the response to test pulses or on potentiation. Scopolamine impairs the establishment of long-term potentiation, and this impairment can be attenuated with glucose. These pharmacological characteristics are similar to those observed in behavioral studies of memory. The findings add further support to the view that circulating glucose levels may regulate cholinergic function. [Supported by ONR N00014-85-K0472 and MH 31141].

AN ALGEBRAICALLY ADDITIVE RELATIONSHIP EXISTS BETWEEN BEHAVIORALLY AND ELECTRICALLY ELICITED INCREASES IN DENTATE GYRUS RESPONSIVENESS TO PERFORANT PATH STIMULATION. K.R. Isaacs, F.-L. Chang, and W.T. Greenough, Neur. & Beh. Biol. Prog. & Depts. Psych. & Cell & Struct. Biol., Univ. of Illinois, Champaign, IL 61820.

If increased dentate gyrus responses to synaptic activation resulting from experience (Green & Greenough, 1986) and conventional LTP have a common mechanism, they should show an additive relationship. Rats were housed at P30 in either EC, together in a large cage filled with toys, or IC, in individual cages, for 30-35 days. Littermates from each condition were operated on the same day. Rats were anesthesized with nembutal and electrodes were placed in the hilus of the dentate gyrus for recording and in the angular bundle for stimulation. An input/output curve (IO) was collected after positioning the electrodes to produce the maximal response. LTP inducing stimulation was then administered using 100Hz, 1 sec duration at a maximal response amplitude determined from the initial IO. LTP trains were separated by 5 min and were administered until a stimulus produced no further increases in response amplitude ($\bar{x}$=5 trains). After 30 minutes a second IO was collected and compared with the pre-LTP IO. In all five pairs of rats, the IC EPSP potentiated more than the littermate EC. Differences in EPSP potentiation ranged from 22.6% to 64.3%, with a mean of 48.08%. (Supported by ONR, EFA & NIMH)

EFFECTS OF GENETICS AND CHRONIC NICOTINE TREATMENT ON ACTIVATION OF NMDA RECEPTORS. J. M. Wehner, R. K. Freund, M. K. Anderson*, K. Kelly*, and A. C. Collins. Instit. for Behav. Genetics, Univ. of Colorado, Boulder, CO 80309

C57BL mice perform better on a spatial learning task than do DBA mice. This task and the phenomenon of long-term potentiation (LTP), may involve activation of NMDA receptors in the hippocampus. We tested granule cell population spike (PS) responses from hippocampal slices for sensitivity to the NMDA antagonist DL-2-aminophosphonopentanoic acid (AP5) in Mg^{2+}-free medium. Responses from C57 slices were slightly more sensitive than those from DBA mice to the inhibitory effects of AP5 (2-16 uM). These strains did not differ in the LTP response to high frequency stimulation (HFS; 400 Hz; 250 ms) in area CA1. Because nicotine may alter learning, the effects of chronic nicotine infusion (4 mg/kg/hr; 8 days) on CA1 PS responses were measured. Increased sensitivity to stimulation (increased I-O slopes) for control and post-HFS responses was observed in nicotine-treated C57 mice; no changes were observed for DBA mice. Slices from nicotine-infused C57 mice were also less responsive to HFS (smaller I-O shift). These results suggest a basal difference in NMDA receptor activation between these mouse strains, and chronic nicotine treatment elicits a larger strain difference on measures of CA1 cell responsiveness. LONG-TERM SYNAPTIC DEPRESSION PRODUCED BY ANTIDROMIC CONDITIONING STIMULI IN CA1. S.Pockett, N.Brookes,* L. Bindman, Department of Physiology, University of Auckland, Auckland, New Zealand.

Pockett & Lippold (Exp.Neurol.91 481, 1986) found, using extracellular recording techniques at room temperature, that when the pyramidal neurons of the CA1 region or hippocampal slices were stimulated antidromically, by a train of pulses in a pattern that would produce long-term potentiation if delivered through a synaptic pathway, a long-term depression (LTD) of the synaptically derived population spike resulted. Here we report that LTD can also be demonstrated when recording intracellularly from slices at 34°C.

E.p.s.p.s were recorded in response to stimulation of the Schaeffer collateral/commissural pathway every 20 sec. Their amplitude remained constant during a 1.5 to 2 hour recording period. Stimuli applied antidromically to the alveus caused antidromic action potentials and sometimes inverted i.p.s.p.s in the CA1 neurons. If the antidromic stimuli were applied in a conditioning pattern of 6 bursts of 50 impulses at 100 Hz, at 10 sec. intervals, a depression of e.p.s.p. amplitude resulted which lasted as long as the recording period (1-2 hours).

It was possible to apply 25mM $Mg2+$ to the preparation and see total obliteration of e.p.s.p.s and i.p.s.p.s, then wash it off and see complete recovery. If the conditioning antidromic stimuli were applied in the presence of $Mg2+$, e.p.s.p.s remained depressed after the washout period. This shows that LTD is not a special case of heterosynaptic depression nor long lasting feed-back inhibition.

OLFACTION AND IMMUNITY FROM CONDITIONED FOOD AVERSION IN MICE. N.E. Kinney, J.W. Wright and J.W. Harding.(Depts. of Psychology and Vet. Comp. Anat., Pharm. & Physiol., Washington State Univ.,Pullman), Dept. of Psychology, SE Missouri State Univ., Cape Girardeau, MO 63701.

Nerve sectioned mice demonstrate a degree of immunity to food aversion formation while anosmic (taste only mediated aversion), but lose this immunity once recovered (Kinney et al, Soc. Neurosci. Abstr. 11:527, 1985). Food deprived male albino mice were given access to novel food (almond) followed by 50 min of rotary motion (60 rpm). These mice then underwent a bilateral olfactory nerve section procedure (Harding et al., Brain Research, 132:11-18, 1977) and after 7 days recovery were given second access to almond. Immunity to conditioned food aversion was provided by nerve section induced anosmia introduced between first and second access. But it was not provided by injection of the centrally-acting antimuscarinic scopolamine hydrobromide (0.1 mg/kg) given prior to rotation. Nor was immunity provided by scenting the almond with a familiar odor (musk) present in home cage from birth to weaning. These results suggest that olfaction plays a central role in the formation of motion induced food aversions since anosmia introduced after first access is not followed by reduced second access consumption as found in controls.

BODY ROTATION-INDUCED CONDITIONED TASTE AVERSIONS IN RATS: COMPARISON OF SOME CONTINUOUS AND INTERMITTENT SCHEDULES OF ROTATION. K.-P. Ossenkopp, K. Desborough* and F. Boon*. Dept. of Psychology, Univ. of Western Ontario, London, Ontario, CANADA N6A 5C2.

Several studies have shown that horizontal body rotation can be used as an effective unconditioned stimulus (UCS) to produce conditioned taste aversions (CTA) in rats. What is not clear from these studies, is whether some schedules of intermittent rotation are as effective as continuous rotation in producing the CTA. This issue was examined in two experiments. In Experiment 1 rats were given a saccharin solution to drink and then sham rotated, rotated for 1 hr (70 rpm), rotated for 1/2 hr, rotated for 1/2 hr after a 1/2 hr delay, or intermittently rotated for 1 hr on a schedule of 10 sec on - 10 sec off. Rats were conditioned every other day for a total of 4 conditioning days. Three days after the last conditioning trial they were given a two-bottle choice test. The strongest CTA was seen after 1 hr continuous or intermittent rotation. In Experiment 2 intermittent rotation schedules (1 hr duration) of 10 sec on-off, 60 sec on-off, or 900 sec on-off, were compared with sham rotation. The strongest CTA was obtained with the 60 sec on-off schedule. Thus, the amount of rotation, the length of the UCS period, and the number of on-off transitions in the UCS period, are important in determining strength of the subsequent CTA. (Supported by NSERC).

MEMORY ENHANCEMENT INDUCED DURING POST-LEARNING PARADOXICAL SLEEP. B. Hars, E. Hennevin, V. Bloch (SPON: J. Serviere). Depart. de Psychophysiologie, CNRS, Gif sur Yvette and Univ Paris XI, Orsay, France.

The hypothesis that newly acquired information is processed during paradoxical sleep (PS) following learning, suggests that the memory trace is in an active state at this time. In a previous work (Hars et al. Behav. Brain Res., 1985, 18, 241-250) rats were submitted to an active avoidance conditioning. After the conditioning session, the conditioned stimulus was given as a cue during PS phases: retention performances were enhanced. When cueing treatment was given during wakefulness or slow wave sleep (SWS) it had no facilitative effect. In the present work rats were trained to run in a maze for food reward. After each daily trial, mild electrical stimulation of the mesencephalic reticular formation was delivered during PS phases: there was a marked improvement in learning curves. The same stimulation was ineffective when delivered, at the same delays after trials, either during periods of SWS or wakefulness. These results give strong support to the hypothesis that the new memory trace is reactivated during post-learning PS.

VASOPRESSIN (AVP) IS RELEASED FROM THE DORSAL HIPPOCAMPUS (DH) OF FREELY BEHAVING MALE RATS: ABSENCE OF A RELATIONSHIP WITH SOCIAL MEMORY. A.D. Ramirez* and E.J. Roy. Depts. of Physiology and Psychology, Univ. of Illinois, Urbana, IL 61801.

Five adult male rats were implanted with push-pull cannulae aimed at the DH. Four rats were perfused (PPP) at a flow rate of 12-13 ul/min for 3.4-5h. A control period of 2h was followed by a 5-min exposure to a juvenile male rat (20-35 days) then re-exposed after 30 min to a second 5-min exposure to the same juvenile (Noninterference). Three rats (two from the previous experiment) were perfused (2.2-4h) in the absence of social interaction (Controls). In the noninterference experiments the behavior of the adult male rats was similar to that described by Thor and Holloway (1982) with a mean investigation value of 119.8 ± 25.5 sec for the first exposure and 79.6 ± 15.5 sec for the second 5-min exposure. Mean values of AVP released ranged from 0.035 to 0.35 pg/10min. No change was observed during these exposures (Pre-exposure x=0.18 ± 0.08, 12 intervals; Exposure period x=0.18 ± 0.03, 9 intervals). In the three control PPP the overall mean release rate of AVP was 0.17 ± 0.06 pg/10min (Range = 0.06-0.43).

In summary these results demonstrate that the DH releases AVP from freely behaving rats. In addition, the function of this peptide from the DH appears not to be correlated to social memory when using this paradigm.

THE NAPLES HIGH AND LOW-EXCITABLE RAT STRAINS: A REVIEW OF PUBLISHED AND UNPUBLISHED DATA. A.G. Sadile, Inst. Human Physiol. & Biomed. Phys., Univ. Naples,, Naples, Italy.

Increased locomotor activity in a novel environment is thought to depend mainly on the integrity of hippocampal formation. For, the Naples High- (NHE) and Low-Excitable (NLE) rat strains, selected on the basis of divergent activity in a modified Làt's box, have been proposed as genetic models to study locomotor hyper/hypo-activity in spatial novelty situations, under a similar background of emotionality, arterial blood pressure and learning ability. Aim of our report is to review evidence from a series of correlative analyses of multidisciplinary nature, which further validates this hypothesis. Behaviorally, both NHE/NLE-rats show an impaired working memory in an unreinforced tunnel maze and an impaired rate of acquisition of lever pressing for water compared to random-bred controls. Electrophysiologically, they are both sensitive to vasopressin and enkephalin induced slow potentials, with the NHE being hyper-sensitive. Both NHE/NLE-rats have fewer mossy fibers than controls. Immunoreactive vasopressin and corticosterone high-affinity binding show different strain dependent correlative profiles. The "metabolic" DNA, a DNA fraction with fast turnover, is not inhibited by spatial novelty in NHE-rats only. Both strains can be used as tool to study spatial information processing in the mammalian brain.

EPILEPSY: HIPPOCAMPUS AND NEOCORTEX I

227.1

EXTRACELLULAR K+ AFFECTS HIPPOCAMPAL IPSPs BY ALTERING THE ACTIVITY OF OUTWARD POTASSIUM/CHLORIDE CO-TRANSPORT. Scott M. Thompson*,† and Beat H. Gähwiler (Spon: Dr. S. DiMauro). Brain Research Institute, University of Zürich, Zürich, Switzerland;† and Dept. of Neurology, Columbia University, NY, NY 10032*.

Activity-dependent elevations of $[K^+]_o$ affect the amplitude of GABAergic IPSPs due to alterations in their reversal potential. Single-electrode voltage-clamp techniques were used to record currents from CA3 cells in organotypic slice cultures of hippocampus in order to investigate the effect of $[K^+]_o$ on E_{Cl^-}.

Reducing $[K^+]_o$ from 5.8 to 1 mM shifted E_{IPSC} from -67.6 to -81.9 mV, and E_{GABA} from -64.7 to -81.1 mV, when V_M was held constant and depolarized with respect to E_{IPSC}. This shift was unaffected by block of K^+ channels with intracellular Cs^+. The dependence of E_{GABA} on $[Cl^-]_o$ was close to that predicted by the Nernst equation in both $[K^+]_o$ = 5.8 and 1 mM saline. Reducing the extracellular Na^+ concentration 50% had no effect on E_{GABA}. Furosemide caused a 69% decrease in IPSP driving force when V_M was clamped depolarized to E_{IPSC}. Reducing $[K^+]_o$ from 5.8 to 1 mM in the presence of furosemide produced a small shift in E_{IPSC} from -61.0 to -71.2 mV, however, washout of furosemide from $[K^+]_o$ = 1 mM saline shifted E_{IPSC} further to -89.8 mV.

We conclude that reducing $[K^+]_o$ lowers the intracellular Cl^- concentration by increasing the efficacy of outward potassium/chloride co-transport. Inhibition of outward Cl^- transport by elevated $[K^+]_o$ may be important in the genesis and spread of epileptiform discharge.

227.2

DEPRESSANT EFFECTS OF LIDOCAINE ON REPETITIVE FIRING OF CA1 PYRAMIDAL CELLS IN THE HIPPOCAMPAL SLICE. R. Capek and B. Esplin. Dept. of Pharmacology and Therapeutics, McGill University, Montreal, Quebec, H3G 1Y6, Canada.

The effects of lidocaine on the CA1 pyramidal cells were studied in the superfused hippocampal slice preparation of the rat by a conventional intracellular recording technique. The cells were activated by injecting a single 500 ms depolarizing current pulse or a train of twenty 3 ms pulses at 5 to 100 Hz through the recording micropipette.

Lidocaine (20 to 100 µM) diminished the repetitive firing evoked by a single depolarizing pulse. The firing evoked by low current intensities was little affected but that evoked by high currents was substantially reduced.

The maximal rate of rise ($\dot{V}_{max}$) of action potentials evoked by trains of short depolarizing pulses at higher frequencies gradually declined. In the presence of lidocaine, $\dot{V}_{max}$ of the first action potential in the train was reduced only slightly or not at all but the decline of $\dot{V}_{max}$ was distinctly steeper.

A use-dependent block of sodium conductance can explain these findings and is the likely mechanism of anticonvulsant action of lidocaine. Since the reported effects of valproate were qualitatively identical (Capek and Esplin, Soc. Neurosci. Abstr. 12: 46, 1986), the present data support the notion that valproate acts the same way.

HIPPOCAMPAL CA3 PHYSIOLOGY FOLLOWING ISCHEMIA-INDUCED LOSS OF CA1. J. Franck, B. Fadeel* and P. Schwartzkroin (SPON: A.B. Harris). Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Hippocampal subfield CA1 often degenerates in individuals with intractable temporal lobe epilepsy. While the mechanism of this cell death is not clear, evidence suggests that remaining cell groups in hippocampus are part of the epileptic "focus."

We have induced a similar loss of CA1 by transient forebrain ischemia and begun to examine the physiologic consequences on remaining CA3 and dentate neurons. Adult male Wistar rats were made ischemic for 15 minutes by clamping the internal carotid arteries following permanent vertebral artery cautery. Several weeks later CA3 single cell and population responses were studied in *in vitro* hippocampal slices in a standard interface chamber perfused with reduced Mg^{++} medium (1.2 mM).

Following verified atrophy of CA1, pyramidal cells in CA3 discharge in burst patterns in response to synaptic activation (stimulation of the dentate gyrus). Furthermore, synchronous population afterdischarge activity and spontaneous multiple population spike episodes are recorded extracellularly. Studies are currently ongoing to determine the mechanisms and chronicity of this aberrant activity.

Long-term alterations in intrinsic properties of remaining hippocampal cells following selective CA1 atrophy and/or in synaptic restructuring between remaining cells may provide a substrate for focal discharge from "sclerotic" hippocampus.

MECHANISMS UNDERLYING SPREAD OF POTASSIUM-INDUCED HIPPOCAMPAL TONIC-CLONIC SEIZURE DISCHARGES. P. Rabenu*, Y. Yaari and M.S. Jensen*. (SPON: D.H. Silberberg). Dept. of Physiol. Hebrew Univ., Jerusalem, Israel and Inst. of Physiol., Aarhus Univ., Aarhus, Denmark.

Exposing rat hippocampal slices to elevated [K] (7 or 8 mM) induces two types of epileptic foci: (i) "spiking" focus in area CA3, which regularly produces brief bursts of population spikes, and (ii) "seizure" focus in area CA1, which recurringly generates tonic electrical seizures. The bursts discharges from CA3 propagate into CA1, where they synaptically evoke burst activity. The bursts triggered in CA1 prior to a seizure episode (interictal) are small, while those evoked immediately after the tonic seizure are gigantic. The latter bursts constitute the clonic phase of seizure.

Seizure discharges commenced in subarea CA1c and the discharge zone slowly (ca. 1 mm/s) expanded towards CA1a. Within this zone, population spikes locally generated during the tonic phase, or synaptically triggered during the clonic phase, spread much faster (ca. 0.3 m/s) in the same direction. The data suggested that the slow spread of the seizure discharge zone is mediated by the spatial dispersion of [K]o, while the fast spread of population spikes within this zone is due to ephaptic interactions among CA1 neurons.

ROLE OF EXCITATORY AMINO ACID RECEPTORS IN POTASSIUM-INDUCED HIPPOCAMPAL SEIZURE DISCHARGES. M.S. Jensen*, P. Rabenu* and Y. Yaari. (SPON: A.K. Asbury). Inst. of Physiology, Aarhus University, Aarhus, Denmark and Dept. of Physiology, Hebrew University, Jerusalem, Israel.

The role of non-NMDA (i.e. quisqualate/kainate) and NMDA receptors in hippocampal interictal and seizure discharges was examined using specific non-NMDA (quinoxaline derivative FG-9041) and NMDA (+-APV) blockers.

Interictal bursts and tonic-clonic seizure episodes were induced in the CA1 fields of rat hippocampal slices by elevating [K] in the perfusing media to 7-8 mM. Interictal and clonic burst generation was totally suppressed by FG-9041, but apparently unaffected by APV. Neither drug alone nor in combination interfered with the generation of tonic seizure episodes.

In between seizures, EPSPs evoked in area CA1 by stratum radiatum stimulation, were markedly reduced by FG-9041 but only mildly attenuated by APV. During the tonic phase of seizure, however, a prominent late component of the EPSP was blocked by APV. This APV-sensitive component could be isolated by perfusing FG-9041.

Thus, while seizure episodes are not initiated by glutamatergic excitation, synaptic activation of NMDA receptors is enhanced during the tonic phase of seizure.

EPILEPTIFORM ACTIVITY INDUCED IN RAT HIPPOCAMPAL SLICES BY HIGH BICARBONATE-CONTAINING MEDIA. J. Church* and H. McLennan* (SPON: J.A. Pearson). Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

The HCO_3'/H_2CO_3 buffer pair is largely responsible for maintaining c.s.f. pH within normal limits. We have examined the effect of altering $[HCO_3']_o$, and thus pH_o, on rat CA1 pyramid function recorded intracellularly.

Perfusion with medium containing 72mM HCO_3' (pH 7.9 after equilibration with $95\%O_2:5\%CO_2$) resulted, within 5 min, in an increase in input resistance and a reduction in threshold for spike generation. Neurons previously quiescent at resting potential often became spontaneously active. Accommodation of spike discharge to depolarizing current injection was enhanced, as was the afterhyperpolarization (AHP) following the spike train, and many neurons developed the ability to generate intrinsic burst discharges. Within 30-120 min spontaneous epileptiform bursts, which could also be elicited synaptically, were seen. These were abolished by addition of 20 μM ketamine. Ketamine did not, however, affect the intrinsic ability of the neurons to generate burst potentials.

It is unclear whether the observed activity results from a direct effect of changing $[HCO_3']_o$ or from the resultant change in pH_o. It is unlikely, however, to be a consequence of the reduced $[Ca^{2+}]$ seen in high-HCO_3' media as Ca^{2+}-dependent processes, including synaptic activity and $G_{K(Ca)}$-mediated AHPs, are well maintained.

LITHIUM AGGRAVATES MALAOXON-INDUCED BRAIN CELL INJURY. A. Naukkarinen*, L. Paljärvi*, M.R. Hirvonen*, H. Komulainen* and K.M. Savolainen. Depts. of Pathology and Industrial Hygiene, University of Kuopio, SF-70210; and Dept. of Hygiene and Toxicology, National Public Health Institute, SF-70700 Kuopio, Finland.

Acute brain cell injury induced by a single dose of malaoxon (26.2 or 39.2 mg/kg i.p.) was studied in the Han/Wistar rat by light and electron microscopy. Astrocytic edema was found in cortical layers 2-3, and hippocampus. The neuronal injury was characterized either by cytoplasmic vacuolation due to enlarged RER cisternae or by cell shrinkage with or without microvacuolation. Cell injury is likely to be epileptic in nature, since the type and distribution of cell injury were similar to those reported in some other models of epilepsy (e.g. Söderfeldt et al., Acta Neuropathol. (Berl), 54: 219, 1981), and definite injury was found only in convulsing animals. Pretreatment with lithium chloride (10 mEq/kg) aggravated both convulsions and cell injury. Parallel experiments suggest that the effects of malaoxon could be mediated by changes in phosphoinositide signalling.

CA3 TO CA1 DELAY REVERSED DURING INTERICTAL TO ICTAL TRANSITION IN 0 Mg^{++} INDUCED ICTAFORM EVENTS IN RAT HIPPOCAMPAL SLICE. L.S. Jones, D.D. Mott* and D.V. Lewis. Dept. of Peds. and Pharm. Duke Univ. Med. Ctr., Durham, NC

It is known that spontaneous interictal epileptiform bursts probably start in CA2-CA3 and spread to CA1 (Wong and Traub, 1983). With ictal activity, however, CA1 may be the primary generator (Traynelis and Dingledine, 1988; Kojima, personal com.). We studied the ictal events produced by removing extracellular Mg^{++} from the perfusate bathing hippocampal slices from adult, male rats. These events are periodic, comprising a preictal build-up of bursting, followed by an ictal event, and a subsequent postictal quiescent phase. Recording from CA1 and CA3, we find preictal bursts occurred first in CA3, but as they became larger and more complex, the CA3-CA1 latency decreased then reversed until CA1 lead by up to 10 msec during the ictal discharges. Also, in stimulus train induced bursting CA1 lead CA3 during electrical afterdischarges following a stimulus train, but CA3 lead CA1 during spontaneous bursts (see figure).

Cl^--DEPENDENT AFTERPOTENTIALS OF EPILEPTIC DISCHARGES IN THE MOTOR CORTEX OF THE RAT. S.Uhlig*, O.W. Witte and E. Valle* (SPON.: EBBS), Neurologische Universitätsklinik, Moorenstr. 5, 4000 Düsseldorf, F.R.Germany

In the present experiments the role of Cl^- currents in generation of afterpotentials of penicillin-induced PDS was further analyzed using intracellular recordings in the motor cortex of anesthetized rats in vivo.

Afterdepolarizations with an average duration (100% to 10% decay time) of 700 ms (fast afterpotentials) could be transformed into afterhyperpolarizations and v.v. by intracellular current injection. Reversal usually occurred between -60 and -70 mV. Intracellular Cl^- injection reversably shifted the inversion potential towards more positive values. It did not affect the slow afterpotentials. The equilibrium potential of the fast afterpotentials also shifted into the positive direction with high intensity stimulation of the brain. The positive shift was already observed following a single stimulus. It increased with repetitive stimulation.

The experiments indicate that Cl^--dependent membrane currents are involved in the generation of the fast afterde- and afterhyperpolarizations and that strong synchronization can lead to significant intracellular Cl^- accumulations.

HYPOXIA-INDUCED ELECTROGRAPHIC SEIZURES IN RAT HIPPOCAMPAL SLICES. K.Kawasaki*, S.F.Traynelis and R.Dingledine (SPON: D.L.McIlwain). Dept. of Pharmacol., Univ. of North Carolina, Chapel Hill, NC 27514.

It has been previously reported that a small proportion of rat hippocampal slices bathed in 8.5 mM $[K^+]_o$ generate spontaneous electrographic seizures. We have found that, in slices not undergoing spontaneous seizures in 8.5 mM K^+, brief periods of hypoxia produced seizures in the CA1 region. Rat hippocampal slices bathed in high K^+ were held in an interface chamber. Hypoxia was induced by changing the overflow gas from 95%O2/5%CO2 to 95%N2/5%CO2 for 5 to 60 sec. In 39% of 176 slices generating interictal bursts in CA3, hypoxia produced seizures in CA1 similar in appearance to spontaneous seizures. The CA3 region appeared considerably more resistant to hypoxia, since only 2% of slices had seizures in CA3. CA3 interictal burst frequency and intensity were not markedly changed before CA1 seizure but were increased during and reduced after seizure. The intensity of hypoxia-induced seizures was decreased by the NMDA receptor antagonist D-APV (30 μM), but not by L-APV. Lowering the temperature from 36-37° to 33-34°C, or cutting the Schaffer collateral input, abolished hypoxia-induced CA1 seizures. Intracellular recordings revealed gradual depolarization of CA1 pyramidal cells preceding seizures. Long-lasting hyperpolarization was also seen after seizures. Hypoxia might decrease uptake of K^+; the resulting acceleration of $[K^+]_o$ accumulation following each incoming interictal could then trigger CA1 seizures.

INVERSE RELATION BETWEEN CA1 EXCITABILITY AND OSMOLALITY IN HIPPOCAMPAL SLICE. B.A. Ballyk and R.D. Andrew. Anatomy Dept., Queen's University, Kingston, Ont. K7L 3N6.

Plasma hyperosmolality draws water from neurons, leading progressively to CNS depression and coma. Similar symptoms result with progressive hyposmolality, but may include increased seizure susceptibility. Using rat hippocampal slices, we examined if CA1 pyramidal cell excitability changed when superfusate osmolality ranged between ± 60 mOsm (normally 290 mOsm). The amplitude of the orthodromic and antidromic population spikes (PS) were inversely related to osmolality: both decreased by ~1% with every mOsm increase (using NaCl or mannitol) and increased by ~1% with each mOsm decrease (using H_2O). The amplitude of the evoked EPSP also decreased with hyperosmolality and increased with hyposmolality, as recorded extra- and intracellularly. Other intracellular parameters (resting potential, input resistance, spike threshold) remained unchanged. The amplitude of the field interictal burst in 0 Mg^{2+} saline was also inversely affected by osmolality. Freely permeable DMSO had no effect at +60 mOsm. These data show that osmolality alters population events but not single neuron properties, probably by changing cell volume and thus ephaptic interactions during synchronous firing. As an example, hyposmotic swelling increases extracellular resistance which increases the field PS and EPSP, possibly making hippocampus more prone to epileptiform activity.

227.12

NEURONAL EXCITABILITY AND OSMOLALITY IN THE RAT NEOCORTICAL SLICE. A.S. Rosen* and R.D. Andrew. Anatomy Dept., Queen's University, Kingston, Ontario, K7L 3N6.

Our hippocampal studies (Ballyk and Andrew, this meeting) prompted an examination of osmolality effects upon neocortical excitability. Plasma osmolality is normally maintained around 287 mOsm and regulated within ±1%. However, clinical disorders can lead to hyperosmolar states (eg diabetes mellitus) or hyposmolar states (eg water intoxication). Clinical manifestations of either state are neurologic, progressing from lethargy to coma. Notably, seizure susceptibility increases in hyposmolar states. We therefore examined neuronal excitability in layers II and III of rat neocortical slices when superfusate osmolality was raised with mannitol or lowered with H_2O. Within a ±60 mOsm range, intracellular recordings (n = 12) displayed little change in resting potential, input resistance, VI relation or spike threshold. However, evoked EPSP amplitude declined 31-66% with increases of +30 to +60 mOsm and increased 25-43% in changes of -30 to -50 mOsm. These effects reversed in normal saline. Orthodromic field potentials were reduced with hyperosmolality and increased with hyposmolality. Thus, the osmolar state affects synchronous population discharge but not single neocortical cell properties. Freely permeant DMSO had no effect at + 60 mOsm. We suggest that cellular swelling augments field interactions and increases evoked EPSPs which may help explain increased seizure susceptibility in hyposmolar states.

227.13

MANGANESE AND EPILEPSY: ROLES FOR BOTH SEIZURES AND GENES IN LOWERED MANGANESE CONCENTRATIONS IN GENETICALLY EPILEPSY PRONE RATS. G.F. Carl,[1,2] J.W. Critchfield,[1] J.L. Thompson[1,2], B.B. Gallagher[3] and C.L. Keen[3]. Dept. Neurol Med. Coll. GA and Med. Res., VA Med. Ctr., Augusta, GA 30910 and Dept. Nutr., U. Cal, Davis, CA 95616.

It has been shown by several investigators that epileptics exhibit lower whole blood concentrations of manganese (Mn) than do controls. One group has suggested that the seizure activity itself is responsible for the depletion. Another group has suggested a possible genetic effect causing lowered blood Mn concentrations. In order to differentiate between these effects we used 14 9 wk old genetically epilepsy prone rats (GEPR-9) and 10, 9 wk old genetically epilepsy resistant rats (GERR) derived from GEPR progenitors. The GEPR-9 animals were divided into two groups of 7 each, and one group was exposed to a 100 decibel sound (ringing bell, 15 sec) twice a day for three weeks producing a 73% seizure rate, while the other group was handled identically but protected from noise. The animals in which seizures were induced consumed more food but gained less weight than either the unexposed GEPR group or the GERR group. Concentrations of Mn were lowered in brain blood and heart of GEPR animals compared to GERR animals while Mn concentrations were lower in blood and liver of seized GEPR animals, compared to unexposed GEPR animals. Therefore, it seems that both seizure activity and genetic difference contribute to the lower Mn concentrations found in genetically epilepsy prone rats.

IONIC CHANGES AND INCREASED MEMBRANE EXCITABILITY FOLLOWING REPLACEMENT OF EXTRACELLULAR Cl^- IN THE RAT HIPPOCAMPUS. J. Louvel*, P. Perreault, C. Drapeau, R. Pumain*, and M. Avoli. (SPON: G. Kostopoulos). MNI, Montreal, Canada and INSERM (U97), Paris, France.

Ion sensitive and intracellular recordigs were performed in the CA1 subfield of the rat hippocampal slice to study the effects evoked by low Cl^- artificial cerebrospinal fluid (ACSF). Measurements performed directly in the ACSF where 95% of Cl^- had been replaced with Methylsulphate or Isethionate revealed marked decreases in the concentration of Na^+ (17 -28%), Ca^{++} (40-50%), K^+ (21-29%) and Mg^{++} (3-15%). Similar changes were observed for $[Ca^{++}]$ and $[K^+]$ when their activity was measured in the extracellular space of the slice during perfusion with low Cl^- ACSF. During such procedure hippocampal pyramidal cells depolarized by 2-7 mV and their input resistance increased by 12-82% (n=8). A 2-6 mV decrease in action potential (AP) threshold and a decrease in AP amplitude were also observed. The repetitive firing evoked by an intracellular depolarizing pulse increased in low Cl^- ACSF, but the subsequent, slow afterhyperpolarization augmented in both duration and amplitude even when the injected current was adjusted to trigger the same number of APs as in control. Our data indicate that cations concentrations decrease in low Cl^- ACSF. These changes might contribute to the increased excitability induced by the low Cl^- ACSF.

227.15

EPILEPTIFORM DISCHARGES INDUCED BY LOW Cl^- ARTIFICIAL CEREBROSPINAL FLUID (ACSF) IN THE RAT HIPPOCAMPAL SLICE. R. Pumain*, C. Drapeau, P. Perreault, J. Louvel* and M. Avoli. (SPON: P. Gloor). MNI, McGill University, Montreal, Que., Canada and INSERM (U97), Paris.

$[K^+]_o$, extracellular and intracellular activities were recorded in the CA1 subfield of hippocampal slices maitained "in vitro" and perfused with ACSF in which 95% of Cl^- had been replaced with Isethionate or Methylsulphate. In this type of medium anti- or orthodromic stimuli evoked synchronous epileptiform bursts sometimes followed by a long-lasting depolarization (up to 15s). The latter was accompanied by an increase in $[K^+]_o$ (up to 11-12 mM) which was maximal at the border between s. pyramidale and s. oriens. NMDA receptors antagonists APV or CPP failed to block these discharges although more current was required to elicit them. Conversely in the presence of bicuculline or picrotoxin the late and long-lasting component of the epileptiform response was blocked and failed to appear even following high intensity stimuli. These data suggest that in the presence of low Cl^- the late component of the epileptiform discharge generated by hippocampal pyramidal cells involves the efflux of Cl^- ions through channels coupled to GABA receptors. Supported by MRC of Canada, FRSQ, INSERM and NATO.

PHARMACOLOGICAL FEATURES OF THE Mg^{++}-FREE EPILEPTIFORM BURSTS IN THE HUMAN NEOCORTEX MAINTAINED "IN VITRO". C. Drapeau, M. Avoli, A. Olivier and J.G. Villemure, MNI, McGill University, Montreal, Que., Canada.

Human tissue was obtained during surgery performed on 16 patients with epilepsy resistant to conventional therapy. Extracellular recordings were performed in slices maintained "in vitro". Spontaneous, synchronous epileptiform bursts were observed within 45-90 min of perfusion with Mg^{++} -free medium. Epileptiform bursts were observed in 60% of the slices studied and occurred at a frequency of .0 9 ± .04Hz, each lasting 4.5±1.9s. The amplitude of the bursts varied according to the position of the electrode in the neocortical layers showing maximum amplitudes in the superficial layers. Bicuculline (50uM) decreased the burst frequency by 37±8% and increased the duration of the burst by 43±28%. The competitive antagonist of NMDA receptors, (1-5 um) CPP reversibly blocked the bursts in a concentration-dependent manner by inducing a gradual increase in the interburst interval. Similar findings were also obtained with the non competitive NMDA antagonist MK-801, although the effects induced by this drug were not reversible. These data further demonstrate that Mg^{++} -free induced bursts in the human tissue are mediated through the activation of NMDA receptors and suggest the presence of active GABAergic mechanisms in this model. Supported by MRC of Canada, FCAR, FRSQ.

KINDLED SEIZURE SUSCEPTIBILITY OF ADULT RABBITS EXPOSED POSTNATALLY TO HYPOXIA. J.A. DeLeo*, C.D. Applegate, A.V. Lorenzo, D.H. Hsi*, J.L. Burchfiel, C.T. Lombroso. Developmental Neurophysiology, Children's Hospital, Harvard Medical School, Boston, MA 02115.

It is suggested that perinatal hypoxia increases the susceptibility to seizures. The effect of postnatal hypoxia on subsequent seizure susceptibility was assessed by amygdaloid kindling in adult rabbits. Rabbits, like humans, are classified as perinatal brain developers. Rabbits from 1 to 44 days were exposed to 100% N_2 for an average of 7 min or until the heart rate was reduced by 70%. Upon removal into room air, they recovered within 1 to 3 min. Non-hypoxic littermates served as controls. At 2 months of age, animals were implanted with bilateral amygdalae electrodes. Control animals required an average of 19 trials to elicit a stage 6 generalized convulsion. By contrast, the experimental animals exhibited significantly advanced motor behavior (average of stage 5) on the first trial. In the experimental group, the behavioral responses were observed at the onset of afterdischarges, indicating a decreased number of stimulations to produce stages of seizures. The duration of afterdischarges on the first trial was longer in experimental animals. These results suggest that exposure to severe, acute hypoxia during postnatal development increases the susceptibility to kindling stimulation. (The Kaplan Foundation, NIH HD 15304, Vallely Family Fund)

227.18

ZERO MG++ INDUCED SEIZURE DISCHARGE IN THE PERIRHINAL-PYRIFORM SLICE PREPARATION. J.R. Plant* and D.C. McIntyre. Dept. of Psychology, Carleton University, Ottawa, Canada, K1S 5B6

Recent in vivo studies have reported a NMDA receptor-dependent epileptogenic effect of magnesium-free (Omg++) perfusate on hippocampal and neocortical slice preparations. Due to the important role NMDA plays in limbic seizures, the present study investigated the effects of Omg++ on spontaneous and evoked activity in coronal slice preparations of the perirhinal-pyriform cortex (CTX) of the rat. Exposure to Omg++ resulted in the gradual ($\bar{x}$ = 12 min) development of ictal discharges which originated in the perirhinal CTX and propagated to the pyriform CTX. Although discharges in the perirhinal CTX usually preceded those in the pyriform CTX ($\bar{x}$ = 21 msec), prolonged exposure to Omg++ resulted in the development of independent discharges in the amygdala-pyriform CTX region. In Omg++, isolated minislices of the perirhinal CTX exhibited characteristic discharge patterns at onset times shorter than those seen in intact coronal sections.

These results suggest an important role for both NMDA receptors and the perirhinal CTX in the development of ictal activity in the amygdala-pyriform CTX region. Difference between kindled and control tissue will be described.

227.19

PERSISTENT SYNAPTIC FAILURE AND NEURONAL DEPOLARIZATION DURING EXPERIMENTAL EPILEPSY. G.B. Watson, R.K. Rader, T.H. Lanthorn. CNS Diseases Research, G.D. Searle, Chesterfield, MO 63198.

Status epilepticus can result in permanent brain damage. We have recently begun to investigate the effects of epileptiform activity in the rat hippocampal slice in low levels of glucose which approximate those occurring during experimental status epilepticus. Low glucose in conjunction with a convulsant results in persistent synaptic failure (PSF), just as low glucose plus hypoxia (experimental ischemia) does (Rader, et al., this meeting). Such models may prove useful in the evaluation of compounds which can prevent brain damage due to status epilepticus and related syndromes. In the zero Mg^{++} model of epileptiform activity, high frequency electrical stimulation (50Hz/5sec) of the Schaffer collateral/commissural fibers can elicit a spreading depression-like event as recorded in CA1. In 10mM glucose, synaptic responses are initially depressed, but recover fairly rapidly following this depolarization. At lower glucose concentrations (2mM), synaptic responses do not recover following high frequency stimulation or following spontaneous depolarizations which occur in 2mM glucose/zero Mg^{++}. Application of the NMDA antagonist CPP (100μM) immediately after the depolarization event has proven effective in reducing PSF, with at least partial recovery seen in all slices tested.

EPILEPSY: SECOND MESSENGERS AND mRNA

228.1

A CALMODULIN ANTAGONIST RETARDS THE DEVELOPMENT OF KINDLING AND REDUCES THE PRODUCTION OF C-FOS PROTEIN FOLLOWING A KINDLING STIMULUS. D.G. Herrera*, M.R. Peterson* and H.A. Robertson. Dept. Pharmacology, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

We have recently shown that kindling stimuli in the rat are accompanied by activation of the proto-oncogene c-fos in the dentate gyrus. This proto-oncogene may be a master-switch, regulating protein production. However, there is only circumstantial evidence suggesting that c-fos is involved in kindling. In cultured cells, the activation of c-fos production is dependent on calcium influx and activation of calmodulin. We therefore studied the effects of the specific calmodulin inhibitor W7 on both kindling and the production of c-fos protein. Here we report that the calmodulin antagonist W7 retards the development of kindled seizures and reduces the production of c-fos protein.

Rats were given saline or W7 (N6-aminohexyl-5-chloronaphtalene-sulphonamide) (15 mg/kg, i.p.) followed by a kindling stimulation through a bipolar electrode implanted in the amygdala. This dose of W7 usually eliminated c-fos protein accumulation in the dentate gyrus. W7 also significantly retarded the development of kindled seizures. These results add to the evidence which suggests that activation of the proto-oncogene c-fos is involved in long-term changes in brain.

LASTING INCREASE IN EXCITATORY AMINO ACID RECEPTOR-MEDIATED POLYPHOSPHOINOSITIDE HYDROLYSIS IN SLICES OF THE AMYGDALA/PYRIFORM CORTEX OF AMYGDALOID AND HIPPOCAMPAL KINDLED RATS. K. Akiyama, N. Yamada* and S. Otsuki*. Dept. of Neuropsychiatry, Okayama Univ. Med. Sch., Okayama 700, JAPAN.

In search of neurobiological alterations underlying lasting seizure susceptibility of kindling, we previously demonstrated that ibotenate (IBO)-stimulated polyphosphoinositide (PPI) hydrolysis increased significantly in the amygdala/pyriform cortex (AM/PC) 7 days after the last seizure in the AM kindled rats (Akiyama et al., Exp Neurol 98:499-508, 1987). The present study examined 1) whether the increase in IBO-stimulated PPI hydrolysis in the AM/PC is more lasting and 2) whether hippocampal (HIPP) kindling elicits similar changes. Electrodes were implanted into either the left AM or the left dorsal HIPP to prepare kindled rats. In the AM-kindled rats, IBO-stimulated accumulation of [^{3}H]inositol 1-phosphate ([^{3}H]IP_1) significantly increased in the AM/PC 1, 2 and 4 weeks after the last seizure. 4 weeks after the last seizure, there was a similar magnitude of significant increase in the contralateral (right) AM/PC and the ipsilateral (left) AM/PC. In the HIPP-kindled rats, IBO-stimulated accumulation of [^{3}H]IP_1 increased significantly in both the AM/PC and HIPP 24 hours, 5 days and 15 days after the last seizure. The remarkable and lasting increase in IBO-stimulated PPI hydrolysis coupled to excitatory amino acid receptors in the AM/PC in the AM and HIPP kindling may be associated with development of kindling and long-term maintenance of kindled events.

SEIZURE-INDUCED ALTERATIONS IN LIPID METABOLISM IN HIPPOCAMPUS AND CEREBRAL CORTEX. D. L. Birkle, P. Kurian*, N. G. Bazan. LSU Eye Center, New Orleans, LA 70112

Alterations in endogenous glycerolipids and free fatty acids (FFA) during electroconvulsive shock (ECS) in hippocampus (HPC) and cerebral cortex (CTX) of Wistar rats and C57BL mice were quantified by analysis of fatty acid methyl esters (FAME). Arachidonic acid (20:4, n-6) turnover in lipid pools were measured using in vivo labeling by intraventricular injection of ^{14}C-20:4. PolyPI of CTX were more highly enriched in 20:4 than HPC polyPI. 30 sec after ECS, FFA in CTX and HPC increased 50%, with major changes in stearic acid (18:0) and 20:4. Diacylglcyerols (DG) accumulated in HPC, with 18:0, 18:1 and 20:4 affected most. There was loss of 20:4 from PIP and PIP_2 in CTX; changes in HPC polyPIs were minimal. Triglycerides (TG) in CTX decreased, particularly polyunsaturated species. There were no alterations in endogenous levels of other glycerolipids, but there was increased ^{14}C-20:4 turnover in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of HPC and CTX. These data indicate major differences between CTX and HPC in lipid responses to stimuli and imply lesser correlation between alterations in polyPI, DG and FFA; thus, other glycerolipids (TG, PC and PE) may contribute to DG accumulation. Also, phospholipase A_2-mediated release of 20:4 from polyPI may account for some polyPI loss and accumulation of free 20:4. These ECS-induced changes in cerebral lipids are not observable in whole cerebrum. (NS23002 and BRSG SO-RR5376).

228.4

PERTURBATION OF HIPPOCAMPAL MEMBRANE-ASSOCIATED ACTIVITY OF PROTEIN KINASE C AND AN INHIBITOR AFTER A GENERALIZED SEIZURE. J.T. Slevin, G.N. Barnes*, and T.C. Vanaman*, Veterans Administration & Univ. of KY Lexington, KY 40536

Brain Protein kinase C (PKC), implicated in long term potentiation and neurosecretion, may play a role in epilepsy. Here we report partial purification of an inhibitory activity of PKC which, in concert with PKC activity associated with hippocampal membranes, changes following administration of electroshock seizures to rats. To separate PKC from the inhibitory activity, particulate and soluble fractions of hippocampi were subjected to DE-52 chromatography. A decrease in membrane-associated PKC activity was seen by four minutes after electroshock with complete return of activity by 10 minutes post-stimulus. No changes were observed in cytosolic activity. PKC inhibitory activity associated with hippocampal membranes demonstrated a parallel time dependent increase with recovery by 10 min while cytosolic activity showed a concomitant loss. This inhibitory activity appears to be a phosphoprotein phosphatase, as judged by sensitivity of the activity to phosphatase inhibitors and ability to release ^{32}[Pi] from histone IIIS. Data suggest that time-dependent changes in the phosphorylation state of PKC substrates in hippocampal neurons may be partially responsible for the post-ictal depression observed in animals, including humans, after a generalized seizure. Supported by the V.A. and NIH grant #5-RO1-NS21868.

228.5

LITHIUM ENHANCES MALAOXON-INDUCED CONVULSIONS BUT ATTENUATES ASSOCIATED INCREASES OF CEREBRAL INOSITOL-1-PHOSPHATE LEVELS IN WISTAR RATS. K.M.Savolainen[1], M.R.Hirvonen[2]*, H.Komulainen[1], L.Paljärvi[3]*, and A.Naukkarinen[3]* (SPON: E.J.Walaszek). [1]Natl. Public Hlth Inst., Dept. Environm. Hyg. & Tox., SF-70700 Kuopio, [2]Dept. Industr. Hyg., and [3]Dept. of Pathology, University of Kuopio, SF-70210 Kuopio, FINLAND.

The potential of a single dose of malaoxon (26.2 or 39.2 mg/kg i.p.) to induce epileptic convulsions and to stimulate the hydrolysis of cerebral phosphoinositides (PI's), as assessed by brain regional inositol-1-phosphate (Ins1P) levels was studied in Han/Wistar rats 24 h after saline or LiCl (10 mEq/kg i.p.) pretreatment. Rats were observed for 1, 4 or 72 h, and then the brains were analyzed for regional Ins1P levels by GLC. Malaoxon induced convulsions at the higher dose only. It dose-dependently elevated Ins1P levels in nonconvulsing rats with a marked persistent additional increase of brain Ins1P during convulsions. LiCl significantly increased the potential of malaoxon to induce convulsions but it attenuated brain Ins1P elevations after malaoxon; the temporal patterns of Ins1P increases after malaoxon were the same with both pretreatments. These results suggest that, in this rat strain, lithium inhibits brain inositolpolyphosphate phosphatases decreasing the accumulation of Ins1P under malaoxon-induced stimulation of the brain (see Majerus et al., J. Biol. Chem., 263:3051, 1988).

MAINTENANCE BUT NOT INITIATION OF STIMULUS TRAIN INDUCED BURSTING (STIB) IS IMPAIRED BY PROTEIN SYNTHESIS INHIBITORS (PSIs). D.V. Lewis, L.S. Jones, and D. Lapadula. Dept of Pharm. and Peds., Duke Univ. Med. Ctr. Durham, NC 27710

We have been examining the effect of PSIs on the STIB model of epileptogenesis. 625 u hippocampal slices from adult, male rats were prepared in the normal manner. When a slice was stable, a PSI was bathed on for 30 min (cycloheximide 35 uM, emetine 15 uM, puromycin 25 uM, anisomycin 50 uM; protein synthesis inhibiton 80% or greater). Then, up to 10 stimulus trains were presented, one every five min, until there were afterdischarges following a stimulus train, and spontaneous bursts between trains. There were no statistically significant differences between the number of trains necessary to elicit afterdischarges in control and PSI-treated slices. Both emetine and puromycin slightly delayed the onset of spontaneous bursts, but the other PSIs were not different from controls. These data indicate that the development of bursts produced by STIB does not depend on protein synthesis. However, in slices that were continuously bathed in either cycloheximide or anisomycin for a further 5 hours following the induction of bursting, there was a more rapid and pronounced decay in the frequency of bursting, suggesting that the protein synthesis inhibitors are interfering with the maintenance of the bursting in CA3 and CA1 in some manner.

DEFICIENT ATP HYDROLYSIS AS A MECHANISM OF EPILEPSY IN SEIZURE PRONE MICE. T. N. Seyfried and A. Wieraszko. Dept of Biology, Boston College, Chestnut Hill, MA 02167.

Inbred DBA/2 (D2) mice have an inherited susceptibility to audiogenic seizures (AGS), whereas inbred C57BL/6 (B6) mice are resistent to these seizures. AGS susceptibility is genetically associated with a deficiency of the ecto-Ca^{2+}-ATPase activity in the brain stem of B6 x D2 recombinant inbred strains and in F_1 hybrids from various strain crosses. Recent studies indicate that ATP, which has potent membrane depolarizing action, is co-released with different neurotransmitters into the neuronal synaptic cleft. The ecto-ATPase may function to terminate the action of ATP on the cell surface and to generate the energy needed for modulating the mechanisms of neural transmission. Moreover, the rapid hydrolysis of ATP will lead to the formation of adenosine (an endogenous anticonvulsant). We propose that the intense, seizure evoking auditory stimulation of D2 mice causes an immediate release of ATP which overwhelms the hydrolyzing capacity of the deficient ecto-Ca^{2+}-ATPase activity. This will cause a persistence of ATP action and will retard the accumulation of adenosine. A failure to quickly hydrolyze the released ATP could sustain membrane depolarization, disrupt neural modulation, and cause an avalanche of convulsive activity. The ecto-Ca^{2+}-ATPase is apparently critical only under intense auditory stimulation since D2 mice are phenotypically normal and do not seize spontaneously under normal physiological conditions. Supported by grants from the NIH (23355 and 2486) and NSF (BNS 8644955).

ANALYSIS OF NEUROTRANSMITTER mRNAS AFTER AMYGDALOID KINDLING OF RATS. H. Shinoda*, J.P. Schwartz and N.S.Nadi (SPON: P.H. Sheridan). CNB and MNB, NINCDS, NIH, Bethesda MD 20892

Changes in neurotransmitter content have been examined extensively in kindled animals. There are several reports of increases of somatostatin (SS), whereas results for GABAergic activity have been mixed. In this study, we have measured the levels of SS, proenkephalin (PE), and glutamic acid decarboxylase (GAD) mRNAs in various brain regions of kindled rats, as well as levels of SS and GAD. Rats were sacrificed 2 weeks after Stage V kindling had been established. Neither GAD mRNA content nor GAD enzyme activity changed in any brain region in the kindled rats. The SS content increased in cortex and striatum, as well as in hippocampus, of kindled rats relative to controls, whereas SS mRNA increased only in cortex and striatum. PE mRNA increased only in amygdala. Although no increase in PE mRNA was observed in hippocampus when analyzed by slot-blot hybridization, in situ hybridization demonstrated an increase in PE mRNA specific to hippocampal granule cells. None of these changes are seen in naive rats receiving only a single stimulus, demonstrating that the responses represent changes occurring at the final stage (Stage V) of kindling. Whether these increases in somatostatin and enkephalin play a causative role or are only secondary to the kindling process is under investigation.

KINDLED SEIZURES DECREASE BRAIN REGIONAL ACTIVITY OF A NAAG-HYDROLYZING ENZYME. J.L. Meyerhoff, M.B. Robinson, M.A. Bixler, S.S. Richards, R.A. Lyn* and J.T. Coyle. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307 and Dept. of Psychiatry, Johns Hopkins University, Baltimore, MD 21205.

N-Acetylated-α-linked acidic dipeptidase (NAALADase) is a Cl^- dependent, membrane-bound peptidase that hydrolyses the endogenous neuropeptide N-acetyl-L-aspartyl-L-glutamate (NAAG), a putative excitatory neurotransmitter. NAALADase cleaves NAAG into glutamate and N-acetyl-aspartate. We previously showed that kindled seizures increase NAAG levels in entorhinal cortex. The present study examined the effect of seizures on regional brain levels of NAALADase. Rats were subjected to daily amygdaloid-kindling electrical stimulation, or non-kindling cortical suprathreshold stimulation (STS), and killed 48 hours after the last of a series of 5 generalized convulsions. Brains were dissected, tissues were coded and then assayed in a blinded fashion. Compared to sham-operated controls, NAALADase activity was decreased in the amygdala, entorhinal cortex, pyriform cortex and hippocampus after kindled seizures. STS-induced convulsions also decreased NAALADase activity in the first 3 regions, but not the hippocampus. Activity was unaffected in the substantia nigra by either type of convulsion. Statistical analysis was by ANOVA ($p<0.01$), followed by a Newman-Keuls test ($p<0.05$).

228.10

ANALYSIS OF HIGH AND LOW AFFINITY OUABAIN BINDING SITES OF THE NA,K-ATPASE IN CEREBRAL CORTEX USING QUANTITATIVE AUTORADIOGRAPHY. M.C. Antonelli*, P.E. Filuk* and W.L. Stahl. VA Medical Center and University of Washington Sch. of Med., Seattle, WA 98108.

Isoforms of the Na,K-ATPase bind ouabain with high and low affinities and have been studied in cerebral cortex of rabbit and monkey brains. In rabbit brain, microsomal membranes were studied by a conventional filtration assay and brain slices were examined by quantitative autoradiography (QAR). Kd values of 11-12 mM for specific high affinity of [^{3}H]ouabain were found by both methods. High affinity [^{3}H]ouabain binding in tissue sections was stimulated by the ligands Mg^{2+}/Pi or Mg^{2+}/ATP/Na^+ and this binding was inhibited by K^+ (IC_{50} = 1 mM), thimerosal (IC_{50} = 0.16 mM) and the neurotoxin erythrosine B (IC_{50} = 0.01 mM). In the presence of erythrosine B, specific low affinity sites were found with a Kd = 1 μM. Specific low affinity sites accounted for approximately one-half of the total binding sites in rabbit cerebral cortex. Ouabain binding was examined in control and epileptic foci from monkeys lesioned with alumina. Specific high affinity ouabain binding was decreased 50% in the focus, which is consistent with the lower Na,K-ATPase activity previously found in the focus and supports the view that the total number of Na,K-ATPase molecules is decreased (Supported by the Veterans Administration and NIH grant NS 20482; M.C.A. was supported by a fellowship from CONICET, Argentina).

228.11

INCREASE OF KAINIC ACID BINDING SITES IN THE HIPPOCAMPUS OF EPILEPTIC INFANTS AND KINDLED RATS. A. Represa,* O. Robain,* E. Tremblay* and Y. Ben-Ari (Spon G. Barbin). INSERM U-29. 123 Bd Port-Royal. Paris 14. FRANCE.

In infants epileptics a highly significant increase of KA binding sites has been observed in the terminal field of the mossy fibers (stratum lucidum of CA3). The density was 42.6 ± 23 and 122 ± 24 f mol/mg tissue) in aged matched controls (n = 8) and epileptics (n = 5) respectively. This increase of labelling was apparently not associated to an aberrant mossy fiber sprouting indicating that it may be due to a change in the synthesis, or affinity of KA receptors.

In rats which had been kindled, aberrant kainic acid binding sites were found in the supragranular region and in the inferior region of CA3. These binding sites are associated with Timm deposits suggesting a sprouting of mossy fibers : a similar sprouting occurs also after seizures induced by kainate (A. Represa et al. Neurosci. 1987).

We conclude that in both human and rats, epilepsy is associated with an enhancement of kainate binding in the hippocampus. Since KA increased neuronal excitability the rise of KA binding observedin both, infant epileptics and kindled rats would compromisethe hippocampal function and facilitate seizure activity.

228.12

KINDLING STIMULATION INDUCES C-FOS M-RNA EXPRESSION IN RAT HIPPOCAMPUS. C. Shin, D.R. Cohen*, L.S. Butler*, and J.O. McNamara. Duke Univ. & VA Med. Ctr., Durham, NC 27705, and Roche Inst. of Mol. Biol., Nutley, NJ 07110

Periodic induction of focal electrical seizure (Afterdischarge [AD]) is an absolute prerequisite for kindling to occur. The molecular mechanism by which periodic ADs lasting tens of seconds result in lifelong kindling effect is unclear. One possibility is that ADs activate transcription of an "early gene" which in turn regulates expression of a host of target genes, the net effect being the kindled state. We determined whether a single kindling stimulation to a naive animal activated c-fos transcription, since PTZ seizures rapidly induced c-fos expression (Morgan et al,1987).

ADs were recorded in both hippocampi (HPCs) of adult male rats stimualted in the angular bundle with 2 sec train of 200 μA 60 Hz biphasic pulses. HPCs were rapidly removed 30 min later. Total RNA was isolated and electrophoresed (3 μg/HPC). Northern blot was hybridized with 32P-labeled cDNA probe to detect c-fos mRNA by autoradiography.

Unstimulated controls had minimal c-fos expression (OD=.009 ±.004; n=8). All 7 stimulated rats exhibited a dramatic induction of c-fos mRNA in HPC ipsilateral to stimulation (OD=.89 ± .03; n=7), and, in 5 of 7, in contralateral HPC (OD=.88±.04; n=5).

Thus a single kindling stimulation induced marked c-fos mRNA expression in HPC. This may lead to increased translation of c-fos protein (Dragunow & Robertson, 1987), and be a pivotal event in the presumed cascade of molecular mechanisms underlying the development of kindling.

RECEPTOR MODULATION AND REGULATION II

229.1

CHRONIC ADMINISTRATION OF BETA-ADRENERGIC AND SEROTONERGIC AGENTS ALTERS SEROTONIN TYPE 2-MEDIATED BEHAVIOR IN THE RAT. A.S. Eison, F.D. Yocca and G. Gianutsos. Section of Pharmacology and Toxicology, School of Pharmacy, Univ. of Connecticut, Storrs, CT 06268 and CNS Research, Bristol-Myers Co., Wallingford, CT 06492-7660.

Noradrenergic (NE) and serotonergic (5-HT) transmission may alter the functional sensitivity of serotonin type 2 ($5\text{-}HT_2$) receptors. We have examined the effects of chronic (14 day) administration of the beta antagonist propranolol and the beta agonist clenbuterol on the quipazine-induced head shake response and cortical beta and $5\text{-}HT_2$ receptor number. Chronic treatment with propranolol resulted in a 44% up-regulation of beta receptors and a potentiation of the head shake response. Chronic treatment with clenbuterol resulted in a marked reduction in head shakes with a concomitant 29% down-regulation of beta receptors. $5\text{-}HT_2$ receptor binding was not modified by propranolol or clenbuterol treatments. We have examined the head shake response following chronic administration of $5\text{-}HT_2$ agonists, antagonists, or imipramine, to naive rats and rats which sustained NE or 5-HT lesions (depletions > 90%). The ability of chronic $5\text{-}HT_2$ agents to produce $5\text{-}HT_2$-mediated behavioral subsensitivity was not altered by 5-HT or NE denervation. Imipramine-induced reductions in behavior were significantly attenuated by serotonin lesions. Saturation binding parameters for beta and $5\text{-}HT_2$ receptors will also be presented.

229.2

(±)-DOI, A HALLUCINOGENIC PHENYLALKYLAMINE, DOWN-REGULATES $5HT_2$ RECEPTORS IN RAT CORTEX A. Himeno,* D. J. McKenna, A. J. Nazarali,* and J. M. Saavedra (SPON:J. S. Gutkind) Section on Preclinical Neuropharmacology, LCS, NIMH, Bethesda, MD 20892

(±)-DOI, an iodinated analog of the hallucinogen DOM, is a $5HT_2$-selective serotonin agonist. We examined the effects of chronic administration of DOI (1 mg/kg) on binding of $5HT_2$ selective ligands in rat cortex. Ligands and concentrations used were: [^{125}I]-R-DOI (0.5 and 5 nM), [^{125}I]LSD (1 nM), and [^{3}H]ketanserin (1 nM). Membrane suspensions from treated and saline-injected control rats were pre-incubated for 10 or 60 min at 37 °C prior to use in the assay. In treated animals specific binding of all 3 ligands was significantly reduced in both the 10 and 60 min preparations. Saturation studies with [^{125}I]DOI and [^{3}H]ketanserin were conducted in controls and treated animals. In treated animals, the Bmax for [^{3}H]ketanserin was less than controls, but the Kd was similar to controls. The Kd for [^{125}I]DOI in treated animals was higher than controls, but the Bmax was similar. These results may help to clarify regulatory mechanisms governing $5HT_2$ receptors.

229.3

M-CHLOROPHENYLPIPERAZINE-INDUCED INCREASES IN PLASMA PROLACTIN AND CORTICOSTERONE AND DECREASES IN FOOD INTAKE ARE DIFFERENTIALLY ALTERED BY CLOMIPRAMINE TREATMENT IN RATS. K.M. Wozniak,* C.S. Aulakh,* J.L. Hill,* and D.L. Murphy* (SPON: C.R. Lake). LCS, NIMH and LCS, NIAAA, Bethesda, MD 20892.

The purpose of the present study was to use m-chlorophenylpiperazine (m-CPP, a 5HT agonist) as a challenge agent to explore functional adaptational changes in serotonergic mechanisms regulating prolactin and corticosterone secretion and food intake following long-term clomipramine (a tricyclic antidepressant) treatment in rats. Clomipramine (5 mg/kg/day) or saline was administered subcutaneously to male Wistar rats by means of osmotic minipumps. Both clomipramine and saline-treated animals were challenged with m-CPP (1.25 and 2.5 mg/kg) during short-term (3-5 day) and long-term (21-23 day) antidepressant treatment.

Administration of m-CPP to rats produced increases in plasma prolactin (peak effect at 15 min) and corticosterone (peak effect at 15-30 min) concentrations and decreases in food intake. Long-term but not short-term clomipramine treatment potentiated m-CPP's effect on prolactin levels whereas both short-term and long-term clomipramine treatment significantly attenuated m-CPP's effect on corticosterone levels. On the other hand, neither short-term nor long-term clomipramine treatment had any significant effect on m-CPP-induced decreases in food intake. These findings are consistent with other clinical and animal studies demonstrating a differential effect of antidepressant treatment on different 5HT-mediated neuroendocrine and behavioral functions.

229.4

DIFFERENTIAL EFFECTS OF ANTIDEPRESSANT TREATMENTS ON 5HT AGONIST-INDUCED INCREASES IN PLASMA PROLACTIN AND CORTICOSTERONE IN RATS. C.S. Aulakh,* K.M. Wozniak,* J.L. Hill,* and D.L. Murphy* (SPON: N.A. Garrick). LCS, NIMH and LCS, NIAAA, Bethesda, MD 20892.

The purpose of the present study was to use fenfluramine (a 5HT-releasing agent) and 8-hydroxy-2(di-n-propylamino) tetralin (8-OHDPAT, a selective $5HT_{1A}$ agonist) as challenge agents to explore functional adaptational changes in serotonergic neurotransmission involved in the secretion of prolactin and corticosterone following long-term treatment with imipramine, clomipramine (tricyclic antidepressants), clorgyline (a selective MAO type A inhibiting antidepressant), and lithium in male Wistar rats. Imipramine (5 mg/kg/day), clomipramine (5 mg/kg/day), clorgyline (1 mg/kg/day), or saline was subcutaneously administered continuously by means of osmotic minipumps. In case of lithium, the animals were given rat chow containing lithium carbonate.

Short-term treatment with lithium but not clorgyline or imipramine potentiated fenfluramine-induced increases in plasma prolactin but not corticosterone. Long-term treatment with clorgyline but not other antidepressants attenuated fenfluramine and 8-OHDPAT-induced increases in plasma prolactin but not corticosterone. Similarly, long-term treatment with clomipramine and to some extent imipramine also, accentuated 8-OHDPAT's effect on plasma prolactin but not on corticosterone. These findings are consistent with several other clinical and animal studies demonstrating dissimilar actions of different antidepressant treatments on two different 5HT-mediated neuroendocrine functions.

229.5

DOWN-REGULATION OF 5-HT_2 RECEPTORS IN RAT CORTEX AND ON PLATELETS BY ANTIDEPRESSANTS. C. Brazell*, S. McClue*, F. Brush* and S. Stahl. Merck Sharp & Dohme Research Labs., Terlings Park, Harlow, Essex, U.K.

The 5-HT receptor on platelet membranes may be analogous to the 5-HT_2 receptor in the CNS. If this analogy is functional then the down-regulation of central 5-HT_2 receptors by antidepressants may be paralleled by the platelet 5-HT receptor. We have tested this hypothesis by 21 day administration of desipramine and amitriptyline (15 mg/kg, i.p., daily) to rats. This is the first report of the use of [^{125}I]-ILSD to determine 5-HT_2 receptors on rat platelets.

Washed platelet and cortical membranes were incubated with [^{125}I]-ILSD (0.1-6 nM, 30 min, 37°C). Ketanserin (10 μM) defined non specific binding. Specific binding of [^{125}I]-ILSD to platelets identified a single receptor site. Competition binding studies confirmed that the ligand labelled a site characteristic of the 5-HT_2 receptor. Binding parameters (% reduction from controls) were:

Treatment (n = 4-7)	Platelet (K_D 1.2 ± 0.4 nM) B_{max} (fmol/mg protein)	Brain (K_D 1.1 ± 0.1 nM) B_{max} (fmol/mg protein)
Control	83.0 ± 24.7	96.6 ± 26.2
Desipramine	66.7 ± 23.7 (-9.3%)*	63.6 ± 14.9 (-22.4%)*
Amitriptyline	51.8 ± 9.7 (-37.7%)*	67.9 ± 26.0 (-31.1%)*

Values expressed as mean ± S.E.M. where *p < 0.05 Student's t-test. Results confirm previous reports that antidepressants can decrease the number of 5-HT_2 receptors in the rat cortex and suggest a similar modulation in the platelet. Thus the platelet 5-HT_2 receptor may be a dynamic model for the 5-HT_2 receptor of the CNS.

229.6

ENHANCED COUPLING OF G PROTEINS TO ADENYLATE CYCLASE SUBSEQUENT TO CHRONIC ANTIDEPRESSANT TREATMENT. Hiroki Ozawa and Mark M. Rasenick. Dept. of Physiology and Biophysics and the Committee on Neuroscience, Univ. of Illinois College of Medicine, Chicago, IL 60680.

Previous studies from this and other laboratories have demonstrated that chronic treatment with tricyclic antidepressants (TAD) or electroconvulsive shock augments adenylate cyclase in rat cerebral cortex synaptic membranes. It appeared in these previous studies that the coupling of G proteins to adenylate cyclase was involved in the effects of antidepressant treatment, but the nature of those effects was not established. Thus, rats were injected (IP) once daily for 21 days with 10 mg/kg of amitryptilline, imipramine or iprindol. Controls included 20 days of saline followed by a single drug injection (acute) or 21 days of saline. In animals from the chronic treatment group, activation of adenylate cyclase by GppNHp or NaF was 71.4-78.1% greater than observed in acute or saline injected animals. When membranes were assayed under conditions where the predominant effect of GppNHp on adenylate cyclase was inhibitory, basal adenylate cyclase activity was 83.5% greater in membranes from the chronic TAD treated animals, but the inhibition induced by GppNHp (as percent of basal activity) was not different in any of the groups (61.1-67.3%). The potency of GppNHp to stimulate or inhibit adenylate cyclase was not altered by antidepressant treatment. Further, the maximal binding of the photoaffinity GTP analog, azidoanilido GTP by synaptic membrane G proteins was not altered. These results are consistent with the hypothesis that chronic antidepressant treatment augments coupling between Gs and the catalytic unit of adenylate cyclase.

229.7

ALTERATIONS IN RECEPTOR BINDING IN THE RAT CNS FOLLOWING CHRONIC TREATMENT WITH TWO NEWER NON-TRICYCLIC ANTIDEPRESSANTS, CLOVAXAMINE AND FLUVOXAMINE. D.B. Vine*, M.F. Madar*, and J.K. Wamsley. (SPON: S.S. Stensaas) Depts of Psych and Pharm, U of UT Sch of Med, SLC, UT 84132.

Since the pharmacologic treatment of depression in humans has been shown, in general, to be efficacious only after the chronic administration of antipressant drugs, neurotransmitter receptor change has continued to be a prominent hypothesis for their mechanism of action. In the present study we have analysed several biochemical changes in the rat CNS following chronic treatment with two 5HT uptake inhibitors. Quantitative receptor autoradiography, using selective ligands for $5HT_2$, 5HT, α_2, β_1, and β_2 adrenergic receptors, has enabled us to determine which receptors and receptor subtypes have been altered following chronic treatment with these two antidepressants. Using [^{3}H]forskolin, adenylate cyclase receptor changes were not significantly different between control and treated animals. Previous reports of in vitro and in vivo studies of decreased α_2 adrenoreceptor mediated inhibition of cAMP production following exposure to imipramine, together with our findings suggest an uncoupling of these receptors without a change in receptor density. Quantitation of the α_2 adrenoreceptors, using [^{3}H]idazoxan, also supports this finding. [^{3}H]dihydroalprenolol and [^{3}H]5HT binding data correspond to the hypothesis of postsynaptic receptor down regulation following chronic treatment with antidepressants.

229.8

INCREASED SEROTONIN$_2$ (5-HT_2) BINDING IN THE BLOOD PLATELETS OF DEPRESSED PATIENTS. R.C. Arora and H.Y. Meltzer, Department of Psychiatry, Case Western Reserve University School of Medicine, 2040 Abington Road, Cleveland, OH 44106.

The role of serotonin (5-HT) in depression has been extensively studied by examining various serotonergic parameters in the blood platelets. We have now studied 5-HT_2 binding in the blood platelets of 29 drug-free, non-psychotic depressed patients and 13 normal controls.

5-HT_2 binding in platelet membranes was determined using ^{3}H-LSD as ligand following the modified method of Geaney et al. (1984). Analysis of covariance (ANCOVA) with group, sex and group x sex interaction as factors indicated a significant difference in B_{max} ($F=10.12$; $df=1,38$; $p=0.0029$) between normals and depressed patients; B_{max} was significantly higher in depressed patients compared to normal controls. There was a trend for group x sex interaction but no sex effect on B_{max}. Female and male depressed patients had 102% and 24% greater B_{max} than normal females and males, respectively. There was no significant difference in K_d between the two groups. There were no correlations between K_d and B_{max} of ^{3}H-LSD binding and admission total Hamilton Depression scale or SADS-C Depression scale score.

If the increased 5-HT_2 binding is confirmed for depressed patients and proves specific, it could serve as a biological marker for depression. Increased 5-HT_2 sites have also been found in suicide brains by us and others.

229.9

MODULATION BY SALTS OF BINDING AFFINITIES AND CAPACITIES AT μ-, δ- and κ-OPIOID BINDING SITES IN GUINEA-PIG BRAIN. L.E. Robson*, S.J. Paterson* and H.W. Kosterlitz. Unit for Research on Addictive Drugs, University of Aberdeen, Marischal College, Aberdeen, AB9 1AS, U.K.

The effects of salts on the saturable binding of [^{3}H]-[D-Ala^2,MePhe^4,Gly-ol^5]enkephalin at the μ-site, of [^{3}H]-[D-Pen^2,D-Pen^5]enkephalin at the δ-site and of [^{3}H]-U-69,593 at the κ-site have been investigated in homogenates of guinea-pig brain (10 mg tissue/ml in 10 mM HEPES-KOH, pH 7.4 at 25°C). At the δ-site NaCl (50 mM) reduces binding affinity 1.7-fold but does not alter binding capacity. In contrast, at the μ-site NaCl (50 mM) reduces binding affinity 3.5-fold and also decreases the binding capacity by 25%. In further contrast, at the κ-site of whole brain NaCl (200 mM), which reduces binding affinity 5.5-fold, increases the binding capacity 2-fold. However at the κ-sites of guinea-pig cerebellum, the effect of NaCl (200 mM) is solely inhibitory; a 5-fold decrease in binding affinity is accompanied by a 40% decrease rather than increase in binding capacity. Thus the kinetic basis of the effects of salts on opioid binding may be different at each site and may be different in brain regions.

229.10

PHYSIOLOGICAL CORRELATE TO MU OPIOID RECEPTOR UP-REGULATION IN THE HIPPOCAMPUS. A.M. Moudy and M.B. Laskowski. Dept. Physiology, St. Louis U. Med. Sch., St. Louis, MO 63104.

Opioid receptor upregulation has been examined biochemically as well as behaviorally. The functional significance of an increased number of opioid receptors remains largely uncharacterized. To demonstrate a direct physiological correlate to such upregulation, a biochemical and electrophysiological approach was taken, utilizing the in vitro hippocampal slice preparation as a model system. Hippocampal membranes were prepared from rats treated for 7 (or 14) days with naltrexone (20 mg/ml) or saline. Homologous displacement of [^{3}H]DAGO binding determined that upregulation of mu receptors occurs in the hippocampus (71%) to a degree similar to that measured in whole forebrain (77%, Moudy et al., 1985). D-Ala^2, MePhe^4, Gly-ol^5 enkephalin (DAGO) is a peptide ligand highly specific to mu opioid receptors. Hippocampal slices were prepared from naltrexone treated rats. When superfused with DAGO, population spike output to the same EPSP input increased by 42% in CA1. Slices from animals treated for 14 days showed an additional increase in excitability. These results indicate that the effect of DAGO on pyramidal cell excitability was potentiated in hippocampi from animals exposed chronically to antagonist. Moreover, they demonstrate a significant physiological correlate of opioid receptor upregulation.

229.11

IN VITRO AGONIST-INDUCED DOWN-REGULATION OF HYPOTHALAMIC μ-OPIOID RECEPTORS. M. MacDonald* and M. Wilkinson. (SPON: R.E. Brown) Physiol. & Biophys., Dalhousie U., Halifax, Canada B3H 4H7

Studies of the down regulation of opioid receptors *in vitro* has been largely restricted to delta receptor agonists in neurotumor cell lines. Similar investigations of μ-receptor regulation have been contradictory. Here we examine the effect of DAGO, a specific μ-agonist, on μ-opioid receptors in hypothalamic tissue punches as a procedure for studying the possible down regulation of μ-receptors *in vitro*. Hypothalamic punches (1.8mm diam. from 350μm slices; McIlwain) from adult female rats were preincubated in PBS buffer for 30 min. at 37°C, washed and then re-incubated (30 min. at 37°C) in PBS buffer with or without DAGO (10^{-6}M). Tissue was then washed 3 times (5 min./wash) in ice-cold TRIS(170 mM, pH 7.4). Cell surface μ-opioid receptors were subsequently quantified with [^{3}H] DAGO, without homogenization, using a method described previously (Neuropeptides 9 357,1987; [^{3}H] DAGO concentration: 0.5-2.0 nm). When the receptors were assayed at 0°C (3hr), B_{max} was markedly reduced in DAGO-treated tissue (control: 29.6±2.7 fmoles/mg; treated: 12.5±4.4 fmoles/mg). Binding affinity (K_d) was unaffected by DAGO treatment (1.7±0.2 nm vs 1.9±0.4 nm). This implies that the reduction in B_{max} is likely not due to residually bound DAGO. This was confirmed in separate experiments by performing the binding assays at 25°C (2 hrs), conditions under which unlabelled DAGO is unlikely to remain bound to the receptor. Once again B_{max} was reduced(61.6±12.0 to 25.5±8.0 fmoles/mg) and K_d remained unchanged (2.6±0.7 nm vs 2.1±0.6 nm). Similar observations were obtained using cerebral cortex. Our results suggest that the brain slice/punch preparation may be a simple but effective technique with which to examine opioid receptor regulation.

Supported by the Canadian MRC.

ACTIVATION OF PROTEIN KINASE C IN THE PRESENCE OF OPIOID AGONISTS DOWNREGULATES δ-RECEPTORS IN NG108-15 CELLS. S. Gucker and J.M. Bidlack. Dept. of Pharmacol., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY, 14642.

Phorbol 12-myristate 13-acetate (PMA), a potent activator of protein kinase C (PKC) was tested for its ability to regulate the number of opioid binding sites in NG108-15 cells. PMA and opioids were cultured with NG108-15 cells for 2 hr at 37° before preparing membranes from the cells, and subsequent measurement of [^{3}H] [D-Ala^2, D-Leu^5] enkephalin (DADLE) binding to the membranes. Treatment of cells with PMA concentrations up to 1 μM had no effect on the binding of [^{3}H]DADLE to NG108-15 membranes. However, when cells were cultured with PMA with 10 nM etorphine, a decrease in the number of [^{3}H]DADLE binding sites occurred without changing the affinity of the remaining sites. Controls consisted of culturing the cells with 10 nM etorphine alone. The loss of [^{3}H]DADLE binding sites was dependent on the PMA concentration with an IC_{50} value of 11 nM and 30 nM PMA producing a maximal inhibition of 40%. When naloxone was added at a 100-fold greater concentration than etorphine, the PMA-induced decrease in the number of binding sites was abolished. Replacing PMA with up to 1 μM 4α-phorbol, a phorbol ester that does not activate PKC, had no effect on [^{3}H]DADLE binding to cell membranes. Studies are underway to delineate the nature of PMA's effect on etorphine downregulation of δ-receptors, a receptor reportedly not linked to phosphatidylinositol turnover and hence PKC activation in NG108-15 cells. (Supported by USPHS grant DA03742 and DA07232.)

229.13

DOSE-DEPENDENCY OF DESENSITIZATION FOLLOWING CHRONIC MORPHINE EXPOSURE ON THE 7315c PITUITARY CELLS. P.S.Puttfarcken and B.M.Cox. Dept. of Pharm., USUHS, Beth., MD 20814

The 7315c pituitary tumor cells contain a homogenous population of μ opioid receptors and opiate activation of these receptors results in inhibition of adenylyl cyclase (AC) activity. Previous studies have demonstrated 100 μM morphine chronic exposure on 7315c pituitary tumor cells resulted in two time-dependent cellular adaptive processes. Desensitization (the loss in the ability of the opioid agonist, D-Ala-D-Leu-Enkephalin (DADLE), to inhibit AC activity) occurred after 5 hours of 100 μM morphine exposure while receptor number was unchanged. Membranes from cells incubated in a drug-free medium did not lose sensitivity to DADLE. Binding studies revealed down-regulation. After 48 hours of 100 μM morphine exposure, a 60% decrease in receptor density was observed. In studies designed to examine the concentration of morphine needed to observe desensitization and down-regulation the ability of the μ-selective agonist Tyr-D-Ala-Gly-N(Me)Phe-Gly-ol (DAGO), to inhibit AC activity in membranes from cells exposed to morphine concentrations from 10 nM to 300 μM for 5 hours and 48 hours was examined. DAGO no longer inhibited AC activity in a dose-dependent manner after 5 and 48 hours of 100 nM morphine exposure. Inhibition of AC by DAGO in membranes from control cells and cells treated with 10 nM morphine for 5 and 48 hours did not differ significantly. Binding studies are in progress to determine at what morphine concentration down-regulation occurs.

ENDOGENOUS OPIOID SYSTEMS AND NEURAL CANCER: SCANNING AND TRANSMISSION ELECTRON MICROSCOPIC OBSERVATIONS. J. Conforti*, P.J. McLaughlin and I.S. Zagon (SPON: T. Lloyd). Dept. Anat., The Penn. State Univ. College of Medicine, Hershey, PA 17033.

Endogenous opioid systems (i.e., opioids and receptors) participate in regulating cancers of the nervous system. Paradigms using opioid agonists and antagonists have been effective in revealing the antitumor function of opioid agonist peptides. To study the influence of opioids on neural cancer, S20Y neuroblastoma cells grown in tissue culture were exposed to (a) methionine enkephalin (ME), a potent growth inhibitory opioid peptide, (b) ME and naloxone, which reverses opioid action, or (c) naltrexone, an extremely potent opioid antagonist which stimulates tumor cell growth. Scanning and transmission electron microscopic studies performed on cultures exposed to opioid agonists/antagonists showed no changes in morphology in comparison to control cultures. These results (a) support the hypothesis that endogenous opioid systems act as trophic factors in regulating growth, (b) reveal that opioid effects on cell growth and survival do not alter the structural biology of cells and (c) strengthen the validity of utilizing opioid agonists and antagonists in exploring the relationship of endogenous opioids and opioid receptor interactions in neural cancer. Supported by NIH grants NS-20623 and NS-20500.

RETINOTOPIC CLUSTERING IN A LOW DENSITY TECTAL PROJECTION IN GOLDFISH: EVIDENCE AGAINST ACTIVITY DEPENDENT COMPETITION. M.D. Olson and R.L. Meyer, Developmental and Cell Biology, Developmental Biology Center, University of California, Irvine, California 92717

When the optic nerve of a goldfish is severed, regenerating fibers from one small retinal region aggregate into several small clusters as revealed by spot injections of WGA-HRP into the retina. This clustering is inhibited by impulse blockade. Since the number of synapses is regulated during regeneration, this clustering may represent an activity-dependent competition for limited synaptic sites.

To test this, we created a low density projection by rerouting regenerating fibers from one retinal quadrant into an otherwise denervated tectum. It was previously shown that fibers form less than half the normal numbers of synapses under this condition. After several months, we then assayed for clustering by making a 2nl spot injection of WGA-HRP into retina. Multiple clusters were found in this low density projection. This indicates that competition for limited synaptic sites is not a prerequisite for clustering. The effect of TTX impulse blockade is being tested. If this low density clustering is found to require activity, this would further suggest that activity-dependent ordering represents a cooperative rather than a competitive process.

EVIDENCE FOR THE STABILITY OF POSITIONAL MARKERS IN THE GOLDFISH TECTUM. U. Busse and C.A.O. Stuermer, Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, D-7400 Tübingen, FRG.

Regenerating retinal axons return to their retinotopic target sites in the tectum over abnormal paths and without impulse activity (Hartlieb & Stuermer '88). This supports the view that they are guided by positional cues on tectum. Such cues could be axonal remnants, transient markers imposed by the earlier axons (Schmidt '78) or longlasting markers intrinsic to tectum. To decide between these alternatives we pursued the paths of axons from a temporal hemiretina in tecta which were deprived of retinal afferents for 5 and 8 months, respectively.

The right tectum was denervated by removing the left eye. Axons from a surgically created temporal hemiretina regenerated into the denervated tectum after removal of the left tectum (T-rem). 180 days after T-rem these axons were labeled by applying HRP to the right optic nerve and visualized in tectal whole mounts.

The vast majority of temporal axons was found in the rostral tectum. In midtectal regions axons performed U-turns and returned into the rostral tectum instead of invading the vacant caudal tectal half. The obvious preference of temporal axons for the rostral tectum was substantiated by quantitative measurements. Labeled axons were counted in rostral, midtectal and caudal tectal regions (N=6). 74,1% ± 4,0 of axons were found rostrally, 25,9% ± 4,0 in midtectal and 0% in caudal regions of tectum.

Thus, in tecta denervated for up to 8 months axons from a temporal half retina occupy their retinotopically appropriate rostral tectum. We did not observe an expansion of temporal axons into caudal tectal regions. These findings argue against the view that positional cues are lost. They suggest that positional markers are intrinsic to tectum and stable, which is supported by recent data from *in vitro*-assays (Vielmetter & Stuermer '88).

230.3

PATH- AND HOMEFINDING OF REGENERATING RETINAL AXONS IN GOLDFISH IN THE ABSENCE OF NEURAL ACTIVITY

E.Hartlieb and C.A.O.Stuermer, Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, D-7400 Tuebingen, FRG

Regenerating retinal axons travel in abnormal routes and extend initially branches over inappropriate regions of tectum. They loose these branches when they establish target-directed routes and develop their terminal arbors at retinotopic sites (Stuermer,1988). To decide whether these events require neural activity we pursued the growth of TTX-blocked axons in tecta at regeneration periods of 24-80d and 120-184d.

After optic nerve section (ONS) the right eye was injected with 0.5µl 0.12mM TTX, and the left eye with Ringer. Axons from a dorso- or ventro-temporal sector in retina (2.5-6% of retinal area) were labeled with HRP and visualised in DAB reacted tectal whole mounts.

At 24-80d after ONS TTX blocked axons crossed through all regions of tectum and extended branches with growth cones like control axons. Despite their abnormal routes, the axons exhibited a preference for their retinotopically appropriate rostral hemitectum: most axons were in rostral (57.9%) and midtectal (36.3%) and fewer in caudal (7.6%) tectal regions. At 120-184d, TTX blocked as well as control axons had lost their side branches, established target directed routes and ended in terminal arbors at retinotopic sites. Axon processes in caudal tectum declined to 1.1%, and 86.6% and 12.4% were in rostral and midtectal regions, resp. The terminal arbors were confined to a distinct zone in rostral tectum, covering no more than 1.1 to 2.6% of the tectal surface.

These findings suggest that regenerating axons do not need their normal impulse activity to course preferentially through their appropriate rostral hemitectum, to extend and withdraw their branches, to develop target-directed routes and to assemble their terminal arbors in well-defined retinotopic territories.

BASKET CELLS OF THE DENTATE GYRUS ESTABLISH SYNAPTIC CONNECTIONS WITH GRANULE CELLS IN FIVE DAY OLD RATS. L. Seress and C.E. Ribak. Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717.

Previous studies have shown that GABAergic inhibitory neurons of the dentate gyrus are generated prenatally. In contrast, the majority of granule cells are formed postnatally. A well-characterized type of GABAergic neuron that is known to provide feedback inhibition of granule cells in adults is the basket cell. Since recent physiological studies by Swann et al. (1988) indicate that inhibition of pyramidal cells in CA3 first occurs in 5 day old rats, it was of interest to determine when a recurrent inhibitory circuitry exists in the dentate gyrus. Golgi-electron microscopic preparations were examined from 5, 10 and 16 day old rats. Basket cells in 5 day old brains displayed axons that formed symmetric synapses with somata and dendrites of granule cells. These terminals were small and contained relatively few pleomorphic synaptic vesicles. The somata of basket cells were larger than those of granule cells, and they also contained more cytoplasmic organelles, such as Golgi complex, granular endoplasmic reticulum and free ribosomes. In addition, somata and both apical and basal dendrites of basket cells were contacted at this age by relatively immature axon terminals that formed mainly symmetric synapses. Some adult features of basket cells, such as intranuclear rods, infolded nuclei and organized Nissl bodies, were first observed in 10 day old brains. By 16 days of age, most basket cells appeared to be similar to those found in adult preparations. For example, the dendrites were contacted by numerous terminals with round synaptic vesicles that formed asymmetric synapses. Such terminals have previously been identified as axon collaterals from mossy fibers. Some terminals with a similar morphology contacted the somata of basket cells at this age. These data suggest that a recurrent inhibitory circuitry is established in the 5 day old dentate gyrus even though basket cells at this age lack the typical adult ultrastructural features. The appearance of infolded nuclei and intranuclear rods in basket cell bodies following the appearance of numerous asymmetric (excitatory type) axodendritic and axosomatic synapses suggests that these structures are related to the increased metabolic activity of basket cells.

Further Characterization of Gap Junctions and Their Messenger RNAs in Cultured Glia and Neurons. K. Spiegel, D.C. Spray, R. Dermietzel, and J.A. Kessler (Spon:D.K. Batter). Depts. Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Gap junctions and their messenger RNAs (mRNAs) were examined in cultures of glia and sympathetic neurons. Northern blot analysis of oligo-dT-cellulose fractionated RNA from cultured glia revealed a predominant 2.5 kb band and a less abundant 1.6 kb band. A previously reported 3.7 kb band was found to represent cross-hybridization to 28S ribosomal RNA. Sympathetic neurons, by contrast, expressed only the 1.6 kb mRNA. These putative gap junction mRNAs were similar in size to the mRNAs for the 21 kD gap junction protein (2.5 kb) and the 27 kD gap junction protein (1.6 kb) found in rat liver, suggesting that astrocytes express predominantly the 21 kD protein whereas neurons express the 27 kD protein. Immunocytochemical studies of cultured astrocytes confirmed the presence of the 21 kD protein and the absence of detectable 27 kD protein. By contrast, oligodendrocytes contained the 27 kD protein. Immunocytochemical stuides of cultured sympathetic neurons using the antibody to the 27 kD protein revealed punctate areas of fluorescence consistent with the presence of small soma-somatic gap junctions. Further studies are necessary to substantiate this observation.

Regulation of gap junction mRNA levels and of dye and electrotonic coupling were examined in astrocytes cultured from different brain regions. Astrocytes from different regions expressed similar levels of gap junction mRNAs and exhibited high levels of dye and electrotonic coupling. The extent of dye coupling was increased in all regions by treatment with dibutyryl cyclic AMP. However, exposure to testosterone or arachidonic acid increased coupling in astrocytes cultured from cortex or striatum, while coupling between hypothalamic astrocytes was dramatically decreased by both treatments. Thus gap junctions are regulated differently in astrocytes from different brain regions. Preliminary studies indicate that levels of the 1.6 kb mRNA in cultured sympathetic neurons are similarly regulated by microenvironmental factors, and that changes in mRNA levels are correlated with changes in electrotonic coupling.

ANALYSIS OF NEURONAL ORGANIZATION IN CELL CULTURE: USE OF LASER-ETCHING TECHNIQUE TO CREATE PATTERNED SUBSTRATE GRIDS. J.S.Whitson*, G.J.Brewer and C.W.Cotman, Dept of Psychobiology, University of California, Irvine, CA, 92717.

In vivo, neuronal organization develops in a complex environment. It appears to be directed by a number of coordinated components including substrate molecules, diffusible trophic factors, and synaptic reinforcement of appropriate connections. Knowledge of the mechanisms of neuronal organization is crucial to our understanding of the central nervous system, where neurons are highly interconnected and interdependent.

Standard explant cultures do not allow detailed examination of the process of neuronal organization because the contacts between individual neurons cannot be clearly defined at a cellular level. Thus, we have developed a system which allows examination of neuronal organization in a clear and quantifiable manner. Plastic tissue culture dishes were coated with polylysine. A square gold screen (1000 mesh) was centered in the dish and irradiated with a single pulse (15nsec, 105mJ/cm^2) from an ultraviolet laser. This etched the substrate not protected by the gold screen, forming a grid pattern of substrate lanes. Cells from well-defined brain areas (e.g. hippocampus and septum) were dissociated and seeded at low density (10,000 cells/cm^2) in etched dishes. After two days in culture, individual hippocampal neurons located on the grids extended neurites that followed the straight lanes and right angle turns of the grid pattern. The restriction of neurites to the pattern in these laser-etched dishes is superior to that obtained on grids formed by inactivation of polylysine under conventional ultraviolet-light.

This system allows neurite affinities for different substrates to be quantified. In co-cultures where one cell population is fluorescently labeled, this system permits characterization of homotypic and heterotypic neuronal connections. This work was supported under an NSF Graduate Fellowship to J.S.W.

230.7

A BASIS FOR SELECTIVE CONNECTIONS IN LEECH. X. Gu* and K.J.Muller. Dept. of Physiol. & Biophys., U. of Miami School of Med., Miami, FL 33101

In many nervous systems, neurons form connections with certain cells but not with others that appear to be suitable targets. For example, axosomatic contacts of nociceptive (N) neuron axons in the leech wrap only certain other sensory cells. The contacts are visible with the light microscope and will regenerate accurately after nerve injury, showing that mechanisms providing for precise wiring also operate in the adult. Normally, the cells wrapped by the lateral N cell are in adjacent ganglia, whereas homologues of the targets in the N cell's own ganglion are never wrapped. However, those homologues become wrapped by sprouting N cell axons if the ganglion is isolated from its neighbors by cutting the paired connectives that link them. Because of the ganglion's bilateral symmetry and the presence of targets on the left and right sides, by cutting only the connectives on the left we found that denervation of targets and not injury to the N cell could account for the sprouting. When the target homologues were selectively denervated by killing their normal presynaptic inputs(8 N cells in the 2 neighboring ganglia injected with protease), the N cells sprouted to wrap cells in their own ganglia. This indicates that normally wrappings by other cells prevent or exclude the N cell from wrapping cells in its own ganglion. (Supported by NIH Grant NS20607.)

RETROGRADE LABELING OF MOTONEURONS REINNERVATING BASEMENT MEMBRANE GHOSTS IN AXOLOTL MUSCLES. V. Boss and D.J. Wigston. Departments of Biology and Physiology, Emory University, Atlanta, GA 30322.

Selective reinnervation of axolotl limb muscles suggests the presence of muscle-specific cues that direct synaptogenesis during regeneration. These cues do not appear to be restricted to myofibers (Wigston and Donahue, 1988; J. Neurosci. in press). We are currently testing whether such cues are associated with muscle fiber basement membranes.

The left posterior iliotibialis muscle (post.ILT) was injected with the long-lasting retrograde tracer diamidino yellow (DY) which labeled the nuclei of the post.ILT motoneurons. A week later the entire right ILT was removed and damaged to destroy its myofibers but not its basement membranes. Three days later it was irradiated to prevent regeneration of new fibers from satellite cells, and sutured in place of the left ILT. After 40-45d, the fiberless post.ILT was injected with rhodamine-HRP (R-HRP). R-HRP was successfully restricted to the post.ILT in about half the animals. The spinal cords of these animals contained motoneurons labeled with both DY and R-HRP, showing that motoneurons that reinnervate basement membrane ghosts can be retrogradely labeled. We are using this strategy to test whether regenerating motoneurons can distinguish between the ant. and post. ILT in the absence of muscle fibers.

"EXPRESSION OF NERVE-MUSCLE TOPOGRAPHY DURING DEVELOPMENT". M.B. Laskowski and J.A. High. Department of Physiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Previous studies have indicated that in two muscles of the adult rat, the anterior serratus and the diaphragm, the rostrocaudal axis of the motoneuron pool projects topographically onto the rostrocaudal axis of the muscle. In the present work we have asked whether this orderly topography emerges as a function of postnatal synaptic rearrangement or whether this pattern is already established at birth. The anterior serratus muscle was studied over the period ranging from embryonic day 17 through postnatal day 30. Using two criteria of topography, average segmental innervation and average target field of cervical roots C6 and C7, we found that a topographic distribution of the motoneuron pool is already present prior to birth and is maintained throughout the postnatal period. Moreover, both C6 and C7 form an orderly map over the surface of the serratus in the embryo, and the topography is sharpened during postnatal periods. The diaphragm also is topographically innervated at birth and undergoes a comparable sharpening of the projection map postnatally. We conclude that the topographic projection of motoneurons is established prior to birth in these muscles, and postnatal synaptic rearrangement serves to sharpen this topographic map toward the adult pattern. 230.10

REGENERATIVE SPECIFICITY FOLLOWING HETEROCHRONIC LIMB TRANPLANTS. P.B. Farel and S.E. Bemelmans* Dept. of Physiology, Univ. N. Car. Sch. Med., Chapel Hill, NC 27599

In the bullfrog tadpole, motor axons transected prior to st. VIII regenerate to the appropriate hindlimb region. After st. VIII, target specificity is lost (JCN 254:125-132, 1986). In order to determine if the loss of regenerative specificity derives from an inability of mature motoneurons to respond to guidance cues, we replaced single hindlimbs in st. X tadpoles with hindlimbs taken from st. IV/V animals. Four weeks following the transplant, HRP was placed in the ventral thigh, and the location of retrogradely labeled motoneurons was mapped. We found specific regeneration along the dorsal-ventral axis of the hindlimb, but specificity along the proximal-distal axis was lost. When spinal nerves were severed without transplanting the limb, regeneration was not specific. These results show that the capacity for regenerative specificity is not lost in mature motoneurons, but expression of this specificity may be prevented under normal conditions.

230.11

EXCITATORY SENSORIMOTOR CONNECTIONS BETWEEN ANTAGONISTS IN THE ISOLATED CHICK EMBRYO SPINAL CORD. M. T. Lee and M. J. O'Donovan. Dept. Physiology & Biophysics, Univ. of Iowa, Iowa City, IA 52242.

In mature vertebrates, stretch-sensitive muscle afferents synapse with motoneurons in a highly specific fashion. Afferents from a given muscle monosynaptically excite motoneurons to that muscle and its synergists and disynaptically inhibit motoneurons to its antagonists. To learn more about the development of this specificity, we have examined the pattern of sensorimotor synaptic connections in the lumbosacral spinal cord of the chick embryo *in vitro*. Responses to muscle afferent stimulation were recorded intracellularly in identified motoneurons and extracellularly in hindlimb muscle nerves at 13-20 days of incubation. (Hatching begins at about 23 days under our laboratory conditions.)

The majority of the intracellular recordings were obtained from motoneurons that innervate the femorotibialis (FT), an extensor muscle in the thigh. Homonymous PSPs (produced by stimulation of the FT nerve) were detectable in all FT motoneurons, usually at stimulus intensities subthreshold for antidromic firing of the motoneurons. In addition, depolarizing PSPs could be recorded in some FT motoneurons following stimulation of the nerve to the adductor, another extensor muscle. Surprisingly, stimulation of *antagonistic* (flexor) muscle nerves, such as the sartorius and anterior iliotibialis, also elicited depolarizing synaptic potentials in some FT motoneurons. In general, non-homonymous PSPs, including those produced by antagonist stimulation, were smaller and of longer latency than homonymous PSPs. Although it is not clear whether the non-homonymous PSPs were produced monosynaptically, they persisted in the presence of APV, picrotoxin, and strychnine, which block IPSPs and eliminate much of the polysynaptic component of afferent-evoked motoneuron potentials.

These results have been corroborated and extended by extracellular recording of motoneuron synaptic potentials from muscle nerves. Such recordings, also made in saline containing APV, picrotoxin, and strychnine, reveal a pattern of widespread connectivity between afferents and motoneurons that includes excitatory connections between antagonists. It will be important to establish whether this pattern is modified as development proceeds following hatching.

230.12

SEGMENTALLY SPECIFIC MUSCLE AFFERENT PROJECTIONS TO BRACHIAL MOTONEURONS IN CHICK EMBRYOS FORM DURING BLOCKADE OF NEUROMUSCULAR ACTIVITY. B. Mendelson and E. Frank. Dept. of Neurobiology, Anatomy and Cell Science, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

Neuromuscular activity was blocked with d-tubocurarine (dtc) in chick embryos from St. 28-38 to learn if segmentally specific connections between muscle sensory afferents and motoneurons would form in the absence of neurogenic muscle contractions. The segmental patterns of monosynaptic connections between muscle sensory afferents and brachial motoneurons were determined by recording motoneuronal synaptic potentials from cut ventral roots in response to the stimulation of afferent fibers in individual muscle nerves. In normal embryos stimulation of either biceps or triceps muscle afferents consistently evoked short latency, monosynaptic potentials in brachial ventral roots. The amplitudes of these synaptic potentials were greatest in the ventral roots that contained the largest number of homonymous motoneurons. Since biceps and triceps motor pools are located primarily in different segments, the synaptic potentials evoked by activity in biceps and triceps muscle afferents are segmentally specific.

In another set of embryos, neuromuscular activity was blocked by daily, *in ovo*, injections of dtc during the period when sensory-motor connections are forming (St 28-38). Ventral root recordings from these embryos treated with curare reveal that the overt pattern of segmentally specific contacts is similar to that observed in normal animals. These observations suggest that the development of specific connections between sensory and motor neurons is not entirely dependent on the normal patterns of neuromuscular activity nor the resultant afferent feedback evoked by muscle movement.

230.13

SELECTIVE INNERVATION OF FAST AND SLOW MUSCLE FIBERS IN NEONATAL MOUSE SOLEUS MOTOR UNITS. T. Fladby, J. K. S. Jansen. SPON: (P. Heggelund). Institute of Physiology, University of Oslo, Karl Johansgt. 47, 0162, Oslo 1, Norway.

We have examined the composition of motor units at postnatal day 5 while the polyneuronal innervation of the muscle fibers is still maximal. Identified with antibodies to F and S myosin there are about equal numbers of F and S fibers after the fiber proliferation is complete at day 2.

Individual soleus motor axons were stimulated in ventral root filaments. Muscle fibers with epps were labeled with injected Lucifer Yellow. Regularly 10 to 15 fibers (5%) were sampled from each motor unit. Alternate cross-sections of the muscle were incubated with F and S anti-myosin and a RITC labled second antibody. Lucifer labled fibers were identified and typed in the same sections.

So far more than half of all the motor units (15) contain only F or S fibers. The others contain both types with one or the other predominating.

We conclude that the F and S muscle fibers are selectively innervated before any net loss of synapses has occurred.

PROCESS OUTGROWTH, GROWTH CONES, AND GUIDANCE MECHANISMS III

231.1

GROWTH CONE ASSORTMENT IN THE OPTIC CHIASM OF FETAL MONKEYS. R.W. Williams & P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, 333 Cedar Street, New Haven CT 06510

A total of 200,000 growth cones (GCs) extend through the chiasm of rhesus monkeys each day during the 2nd month of gestation. At the chiasm they assort: half cross midline and ascend in the contralateral tract; the other half grow into the ipsilateral tract. We are interested in how this sorting takes place. GCs are distributed widely in cross-sections of the distal nerve and chiasm. Densities vary up to 10-fold, and this variation corresponds with the sequence of ganglion cell genesis in this species (LaVail et al., ARVO '85). Regions that contain the fewest GCs (<10 GCs/100 μm^2) correspond to central retina while regions that contain the highest GC densities (50 GCs/100 μm^2) correspond to the edge of the retina where ganglion cells genesis is most active.

By following the trajectories of fibers backward and forward through serial thin and semithin sections we have been able to divide the distal nerve and chiasm into regions that contain heavy concentrations of GCs from the nasal and temporal sides of the eye. While we have not succeeded in distinguishing nasal and temporal GCs on the basis of differences in size, shape, or ultrastructure, we have found that the cellular environment into which these GCs grow differ markedly. Nasal GCs grow into the ventral and anterior part of the chiasm that is peppered with glial cells at early stages. In contrast, temporal GCs grow into the lateral and posterior parts in which there are virtually no glial cell bodies. This finding raises the possibility that GCs from nasal and temporal retina differ initially in their affinity for glial cell processes.

231.2

ULTRASTRUCTURE OF CELLULAR CONTACTS MADE BY HRP LABELED GROWTH CONES IN THE HAMSTER CORPUS CALLOSUM. C.R. Norris* and K. Kalil. (SPON: E. Schweitzer) Dept. of Anatomy and Neurosciences Training Program, Univ. of Wisconsin, Madison, WI 53706.

The motile exploratory tip of a growing axon, the growth cone, responds to environmental cues by changing its shape and direction of movement. To investigate the possibility that growth cones in the mammalian CNS might be using specific cellular contacts as cues for migratory behavior, we studied at the EM level HRP labeled growth cones in the hamster corpus callosum which had been identified at the light microscopic level.

The hamster corpus callosum develops almost entirely postnatally. Thus, the relationship of the earliest growth cones to their environment could be compared with those arriving later. Hamsters ranging from newborn to 3 days after birth received small injections of HRP into the sensorimotor cortex. After a 2 hour survival time, perfusion fixed brains were processed for EM. At each stage of sectioning, growth cones were reidentified and photographed. Serial sections were collected so that growth cones could be reconstructed.

A striking feature of growth cones is the large area over which they spread, even in animals 2-3 days old when the packing density is tight and there is little extra-cellular space. The veils of lamellipodial growth cones wrap around many axons and contact diverging axon bundles. Branches of filopodial growth cones interdigitate among different bundles of axons and growth cones. Although growth cones were primarily associated with other neuronal structures, occasionally processes of growth cones were closely apposed to nonneuronal cells such as glia and blood vessels. However, specialized contacts were never observed between growth cones and these cellular elements. These observations argue strongly against a model of axonal guidance in which growth cones form obligatory contacts with nonneuronal cells or with specific axons along their trajectory.

231.3

WAITING PERIODS AND SUBCORTICAL COLLATERALIZATION: AXON GROWTH PROGRAMS OF VISUAL AND MOTOR CORTICAL NEURONS ARE SIMILAR. T. Terashima*& D.D.M. O'Leary (Spon: R.L.Grubb), Dept Neurosurg & McDonnell Ctr for Studies of Higher Brain Function, Washington Univ Sch Med, St.Louis, MO. 63110

We find that the growth and collateralization of subcortical axons of layer V neurons of motor and visual cortex are similar despite the fact that they retain projections to different subsets of a common set of initial targets. Axons are labeled with DiI injected in visual or motor cortex of postnatal rats, or crystals of DiI placed in these areas in aldehyde fixed fetal brains. To illustrate, we describe the projection from cortex to the basilar pontine nuclei (BPN). Axons from visual cortex reach pons at birth, but continue to grow caudally past BPN, through the medulla and into the spinal cord. At P2, buds appear on these axons at a point overlying rostro-lateral BPN; collaterals develop from the buds and by P2.5 extend well into BPN. The axon segment caudal to the collateral point is later eliminated. Axons from motor cortex behave similarly but budding takes place 2 days earlier, primarily at caudal BPN, and the axon caudal to the collateral is retained. Thus, in this system, the "waiting period" is not due to axons pausing near the target and later entering it, but to a delay in formation of collaterals off of axons that have grown past the target. We find that other layer V subcortical projections also develop as interstitial collaterals in a similar way.

231.4

DEVELOPMENT OF TOPOGRAPHIC PRECISION IN CHICK RETINOTECTAL PROJECTION INVOLVES MAJOR REMODELING, H. Nakamura & D.D.M. O'Leary (SPON: J. McCasland) Dept. Neurosurgery & McDonnell Ctr Higher Brain Function, Washington Univ. Med. Sch., St. Louis, MO. 63110

Using the anterograde tracer, DiI, we have studied in E9 to E18 chicks the development of topographic order of the projection from temporal retina to rostral optic tectum. The labeled retinofugal axons course intraretinally in a compact bundle from the point of labeling to the optic fissure. Very few deviate from this bundle, but in it, much crossing over and mixing occurs. None appear to branch. The axons enter the contralateral optic tectum at its rostral edge and grow caudally, most extending well past their appropriate terminal zone in rostral tectum. After considerable elongation along the rostral-caudal tectal axis, the axons develop numerous side branches and arbors, both in and well outside of the appropriate region of tectum. Most of the overshooting axon segments and inappropriate branches and arbors appear to degenerate over the ensuing few days. A small number of overshooting axons reverse course 180^{o} and grow back to the terminal zone. Many axons enter the tectum with a positional error along the medial-lateral tectal axis; some correct this error by making dramatic alterations in their trajectory, others by extending collaterals. A proportion of the erroneous axons eventually elaborate an appropriately positioned arbor and survive. These events lead to the establishment by E16 of a discrete and highly focused zone of terminal arborization characteristic of the mature projection.

231.5

A STUDY OF THE DEVELOPING CORPUS CALLOSUM WITH A METHOD FOR STAINING NEURONAL PROCESSES IN FIXED TISSUE.
S.Catalano* and H.P.Killackey. Depts. of Anat. & Neurobio. and of Psychobio, Univ. of Calif., Irvine CA 92717

Two difficulties in tracing pathways in the developing brain are tracer diffusion and the need for a survival period post-injection during which the system continues to develop. Both of these difficulties can be overcome by the use of the fluorescent tracer DiI which diffuses through the lipid membranes of aldehyde fixed tissue (Godement,P. et al.,Develop. 101:697, 1987).

Rat pups (ages E 18 to PND 7) were sacrificed and then perfused transcardially with 4% buffered paraformaldehyde. The brains were bisected along the midsagital plane and crystals of diI placed in the corpus callosum under a dissecting microscope. The brains were then stored in the fixative at room temperature for at least one week and sectioned with a vibratome. The sections were then mounted in buffer and sealed under a coverslip, and examined with an epifluorescent microscope.

At all ages, labeled fibers and growth cones could be observed in the white matter and at later ages, they could also be observed within the cortical layers. Our preliminary observations suggest that growth cone morphology varies at different points of the pathway. In the white matter growth cones are elongate in form. Upon turning up towards cortex, they are broader with many filopodia, and on entering cortex, they exhibit a branched form tipped with many small growing ends.

231.6

THE DEVELOPMENT AND INNERVATION OF THE EPAXIAL MUSCLES.
K. W. Tosney, Biology Dept., University of Michigan, Ann Arbor, MI. 48109.

The developing epaxial muscles provide a highly specific cue that is essential for the outgrowth of the epaxial motoneurons (Tosney, *Devel. Biol.* 122: 540). I have found that the myotome originates from the cranial side of the dermamyotome shortly before axon outgrowth. Two epaxial muscles develop *in situ* from each myotome. The longissimus dorsi initially forms as a discrete series of segmental units and then reorganizes to form the long muscle of the back. The intervertebral muscles develop in each segment; they persist in thoracic and regress in lumbosacral segments. The fate of innervation during muscle reorganization and regression is under study.

The nature of the target-related cue has been partially clarified. 1) Even when the intervening sclerotome is substantially deleted, the epaxial motoneurons exhibit target-dependent and target-directed outgrowth. This suggests that the target does not act indirectly by altering the sclerotome. For instance, the target is unlikely to induce the sclerotome to form a gradient of adhesivity that orients epaxial motoneuron outgrowth. 2) The dependence of epaxial motoneurons on their target is apparantly not due to the stabilization of a few growth cones that have grown out randomly and contacted target. When the prospective target is removed from a single segment, epaxial motoneurons extend entirely within that segment and do not contact target in the more anterior segment until 2 days later. In contrast, no epaxial growth cones emerge from a spinal nerve when all epaxial target within 300 μm has been removed. These results strongly suggest that the epaxial muscle cue is relatively long-distance and may be diffusible. I am beginning to assess this possibility using a hybrid *in vivo/ in vitro* system that allows finer spatial and temporal analysis. Supported by NIH #NS21308.

NEURONAL ADHESION AND NEURITE GROWTH ON GLIA-ENRICHED SUBSTRATES FROM TARGET AND NON-TARGET BRAIN REGIONS.
E. Lieth, D.R. McClay*+ and J.M. Lauder. Dept. of Cell Biol. and Anat., UNC, Chapel Hill, NC, 27599, and +Dept. of Zool., Duke Univ., Durham, NC, 27707.

Two parameters of in vitro cell-cell interactions between serotonergic neurons and glia-enriched substrates from temporally defined target, non-target, or home brain regions were measured: strength of adhesion and extent of neurite outgrowth. Whereas the length of serotonergic neurites on home metencephalic substrates was at least 26% greater than growth on either target mesencephalic or non-target spinal cord substrates, mesencephalic substrates proved to be at least 62% more adhesive than home or non-target regions. This finding indicates that for developing serotonergic neurons, and perhaps other transmitter-identified neuronal types, specific target recognition correlates with increased adhesion, which in turn might be associated with cessation of axonal growth. Although it was previously shown that on fibroblasts or postnatal astrocytes increases in adhesive recognition can accelerate neurite growth, the current study shows that the increased adhesivity of a temporally appropriate target may cause neurite growth to slow down.

231.8

TRANSIENT EXPRESSION OF ADHERON MOLECULES AT THE EARLY STAGE OF SYNAPTOGENESIS.
H-C.T.Tsui and W.L.Klein. Dept. Neurobiology and Physiology, Northwestern University, Evanston IL 60202.

Adherons are multimolecular adhesion-promoting complexes obtained from media conditioned by cultured cells. EM immunogold studies recently have shown that adheron antigens occur in filamentous material that crosslinks pairs of adherent filopodia, suggesting that adherons may have an important role in establishing adhesive junctions such as synapses (Tsui et al., J. Cell Biol. in press). We now have found that during chick retina development in ovo, adheron immunoreactivity is transiently expressed at specific regions in the cellular and synaptic layers. At early stage only general labeling was found over the entire neural retina, but at E11 segregation of labeling started to occur. By the beginning of synaptogenesis at E14, only selected cells within the inner nuclear layer were brightly labeled. These cells were close to the inner synaptic layer. Also the inner part of the inner synaptic layer was more brightly labeled than the rest of the synaptic layer. After E17, adheron-immunoreactivity was significantly decreased and homogeneous except for the increasing labeling of the interphotoreceptor complex. This transient expression of adheron antigens at the beginning of synaptogenesis further supports the idea that they are involved in the transition from growth cones to synapses.

231.9

COMPARTMENTALIZATION OF CYTOSKELETAL AND CELL SURFACE PROTEIN EXPRESSION DURING INITIAL PROCESS OUTGROWTH OF HIPPOCAMPAL NEURONS.
K.R. Pennypacker and P. Levitt. Dept. Anatomy, Med. Coll. Pa., Philadelphia, Pa. 19129.

Neurofilament (NF) and microtubule-associated protein 2 (MAP2) have been used as protein markers of axons and dendrites, respectively. The limbic system-associated membrane protein (LAMP), which mediates target recognition by limbic axons, is expressed on developing axons in vivo. We have used antibodies to each of these proteins to investigate the molecular organization of initial process outgrowth. Monolayer cultures from E16 rat hippocampus expressed LAMP, MAP2 (antibody provided by Dr. I. Fisher, Shriver Center) and NF (200, 160kd) at each time examined. MAP2 positive cells were counted and examined for NF-positive neurites. Within 2 hr of plating, NF protein was expressed in 20% of MAP2-positive cells. By 20 hr, nearly 50% were NF-immunoreactive. Initially, nearly 60% of the NF-positive neurites exhibited MAP2 staining, but this colocalization decreased over time. At 2-4 days, many processes were stained proximally for MAP2 and distally in the same neurite for NF, suggesting an active redistribution and compartmentalization of the proteins. By 8 days, few double-stained neurites were seen. While previous studies have reported delayed (3-4 days) NF expression in culture (Shaw, G., et al, Eur. J. Cell Biol. 39:205-216, 1985), our data suggest an early and specific expression of both MAP2 and NF. The presence of LAMP during initial process outgrowth is consistent with its role as an important component of limbic connectivity. RELATIONSHIP OF LAMELLIPODIAL STRUCTURE TO RAPID LOCOMOTION IN GROWTH CONES.
N. Kleitman and M.I. Johnson+. Depts. Anatomy and +Pediatrics, Washington Univ. Sch. Med., St. Louis, MO 63110

Previous work suggested that the rate of growth cone locomotion is correlated with growth cone morphology and dependent on neuronal age (Argiro et al., J. Neurosci. 4:3051). On laminin rat sympathetic neurites elongate at rates rivalling growth in vivo and growth cone forms range from lamellipodial to entirely filopodial. We analyzed a large sample of growth cones from perinatal (E21) and postnatal (P30) rats using time lapse cinematography. As on collagen, growth cones locomote on laminin most rapidly when lamellipodial in form. Lamellipodial E21 growth cones (1 day in vitro) with no underlying filopodia move most rapidly (1.5 μm/min) compared to those with microspikes at the leading edge (0.9 μm/min) or to filopodial forms with or without small veils between adjacent filopodia (0.7 and 0.3 μm/min, respectively). When fixed and stained with fluorescent phalloidin, a probe for F-actin, 69% of E21 growth cones were predominantly lamellipodial with a meshwork of actin (in comparison to actin bundles in filopodia). Although we had never observed lamellipodial P30 growth cones on collagen, these made up 38% of the growth cones observed after 1 day in vitro on laminin, and were the fastest growing P30 neurites. In the postnatal cultures, growth cones spent less time in lamellipodial form and had slower overall growth rates. In both age groups, the proportion of lamellipodial growth cones decreased over the first week in vitro, but the rate of locomotion was more closely correlated with growth cone structure than age or length of time in vitro. (NIH NS07071, NS08069, NS21771; NSF BNS8508148.)

231.11

Growth cone-growth cone interactions in cultures of rat sympathetic neurons: A time-lapse video microscopic study. J.K. Ivins and R.N. Pittman. Dept. of Pharmacology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

The nerve growth cone is a highly motile and dynamic structure intimately involved in such diverse phenomenon as neurite outgrowth, target cell recognition, and synaptogenesis. We are interested in understanding how growth cone motility is regulated by environmental factors such as contact with other growth cones and neurites.

Sympathetic neurons from neonatal rat superior cervical ganglia were mechanically dissociated and plated on glass coverslip dishes coated with polylysine and laminin for time-lapse studies.

A variety of behaviors were observed. Most commonly, one growth cone retracted upon filopodial contact with the growth cone of another sympathetic neuron. This is often accompanied by a rapid and transient burst of lamellopodial activity 20-30 microns proximal to the retracting growth cone. On several occasions, growth cones were seen to track other growth cones, although fasciculation was relatively rare. Retraction was also occasionally seen in growth cone-neurite interactions. In general, the interactions observed between sympathetic growth cones were more complex than have previously been reported for neurons from diverse sources. (Supported by the McKnight Foundation and the PMA).

NEURITE OUTGROWTH BY AN IDENTIFIED NEURON: PROMOTION BY L-GLUTAMATE IN SITU AND IN VITRO. A.G.M. Bulloch and G. Hauser*. Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Sprouting from intact neurons of the snail Helisoma occurs in response to stress. Additionally, such stresses have been correlated with an elevation of blood-borne acidic amino acids. The present study tested the hypothesis that L-glutamate, either indirectly or directly, can induce neurite outgrowth by Helisoma neurons. Neuron B5 was examined both isolated in vitro, and also intact in situ using a newly developed preparation. L-glutamate did not induce sprouting by either intact or isolated neurons B5. We also tested whether L-glutamate can enhance conditioned medium which is known to induce neurite outgrowth. Conditioned medium is normally produced by incubating Helisoma ganglia in defined medium for 72 hrs, a procedure which releases trophic proteins; in this study medium was conditioned for only 24 hrs. Little or no neurite outgrowth occurred in such medium that lacked L-glutamate. However, the medium conditioned in the presence of L-glutamate (150-300 μM) was found to be very effective in evoking neurite outgrowth both from intact neurons in situ and also from isolated neurons in vitro. These results support the hypothesis that L-glutamate can enhance neurite outgrowth via an indirect mechanism, possibly involving either release and/or activation of proteinaceous trophic factors.

NEURITE OUTGROWTH OF AN IDENTIFIED NEURON: AN ULTRASTRUCTURAL ANALYSIS OF CELL-CELL INTERACTIONS IN SITU AND IN VITRO. R.C. Berdan, G. Hauser* and A.G.M. Bulloch. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1

We examined the ultrastructural basis of cell-cell interactions of an identified neuron following neurite outgrowth induced by axotomy. Axotomized neurons B5 from the buccal ganglion of Helisoma were compared with isolated neurons B5 in culture. Buccal ganglia containing axotomized neurons were cultured in host snails, hanging drops of blood and conditioned medium. Neuron B5 and its processes were identified in plastic sections by electron microscopy following intracellular injection with horseradish peroxidase. Putative chemical synapses were abundant on cell processes of neuron B5 prior to and following axotomy. Gap junctions were occasionally (N=3) seen between regenerating neurites and glia in situ. Small gap junctions (punctate contacts) were found to connect processes of electrically coupled pairs of neurons B5 in vitro. Furthermore, rough endoplasmic reticulum was abundant within the regenerating neurite processes. The surface features of isolated neurons were examined by scanning electron microscopy and although non-neuronal cells may associate with the giant neurons in vitro, isolated neurons were free of associated glia. This is the first study to compare cell-cell interactions of an identified neuron both in situ and in vitro and indicates that a regenerating neuron may form several types of membrane specializations with other neurons and glia.

Supported by Alberta Heritage Foundation for Medical Research.

SUCCESS OR FAILURE OF IN VIVO AXONAL REGENERATION DEPENDS ON THE AXOTOMY SITES IN AN IDENTIFIED NEURON WITH TWO AXONS. P.J. Kruk* and A.G.M. Bulloch (SPON: R.G. Lee). Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

Regeneration of an identified buccal neuron (B4) after axotomy was examined in adult Helisoma. This neuron has two axons, one innervating the ipsilateral salivary gland and the other the contralateral salivary gland. Esophageal trunks (left, right or both) containing these axons were crushed very close to the buccal ganglia in situ. One week following axotomy one of the two neurons B4 was stained with Lucifer Yellow. We studied the response of the neuron to three different conditions of axotomy:

a) Contralateral proximal axotomy left an axon stump. This procedure caused neurite outgrowth restricted to the tip of this stump and resulted in the regeneration of the contralateral axon.
b) Unexpectedly, no neurite outgrowth occured after ipsilateral proximal axotomy. This procedure completely removed the ipsilateral axon, which subsequently failed to regenerate.
c) Bilateral axotomy, as in (a) and (b) together, evoked extensive sprouting from the soma and axon stump and resulted in the regeneration of both axons.

Thus, after complete removal by proximal axotomy, regeneration of the ipsilateral axon in this neuron depends upon somatic sprouting, which in turn requires proximal contralateral axotomy. So the failure of regeneration may result from a specific conditions of axotomy rather than from a general lack or loss of regenerative ability.

CALCIUM HOMEOSTASIS IN MOLLUSCAN AND MAMMALIAN NEURONS: NEURON-SELECTIVE SET-POINT OF CALCIUM REST CONCENTRATION. P. B. Guthrie, M. P. Mattson, L. R. Mills and S. B. Kater. Program in Neuronal Growth & Development and Dept of Anatomy & Neurobiology, Colorado State Univ., Ft Collins, CO 80523

Considerable evidence has recently accumulated in support of the calcium hypothesis of growth cone regulation: **growth cone structure and behavior are tightly controlled by variable levels of free cytoplasmic calcium.** Regulation of calcium levels must therefore be critical to proper behavior of growth cones. We have begun an investigation of calcium homeostasis by asking: Do individual neurons have characteristic set-points for rest calcium levels?

Intracellular calcium concentrations were measured with Fura2 using a low-light level fluorescence microscope/image-analysis system. Neurons in culture from two sources were examined: identified neurons from the buccal ganglion of the pond snail *Helisoma*, and dissociated neurons from embryonic (18 d.) and postnatal (5 d.) rat hippocampus; in all cases, different neurons had characteristic, different rest calcium concentrations. Neurons B5 and B19 from *Helisoma* had distinct calcium rest levels [B5: 221±21 nM (n=20); B19: 141±22 nM (n=13); $p<0.02$]. In embryonic hippocampal cultures, bipolar neurons had consistantly lower levels than pyramidal neurons [72±3 nM (n=15) versus 86±2 nM (n=15); $p<0.001$]. In cultures from regions of post-natal hippocampus, neurons from the dentate gyrus (presumptive granule neurons) had lower concentrations [74±2 nM (n=25)] than did pyramidal neurons from CA2 and CA3 [102±7 nM (n=11), 107±6 nM (n=13) respectively]. More striking is the observation that, even within the same class, mitotic sister neurons (neurons having undergone their final mitosis in culture) have highly correlated calcium concentrations [$r^2=0.621$; $p<0.001$]. Non-neuronal hippocampal cells had higher calcium rest levels than did any hippocampal neuron type [144±6 (n=24)].

Additional studies are now demonstrating that specific regions of single neurons will have different calcium rest levels. Thus, different neurons have the ability to set, both locally and the globally, intracellular calcium to characteristically different levels.

231.16

CALCIUM HOMEOSTASIS IN MOLLUSCAN AND MAMMALIAN NEURONS: DYNAMICS OF CALCIUM REGULATION. S. B. Kater, P. B. Guthrie, M. P. Mattson, L. R. Mills and R. S. Zucker[1]. Program in Neuronal Growth & Development and Dept Anatomy & Neurobiology, Colorado State Univ., Ft Collins, CO 80523, and [1]Dept Physiol. & Anat., Univ. of California, Berkeley, CA 94720

Since neurons can selectively set their rest calcium concentrations (preceding abstract), they must do so through regulation of influx, pumping, buffering, and/or sequestration. We are investigating the dynamics of calcium regulation by perturbing intracellular calcium levels and asking: will neurons attempt to restore calcium to original levels? Neurons in culture from two sources were examined: identified neurons from the buccal ganglion of the pond snail *Helisoma*, and dissociated neurons from embryonic rat (18 d.) hippocampus. Calcium levels were measured using Fura2.

Addition of the calcium channel blocker La^{3+} to *Helisoma* neurons B5 and B19 caused a significant decrease in intracellular calcium concentrations; within 15-30 min, levels started returning to the original levels. Similarly, removing calcium from the medium of hippocampal cultures reduced calcium concentrations in pyramidal-like neurons; even while maintained in 0mM Ca^{2+} medium, levels tended to be restored towards original concentrations.

Increasing cytoplasmic calcium concentrations with bath application of the ionophores A23187 and ionomycin raised calcium concentrations in both *Helisoma* and hippocampal neurons; again, levels were restored towards normal after 5-15 min.

A striking demonstration of active regulation of calcium levels came from experiments with the photo-labile calcium chelator NITR7. Irradiation of injected *Helisoma* neurons dramatically increased calcium levels; within minutes, calcium concentrations dropped below original levels, suggesting rapid activation of pumping or sequestration mechanisms.

These data indicate that neurons actively regulate calcium levels when perturbed. Thus, the temporal dynamics of calcium concentration changes must be considered, especially when studying the regulation of growth cone behavior in response to external stimuli both in culture (next abstract) and in situ (second abstract following).

231.17

INTRACELLULAR CALCIUM CONCENTRATIONS IN NEURONAL GROWTH CONES CHANGE WITH INDUCED TURNING AND BRANCHING BEHAVIOR. L.R. Mills, M. Murrain, P.B. Guthrie, and S.B. Kater, Program in Neuronal Growth & Development and Dept. of Anatomy & Neurobiology, Colorado State Univ., Ft Collins 80523

Physical interactions of the growth cone with its environment are among a wide variety of physiological stimuli known to influence neuronal growth cone morphology and neurite extension. We have begun to investigate these physical interactions using three paradigms that reproducibly evoke turning and branching behaviors in neuronal growth cones. Identified neurons in culture from the buccal ganglia of *Helisoma* were presented with three types of mechanical stimuli: 1) synthetic barriers were placed in front of growth cones, 2) a probe (3 micron tip) was used to touch selected sites on individual growth cones, 3) a micropipette containing medium from the culture dish was used to "puff" individual growth cones. Morphological changes in the growth cones e.g. the initiation of turning and branching were evident within minutes of growth cones reaching a barrier or within 5-10 minutes after application of the probe or puff.

Previous studies have shown that intracellular calcium levels rise in response to other stimuli (electrical activity and neurotransmitters), that inhibit growth cone motility. We are now asking: **Do physical interactions that induce turning and branching behavior also evoke changes in intracellular calcium?** Intracellular calcium concentrations were measured within growth cones using Fura2. Both touching (n=13) and puffing (n=6) evoked a rapid 2-3 fold rise in intracellular calcium level which was localized to the stimulated growth cone; after 2-10 minutes calcium levels were restored to their original rest levels, and subsequently calcium fell below rest levels. These data indicate that 1) mechanical stimuli can evoke changes in intracellular calcium in the growth cone 2) the growth cone can actively restore intracellular calcium levels following the changes induced by mechanical stimulation.

231.18

VISUALIZATION OF INTRACELLULAR CALCIUM CONCENTRATIONS IN *HELISOMA* NEURONS IN SITU. M. Murrain, L.R. Mills and S.B. Kater, Program in Neuronal Growth & Development and Dept of Anatomy & Neurobiology, Colorado State Univ., Ft Collins, CO 80523

Calcium is thought to play an important role in the control of neuronal outgrowth, as well as many other cellular and developmental processes. Previously, intracellular calcium concentrations have been visualized in cell culture, by loading individual *Helisoma* neurons with the calcium indicator dye, Fura2.

This study reports a method which allows for visualization of intracellular calcium in *Helisoma* neurons in situ. We have measured the calcium concentrations of neurons in freshly isolated buccal ganglia, as well as neurons in buccal ganglia where nerve trunks were crushed, to induce regeneration of specific neurons. It has previously been shown that application of serotonin, which regulates neurite outgrowth in isolated buccal neurons B19 in culture, results in an increase in the level of intracellular calcium from approximately 125 to 330 nM (Cohan, Conner and Kater, J. Neurosci. 7:3588-3599). We now find that the application of serotonin to buccal ganglia with Fura2 filled B19s results in an increase in the intracellular calcium concentration from approximately 90-100 nM up to 200 nM. Moreover, this rise in calcium has specific temporal and spatial patterns. Additionally, factors which are known to modulate growth and intracellular calcium concentrations in vitro have similar effects on calcium in situ. Because we can now visualize calcium concentrations in situ, we can extend our understanding of the role of calcium in neuronal outgrowth from neurons in culture to neurons in an environment that closely resembles their environment in vivo.

MACROPHAGE FUNCTION DURING WALLERIAN DEGENERATION OF RAT OPTIC NERVE: CLEARANCE OF DEGENERATING MYELIN AND IA EXPRESSION. Guido Stoll*, Bruce D. Trapp* and John W. Griffin. Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. The role of macrophages in Wallerian degeneration in the CNS is still controversial. This study was undertaken to investigate whether macrophages are involved in the phagocytosis of myelin debris and concomitantly express Ia antigen, a product of the immune response genes, in the transected optic nerve using 1-μm and thin-frozen sections. Serial 1-μm frozen sections were stained by avidin-biotin-peroxidase complex immunocytochemistry using monoclonal antibodies to rat Ia antigen (Ox6) and two antibodies which define cell types: GFAP for astrocytes and ED1 for macrophages. After transection an increasing number of ED1 positive macrophages appeared in the injured optic nerve. A subpopulation of these macrophages expressed Ia antigen. In thin frozen sections, Ia immunoreactivity was found exclusively in cells containing multiple vacuoles and myelin debris and lacking intermediate filaments. Virtually the same cell type was labeled by ED1 antibodies. GFAP positive astrocytes did not contain myelin debris in their cytoplasm. In conclusion macrophages seem to be responsible for removal of debris and concomitantly express Ia antigen in CNS Wallerian degeneration.

232.2

ACTIVATION OF ASTROCYTIC LYSOSOMAL PROTEINASES BY FACTORS RELEASED BY MONONUCLEAR LEUKOCYTES. C.T. Bever*, D.S. Snyder, R.O. Endres*, K.D. Morgan*, A. Postlethwaite*, and J.N. Whitaker (SPON: R.F. Mayer). Res. Service, VAMC, Dept. Neurol., and Div. Rheum. U.T.M., Memphis, TN, Dept. Neurol., UMAB, Baltimore, MD, and Dept. Neurol., UAB, Birmingham, AL

Lysosomal proteinases are increased in the tissue lesions of experimental allergic encephalomyelitis (EAE) but their cellular origins are not known. To evaluate their potential as a source of these proteinases astrocytes from fetal rat brains were prepared and grown in culture by the method of McCarthy and DeVellis. Lysates of astrocytes were assayed for two lysosomal enzymes found in EAE lesions, cathepsin B (CB) and cathepsin D (CD), using established assays based on the degradation of carbobenzoxy-alanyl-arginyl-arginine-methoxy-naphthalamide for CB and [^{14}C] methemoglobin for CD. Because astrocytes are activated by inflammatory mediators in demyelinating lesions the effect of the addition of lymphokine-containing medium to cultured astrocytes was examined. Culture supernates from mononuclear leukocytes grown in the presence of phytohemagglutinin (PHA sup) induced significant increases ($p < .01$) in the astrocytic CB (8.91 ± 0.04 mU/ug protein versus 3.89 ± 0.15) and CD (49.6 ± 0.66 ng/mg protein versus 20.5 ± 0.90). Neither PHA alone, nor commercially available preparations of human interleukin-1, interleukin-2, or gamma-interferon induced significant increases when added to cultured astrocytes. PHA sup was fractionated on a Sephadex G-100 column and activity was found in fractions corresponding to a molecular weight of 45-50,000. Reactive astrocytes could make a major contribution to the increased CB and CD activity found in the lesions of EAE (Supported by the VA Research Program).

232.3

CELLULAR RESPONSE TO OPTIC TERMINAL DEGENERATION K. Rao and R. D. Lund. Dept. Neurobiol., Anat. and Cell Sci., U. Pittsburgh, Pittsburgh, PA 15261.

We have previously shown that CD1 mouse retinae transplanted to the tectal region of neonatal Sprague-Dawley rats were immunologically rejected within 3 weeks after the removal of an eye from a month old host. Here we examine whether optic terminal degeneration is associated with a sequence of cellular events, that may precipitate the rejection process.

Unilateral eye removal was done in one month-old normal Sprague-Dawley rats. Animals were perfused from 1 day to 18 days later and frozen sections of the midbrain were cut. Alternating series were stained with the following immunohistochemical stains: (1) OX-6 for class II MHC antigens, (2) OX-18 for class I MHC antigens, (3) OX-42 for microglia/macrophages and (4) GFAP for astrocytes. In normal rats, no staining of the midbrain parenchyma was seen with either OX-6 or OX-42, but 3-4 days after eye removal, both antibodies stain cells in the region of the superior colliculus in which terminal degeneration is found. There is also a simultaneous and progressive increase in the number of stained astrocytes and macrophages/microglia in the same area.

It is therefore possible, given the induction by the degeneration process of MHC expression in tectal cells, that this may be an important factor in the instability of neural xenografts lying in the vicinity of regions in which neural degeneration is in progress. Supported by grants from Winters Foundation and NIH (EYO5283 and EYO5308).

STRUCTURAL SIMILARITY OF GLIAL HYALURONATE BINDING PROTEIN (GHAP) AND HA-BINDING REGION OF CARTILAGE PROTEINS. G. Perides*, W.S. Lane*D. Andrews*D. Dahl and A. Bignami. Harvard Medical School, and VA Medical Center, Boston, MA 02132 and The Biological Laboratories, Harvard University, Cambridge, MA 02138.

We previously reported on the localization in white matter astrocytes of GHAP (Bignami and Dahl, J. Neurocytol. 15:671, 1986). Here we report on the partial characterization of this protein. GHAP with an isoelectric point 4.3-4.4 was isolated from human brain white matter, the yield being 4 mg protein/50 g wet tissue. Comparison with GHAP from a viable glioma removed at surgery showed that the 60 kDa protein isolated from autopsy material is not a degradation product resulting from postmortem autolysis. After enzymatic deglycosylation an immunoreactive 47 kDa polypeptide was obtained. Proteolytic degradation with carboxypeptidase Y showed that the binding sites to HA are in the carboxy-terminal half of the protein. A 48 amino acid sequence of GHAP showed a striking similarity (up to 89%) with the HA binding region of cartilage proteins (bovine nasal cartilage proteoglycan, rat and chicken link protein). However, the amino acid composition and other amino acid sequences suggested that there are also major differences between brain specific GHAP and cartilage proteins. Supported by NIH grant NS 13034 and by the VA.

RETINAL GLIAL CELLS POSSESS FUNCTIONAL $GABA_A$ RECEPTORS. R. P. Malchow, H. Qian*, and H. Ripps, Depts. Ophthalmology and Anatomy & Cell Biology, Univ. Illinois College of Medicine, Chicago, Il. 60612.

Recently we reported that the radial glia of the retina (Muller cells) were depolarized by GABA and that GABA could induce large currents in these cells (Invest. Ophthal. Vis. Sci. suppl. 29, 1988). We describe here experiments suggesting that the effects of GABA are due to activation of $GABA_a$ receptors. Muller cells were dissociated from skate retina and responses to GABA examined using the whole-cell voltage clamp technique. When clamped at -70 mV, micromolar concentrations of GABA and the $GABA_a$ agonist muscimol elicited large inward currents (typically 1 nA); application of the $GABA_b$ agonist baclofen was without effect. Both bicuculline and picrotoxin were capable of antagonizing the effects of GABA. Further, the currents generated by GABA were found to depend on chloride, with the reversal potential of the GABA response varying linearly as a function of the log of the chloride concentration.

Preliminary experiments have also shown that B-alanine and taurine are also potent depolarizers of Muller cells. These experiments demonstrate that glia have a wider repertoire for responding to changes in the extracellular milieu than was previously suspected.

Supported by a research grant (EY-06516) from the N.E.I., and unrestricted awards to HR from Research to Prevent Blindness, Inc., and the Retina Foundation of Houston, Texas.

232.6

IDENTIFICATION AND PARTIAL CHARACTERIZATION OF A GLIAL-DERIVED CYTOPLASMIC ANTIGEN GA-1 BY MONOCLONAL ANTIBODY. N.C. Chang*, Y.H. Lin*, R.L. Chou* and A.C. Chang* (SPON: B. Azzarelli). Inst. Neurosci. & Inst. Microbiol. & Immunol., National Yang-Ming Med. Coll., Taipei, Taiwan, Republic of China.

The advent of hybridoma technique has paved the way that spectrum of powerful monoclonal antibodies (MAb) thus obtained would allow the identification of various glial-derived macromolecules of potential functional significance in glia-neuron interaction, glial differentiation and neoplastic transformation. Production of MAb against glia was carried out by the standard methodology. After preliminary specificity screening, one MAb, an IgG2a, kappa secretor was selected to further characterize its antigen, designated as GA-1. Basic polyacrylamide gel electrophoresis (PAGE)-Western blot revealed GA-1 as a single band (Rf=0.09) which may be further resolved into 2 subunits of molecular weight 200 and 78 kDa by SDS-PAGE and radioimmunoprecipitation under non-reducing conditions. Subcellular localization by immunocytochemistry revealed its cytoplasmic presence with a punctate pattern perinuclearly. While significant expression of GA-1 may be detected in two rat glioma and two glial cell lines derived from neonatal rat brain, no expression may be detected in various tissues and brain regions of adult normal rat (Sprague-Dawley). Nor can GA-1 be detected in 19 mammalian cell lines of different species and cell types. The above data suggest that GA-1 is a species (rat)-specific, cytoplasmic glial antigen. (Supported by R.O.C.-N.S.C. grant # B010-24)

232.7

GOMORI-POSITIVE PERIVENTRICULAR GLIA IN THE HUMAN BRAIN. H.M. Schipper, E.G. Stopa and T. Wheelock. Tufts Univ. Sch. of Med., Dept. of Endocrin. and Path., Boston, MA and Human Brain Tissue Resource Center, McLean Hosp., Belmont, MA.

A unique subpopulation of periventricular astrocytes has been described in amphibia and rodents. The cells contain thiol-rich cytoplasmic granules exhibiting an affinity for Gomori's chrome alum hematoxylin (CAHP) stain peroxidatic activity, and auto-fluorescence in the porphyrin range. In rodents, Gomori glia increase with age. Estrogen accelerates, and gonodectomy retards, age-related granule accumulation in the rodent female hypothalamus. Estrogen may stimulate peroxidase and porphyrin synthesis by these cells.

In the present study, sections of human diencephalon were serially stained with either DAB medium for peroxidase activity or CAHP. Topographically superimposable CAHP-and DAB-positive astrocytes were noted in the OVLT, anterior periventricular area, infundibular region, and capsule of the mammillary body. Female and aged brains appeared to contain greater numbers of these cells. The distribution and tinctorial properties of this human periventricular glial system suggest that these cells may be homologous to the Gomori-positive glia observed in lower vertebrates.

GLIA MATURATION FACTOR (GMF) REDUCES BEHAVIORAL DEFICITS AFTER CAUDATE NUCLEUS (CN) INJURY IN RATS. C.M. Palatucci, D. Charbonnier*, R. Lim# and D.G. Stein. Brain Research Lab., Clark Univ., Worc., MA 01610 #Dept. of Neurol., Univ. Iowa, Iowa City, IA 52242

GMF is an acidic protein derived from brain tissue (Lim and Miller, *Methods in Enzymology* 147 225-235 (1987)) of about 14 kDal. which has the ability to promote phenotypic expression of brain cells *in vitro*. It is chemically distinct from Nerve Growth Factor and Fibroblast Growth Factors. We now present the results of intracaudate injections of GMF in adult rats after electrolytic CN lesions.

Fifty adult male Sprague Dawley rats (about 70 days old at the time of surgery) were randomly assigned to one of five experimental groups (n=10/gp.). Sham rats (S) received superficial retraction of scalp tissue. All other rats received bilateral electrolytic lesions of the CN. Group B rats were then injected with 200 ng Bovine Serum Albumin (BSA) as control, H (high dose) rats with 200 ng GMF, M (middle dose) rats with 100 ng GMF and L (low dose) rats with 50 ng GMF. Both GMF and BSA were diluted in lactated Ringer's solution to 5 μL (2.5 μL/side), and BSA was used as the vehicle for the GMF. Three days after surgery all animals began testing on an active avoidance/spatial reversal task, ten trials/day for the following twenty days. One day after testing was completed, all animals were trans-cardially perfused by the Karnovsky's method.

A one-way ANOVA indicated a significant lesion effect, and H rats were indistinguishible from B rats on many behavioral measures. Importantly, on number of failures/reversal, L rats performed at sham level while all other lesioned groups were signifigantly worse than shams. Also, L rats were better than H and B rats on a number of other behavioral measures. These data are consistent with e.g. those of Kesslak et al. (*Exptl. Neurol.* 92, 377-390 (1986)) which indicate that exogenously administered substances which manifest their effects principally on glial cells are capable of promoting behavioral recovery. Cresyl violet staining and Glial Fibrillary Acidic Protein immunohistochemistry are underway and will be discussed.

232.9

Further Characterization of the Myelin-Like Membranes from Earthworms (Lumbricus terrestris L.) Pereyra*, P.M. and Roots, B.I. Univ. of Toronto.

Initial characterization of the myelin-like membranes from earthworm nerve cords by SDS-PAGE and immunoblotting showed that the composition of these membranes is substantially different from the structural component of vertebrate myelin (Pereyra and Roots, Neurochem. Res. in press (1988)).

Comparative studies were also undertaken using epifluorescent light microscopy to determine autofluorescence (due mostly to NAD(P)H and FAD's and tetracycline-metal interactions in myelin and myelin-like membranes (Pereyra and Roots, Brain Res., under rev.).

It became clear from these studies that the similarities between the myelin-like ensheathments of invertebrates and myelin, might derive their common structure as a result of similar underlying metabolic processes despite variations in their structural composition.

As a first step, this hypothesis is being tested by determining the activities of various Oxidoreductases and ATPases in earthworm giant axon preparations and purified myelin-like membranes. Also, the susceptibility of the autofluorescence to various uncouplers and ionophores is being used to determine the source of the redox potential in these membranes.

The result of these two approaches will be presented and discussed in relation to similar observations made on vertebrate myelin.

232.10

AUTOFLUORESCENT EXTRACELLULAR PRODUCTS OF GLIAL ACTIVATION FOLLOWING SENSORY AXON DEGENERATION ARE ELICITED TRANSNEURONALLY IN AN INSECT *ACHETA DOMESTICUS*. J.S. Edwards, P. Brunner, M.R. Meyer and S. Raj. Zoology Dept., Univ. of Wash., Seattle, WA 98195.

Sensory axons of insects degenerate rapidly when severed from their cell bodies. Ultrastructural changes which are evident at terminals within four hours, lead to the appearance of the well known subterminal osmiophilic degeneration figures used in mapping. As degeneration proceeds rapidly throughout the severed axon, glial cells are activated and extracellular material increases in lacunae left by collapsing axons. Activated glial cells contain extensive arrays of tubular structures associated with dense plaques and superficially similar to hemidesmosomes. Matrix material accumulates outside the plaques and appears to arise from them.

We report here a previously unrecognised response to sensory axon degeneration. Autofluorescent extracellular material appears distally in the severed cercal sensory nerve less than 2 days after axotomy and proceeds centripetally throughout the central projection, reaching a peak at 4-5 days and persisting for at least two weeks. We postulate that the autofluorescent material is a component of the extra cellular matrix described above. Autofluorescent material appears in the ipsilateral connective in layers surrounding giant interneurons. Its initiation must be signalled transneuronally and may reflect altered metabolic activity in giant interneurons that receive cercal sensory input. The autofluorescent glial product is currently being characterised.

EVIDENCE FOR ELECTROGENIC $Na^+/HCO3^-$ COTRANSPORT IN GLIAL CELLS OF MUDPUPPY (NECTURUS MACULOSUS).

M.L. Astion* and R.K. Orkand (SPON: I.D. Hentall) Institute of Neurobiology, University of Puerto Rico Medical Sciences Campus, Old San Juan, PR 00901.

In the presence of Ba^{++} (2-5 mM), the K^+ conductance of mudpuppy glial cells is blocked and other membrane permeabilities can be examined. We have used this fact to reveal a hyperpolarizing effect of HCO_3^- (Astion et al., Neurosci. Lett., 76:47, 1987). The experiments reported here investigate the mechanism of the HCO_3^- effect.

In experiments using microelectrodes and done in the presence of 2 mM Ba^{++} we found the following: 1)In low Na^+ solutions (12 mM, Na^+ replaced with N-methyl-D-glucamine), the hyperpolarizing effect of 10 mM HCO_3^- was reduced by about 80%., 2)SITS reduced the HCO_3^- effect by more than 50%., and 3)In the presence of HCO_3^-, reduction of Na^+ from 112 to 12 mM caused a depolarization which was much greater than that seen in HCO_3^--free solutions. These observations suggest the presence in the glial membrane of an electrogenic Na^+/HCO_3^- cotransporter in which the stoichiometry of HCO_3^- to Na^+ is greater than 1. Electrogenic Na^+/HCO_3^- cotransport has been described in a variety of tissues (e.g. Boron and Boulpaep, J. Gen. Physiol., 81:53, 1983), but to our knowledge, this is the first report of its presence in the vertebrate nervous system. Supported by NIH grants NSO7464, NS12253, GM 07170 (MSTP Univ. Pennsylvania), and RII8705802 (NSF).

232.12

A POSSIBLE MECHANISM FOR LONG TERM SURVIVAL OF SEVERED MEDIAL GIANT AXONS IN CRAYFISH.

R.A. Sheller, M.M. Curie*, M.E. Smevers*, S.L. Tanner*, and G.D. Bittner. Department of Zoology and Institute for Neurological Science, University of Texas, Austin, TX 78712.

A crayfish Medial Giant Axon (MGA) severed from its cell body remains morphologically and physiologically intact for 50-300 days. A possible mechanism for the long term survival (LTS) of an MGA is intercellular protein transfer from adaxonal glia to the MGA.

Large portions of a severed distal stump of an MGA or a nonsevered MGA can be microdissected from the ventral nerve cord (VNC), homogenized, and prepared for protein analysis by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). We also obtain diluted axoplasm from a severed distal stump or nonsevered MGA by perfusion of the axon with microcapillary pipettes. This "axoperfusate" is analyzed for protein content by SDS-PAGE. During the perfusion, the MGA is isolated from its own cell body and extracellular fluids in order to obtain only axonal protein. Similar protein bands (200-30 kD) are seen in axoperfusate samples from both severed and nonsevered MGA's. When labelled amino acids are placed in the bath surrounding the VNC, labelled protein can be collected in a 3-hour axoperfusate from severed and nonsevered MGA's. This indicates that there is another trophic source for the MGA other than its cell body. Protein synthesis, which might be responsible for the LTS of the MGA, could be occurring within other cells of the VNC which then transport proteins to the MGA. The adaxonal glia of the MGA are a likely candidate for an MGA trophic source because they are in close proximity to the axon, they have a specialized morphology which might allow for transfer, and they respond to the severence of the MGA by increasing in both size and number. Suppported by TATP grant from Texas.

232.13

LONG TERM SURVIVAL OF ENUCLEATED MAUTHNER AXONS

J.W.Moehlenbruck*, J.A.Blundon, and G.D.Bittner, Dept. of Zoology and Inst. for Neuroscience, Univ. of Texas, Austin

We have observed that severed distal segments of myelinated Mauthner axons (M-axons) in goldfish (Carassius auratus) survive morphologically and physiologically intact for 160-190 days at 10°C, 30-60 days at 20°C, and 20-30 days at 30°C. Cancalon (J.Cell Bio.97:6-14,1983) has reported that unmyelinated axons in garfish olfactory nerve show temperature dependent degeneration in a proximal to distal sequence. This degeneration proceeds at a rate equal to that of slow axonal transport, which is also temperature dependent.

We are now collecting detailed light and electron microscopical data on the possible existence of a proximo-distal sequence of degeneration of severed M-axons in animals kept at 10-30°C. In particular, we are examining whether the degenerative sequence involves a loss of integrity of cytoskeletal elements (e.g. neurofilament and microtubules), an increase in number of vacuoles and lysosomes, and alterations of the myelin sheath surrounding these axons.

We are also examining whether long term survival of severed M-axons might be due to axoplasmic protein synthesis or transfer of proteins from adjacent glia.

Supported by a TATP grant from Texas.

GLIOTOXIC ACTIVITY OF ACIDIC AMINO ACIDS.

B.J. Cummings*, R.J. Bridges, A. Kundi*, and C.W. Cotman. (SPON: D. Aswad) Depts of Psychobiology and Neurology, Univ. California, Irvine, CA 92717.

The gliotoxic action of L-α-aminoadipic acid has been known for several years. Little, however, is known about the mechanisms or pharmacological specificity of this toxic effect. In the present investigation we have identified several acidic amino acids that mimic the gliotoxic action of L-α-aminoadipic acid.

Primary cultures of astrocytes were prepared from four day old rat cortex and purified as described by McCarthy and de Vellis (J. Cell Biol., 85, 890, 1980). The cells were grown in Dulbeccos modified Eagle's medium and Ham's F12 (1:1) supplemented with 15 mM HEPES buffer and 10% fetal calf serum. Potential gliotoxic amino acids were included in the cultures with normal media and their effects on the astrocytes followed by phase contrast microscopy for 96 hours.

L-Homocysteic acid, L-cysteine sulfinic acid and serine- O-sulphate were found to exhibit the most potent gliotoxic action. Analogues that exhibited little or no activity included: D- α-aminoadipic acid, α-ketoglutarate, α-ketoadipate, kainate, NMDA, and serine-O-phosphate. Upon exposure to the gliotoxins, the astrocytes appeared to go through a series of morphological changes that eventually ended with massive cellular destruction. These changes, which included nuclear swelling and prominent nuclear rims and nucleoli, were suggestive of Alzheimer's type II astrocyte morphology. Interestingly, a number of compounds, including L-glutamate, appeared to initiate this sequence of events, but proved to be non-toxic, as the cells returned to an apparently more normal morphology without cellular degeneration. Supported by MH-19691 and the PEW Foundation.

ENDFEET OF RETINAL GLIAL (MULLER) CELLS HAVE A NON-RECTIFYING K+ CONDUCTANCE.

A.R. Maranto and E.A. Newman. Eye Research Institute, Boston, MA 02114.

Retinal Muller cells are almost exclusively permeable to K+. In amphibians, these cells shunt extracellular K+ produced during neuronal activity into the vitreous humor by having 95% of their K+ conductance in their endfoot processes which lie adjacent to the vitreous. To further characterize this nonuniform distribution of K+ conductance, we voltage-clamped intact and endfootless Muller cells from the salamander (*Ambystoma tigrinum*) with the whole-cell patch technique. Isolated cells were prepared by enzymatic dissociation and perfused with HEPES-buffered saline containing 80 mM K+. Current response amplitudes to 1 sec voltage steps from a -10 mV holding potential are shown (mean ± SD for n cells). Cells which have lost their endfeet (o, n=5) show less conductance and more inward rectification than do cells with endfeet (Δ,n=2). Subtracting current responses of endfootless cells from those of intact cells approximates the current-voltage (I-V) relationship for the endfoot conductance alone. The resulting nearly linear I-V relationship (●) indicates that the conductance of the endfoot is non-rectifying and may be mediated by a different type of K+ channel than those found elsewhere on the cell.

SEPARATE POPULATIONS OF ENDOGENOUS NON-NEURONAL CELLS PROLIFERATE AND DIFFERENTIATE IN ADULT EXPLANTS OF SENSORY GANGLIA,

C. M. Morshead, T. P. O'Connor, and D. van der Kooy. Neurobiology Research Group, Department of Anatomy, University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

An extensive gliotic response is elicited in adult rat trigeminal ganglia after axotomy and explant culture. The absence of blood-born cells in the culture enables us to study the response of endogenous non-neuronal cells within the structually intact trigeminal ganglia. Cellular responses to axotomy and culture may elucidate the lineages of the endogenous non-neuronal cells within sensory ganglia.

On the basis of biochemical and proliferative studies we observed four distinct populations of cells. (1) A small proliferative population of cells were found in both the fibre tract regions and neuronal cell body areas of the ganglia. These cells were vimentin (Vim)-'ve, glial fibrillary acidic protein (GFAP)-'ve, and S-100-'ve. (2) A small population of GFAP+'ve, Vim-'ve and S-100-'ve cells turned off GFAP synthesis or died after axotomy and culture. (3) A large S-100+'ve, GFAP-'ve, and Vim-'ve population did not alter protein synthesis in culture and (4) a subpopulation of S-100+'ve cells started to synthesize Vim in response to axotomy. This subpopulation is located within the neuronal cell body areas and thus the turn on of Vim may be due to a local cue from neuronal perikarya. These four subpopulations of peripheral non-neuronal cells appear to cut across the previous subdivisions of peripheral glial (satellite versus fiber tract cells or myelin versus non-myelin forming cells) that were based on descriptive morphological criteria in normal tissue. We suggest that the peripheral glial cell population may consist of at least four cell lineages.

A STAGE-SPECIFIC CELL SURFACE ANTIGEN OF SCHWANN CELLS, C4, IS ALSO EXPRESSED BY CELLS IN THE CENTRAL NERVOUS SYSTEM. Cornbrooks, C.J. and Neuberger, T.J., Dept. of Anat. and Neurobiol., Univ. of Vt., Burlington, Vt., 05405.

Schwann cell (Sc) differentiation, a necessary requirement for normal development and regeneration, is induced by extracellular cues. It is therefore hypothesized that molecules in the Sc plasmalemmae are required to mediate and promote normal interactions with neurons. Immunohistochemical methods were used to identify and localize a trypsin sensitive epitope, C4, associated with a 75kD protein located on the Sc membrane. During development, most if not all, Sc expressed the C4 antigen. As Sc differentiation ensued, C4 immunoreactivity began to segregate with a portion of the Sc. In the normal adult animal, the C4 antigen was expressed on the surface of ensheathing Sc, but not on the surface of myelinating Sc. When the normal nerve was transected, Sc associated with the injured axons in the distal stump ceased to express C4 on their surface. However, upon contact with regenerating axons, C4 was transiently associated with the Sc cytoskeleton and reappeared on the plasmalemmae of nonmyelinating Sc. In the normal CNS, the C4 antigen was associated with astrocytes in the optic nerve and tanicytes but not with the majority of glia in the parenchyma. Upon injury to the CNS, C4 is also expressed by reactive astrocytes that grew in and near the lesion cavity.

Current evidence suggests the C4 antigen is involved with Sc polarization; however, its function in the CNS remains unknown. Supported by PHS RO1 20189.

MORPHOLOGICAL STUDIES FOLLOWING KAINIC ACID INJECTION INTO THE RAT HIPPOCAMPUS. C.M. Severin, C.L. Bowman, D.J. McFarland, and J.W. Swann. (SPON: F. Sansone). School of Medicine, SUNY-Buffalo, Buffalo, NY 14214 and Wadsworth Center, NYS Department of Health, Albany, NY 12201.

The cytology of scar tissue was examined several months following injection of 4 nmol of kainic acid into the CA3 part of the dorsal region of the rat hippocampus. Gross observation showed considerale variation in the degree of damage. Two animals displayed a total unilateral loss of the hippocampus while in four others it was present but significantly reduced in size. In these animals, light and electron microscopic analyses confirmed an anisomorphic astrocytosis. Under light microscopy numerous spherical pale staining structures (1-3μm in diameter) with a dense central core were observed after staining with toluidine blue. A few large cells (10-20μm) with light or dark staining nuclei were scattered throughtout the scar. Electron microscopic examination showed the structures to be astrocytic processes while the cells were tentatively identified as reactive astrocytes. No neuronal cell bodies were present, but several neuronal processes were observed. In vitro electrophysiological studies of this preparation have shown inexcitable cells with large processes (Bowman et. al. The Biochemical Pathology of Astrocytes, pp. 135-136, 1988, Alan R. Liss, Inc.). The fimbrial area adjacent to the scar appeared normal.

EFFECTS OF POTASSIUM AND CALCIUM CHANNEL BLOCKERS ON THE PROLIFERATIVE RESPONSE OF EXPLANTED RAT OPTIC NERVES. Hsu, P.* and S.Y. Chiu. (SPON: P. H. Smith) Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Recent studies have shown that the proliferative response of explanted PNS rabbit sciatic nerves was inhibited *in vitro* by K channel blockers and that K channels in Schwann cells might be functionally important for proliferation. We have now extended these studies to the CNS. Undesheathed optic nerves from adult rats (5 and 12 weeks) were cut into 2 mm segments and placed in culture medium (DMEM+10%FBS). Proliferative response, as measured by scintillation counts of ^{3}H-thymidine incorporation in the segments, increased following explant, reached a peak at day 4 and declined afterwards. The proliferative response was virtually competely inhibited when K channel blockers (quinine, 0.35 mM; 4-AP, 9 mM; TEA, 10 mM) or Ca channel blocker (Cd, 0.03 mM) was present in the culture medium. Compared to TEA (10 mM), TMA (10 mM) produced no significant inhibition. Washing away the blockers after 2-4 days of treatment led to resumption of a normal proliferative response for TEA and 4-AP, but not for cadium or quinine. From the dose response curves for proliferation block measured after 4 days of treatment, the half-block concentrations are (mM): 0.0035 (Cd), 0.18 (quinine), 3.5 (4-AP) and 6.5 (TEA).

Since astrocytic proliferation presumably contributed to the proliferative response, one possible explanation is that K and Ca channels that are known to be present on astrocytes could be functionally important for proliferation.

Supported by NS-23375 (NIH), RG-1839 (National Multiple Sclerosis Society) and a PEW Scholar Award in Biomedical Sciences to S.Y.C.

232.20

A NOVEL MARKER FOR A SUBSET OF PRIMATE ASTROGLIA: IMMUNOCYTOCHEMICAL CHARACTERIZATION. C.T. McDonald and J.M. Allman. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

We have employed a modification of the immunosuppression protocol of Matthew and Patterson (CSHSQB, **XLVIII:** 625, 1983) to generate monoclonal antibody (mAb) markers against elements of the newborn and adult primate cerebral cortex. In our most recent fusion, newborn (P0) macaque striate cortex was used as the primary immunogen to generate a novel glial marker, mAb 13C3.

MAb 13C3 recognizes in newborn and adult macaque cerebral cortex an antigen associated with the membranes of astrocytes in the underlying white matter as well as cells and fibers in cortical layer 1. In the newborn macaque cortex, numerous transitional astrocytic cells can be seen in white matter, probably corresponding to a population first described by Schmechel and Rakic (Anat. Embryol., **152:** 115, 1979). Unlike anti-GFAP (Boehringer), mAb 13C3 does not appear to recognize the numerous astrocytes present within the cortical plate. MAb 13C3 does, however, stain a vimentin-positive, GFAP-negative population of lepto-meningeal cells and fibers. In the new born macaque cerebellum, Bergmann glia are positive for all three markers. MAb 13C3 stains GFAP-positive, vimentin-negative astrocytes in the underlying white matter in addition to a few scattered astrocytes in the granular layer.

A previous fusion, using adult macaque striate cortex as the primary immunogen, demonstrated the existence of an antigen (mAb 6F2) present only in glial fibers of layer 1 in the adult primate cerebral cortex (McDonald, C.T. *et al.*, Soc. Neurosci. Abstr., **12:** 131, 1986). A second population of fibers, closely apposed to a transient zone of germinal cells underlying striate cortex, is also recognized by mAb 6F2 in the infant (P7) marmoset monkey.

With specificity to a subset of astrocytes, mAb 13C3 further underscores the biochemical heterogeneity of primate neuroglia. MAb 13C3 may serve as a developmental probe to assay that subset of glial progenitors destined to become the astrocytes of layer 1 and the white matter of primate cerebral cortex.

Supported by NIH grants EY-03851, RR 07003, and 1 T32 GM 07737, and a Markey Foundation Grant in Developmental Biology (CIT).

TRANSPLANTATION: HIPPOCAMPUS

233.1

TRANSPLANTATION OF A HIPPOCAMPALLY-DERIVED, IMMORTAL, TEMPERATURE-SENSITIVE, NEURONAL CELL LINE INTO ADULT RAT CNS. S.R. Whittemore, V.R. Holets, M. Gonzalez-Carvajal* and D. Levy*. Dept. Neurological Surgery, Univ. Miami, Miami, FL 33136

Primary cultures of dissociated E18 hippocampus were infected with a retrovirus encoding the temperature-sensitive mutant of the SV40 large T antigen to generate an immortal cell line, HT4, which differentiates at non-permissive temperature (39 C) in vitro with neuronal phenotype and expresses neuron-specific surface antigens and nerve growth factor (NGF) mRNA (Levy et al., submitted).

HT4 cells, transplanted into a lesion cavity which interrupted the fimbria-fornix, either prelabelled with the vital dye DiI or identified by residual T antigen, were observed up to 8 weeks in vivo, the longest time examined. HT4 cells appear to differentiate, extending processes and are non-tumorigenic at rat body temperature.

In situ hybridization demonstrated that HT4 cells make NGF mRNA in vivo. Preliminary results suggest that transplanting HT4 cells, but not another similarly-derived cerebellar cell line, subsequent to unilateral fimbria-fornix transection, partially spare septal cholinergic neurons.

233.2

FETAL CA1 NEURONS GRAFTED TO ISCHEMIC LESIONS CONNECT WITH THE ADULT HOST HIPPOCAMPUS. J. Zimmer*, N. Tønder*, T. Sørensen* and F.F. Johansen* (Spon. M. West). PharmaBiotec Res. Cent., Institute of Neurobiology, University of Aarhus, DK-8000 Aarhus, Denmark.

Ischemic damage to the dorsal CA1 of adult rats was induced by transient four-vessel occlusion, followed one week later by grafting of a fetal, E19 CA1 cell suspension. After 6 weeks graft connections were examined by - a) retrograde axonal transport of Fluorogold injected into the ipsilateral host hippocampus and subiculum, - and b) EM of anterograde degeneration of host commissural fibers 3 days after contralateral fimbria transections.

About 80% of the grafts survived and had grown well in the lesioned area. By EM degenerating host commissural terminals were found even deep in the CA1 graft neuropil. The terminals made synaptic contacts with dendritic spines and shafts. Graft efferent projections to the ipsilateral host CA1 and subiculum were demonstrated by retrograde labelling of graft pyramidal cells after Fluorogold injections into these areas which normally are innervated by CA1. The presence of possible graft projections to the septum (normal) and the contralateral hippocampus (abnormal) are being examined.

We conclude that fetal CA1 neurons can exchange connections of normal type with the adult host brain after grafting to ischemic CA1 lesions.

233.3

A HUMAN NEUROFILAMENT TRANSGENE AS A GENOTYPE MARKER FOR MOUSE EMBRYONIC SEPTAL NEURONS TRANSPLANTED INTO ADULT RAT HIPPOCAMPUS. M. Vidal-Sanz*[1], M.P. Villegas-Pérez*[1], D.A. Carter*[1], I. Tretjakoff*[2], J.P. Julien*[3], A. Peterson[2] and A.J. Aguayo[1]. [1]Neuroscience Unit, The Montreal General Hospital and McGill University; [2]Ludwig Institute; [3]Institut du Cancer; Montreal, Quebec, Canada.

To identify the projections of neurons transplanted into the adult host CNS, we grafted embryonic septal cells from transgenic mice that express the neurofilament light gene (Julien et al. Genes Dev. 1:1085, 1987). After transecting the right fimbria-fornix in adult immunosuppressed rats we injected a septal cell suspension from E14-15 transgenic embryos into the right hippocampus using standard grafting techniques (Bjorklund et al. Acta Physiol. Scand. Suppl 522:49, 1983). After intervals of 3 weeks to 3 months, the host rats were investigated immunohistochemically with a monoclonal antibody that recognizes the transgene product (Julien et al. 1987).

Anti-human neurofilament immunoreactivity was observed exclusively in the transplanted neurons, primarily within fine neuronal processes and occasionally in neuronal somata. Our findings indicate that nerve cells from these transgenic mice express the human neurofilament light gene after transplantation. The visualization of neuronal processes obtained with this technique provides a promising tool for the identification of the projections originating from the grafted neurons.

233.4

SEPTAL CELL DEATH FOLLOWING FIMBRIA/FORNIX TRANSECTION, AND HIPPOCAMPAL CHOLINERGIC REGENERATION FOLLOWING NERVE GROWTH FACTOR INFUSION PLUS GRAFTING OF SYNTHETIC AND NEURONAL BRIDGES. M. H. Tuszynski, G. Buzsaki, G. Stearns* and F.H. Gage. Dept. Neurosci. M-024, UCSD School of Medicine, La Jolla, CA. 92093.

Following fimbria/fornix (F/F) transection in the rat, cholinergic neurons of the medial septum degenerate as measured by cholineacetyltransferase (ChAT), nerve growth factor-receptor (NGF-r)(courtesy E. Johnson), acetylcholinesterase (AChE) and Nissl stains, and extrinsic hippocampal (HC) cholinergic innervation is lost. NGF infusion will prevent septal cholinergic cell loss but will not restore HC innervation. To address whether loss of septal cellular staining might represent cell *dysfunction* rather than *death*, rats were injected with rhodamine fluorescent microspheres (FM's) that are retrogradely transported to the cellular cytoplasmic component, and are lost after cell disruption. 25 rats received unilateral FM injections followed 5 days later by either no lesion, unilateral, or bilateral F/F lesions, and sacrifice 4 weeks later. An additional group received bilateral F/F lesions plus 4 weeks of NGF infusion and placement of Matrigel "bridges" mixed with fetal HC neuronal grafts in an attempt to restore HC innervation. Compared to controls, animals that received either unilateral or bilateral F/F lesions showed extensive loss of FM's (87% and 93% respectively, $p<.01$), ChAT (82% and 76% respectively, $p<.01$), and NGF-r (75% and 68% respectively, $p<.01$). Thus, cells appear to die after F/F transection, and this correlates with ChAT and NGF-r loss. Some cells were double-labelled for FM's and NGF-r or ChAT after F/F lesions, indicating that some septal cells projecting to the HC derive NGF support from another source, or are not NGF-dependent despite possessing NGF receptors. Some animals with lesions followed by NGF and "bridges" regained AChE-positive HC fibers.

233.5

FETAL HIPPOCAMPAL CELL IMPLANTS ALLEVIATE A WORKING-MEMORY DEFICIT RESULTING FROM NMDA-INDUCED HIPPOCAMPAL PYRAMIDAL CELL LOSS. Yvonne Wilsdon[1], Pushpa Tandon[2], Ronnie L. McLamb[2], Richard A. King[1], Hugh A. Tilson.[2] [1]Dept. of Psychology, Univ. N. Carolina, Chapel Hill 27514. [2]Lab. Molec. Integrative Neurosci., NIEHS, Research Triangle Park, N.C. 27709.

Behavioral recovery of memory function after hippocampal lesions has been demonstrated using implants of fetal cells taken from locus coeruleus or medial septum, but little work has been done on memory recovery after implantation of fetal hippocampal cells.

Pyramidal cell lesions were made in both dorsal and ventral CA2/CA3 hippocampal areas of male Fischer 344 rats. Lesions were made with 10 µg. per site of N-methyl-D-aspartate (NMDA). Three weeks after lesioning, a suspension of cells obtained from 17-18 day old fetuses of the same rat strain were implanted into the site of the original lesion. A 2x2 design was used, in which rats received either NMDA or vehicle, and either implants or vehicle. Beginning a week after the implant, rats were trained in a standard T-maze forced-choice alternation paradigm for food reward. There was a 20-second delay between the forced trial, in which a block of wood in one randomly determined arm prevented entry, and the choice trial, in which subjects were reinforced for entering the arm not previously entered.

Subjects with a combination of pyramidal cell lesions and viable cell implants performed significantly better than those with lesions alone. Furthermore, the performance of the lesioned implanted animals did not differ significantly from unlesioned controls with or without fetal cell implants.

Following behavioral studies, subjects were transcardially perfused and brain slices were stained with cresyl violet and counterstained with luxol fast blue. Cells from the implant which stained normally were seen adjacent to the lesion site, either within the hippocampus proper or in a nearby area of the ventricle.

A MONOCLONAL ANTIBODY MARKER FOR IDENTIFICATION OF TRANSPLANTED RAT HIPPOCAMPAL CA3 PYRAMIDAL CELLS. (SPON: G. Raisman) P. L. Woodhams*, P. J. Seeley*, M. Webb**, & D. J. Atkinson*. Norman and Sadie Lee Research Centre, Nat. Inst. for Medical Research, London NW7 1AA, and *Sandoz Institute, London WC1E 6BN, U. K.

A monoclonal antibody was raised against glycoproteins isolated from 21 day old rat hippocampus using a lentil lectin column followed by an antibody affinity column to remove the immunogenic protein Thy-1. Hybridomas were first screened by ELISA and then by immunoperoxidase staining of frozen 21 day old rat forebrain. Antibodies from clone 11A4 strongly stained large pyramids in hippocampal field CA3, whilst small pyramids in CA1 and dentate granule cells were unstained in polyester wax sections. This specificity was retained during development, antigen becoming detectable on CA3 pyramids postnatally and increasing markedly during the second week. In mature grafts of sub-dissected embryonic hippocampal fragments transplanted to adult hippocampus antibody 11A4 provided a useful means of distinguishing the neuronal cell types present. The antigen was detected on western blots as a single band of apparent MW >200 kDa.

NON-SPECIFIC EFFECTS OF FETAL BRAIN GRAFTS ON RESTORATION OF A CHOLINERGIC EPSP IN HIPPOCAMPAL SLICES FROM FORNIX LESIONED RATS. W.D. Knowles and E. Korfali*. Cleveland Clinic Foundation, Cleveland, OH 44195 and Uludag University, Bursa, Turkey.

Ten to 16 days following fornix lesion, 6 "septal graft" rats received a graft of fetal septal tissue into the fornix lesion cavity. Three "cerebellar graft" rats received a graft of fetal cerebellar cortex. Ten to 27 weeks after the fornix lesion, cholinergic function was evaluated by the presence of a slow EPSP in intracellular recordings from CA1 pyramidal cells using in vitro hippocampal slices.

In 7 non-lesioned animals, 62% of 24 cells had the slow EPSP (2.4±1.5 mV amplitude; mean±S.D.). In a "lesion only" group (no graft), much fewer, 30% of 10 cells, had the slow EPSP (1.2±0.3 mV). In the "septal graft" group, there was a large increase in the number, 86% of 7 cells, that had the slow EPSP (2.0±2.0 mV). This increase was also seen in the "cerebellar graft" group in which 80% of 5 cells had the slow EPSP (2.7±1.0 mV).

Thus, grafts of both septal and cerebellar tissue produced an increase in slow EPSPs in the hippocampus of fornix lesioned rats. We conclude that the grafts had nonspecific enhancing effects, possibly on the sprouting and reinnervation by host cholinergic fibers.

VIABILITY OF GABAERGIC STRIATAL NEURONS GRAFTED INTO NORMAL HIPPOCAMPUS. P.A. Schwartzkroin and D.D. Kunkel. Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

The transplantation of neuronal populations from fetal central nervous system to mature host brain has become a well accepted technique in neurobiology. In most studies, successful grafting is carried out against the background of a lesioned or damaged host CNS. However, it is not always clear that gross morphological changes underlie, or accompany, neurological deficits (e.g., in many models of epileptiform activity). We have been interested in the possibility of using transplanted inhibitory neurons (i.e., cells that contain GABA) to modulate CNS hyperexcitability, and have previously shown that GABAergic striatal cells can be successfully grafted into the hippocampus of rats treated with the epileptogenic agent, kainic acid. It is unclear, however, if graft maintenance in this environment is dependent on the effects of the kainate-induced lesion. We now report that striatal cells transplanted into normal hippocampus (with no lesion) also survive and maintain GABA expression (as seen with GABA and GAD immunocytochemistry). As was the case in kainate-lesioned animals, however, the cells of the striatal graft appear to cluster in a well-circumscribed area (often at the ventral border of hippocampus). GABAergic fibers and terminals from the graft also appear to be maintained within the confines of the graft, and do not extend significantly into host hippocampal regions. Studies are currently underway to assay the electrophysiological effects of graft stimulation on host excitability.

These studies are supported by a Klingenstein Foundation Fellowship (P.A.S.).

ALTERATIONS IN MUSCARINIC BINDING IN RAT HIPPOCAMPUS PROVIDES EVIDENCE FOR FUNCTIONAL REINNERVATION OF FIMBRIA-FORNIX LESIONS BY FETAL SEPTAL TRANSPLANTS. V.L. Dawson, F.H. Gage[1], and J.K. Wamsley. Depts. of Pharm. and Psych. Univ. of Utah Sch. of Med., Salt Lake City, UT. 84132, Dept. of Neuroscience, UCSD, La Jolla, CA. 92093

A unilateral fimbria-fornix lesion by micropunch was performed on male Sprague-Dawley rats, half of which received fetal septal transplants. Control rats had sham operations. After six months the animals were prepared for study. Acetylcholinesterase staining in the hippocampus of lesioned animals was absent, but staining was present in control levels in animals with transplants. Muscarinic receptors labeled with [^{3}H]-QNB showed up-regulation in areas CA2 and CA3 of stratum oriens and radiatum, and the dentate gyrus in animals with lesions. The receptor up-regulation was determined to be of the M1 subtype in stratum radiatum of areas CA2 and CA3 and area CA3 stratum oriens, and of the M2 subtype in stratum oriens of areas CA2 and CA3 through the use of [^{3}H]-pirenzepine (PZ) and [^{3}H]-QNB + 100nM PZ respectively. In transplant animals the density of muscarinic receptors was present at control levels. In lesioned animals the density of [^{3}H] hemicholinium-3 binding was below background levels. The binding in transplant animals was present at control values in the dentate gyrus molecular layer, the strata oriens and radiatum. These data indicate the transplants are providing a source of cholinergic activity.

RESTORATION OF EXTRAHIPPOCAMPAL PROJECTIONS BY HIPPOCAMPAL NEURONS TRANSPLANTED INTO THE ISCHEMICALLY LESIONED HIPPOCAMPUS. L.A. Mudrick & K.G. Baimbridge. Dept. of Physiology, University of British Columbia, Vancouver, B.C., V6T 1W5.

Immature neuronal tissue may have the capacity to repair acute lesions in the CA1 region of the *adult* rat hippocampal formation (HF). Electrophysiological analyses have shown that afferent synaptic contacts and efferent projections, within the HF, can be reinstated by the transplanted neurons. We have now examined the ability of the transplanted neurons to project neurites along the normal efferent pathway to the lateral septal nucleus (LSN): the chief extra-hippocampal target for HF pyramidal cells.

Severe forebrain ischemia was used to lesion the dorsal CA1 region of the HF. One week later this region was repopulated with suspensions of 18 day old fetal hippocampal tissue. After 6-14 months Fluoro-gold (FG) was pressure injected into the dorsomedial area of the LSN. Following an 8-10 day survival period the brain tissue was fixed and 30*um* cryostat sections were made. Retrogradely transported FG could be observed in transplanted neurons up to 4.0mm caudal to the injection site. The number of labelled cells decreased from 85% to <10% in a rostro-caudal direction. In animals where neurons had been transplanted too deeply, few FG positive neurons were observed.

Guidance for the neurite projections from the transplanted neurons to extrahippocampal targets may be provided by the release of neurite promoting factors along degenerating CA1 efferent pathways. The target specificity of these projections are now being investigated by electrophysiological and anterograde tracing techniques.(Supported by the B.C. Heart Foundation and an MRC Program Grant)

CONNECTION SPECIFICITY BETWEEN HOST HIPPOCAMPUS AND GRAFTED SEPTAL NEURONS. O.G. Nilsson*, D.J. Clarke*, P. Brundin* and A. Björklund (SPON: G. Doucet). Dept. of Medical Cell Research, Univ. of Lund, Biskopsg. 5, S-223 62 Lund, Sweden.

To understand the basis for the effects mediated by intracerebral neural grafts, it is important to have an idea about the specificity by which host areas are innervated by the graft and to what extent different neuronal elements in the graft and host can establish connections. The present experiments were performed in order to study (1) the specificity by which cholinergic grafts of different origins reinnervate the denervated hippocampus, and (2) the afferent and efferent connections made between a septal graft and the host hippocampus. Cholinergic rich tissue from the septum, nc basalis, striatum, brain stem and spinal cord was grafted into the cholinergically denervated hippocampus. Three to 4 months after transplantation the brains were analyzed using acetylcholinesterase (AChE) histochemistry and immunocytochemistry, and the septal grafted rats were in addition injected with neuronal tracers. There were great differences between the graft types in the degree and lamination of the AChE-positive reinnervation of the hippocampus, and in the ability to form synaptic contacts with host neurons. The septal grafts produced the most normal connections, whereas the grafts of brain stem and spinal cord origin were most abnormal. In the tracing experiment we combined retrograde tracing with immunocytochemistry and preliminary observations show that not only cholinergic cells innervate the hippocampus, but that also at least substance P-positive cells do. More results from the tracing experiments will be presented.

CYTOSKELETON AND AXONAL TRANSPORT II

234.1

CHARACTERIZATION OF A MICROTUBULE-ASSOCIATED COFACTOR INDEPENDENT PROTEIN KINASE. Clay W Scott*, Claudia B. Caputo* & Andre I. Salama. (SPON: R. Krell) Pharmacology Dept., ICI Pharmaceuticals Group, Wilmington, DE 19897.

We have identified a cofactor independent protein kinase which copurifies with microtubules (MT) through repetitive cycles of MT assembly/disassembly. The MT-associated protein kinase (MTAK) from pig brain was not stimulated by cyclic nucleotides, polyamines, Ca2+/calmodulin, or Ca2+/phospholipids. MTAK activity was unaffected by a synthetic peptide inhibitor of cAMP-dependent protein kinase (cADPK), suggesting that MTAK is not the active catalytic subunit of cADPK. MTAK phosphorylates various MT-associated proteins and can be inhibited with trifluoperazine (IC_{50} = 300 µM) in a Ca2+-independent fashion. MTAK was maximally active with 3.0 mM MgCl2, showed a broad pH maxima from 6.4 to 8.4 and had a Km for ATP of 18 µM. Histone IIIS was a suitable exogenous substrate for MTAK (Km = 0.3 mg/ml), while synapsin I, tubulin, neurofilaments, histone IIA and VIIIS, casein, phosvitin and glycogen synthase were not phosphate acceptors. MTAK did not phosphorylate synthetic peptides which are substrates for cADPK, cGMP-dependent protein kinase, smooth muscle myosin light chain kinase, or protein kinase C. Together, these data confirm that MTAK has a substrate specificity which is distinct from the known cofactor-dependent kinases and casein kinases. MTAK is a unique protein kinase which copurifies with microtubule structures.

234.2

AN UNIQUE EPITOPE MEDIATING THE ATTACHMENT OF ASSOCIATED MOTOR MOLECULES TO MICROTUBULES MAPS TO THE ß-SUBUNIT OF THE TUBULIN HETERODIMER. M.Goldsmith, L.A.Connolly, N.Kumar* and D.van der Kooy, Dept. of Anatomy, University of Toronto, Toronto (Ontario), Canada, M5S 1A8.

Microtubule based, ATP-dependent motility systems include the dynein ATPase of cilia and flagella and vesicle transporters in neurons. We asked if homologous stuctural elements underlie the motility in these different microtubule based systems. Previous experiments showed that the unique antitubulin sera, NS20, could inhibit axonal transport in vivo and in vitro. Furthermore, we have shown that NS20 inhibits motility in demembranated sea urchin sperm whereas a control antiserum against tubulin, PC13, does not. Western blot analysis with NS20 revealed only reactivity against tubulin in whole brain, twice cycled tubulin, and crude dynein (provided by Dr.I.Gibbons) preps. Moreover, radioimmunoassays confirmed that the intriguing functional effects of NS20 relative to PC13 did not result from differences in the overall antitubulin activity of the two sera. We now report that preincubation of NS20 with recombinant beta, but not alpha, tubulin (provided by Drs.K.Yarbrough and J.Wu) abrogates the inhibitory effect of the antiserum in the sperm motility assay. As this tubulin is expressed in E.Coli (and thus completely devoid of microtubule associated proteins), an IgG activity against an epitope of ß-tubulin must account for the biological effect of the NS20 antiserum.We propose that this unique epitope of ß-tubulin mediates the attachment of tubulin associated motors. Moreover, the results suggest a fundamental structural homology in the microtubule based mechanisms underlying sperm motility and axonal transport.

234.3

ROLE OF EXTRACELLULAR Ca^{++} IN NORMAL AND PARATHYROID HORMONE STIMULATED FAST AXONAL TRANSPORT. A.C. Breuer, M.B. Atkinson* and C.M. Ferrario. Depts. of Neurology and Brain and Vascular Research, Cleveland Clinic Foundation, Cleveland, OH 44195

Parathyroid Hormone (PTH - rat, synthetic fragment 1-34) has previously been demonstrated to increase the rate of fast axonal transport (FAT) both in the anterograde (ANTERO) and retrograde (RETRO) directions (Breuer, A.C. & Atkinson, M.A., Soc. for Neuroscience Abs, 13 (Part 1):123, 1987). The intracellular mediator of this effect is of great interest as a potential regulator of axonal transport speeds. Ca^{++} has been implicated in the PTH response (Breuer, A.C. & Atkinson, M.A., Ann Neurol, 1988, in press) and the current study further explores the validity of this hypothesis.

Axonal preparations from male, Spraque-Dawley rats were treated with PTH in normal (with Ca^{++}) or Ca^{++} free buffer (+ 1 mM EGTA) and video-recorded under DIC optics for later analysis by computer methods. ANTERO and RETRO FAT speeds were decreased by 31.1 ± 2.5% ($p < 0.001$) and 14.3 ± 1.6% ($p < 0.001$) respectively in Ca^{++} free buffer (controls in normal buffer). PTH in normal buffer increased ANTERO FAT by 13.0 ± 2.5% ($p < 0.05$) and RETRO FAT by 18.0 ± 1.1% ($p < 0.001$) (controls in normal buffer). PTH in Ca^{++} free buffer failed to increase either ANTERO or RETRO FAT (controls in Ca^{++} free buffer). These results substantiate the importance of Ca^{++} as an intracellular mediator of transport speed alterations and its potential role in regulating fast axonal transport speeds in mammalian axons.

IDENTIFICATION OF A PHOSPHORYLATION SITE IN THE 68 KD NEUROFILAMENT POLYPEPTIDE L. Zuo-Shang Xu* and Mark Willard, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

Each of the three polypeptides, H, M, and L that compose neurofilaments, is phosphorylated at multiple sites. The average phosphate content of the L polypeptide from rat has been estimated to be 3 moles per mole of L (Julien, J.-P., & Mushynski, W. E., J. Biol. Chem. 257:1046, 1982). We have identified one site on the L polypeptide that is phosphorylated in vitro by an endogenous protein kinase activity. Rat spinal cord was extracted with Triton X-100, and the insoluble material was incubated with 32P-ATP to label substrates of endogenous protein kinases. L was separated from other proteins by HPLC, first on a DEAE matrix, and then on a reverse phase C-4 matrix. The purified L was digested sequentially with trypsin and S. aureus V8 protease. The resulting peptides were separated by HPLC on a reverse phase C-18 matrix. One peak contained approximately 40% of the total eluted radioactivity - four times more than the next largest radioactive peak. This peak contained two peptides of overlapping sequences: AKDEPPSEGE and DEPPSEGE. We conclude that the serine in these peptides, which is located sixty seven amino acids from the carboxy terminal end of the reported mouse L sequence (Julien, J.-P. et al., Mol. Brain Res. 1:243, 1986), is the major phosphorylation site for the endogenous kinase activity in this preparation.

A CELL CULTURE MODEL FOR VIRUS-HOST CELL TARGETING AND FUSION SJ Morris(1,2)*, DP Sarkar(2)*, JM White(3)*, JJ Zimmerberg(4)*, O Eidelman(2)* and R Blumenthal(2)* (SPON: BM Chronwall). (1)Div. of Mol. Biol. and Biochem., School of Basic Life Sciences, Univ. of Missouri at Kansas City, MO. 64110; (2)Sect. on Membrane Structure and Function, LTB, NCI and (3)Sect on Biol. Physics, LBM, NIDDK, NIH, Bethesda, MD, 20892; (4)Dept of Pharm. and Cell Biol. Program, Univ. of California San Francisco, CA, 94143-0450.

Most envelope viruses invade by attachment to cell surface receptors followed by fusion to the host membrane, either at neutral pH (eg, Sendai virus), or at low pH in an endocytic vesicle (eg, influenza virus). Fusion is catalysed by viral spike glycoproteins, the hemagglutinin (HA) of influenza being the best-characterized.

3T3 fibroblasts were transfected to express HA on their extraplasmic cell surface. Human red blood cells (RBC) were labelled either with a fluorescent rhodamine membrane probe, a soluble fluorescent NBD probe, or both. After attachment of the RBC to the 3T3, fusion was monitored by spectrofluorometry as dequenching of the probe(s). Upon lowering the pH below 5.4, the fluorescence increased after a delay of about 30 s at 37°C, and leveled off within 2 min. In control experiments where RBCs bound to 3T3 cells expressing the uncleaved precursor hemagglutinin (HAo) were incubated at 37°C and low pH, no fluorescence increase was observed, indicating that dequenching occurred as a result of HA-induced fusion of plasma membranes. Fusion showed a very steep pH-dependence with a threshold at pH 5.4, similar to that for HA-induced fusion seen previously. The fusion rate increased and the delay for the onset of fusion decreased as the temperature was raised above 20 °C. The delay had a breakpoint at about 27 °C. Low pH-activation of the fusion process at 37°C could be partially arrested by raising the pH after 2-10 s, but not after 15 s, indicating that the irreversible pH-activated conformational change of HA necessary for fusion was complete within about 15 s. Hill analysis of the data indicates that the pH-induced membrane fusion activity of HA is a highly cooperative event, similar to calcium dependence of neurotransmitter exocytosis.

Fusion also could be seen by fluorescence microscopy. Image-enhanced fluroescence videomicroscopy has allowed time resolution of single fusion events, which are amenable to stochastic modelling. A video tape demonstration of the technique will be presented.

234.6

NEUROFILAMENT SPACING AND CROSS-LINKING INTERACTIONS. G. Shaw*, T. McCabe, H. Zhao-Chen and J. Harris. (SPON. G. Freund). Department of Neuroscience, JHMHC Box J-244, Gainesville, Florida, 32610.

We have recently developed a simple method for the extraction of neurofilamentous cytoskeletons from mammalian peripheral nerve and spinal cord. Our experiments show that this material forms well defined bundles, each bundle apparently consisting of the neurofilamentous complement of one axon. This finding also points to the existence of a physiologically stable neurofilament bundle forming interaction. We have examined the stability of these bundles to a variety of agents, such as extremes of pH and salt concentration. Bundles of neurofilaments are extremely resistant to these treatments. We could find no evidence for a breakdown of neurofilaments to single filaments prior to solubilization of the neurofilament bundles. We conclude that the interaction which holds neurofilaments into bundles, possibly localized in the neurofilament "tail" domains, is an extremely strong one, and seems to be comparable in strength to the interaction that holds individual neurofilament subunits into neurofilaments. Enzymatic dephosphorylation does not result in breakdown of the neurofilament bundles. The spacing of filaments in bundles can be altered by changes in salt concentration in a manner suggesting that filament spacing is the result of an electrostatic repulsion phenomena. We are currently looking at fusion proteins coded for by cDNA sequences specifying neurofilament tail sequences to try to localize the regions responsible for neurofilament spacing and cross-linking.

234.7

VIRAL COAT AND LIPOSOMAL INFUSION AND BINDING TO PRIMARY NEURONAL CULTURES AND SYNAPTOSOMES FROM RAT BRAIN. E.M. Meyer, S. MacKay*, D.H. Otero*, J.H. Judkins*, D. Bottiglieri*, and M.-T.T. Nguyen*. Department of Pharmacology, U.Florida, Gainesville, 32610.

The introduction or infusion of large or charged macromolecules into neurons, with or without selectivity, remains one of the obstacles in studying intracellular processes and modulating neurotransmission presynaptically. We therefore began two lines of study to develop this capability in vitro, each with the potential to introduce substances selectively into selected neuron-types.

The first involved liposomes consisting of 95% dipalmitoylphosphatidylcholine and 5% phosphatidylethanolamine. Although these liposomes were found to infuse calcium ions into cholinergic synaptosomes at high concentrations and to encapsulate significant amounts of a large enzyme, acetylcholinesterase, we were only able to demonstrate modest infusion of this enzyme into nerve terminals or neuronal cultures. Attachment of an antibody against the NGF receptor (generously provided by Dr. Eugene Johnson) increased binding to synaptosomes at low liposome concentrations but did not appear to increase infusion of the enzyme into cholinergic terminals.

We therefore recently turned to Sendai viral coats, which are devoid of indigenous nucleotides and which we find to be very potent with respect to infusing substances into cholinergic, GABAergic, and noradrenergic terminals.

234.8

ARREST OF ORGANELLE TRANSPORT IN AXONS REGENERATING IN VITRO BY SIALIC ACID-SPECIFIC LECTINS IS REVERSED BY CYTOCHALASIN D. B. Edmonds* and E. Koenig. Dept. of Physiology, State Univ. of New York, Buffalo, NY 14214.

Goldfish retinal ganglion cell (RGC) axons regenerating in vitro contain several classes of organelles and aggregate structures (e.g., varicosities) that undergo translocation, as viewed by videomicroscopy. Lectins, which bind sialic acid residues, partially or completely inhibit transport. Wheat germ agglutinin (WGA; 300 ug/ul), not specific of sialic acid, maximally reduces organelle transport frequency by 60-70%, while Limax Flavus agglutinin (LFA; 100 ug/ul), specific for sialic acid, arrests transport completely. Sialic acid included with the lectin blocks lectin-induced arrest or it reverses it after it is induced. Focal application of LFA to a single varicosity blocks all transport reversibly. Pretreatment with cytochalasin D (CD; 10 uM) blocks LFA-induced arrest of transport. CD also reverses the arrest after it is induced. FITC-phalloidin labels F-actin in the cortex of varicosities and in intervening segments after LFA binding, and CD pretreatment prevents the labeling. The results indicate that the arrest of transport caused by an apparent cross-linking of an axonal surface sialoglycoconjugate may involve a polymerization and/or reorganization of axoplasmic actin. Supported by NIH grant NS21843.

234.9

MOLECULAR CLONING OF RAT OLFACTORY NEURON-SPECIFIC cDNAs BY DIFFERENTIAL SCREENING. E. Barbosa*, B. Paven§*, and R.R. Reed§* (SPON: D.L. Price). Neuropathology Lab. and §Howard Hughes Med. Lab. of Genetics, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

Unlike other neuronal tissue, the vertebrate olfactory neuroepithelium retains the capacity to form functional neurons from residing stem cells throughout adult life. Pulse labeling of animals with [^{3}H] thymidine following unilateral bulbectomy led to uptake in stem cells with their subsequent division, migration, and differentiation into typical bipolar neurons. In an effort to identify and characterize genes that are neuron specific and developmentally regulated, a normal rat olfactory cDNA library was prepared in λgt-10. Replicate plaque lifts of this cDNA library were probed with [^{32}P] cDNA prepared from polyA+ RNA from either untreated animals or animals eight days following bulbectomy (time of maximal neuronal cell loss). In this manner, we have identified several olfactory neuron-specific cDNAs as well as a cDNA common to both olfactory and brain neurons. We will describe the characterization of a neuron-specific cDNA that is regulated developmentally and present both in olfactory and brain neurons. Finally, by differential screening, libraries made at times of division, migration, and differentiation may provide a source in which to identify cDNAs that are essential to processes of neuronal differentiation in mammals.

234.10

EVIDENCE THAT PROTEINS OF THE SYNAPTIC MEMBRANE ARE SYNTHESIZED LOCALLY WITHIN DENDRITES: STUDIES OF SYNAPTOSOMAL PROTEIN SYNTHESIS. A. Rao*, E. R. Torre* and O. Steward, Dept of Neuroscience, Univ. of VA., Charlottesville, VA., 22908.

Recent studies have revealed that protein synthetic machinery (polyribosomes and associated membranous organelles) is selectively localized beneath postsynaptic sites on CNS neurons. This machinery is particularly prominent during periods of synaptogenesis, suggesting that it may synthesize constituents of the postsynaptic membrane specialization. The present study evaluated this hypothesis by determining whether proteins synthesized in synaptosome preparations (containing pre and postsynaptic components and contaminant mitochondria) are synaptic plasma membrane proteins.

Synaptosomes were isolated from developing (10-20d) rat forebrain. Comparision of protein synthesis in the presence of cycloheximide (CHX), chloramphenicol (CAP) or RNase confirmed previous studies showing that approximately 70-80% of the synthetic activity was due to a eucaryotic membrane-sequestered component. Labelled synaptosomes were fractionated into total membrane, synaptic plasma membrane (SPM) and synaptic junctional complex (SJC) preparations and subjected to SDS-PAGE and fluorography. In total membrane preparations, 12 labelled bands were apparent, 4 of which were faintly labelled. Labelling of 8 of these bands was CHX-sensitive and CAP-insensitive. In SPM fractions 10 labelled bands remained and two minor CAP-sensitive bands were no longer apparent. In SJC preparations only 9 of these bands were seen, among which the single remaining CAP-sensitive protein was very faintly labelled. These results are consistent with the hypothesis that certain proteins of the synaptic junction are locally synthesized. Supported by NIH NS12333.

234.11

LOCAL PROTEIN SYNTHESIS WITHIN DENDRITES OF CULTURED HIPPOCAMPAL NEURONS. L. Davis, G.A. Banker[1], and O. Steward. Dept. of Neuroscience and the Neuroscience Program, Univ. of VA, Charlottesville, VA 22908. [1]Dept. of Anatomy, Albany Medical College, Albany, NY, 12208.

Previous studies have demonstrated that polyribosomes, consisting of mRNA and ribosomes, are selectively localized in the cytoplasm beneath postsynaptic sites on CNS neurons (Steward and Levy, (1982) J. Neurosci. 2; 284-291). To determine whether dendritic polyribosomes are translation-competent we pulse-labeled low density cultures of hippocampal neurons with ^{3}H-leucine (125uCi/ml) for 10, 30, 60, or 90 minutes prior to fixation and processing for autoradiography. Radiolabeling at the 10 minute interval will reveal the extent of protein synthesis at particular sites, since 10 minutes is too short a time for there to be significant transport of recently synthesized protein from the site of synthesis. The pattern of labeling at longer intervals will reveal the transport of newly synthesized proteins.

Cultures prepared after a 10 minute pulse exhibited heavy labeling over cell bodies, and substantial labeling of dendrites. Axons were unlabeled. There was no labeling when the cultures were pulse-labeled with ^{3}H-leucine in the presence of puromycin (10^{-5}M), a protein synthesis inhibitor. This indicates that the labeling reflects protein synthesis and not uptake and/or binding of the precursor. At later time points dendritic labeling increased and radiolabel first appeared over axons extending several hundred micrometers from the cell body. This suggests that recently synthesized proteins are transported into axons only after a delay. Taken together, these results indicate that dendrites, like somata, contain functional protein synthetic machinery. Supported by NIH NS23094 to GB and OS. LD was the recipient of a predoctoral fellowship from NIH NS07199.

234.12

MICROTUBULE POLARITY IS UNIFORM IN THE AXONS BUT MIXED IN THE DENDRITES OF HIPPOCAMPAL NEURONS IN VITRO. J.S. Deitch, P.W. Baas*, M.M. Black*, and G.A. Banker. Dept. of Anatomy, Albany Med. Coll., Albany, NY, 12208 and Dept. of Anatomy, Temple Univ. Sch. of Med., Philadelphia, PA 19140.

We have compared the polarity orientation of microtubules in the axons and dendrites of rat hippocampal neurons growing in vitro. Microtubules are polar structures—subunits are preferentially added to the [+] end and lost from the [-] end. In many non-neuronal cell types the [-] end is stabilized by association with a microtubule organizing center (MTOC). Microtubule polarity was assayed by determining the orientation of hooks formed on the microtubules by polymerization of exogenous tubulin.

Axonal microtubules were uniformly oriented, with their [+] ends pointing toward the tip (95 ± 8%; $\bar{x}$ ± s.d.), as reported for axons of other neurons. In the dendrites, however, nearly half of the microtubules (43 ± 6%) were oriented with [+] ends pointing toward the soma. Microtubules of opposite polarities were interspersed within the dendrites. At the tip of the dendrite the microtubules were uniform in polarity, their [+] ends pointing distally. No MTOC was identified for microtubules of either polarity.

These results show a fundamental difference between axons and dendrites in the organization of their microtubules; this difference may form the basis for differential sorting and transport in axons and dendrites.

234.13

ISOLATION AND CHARACTERIZATION OF FAST AXONALLY TRANSPORTED PROTEINS: AN IMMUNOCHEMICAL APPROACH. R.L. Rotundo, D.L. Wilson and G.W. Perry. University of Miami School of Medicine, Miami, Florida.

Due to their low abundance in nerves, fast axonally transported proteins (FTPs) remain a difficult family of proteins to isolate, identify and characterize. Consequently, the functions of the vast majority of FTPs, as well as the molecular mechanisms underlying their sorting and localization remain unknown. Acetylcholinesterase (AChE), one of the most thoroughly studied FTPs, is packaged together with other FTPs into vesicles for transport along the axon. We have now developed a method based on the AChE density-shift technique of Porter-Jordan et al. (J. Neurosci. 6:3112, 1986) to prepare enriched fractions of FTP-containing vesicles from frog sciatic nerve. Monoclonal antibodies generated against this fraction recognize two general classes of antigens. The first, designated ECM antibodies, recognize antigens associated with the Schwann cell extracellular matrix and/ or nerve sheaths. The second class of antibodies recognizes antigens localized within the axoplasm or on the axonal plasma membrane. These antigens can be metabolically labelled with 35S-methionine and are rapidly transported along the axons of organ-cultured dorsal root ganglia. Eight monoclonal antibodies recognizing ECM and FTP antigens were chosen for initial characterization. Immunofluorescence localization studies show that all eight antibodies recognize epitopes surrounding or associated with motor and sensory fibres in the sciatic nerve. In addition, a few of the antibodies also recognize epitopes in the frogs optic nerve. The presence of the FTP antigens along both branches of the dorsal root ganglia processes shows they are not transported specifically in either branch.

Supported by grants from the NIH to RLR, DLW and GWP, and The National Parkinson Foundation to GWP.

ELECTRICAL STIMULATION OF DORSAL ROOT GANGLIA INHIBITS FAST AXONAL TRANSPORT. R. Hammerschlag, J. Bobinski*, D. McKenna* and D. McAfee. Div. of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte CA 91010 and Dept. of Pharmacology, Nelson Res. Ctr., Univ. California, Irvine CA 92715.

Fast axonal transport of newly-synthesized protein was examined *in vitro* using bullfrog dorsal root ganglia (DRG) with roots and nerves attached. This preparation was placed in a compartmentalized chamber permitting selective pulse-labeling of DRG ([3H]leucine, 1 h) and subsequent washing with medium containing the protein synthesis inhibitor, cycloheximide. The spinal nerve or DRG was then supramaximally stimulated (0.1-10Hz) through suction electrodes for 1-4 h. The contralateral nerve or ganglion served as a sham stimulated control. Stimulation produced a frequency dependent decrease in the amount of acid-insoluble radioactivity detected after 16 h at a nerve ligature 20 mm from the DRG. Stimulation of the nerve inhibited transport by 23% (10Hz/4h), while stimulation of the DRG inhibited transport by 62% (10Hz/1h) or 38% (1Hz/1h). The effects of stimulation were inhibited by TTX and were not mimicked by incubation of DRG in 50 mM K+. Stimulation reduced the amount but not the rate of transported protein in non-ligated nerves. We hypothesize that afferent stimulation may alter the amount of protein that is "loaded" onto the axonal transport system. Supported by BNS 8417380 and NS 22470.

BETA-TUBULIN AND SEVERAL INTERMEDIATE FILAMENT PROTEINS SHARE A COMMON EPITOPE IDENTIFIED BY MONOCLONAL ANTIBODY G6. C.E.Miller and V.M.Ingram. Dept. of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139.

Microtubules and intermediate filaments are two of three major components of the neuronal cytoskeleton.

Monoclonal antibodies G6 and G2 were raised against a growth cone preparation from embryonic rat brain. They recognize several proteins in a Triton-X100-insoluble rat brain extract. These include the smallest neurofilament protein, NF68, a 66kD protein, vimentin and GFAP. This cross-reactivity may reflect recognition of an epitope within the α-helical rod region conserved among these intermediate filament proteins. Interestingly, neurofilament proteins NF150 and NF200, which also contain the rod region, are not recognized by either antibody. G6 also recognizes a soluble 53kD protein, beta-tubulin. G6 recognizes four mouse beta-tubulin isotypes expressed from cDNA clones(JCB 101:852,1985) in E. coli. Immunocytochemical staining patterns are consistent with immunoblot results.

G6 and G2 recognize NF68 protein expressed from a cDNA which lacks only the first 22 amino acids of NF68(Mol.Cell Biol.6:1529,1986). We are precisely mapping the epitopes for G6 and G2 on NF68 subclones generated by Exonuclease III deletion mutagenesis. Positively-reacting subclones will define the minimum epitope. This knowledge will help to define functional sites and aid the investigation of intermediate filament and microtubule functions.

TUBULIN REMAINING BEHIND THE PEAK OF SLOW AXONAL TRANSPORT IS PREFERENTIALLY ASSOCIATED WITH STABLE MICROTUBULES. D.F. Watson, P.N. Hoffman and J.W. Griffin. Department of Neurology, Johns Hopkins Hospital, Baltimore, MD 21205

We have investigated the relationship between cold-stable microtubules (MT) and the pool of axonally transported tubulin. Rat L5 dorsal root ganglia were labeled with ^{35}S methionine, and segments of sciatic nerve 20-30 mm from the ganglion were analyzed at times indicated below. Nerves were fractionated into soluble tubulin, cold-labile MT, and stable MT fractions. The radioactivity in tubulin bands from SDS gels of each fraction was determined and expressed as a percentage of the total tubulin recovered:

Age at labeling	Transport interval	N	Labile MT % (SEM)	Stable MT % (SEM)
3 weeks	7 days	8	36.3 (2.7)	22.2 (1.7)
3 weeks	20 days	7	30.2 (2.1)	47.0 (2.3)
3 weeks	40 days	8	3.9 (1.4)	55.1 (2.9)
7 weeks	10 days	8	9.2 (1.3)	43.0 (4.1)

The "tail" of labeled tubulin remaining after the peak of transport had passed (3 wk\40 day group) was more highly associated with stable MT than the peak in animals which were the same age at labeling (3wk\7day) or the same age at sacrifice (7wk\10day). These results suggest that some tubulin in maturing axons becomes associated with a pool of stable microtubules which is stationary or very slowly transported.

Distribution of Microtubules in the Soma of NGF Activated PC12 Cells: The Nuclear Microtubular Basket. J.K. Stevens, J. Trogadis*. Playfair Unit, Toronto Western Hospital, and University of Toronto, Toronto, Ontario, M5T2S8, Canada.

PC12 cells have become a widely adopted model of the developing neuron. The undifferentiated cells are grown in tissue culture, and, when nerve growth factor (NGF) is added, produce neurites within a few days. We have serially reconstructed the soma at the EM level in a total of seven NGF activated PC12 cells. We have carried out complete somal reconstructions as well as sample MT density at selected regions within the soma. MT density is given as the total length of MT's contained within a cubic micron box of cytoplasm.

Unexpectedly, we find that the nucleus is surrounded by a "basket" of long, dense microtubules (20 MT microns/cubic somal micron). Both serial EM and immunofluorescence show that the centrioles are always found adjacent to the nucleus in pairs and are surrounded by many randomly oriented, short segment MT's (2.5 MT microns/cubic somal micron). It should be emphasized that these short centriolar MT's are only a few microns away from the longer MT's surrounding the nucleus. Any random sample from the somal cytoplasm reveals short segment MT's of varying density similar to those adjacent to the centrioles. Finally, the MT's, found in the initial segment and neurites, attached to the same cell, are longer and packed at a high density (47 MT microns/cubic somal micron).

These data suggest that NGF activated PC12 cells may contain many sites where MT's can be either *polymerized* or *annealed*. Specifically, it appears that both the nuclear surface and the neurite itself play a special role. In contrast, the region around the centriole appears to be no different than any random somal sample. It is interesting to speculate that the dense basket of microtubules around the nucleus might be the "motor" responsible for nuclear rotation often reported in these and other cells. NUTRITIONAL AND PERINATAL FACTORS IN DEVELOPMENT

235.1

LIMB DEFECTS IN GRAY OPOSSUMS FOLLOWING POSTNATAL INJECTION WITH ETHANOL OR SALINE. B. Fadem-Chenal*, R. A. Tassava* and S.I. Miller*, (SPON: A. Beyer-Mears) Dept. Psychiat., UMDNJ-New Jersey Medical School, Newark and Dept. Anat., Ohio State Univ., Columbus.

Limb abnormalities have been described in mammalian fetuses following maternal exposure to alcohol. Newborn marsupials are useful for studying the teratogenic effects of alcohol on limb development since their hindlimbs at birth are in an embryonic "paddle" stage of development.

In this study, 62 newborn gray opossums were injected with 10 μl 25% ethanol (ETOH)/physiologic saline (SAL) (v/v) (n=29) or 10 μl SAL only (n=33) in the right or left hindquarter on days 2 and 4 of postnatal life. Forty-four percent (n=11) of surviving animals in the ETOH group and 16% (n=4) of animals in the SAL group had limb defects in the limb associated with the hindquarter that was injected. Impairment of gait, reduced limb size and clubbing of the foot were seen in the SAL group. In addition these defects, absent digits, fused digits and absent limbs were seen in animals in the ETOH group.

It is likely that damage to the developing sciatic nerve by injection or introduction of fluid was involved in these defects since caudal neural lesions in neonatal gray opossums produce defects similar to those seen here. Presence of significant digital defects in ETOH but not SAL animals indicates that alcohol itself may have a further teratogenic effect on limb development.

SEROTONIN AND 5-HYDROXYINDOLEACETIC ACID ARE DECREASED IN THE MOTOR AND SOMATOSENSORY CORTEX IN RATS EXPOSED TO ETHANOL IN UTERO. M.J. Druse-Manteuffel and N. Tajuddin*. Department of Biochemistry, Loyola U. Stritch School of Medicine, Maywood, IL 60153.

This laboratory previously demonstrated a cortical deficiency of serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA), decreased 5-HT uptake in the motor cortex, and decreased 5-HT_1 sites in the motor and somatosensory cortices of the developing offspring of rats, fed a 6.6% (v/v) ethanol liquid diet on a chronic basis prior to parturition. This study extends previous work by assessing the concentrations of 5-HT and 5-HIAA in the motor and somatosensory regions of the cerebral cortex. Samples were separated by HPLC, using electrochemical detection.

The levels of both 5-HT and 5-HIAA were consistently lower in the motor and somatosensory regions of the cerebral cortices from the 19- and 35-day-old offspring of control and ethanol-fed rats. There was a significant ($P < 0.05$) 50% decrease in the concentration of 5-HT in the motor cortices of 19- and 35-day-old ethanol-exposed rats. In addition, the concentration of 5-HIAA was decreased by 30-50% in this region. Within the somatosensory cortex, there was a 20-40% deficiency of 5-HT and 5-HIAA in the 19- and 35-day-old offspring of ethanol-fed rats. These results emphasize the sensitivity of the developing serotonergic system to ethanol.

FETAL EXPOSURE TO ALCOHOL ALTERS POSTNATAL DEVELOPMENT IN RATS: AN EXAMINATION OF NEUROBIOCHEMICAL PARAMETERS. F. Chiappelli, A.N. Taylor, A. de los M. Espinosa*, J. de Vellis and H. Weiner. Depts. of Microbiology & Immunology, Anatomy, and Psychiatry, UCLA, and West Los Angeles VA Medical Center, Brentwood Div., Los Angeles, CA 90024.

Fetal exposure to alcohol is associated with neurobehavioral dysfunction both in animal models and in humans. Sprague-Dawley rats subjected to 5% ethanol (EtOH) during the last 15 days of gestation give birth to pups who exhibit alterations in the ontogeny of the brain-pituitary-adrenal axis (Taylor et al, 1986). Using the same animal model, we present data outlining the early ontogeny of neurobiochemical parameters in vitro. By initiating mixed whole brain neonatal cultures, maintaining them under standard culture conditions, and fixing and immunostaining them at given time points for up to 28 days approximate brain age, we found that prenatal EtOH exposure retards the appearance of selected markers. The expression of specific oligodendrocytic markers, such as glycerol phosphate dehydrogenase, cyclic nucleotide phosphohydrolase, and to a major extent myelin-basic protein and transferrin, is delayed in prenatal EtOH pups compared to controls. These data suggest that fetal exposure to alcohol may lead to profound alterations in the process of myelinogenesis. Astrocytic (e.g., glutamine synthase, glial fibrillary acidic protein) and neuronal (e.g., neuro-specific enolase, neurofilament) markers seem less severely affected by prenatal alcohol exposure.

235.4

PRENATAL ETHANOL EXPOSURE AFFECTS METHIONINE-ENKEPHALIN (m-ENK) FIBERS IN THE MEDIAL PREOPTIC AREA (MPOA) OF RATS. D.E. ADAM, C.A. FOX, J. HANNIGAN, E.P. RILEY AND C.D. JACOBSON. Dept. Veterinary Anatomy, Iowa State University, Ames, IA. 50011 and Center of Behavioral Teratology, SUNY, Albany, NY 12222.

Prenatal ethanol exposure alters the adult morphology of the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA) in male rats. In this study, we examined the effects of in utero alcohol exposure on the immunohistochemical localization of m-ENK in the MPOA. Adult offspring of dams fed liquid diets containing either 35% or 0% ethanol derived calories (EDC) on gestation days 6-20 were used. Offspring of dams given lab chow ad libitum served as another control group. m-ENK staining was obtained using the avidin-biotin-nickel-enhanced immunocytochemical technique. The m-ENK-like immunoreactive fiber plexus in the MPOA was markedly reduced in 35% EDC males and somewhat reduced in 35% EDC females as compared to both control groups. There also appeared to be more immunoreactive fibers in the female MPOA, including the area encompassing the SDN-POA, than in the male, regardless of prenatal treatment condition. In addition, the sexually dimorphic m-ENKergic periventricular band located in the MPOA was not altered by prenatal alcohol exposure. Further studies are in progress in order to investigate effects of prenatal ethanol exposure on sexual differentiation of the brain.

Prenatal alcohol ingestion and brain development:neurochemical and morphologic observations. M.C. Yu, Z.Y. Zang*, Z. Cherf and C.I. Giambelluo. Dept. of Anatomy, N.J. Med. Sch., Newark, NJ 07103 and Rhode Island Psychiat. Res. and Training Center, RI 02920 (CTG).

The purpose of this study was to make biochemical determination of brain neurotransmitter metabolism, and to observe morphological changes of rat pups exposed to alcohol in utero during gestation. Female Sprague-Dawley rats were fed an isocalonic liquid ethanol diet of 6.6% (vol/vol) for two weeks prior to mating. These dams, rendered pregnant on the first day (positive vaginal smear) were maintained on the diet for the duration of gestation, and after birth of the pups. A control group of dams was fed a regular rat chow diet. At postnatal days 7, 17 and 30, both groups of pups were sacrificed. Tissues from the corpus striatum and hippocampus were dissected out and frozen at -80°C until use. Tissues were homogenized in 10 volumes of 0.1N perchloric acid containing 1nq/ul DHBA as internal standard, centrifuges and filtered. The supernatent was used for quantitative assay by high pressure liquid chromatography while the lower solid phase was used for protein analysis.

In the corpus striatum, the dopamine concentration of the alcohol pups were significantly greater that the control group at 7 and 16 postnatal days, but was slightly more by 30 days. The concentrations of the two metabolites, DOPAC and HVA, however, were significantly higher in the control than the alcoholic group at the corresponding periods. In the hippocampus, the concentration of serotonin was similar at day 7, but greater in the alcoholic pups at postnatal days 17 and 30. The levels of 5-hydroxyndoleacetic acid were consistently higher in the control than the alcoholic pups. Preliminary electron microscopic observation of the caudate nucleus revealed the presence of edema, a less developed complement of organelles in the neurons of alcoholic pups at 7-day of age. By days 17 and 30, there was glycogen accumulations in astrocytes but no other changes.

235.6

INTERACTIVE EFFECTS ON BRAIN DEVELOPMENT IN MICE OF FETAL ETHANOL EXPOSURE AND DIETARY ESSENTIAL FATTY ACIDS. P.E.Wainwright,Y.S.Yuang*,D.E.Mills*,G.R.Ward*,R.P.Ward* and D.McCutcheon*.Dept. of Health Studies, University of Waterloo, Waterloo, Ontario, N2L 3G1, Canada.

Polyunsaturated fatty acids (PUFA),particularly arachidonic acid(AA,20:4 n-6)and docosahexaenoic acid(DHA,22:6 n-3)accrue in the developing brain.Ethanol affects fatty acid metabolism by reducing the conversion to longer chain derivatives.Thus ethanol may affect brain development by altering PUFA availability.This study examined whether dietary supplementation with PUFA's would ameliorate the effects of ethanol on brain and behavioral development.Pregnant mice were fed a liquid diet with 20% (Cal.)ethanol and 20% either safflower oil (S) or a combination of S with a fish oil concentrate (F,containing preformed,long chain n-3 PUFA).Pair-fed controls has maltose-dextrin substituted isocalorically for ethanol and a group fed chow ad-libitum served as a nutritional control.Treatment ceased prior to parturition.Blood alcohol concentrations did not differ between the groups.Two days after birth there was an effect of nutrition only on pup body and brain weight.Ten days later there was a significant ethanol by EFA interaction on brain weight,with the F animals receiving ethanol having heavier brains than controls,whereas the reverse was true in the S group.Ethanol retarded behavioral development,but PUFA supplementation had no effect.Fatty acid profiles of the brain membrane phospholipids will also be presented.

235.7

BEHAVIORAL AND NEUROANATOMICAL RECOVERY AFTER PRENATAL ETHANOL EXPOSURE IN THE RAT. N.J. Lobaugh, T. Wigal, P. Greene, J. Diaz-Granados, and A. Amsel. Department of Psychology, University of Texas, Austin, TX 78712.

We have recently demonstrated that prenatal ethanol exposure eliminated the Partial Reinforcement Extinction Effect (PREE) in 15-day-old rats (Wigal et al., 1988). This absence was due to equally rapid extinction after both partial (PRF) and continuous (CRF) reinforcement training. The present experiment demonstrates that, in animals prenatally exposed to ethanol, persistent responding after PRF training recovers with age. Three prenatal treatments, ETOH, PAIR-FED, and LAB CHOW, were combined factorially with PRF or CRF training at 21 days or 6 months of age. The results at 21 days replicated those of Wigal et al. for 15-day-olds: The ETOH-PRF and ETOH-CRF animals extinguished at the same rate, both faster than PRF controls. ETOH-CRF animals did not differ from CRF controls. However, when tested as adults, the ETOH-exposed animals showed complete recovery of function: a strong PREE, with no deficit relative to controls.

Analysis of hippocampal CA1 pyramidal cell number and density was made in horizontal, midtemporal, 3μ sections. We found that at 21 days, the prenatal ETOH treatment resulted in 18% fewer CA1 cells, and significantly reduced cell density. However, the adults exposed to ethanol prenatally did not differ from controls in either measure.

235.8

EFFECTS OF PRENATAL EXPOSURE TO ETHANOL ON HEART AND HIPPOCAMPAL MUSCARINIC AND BETA-ADRENERGIC RECEPTORS IN INFANT RATS. S.B. Wigal, R.E. Wilcox and A. Amsel. University of Texas, Austin, TX 78712.

The present work assessed the development of myocardial and hippocampal muscarinic and beta-adrenergic receptors in 8- and 17-day-old rat pups following prenatal exposure to ethanol.

Multiparous rats were intubated with either 6 g/kg ethanol or isocaloric dextrose twice daily from gestational Days 10 to 16. At birth, offspring were fostered to untreated mothers. Hearts were removed and the hippocampus from the right half of each brain was dissected from 8- and 17-day-old animals. Two concentrations of each ligand were used: [^{3}H]-quiuclidinyl benzilate (QNB): 300 and 1000 pM ± 300 nM atropine; and [^{125}I] -pindolol (IPIN): 300 and 600 pM ± 1 μM propranolol.

Prenatal alcohol exposure did not affect either beta-adrenergic or muscarinic binding in the heart. In the hippocampus, an ontogenetic increase in beta-adrenergic and muscarinic binding was apparent from 8 to 17 days of age. In addition, 17-day-old animals exposed to ethanol in utero showed a smaller increase in beta-adrenergic binding than the same-aged control animals. However, analyses of total protein yielded no significant differences between offspring of ethanol- and control-intubated mothers. Results suggest an ethanol-associated attenuation of beta-adrenergic receptor development.

235.9

THE NUMBER OF NEURONS AND GLIA IN SOMATOSENSORY CORTEX ARE AFFECTED BY PRENATAL EXPOSURE TO ETHANOL. G. Potempa* and M.W. Miller (SPON: M.E. Friedlander). Department of Anatomy, School of Osteopathic Medicine and Robert Wood Johnson Medical School, UMDNJ, Piscataway, NJ 08854.

Microcephaly is one of the charactersitic features of fetal alcohol syndrome. The number of cells in each layer of the somatosensory cortex of rats prenatally exposed to ethanol was determined using stereological methods. Pregnant rats were fed a liquid diet containing 6.7% (v/v) ethanol (E) or pair-fed a nutritionally matched, isocaloric diet (C). The offspring of these rats were examined on postnatal day 30. Prenatal exposure to ethanol affected the size and number of cells in each layer of cortex. The somatic diameter of neurons in each layer of somatosensory cortex, except layer V, was smaller ($p<0.01$) in E-treated rats. In contrast, the size of glia in each cortical layer was significantly greater ($p<0.01$) in the E-treated rats. Despite these changes, the cell packing density was similar in C- and E-treated rats. The volume of each layer was 27-41% less in E-treated rats. Overall, the estimated total numbers of neurons and glia in each layer of the somatosensory cortex of E-treated rats was 35% less than in pair-fed controls. The total volume occupied by neuronal cell bodies was less ($p<0.01$) in E-treated rats; consequently the neuropil occupied relatively more space in E-treated rats. Thus, ethanol-induced microcephaly is associated with structural changes in each layer of cortex. Funded by AA 06916, AA 07568, and DE 07734.

235.10

EFFECTS OF PRENATAL EXPOSURE TO BENZODIAZEPINES ON EXPLORATORY BEHAVIOR AND MESOLIMBIC DOPAMINE TURNOVER. R.J. Gruen, A.Y. Deutch, and R.H. Roth. Department of Pharmacology, Yale Univ. School of Medicine, New Haven, CT

Prenatal exposure to benzodiazepines (BZD) has been shown to lead to a variety of behavioral changes including learning deficits and alterations in motor and exploratory behavior. These latter deficits suggest that prenatal BZD exposure may impact on mesotelencephalic dopamine (DA) systems. We have therefore examined the behavioral and neurochemical sequelae of prenatal exposure to diazepam (gestational days 8 through 21) in rats. BZD-treated animals exhibited a significant decline in exploratory behavior (but not spontaneous locomotor behavior) at 90, but not 60 days after birth compared to vehicle-pellet implant and control subjects. These changes were paralleled by a significant decrease in DA turnover (DOPAC/DA) in the nucleus accumbens (NAS), but not in the other DA terminal fields examined (amygdala, olfactory tubercles, striatum, prefrontal and cingulate cortices). Treated animals had the lowest turnover in the NAS, followed by vehicle-pellet implant and control subjects. In addition, DA turnover in the ventral tegmental area was decreased in the BZD treated subjects, but not controls. These results suggest that alterations in exploratory behavior induced by prenatal exposure to diazepam are associated with significant changes in DA turnover in the NAS, a site previously shown to subserve exploratory behavior.

235.11

NUTRITIONAL INFLUENCES ON DEVELOPMENT OF CENTRAL AND PERIPHERAL NEUROTRANSMITTER SYSTEMS. C. Lau, NSI-ES/US EPA, RTP, NC, J.M. Bell, H.A. Navarro*, F.J. Seidler* and T.A. Slotkin, Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710

Maturation of the adrenal medulla and development of splanchnic innervation were evaluated in over- or undernourished rats (enlarged or diminished litter size), and compared to ontogeny of the central cholinergic and catecholaminergic neurons. Activities of choline acetyltransferase (ChAT) and tyrosine hydroxylase (TH) in the brain were monitored. Adrenal catecholamine (CA) stores, activities of TH and phenylethanolamine N-methyltransferase (PNMT) were measured, along with ChAT as a marker for the preganglionic neurons innervating the chromaffin cells. Neonatal nutritional deprivation slowed body weight gain and retarded development of the chromaffin cells, as evidenced by subnormal CA stores, TH and PNMT activities. These effects persisted despite recovery of body weights post-weaning. Neonatal nutritional enrichment promoted body weight gain but failed to enhance adrenomedullary development. In contrast, maturation of neurons in the brain was unaffected by nutritional status and only minor effects were seen in development of neurons innervating the chromaffin cells. These results suggest that development of central transmitter systems is spared from nutritional changes, but these protective mechanisms are not extended to similar tissues in the periphery: ontogeny of chromaffin cells is adversely, and perhaps permanently, affected by neonatal nutritional deprivation. (Supported by EPA-68-02-4450 and USPHS HD-09713)

PRENATAL PROTEIN MALNUTRITION ALTERS DEVELOPMENT OF PERFORANT PATH KINDLING IN THE RAT. **J.D. Bronzino, R.J. Austin-LaFrance* and P.J. Morgane. Dept. of ECS, Trinity College, Hartford, CT 06106 and The Worcester Found. for Exp. Biol., Shrewsbury, MA 01545.**

Nutritional insults have been shown to have profound effects on the developing CNS. In the present study pups born to dams maintained on either a 25% or 6% protein diet during gestation were fostered to dams on the 25% diet at birth, creating two experimental groups: 25%-25% (control) and 6%-25% (test). At 90 days of age these pups were tested for seizure susceptibility by daily application of a kindling stimulus to the medial perforant pathway during the vigilance state of quiet waking (QW). The kindling train was delivered at the minimum intensity required to elicit an afterdischarge within the granule cell field of the ipsilateral dentate gyrus. Preliminary data indicate that animals of the 6%-25% diet group require: 1) a significantly lower stimulus intensity to evoke afterdischarge activity, and; 2) significantly more daily stimulations to achieve the motor seizure state (stage 5) indicative of complete kindling. These results agree with previously published findings of this laboratory in which kindling stimulations were applied to region CA1 during QW. This study provides evidence for the fact that the prenatal dietary insult results in higher seizure susceptibility and retardation in the development of kindling even in the face of dietary rehabilitation at birth. **Suppoted by NIH Grant # 1 P01 HD22539-01**

235.13

THE EFFECTS OF KINDLING ON PAIRED-PULSE RESPONSE IN THE DENTATE GYRUS. **R.J. Austin-LaFrance*, P.J. Morgane and J.D. Bronzino (SPON: O. Resnick) Dept. of ECS, Trinity College, Hartford, CT 06106 and The Worcester Found. for Exp. Biol., Shrewsbury, MA 01545.**

This study was designed to investigate the effects of kindling on inhibitory activity within the dentate gyrus of the rat. Paired-pulse stimulations using inter-pulse intervals (IPIs) ranging from 20msec. - 1sec. were applied to the medial perforant pathway. Field potential responses to these stimuli were recorded from the granule cell field of the ipsilateral dentate gyrus before, during and after daily application of kindling stimulation to the same pathway. Paired-pulse stimulations were applied at intensities determined to elicit a population response to the first pulse equal to 75% of the maximal population response. Prelimnary data indicate that kindling enhances depression of the evoked action potential (EAP) response to the second pulse of a pulse pair at all IPIs tested, with the most significant enhancement occurring between the first and second afterdischarge. This enhanced depression is most marked at both the lower and upper end of the range of IPIs tested, suggesting that kindling alters mechanisms associated with both intrinsic recurrent and feed-forward inhibition within the dentate gyrus. Results of these studies will be used as control data to assess the effects of prenatal protein malnutrition on these inhibitory mechanisms during the development of kindling. **Supported by NIH Grant # 1 P01 HD22539-01**

235.14

VIGILANCE STATE MODULATION OF PAIRED PULSE RESPONSES IN RAT HIPPOCAMPUS. C. Beiswanger*, K. Austin*, J. Bronzino, and P.J.Morgane (SPON: J. McKearney). Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Recently we found that the level of inhibition and/or facilitation in the dentate gyrus (DG) is dependent on vigilance state (Austin et al., in press). In the current study, the paired pulse technique was used to establish an index of inhibition/facilitation in the DG by determining the ratio of inhibitory to facilitory responses to perforant path stimulation in four behavioral states (immobile waking (IW), active waking (AW), slow wave sleep (SWS) and REM sleep). In rats 90 to 120 days of age, a stimulus-response curve was determined in each behavioral state before paired pulse testing was done at IPIs between 20 and 1000 msec. Paired pulse tests provide evidence of a changing ratio of inhibition to facilitation of the population spike in DG at several IPIs. The ratio of facilitory to inhibitory responses at short IPIs is significantly greater during AW than during IW, SWS and REM, suggesting that inhibition (recurrent or feed-forward) may be suppressed during AW. Since prenatal nutritional insults to the developing CNS have effects persisting into adulthood, especially in highly plastic structures such as the hippocampus (Morgane et al., 1986; Austin et al., 1986; Bronzino et al., 1986), we are assessing how prenatal protein malnutrition affects vigilance state modulation of the index of inhibition/facilitation (Supported by NIH grants HD23338 and HD22539).

235.15

ASPARTAME(ASM)-INDUCED CHANGES IN PLASMA AND BRAIN AMINO ACIDS IN THE ABSENCE OF EFFECTS ON SEIZURE SEVERITY. S.M. Lasley, P.C. Jobe, R.L. Burger*, A.F. Bettendorf* and J.W. Dailey. U. of Ill. Coll. of Med., Peoria, IL 61656.

It has been hypothesized that the dipeptide sweetener ASM (aspartyl-L-phenylalanine methyl ester) facilitates seizures in animals and man by an action of its metabolite phenylalanine (PHE) on the synthesis of monoamine neurotransmitters in brain (e.g., norepinephrine (NE)). Previous studies have demonstrated that seizure predisposition and severity in genetically epilepsy-prone rats (GEPR) are partially determined by, and inversely related to, brain noradrenergic deficits, thus offering an excellent model by which to test this hypothesis. Dose-response relationships were determined for ASM and seizure severity and plasma and brain neutral amino acid concentrations, employing both moderate seizure (GEPR-3) and severe seizure (GEPR-9) animals. ASM was suspended in 0.5% methylcellulose and 0.1% polysorbate-80 and administered by gavage in the range of 0-2000 mg/kg. One hour later half the animals were tested for audiogenic seizure severity and the other half were sacrificed for plasma and brain amino acid determinations. At 2000 mg/kg ASM produced substantial increases in PHE in plasma and brain (maximum increase 276%) and in tyrosine in plasma and brain (maximum increase 122%), but decreased brain tryptophan by 30%. ASM did not alter audiogenic seizure severity in either GEPR-3s or GEPR-9s at any dose. These findings indicate that ASM does not facilitate seizures in animals whose seizure predisposition is at least partially dependent on noradrenergic deficits. (Supported in part by the NutraSweet Co.)

235.16

NEUROBEHAVIORAL EFFECTS OF PRENATAL EXPOSURE TO ANTIADRENERGIC ANTIHYPERTENSIVE DRUGS (AHD'S). C. L. Ryan* and B. A. Pappas. Dept. of Psychology, Carleton Univ., Ottawa, Canada, K1S 5B6.

AHD's are prescribed to treat hypertensive disorders of pregnancy. Since little is known concerning the long-term consequences of fetal exposure to these drugs, we investigated the effects of prenatal administration of three AHD's. Wistar dams were orally administered throughout gestation, one of clonidine (20 or 100 µg/kg), propranolol (5 or 20 mg/kg) or atenolol (5 or 20 mg/kg). Analysis of physical and behavioral development using parts of the Cincinnati Test Battery revealed no differences among the groups. At weaning, half the pups were housed in impoverished (I) and half in enriched (E) conditions for 40 days. They were then tested in a modified Hebb-Williams maze consisting of 5 training problems followed by 11 test problems (one/day). The E-reared animals made fewer errors than the I-reared rats. Exposure to propranolol, but not clonidine or atenolol, impaired maze performance. Furthermore, there was a high mortality rate during maze testing, but only from the E-reared females prenatally exposed to the high dose of clonidine. This was associated with gastric ulceration, thymic atrophy, and adrenal hypertrophy.

In summary, prenatal exposure to propranolol impaired problem-solving ability while clonidine had a latent and lethal effect in females which was precipitated by environmental factors.

ADULT-ONSET CALORIC RESTRICTION: LACK OF EFFECT ON HIPPOCAMPAL CA3 PYRAMIDAL CELL MORPHOMETRY. A. Andrews*, R. Rountree*, W. Nowak, R. Hart*, and A.C. Scallet. Natl. Ctr. for Tox. Res., Jefferson, AR 72079 and Univ. of Ark. for Med. Sci., Little Rock, AR 72205.

Previous analyses of the dendritic trees of rodent cortical neurons suggest nutritional and age-related factors as well as various neurotoxic exposures might produce reductions in the extent of dendritic arborization. Caloric restriction (CR) has been extensively used to delay the appearance of various age-related parameters. The aim of the present study was to identify several measures of hippocampal CA3 dendrites potentially useful in such studies. We measured 6 Golgi-Cox impregnated CA3 cells/rat from 4 calorically retricted and 4 control 18-month old male rats using a motorized microscope stage interfaced to a personal computer. No differences in CR vs control soma areas (453 ± 89 vs 403 ± 29 square microns), number of dendrites per cell (4.8 ± 0.5 vs 4.9 ± 0.3), or total length of dendrites per cell (1183 ± 195 vs 1187 ± 206 microns) were measured. The data suggest CR beginning in young adult rats (at 14 wk) is without effect on several morphometric parameters of the 18-month old rat hippocampus.

235.18

PRENATAL EXPOSURE TO MORPHINE: EFFECTS ON TOLERANCE AND WITHDRAWAL OR NOCICEPTION AND ACTIVITY? C. P. Cramer, R. A. Fite, and M. S. Fanselow*. Dartmouth College, Hanover, NH 03755.

Many authors have described the postnatal sequelae of prenatal opiate exposure in terms of addiction. Because, in previous studies, we have been unable to demonstrate tolerance and withdrawal in infant rats younger than 15 days postpartum, in the present experiments we analyzed these addiction-related behaviors in neonates that were prenatally exposed to morphine.

Rat dams were injected daily with either isotonic saline, 10 mg/kg morphine, or 20 mg/kg morphine at least 3 weeks prior to conception and throughout gestation. After birth and 24 hr after the last morphine injection, pups were randomly assigned to 1 of 5 drug groups: saline, 1, 2, or 4 mg/kg morphine, or 10 mg/kg naloxone. Pups were tested at 30 min intervals for nociception using a modified hotplate (52°C) technique; pawlift latency was measured. Pups receiving naloxone were also weighed at hourly intervals and were viddeotaped for 2 hr after injection. Videotapes were analyzed both for general activity (squares entered) and for specific behaviors.

Pups exposed prenatally to morphine responded more quickly to the nociceptive stimulus, however they did not show reduced responsivity to morphine. That is, they were not tolerant. Similarly, they were more active following naloxone injection, but their behavioral profiles were not clearly suggestive of withdrawal.

NERVE DEVELOPMENT IN GROWTH RETARDED FETAL SHEEP S. Rees*, R. Harding*, U. Proske* (SPON: W. Webster) Department of Physiology, Monash University, Clayton, Victoria, 3168, Australia.

We have studied the effects of experimental growth retardation on the development of both the peripheral and central nervous systems of fetal sheep. Growth retardation was produced by restriction of placental growth in 7 ewes. At 140 days of gestation (term = 145 days) three different nerves were examined, the optic, trochlear and peroneal. Morphometric analysis of myelinated fibres in the optic nerve showed that in growth retarded animals the myelin sheath was abnormally thin. In the trochlear nerve the normal myelin to fibre ratio was maintained but there was an abnormally large number of small axons. Measurements of whole-nerve conduction velocity in the peroneal nerve showed, for the most rapidly conducting fibres, a significant slowing from the normal value of 48.9±2.8 to 33.8±3.3 m/s ($p<0.05$).

Hence we have shown in these nerves that conduction velocity, or factors which are known to affect it, are altered in the growth retarded fetus at birth. The mechanisms which interfere with the normal development of nerves may differ according to location in the nervous system. NORMAL RAT DEVELOPMENT FROM WEANING TO ADULT M. Sakuma, L.M. Hryhorczuk,* Dept. of Biol. Sci., Wayne State Univ., Detroit, MI 48201: Lafayette Clinic, Detroit, Mi 48207

Sprague-Dawley rats born to dams fed a diet differing in tryptophan (TRP) content during the second half of gestation were investigated in a series of studies of development. This report deals only with the long-term developmental changes (from week 3 to week 15) observed in rats born to dams on a regular diet (Purina Lab Chow). The animals, segregated by sex (12 male, 14 female), were evaluated weekly by body weight and in 5 min open field tests. The animals were scored on the basis of rearing counts, latency of rearing, face washing counts, latency of face washing, and defecation. Two way analysis of variance with repeated measures revealed that all variables showed an age dependency at $p<0.01$. With respect to sex differentation, males had a greater weight gain ($p<0.01$) and lower number of rearings ($p<0.01$). These differences will be examined with results on animals born to dams on diets high and low in TRP content. This study was in compliance with the NIH Guide for the Care and Use of Laboratory Animals.

WORKSHOP: HIPPOCAMPAL CELLULAR ACTIVITY AND SPATIAL-COGNITIVE PROCESSING. P.J. Best, U. New Orleans and J.B. Ranck Jr. SUNY Med. Ctr. Brooklyn, (Chairpersons); J. Kubie, SUNY Med. Ctr., B. McNaughton, U. Colorado, S. Deadwyler, Bowman Gray, H. Eichenbaum, Wellesley, D. Olton, Johns Hopkins.

Activity of hippocampal pyramidal cells is highly related to the animal's position or place in the environment. Each neuron fires in a small place field in the test arena. The workshop examines the nature of the information required for place field activity and the subsequent processing of that information. Place field activity is normally stable for extremely long periods of time, and is very dependant on distal environmental cues. Yet place cells are not merely sensory cells. The fields are affected by the animal's motion, and the fields can be brought under the control of local, biologically relevant stimuli. Further, the same cells can show a remarkable degree of plasticity under appropriate conditions. Their place fields can be modified by varying stimuli or past experience, and they show phasic responses to discrete nonspatial stimuli, which can be modified by experience. The implications of the new data for the interpretation of behavioral-cognitive correlates of hippocampal cellular activity and for theories of hippocampal function will be discussed.

SYMPOSIUM. SEX DIFFERENCES AND HORMON/ INFLUENCES ON COGNITIVE BRAIN FUNCTION. R. Lewis, Pomona Coll.(Chair); B. Kolb, U. Lethbridge; C. Williams, Barnard Coll.; M. Hines, UCLA; E. Hampson, U. Western Ont.; D. Kimura, U. Western Ont. (Organizer) Men generally excel on extrapersonal spatial tasks, women on intrapersonal motor/ articulatory skills. Previous studies have shown greater dependence on left anterior regions in women, left parietal in men, for motor programming function. Kolb- anterior/posterior differences exist also in male and female rats, with females more affected on locomotor orientation tasks by frontal, males by parietal, lesions. Williams- early sex hormone treatment in rats alters the preference of males and females, respectively, for geometry vs. landmark cues. Hines- in adult humans, cognitive, brain asymmetry and social effects are associated with early anomalous sex hormone exposure. Hampson- menstrual cycle hormone fluctuations in women alter spatial and motor skills in reciprocal ways, predictable from the known sex differences. Kimura- post-menopausal women show enhanced motor programming skills during phases of estrogen therapy.

PROCESS OUTGROWTH, GROWTH CONES, AND GUIDANCE MECHANISMS IV

240.1

DAMAGE OF A MIDLINE BOUNDARY AND FORMATION OF A TISSUE BRIDGE ALLOWS THE MISGUIDANCE OF OPTIC AXONS ACROSS THE MIDLINE IN HAMSTERS. M. Poston*, S. Jhaveri*, G. Schneider and J. Silver. Case Western Reserve Univ., Cleveland, OH 44106. Massachusetts Institute of Technology, Cambridge, MA 02139.

We are interested in the events which control axonal guidance and misguidance in the vertebrate superior colliculus (SC). In this study we examined, at light microscopic and TEM levels, the morphology of the midline between the two halves of the SC in normal and lesioned hamsters. Postnatal day one (P1; PO=day of birth) hamsters were lesioned by placing a heated pin onto the cartilage overlaying the right SC and part of the SC midline. The midline of newborn unlesioned hamsters, which optic axons do not normally cross, consists of cells whose processes form a wedge-shaped structure which serves as an axon-refractory boundary between the two halves of the SC. In contrast, in the lesioned hamsters the midline is drastically changed. No wedge-shaped cellular boundary separating the SC halves is present. Rather, a tissue bridge spanning the lesion-induced cavity is contiguous from the lateral aspects of the right SC to the medial aspects of the left SC. Optic axons grow along this bridge, cross the altered midline and enter the left SC. Cells of the tissue bridge possess radial processes containing intermediate filaments and glial endfeet covered with an intact external limiting membrane. Thus, the tissue bridge presents the crossing axons with a terrain that is morphologically similar to the normal marginal zone where optic axons readily grow. We propose that at least three events occur which allow optic axons to cross the SC midline in lesioned hamsters: damage of an axon-refractory boundary at the midline, rehealing of the external limiting membrane and marginal zone of injured brain, and formation of a suitable substrate for the misguidance of optic axons. Supported by NIH EY05952.

240.2

EVIDENCE FOR A DIFFUSIBLE FLOOR PLATE-DERIVED FACTOR THAT CONTRIBUTES TO AXONAL GUIDANCE IN THE EMBRYONIC RAT SPINAL CORD. M. Tessier-Lavigne*[1,2], M. Placzek*[1], A. Lumsden*[3], J. Dodd[1], and T. Jessell[1,2]; [1]Center for Neurobiology and [2]Howard Hughes Medical Institute, Columbia University, New York, NY 10032, and [3]Department of Anatomy, Guy's Hospital Medical School, London, England.

Two classes of projection neurons differentiate concomitantly in the dorsal region of the embryonic rat neural tube. Association (A) neurons send axons ipsilaterally to form the lateral funiculus, whereas the axons of commissural (C) neurons project ventrally and medially, cross the midline of the neural tube at the floor plate (a specialized set of epithelial cells), and turn longitudinally to form the contralateral ventral funiculus. To determine the mechanisms underlying the selection of distinct pathways by the axons of A and C neurons, we have investigated whether floor plate cells release a diffusible factor(s) that contributes to the guidance of C axons towards the ventral midline.

Evidence for the existence of a diffusible floor plate-derived factor was obtained by examining the effect of the floor plate on axon extension from the dorsal neural tube, when explants of both regions were cultured 100-300 μm apart in a collagen gel matrix. Explants were taken from embryonic day 11 neural tube, when C neurons are beginning to extend axons. Axons did not project from dorsal neural tube explants that were cultured alone for 36 hrs. In the presence of floor plate, however, axons emerged from such explants within 20-24 hrs, and projected towards the floor plate explant in thick fascicles. These axons appear to derive from C neurons since they express the TAG-1 antigen, a cell-surface glycoprotein expressed on C but not A axons during their initial extension. The presence of floor plate also appears to have an orienting effect on the trajectory of C axon growth, since in dorsal explants that were cultured with the original dorso-ventral axis parallel to a floor plate explant, a large majority of the emerging axons grew towards the floor plate, deviating significantly from their normal trajectory. These findings suggest that floor plate cells release a diffusible factor(s) that may influence the guidance of C axons in vivo.

240.3

TISSUE SPECIFICITY AND PROPERTIES OF A FLOOR PLATE-DERIVED FACTOR THAT INFLUENCES COMMISSURAL AXON OUTGROWTH. M. Placzek*, M. Tessier-Lavigne*[1], T. Jessell[1] and J. Dodd. Center for Neurobiology and [1]Howard Hughes Medical Institute, Columbia University, New York, NY 10032.

Floor plate cells of the embryonic rat spinal cord may play a role in guiding the axons of commissural neurons to the ventral midline of the neural tube by releasing a diffusible tropic factor(s) (Tessier-Lavigne et al., companion abstract). To determine whether this factor is restricted to floor plate cells, a number of embryonic tissues were assayed for their ability to substitute for floor plate in the co-culture bioassay. Embryonic notochord, gut, brain, ventral spinal cord, somite, mandibular process, kidney, adrenal and lung did not mimic the effect of floor plate on commissural axon outgrowth. Moreover, the ability of floor plate to induce axon outgrowth is selective with respect to neuronal subtype. Embryonic trigeminal ganglion, dorsal root ganglion, ventral spinal cord and retinal neurons did not respond to floor plate explants with enhanced axonal outgrowth.

To characterize further the properties of the floor plate-derived factor, we examined the activity of defined medium conditioned in vitro by exposure to floor plate explants. Axon extension from dorsal neural tube explants cultured with conditioned medium was comparable to that observed when explants were cultured with floor plate. The active component in floor plate conditioned medium was retained by an ultrafiltration membrane with a 30 kDa exclusion limit and was inactivated by trypsin. The fact that most neurons did not respond to the presence of floor plate and that laminin is not detectable in the rat floor plate suggests that laminin is not the active component. Since the floor plate is located in the neural tube, but shares biochemical properties with the notochord, an axial mesodermal structure, we tested known neurotrophic and mesodermally-derived growth factors for their ability to mimic floor plate conditioned medium. The effects of conditioned medium were not mimicked by EGF, aFGF, bFGF, PDGF, TGFβ, NGF, CNTF, BDNF or by medium conditioned by the mesodermally-derived XTC cell line. The floor plate may therefore release a factor distinct from those examined or a combination of factors that act in concert to influence axon outgrowth.

Role of Glia in the Formation of Axon Pathways in the Drosophila CNS Revealed by Cell Lineage Markers and Developmental Mutants J.R. Jacobs and C.S. Goodman. Dept. of Biochemistry, Univ. Calif. Berkeley, Berkeley, CA 94720 .

Each segment of the Drosophila CNS contains a bilateral pair of longitudinal tracts, two major commissures which bridge these tracts, and two major peripheral nerve roots. Prior to growth cone extension, the location of the longitudinal and commissural tracts, and the intersegmental nerve, are prefigured by different classes of glial cells positioned under the basement membrane on the dorsal surface of the neuroepithelium. We characterized the origin and development of two of these classes of glia with electron microscopy, and using a P-element lineage marker (provided by Yash Hiromi) which directs the expression of B-galactosidase in a specific glial lineage. Using this B-gal marker, we find that the three pairs of glial cells which prefigure the longitudinal connectives in each hemisegment arise from the division and subsequent migration of progeny from a single glioblast. The two commissures are prefigured by a different class of glia which originate from the midline neuroepithelial cells. We hypothesize (i) these different classes of glia interact with one another to establish their characteristic patterns, and (ii) the first growth cones interact with these glia to establish their characteristic axon pathways. We have begun using these and other probes to examine mutants which are abnormal in these events. For example, in the single-minded mutant (Thomas et al., 1988; Crew et al., 1988) and the slit mutant, the commissures do not properly form. The longitudinal connectives fail to properly form in the midline mutant. The commissures develop abnormally in the Star mutant and in deficiencies which remove the fasciclin III gene. Analysis of the ontogeny of the phenotypes of these mutants will help reveal the role of cell interactions in the patterning of these early glia and of the axon pathways which form along their surfaces.

240.5

MUTATIONS AFFECTING GROWTH AND GUIDANCE OF MECHANOSENSORY NEURONS IN THE NEMATODE CAENORHABDITIS ELEGANS.
S. S. Siddiqui. Laboratory of Molecular Biology, Toyohashi University of Technology, Toyohashi 440, Japan.

Six mechanosensory receptor neurons called microtubule cells mediate touch sensitivity in C. elegans(Chalfie, M. Sulston, J. Develop Biol. 82, 278, 1981). Each of the six receptor cells has a long process which is apposed to the cuticle of the animal. We have previously shown that a monoclonal antibody 6-11B-1 raised against Sea Urchin axonemes and specific for acetylated alpha tubulin(Piperno G. and Fuller, M, J.C.Biol 101, 2085, 1985) stains touch cells in C. elegans(Siddiqui, S. S., Aamodt, E., Rastinejad, F. and Culotti, J. G. 1988). Here we have analysed the morphology of touch cells in uncoordinated mutants of C. elegans representing 90 unc genes, immuocytochemically, using 6-11B-1 on wholemount animals. In mutants of 15 genes(unc-5, unc-6, unc-13, unc-33, unc-34, unc-44, unc-49, unc-51, unc-55, unc-61, unc-71, unc-73, unc-76, unc-98, and unc-102) a variety of axonal guidance errors were seen in a fraction of stained animals. Most frequently the stained receptor processes ran in abnormal dorsal or ventral positions, sometime reaching the ventral nerve cord or the dorsal nerve cord in abnormal positions. In addition, we observed abnormal bifurcation of axonal processes and multipolar touch cells. Mutants of unc-59 and unc-85 exhibit binucleate touch cells with multiple axon processes. The touch sensitivity data will be shown.

240.6

NERVE GUIDANCE GENES OF C. ELEGANS. J.Culotti*[1], N. Ishi*[2], C.Leung-Hagesteijn*[1], B.Stern*[3], E.Hedgecock*[3], and D.Hall[4] (1)Mt. Sinai Hosp. Res. Inst., Toronto, M5G 1X5, Canada (2)Tokai U., Isehara, Japan (3)Johns Hopkins U:, Baltimore, Md 21218, (4)A. Einstein Coll., Bronx, N.Y. 10461

The nematode epidermis is a cylindrical neuroepithelium which supports neurons, precursors, a basal lamina, and attached mesodermal cells on its basal surface. Mutations in 3 genes disrupt the circumferential migrations along the epidermis of both pioneer axons and mesodermal cells. unc-5 mutations disrupt dorsalward migrations, unc-40 mutations primarily disrupt ventralward migrations, and unc-6 mutations disrupt migrations in both directions. These genes identify a circumferential guidance system acting throughout the animal.

We have cloned the unc-5 and unc-6 genes by transposon tagging. The predicted unc-5 protein contains an exon of 122 amino acids comprising a tandemly arranged pair of homologous domains each beginning with the tryptophan rich sequence DGGWSXWSXW. Similar domains are found in apparently unrelated proteins involved in cell adhesion, including the platelet protein thrombospondin, complement components C8 alpha, C8 beta, and C9 and the circumsporozite proteins of malarial parasites. In thrombospondin, 3 tandemly arranged copies of this domain are present in a region of the protein which is believed to bind to various extracellular matrix components including laminin. Therefore, this domain may be adapted for binding to the extracellular matrix. This possibility is particularly appealing since, based on its amino terminal sequence, unc-6 appears to be a nematode B2 laminin.

240.7

REDUPLICATION OF SPECIFIC BRANCHING PATTERNS EXPRESSED IN THE CNS OF THE LEECH BY ISOLATED IDENTIFIED NEURONS IN CULTURE. S.E. Acklin and J.G. Nicholls, Biocenter, Basel, Switzerland, 4056.

Two identified interneurons (designated, alas, as 61 and 21) exhibit a series of well-defined physiological and morphological properties in situ. These cells, initiate swimming, secrete 5-HT, are electrically coupled to one another, and display rhythmical bursts of impulses. Within the ganglion, they branch in a stereotyped and distinctive manner (Lent, C.M., J.Exp.Zool., 216:311-361, 1981). In both cells the initial process divides to form two principal elongated neurites. In one (21) the arborization resembles the letter Y, in the other the letter T. The cells were isolated and plated on Con A in L-15 medium. Their resting and action potentials remained normal and they became coupled electrically. One novel finding was that Lucifer Yellow spread from cell to cell. Another was that a single cell could continually procuce bursts of impulses similar to those arising in the ganglion. Quite unexpectedly, each cell in culture faithfully reproduced the configuration Y or T. In the absence of any external cues the first sprouts grew in specific directions, with subsequent fasciculation. Other types of leech neurons growing in culture have not reproduced patterns formed during development. These two cells with their regular and simplified conformations provide favorable preparations for analysing intrinsic and external factors involved in directed growth. (Supported by grants from the Swiss National Fonds and the U.S. Navy.)

240.8

A GROWTH CONE COLLAPSING ACTIVITY FROM EMBRYONIC CHICK BRAIN MEMBRANES. J.A. Raper and J.P. Kapfhammer*. Max-Planck-Institut für Entwicklungsbiologie, D-7400 Tübingen, FRG.

It is often assumed that growth cones are guided to their destinations by localized neurite promoting activities. Less attention has been paid to the possibility that specific, localized, growth inhibiting activities control growth cone behavior. We recently found that particular types of growth cones collapse and consequently fail to locomote on contact with specific axons in culture (J. Neurosci. 6:2527-34; 7:201-12; 7:1595-1600). We proposed that growth cones collapse when they recognize signals associated with specific axon membranes.

We have found that growth cones which are always in contact with a permissive laminin substratum can be induced to collapse when exposed to a suspension of embryonic chick brain membranes. Time lapse studies show that collapse is reversed if the membrane suspension is removed, suggesting that the cells are healthy and that the substratum is not damaged by the membranes. Similar preparations from liver or fibroblasts are ineffective.

The collapsing activity is lost if the particulate portion of the membrane suspension is removed by centrifugation, suggesting that it is an insoluble, membrane associated activity. The activity is lost after heat or trypsin treatment, suggesting that one or more proteins are involved. The activity can be solubilized with detergent and reconstituted by its removal. We are currently purifying the collapsing activity.

The results support the hypothesis that growth cone collapse can be triggered by contact with membrane proteins, and provide us with a practical assay for purifying at least one causal agent.

240.9

CELL SURFACE BINDING SITES FOR PLASMINOGEN ACTIVATORS. R.N. Pittman. Dept. of Pharmacology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

Cultured rat sympathetic neurons release both urokinase plasminogen activator (UK) and tissue plasminogen activator (t-PA). Inhibition of UK and/or t-PA results in increased neurite outgrowth. In addition to being present in the culture medium, both t-PA and UK are present on the surface of neurons. At least two and probably three independent binding sites are present on the surface of sympathetic neurons. One cell surface binding site is selective for t-PA, binds with high affinity to a region of t-PA distinct from the active site, and is present in high concentrations (>200,000 sites/neuron). Immunohistochemical localization of surface bound t-PA indicates fairly smooth homogenous binding at the cell body and along the processes. At the growth cone, more surface bound t-PA appears to be associated with filopodia than lamellipodia. A second cell surface binding site has a MW of ca. 50 kDa, binds to the active site of UK and t-PA and appears to be associated with cell surface heparan sulfate proteoglycan. A third binding site appears selective for UK and binds to a region of UK distinct from the active site. Localization of surface bound UK has been somewhat inconsistant but appears to be punctate, heterogenous, and on the bottom surface of neurons next to the substrate. Supported by grants from the NIH (NS 22663) and McKnight Foundation.

240.10

MONOCLONAL ANTIBODIES THAT DEFINE ROSTRO-CAUDAL POSITION IN THE MAMMALIAN NERVOUS SYSTEM. T. Suzue*, J. Imrich* and P. H. Patterson. Biology Div., 216-76, California Institute of Technology, Pasadena, CA 91125.

Transplantation experiments have shown that spinal cord neurons can distinguish rostral vs. caudal sympathetic ganglia, as well as rostral vs. caudal intercostal muscles, when the muscles are transplanted in place of the ganglia. This raises the possibility that the ganglia and the muscles share a molecule(s) that has a differential distribution along the rostro-caudal axis, and that the molecule is involved in specific synapse formation or axon guidance. In an attempt to identify molecules with such a distribution, we employed the immunosuppression technique. Mice were first injected with membranes from newborn, caudal sympathetic or dorsal root ganglia, followed by injection of the immunosuppressant drug, cyclophosphamide. After injection of membranes from rostral ganglia, hybridomas were generated. Many mAbs were produced which preferentially bind to rostral ganglia, and some of these also stain the nerves that innervate intercostal muscles. The staining of one of the mAbs is highest in the rostral nerve and it declines in a graded manner in the caudal segments. Surprisingly, this mAb appears to stain glial cell surfaces rather than axons. Since glial surfaces can promote axon growth, this antigen could play a role in the rostral preference displayed by rostral spinal cord axons.

240.11

ULTRASTRUCTURAL LOCALIZATION OF STAGE-SPECIFIC NEURITE-ASSOCIATED PROTEIN (SNAP) IN DEVELOPING RAT CORTEX AND CEREBELLUM. M. Yamamoto, J.E. Crandall and L. Hassinger* Dept. of Developmental Neurobiology, E.K. Shriver Center, 200 Trapelo Rd., Waltham MA 02254

SNAP (or TAG) antigen recognized by 4D7 MAb is expressed on the plasma membrane of growing axons in the embryonic rodent nervous system. Light microscopic study demonstrated that this glycoprotein is expressed in a subset of axons during narrow temporal window of development (Yamamoto et al. 1986 J. Neurosci. 6:3576). The ultrastructural localization of the SNAP antigen was studied in embryonic (E15-17) cerebral cortex and postnatal (P4) cerebellum using HRP conjugated secondary antibody. Immunoreactivity was localized predominantly in the intermediate zone (IZ) of the cortex where afferent and efferent axons course. Some immunoreactivity was also seen in the cortical plate (CP) and subplate. Immunoreactivity was associated with the plasma membranes of neuritic processes, neural somata and selective groups of fasciculated axons. In the IZ SNAP positive axons could be found in distinct bundles. In the CP SNAP immunoreactivity was detected on only some portions of individual neuronal somata. Along stained membranes SNAP appeared to be localized in a regularly spaced, punctate fashion with a periodicity of 50-100 nm. The distinctive distribution of SNAP antigen along developing neuronal membranes suggests a possible role for this molecule in selective axon-axon interactions. Supported by grants NS24746 to M.Y. and NS24386 to J.C.

DEVELOPMENTAL REGULATION OF $pp60^{c-src}$ AND TYROSINE PHOSPHORYLATION OF A 53-55 KD PROTEIN IN NERVE GROWTH CONES. Patricia F. Maness and Muriel Aubry*. Dept. Biochemistry, Univ. North Carolina, Chapel Hill, NC 27514.

Differentiating neurons express high levels of the proto-oncogene product $pp60^{c-src}$, a tyrosine kinase of unknown function. $pp60^{c-src}$ is concentrated approximately 10-fold in membranes from a subcellular fraction from fetal rat brain that is enriched in nerve growth cones. Indirect immunofluorescence staining showed $pp60^{c-src}$ in neuronal growth cones and processes, with a concentration in growth cones of long neurites. $pp60^{c-src}$ was present at lower levels in subcellular fractions from mature brain but was not enriched in synaptosomal membranes. Using antibodies directed against phosphotyrosine, we have identified a 53-55 kD protein in the growth cone membrane fraction as the major protein phosphorylated at tyrosine in vivo. This protein was highly enriched in growth cone membranes relative to fetal brain homogenate or synaptosomal membranes. In protein kinase reactions with isolated growth cone membranes, the major protein phosphorylated at tyrosine is also a 53-55 kD protein identified as α- and β-tubulin. These results indicate that $pp60^{c-src}$ and tubulin tyrosine phosphorylation may be important determinants of growth cone-mediated neurite extension and synaptic plasticity.

ION CHANNELS: SODIUM CHANNELS I

241.1

EXPRESSION OF Na CHANNEL SUBTYPES DIFFERS IN TWO POPULATIONS OF VERTEBRATE SENSORY NEURONS. D.T. Campbell. Hatfield Marine Science Center, Oregon State University, Newport, OR 97365.

Dorsal root ganglion cells from garter snake (T. sirtalis) and frog (R. temporaria) were enzymatically dissociated and maintained in culture media for 1-3 weeks. Ionic currents were measured using the whole-cell voltage clamp technique. Test solutions contained 5-10 μM La, 1 mM Ca and 9 mM Mg to minimize current through Ca channels. When TEA·Cl replaced all or part of the NaCl in test solutions the reversal potential of the early transient current followed the Na equilibrium potential, suggesting that this current was due to Na ions flowing through Na channels. Cell capacitance ranged from 4-40 pF (snake) and from 15-110 pF (frog). The Na current of the largest cells of both species (>23 pF, snake; >50 pF, frog) was virtually completely blocked by 1 μM TTX. By contrast, in the majority of smaller cells of both species, 10-90% of the Na current was extremely resistant to block by TTX. TTX concentrations up to 100 μM failed to elicit appreciable block of the resistant channels. In both species, the TTX-resistant channels activate at more negative potentials and exhibit ~3-times slower inactivation than the TTX-sensitive channels seen in the larger cells. The TTX-resistant channels of snake were not appreciably blocked by 1 μM STX, whereas the TTX-resistant channels of frog were 90-95% blocked by 1 μM STX. The differential expression of Na-channel subtypes in large and small DRG cells suggests that their kinetics may play a role in determining the distinct action potential characteristics of large and small sensory neurons.

PROTON-GATED SODIUM CURRENTS IN MAMMALIAN CENTRAL NEURONS R. Grantyn, M. Perouansky and H.D. Lux+. Max Planck Inst. for Psychiatry, 8033 Martinsried, F. R. G.

A transient proton-activated sodium current ($I_{Na(H)}$) is described for chick dorsal root ganglion neurons (Konnerth, Lux and Morad 1987) and assigned to transformed Ca channels (Davies, Lux and Morad 1988). Cultured neurons from the tectum of E12 rat embryos were now used to characterize pharmacological properties and development of $I_{Na(H)}$ in a defined population of neurons from the mammalian brain.

After two weeks in vitro, all tectal neurons generate $I_{Na(H)}$. Under optimal activation conditions (low Ca and Mg, holding pH 7.9, fast application) $I_{Na(H)}$ exceeds in amplitude all other inward currents, the EC_{50} for $/H^+/_o$ being 0.14 uM. Comparing the effect of Ca channel antagonists on $I_{Na(H)}$ and on two types of voltage-activated Ca-currents ($I_{Ca(LV)}$ and $I_{Ca(HV)}$) it was found that $I_{Na(H)}$ is pharmacologically close to $I_{Ca(LV)}$. Both currents are blocked by low doses of 5-amino-diethylamiloride (IC_{50}: 7.5 uM), while $I_{Ca(HV)}$ was unaffected by this compound. Suppression of $I_{Ca(LV)}$ for the duration of $I_{Na(H)}$ suggests that these currents are, in fact, carried through the same channels.

During early differentiation (first day in vitro), $I_{Na(H)}$ and $I_{Ca(LV)}$ appear roughly in parallel, provided that laminin is used as a growth substrate. The absence of this extracellular matrix protein results in dissociated expression of $I_{Na(H)}$ and $I_{Ca(LV)}$, indicating that the proton- and voltage-gating property of Ca channels may evolve independently.

PHARMACOLOGY OF INSECT SODIUM CHANNELS, Sarah C.R. Lummis* and David B. Sattelle, AFRC Research Unit, Dept of Zoology, Downing Street, Cambridge, CB2 3EJ, UK.

Saxitoxin (STX) has proved extremely useful in the isolation and characterization of sodium channels. Voltage-clamp experiments on isolated giant axons of the cockroach (Periplaneta americana) show that STX specifically and reversibly blocks transient inward sodium currents. From the concentration dependence, it appears that individual sodium channels are blocked by single molecules of STX, which bind reversibly to the channel with a K_d of 3nM. Membrane extracts from the cockroach nervous system contain a saturable component of specific [^{3}H]STX binding. Scatchard analyses yielded a K_d of 2nM, similar to that determined from electrophysiological studies. The specific binding component was blocked by STX and TTX, but not by veratridine or deltamethrin, which act at different sites on the channel molecule. Unlabelled STX samples prepared from different sources (Mytilus, Saxidomus and Gonyaulax) were all effective as inhibitors of [^{3}H]STX binding. Specific, saturable binding sites for [^{3}H]batrachotoxin, have also been identified in a cockroach CNS membrane preparation, although experimental conditions are distinct from those required to optimise binding of this ligand to vertebrate CNS membranes. The results demonstrate that, using the nervous system of the cockroach, a multidisciplinary experimental approach can be applied to the characterization of insect sodium channels - major molecular targets of pyrethroid insecticides.

BREVETOXIN ACTIONS ON SINGLE SODIUM CHANNELS IN NG108-15 CELLS. **R. E. Sheridan and M. Adler. Neurotox. Br., USAMRICD, APG, MD 21010 and Dept. of Pharm., Georgetown Univ., Washington, DC 20007.**

The actions of the marine toxin brevetoxin (PbTX-3) were studied on voltage-dependent sodium channels in clonal NG108-15 neuroblastoma x glioma cells. Single sodium channels were recorded in cell-attached and in excised inside-out or outside-out membrane patches at 21-25°C. PbTX-3 (20 μM) shifted the activation of sodium channels to membrane potentials more negative than normal, but did not increase the maximum probability of channel opening near 0 mV. The effect was equivalent to a shift in the voltage-dependence of activation by -8 mV. PbTX-3 did not change the single channel mean open lifetime, which was approximately 330 μsec for all potentials between -50 and -20 mV. This lack of change in mean lifetime suggests that PbTX-3 did not alter the inactivation rate of sodium channels. There was also no change in single channel conductance. These results suggest that brevetoxin increases the probability that voltage-dependent sodium channels will open at rest and that the resulting depolarization is self-limiting due to the presence of normal inactivation. Preservation of normal inactivation distinguishes brevetoxin from other activators of the sodium channel, such as batrachotoxin.

MOLECULAR PROPERTIES OF SINGLE SODIUM CHANNELS FROM DISEASED AND NON-DISEASED HUMAN BRAIN IN BILAYERS.
C. Frenkel*, D.S. Duch*, E. Recio-Pinto* and B.W. Urban. Depts. of Anesthesiology and Physiology, Cornell Univ. Medical College, New York, N.Y. 10021.

With approval of our Committee on Human Rights in Research, cortical tissue samples were obtained from patients undergoing craniotomies for removal of diseased (tumorous) and non-diseased (aneurysm and hydrocephalus operations, etc.) tissues, and synaptosomes prepared. Channels were incorporated into lipid bilayers in the presence of batrachotoxin and characterized under our standard conditions (500mM NaCl). The single channel slope conductances were 26.3 ± 0.7 pS (S.D.; n=37 membranes, diseased) and 26.2 ± 0.5 pS (n=30 membranes, non-diseased); averaged steady state activation midpoints were -87.0 ± 10.4 mV (S.D.; n=16 membranes, diseased), and -85.1 ± 7.8 mV (n=7, non-diseased); fractional open times outside the gating region were 0.95 ± 0.03 (S.D.; n=14 membranes, diseased, and 0.94 ± 0.06 (n=11, non-diseased). Subconductance states of 5-6 pS as well as similar channel incorporation rates were observed in both preparations. These results indicate that single sodium channels, originating from either diseased or non-diseased human brain tissue, do not differ significantly in their measured characteristics. Preparations from either tissue may be used as viable sources for future bilayer studies of sodium channels and their electrophysiological and pharmacological properties.

241.6

VERATRIDINE MODIFICATION OF PURIFIED SODIUM CHANNELS FROM EEL ELECTROPLAX IN PLANAR BILAYERS.
D.S. Duch,* E. Recio-Pinto* and B.W. Urban (SPON: W.F. Riker). Depts. of Anesthesiology and Physiology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

Highly purified, reconstituted sodium channels from the electric organ of the electric eel were incorporated into planar bilayers in the presence of veratridine. In symmetrical 500 mM NaCl, veratridine activated channels in a voltage-dependent manner, with depolarizing potentials increasing both the probability of channel opening and mean open times. Fractional open time reached half its maximum at -25 mV (physiological potential, at least 26 channels in 6 different membranes). I/V curves were linear with an average slope of the predominant single channel conductance of 11.3 ± 0.94 pS (sd;n=139). Smaller conductances ranging between 2 and 9 pS were also present in many membranes, representing approximately 25% of measured transitions. These smaller conductances were rarely found in the absence of larger conductances. TTX blocked channels in a voltage-dependent manner similar to BTX, with a $K_{\frac{1}{2}}$ value of 17.6 ± 1.7 nM (sem;n=6) at 0 mV. In contrast to the results with eel sodium channels, no 10-13 pS sodium channels were recorded when either dog (21 membranes with channel activity from 4 preparations) or human (3 membranes, 1 preparation) brain synaptosomes were fused with bilayers in the presence of veratridine. Instead, the primary conductances were 3-6 pS.

241.7

THE DROSOPHILA PARA LOCUS IS A SODIUM CHANNEL STRUCTURAL GENE
B. Ganetzky and K. Loughney*. Laboratory of Genetics, University of Wisconsin, Madison, WI 53706

The $para^{ts}$ mutation in Drosophila was previously shown to block conduction of nerve action potentials in a temperature-dependent fashion. Based on this and other observations it was proposed that the para locus affected sodium channels in some way (Wu and Ganetzky, Nature 286:814, 1980). To elucidate the molecular nature of the para gene product we cloned the para region by means of P-element transposon tagging (Loughney and Ganetzky, Soc. Neurosci. Abstr. 11:782, 1985; Ganetzky et al., Ann. New York Acad. Sci. 479:325, 1986). We mapped the extent of the para gene by localizing the molecular lesion associated with a number of mutant para alleles and found that it spans a region of at least 70 kb. cDNAs that derive from this region have now been isolated and their nucleotide sequence determined. The sequence analysis reveals that the para gene product shares extensive amino acid similarity with the alpha subunit of sodium channels from rat brain. The para amino acid sequence can be aligned with each of the four internally homologous domains of the rat channel. Furthermore, in each domain, the para gene product conserves the S1-S6 membrane spanning regions of the rat polypeptide (Noda et al. 320:188, 1986). This structural similarity between the rat sodium channel together with the patch-clamp evidence that para mutations disrupt sodium currents (O'Dowd et al. Soc. Neurosci. Abstr. 17: 577) argues strongly that para is a sodium channel structural gene. Although other sodium channel genes have been cloned from Drosophila by homology to the vertebrate gene, (Salkoff et al. Science 237:744, 1987), so far para is the only one of these for which mutations exist. Therefore, the para locus provides a unique opportunity for the detailed mutational analysis of sodium channel function, regulation and expression in the Drosophila nervous system.

ISOLATION OF cDNA CLONES ENCODING A FULL LENGTH RAT SKELETAL MUSCLE SODIUM CHANNEL.
J. S. Trimmer, W. S. Agnew, S. A. Tomiko, S. M. Crean, Z. Sheng[#], R. Kallen[#], R. L. Barchi[+], S. S. Cooperman, R. H Goodman, and G. Mandel. Dept. of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT, 06510; [#]Dept. of Biochemistry and Biophysics, and [+]Mahoney Inst. of Neurological Sciences, University of Pennsylvania School of Medicine, Philadelphia, PA, 19104; Division of Molecular Medicine, Tufts-New England Medical Center, Boston, MA, 02111.

To generate a cDNA clone encoding a full length rat skeletal muscle sodium channel, we have screened a denervated muscle cDNA library with two probes, a 1.2 kb cDNA encoding for the carboxyl terminus of the rat brain type II sodium channel and a 120 base cDNA encoding the first 40 amino acids of the rat brain type I sodium channel. Twelve cDNA clones were isolated and characterized. DNA sequence analysis of these clones reveals large regions of homology with the rat brain type II sodium channel. However, the predicted amino acid sequence of the muscle sodium channel differs from the brain and electroplax channels in several regions. These cDNA clones hybridize to a 9.5 kb mRNA on Northern blots of RNA isolated from neonatal, innervated adult and denervated adult rat skeletal muscle. A full length cDNA clone encoding a skeletal muscle α-subunit has been constructed from three overlapping cDNA clones. Expression of mRNA transcribed *in vitro* from this cDNA is being examined in a number of heterologous expression systems. Our results indicate that skeletal muscle sodium channels represent distinctive members of the mammalian sodium channel multigene family. A comparison of the predicted amino acid sequences between muscle and brain sodium channel proteins indicates regions which may be responsible for the observed differences in pharmacological and functional properties of these two channel classes.

A RAT BRAIN Na CHANNEL α SUBUNIT WITH ALTERED INACTIVATION PROPERTIES.
A.L. Goldin[1], D.S. Krafte[1], V.J. Auld[2], R.J. Dunn[2], N. Davidson[1] and H.A. Lester[1]. [1]Division of Biology, Caltech, Pasadena, CA 91125 and [2]Dept of Medical Genetics, U. Toronto, Toronto, Canada.

We have investigated the macroscopic and single-channel properties of Na channels induced in *Xenopus* oocytes by *in vitro* transcripts of the rat brain IIA α subunit cDNA clone. Our data show that the steady-state voltage dependence of inactivation is shifted by 10 mV in the depolarizing direction relative to that for Na currents induced by injection of rat brain poly(A) RNA. In addition, the rate of recovery from inactivation is altered for rat IIA channels. When a train of depolarizing pulses is given from a holding potential of -100 mV to +10 mV at 10 Hz there is no change in the peak amplitude of Na current in oocytes injected with poly(A) RNA. In oocytes injected with rat IIA RNA there is a marked reduction in current amplitude during the train. Pulsing at 10 Hz reveals two kinetic components in the rat IIA currents. One component has a slow inactivation rate and is completely eliminated at this frequency while the other inactivates rapidly and is not removed at 10 Hz. The slow component is attenuated even for stimulation frequencies as slow as 1 Hz. The rate of recovery from inactivation of this slow component is voltage dependent. There is less attenuation of current if the holding potential is -120 mV as opposed to -80 mV. We have begun a quantitative characterization of the single-channel properties of Na channels induced by rat IIA RNA. At the single-channel level we see a decreased open time relative to Na channels from poly(A) RNA and an increased probability of reopening at a given potential. Supported by NS-11756, GM-10991, and fellowships from NIH and the Markey Trust.

241.10

LOW MW RNA ENCODED PROTEIN(S) MODIFIES THE FUNCTIONAL PROPERTIES OF THE RAT BRAIN Na CHANNEL.
D.S. Krafte[1], A.L. Goldin[1], V.J. Auld[2], R.J. Dunn[2], H.A. Lester[1], and N. Davidson[1]. [1]Division of Biology, Caltech, Pasadena, CA 91125 and [2]Dept of Medical Genetics, U. Toronto, Toronto, Canada.

We have investigated the inactivation properties of Na channels induced in *Xenopus* oocytes by co-injection of low molecular weight (mw) RNA and RNA transcribed from the rat brain IIA α subunit cDNA clone. Na channels induced by injection of rat IIA RNA alone demonstrate 2-4 fold slower inactivation, a 10 mV shift in the steady-state voltage dependence, and a 20-25 mV shift in the voltage at which maximum inward current occurs compared to channels induced by rat brain poly(A) RNA. A low mw sucrose gradient fraction of rabbit brain RNA from 1-2.5 kb or a fraction < 4 kb from rat brain restores the rate and steady-state voltage dependence of inactivation to normal. These changes render the currents induced by rat IIA plus low mw RNA essentially indistinguishable from those induced by injection of poly(A) rat brain RNA with respect to inactivation. Although normal rapid inactivation is restored, the voltage for maximum inward current is not. This may have interesting implications for state models of the Na channel. We have begun single-channel recording from Na channels induced by injection of rat IIA RNA plus low mw rat brain RNA. Preliminary results indicate that the probability of re-opening is returned to values similar to those measured for Na channels induced by rat brain poly(A) RNA. We are currently employing a functional cDNA cloning strategy using the low mw RNA fractions to isolate a specific cDNA clone which modifies the rat brain α subunit. Supported by NS-11756, GM-10991, and fellowships from NIH and the Markey Trust.

242.1

DIFFERENCES IN THE ACTIVITY AND cAMP-DEPENDENT REGULATION OF NEW AND OLD ACETYLCHOLINE RECEPTORS ON BOVINE ADRENAL CHROMAFFIN CELLS. L.S. Higgins and D.K. Berg. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

Activation of nicotinic acetylcholine receptors (AChRs) on bovine adrenal chromaffin cells leads to the release of endogenous catecholamines. Here we report that AChRs newly inserted into the plasma membrane appear to be more active than are older receptors. In addition, cAMP analogs substantially enhance the nicotinic response of older AChRs but have little effect on new AChRs.

cAMP analogs increased nicotine-induced ^{3}H-norepinephrine (^{3}H-NE) release from the cells 66±15% and increased the nicotine-induced membrane conductance (g_{nic}) 3-fold. No change was observed in K^+-induced ^{3}H-NE release or in the current-voltage relationship of the membrane, confirming that the increases represented effects on AChRs. The effect was specific for a cAMP-dependent process and acted on existing AChRs in the plasma membrane.

To compare the properties of new and old AChRs, cells with only new AChRs were obtained by allowing new AChRs to accumulate on the cells for 3-6 hours (ca. 0.2 AChR half lives) after either blocking existing AChRs with affinity alkylation or removing them with antigenic modulation. Cells with old AChRs were obtained by blocking the appearance of new receptors for 24 hours (ca. 1 AChR half life) with tunicamycin or puromycin, allowing existing receptors to age. Cells with new AChRs had 2-3 times more nicotinic response per equivalent number of AChRs than did control cells, assayed either by ^{3}H-NE release or by g_{nic}. The nicotinic response of cells with new AChRs was not increased by treatment with a cAMP analog. Cells with old AChRs had about the same nicotinic response per AChR as did control cells and the response was tripled by treatment with a cAMP analog. The results indicate that AChRs and/or associated components undergo a maturation in the plasma membrane that alters their function and regulation by second messengers. CYCLIC AMP MODULATES ACETYLCHOLINE RESPONSES IN OLD BUT NOT YOUNG CHICK CILIARY GANGLION NEURONS. D. Gurantz*, V.E. Dionne*, D.K. Berg, and J.F. Margiotta. Depts. of Pharmacology and Biology, UCSD, La Jolla, CA 92093.

In ciliary ganglion neurons grown in culture, cyclic AMP (cAMP) analogues increase the peak whole-cell acetylcholine (ACh) current by 2-3 fold (Margiotta et al., PNAS 84:8155, 1987). The enhanced response probably reflects a cAMP-dependent activation of non-functional ACh receptors (AChRs) since neither the properties of functional AChRs, nor the total number of surface AChRs are altered by the treatment. To ask whether the cAMP-dependent AChR modulation is developmentally regulated, neurons isolated from young and older ganglia were incubated in saline ± 8-bromo-cAMP and IBMX for 6h. Treated and untreated neurons from young ganglia (E8,9) displayed similar whole-cell currents in response to microperfusion with 500 uM ACh. In contrast, treated neurons isolated from older ganglia (E13,14) displayed about 2-fold larger ACh currents (n=12) than did untreated controls (n=12), as was seen in neurons grown in culture for 5-8 d. The cAMP-dependent increase in ACh response observed in acutely isolated older neurons could not be accounted for by a proportional change in the total number of AChRs detected with ^{125}I-mAb 35. The results demonstrate that cAMP-dependent modulation of AChRs on ciliary ganglion neurons is developmentally regulated, and parallels other developmental changes in receptor function such as increased channel open time and reduced apparent affinity for ACh. Supported by NIH grants NS24417 and NS12601.

242.3

SUBUNIT COMPOSITION AND PHOSPHORYLATION OF NEURONAL ACETYLCHOLINE RECEPTORS FROM CHICK CILIARY GANGLIA. S.W. Halvorsen and D.K. Berg. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

Chick ciliary ganglion neurons are parasympathetic and have nicotinic acetylcholine receptors (AChRs) that mediate primary synaptic transmission through the ganglion. The ACh response of the neurons in culture can be modulated by a cAMP-dependent process. We report here that AChRs purified from chick ciliary ganglia have a subunit composition similar to brain AChRs and different from muscle AChRs. In addition, one of the receptor subunits can be phosphorylated in the membrane by cAMP-dependent protein kinase.

AChRs were isolated from embryonic ganglia by ion exchange and immunoaffinity chromatography. Analysis of the purified and radioiodinated material by SDS-PAGE revealed two major polypeptides with M_rs of 52 K and 60 K. Both components appear to be constituents of the AChR since they were specifically depleted from ganglion extracts by the immunoaffinity column and were prevented from binding to the column when an excess of anti-AChR antibody was used to compete with the immunoaffinity resin for the receptor. Partial proteolytic digestion of the isolated polypeptides with papain produced distinct peptide maps for the two species, indicating that they represent separate subunits. Both subunits are glycoproteins since their mobilities on SDS-PAGE were markedly increased by treatment with glycopeptidase F.

The ability of the receptor to serve as a substrate for cAMP-dependent protein kinase was examined by incubating a ganglionic membrane fraction with the catalytic subunit of the enzyme and [γ-^{32}P]ATP. AChRs were then immunoaffinity purified and analyzed by SDS-PAGE autoradiography. A 60 K [^{32}P]-labeled protein was identified, corresponding to the 60 K AChR subunit. Additional experiments will be required to determine the significance of the phosphorylation for receptor regulation. (Supported by NS12601 and NS25916)

242.4

EXPRESSION OF NICOTINIC ACETYLCHOLINE RECEPTORS AND RECEPTOR mRNA IN A SUBPOPULATION OF CHICK DORSAL ROOT GANGLION NEURONS *IN VIVO*. R.T. Boyd[1], M.H. Jacob[2], A.E. McEachern[1], and D.K. Berg[1]. [1]Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093 and [2]Worcester Foundation for Exptl. Biology, Shrewsbury, MA 01545.

The dorsal root ganglion (DRG) contains subpopulations of neurons that can be distinguished by various criteria including size, fields of innervation, and neuropeptide content. We report here that a stable proportion of DRG neurons *in vivo* expresses an mRNA encoding the neuronal acetylcholine receptor (AChR) alpha3 subunit, and many DRG neurons have functional nicotinic AChRs.

In situ hybridization on cryostat sections with an alpha3 probe at high stringency revealed alpha3 RNA in chick DRG neurons at all ages examined (embryonic day 8 to posthatch 1 year). Little decline occurred in the size of the neuronal subpopulation with age: 22 ± 2% of the neurons in DRG sections from 1 month old chicks contained detectable hybridizing material as did 18 ± 2% of the neurons in DRG sections from one year old chickens. Northern analysis and RNase protection experiments found no differences in the alpha3 gene product in dorsal root ganglia and that expressed in brain and ciliary ganglia.

The presence of AChRs in DRG neurons was confirmed by immunological and electrophysiological studies. An anti-AChR monoclonal antibody together with fluorescently labeled avidin-biotin antibody complex detected AChRs in 16 ± 3% of neurons in 18 day embryonic DRG sections. Intracellular recording from freshly dissociated neurons of the same age indicated that a quarter of the cells (16 out of 67 tested) had ACh sensitivities that averaged about 30% as high as those observed for ciliary ganglion neurons in culture. Another quarter (16 out of 67) had lower levels of ACh sensitivity while half of the neurons had no detectable response to ACh. d-Tubocurarine (100 µM) reversibly blocked the ACh responses. The results demonstrate that a subpopulation of chicken DRG neurons expresses functional nicotinic AChRs *in vivo*. (Supported by NS12601 and NS21725)

242.5

EFFECTS OF DENERVATION ON CLUSTERS OF ACETYLCHOLINE RECEPTOR-LIKE MOLECULES ON THE SURFACE OF CARDIAC GANGLION CELLS. P.B. Sargent, D. Pang*, and J.M. Lindstrom, Division of Biomedical Sciences, University of California, Riverside, CA 92521, and The Salk Institute for Biological Studies, San Diego, CA 92138.

The effect of denervation on the number, size and distribution of clusters of nicotinic acetylcholine receptor (AChR)-like molecules was examined in the parasympathetic cardiac ganglion of the frog *Rana pipiens*. AChR-like immunoreactivity was measured using immunofluorescence and immunoperoxidase techniques and a monoclonal antibody (mAb 22) made against AChRs from *Electrophorus electricus* which cross-reacts with AChR-like molecules on the cardiac ganglion cell surface. In normally innervated ganglia peroxidase staining is found in small patches occupying about 0.4% of the cell surface. Most (about 80%) of the patches are located at sites of synaptic bouton contact, where the immunoreactivity is found in register with the postsynaptic electron-dense specialization. Immunofluorescence studies indicate that several patches of immunoreactivity are often associated with single boutons, which can have several active zones. Following 2 weeks of denervation there is a 30% decrease in the number of patches of AChR-like immunoreactivity on the cell surface and a 4-fold decrease in their size. Immunoreactive patches on denervated neurons tend to be more dispersed than normal. These results suggest that subsynaptic clusters of AChRs on the ganglion cell surface are not stable following the loss of innervation. Immunoperoxidase studies using mAb 22 in frog skeletal muscle indicate no loss of AChR-like patches nor any change in their size after 2 weeks of denervation. Thus, the myofibers and neurons studied here respond differently to denervation: AChR clusters appear to be stable after short periods of denervation in muscle but not in nerve. (Supported by NIH NS24207).

242.6

CHOLINERGIC LIGAND EFFECTS ON EXPRESSION OF FUNCTIONAL NICOTINIC RECEPTORS BY THE TE671 HUMAN MEDULLOBLASTOMA CLONAL LINE. Ronald J. Lukas, Division of Neurobiology, Barrow Neurological Institute, 350 West Thomas Road, Phoenix, AZ 85013.

Cells of the TE671 cerebellar line are of primitive neuroectodermal origin and express nicotinic acetylcholine receptors (nAChR) that are fully sensitive to functional blockade by alpha-bungarotoxin (Bgt) and otherwise resemble the class of nAChR that also are found at the vertebrate neuromuscular junction. Other studies from this laboratory have shown that chronic treatment (24-48 hr) of TE671 cells with certain nicotinic agonists induces an increase in the expression of cell surface and crude particulate fraction binding sites for radiolabeled Bgt. This report concerns the contrasting effects of chronic drug treatments on the expression by TE671 cells of functional nAChR detected by the use of $^{86}Rb^+$ ion efflux assays.

Loss of functional nAChR activity is seen following chronic exposure to carbamylcholine or nicotine with dose-dependences comparable to those observed for activation of nAChR function by shorter term (1-5 min) exposure to carb or nic, evolves quickly ($T_{1/2}$=5 min) and reverses slowly (est. $T_{1/2}$=24 hr). Effects of chronic agonist treatment are not blocked by coincubation with d-tubocurarine (d-TC) or decamethonium (C_{10}), but rather are mimicked by chronic exposure to d-TC or C_{10} alone with a dose-dependence that is similar to that observed for d-TC- or C_{10}-mediated blockade of shorter-term agonist activation of nAChR function. By contrast, chronic pancuronium or alcuronium (1mM) treatment has no effect alone, but rather protects functional nAChR sites from agonist-induced down-regulation. The full presentation of these data will include discussions of technical considerations and the general implications of these results on the interpretation of data concerning and the mechanisms underlying the regulation of receptor expression.

CONFORMATIONAL CHANGES DURING FORMATION OF THE COMPLEX BETWEEN α-BUNGAROTOXIN AND SYNTHETIC PEPTIDES THAT MIMIC A BINDING DOMAIN. E. Hawrot and Q.-L. Shi*. Dept. of Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510.

The region containing residues 173-204 of the α-subunit of the nicotinic acetylcholine receptor is a major determinant of the α-bungarotoxin (BGTX) binding site as shown by a number of studies including those utilizing synthetic peptide mimics (prototopes). Several shorter peptides within this region also bind BGTX but often with reduced affinity as compared to the 32mer. Previous binding studies have relied on solid-phase assays that may underestimate binding affinities. We have now developed soluble binding assays based on spectroscopic techniques which, in addition, provide valuable structural information and reveal a number of conformational changes that occur upon complex formation.

We have used circular dichroism (CD) and proton nuclear magnetic resonance (NMR) to measure BGTX binding to several short synthetic peptides. CD changes upon binding provide a sensitive probe of changes in secondary and tertiary structure in a number of other ligand-protein interactions. We detect large CD changes in both the near and far UV regions upon addition of equimolar amounts (2.5-60 μM) of BGTX and a synthetic 18mer (α-residues 181-198). The far UV CD spectrum is indicative of a large increase in β structure, whereas the near UV CD spectrum strongly suggests a large change in the environment of the side chains, especially the aromatic residues as well as those regions surrounding the disulfide bridges in BGTX. Binding could be detected under acidic conditions (pH 3) as well as at pH 7. Similar CD changes occur upon addition of BGTX to a synthetic 12mer containing α-residues 185-196 and indicate an apparent K_D of 1 μM. NMR investigations confirm the structural changes in aromatic residues of both BGTX and the synthetic peptides. Measurements of the spin-lattice relaxation rates (T_1) for the aromatic protons in the 12mer indicate a decreased mobility of these residues upon binding. In addition, a disulfide bond between the adjacent cysteines (Cys192-Cys193) does not appear to be essential for BGTX binding as monitored in CD assays. An 11mer (α-residues 186-196) with an Ala substituted for Cys192 continues to bind BGTX as measured by changes in CD. Binding does, however, become pH sensitive with this amino acid substitution, being undetectable under acidic conditions.

Supported by the MDA, NIH, and the AHA.

242.8

MONOCLONAL ANTIBODIES AGAINST α-BUNGAROTOXIN RECOGNIZE NICOTINIC BUT NOT MUSCARINIC RECEPTOR LIGANDS. M. Quik, S. Geertsen*, R.L. Kenigsberg* and A.C. Cuello (SPON: P. Etienne). Dept. Pharmacol., McGill U., Montreal, Canada.

The aim of this study was to raise monoclonal antibodies (mAb) against α-bungarotoxin (α-BGT) which could recognize an epitope on the toxin molecule that interacted with the receptor. Hybridomas secreting mAbs against α-BGT were produced from the fusions of lymphocytes from hyperimmune animals with myeloma cells. Screening for the presence of anti-α-BGT Abs was done using the ^{125}I-α-BGT binding assay. Several mAbs were identified which interfered with the binding of α-BGT. Their crossreactivity with cholinergic receptor ligands was subsequently investigated. MAb spB57 interacted most potently with nicotinic agonists; it also interacted with d-tubocurarine, but to a lesser degree, and not with other nicotinic antagonists. Muscarinic agents did not crossreact with spB57. Another mAb nsB8 also bound to α-BGT; however, cholinergic ligands did not interact with nsB8.

These results indicate that mAb spB57 raised against α-BGT crossreacts more potently with nicotinic agonists than antagonists. This could suggest that the α-BGT site is more closely linked to the agonist recognition site than the site to which nicotinic antagonists bind. This latter feature may distinguish the nicotinic α-BGT site from other nicotinic receptor populations.

242.9

STIMULATION OF ARACHIDONIC ACID RELEASE IN TRANSFECTED CELLS EXPRESSING CLONED MUSCARINIC RECEPTORS.

Bruce R. Conklin*, Mark R. Brann*, Alice L. Ma*, Noel J. Buckley*, Tom I. Bonner*, Julius Axelrod. Laboratory of Cell Biology, NIMH, Laboratory of Molecular Biology NINCDS, NIH, Bethesda, MD 20892

A family of genes encoding four distinct muscarinic receptors (m1-m4) have been cloned (Science 237, 527), and stably expressed in A9 L cells. When the m1 and m3 receptors were stimulated with carbachol there was a rapid rise of liberated arachidonic acid (AA), cAMP, and phosphatidylinositol (PI) turnover, while m2 and m4 receptor stimulation had no effect on these second messengers. Pretreatment with the phorbol ester PMA for 30 minutes caused a marked acceleration and amplification of m1 and m3 receptor mediated AA release. In contrast m1 and m3 mediated PI turnover was inhibited by a 30 minute PMA pretreatment. PMA caused no change in basal AA release or PI turnover. To examine the role of protein kinase C, the cells were preincubated with PMA for 24 hours to desensitize protein kinase C, and the PMA amplification of AA release was abolished. AA release was also unaffected by the cAMP analog, dibutyryl cAMP, or the phosphodiesterase inhibitor IBMX. The phospholipase A_2 (PLA_2) inhibitor mepacrine (100μM) inhibited 79% of the AA release while inhibiting 30% of PI turnover.

Carbachol stimulation of the m1 and m3 receptors also decreased mitogenesis as measured by [3H] thymidine incorporation. The cyclooxygenase inhibitor, indomethacin (10μM) partially blocked (20%) the carbachol induced inhibition of mitogenesis of m1 transfected cells while having no effect on basal mitogenesis.

These experiments demonstrate that AA release by the m1 and m3 receptors is regulated independently of PI turnover and cAMP accumulation. Furthermore the differential effects of PMA and the PLA_2 inhibitor on AA release and PI turnover indicates that the main source of AA release mediated by m1 and m3 muscarinic receptor activation is phospholipase A_2.

Cloned muscarinic receptors couple to different G-proteins and second messengers. Mark R. Brann*, Bruce R. Conklin*, S. V. Pe nelope Jones*, Nick M. Dean*, Regina M. Collins*, Tom I. Bonner* and Noel J. Buckley*.(SPON: M. Walton) Laboratories of Molecular Biology & Neurophysiology, NINCDS, Laboratory of Cell Biology, NIMH, Laboratory of Biological Chemistry, NCI, Metabolic Diseases Branch, NIDDK, National Institutes of Health, Bethesda MD 20892.

The existence of four distinct muscarinic receptor subtypes (m1-m4) has recently been shown using molecular cloning methods (Science 237, 527). The ability of these receptors to couple to different signal transducing G-proteins and second messenger systems, was examined using A9 L cell lines stably expressing each of the cloned receptors. The interactions of the muscarinic receptors with G-proteins were characterized by measuring the effect of guanine nucleotides, and pertussis and cholera toxins on the affinity of the agonist carbachol for each receptor. Guanine nucleotides decreased the affinity of carbachol for the m1, m2, and m3 receptors, but had no effect on m4 receptors, suggesting that m4 receptors do not couple with a G-protein endogenous to A9 L cells. Pertussis and cholera toxin decreased the affinity of carbachol for m2 but not to m1 and m3 receptors, indicating that m2 receptors couple to a different G-protein. Application of agonist to m1 and m3 receptors increased cAMP levels, phosphatidylinositol hydrolysis, arachidonic acid release and conductance through Ca++ dependent potassium channels. Pertussis and cholera toxin treatments had no effect on these responses, and the m2 and m4 receptors had no detectable effects on these second messengers. These data suggest that muscarinic receptors couple to different G-proteins and second messengers.

AN M_1 MUSCARINIC RECEPTOR EXPRESSED IN THE TRANSFECTED MURINE FIBROBLAST B82 CELLS IS COUPLED TO THE HYDROLYSIS OF INOSITOL LIPIDS. L. Mei, J. Lai, W.R. Roeske, J.C. Venter and H.I. Yamamura. Depts of Pharmacology & Internal Medicine, Univ. Arizona, Tucson, AZ 85724; Section of Receptor Biochemistry and Molecular Biology, LCMN, MINCDS, NIH, Bethesda, MD 20892.

The radioligand binding properties of the muscarinic receptor expressed in the transfected B82 cells and its possible coupling interactions were studied. [^{3}H](-)QNB binding to the intact transfected cells was saturable and displaceable by atropine. The K_d and B_{max} values of [^{3}H](-)QNB were 12 pM and 17 fmol/10^6 cells, respectively. Inhibition studies of [^{3}H](-)QNB binding to the intact transfected cells suggested that the muscarinic receptor is of an M_1 type since it has high affinity for pirenzepine but low affinity for AF-DX 116. The muscarinic agonist carbachol stimulated [^{3}H]IP_1 accumulation in the transfected B82 cells, which could be inhibited by pretreatment of the cells with pertussis toxin or by muscarinic antagonists. The rank order of muscarinic antagonists in inhibiting carbachol-induced [^{3}H]IP_1 accumulation was atropine > PZ > AF-DX 116, in a good agreement with that from ligand/[^{3}H](-)QNB competition studies. Carbachol at 10 mM had neither stimulatory nor inhibitory effect on the basal or PGE_1-induced cAMP formation in the presence of 5 mM IBMX. These results suggest that the M_1 muscarinic receptor expressed in the transfected B82 cells is coupled to the hydrolysis of PI possibly via a pertussis toxin-sensitive G protein.

USE OF BACCULOVIRUS FOR THE EXPRESSION OF CLONED DNA ENCODING G-PROTEIN COUPLED RECEPTORS. M. Dennis*, M. Caron* and P. Payette* (SPON: E. MacKenzie) Biotechnology Research Institute, 6100 Royalmount Ave., Montréal, Québec, Canada, H4P 2R2.

Detailed studies of the molecular basis of receptor function require homogeneous preparations of receptor protein in sufficient amounts for biochemical and biophysical analyses. We are investigating the use of bacculovirus for the high-level expression of two G-protein coupled receptors from cloned DNA in insect cells. Genomic clones encoding yeast α-mating factor receptor STE2; a gift from J. Thorner, Univ. of Calif.) and human muscarinic receptor HM1 subtype (generously provided by D. Capon, Genentech, Inc.) were subcloned into the F1 - containing plasmid pTz and single stranded DNA prepared. Synthesis of the second strands was primed with synthetic oligonucleotides (32-42 n) complementary to the 5' and 3' ends of the coding sequences, but containing mismatches specifying Bam H1 restriction sites, and transformants screened by hydridization at high stringency with the ^{32}P-labeled oligonucleotides. Two rounds of mutagenesis yielded plasmids containing the yeast STE2 coding sequence flanked by Bam H1 sites; analogous work is proceeding with the human HM1 sequence. The coding portions for the two receptor genes are to be cloned into the Bam H1 site of the plasmid pAc 373 for homologous recombination into bacculovirus and expression in SF9 insect cells. This work was supported in part by the Medical Research Council.

SCOTOMA INDUCED BY FOCAL ACTIVATION OF CALCARINE CORTEX WITH THE MAGNETIC COIL. R.Q. Cracco, V.E. Amassian, P.J. Maccabee*, J.B. Cracco*, A. Rudell* and L. Eberle*. Depts. of Neurology and Physiology, SUNY, Health Sci. Ctr. at Brooklyn, New York 11203.

Using ourselves as subjects, the effect of magnetic coil (MC) stimulation on perception of letters randomly permutated in groups of 3 by a computer and displayed horizontally or vertically was studied. Topographical relations were investigated by placing a Cadwell MC tangentially on the scalp such that the distal edge was 2 cm above the inion and then shifting it to the left or right using a visual stimulus - MC pulse interval of 100 ms. Letters were rarely correctly reported with midline placements of the MC but shifting it to the left or right caused more errors in reporting letters at the extreme right or left, respectively, implying a focal cortical effect. Similarly, shifting the MC rostrally caused failure in reporting the bottom letter of a vertical array.

Stimuli delivered by the MC at midline locations were then given 0 to 200 ms after the visual stimulus at 20 ms increments. The letters were nearly always correctly reported at visual stimulus - MC pulse intervals either less than 60-80 ms or greater than 120-140 ms; letters were rarely correctly reported at intermediate intervals of 80-100 ms. Thus by 120-140 ms after the visual stimulus, information related to letter recognition is relayed from human calcarine cortex.

LOCAL CONNECTIONS OF HUMAN VISUAL CORTEX. A. Burkhalter and K.L. Bernardo*. Department of Neurosurgery & McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

Local connections in the human cortex are largely unknown. We have, therefore, begun to study connections within primary visual cortex (V1) and its reciprocal projections with area V2, using fiber tracing with the fluorescent dye, DiI, (Godement, P., et al., Development, 101:697, 1987) in post-mortem, fixed human visual cortex.

Experiments were performed in 2 adults. After injections into V1, tangential sections through layers 2 and 3 showed a sunburst pattern of labeled terminal clusters (300um in diameter) surrounding the injection site, similar to the projections between blobs, or between interblob regions, in non-human primates. In transverse sections we identified clustered, interlaminar projections from layer 2/3 to 5, layer 5 to 2/3 and 4Cb to 4A. The projections from V1 to V2 terminated in layers 2,3 and 4, avoiding infragranular layers. Large V2 injections revealed projections to V1 terminating in 300um wide clusters in layers 2,3,4A and 5. The center-to-center spacing was 500um. These results show that modern tracing techniques can be used to study connections in the human brain. In addition, they demonstrate that the local connections in V1 in humans and monkey are similar, and that the reciprocal connections between V1 and V2 show the laminar organization typical for forward and feedback projections. (Supported by NIH grant EY05935).

243.3

CYTOCHROME OXIDASE IMMUNOHISTOCHEMISTRY IN THE PRIMATE VISUAL CORTEX. R. F. Hevner and M. Wong-Riley. Department of Anatomy & Cellular Biology, Medical College of Wisconsin, Milwaukee, WI, 53226.

Studies of various brain regions using cytochrome oxidase (C.O.) histochemistry have shown that C.O. activity is not distributed homogeneously between and within these regions. In the primate visual cortex, C.O. activity forms distinct laminar and areal patterns (*e.g.*, puffs). This pattern can change over time in response to altered impulse activity from the retina (Wong-Riley and Carroll, Nature 307, 1984). How then is local C.O. activity regulated in the brain? We hypothesized that the amount of C.O. protein might be an important factor. We chose to test our hypothesis by C.O. immunohistochemistry. We reported last year that we had successfully purified C.O. (from calf brain) for use as an antigen. Since then we have obtained antisera from rabbits immunized with C.O. Antibodies to C.O. were demonstrated by ELISA, indirect immunoprecipitation of C.O. with protein A-Sepharose 4B, and slot blot. The antibodies reacted intensely with C.O. subunit IV by Western blot. We applied the antibodies in immunohistochemical studies of the macaque striate cortex, using the indirect immunoperoxidase and ABC methods. In sections cut tangential or perpendicular to the cortical surface, the immunohistochemical pattern closely resembled that seen by C.O. histochemistry. In particular, puffs of high C.O. immunoreactivity were visible in the supragranular layers in either plane of section. Omission of the primary antibody or substitution of pre-immune serum abolished the pattern.

These results support our hypothesis that the amount of brain C.O. protein is directly related to the activity of C.O. under normal conditions. We can not, however, rule out a role for variable molecular activity (turnover number) of the enzyme. In future studies we will see if the relationship between C.O. activity and amount holds true under experimental conditions.

Macaque brains were gifts of Drs. V. Haughton and H. Canh. (Supported by NIH NS18122 & EY05439 to MWR, and an MCW MSTP Fellowship to RFH.)

IMMUNOSTAINING REVEALS MORPHOLOGY AND DISTRIBUTION OF MEYNERT CELLS IN PRIMATE VISUAL CORTEX. B.A. McGuire and J.R. Naegele. The Rockefeller University, New York, NY 10021.

Meynert cells have been intriguing due to their large size, sparse distribution and projections to extrastriate areas such as MT. To learn more about their quantitative anatomy, we have stained macaque striate cortex with a monoclonal antibody raised against fixed cat lateral geniculate nucleus. Several neuronal cell types were immunoreactive, however Meynert cells were identified by their location in uppermost layer 6 and by their distinctively large size: the diameter of the labeled somas averaged about 27 μm, and that of the basal dendritic trees measured up to 1.4 mm. The immunoreactivity diffusely filled the cytoplasm and dendritic shafts, but left spines unstained. All layer 6A neurons of comparable size were immunoreactive, suggesting that every Meynert cell was stained. The population was distributed with some regularity, though some cell-free gaps of 300-400 μm in diameter were also present. The average area of the basal dendritic tree reconstructed for 7 cells was 0.412 mm^2, giving an overall coverage of 9.6. It will be important to determine the correspondence between these immunoreactive Meynert cells and both the cytochrome oxidase-rich blob columns, thought to be important in color processing, and the area MT-projecting cells, believed to be an important component of a system for analyzing motion.

SEGREGATION OF NEUROPEPTIDE Y-CONTAINING NEURONS OUTSIDE CYTOCHROME OXIDASE PUFFS IN THE MONKEY VISUAL CORTEX DEVELOPS IN THE ABSENCE OF VISUAL INPUT. R.O. Kuljis and P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510-8001.

Neuropeptide Y-containing neurons (NPYn) are situated predominantly outside the cytochrome oxidase (CO) puffs in layers II/III of macaque striate cortex (Kuljis & Rakic, Neurosci. Abs. '87). The distribution of NPYn (avidin-biotin-peroxidase) in relation to CO puffs (histochemistry) was analyzed in layers II/III of a normal newborn, and a 10-month old macaque enucleated binocularly six weeks before birth. Findings are expressed as: total No. of NPY neurons/No. neurons inside puffs/No. neurons expected inside puffs if uniformly distributed/% volume of layers II/III occupied by puffs/statistical significance (Chi square). In the neonate: 104/15/23/22%/p<0.46. In the enucleate: 130/1/16/12%/p<0.05. These findings indicate that the segregation of NPYn observed in adult animals begins prenatally and is completed postnatally. Visual experience (absent in the neonate), and in particular, retinal input (absent in the enucleate), appear not essential to trigger or maintain the segregation.

ARBORIZATION OF INDIVIDUAL AXONS FROM AREA V2 TO V1 IN THE MACAQUE MONKEY: A STUDY USING PHA-L. K.S. Rockland and A. Virga*. Eye Research Inst., Boston, MA. 02114 and ENRM V.A. Hospital, Bedford, MA. 01730.

In the macaque monkey, area V2 projects back to V1, with terminations (labeled by HRP or 3H-amino acids) mainly in layers 1 and 5. We have injected Phaseolus vulgaris (PHA-L) into area V2 in 4 monkeys, with the goal of clarifying aspects of axon morphology, as described below. Branching and Extent. Two axons (of 18 reconstructed) terminated in a "restricted" pattern: a single cluster (300um or 500um) in layers 1 and 2. More typically (16 profiles), axons ascended (either unbranched or with branches in the deeper gray matter) to L.1, where they had a "widespread" distribution. After branching asymmetrically, they traveled in L.1 for 0.75-0.90mm(6 axons), 1.0-1.8mm (5 axons), 2.2-2.8mm (4 axons), or 3.45mm (1 axon). Thus, individual axons from V2 can traverse 1-3 hypercolumn units in V1. Terminations. Delicate sprays of boutons occurred at intervals along the main trunk in L.1. Spacing, although variable, tended to be 300um or 600um. Frequently, secondary branches, parallel to the main branch in L.1, had scattered boutons along their length, as well as clustered sprays. Both beads and spines were observed. Layers. Supragranular terminations occurred mainly in L.1, but also L.2. There were arborizations in L.5; but these were consistently more restricted (200um-500um wide) than the supragranular ones. (EY07058)

VISUAL RESPONSES OF NEURONS IN AREA V2 AND IN THE SUPERIOR TEMPORAL SULCUS OF THE MACAQUE MONKEY DURING REVERSIBLE INACTIVATION OF AREA V1. **J. Bullier and P. Girard*. INSERM U 94, 16 av. Doyen Lépine, 69500 BRON, FRANCE.**

We have examined how the reversible inactivation of area V1 by cooling affects the responses of cells in area V2 and in the superior temporal sulcus (STS). We first determined that neural responses in area V1 are completely blocked for temperatures ranging between 6 and 20°C. After having measured the temperature gradients in the cortex, we recorded in a region of V2 sufficiently distant from the cooled region that the neuronal activity could not be directly blocked by the cold. Recording was also restricted to a region of V2 representing the same portion of the visual field as the cooled area in V1.

In these conditions, the overwhelming majority of area V2 neurons (215 out of 218 recorded sites) ceased to respond when V1 was reversibly inactivated.

In contrast, in MT and surrounding areas in the STS, many neurons with receptive fields contained within the region of the visual field represented in the cooled region of V1 remained active when V1 was reversibly blocked.

These results suggest that, for a number of neurons in STS, the visual information is not exclusively channeled through area V1. Area V2, on the other hand, appears to be almost entirely under the control of area V1.

243.8

CORTICAL CONNECTIONS OF MT AND DL IN THE PROSIMIAN GALAGO: EVIDENCE THAT MODULAR SEGREGATION OF PARALLEL PATHWAYS IS A PRIMITIVE FEATURE IN PRIMATES. L. A. Krubitzer and J. H. Kaas. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

In monkeys, parallel streams of visual processing involve neurons that project from distinct modules in area 17 to separate bands of neurons in area 18, which in turn relay either to the middle temporal visual area (MT) and onto the parietal lobe, or to the dorsolateral visual area (DL or V-4) and onto the temporal lobe. A demonstration of such connections in prosimian primates would suggest that these streams developed early in primate evolution, and a segregation of parallel streams is a general feature of primate visual cortex. To investigate this possibility, we injected one retrogradely transported tracer (fast blue) into MT, and another (diamidino yellow) into DL in the same galago (Senegalensis) to determine if inputs from area 18 were nonoverlapping. Cortex was flattened and cut parallel to the surface to favor visualization of bandlike patterns of label in area 18. Alternate sections were stained for cytochrome oxidase (CO). The CO dense bands typically seen in area 18 of monkeys were only weakly and inconsistantly revealed in galagos. Nevertheless, neurons labeled by MT injections were completely segregated from neurons labeled by DL injections. The zones of label from DL and MT while in the same general region of area 18 were offset from each other. Neurons related to both injections formed bandlike arrays, as in monkeys. Thus, separate visual processing streams related to temporal and parietal lobe functions probably differentiated over 50 million years ago, perhaps even before the primate divergence from Toketherian mammals. Supported by EY-02686.

243.9

DISTRIBUTION AND MORPHOLOGY OF NEURONS IN CAT AREA 17 THAT PROJECT TO THE MEDIAL BANK OF THE LATERAL SUPRASYLVIAN SULCUS. G. Einstein and D. Fitzpatrick. Department of Neurobiology, Duke University Medical Center, Durham, NC 27710.

We have used retrograde transport tract tracing methods combined with intracellular injections of lucifer yellow in lightly fixed tissue sections (Einstein and Fitzpatrick, Soc. Neurosci. Abstr., 13:676, 1987) to study the distribution and morphology of Area 17 neurons that project to the lateral suprasylvian sulcus (LS). Most of the LS projection originates from a heterogeneous population of pyramidal neurons distributed from the top of layer II to the upper portion of layer IV. These range in size from 100 um^2 to 500 um^2 and exhibit a variety of dendritic branching patterns; some neurons, at the top of layer II, have nearly radial dendritic fields that ramify extensively in layer I while others, in III and IV, have more conventional apical and basal dendritic systems. A population of neurons in the infragranular layers also projects to LS; among these are large pyramidal cells in layer V and small, bitufted neurons in layer VI. The morphological variation observed within and between layers suggests that the projection from Area 17 to LS comprises functionally diverse classes of neurons. Since this projection arises, in part, from the infragranular layers some of these neurons may also project to subcortical targets. Supported by NEI grants EY06661 and EY05546.

PRESUMED AFFERENTS FROM AREAS 17 AND 18 TO THE CAT'S CLARE-BISHOP AREA: RESPONSE PROPERTIES AND FUNCTIONAL ORGANIZATION. Helen Sherk Dept. of Biological Structure, U. of Washington, Seattle, WA 98195.

Areas 17 and 18 in the cat have two major cortical targets, area 19 and the Clare-Bishop area (CB). A novel technique was used to investigate the responses and functional organization of the of the pathway to CB. Local injections of kainic acid were made in CB to silence neurons; it was then possible to record directly from what appeared to be axon terminals. Their response properties indicated that these were cortical in origin, most likely from areas 17 and 18. Axons from both simple and complex cells could be identified.

A detailed comparison was made between a sample of about 400 afferents and a similar sample from laminae 2+3 of area 17. Response properties were quite similar. A somewhat larger fraction of the afferents were direction-selective. End-stopping, on the other hand, was extremely rare. Afferents' response characteristics were markedly different from those of neurons in CB.

In long tangential penetrations through CB, afferents showed a clear organization according to preferred orientation. Within this framework, afferents were also ordered according to preferred direction.

BANDED CONNECTIONS BETWEEN AREAS 17 AND PMLS IN CAT VISUAL CORTEX: POSSIBLE FUNCTIONAL ROLE FOR GLOBAL MOTION PROCESSING. Josef P. Rauschecker and Andreas Kreiter*, Max-Planck-Institut für biologische Kybernetik, Tübingen, FRG

We have reported recently (Rauschecker et al., J. Neurosci. 7: 943-958, 1987) that many neurons in the cat's lateral suprasylvian visual cortex (PMLS) prefer stimulus movement away from the area centralis ("centrifugal motion"). This finding gave a hint as to a possible functional role of PMLS in the evaluation of optic flow and 3-D motion. We are now trying to determine how this global network property is generated from other inputs. It is known that PMLS receives inputs from cortical areas 17, 18 and 19, among others, as well as from parts of the LP-pulvinar complex that show the same kind of centrifugal direction bias as PMLS (Rauschecker, Progr. in Brain Res., 1988). Here, we are especially interested in the organization of cortical input to PMLS and have started investigations using two different experimental approaches.

Physiologically, we have corroborated our original finding with more quantitative and randomized methods. In addition, using global flow field stimuli reveal cooperative effects between different parts of the visual field that may in part be responsible for the global processing properties found. Anatomically, by making small injections of rhodamine labelled latex beads and/or fluorogold into a localized part of PMLS (after identifying the direction preference of the same site by unit recording), we find that one such "column" receives input from distinct clusters of cells in area 17. In serial reconstructions these clusters form parallel bands of labelled cells, often with a periodicity close to 0.5 mm. As a next step we are doing simultaneous recording from PMLS and from area 17 trying to correlate the activity of neurons in both areas with regard to direction preference.

243.12

BACKGROUND DEPENDENCE OF DIRECTION SELECTIVITY IN CORTICAL NEURONS OF AREAS 17, 18, 19, 7 AND PMLS OF THE CAT. **K. Krüger*, H.R.O. Dinse (SPON. K. Behrend), Dept. of Zoology III, Biophys. Sect., University of Mainz, Saarstr. 21, D-65 Mainz, West Germany**

Neurons in visual cortical areas 17, 18, 19, 7 and PMLS were stimulated with a bar superimposed on a large field visual noise (2-dimensional Gaussian white noise covering 50 x 50 degrees of the visual field). The bar was always moved with optimal orientation, length and velocity, the background was kept stationary or moved at different velocities inphase or anti-phase to the bar. An index (DI) of the degree of direction selectivity was determined on the basis of the maximal amplitude in the PSTHs. According to this index, all cells were subdivided in three classes of direction selectivity (non-direction selective, direction sensitive, direction selective). For each class we determined the percentage of cells whose classification of directionality could be influenced by changes of the background condition.

1. The percentage of direction selective cells is very specific in the 5 cortical areas tested. Direction selective cells (DI > 50) were found predominantly in area 18 and PMLS. 2. Direction selectivity of a cell depends on the stimulus (background condition) in 70% of all tested neurons. 3. While in areas 17, 18, 19 and area 7 only 15-30% of all neurons are "direction-permanent" for all conditions tested, i.e. their degree of directionality is not influenced by the background condition, PMLS is a rather special case insofar as more than 50% of all PMLS cells are "direction permanent". We found no difference for the two eccentricity classes tested (10 deg within area centralis, peripheral visual field).

We conclude that PMLS is especially qualified to code absolute directions of motion independently of the stimulus configuration.

244.1

A PARADOXICAL RESULT: INHIBITION *INCREASES* OPTIC NERVE ACTIVITY. R. B. Barlow, Jr., Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

Inhibition has long been known to have a major role in processing information in the visual system. Transmission of inhibitory signals among neighboring elements of the retina can modulate gain and enhance borders and edges in the visual field. These inhibitory actions extend the dynamic range of the retina and enhance contrast sensitivity.

I report here that inhibition in the *Limulus* eye may serve the additional function of preserving the response of the light-adapted retina. Exposing a single retinal receptor (ommatidium) to daytime illumination for >15 min often causes a complete cessation of its optic nerve response.

A normal response can be restored immediately upon illumination of a nearby region of the retina to generate inhibition. Offset of illumination of the neighboring region again leads to a rapid cessation of the optic nerve activity from the recorded unit.

A paradoxical result: onset of inhibition increases optic nerve activity while offset of inhibition decreases it.

Inhibition thus appears to be essential for maintaining the response of the light-adapted retina. Inhibition may achieve this function by *protecting* spike encoders from the effects of high excitatory inputs.

WHOLE-CELL CURRENTS AND SINGLE-CHANNELS ACTIVATED BY GABA AND GLYCINE IN GANGLION CELLS FROM THE GOLDFISH RETINA. B. Cohen* and G. L. Fain. The Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles CA 90024

GABA and glycine evoked currents in most ganglion cells isolated from the goldfish retina. Whole-cell currents were carried by Cl^- since their reversal potential shifted with E_{Cl} when isethionate was substituted for internal Cl^-. Bicuculline methochloride selectively blocked GABA-induced currents. Bicuculline, strychnine, and picrotoxinin blocked both GABA-induced and glycine-induced currents.

The slope conductance for the most frequent state of the GABA channel in symmetric 140 mM Cl^- was 14 pS. The extrapolated reversal potential was 2 mV. Glycine channels in symmetric 140 mM Cl^- could be separated into 3 groups based on the slope conductance of their most frequent state: 25-26, 29-30, and 40 pS. The reversal potentials for the groups were around 0 mV. The 25 and 30 pS channels had a substate around 14 pS. When isethionate was substituted for internal Cl^-, the reversal potential for the glycine channels shifted negatively. The I-V data were well fit by the Goldman current equation for Cl^-.

ALPHA (TYPE I) GANGLION CELLS OF RAT RETINA DIFFER FROM THOSE OF OTHER MAMMALS. L. Peichl* (SPON: J.I. Nelson). Max-Planck-Inst. f.Hirnforschung, D-6000 Frankfurt 71,FRG

Alpha cells, common to mammalian retinae, are large ganglion cells with a distinctive dendritic morphology. They branch in an inner or outer stratum of the IPL and are the presumed correlate of on-centre and off-centre Y cells respectively.

The present study used intracellular injections of Lucifer Yellow and reduced silver staining in retinal whole mounts to quantify rat alpha cells (termed type I cells by other authors). Outer stratifying alpha cells (α_o) show significantly denser dendritic branching compared to inner alpha cells (α_i). Their dendritic field sizes increase differently with eccentricity (central retina: α_o 280-340 µm Ø, α_i 220-280 µm Ø; peripheral retina: α_o350-500µm Ø, α_i 570-780µm Ø). The size difference is complemented by a difference in the density ratio α_i: α_o which is 4:3 in central retina and shifts towards 1:3 in peripheral retina, ensuring a constant dendritic overlap (coverage) of 3-4 fold for either population. The qualitative and quantitative differences between rat inner and outer alpha cells constitute a departure from the general mammalian pattern where inner and outer alpha cells are similar. The larger dendritic fields of inner (on) alpha cells suggest their receptive field centres are larger than those of outer (off) alpha cells. The greater number of outer alpha cells may reflect dominance of the "off" pathway.

QUANTITATIVE / FRACTAL ANALYSIS OF DENDRITIC TREES OF IDENTIFIED RABBIT RETINAL GANGLION CELLS F. R. Amthor. Dept. of Psychology & Neurobiology Research Center Univ. of Alabama at Birmingham 35294

Physiologically characterized rabbit retinal ganglion cells of virtually all major concentric and complex classes have been intracellularly injected with HRP. Each major physiological class is associated with a unique, identifiable dendritic morphology. In addition to differences in their 3-D structures, differences in the flat mount appearances of these cells have been investigated by the use of quantitative analyses of dendritic coverage such as their Fractal / Hausdorf-Besicovitch dimensions. These were computed using both interior box-counting and expanding area algorithms. On-Off directionally selective ganglion cells, which exhibit apparent dendritic loops, consistently have the highest Fractal dimensions of about 1.85, a value rarely found for any non-self intersecting branching structure. Some sparsely branching cell classes such as sluggish-transient concentric cells exhibit two distinct fractal dimensions at "micro" vs. global size size scales, possibly related to overall (skeletal) versus terminal dendritic branching strategies. Fractal and other quantitative analyses allow concentric classes such as brisk versus sluggish and sustained versus transient concentric cells to be distinguished from On-Off and On directionally selective, orientation selective, local edge detecting and uniformity detecting ganglion cell classes, and may suggest branching strategies during growth. Theoretical limits for some of these have been determined.

Supported by EY05070 and the Sloan Foundation.

WHAT ARE THE DIRECTIONALLY SELECTIVE SUBUNITS OF RABBIT RETINAL GANGLION CELLS? N. M. Grzywacz & F. R. Amthor[1].
Center for Biological Information Processing, MIT E25-201, Cambridge, MA 02139 & [1]Dept. of Psychology & Neurobiology Research Center, Univ. of Alabama at Birmingham 35294

Subunits have been postulated to account for motion selectivity over small distances within the receptive field (RF) center of On-Off direction-selective rabbit retinal ganglion cells. We investigated the spatial and temporal characteristics of these hypothesized subunits by determining extracellular responses to two-slit apparent motions in the null and preferred directions. For apparent motion in the null direction the first slit inhibited the response to the second regardless of whether the distance was a small or large fraction of the RF center. Within this large inhibitory field there was no temporal dependence on distance between the slits, and very little interaction between On and Off mechanisms. Subunit-like behavior thus cannot due to a restricted extent of the inhibitory region, but appears to result from a large inhibitory field interacting locally with excitation. Our data suggest that this inhibitory interaction is mediated by a shunting, rather than a hyperpolarizing mechanism having a time course resembling a low pass filter with τ about 100 ms. Two slit apparent motion in the preferred direction revealed facilitation over a large region with distance-independent temporal properties. Direction selectivity thus involves both inhibitory and facilitatory mechanisms that are spatially asymmetric, and extend over much of the RF center. A synaptic model we have formulated successfully accounts for these results.

IDENTITIES OF LGN PROJECTING RABBIT RETINAL GANGLION CELLS M.L. Pu* and F. R. Amthor[1]. (Spon. E. Taub) School of Optometry; [1]Dept. of Psychology & Neurobiology Research Center, Univ. of Alabama at Birmingham 35294

In order to determine what classes of ganglion cells project to the Rabbit LGN, diffuse and focal injections of fluorescent tracers Fast Blue and Rhodamine Latex beads, respectively, were made there. Following survival times of about ten days, the dyes were found to be retrogradely transported to projecting ganglion cell somata within the retina. These cells were injected intracellularly with Lucifer Yellow in living and lightly fixed tissue, so that projecting classes could be identified from knowledge of the dendritic morphologies of physiologically identified cells (Amthor et al., Invest. Ophthal. Vis. Sci. Suppl. 27(3):332). The classes of ganglion cells labeled varied somewhat with the survival time, fluorescent dye used and the injection location. Nearly all injections labeled ganglion cells that had large somata. Following Lucifer Yellow injection, many of these exhibited an Alpha-like morphology known to correspond to that of the brisk-transient concentric cells. However, ganglion cells with large somata but sparse dendritic trees were also found, which correspond to the dendritic morphologies of sluggish concentric cells. Some medium to large somata were those of the bistratified dendritic morphologies of On-Off direction selective ganglion cells. Somewhat less frequently labeled were ganglion cells with small dense arborizations and small somata, which correspond to the brisk-sustained-linear concentric cells.

ASSOCIATION OF ALPHA CELL DENDRITES WITH CHOLINERGIC AMACRINE PROCESSES. N. Vardi, P. Masarachia* and P. Sterling. Dept. Anat. Univ. Penn., Phila, PA 19104.

The cholinergic amacrine cells in cat form planar arbors in the inner plexiform layer (IPL). Within each arbor the processes from adjacent cells associate intimately with each other over about 70% of their lengths. As the bundles cross each other, "loops" are created of irregular size and shape. Loop diameter averages 15μm in the area centralis and increases with eccentricity. The α cells also form planar arbors at the corresponding levels of the IPL. Their crossing dendrites also create loops comparable in size and spacing to those of the cholinergic network. To investigate a possible association between the two networks we first injected α cells with Lucifer yellow and then immunostained for choline acetyltransferase. When viewed in the same focal plane, there were many instances where α and cholinergic processes ran parallel and close together (within 5μm) over long distances (up to 80μm); also, elements of both networks divided or curved in a similar way. About 25% of the total α cell dendritic arbor was aligned with the cholinergic network. When composites of 4 α cells were placed in random orientations upon the cholinergic network, the degree of alignment was about 9%. Thus, the association between α and cholinergic processes is specific, though it is weaker than the association between the cholinergic processes themselves.

ANATOMICAL CIRCUIT FOR THE GAUSSIAN CENTER OF THE ON-BETA GANGLION CELL. E. Cohen, and P. Sterling. Dept. Anatomy, U. Penn, Phila, PA 19104-6058.

Sensitivity in the ganglion cell receptive field center was observed by Kuffler to peak at the middle and decline toward the edge. The anatomical basis for this distribution, to which Rodiek fitted Gaussian, is unknown. We reconstructed from electron micrographs of serial sections the connections between arrays of cones, CBb_1 bipolars, and on-beta ganglion cells. Adjacent cones converged in small numbers (4-7) on a CBb_1, and adjacent CBb_1s (6-8) converged on a beta cell. We estimate that the complete circuit at this eccentricity (1^o) connects 34 cones to the beta cell via 9 CBb_1s. Bipolar axons near the beta dendritic field center supply many synapses (25-30), and those near the dendritic field edge supply few (1-5). This arrangment weights a cone's contribution according to the number of synapses that its CBb_1 bipolar provides to the ganglion cell. These weights plotted against distance of each cone from the beta dendritic field center have a dome-shaped distribution. This distribution, when convolved with the linespread function of the cat's eye and the luminance profile of a 0.1^o stimulus, matches closely the distribution of sensitivity measured physiologically for a beta cell at the corresponding eccentricity. Thus, the nonuniform distribution of synapses to an on-beta cell from its CBb_1 axons may explain the receptive field's Gaussian center.

CONE RECEPTIVE FIELD COMPUTED FROM MICROCIRCUITRY AND RECEPTIVE FIELDS OF X AND Y CELLS. R.G. Smith* and P. Sterling. (SPON: A.C.Rosenquist) Dept. Anat, Univ. of PA, Phila, PA 19104-6058.

The origin of the center-surround receptive field in the cat ganglion cell is unknown. A surround is already present at the level of the CBb_1 bipolar cell, whose array contributes significantly to beta (X) and alpha (Y) ganglion cells, suggesting that a center-surround receptive field might be established first in the cone. We computed the cone receptive field by asking: what cone sensitivity profile, when summed linearly over a cone array of appropriate size, spacing, and spatial weighting, would be required to account for the ganglion cell center and surround? Further, would the same cone receptive field computed in this manner account for both X (beta) and Y (alpha) receptive fields? The cone arrays for beta and alpha cells and the spatial weighting functions were drawn from recent anatomical studies from this laboratory (Cohen and Freed); the center and surround measurements for X and Y receptive fields at the corresponding eccentricity (1 deg.) were drawn from Cleland et al. '79 and Linsenmeier et al. '82.

The computed cone receptive field center is about 60 um, nearly equal to that of an X cell (65 um), and sums to match both X and Y cell centers. The computed cone surround is about the same diameter as the X cell's but the amplitude is reduced by about 1/3. The overall result recalls the broad, center-surround receptive field observed in turtle cones by Baylor et al. '71. Possibly in mammalian retina too contrast sensitivity originates at the cone.

244.10

COLLECTIVE CODING IMPROVES THE SIGNAL/NOISE RATIO OF THE GANGLION CELL. Y. Tsukamoto*, R. G. Smith* and P. Sterling. Dept. Anat., Univ. Penn., Phila., PA 19104.

The dome-like distribution of sensitivity in the receptive field center of a beta ganglion cell in cat area centralis expresses a weighted sum of signals from about 34 cones. We explored computationally the hypothesis that the reason for collecting signals from many cones is to improve the ganglion cell's signal/noise (S/N) ratio. Signals in adjacent cones tend to be strongly correlated because of local correlation in the visual scene and optical blurring. Were the signals identical, to pool them with equal weight would improve the S/N ratio as the square root of the number of cones. However, the correlation declines sharply with distance, so cones at the edge of the receptive field center must contribute less to S/N improvement than those near the center. We computed, according to equations resembling those of Yule-Walker, weights for collecting cone inputs that would maximally improve the S/N ratio. For a ganglion cell center of given diameter and cone density, the optimal weighting function is dome-like. For this weighting function and a given cone density, as ganglion cell center diameter increases, the S/N ratio rises sharply and then asymptotes. For this weighting function and a fixed center diameter, the S/N ratio rises linearly with the square root of cone density. Thus, by collecting many signals with a Gaussian weighting function, the beta ganglion cell may optimally improve its S/N ratio by a factor proportional to the square root of cone density.

FLICKER SENSITIVITY OF MACAQUE GANGLION CELLS. P.R. Martin*, B.B.Lee and A.Valberg* (SPON:G.Fox) Max-Plank-Inst. Biophys. Chem., 34 Göttingen,F.R.G

As reported previously, the sensitivity of phasic ganglion cells to luminance flicker of different temporal frequencies closely approximates that of a human observer. Sensitivity of tonic cells to chromatic flicker at low temporal frequency (tf) is similar to man's, but even higher at high tfs, showing tonic cell activity is attenuated at higher levels. We have also measured sensitivity to silent substitution flicker, where M- or L- cones are selectively modulated. We found red and green on-centre and phasic cells all to have similar sensitivity to M- or L- cone flicker. This means that tonic cell sensitivity to chromatic flicker is derived equally from center and surround, and that tonic cell insensitivity to luminance flicker is a consequence of cone opponency rather than intrisically low sensitivity.

Sensitivity of tonic cells to chromatic flicker could be well predicted from their sensitivity to M- and L- cone flicker, indicating linear summation of cone signals, but sensitivity of phasic cells to luminance flicker could not be so well predicted. This may be another manifestation of non-linear cone summation in phasic cells.

PATTERN ERG IN RATS FOLLOWING SECTION OF THE OPTIC NERVE. L. Domenici,* N. Berardi,* A. Gravina* and L. Maffei* (Spon: A. Cangiano). Institute of Neurophysiology of CNR, Via S. Zeno 51, 50100 Pisa, Italy.

Flash and pattern ERG were recorded from urethane anaesthetized hooded rats (Long Evans) by means of silver rings or small silver plates inserted under the eyelids. The signal from the stimulated eye was conventionally amplified, filtered and computer analyzed on-line and off-line. The pattern ERG was evoked by phase alternating gratings of various spatial frequencies and contrast. The pattern ERG amplitude was function of contrast and increased up to 30% contrast. The optimum mean luminance of the gratings was betweeen 15 and 20 cd/m^2. Higher luminances resulted in lower pattern responses. The largest amplitudes of pattern ERG were recorded for spatial frequencies of .1 c/deg while the optimum rate of alternation was around 4 Hz. The highest spatial frequency that elicited a reliable ERG response was .35 c/deg. Following section of the optic nerve the pattern ERG showed a progressive decrease in amplitude and eventually disappeared. The flash ERG remained unaffected.

245.1

THE JOURNEY OF YOUNG MIGRATING NEURONS IN THE ADULT CANARY BRAIN. Arturo Alvarez-Buylla* and Fernando Nottebohm (SPON: D. Griffin). The Rockefeller University, New York, N.Y. 10021

The adult bird brain continues to produce new neurons. These cells are born in the ventricular zone (VZ) sometimes up to 5 mm away from the location where some of these neurons finally mature. To study the intervening steps between birth and neuronal differentation, groups of 3 canaries were sacrificed 1, 3, 6, 15, 20, 30 and 40 days after receiving 2 injections of ^{3}H-thymidine. The position and type of labeled cell was mapped in frontal brain sections at the level of the anterior commissure. Small elongated cells that originated from the VZ lining the lateral walls of the lateral ventricle moved laterally into the telencephalic parenchyma. Before day 15 the labeled elongated cells were concentrated in areas rich in radial glia and were frequently attached to radial glia fibers. During this time the leading front of the elongated cells moved away from the VZ at 28um/h. This rate dropped to 8um/h as cells became scattered throughout the section. The number of labeled migrating cells decreased rapidly after day 20 as labeled neurons started to appear throughout the telencephalon. We conclude that the migrating cells are young neurons.

245.2

RADIAL GLIA DIVIDE AND MAY GIVE BIRTH TO NEURONS IN ADULT AVIAN BRAIN. F. Nottebohm, M. Theelen* and A. Alvarez-Buylla*. The Rockefeller Univ., New York, NY 10021

Neurons are born in the lateral wall of the lateral ventricle of the adult avian forebrain. Neurogenesis is particularly intense within the dorsal and ventral tips of this ventricular zone. Radial glia, with bodies in the ventricular zone, are also particularly abundant within these two regions. Many new neurons migrate from there closely apposed to the long fibers of the radial glia. We now report that these same radial glia, with bodies in the ventricular zone, may give birth to the neurons. This was determined as follows. The forebrain of adult female canaries that had received a single injection of ^{3}H-thymidine was cut transversely into 0.5 mm slices. A thin strip of the lateral wall of the lateral ventricle was then dissected and slightly trypsinized. This tissue was smeared onto a glass slide and stained with our anti-vimentin antibody (40E-C), covered with photographic emulsion and incubated for autoradiography for 4 weeks. Eighty percent of the ^{3}H-thymidine labeled cells were positive to the antibody and of these 68% had single processes of the kind that characterize radial glia. Since proliferation of cells in the ventricular zone of the adult avian brain is closely related to neurogenesis, and since the vast majority of our labeled cells had radial glia morphology, we suggest that neurons are born in the ventricular zone when radial glia undergo mitosis.

245.3

ANALYSIS OF PREFERENTIAL GENE EXPRESSION IN THE SONG CONTROL NUCLEUS HVC OF CANARIES. D. F. Clayton, M. Huecas*, and K. L. Nastiuk. Lab. of Animal Behavior, The Rockefeller Univ., New York, NY 10021.

HVc, a primary song control nucleus in the telencephalon, exhibits profound anatomical and functional plasticity in response to steroid hormones. To provide molecular probes for analyzing gene regulation and anatomical organization in this nucleus, cDNA clones that hybridize to mRNAs more abundant in nucleus HVc than in midbrain plus hindbrain were selected from an HVc library. The anatomical distribution of these mRNAs was determined using in situ hybridization. None of the RNAs yet examined is absolutely specific for the nucleus, although specificity for cell subsets with unique distributions in the brain is evident. These results extend our earlier observations of overlapping patterns of mRNA distribution in brain cell subsets (Clayton et al., Neuron May 1988). Further analysis may identify genes that respond to steroids in HVc, and that may be involved in regulating the neuronal growth in adulthood characteristic of this nucleus.

245.4

BIRTH OF LONG PROJECTION NEURONS IN DEVELOPING AND ADULT AVIAN BRAIN. M. Theelen*, A. Alvarez-Buylla* and F. Nottebohm (SPON: G.Adelman). Rockefeller Univ., New York, NY 10021

The higher vocal center (HVc) of the canary brain has two projections, one to nucleus robustus archistriatalis (RA) and another one to area X of lobus parolfactorius. To determine the birth dates of neurons projecting to these two targets, 38 canaries of both sexes received ^{3}H-thymidine at one of the following ages: E5, E9, E10, E12, and post hatching days 10, 35, 58, 93, 120 and 240. At 13 months all birds received injections of the retrograde tracer fluorogold into RA of one hemisphere and into area X of the other hemisphere, and were killed 4 days later. As many as 76% of the cells backfilled from area X were labeled with ^{3}H-thymidine before hatching, vs. a maximum of 0.7% of RA backfilled cells. The percent labeled per day between hatching and 240 days was 0.2% for X projecting cells and 0.8% for RA projecting cells. In addition 2 birds were treated with ^{3}H-thymidine at 18 months of age. In them 0.1 - 0.3 % of the neurons backfilled from RA were labeled per day of ^{3}H-thymidine treatment. Thus, one type of HVc long projection neuron is produced predominantly during early development, whereas another type is produced throughout development and during adulthood. This is the first report of long projection neurons produced in adult vertebrate brain.

NGF EFFECTS ON CHOLINERGIC INTERNEURONS OF THE ADULT RAT STRIATUM AND NUCLEUS ACCUMBENS. S. Varon, T. Hagg, H.L. Vahlsing*, M. Manthorpe. Dept. Biology, Univ. of California, San Diego, La Jolla, CA 92093.

Cholinergic neurons of the striatum (STR)(caudate-putamen) respond to NGF with a dose-dependent increase in choline acetyltransferase (ChAT) activity during development, but this response decreases at an early postnatal stage. Adult STR contains low levels of NGF and NGF-mRNA and no (low affinity) NGF receptors can be detected by regular immunocytochemical techniques, although some neurons are able to bind radiolabelled NGF with high affinity. We addressed the question whether adult CNS cholinergic interneurons of the STR and nucleus accumbens (ACC) are still responsive to (exogenous) NGF, as are those in the basal forebrain.

NGF or vehicle was administered by unilateral intraventricular infusion through a small 32 gauge cannula to normal adult rats and to rats that had received a unilateral transection of the fimbria-fornix. Sections were evaluated for immunostaining of ChAT (1E6, P.Salvaterra) and NGF-receptor (192-IgG, E.M. Johnson). The ChAT-reactivity of the neuropil and neuronal cell bodies was increased and the average cross-sectional area of the somata enlarged by 40% in the STR and by 20% in the ACC on the side of the NGF infusion. This response could be elicited on either side of the fimbria-fornix transection, as well as in normal, non-lesioned animals. Unlike the case of the medial septum neurons, the increase in ChAT was not accompanied by an appearance or intensification of immunoreactive receptors for NGF. These results indicate that the apparently undamaged adult cholinergic interneurons of the STR and ACC are still responsive to exogenous NGF and this effect is most likely transduced by the high affinity receptor for NGF. Supported by NIH grant NS 16349

245.6

NGF-REGULATED PLASTICITY IN THE ADULT NERVOUS SYSTEM. J. Diamond, M. Holmes* and B. Visheau*, Dept. Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5.

During our studies that revealed the NGF dependency of collateral sprouting of heat-nociceptive C fibers in adult rat skin (PNAS, 84:6596, 1987) we observed that daily anti-NGF administration not only prevented the expansion of the "heat-fields" into surrounding denervated skin, but actually caused them to shrink, by about 50% in a month. We measure nociceptive fields in the anesthetized rat by a spinal reflex; thus we are examining a possible "central" origin of the shrinkage due, e.g., to reduced substance P (Schwartz et al., 1982, Brain Res. 244:378) causing a reduced synaptic drive. We are however obtaining evidence for a peripheral effect of the treatment. In the EM we see occasional abnormal sensory C axon profiles in normal skin, but significantly more in the skin of anti-NGF treated animals. Moreover, using a new "trophic assay", we find that the time for the C fiber terminals to degenerate following axotomy is almost halved in skin from animals on 4 wks of anti-NGF treatment. We suggest: (i) that there is a normal turnover of sensory C fiber terminals; (ii) that this is regulated by endogenous NGF; (iii) that this NGF is critical to the maintenance of both the function and the structure of these nerve endings.

Generalized, our findings point to a plasticity in the adult nervous system that is regulated by endogenous growth factors.

245.7

AXOTOMY-INDUCED LOSS OF BOTH CHAT AND NGF-RECEPTOR POSITIVE MEDIAL SEPTUM NEURONS IS REVERSED BY DELAYED NGF TREATMENT.

T. Hagg, H.L. Vahlsing*, B. Fass, M. Manthorpe, S. Varon. Dept. Biology, Univ. of Calif., San Diego, La Jolla, CA 92093.

Intraventricular Nerve Growth Factor (NGF) infusion in the adult rat can prevent and, if delayed, reverse most of the disappearance of axotomized medial septum cholinergic (MSC) neurons immunostained for choline acetyltransferase (ChAT). The reversibility indicated that the apparent loss may be largely due to a loss of ChAT enzyme rather than to neuronal death. We have repeated and extended previous findings by immunostaining the MSC neurons for the low affinity NGF-receptor (192-IgG, E.M. Johnson) in addition to the ChAT marker (1E6, P. Salvaterra) and extending the delay time between axotomy and NGF treatment. NGF or vehicle was continuously infused into the ipsilateral ventricle for 14 days beginning immediately, 7 days or 95 days after unilateral fimbria-fornix transection. Additional animals were infused for 1, 3 or 7 days beginning 7 days post-lesion. The number of ChAT-positive MSC neurons dropped to 50% by 7 days post-lesion and to a baseline of 20% by 14 days or longer in vehicle infused rats. All the neurons remained detectable by 14 days when NGF treatment was started immediately post-lesion. A 90% level was rapidly achieved in 3 days when NGF infusion was started after 7 days. Even when delaying the infusion up to 95 days, 60% of the neurons were again detectable. The NGF-receptor immunoreactive MSC neurons dropped to 50% after 7 days post-lesion and to a baseline of 35% by 14 days in vehicle infused rats. Full protection resulted when a 2 week NGF infusion was started immediately after the transection. The receptor positivity was fully restored in 3 days if treatment was started 7 days post-lesion. A 65% level was reached when treatment was delayed for 95 days. Thus, NGF treatment can re-establish both ChAT and NGF-receptor positivity of axotomized MSC neurons. Supported by NIH grant NS 16349 and NS 25011

245.8

SEXUAL MATURITY-DEPENDENT NEURAL PLASTICITY IN THE PRE-PACEMAKER NUCLEUS OF ADULT KNIFEFISH.

G.K.H. Zupanc and W. Heiligenberg. Scripps Institution of Oceanography, Neurobiology Unit, UCSD, A-002, La Jolla, CA 92093.

Eigenmannia (Gymnotiformes, Teleostei) can modulate its otherwise very stable electric organ discharge (EOD) by gradual frequency shifts during courtship and the jamming avoidance response, and by abrupt shifts in the context of agonistic and reproductive behavior. The EOD, produced by a specialized electric organ, is under the control of a pacemaker nucleus (PN) in the medulla oblongata. Injection of horseradish peroxidase into the PN only labelled cells within the diencephalic pre-pacemaker nucleus, PPN (Heiligenberg et al., Brain Research, 211:418, 1981). Microstimulation experiments revealed a morphological and functional dichotomy of the PPN showing that both types of EOD modulations can be elicited from two distinct areas within the PPN (Kawasaki et al., J. Comp. Neurol., in press; Rose et al., J. Comp. Physiol., in press).

As shown in this study, in both sexes the normalized length of the dendritic arbors of the PPN is larger in mature animals than in immature specimens. Even more pronounced are differences in the number of varicosities on the dendrites: Fish with well developed gonads show up to 20 times more varicosities than do fish with immature or regressed gonads. These varicosities may represent growing buds, or regions of synaptic contact, or both.

245.9

INCREASED PHRENIC NERVE ACTIVITY OCCURRING WITHIN HOURS OF AN IPSILATERAL C2 SPINAL CORD HEMISECTION IN ADULT RATS.

T. E. O'Hara, Jr.* and H. G. Goshgarian. Dept. of Anatomy, Wayne State Univ., Sch. of Med., Detroit, MI 48201

Recent studies in our laboratory have demonstrated a rapid morphological alteration of the normal ultrastructure of the phrenic nucleus within 4 hours of an ipsilateral C2 spinal hemisection. We have suggested that these changes may be related to functional recovery of the ipsilateral hemidiaphram which was paralyzed by spinal cord injury. The present study was designed to determine if there is an increase in phrenic nerve activity that temporally coincides with our observed morphological changes. A left C2 spinal hemisection was followed by the immediate application of xylocaine to the right phrenic nerve. Rectified and integrated compound action potentials were then recorded from the left phrenic nerve. Current flow through the nerve was calculated. The animals were allowed to survive and left phrenic nerve activity was again recorded at various intervals up to 5 days post hemisection. Immediate post injury current flow was subtracted from the current flow measured at a later interval for each animal. The results showed a significant increase in phrenic nerve activity occurring within hours after spinal cord injury. By 4 hours post spinal cord injury, left phrenic nerve activity could be recorded without the application of xylocaine to the right phrenic nerve. These results correlate with our previous morphologic studies. Supported by U.S. Public Health Service Grant NS-14705.

245.10

NEURAL PLASTICITY IN AFFERENT AND EFFERENT PATHWAYS TO THE URINARY BLADDER FOLLOWING URETHRAL OBSTRUCTION IN THE RAT.

W. Steers, J. Ciambotti*, B. Etzel*, S. Erdman* and W.C. de Groat. Depts. Pharmacol., Urol. and Behav. Neurosci., Univ. Pittsburgh, Pittsburgh, PA 15261.

Partial urethral ligation in rats produces functional changes consistent with obstruction and detrusor hyperreflexia, as well as enhancement of a spinal micturition reflex. Changes in the neural pathways to the bladder (BLD) were examined by injecting 50 µl of 1% WGA-HRP or 4% fluorogold (FG) into opposite sides of the BLD of obstructed (OBSTR) and control rats. Fast blue dye was injected into the distal colon as an internal control. OBSTR rats showed enlargement of FG labelled BLD postganglionic (PG) cells (553.5±175.2 μ^2,n=4), but not colon cells in the pelvic ganglion compared to controls (298.8±60.7 μ^2,n=4). No difference was noted in size of PG BLD neurons in the lumbosacral chain ganglia in control (544.3±122.7 u^2) vs OBSTR rats (570.2±125.5 μ^2). BLD afferent cell sizes in the L_6 and S_1 dorsal ganglia were also increased in OBSTR rats. A 40% increase of BLD afferent terminals in the L_6 and S_1 spinal cord in the region of the parasympathetic nucleus was found in OBSTR rats. These changes may be produced by increased neuronal activity, increased axonal transport of tracer or sprouting of terminals.

245.11

CHANGES IN THERMAL PLASTICITY OF RAPHE NEURONES AFTER INTERRUPTION OF DIFFERENT PATHWAYS.

P. Hinckel, A. Holm*, W. Th. Perschel*, Ch. Rüsing* and S. Steil*. Physiological Institute, University of Giessen, Aulweg 129, D-6300 Giessen 1, F.R.G.

Neurones in the nucleus raphe magnus (NRM) have been shown to belong to the thermoafferent system. In cold-acclimated guinea-pigs (CA, 6-9 weeks in 4°C) average maximum activity and average basic spike rate of warm-responsive NRM units were significantly larger than in normal-acclimated animals (NA, 21°C).

After interruption of the dorsal and rostral afferents and efferents of the NRM by microcuts no significant differences were seen in the average frequency-temperature-characteristic of warm-responsive NRM units in NA guinea-pigs. By contrast, after interruption of the dorsal and rostral pathways in CA animals basic spike rate was significantly reduced (to the basal level in NA animals), whereas the maximum spike rate was not changed. Control lesions of lateral and ventrocaudal pathways did not show any effect in NA guinea-pigs.

It is concluded that the cold-adaptive increase of average peak activity of NRM units after long-term cold acclimation is generated at a lower level, whereas the increase of tonic basal spike rate is mediated by higher pathway loops. In summary, interactions in complex neuronal networks of the lower brainstem may be involved in generating thermal plasticity.

246.1

SHORT AND LONG TERM LEARNING IN THE NEMATODE *C. ELEGANS*

C. H. Rankin and C. M. Chiba*, Department of Psychology, University of British Columbia, Vancouver, B.C. V6T 1Y7

Although to date relatively little is known about the learning and memory capabilities of *C elegans*, the unique combination of detailed genetic, developmental, and neuroanatomical data available for this animal provides an excellent basis for exploring mechanisms underlying the development and expression of behavioral plasticity.

To begin an analysis of non-associative and associative learning in *C. elegans* we have focussed on a simple form of learning, habituation. In these studies we elicited responses by delivering a vibratory stimulus through the agar medium. Animals responded to this stimulus by reversing direction, moving several body lengths backwards. With 60 presentations of stimuli at a 10 sec ISI reversals became progressively shorter, changing to pauses in forward motion, and eventually responding ceased. A scorer blind to the experimental design rated videotaped responses on a scale of 0-4, (4= reversal >1 body length; 0= no response). We observed significant habituation with a mean initial response of 3.35 +0.95, and a mean habituated response of 0.8+0.28, (N=10, t(9)= 5.314, p=.0005). Significant dishabituation was observed in response to a shock of 60V with an increase above the mean habituated response to 1.9+.35, (N=10, t(9)=2.577, p=.03). We tested for long term habituation by presenting 6 blocks of 20 habituation stimuli over two days, testing on the third day, 15 hours after training. When compared to control animals, trained animals showed significantly greater habituation (Mean Control 1.8+.19, N=7; Mean Experimental 1.0+.18, N=7, t(12)=2.9, p=.01).

Thus, the nematode *C. elegans* is capable of two non-associative learning processes, habituation and dishabituation, and is also capable of long term learning, retaining habituation training for at least 15 hours.

246.2

POSSIBLE LOCI FOR HABITUATION OF THE LEECH LOCAL BENDING REFLEX. S.R. Lockery and W.B. Kristan, Jr. Dept. of Biol., Univ. of Calif., San Diego, La Jolla, CA 92093.

Local bending, a defensive withdrawal reflex, habituates upon repeated mechanical stimulation. To study the mechanism of habituation, we used a semi-intact preparation that reduces the behavioral circuit to one sensory neuron (the P cell), two motor neurons (cells 3 and L), and a number of interneurons. The connection from the P cell to the L cell is monosynaptic, while the connection to cell 3 is polysynaptic. Motorneuron recordings during habituation indicated that the functional plasticity for habituation resides solely in the polysynaptic pathway since the number of stimulus-evoked action potentials in the L cell was constant while the number of cell-3 impulses declined. To further localize the plastic site, we identified seven interneurons that received short latency epsps from the P cell and, when depolarized by current injection, activated cell 3. Three interneurons appeared to make a necessary contribution to cell-3 activity: hyperpolarizing them reduced the number of cell-3 action potentials evoked by P-cell stimulation. For one interneuron, cell 218, hyperpolarization reduced the number of action potentials by up to 50%. Repeated stimulation of the P cell sufficient for habituation decreased the amplitude of epsps recorded from cell 218. Repeatedly depolarizing cell 218 by current injection reduced the number of action potentials recorded from cell 3 in response to depolarization by as much as 100%. Thus the polysynaptic pathway of the local bending reflex contains two possible sites of habituation.

SENSITIZATION OF THE TRITONIA ESCAPE SWIM: BEHAVIORAL AND CELLULAR MODIFICATIONS. W.N. Frost, G. Brown* and P.A. Getting. Dept. Physiology & Biophysics, Univ. of Iowa, Iowa City, IA 52242.

It has previously been shown that in the sea slug Tritonia, repeated noxious epithelial stimulation produces habituation of escape swimming. We now report that a single stimulus produces rapid sensitization of multiple aspects of the swim: number of cycles, onset latency and threshold. Cycle number and onset latency were examined by comparing, for each animal, a swim produced by a tail stimulus alone (T) with a swim produced by a tail stimulus coming 5 minutes after a head stimulus (H-T). The response to the tail stimulus of the H-T sequence had a larger number of cycles (6.8 vs 5.4) and a shorter latency (8.2 vs 4.3 seconds) than the response to the tail-alone stimulus ($p<.05$, N=10). A control group receiving T-H on day 1 and T on day 2 showed no difference in cycle number or latency. In a second experiment the T intensity was first adjusted to be subthreshold for producing a swim. In 10 of 14 animals this tail stimulus became suprathreshold in the H-T paradigm ($p<.01$), indicating that the head stimulus produced sensitization (a reduction) of the threshold for the subsequent tail stimulus.

In isolated brain preparations, brief electrical stimulation of pedal nerves triggers the neural program for the escape swim. Following such a stimulus, the interneuron C2 displayed: 1) a prolonged increase in excitability as measured by the number of spikes elicited by a 5 second constant current pulse (avg pre = 7, avg post = 23) and, 2) a decrease in the amplitude of the spike undershoot (avg pre = 5.3mV, avg post = 3.0mV), both measured from the same resting potential ($p<.05$, N=5).

Using a computer reconstruction of the known swim circuitry we have begun an evaluation of the relationship between the multiple behavioral changes and the circuit modifications underlying sensitization. Our preliminary findings suggest that the change in C2 excitability may contribute to the increase in cycle number.

ASSOCIATIVE LEARNING IN HERMISSENDA II. ROLE OF FOOT CONTRACTION IN CS-MEDIATED REDUCTION OF PHOTOKINESIS. L.D. Matzel*, B.G. Schreurs*, I.I. Lederhendler*, and D.L. Alkon (SPON: R. Desimone). Lab. of Molecular and Cellular Neurobiology, NIH, Bethesda, MD 20892.

We have recently reported that pairings of light with orbital rotation result in a prolonged associative reduction of photokinesis in Hermissenda. Here, we examined the contribution of foot contraction to that response. The degree of unconditioned foot contraction was found to be directly proportional to the speed of the rotation. Contraction was evident for up to 30 sec after the offset of rotation and was concomitant with a reduced rate of locomotion during that period. This graded unconditioned response to rotation was directly related to the strength of the conditioned response that rotation supported as indexed by the reduction of photokinesis following light(CS)-rotation(US) pairings. Moreover, foot contraction was found to be a short latency conditioned response to light following light-rotation pairings and persisted long after the onset of the light. In total, these results indicate that associative reduction of photokinesis is mediated by a long-lasting contraction of the Hermissenda's foot. The observation of conditioned contraction is consistent with a previous report (Lederhendler, Gart, & Alkon, 1986) demonstrating a transfer of properties from the US to the CS, and may be mediated by direct excitatory pathways from the photoreceptors to the motoneurons of the foot.

ASSOCIATIVE LEARNING IN HERMISSENDA: I. PROLONGED CS-MEDIATED REDUCTION OF PHOTOKINESIS. B.G. Schreurs*, L.D. Matzel*, I.I. Lederhendler* and D.L. Alkon (SPON: J.S. McIntosh) LMCN, NIH-NINCDS, Bethesda, MD 50892.

Pairings of a light and high-speed rotation result in a reduction of phototactic behavior in Hermissenda crassicornis. High-speed rotation prevents precise specification of stimulus onset due to the gradual onset characteristics (approx. 1-2s). To overcome these onset characteristics, previous studies have employed rotation of long duration (30s) to ensure maximum stimulus intensity and have yielded conditioning using "simultaneous" pairings. We report three experiments employing a shaker device to provide intense, short latency, orbital rotation of brief duration (2s). Experiment 1 revealed that pairings of light (3s) and orbital rotation (2s) reduced posttest movement around a circular track relative to unpaired light and rotation. Experiment 2 showed marked reduction of movement at interstimulus intervals of 1 and 2s but not at 10s. Experiment 3 examined the role of stimulus onset and offset and revealed that forward overlapping stimulus presentations were superior to sequential or simultaneous presentations.

OPERANT CONDITIONING OF IDENTIFIED NECK MUSCLES AND INDIVIDUAL MOTOR NEURONS IN *APLYSIA* D.G. Cook & T.J. Carew, Dept. Psychology, Yale University, New Haven, CT 06520.

Aplysia can be operantly trained to change their head-waving behavior to avoid presentation of an aversive bright light (Cook & Carew, 1986). In the present study we asked whether the neck muscles involved in head-waving (Lateral Columellar Muscles [LCMs]), as well as individual neck motor neurons, are capable of operant conditioning.

EMG activity in the LCMs was recorded using implanted cuff electrodes in freely moving animals. Differential (left vs. right) EMG output of a CONTINGENT group (N=15) was operantly trained with light, while a YOKED CONTROL group (N=15) received non-contingent reinforcement. Following training, CONTINGENT animals showed a significant change in differential EMG activity compared both their own baseline ($p<.025$) and to YOKED CONTROLS ($p<.025$). YOKED CONTROLS showed no learning.

Next, using a split-foot preparation, intracellular recordings were made from single neck motor cells in the pedal ganglion. CONTINGENT cells (N=8 preparations) received either uptraining (light whenever firing rate fell below baseline); or downtraining (light whenever firing exceeded baseline). YOKED CONTROL cells (N=8) received non-contingent reinforcement. Following training CONTINGENT trained cells showed a significant alteration in firing rate, ($\bar{x}$ change = 93 A.P.s, $p<.05$), largely due to successful downtraining (4 of 4 in predicted direction, compared to 2 of 4 uptrained cells). YOKED CONTROLS showed no significant change from baseline.

Our results show that identical training procedures can contingently modify intact behavior, muscle activity, and the excitability of individual motor cells. It will now be important to determine the neuronal sites which produce the learning we observe at all three levels of analysis.

ANALYSIS OF DIRECTED HEAD MOVEMENTS IN RESPONSE TO FOOD STIMULI IN *APLYSIA*

T. Teyke*, K.R. Weiss and I. Kupfermann (SPON: M. Terman).
Center for Neurobiology and Behavior, Columbia University, Coll. P & S, and NYS Psychiat. Inst., New York, NY 10032.

Aplysia, when oriented in their characteristic feeding posture, respond with head and neck movements directed toward food stimuli that are applied briefly to various loci on their tentacles or rhinophores. Video analysis showed that the velocity and the final turning angle of the head correlates with the eccentricity of the stimulus position. In all cases, the turning angle of the animal greatly exceeds the stimulus position, i.e., the animal markedly over-shoots. In contrast to a brief stimulus, a maintained stimulus leads to centering of the food, followed by one or several bites. During a biting response, stimuli are completely ineffective in eliciting a turning response, although bites per se do not suppress ongoing turning movements. This inhibition is not present during head turning movements. Having established some of the behavioral characteristics of the head orienting response, we were in a position to examine the properties of central neurons that might mediate the response. As a first approach we focussed on neurons in the cerebral B cluster, since available data (e.g., Fredman & Jahan-Parwar 1980; Bablanian et al. 1987) made them candidate motoneurons for head orientation. These cells respond to tactile and chemical stimulation on the tentacles, and firing the cells leads to contraction of muscles in the neck and body wall. Dye fillings and intracellular recordings from neurons in the B cluster in isolated ganglia and semi-intact preparations revealed two distinct types of neurons, which differ in their morphology, their electrophysiological properties, and their response to tentacle stimulation. However, the properties of neither type of B cluster neurons matched the criteria for involvement in head orientation, as established by the behavioral studies. Chronic recordings of units in the cerebro-pleural connective (most likely spikes from contralateral B neurons) showed activity which was correlated with stimulation of both the ipsi- and the contralateral side of the head. The peak of the neuronal activity occurred immediately after the stimulus but did not persist while the animal was turning its head and did not generally occur during 'spontaneous' head movements. We are currently investigating other neurons that might be involved in head orientation to food.

246.8

ACTIVITY OF CBI-2 OF *APLYSIA* ELICITS BITING-LIKE RESPONSES.

S. C. Rosen*, M. W. Miller*, K. R. Weiss, and I. Kupfermann (SPON: D. Kelly). Cntr. Neurobiol. & Behav., Coll. Phys. & Surg., Columbia Univ., NYS Psychiatric. Inst., New York, N.Y. 10032.

Biting is a consummatory feeding behavior involving coordinated movements of the buccal mass (biting apparatus) with a characteristic radula protraction-retraction sequence. Rhythmic biting is elicited when a food stimulus is continuously applied to the inner lips (perioral zone). An interganglionic cerebral-buccal interneuron (CBI-2) was previously identified which evokes a robust rhythmic buccal motor program (BMP). We have found that the BMP involves phasic activation of various identified buccal neurons, including ARC motoneurons B15 and B16, interneurons B4 and B5, and the putative central pattern generating neurons B31 and B32. B15 and B16 fire in a pattern that is seen during normal biting in intact animals (see Cropper et al., these abstracts), but is not observed in the same cells during swallowing, rejection, or withdrawal. CBI-2 also drives cerebral neurons, including the serotonergic, metacerebral cells. The other cerebral neurons, however, may not be necessary for activation of the BMP since the efficacy of CBI-2 driving of the BMP is little affected by blockade of synaptic transmission in the cerebral ganglion with 10 mM Co++. In dissected preparations consisting of the cerebral and buccal ganglia, and the buccal mass, firing of CBI-2 reliably produces rhythmic buccal mass movements which are similar in topography and timing to biting movements seen in intact, food-aroused animals. Video image analysis was used to show that the rhythmic buccal movements elicited by CBI-2 exhibit a build-up in speed and strength, similar to that seen in normal biting. Our data thus indicate that CBI-2 may play a role in the initiation and maintenance of biting. The identification of a neuron that drives a BMP and a specific class of consummatory behavior in a dissected preparation, opens the way for detailed analyses of central and peripheral mechanisms of neuromodulation underlying food-induced arousal and satiation of feeding in *Aplysia*, and will permit comparison with similar neurons that have been described in other molluscan species.

246.9

GUT STIMULATION EVOKES A SLOW IPSP IN HISTAMINERGIC NEURON C2, MEDIATED BY CCK-GASTRIN LIKE IMMUNOREACTIVE BUCCAL NEURON, B18.

S.L. Hooper, K.R. Weiss, and I. Kupfermann, Cntr. Neurobiol. & Behav., Columbia U. P&S and NYS Psych. Inst., NY, NY 10032

The identified mechanoafferent neuron C2 makes extensive synaptic contact with neurons controlling feeding in Aplysia, and is believed to shape aspects of the feeding response as well as contribute to the maintenance of food-induced arousal. The synaptic output of C2 is powerfully gated by inhibitory input to the cell, including a slow inhibition evoked by esophageal nerve stimulation. We show here that this slow IPSP is caused by B18. Esophageal nerve stimulation with a 1 second, 10Hz train of pulses results in a burst of fast IPSPs in C2 followed by a long lasting (several seconds) hyperpolarization, and a simultaneous burst of spikes in B18. Firing B18 by injecting depolarizing current has similar effects on C2, and hyperpolarization of B18 to prevent its firing during esophageal nerve stimulation abolishes C2's response. When the amplitude of B18's IPSP in C2 is augmented by bathing the cerebral ganglion with high Ca++ containing saline, single B18 spikes induce in C2 a fast IPSP followed by a slow, long lasting (relative to the membrane time constant) IPSP. These IPSPs are likely monosynaptic, as they follow B18 spikes one for one when B18 is made to fire at high frequency. In double labeling experiments B18 neurons iontophoretically marked with Lucifer Yellow showed immunoreactivity with a CCK/gastrin antiserum.

The nature of the esophageal nerve inputs to B18 were studied in preparations with the esophagus and gut left connected to the buccal ganglion. Mechanical stimulations mimicking dilation of the esophagus/anterior gut caused B18 depolarization and firing similar to those observed with esophageal nerve stimulation, and our electrical stimulations are therefore likely activating esophageal/anterior gut mechanosensory inputs to B18. This pathway thus allows sensory input from the esophagus/anterior gut access to neurons involved in the control of the buccal mass and food induced arousal, and may effect modifications in feeding behavior as a function of the state (e.g., dilation) of the esophagus/anterior gut.

246.10

GILL ARITHMETIC: INTERACTIONS BETWEEN IDENTIFIED MOTOR NEURONS AND THEIR EFFECT ON EVOKED BEHAVIORS OF APLYSIA GILL.

J.L. Leonard*#, M. Martinez Padron*@ and K. Lukowiak@ (SPON: N. Tumosa). #Dept. of Zoology, Univ. of Oklahoma, Norman, OK 73019 and @Neuroscience Research Group, Univ. of Calgary, Alberta, Canada T2N 1N4.

The movements evoked by depolarization of individual gill motor neurons, although variable in amplitude, are qualitatively consistent. Two cells, RDG and L7, produce a very similar movement involving principally Shorten and Antiflare. The movement produced by L9 is a weak Lift; LDG1 combines Shorten, Antiflare, and Roll; and LDG2 produces a movement combining Flare, Curl, and Roll. Simultaneous depolarization of qualitatively congruent cells such as two LDG2s or L7 and RDG produces a movement whose amplitude is greater than the sum of the individual movements. Also L9 enhances the effect of L7, while making no obvious change in the movements of other cells. L7 and LDG2 add in amplitude as reported previously (Kupfermann et al. 1974). Their qualitative interaction will be discussed. The effect of hyperpolarization or depolarization of major motor neurons on the GWR may depend on behavioral state. In suppressed preparations hyperpolarization of L7 and/or RDG may have no effect, qualitative or quantitative, on the GWR.

246.11

A FIRST ATTEMPT TO MINIMIZE THE NUMBER OF NEURONS THAT PARTICIPATE IN THE APLYSIA GILL-WITHDRAWAL REFLEX.

H.-P. Höpp,* J.-Y. Wu,* L.B. Cohen, C. Xiao*, and D. Zecevic. (Spon: J.A. London) Dept. of Physiology, Yale Univ. Sch. of Med., New Haven CT, 06510.

Previously published results from optical recordings suggested that as many as 300 neurons in the abdominal ganglion might be involved in the gill-withdrawal reflex. We began efforts to determine if the reflex could be elicited in conditions where a smaller number of neurons might be involved. We compared the number of active neurons in two situations, the control situation with sea water bathing the siphon, ganglion, and gill, and the experimental situation where both the siphon and gill were bathed in a low-calcium high-magnesium sea water to block contraction and possible recurrent sensory feedback to the ganglion. Surprisingly, the number of active neurons in the experimental situation was slightly larger in three preparations; 107% $\pm$ 1% (mean and standard error of the mean) of the control value. When the time courses of the increased spike activity following the water jet to the siphon were compared in the two situations, they were found to be similar. Recurrent activity from siphon and gill contractions did not have large effects on the neuron activity in the ganglion.

246.12

SENSITIZATION AND SENSORY SIGNALS IN APLYSIA I. NEUROMODULATOR EFFECTS ON PERIPHERAL EXCITABILITY.

A.J. Billy and E.T. Walters. Dept. Physiol. & Cell Biol., U.Texas Med.Sch, Houston, TX 77225.

Previous work (and next abstract) suggests coordinate central modulation of single sensory neurons at multiple cellular loci during sensitization. Recently we found that noxious stimulation causes long-term (10-15d) enhancement of peripheral sensory excitability. Here we describe acute effects of peripherally applied neuromodulators on tail mechanosensory thresholds of individual VC neurons. Threshold was determined (blind) before, during, and after injection of either seawater or an endogenous neuromodulator (each 10^{-6}M except ACh, 10^{-5}M) into the tail field. The test sequence was then repeated with the other solution. Comparisons to seawater within animals showed significant threshold depression by SCP_B, and significant elevation by dopamine, FMRFamide, and ACh. 5HT depressed threshold during later pretests of cells in the same animal, obscuring within-animal 5HT effects. Comparisons between animals, however, showed significant depression of threshold by 5HT for at least 10-15 min after washout and equally persistent elevation by FMRFamide. Similarities to central neuromodulatory patterns in these cells suggest that bidirectional modulation of sensory signalling by noxious stimuli may be produced centrally and peripherally by the same set of neuromodulators.

246.13

SENSITIZATION AND SENSORY SIGNALS IN APLYSIA II. MODULATION OF CENTRAL BURSTING AND SPIKE CONDUCTION. A.L.Clatworthy*and E.T. Walters. Dept. Physiol. & Cell Biol., U.Texas Med.Sch, Houston, TX 77225.

Regenerative bursts triggered by soma stimulation after noxious training indicate sensitization can alter sensory spike patterns at central loci (Walters, 1987). We now report that nerve stimulation causing afferent spike trains like those evoked by cutaneous injury elicits long-latency regenerative spikes centrally, which add to the afferent volley. 49 of 66 VC sensory neurons (74%) showed regenerative bursts (1-15 spikes). Regenerative bursts required more intense nerve stimuli (2.5 x VC axon threshold), indicating a heterosynaptic component. In 13 of 20 cells soma hyperpolarization reversibly blocked regenerative bursts ($p<.001$), indicating a central locus. Centrally applied $CoCl_2$ (100mM) blocked regenerative bursts in 9 cells, altered the bursts in 3 cells, and had no effect in 3 cells. Regenerative bursts appeared to originate outside the soma. Short-latency spikes evoked one-for-one by nerve stimulation could also be modified in the CNS: afferent volleys from 1 nerve were sometimes completely or partially blocked, or enhanced, by stimulating a second nerve. Noxious stimuli can thus modulate several aspects of sensory spike signalling, in addition to synaptic and perhaps transducing functions (preceding abstract).

SEROTONIN RECEPTORS II

5-HT2 RECEPTOR REGULATION IN RAT FRONTAL CORTEX: PUTATIVE SELECTIVE AGONIST AND ANTAGONIST STUDIES. M. R. Pranzatelli. Department of Neurology, Columbia University, NY, NY 10032.

DOI [1-(2,5-dimethoxy-4-iodo-phenyl aminopropane)-2] has recently been suggested as a selective 5-HT2 receptor agonist. Because of the potential importance of such a tool for investigations of 5-HT2 receptor regulation, receptor binding studies were performed in rats after chronic daily treatment with DOI, the selective 5-HT2 antagonist ketanserin, or with vehicle. In naive frontal cortex, competition experiments revealed shallow curves with significantly different IC50s (nM) for (±)DOI of 2.3 (^{3}H-DOB), 44.4 (^{3}H-ketanserin), and 2216 (^{3}H-5-HT). Yet chronic daily treatment with DOI (3-9 mg/kg) down-regulated 5-HT2 sites in frontal cortex identified with either ^{3}H-ketanserin (-60%) or with ^{3}H-DOB (-75%), without affecting 5-HT1 sites. Kds were not altered. Chronic treatment with ketanserin (10 mg/kg) also down-regulated both ^{3}H-ketanserin (-37%) and ^{3}H-DOB (-55%) sites in frontal cortex, without changes in 5-HT1 sites. These data indicate that in chronic treatment, DOI, like ketanserin, is highly selective for 5-HT2 vs 5-HT1 sites at behaviorally useful doses. However, the similar effects of a representative putative 5-HT2 selective agonist and antagonist on proposed high- and low-affinity 5-HT2 sites suggests that the regulation of 5-HT2 sites, as so defined, is unusual and unlike that of 5-HT1 sites. Supported by NIH grant 1-KO8-NS01158 and the Myoclonus Research Fund.

247.2

[^{125}I]-2-(2,5-DIMETHOXY-4-IODOPHENYL)AMINOETHANE (2C-I) LABELS THE GTP-SENSITIVE STATE OF THE 5-HT$_2$ RECEPTOR. M. P. Johnson*, D. E. Nichols, and C. A. Mathis*. (SPON: G.K.W. Yim). Depts. of Med. Chem. & Pharmacog. and Pharmacol. & Toxicol., Purdue Univ., Sch. of Pharmacy, W. Lafayette, IN 47907.

Recent studies of 5-HT$_2$ receptor binding have focused on the agonist state of the receptor using racemic [^{3}H]-DOB (Lyon et al., Mol. Pharmacol. 31:194, 1987) or the isomers of [^{125}I]-DOI (Johnson et al., Neuropharmacol. 26:194, 1987) as radioligands. We present here evidence that a new achiral ligand, [^{125}I]-2C-I labels the same site. Saturable specific binding (70%) was found in rat frontal cortex. Scatchard analysis yielded a single site model with K_D=1.52±0.10 nM and B_{max}=87±3.8 fmol/mg. Addition of 1 mM GTP inhibited specific binding to less than 10%.

Displacement results showed a low affinity for the 5-HT$_{1A}$/5-HT$_{1B}$ antagonist pindolol, as well as for DA, NE, histamine, and 8-OH-DPAT. The purported 5-HT$_{1B}$ agonist TFMPP had high affinity for this site. Stereoselectivity was demonstrated for the more active isomers of the hallucinogens DOI, 5-MeO-AMT and DMCPA. It was found that 4-OH or 5-MeO substitution on the DMT nucleus to give psilocin and 5-MeO-DMT, respectively, yielded a 3-4 fold increase in affinity. Therefore, [^{125}I]-2C-I can be used to label the 5-HT$_2$ receptor, with the advantages of high specific activity and an achiral molecule, avoiding the need to use pure isomers of DOB or DOI as ligands.

247.3

R(-)-4-^{77}BROMO-2,5-DIMETHOXYAMPHETAMINE [^{77}Br-R(-)DOB] LABELS A NOVEL 5-HYDROXYTRYPTAMINE BINDING SITE IN BRAIN MEMBRANES. S.J. Peroutka, A. Hamik, M.A. Harrington, C.A. Mathis*, P.A. Pierce and S.S.H. Wang. Department of Neurology, Stanford University, Stanford, CA 94305.

R(-)-4-^{77}Bromo-2,5-dimethoxyamphetamine (^{77}Br-R(-)DOB) was synthesized to a high specific activity (7500 ± 200 Ci/mmol) and used to label membrane-associated recognition sites in rat brain. ^{77}Br-R(-)DOB displayed high affinity (K_D = 0.15 ± 0.02 nM) for a relatively low density of binding sites (B_{max} = 0.31 ± 0.04 pmole/g tissue) in rat cortical membranes as compared to ^{3}H-ketanserin (K_D = 0.65 ± 0.1 nM; B_{max} = 6.2 ± 0.6 pmole/g tissue). Guanine, but not adenine, nucleotides were found to inhibit specific ^{77}Br-R(-)DOB binding. 10^{-4} M GTP did not eliminate specific ^{77}Br-R(-)DOB binding but caused a competitive inhibition of the radioligand. A significant correlation ($p < 0.01$) exists between drug potencies for ^{77}Br-R(-)DOB labeled sites and both 5-HT$_2$ binding sites ($r = 0.64$) and 5-HT$_{1C}$ binding sites ($r^2 = 0.68$). However, the sites do not appear to be identical. We conclude that ^{77}Br-R(-)DOB labels a unique 5-HT recognition site in rat brain which does not coincide with previously described 5-HT binding site subtypes. The ^{77}Br-R(-)DOB site does not appear to be a high affinity "state" of the 5-HT$_2$ receptor but may play a role in the pharmacological effects of hallucinogenic drugs.

247.4

5HT-2 RECEPTOR PET QUANTIFICATION USING UNLABELLED ANTAGONISTS. D.F. Wong*, A. Gjedde*x, C. Ross*, R. Frank*+, R.F. Dannals*, P. Thyrum*+, D. U'Prichard, H. N. Wagner, Jr* (SPON: W. Jankel). Johns Hopkins Med. Inst., xMontreal Neuro Inst. and +ICI Pharmaceuticals Group, Wilmington, DE.

We have developed a model for reversible neuroreceptor radioligands competing with inhibiting drugs. For measuring human 5HT-2 receptors parameters in vivo we used the putative 5HT-2 antagonist, ICI 169,369. Six subjects received 30 milligram BID of the drug or placebo in a double blind crossover study for 1 wk. each. Subsequently each subject received C-11 NMSP IV, frontal cortex (FC) binding was measured by PET. Input function was determined by plasma sampling throughout the study with simultaneous drug samples. Rate constants K1-k4 and volumes of distribution at equilibrium were determined. The percentage change from control to drug PET scan for the parameters k3/k4 declined during drug 5-40%; maximum FC/cerebellum declined 3-20%. Using partition coefficient assumptions, and in vitro affinity ratios, preliminary Bmax & KD estimates averaged 93 pmoles/g, 18nM, resp. This is analogous to using competition with irreversible binding (JCBFM 6:137, 1986). Although Bmax can be measured by varying specific activity (J Nuc Med 28:611, 1987) this protocol allows screening new drugs with C-11 NMSP & even more specific PET ligands.

247.5

INDOLEALKYLAMINES AND PHENALKYLAMINES HAVE OPPOSITE EFFECTS ON PHOSPHATIDYLINOSITOL HYDROLYSIS IN RAT CORTEX. P.A. Pierce and S.J. Peroutka. Department of Neurology, Stanford University School of Medicine, Stanford, CA 94305.

5-Hydroxytryptamine (5-HT) stimulates phosphatidylinositol hydrolysis at micromolar concentrations via the 5-HT_2 receptor in rat cortex (Conn,P.J. and Sanders-Bush, E.,Neuropharmacol.,23:993,1984). This response is blocked by the 5-HT_2 antagonist ketanserin. The phenalkylamines 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) and 1-(2,5-dimethoxy-4-bromophenyl)-2-aminopropane (DOB) are partial agonists, producing a lower PI stimulation relative to the 5-HT PI response. This phenalkylamine PI response is also blocked by ketanserin. In contrast, the indolealkylamines d-lysergic acid diethylamide (d-LSD) and N,N-dimethyltryptamine (DMT) only slightly stimulate PI hydrolysis at high concentrations (greater than 10 uM). This response is not blocked by ketanserin. At high concentrations, this ketanserin-insensitive PI stimulation has been reported for 5-HT_2 antagonists (Conn, P.J. and Sanders-Bush, E.,J. Pharmacol. Exp. Ther.,242:552,1987). At lower concentrations, d-LSD (10 nM) and DMT (1 uM) significantly inhibit the PI response to 10 uM 5-HT. These data indicate that phenalkylamines (DOI, DOB) are partial agonists at the 5-HT_2 receptor in rat cortex while indolealkylamines (d-LSD, DMT) are antagonists at the 5-HT_2 receptor yet stimulate PI hydrolysis through another interaction at high concentrations.

247.6

ACUTE AND CHRONIC EFFECTS OF HP 370 ON D_2 AND 5HT_2 RECEPTORS AND DA METABOLISM. C.A.Wilmot, A.M.Szczepanik*, P.G. Conway, L.R.Brougham*, J.C.Wilker* and D.B. Ellis*. Department of Biological Research, Hoechst-Roussel Pharmaceuticals, Inc., Somerville NJ 08876.

HP 370 4,9-dibromo-6-(4-methyl-1-piperazinyl)benzo[b]pyrrolo [3,2,1-jk][1,4]benzodiazepine, is a potential antipsychotic which resembles clozapine (CLZ) in behavioral and electrophysiological tests predictive of an atypical agent but, unlike CLZ, HP 370 is inactive at cholinergic receptors. Receptor autoradiography was used to examine site-specific interactions of CLZ and HP 370 with D_2 and 5HT_2 receptors and compared to the typical neuroleptic haloperidol (HAL). CLZ and HP 370 produced 50-75% inhibition of [^{3}H]-spiperone binding to 5HT_2 receptors after acute treatment with 10-40 mg/kg, ip, which persisted for at least 24 hours with HP 370. Chronic administration of CLZ (20 mg/kg, ip) or HP 370 (20-40 mg/kg, ip) decreased the B_{max} for cortical 5HT_2 receptors by 55% and >80%, respectively, with no significant changes in the B_{max} for D_2 receptors in the striatum or n. accumbens. Neither acute nor chronic treatments with HAL affected binding to 5HT_2 receptors. HP 370 increased the ratios of DOPAC/DA and HVA/DA to 175-250% of control following a single dose (20-40 mg/kg, po) but not following chronic dosing. Similar to CLZ, the effects of HP 370 on DA metabolism were not potentiated by amfonelic acid. Acutely, HP 370 (10-40 mg/kg, ip) also significantly antagonized HAL-induced catalepsy. These studies suggest that strong interactions with 5HT_2 receptors may be a significant component of the profile of an atypical neuroleptic.

247.7

1-(2,5-DIMETHOXY-4-IODOPHENYL)-2-AMINOPROPANE (DOI) ACTS AT 5-HT2 RECEPTORS TO CONTRACT THE PORTAL VEIN IN VITRO AND INHIBIT FEEDING IN VIVO. L.E. Schechter, P.M. Consigny* and K.J. Simansky.Depts. Pharmacol. & Physiol., Med. Col. PA, Phila., PA 19129.

Previously we have reported that DOI produces an anorexic action in rats that is blocked by the 5-HT2 antagonists LY53857, ketanserin and 1-(1-naphthyl)-piperazine but not by the peripherally-acting 5-HT2 antagonist xylamidine (Psychopharmacol. 94(3):342, 1988). This contrasted sharply with the ability of xylamidine to antagonize the anorexic effect of peripherally administered serotonin. Thus, either DOI does not act as a 5-HT2 agonist at peripheral 5-HT2 sites or xylamidine does not block the anorexic effect because this action is mediated in the brain. Accordingly, DOI was tested in the rat portal vein which is a model for peripheral 5-HT2 receptor stimulation. Using noncumulative additions of agonists, DOI contracted the portal vein in a dose-related fashion [4 nM-40 uM; ED50 = 38 (7-201) nM] with full agonist activity compared to that of serotonin [max contraction (g) = .82 ± .08 vs. .90 ± .03, respectively] . In contrast, adding DOI in a cumulative fashion reduced the maximal response. Thus depending upon the experimental conditions DOI can appear to be a full or partial agonist. Notably, xylamidine produced a dose-related antagonism (1-100 nM) of the contractile effect of DOI (80 nM) with an ID50 of 6 (2-16) nM. The contractile activity of DOI (80 nM) was also blocked by spiperone (100 nM) and ketanserin (100 nM) but not by pindolol (20,000 nM). In vivo, spiperone (0.17 umol/kg) antagonized the anorexic effect of DOI (6 umol/kg) in rats. Taken together, the results demonstrate that DOI is a 5-HT2 agonist that can stimulate peripheral 5-HT2 receptors in the portal vein. Furthermore, this action is blocked by xylamidine. In view of our previous findings, this suggests the anorexic action of DOI is mediated at central 5-HT2 receptors. Supported by NIMH 41987 to KJS.

SEROTONIN EXCITATION OF FACIAL MOTONEURONS: MEDIATION THROUGH A 5-HT-2 RECEPTOR. Kurt Rasmussen and George K. Aghajanian. Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06508

Serotonin (5-HT) and norepinephrine (NE) increase the excitability of facial motoneurons by producing a slow depolarization. We have examined this response with ligands selective for various 5-HT receptor subtypes in an effort to determine the subtype(s) of 5-HT receptor(s) involved in this response. In chloral hydrate anesthetized male rats, DOM, a putative 5-HT-2 agonist, applied iontophoretically (20 nA) or systemically (100 µg/kg) acts as an agonist while 8-OH-DPAT, a 5-HT-1A agonist, applied iontophoretically has little or no effect. The action of DOM differs from that of 5-HT in that it was much longer in duration (e.g., > 30 min) following a single iontophoretic application. Similar results were obtained for these compounds when applied iontophoretically to facial motor neurons recorded in the in vitro brain slice preparation. Intracellular recordings in the brain slice preparation show that DOM, like 5-HT, causes a slow depolarization of facial motoneurons, but its action is much more prolonged than that of 5-HT. The non-selective 5-HT antagonist methysergide was effective in blocking the action of 5-HT, but not NE, when administered systemically in vivo (0.1-0.2 mg/kg) and iontophoretically in vitro (10 nA). The selective 5-HT-2 antagonist ritanserin was also effective in blocking the action of 5-HT, but not NE, when administered systemically in vivo (0.2-0.4 mg/kg) and when added to the bath in vitro (20 µM). However, another 5-HT-2 antagonist, LY 53857, was not able to block the action of 5-HT and may display some agonist activity when applied systemically in vivo or iontophoretically in vitro. Thus, the action of 5-HT on facial motor neurons seems to be due primarily to activity at 5-HT-2 receptors, however this 5-HT-2 receptor may have different properties than 5-HT-2 receptors in other brain regions.

^{3}H-QUIPAZINE LABELS 5-HYDROXYTRYPTAMINE$_3$ RECEPTORS IN RAT CORTICAL MEMBRANES. C.M. Milburn, A. Hamik and S.J. Peroutka. Department of Neurology, Stanford University, Stanford, CA 94305.

5-Hydroxytryptamine$_3$ (5-HT_3) receptors have been extensively characterized in the peripheral nervous system and have recently been identified in the central nervous system. Since quipazine displays potent antagonist effects at peripheral 5-HT_3 receptors, ^{3}H-quipazine was used to radiolabel putative 5-HT_3 receptors in rat cortical membranes. ^{3}H-quipazine labels a single population of binding sites with an affinity of 1.3 ± 0.1 nM. Specific binding was defined as the excess over blanks taken in the presence of 100 nM ICS 205-930. Quipazine, ICS 205-930, BRL 43694A and Lilly 278584 had affinities of 1 nM or less for this site. The affinities of 5-HT, bufotenine, MDL 72222, mCPP, metoclopramide and RU 24969 were between 10 and 500 nM, and that of cocaine was 2880 nM. Mesulergine, ketanserin, methysergide and d-LSD were inactive (i.e., ≥ 50,000 nM). Nucleotides did not significantly inhibit binding to these sites. The pharmacology of this site suggests that ^{3}H-quipazine labels 5-HT_3 receptors in rat cortex.

247.10

SPECIES VARIATIONS OF [^{3}H]QUIPAZINE BINDING TO 5-HT_3 RECEPTORS. A. Hamik* and S.J. Peroutka (SPON: E. Smith). Department of Neurology, Stanford University Medical Center, Stanford, CA 94305.

[^{3}H]Quipazine has been shown to label 5-HT_3 receptors in rat brain. (Peroutka and Hamik, Euro. J. Pharm., 148:297, 1988) Specific binding was defined as the excess over blanks in the presence of 100 nM ICS 205-930. Eight species were examined for specific [^{3}H]quipazine binding to 5-HT_3 receptors. In rat cortex, the sites were labelled with a K_D of 1.3 ± 0.1 nM and a B_{max} of 2.9 ± 0.5 pmol/g-tissue. Pig cortex showed a K_D of 2.1 ± 0.2 nM and a B_{max} of 2.6 ± 0.2 pmol/g-tissue. By contrast, no significant specific binding was shown in human, cow, rabbit, guinea pig, chicken, or turtle brain. For example, in the presence of 0.6 nM [^{3}H]quipazine, rat cortex shows a total binding value of 1,270 ± 30 cpm, and a non-specific binding value of 540 ± 10 cpm. In human cortex, total [^{3}H]quipazine binding equals 610 ± 40 cpm, and non-specific binding equals 550 ± 20 cpm. Therefore, species variations in either the density or presence of 5-HT_3 receptors appear to exist.

247.11

5-HT_3 RECEPTORS CONTROL DOPAMINE RELEASE IN THE LIMBIC SYSTEM OF FREELY-MOVING RATS. A.Imperato* and L.Angelucci* Farmacologia 2a, Università di Roma "La Sapienza", P.le A.Moro 2, 00185 Roma, Italia. (SPON: M. Karobath)

Classication of 5-hydroxytryptamine (5-HT) receptors into 5-HT_1 , 5-HT_2 and 5-HT_3 subtypes, has been recently proposed on functional and pharmacological grounds. Contrary to 5-HT_1 and 5-HT_2 receptors found in various tissues, including neurons of the CNS, until now 5-HT_3 receptors have only been demonstrated in PNS.Here we show, by the use of microdialysis, that 5-HT_3 receptors, located on neurons in the ventral tegmental area (VTA), regulate dopamine release in the nucleus accumbens of conscious rats. ICS 205-930, a potent and selective 5-HT_3 receptor antagonist, either systemically (50 ug/Kg s.c.) or into the VTA (0.5 ug), prevented the increase in dopamine release by s.c. morphine, nicotine, ethanol. This is the first direct evidence of the existence of functional 5-HT_3 receptors in the brain. Since the mesolimbic DAergic system is thought to mediate the rewarding properties of abuse drugs,these findings point to a possible therapeutic usefulness of ICS 205-930.

247.12

CHARACTERIZATION OF [^{125}I] DOI BINDING SITES IN RAT BRAIN. D.J. McKenna[1], C.A. Mathis*[2] and S.J. Peroutka[1]. 1. Department of Neurology, Stanford University Medical Center, Stanford, CA 94305. 2. Donner Laboratory, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.

DOI is a hallucinogenic phenylalkylamine which interacts stereospecifically with serotonergic receptors. Autoradiographic investigations have demonstrated [^{125}I]DOI specific binding in regions known to contain high densities of 5-HT_2 receptors. Scatchard analysis of [^{125}I]DOI binding in rat cortex indicates that [^{125}I]DOI labels an intermediate density of sites compared to [^{77}Br]-R-DOB and [^{3}H]ketanserin (0.31, 4.9 and 6.2 pmol/g tissue, respectively). The observation that DOI labels only 70 to 80% of the number of sites labeled by [^{3}H]ketanserin suggests it may label a unique 5-HT_2 receptor subtype in the rat central nervous system. Nucleotides did not effect either the K_D or B_{max} values. The results of competition studies using various subtype-selective 5-HT ligands at [^{125}I]DOI-labeled sites will be presented, and the relevance of the "DOI site" to other 5-HT receptor subtypes will be discussed.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: OCULOMOTOR SYSTEM I

248.1

DIFFERENTIAL ROLES OF GABA AND GLYCINE AS INHIBITORY NEUROTRANSMITTERS IN CAT EXTRAOCULAR MOTOR NUCLEI. R.F. Spencer, R.J. Wenthold, and R. Baker. Dept. Anat., Med. Col. of Virginia, Richmond, VA 23298; Lab. Neuro-otolaryngol., N.I.N.C.D.S., N.I.H., Bethesda, MD 20892; and Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

The immunohistochemical localization of GABA and glycine in the cat oculomotor, trochlear, and abducens nuclei has been examined by light and electron microscopy. In the oculomotor nucleus, GABA-immunoreactive synaptic endings were distributed within all motoneurone subdivisions except the medial rectus, in which there was a near absence of labelled profiles. The trochlear nucleus exhibited the highest density of GABA-immunoreactive axo-somatic and axo-dendritic synaptic endings that contained numerous pleiomorphic synaptic vesicles. By contrast, the abducens nucleus was characterized by a paucity of GABA-immunoreactive synaptic endings.

The immunohistochemical localization of glycine demonstrated a high density of immunoreactive synaptic endings in the abducens nucleus that presumably are associated with vestibular, reticular, and prepositus hypoglossi inhibitory inputs. Glycine-immunoreactive synaptic endings in the abducens nucleus also contained pleiomorphic synaptic vesicles and exhibited a widespread soma-dendritic distribution. By contrast, the oculomotor and trochlear nuclei exhibited sparse glycine-immunoreactive staining. These differences appear to be related to differences in immunoreactive staining of axons in the ascending (GABA) and descending (glycine) MLF. The findings are consistent with the differential roles of GABA and glycine as inhibitory neurotransmitters in the vertical and horizontal eye movement systems, respectively.

Supported, in part, by U.S.P.H.S. Research Grants EY02191 and EY02007.

THE CEREBELLOTECTAL PATHWAYS: ORIGINS AND RELATIONSHIP TO THE CROSSED TECTORETICULAR NEURONS IN A PRIMATE. P.J. May and J.D. Porter. Depts. of Anatomy and Ophthalmology, Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

The anatomical relationship of the superior colliculus, an important premotor saccade center, and the cerebellum, which is believed to play a critical role in the feedback regulation of saccades, has not been investigated in primates, the order having the most extensive saccadic repertoire. Our previous retrograde results demonstrated two populations of cerebellotectal neurons: a contralateral one in the posterior interpositus and adjacent dentate nuclei and a bilateral one in the fastigial nucleus. Injection of WGA-HRP into the posterior interpositus and dentate nuclei of the Macaca fascicularis resulted in a moderately dense band of anterogradely labelled terminals in the ventral half of the intermediate grey layer, throughout the rostrocaudal extent of the superior colliculus. The deep grey layer was more lightly labelled. Following injection of WGA-HRP into the fastigial nucleus, labelled terminals were distributed in the same laminar pattern, but were present bilaterally and were restricted to the rostral pole of the colliculus. In both cases, a few retrogradely labelled neurons were observed in the collicular deep layers. To determine the relationship of the cerebellotectal termination pattern to the sources of descending tectal pathways, WGA-HRP was placed unilaterally in the rostral pontine reticular formation. The retrogradely labelled neurons in the contralateral superior colliculus were restricted to the ventral half of the intermediate grey layer, throughout the colliculus. This band of labelled cells co-localized with an acetylcholinesterase rich band in the intermediate grey layer. Labelled cells in the ipsilateral colliculus were located dorsal and ventral to this lamina. The precise laminar correspondence between the distribution pattern of cerebellotectal terminals and the location of the cells of origin of the predorsal bundle (crossed) pathway, indicates that the cerebellum plays a direct role in modifying the activity of saccadic premotor neurons in the superior colliculus. Supported by NEI grants EY07166 (PJM) and EY05464 (JDP).

OCULOMOTOR-RELATED CONNECTIONS OF THE CEREBELLAR FASTIGIAL NUCLEUS IN THE MONKEY, AND THEIR RELATIONSHIP TO FRONTAL EYE FIELD EFFERENTS. G.R. Leichnetz and A. Gonzalo-Ruiz*, Dept. of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Lesions of the fastigial nucleus (FN) have a profound effect on the production of saccadic eye movements. While the cerebellum is not necessary for the generation of eye movements, it is essential for the coordination of features of the movements (eg. size, velocity) in response to changing motor commands. The frontal eye field (FEF), on the other hand, participates in the initiation of voluntary purposeful saccades in trained monkeys. We have been interested in the interaction of cortical and cerebellar influences in the control of eye movement (see JCN 268: 508-526, 1988).

Both the FN and FEF project to the superior colliculus, supraoculomotor periaqueductal gray, paramedian pontine reticular formation (including raphe), and the nucleus prepositus hypoglossi. The FEF projects to the medial nucleus reticularis tegmenti pontis, and the dorsomedial basilar pontine nuclei (DMPN), and to a lesser extent the dorsolateral basilar pontine nuclei (DLPN). The FN appears to receive input from both DMPN and DLPN. While the FEF projects to preolivary "paraoculomotor" cell groups, including the nucleus of Darkschewitsch, medial accessory nucleus of Bechterew, and dorsomedial parvicellular red nucleus, none of these appear to receive from or project to the FN. The medial accessory olivary nucleus and vestibular complex, which project to the FN, do not receive FEF input. We are now attempting to understand the importance of their points of convergent vs. distinctive connectivity in terms of their contrasting roles in ocular motility.

PROJECTIONS FROM THE ROSTRAL MESENCEPHALIC RETICULAR FORMATION TO THE SPINAL CORD. An HRP and autoradiographic tracing study in the cat. G. Holstege[1] and R.J.Cowie[2],[1] Dept. Anatomy, Univ. California San Francisco CA 94143 [2] Dept. Anatomy Howard University Washington DC 20059.

Eye and head movements are strongly interconnected, because they play an important role in determining the direction of the visual field. The caudal Field H of Forel, including the rostral interstitial nucleus of the MLF (riMLF) and the interstitial nucleus of Cajal with adjacent reticular formation (INC-G) contain neurons controlling vertical eye and head movements. Injections of ^{3}H-leucine in these areas and HRP spinal cord injections revealed that:

1: Unlike the neurons projecting to the extra-ocular muscle motoneurons, the major portion of the spinally projecting neurons are not located in the riMLF or INC proper but in adjacent areas, i.e. in the ventral and lateral parts of the caudal third of the Field H of Forel and in the INC-G.

2: Neurons in caudal Field H of Forel project, via the ventral part of the ventral funiculus, to the lateral part of the upper cervical ventral horn. This area includes motoneuronal cell groups, innervating the cleidomastoid, clavotrapezius and splenius muscles. At lower cervical levels labeled fibers are distributed to the medial part of the ventral horn.

3: Neurons in the INC-G project, via the dorsal part of the ventral funiculus, bilaterally to the medial part of the upper cervical ventral horn. This area includes motoneurons innervating prevertebral flexor muscles. Further caudally labeled fibers are distributed to the medial part of the ventral horn (laminae VIII and adjoining VII) throughout the length of the spinal cord.

It is proposed that neurons in the caudal Field H of Forel, projecting to the spinal cord, might be especially involved in the control of fast vertical head movements and the INC-G-spinal neurons in slower, smaller movements controlling the position of the head in the vertical plane. Supported by NASA Grant 2-484903-26308

GAZE CONTROL IN HEAD-FREE CATS: TASK DEPENDENT TRAJECTORIES AND EVIDENCE FOR A COMMON MOTOR DRIVE TO THE EYES AND HEAD. D. Guitton and D.P. Munoz. Neurology and Neurosurgery Dept. McGill University, Montreal, Canada, H3A 2B4

Orienting movements, consisting of combined eye and head displacements, are routinely used to direct the visual axis to the source of a sensory stimulus. Tectoreticulospinal and reticulospinal neurons in the cat are important pathways that participate in the control of eye and head movements. The afferents to these neurons as well as the nature of their movement related discharges suggest that the degree of coupling between eye and head movements can be quite variable. We examined eye-head coupling when cats performed two tasks: 1)a "collicular" task in which the cat oriented to a target that appeared unexpectedly in the periphery (VT task); 2)a more cognitive, "cortical" task in which the cat oriented to a location where it predicted the target would appear (PT task). For a gaze shift of given amplitude both the eyes and head, and consequently gaze, movements were slower in PT compared to VT. The onset times of the eyes and head always covaried. When the target appeared just prior to a gaze shift initiated by predictive cues, the eyes accelerated in mid-flight and so too the head, 20-30 ms later. Thus in all cases the eyes and head appeared to share a common motor drive. The most striking evidence for this mechanism was that the head acceleration and eye velocity profiles when superimposed, could hardly be distinguished from one another.

SMOOTH PURSUIT INITIATION IN HUMANS WITH CEREBRAL HEMISPHERIC LESIONS. M.J. Morrow* and J.A. Sharpe. Division of Neurology, Playfair Neuroscience Unit, The Toronto Hospital, University of Toronto, Toronto, Ont. M5T 2S8

We studied horizontal smooth pursuit maintenance (SPM) and initiation (SPI) in 18 patients with unilateral cerebral lesions, using magnetic search coil oculography. SPM was recorded in response to nine groups of predictable target sinusoids differing in frequency and amplitude. Responses to unpredictable foveopetal and foveofugal step-ramps measured SPI and allowed distinction between retinotopic and directional pursuit deficits.

Six patients had significant SPM asymmetry, all with lower ipsilateral gains. Two of these did not have directional SPI asymmetry. In contrast, 3 patients without SPM asymmetry had directional SPI deficits with reduced initial eye acceleration and increased latency for ipsilateral step-ramps. Seven patients had retinotopic SPI deficits; only four of these had hemianopic field loss involving the area of SPI loss. Four patients with complete homonymous hemianopia could generate low velocity SPI to targets moving in their blind fields.

These data indicate that directional deficits of SPM and SPI can be disparate. Retinotopic pursuit loss in humans does not specify damage to optic radiations or striate cortex.

248.7

THE USE OF TARGET SPEED IN PLANNING CORRECTIVE SACCADES IN SMOOTH PURSUIT EYE MOVEMENTS IN MONKEY. E.L. Keller and S.D. Johnsen*. Smith-Kettlewell Eye Research Institute and Dept. of Electrical Engineering and Computer Sciences, University of California, Berkeley, CA 94115.

In response to a sudden onset of smooth visual target motion, primates are able to initiate a smooth tracking eye movement that rapidly matches eye speed to target speed. Because of the latency of this response and the possible initial offset in the position of the eyes with respect to the target, this smooth tracking response is generally coupled with a longer latency corrective saccade which reduces the position error between eye and target. Since these corrective saccades actually move the eye very close to the moving target's position, it has been assumed that information about target speed is utilized in the planning of these saccades. However, in the only quantitative study providing a test of this notion (Heywood and Churcher, Vis. Res. 21, 479, 1980), it was found in human subjects that accurate information about target speed was not incorporated into the programming of saccades. We reinvestigated this subject in the monkey, and found that information about target speed is used in this species in the production of corrective saccades. Multiple linear regression analysis supported the hypothesis that the position error and the retinal slip velocity that exist at about 100 msec prior to saccadic onset are both required to provide an accurate statistical prediction of saccade size.

248.8

VERGENCE-RELATED CELLS NEAR THE ABDUCENS NUCLEI J.W. Gnadt, P.D.R. Gamlin, L.E. Mays and Y. Zhang. Dept. of Physiological Optics, School of Optometry, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Twenty-five vergence-related neurons were recorded near the abducens nuclei in 8 macaques. Twenty-three of these cells increased their activity for convergence: mean = 8.2 (spikes/sec)/deg of vergence (range: 2.2 to 20.9). The activity of the cells preceded the vergence movements by a mean of 25 ms, though this varied considerably. Many cells had a smaller, but significant, sensitivity to vergence velocity: mean = 1.1 (spikes/deg)/(deg/sec). Seven cells also increased their firing rate for ipsilateral horizontal conjugate eye movements, and 3 of these showed increases for downward eye position. The mean ratio of vergence to conjugate gains was 5.7. Many of the cells were located near medium-lead burst or omniburst neurons.

In one monkey, recording sites of 5 cells were recovered histologically. Three were in the reticular formation lateral and caudal to abducens, one was at the border of the medial vestibular nucleus and the last was in the lateral vestibular nucleus.

These data have shown that a heterogenous population of vergence-related cells exist in the posterior brainstem and document the prenuclear mixing of vergence and conjugate signals. The purely vergence-related signals would be appropriate as inhibitory input to abducens neurons. (Supported by Grant EY03463 and P30 EY03039).

LIDOCAINE-INDUCED UNILATERAL INTERNUCLEAR OPHTHALMOPLEGIA: EFFECTS ON ACCOMMODATIVE VERGENCE. P. D. R. Gamlin, J. W. Gnadt and L. E. Mays. Department of Physiological Optics, University of Alabama at Birmingham, Birmingham, AL 35294.

Abducens internuclear neurons decrease their firing rate during symmetrical convergence (Gamlin *et al.*, Invest. Ophth. Vis. Sci. (Suppl) 29:345, 1988). This should result in an inappropriate vergence signal being sent to medial rectus motoneurons during vergence movements. Unilateral lesions of the medial longitudinal fasciculus (MLF) would block this incorrect signal, thereby facilitating convergence.

Reversible unilateral blockade of the MLF was produced by injections of 100 nl of 10% lidocaine HCl in two Rhesus monkeys. Both horizontal conjugate gain and the accommodative convergence/accommodation ratio (AC/A) were measured before and during the blockade. As expected, conjugate adduction was severely affected on the side of the blockade. When the effects of decreased conjugate gain are considered, the net AC/A ratio was increased by MLF blockade. These results confirm that that the MLF is indeed carrying an inappropriate vergence signal, which is cancelled by another, more potent vergence input to medial rectus motoneurons. (Supported by NIH Grant EY03463 and P30 EY03039).

248.10

OCULAR REALIGNMENT DURING AND AFTER SACCADES USING PREPROGRAMMED VERGENCE. L. Levi*, D.S. Zee, T.C. Hain, W.A. Fletcher* and M.L. Rosenberg*. Dept. of Neurology, The Johns Hopkins Hospital, Baltimore, MD, 21205.

The difference in power between anisometropic spectacle lenses induces a prismatic effect that varies with gaze direction. To fuse rapidly, the anisometropic subject needs to change the relative alignment of the visual axes during a saccade. We predicted that this capability would be under adaptive control.

Spectacle-corrected anisometropia was simulated in two normal myopic subjects (-8 and -10 diopters, respectively) by having them wear a contact lens on the right eye and a spectacle lens in front of the left eye for several days. Horizontal and vertical saccades were recorded with binocular coils prior to wearing the combination and after resuming normal corrections. Viewing was both monocular and binocular. In one subject saccades were also measured on first wearing the combination, and immediately prior to resuming his usual correction. The vergence change was derived by subtracting the left and right eye positions.

Both subjects, upon resuming their usual corrections, still demonstrated an intra- and post-saccadic vergence change appropriate to the induced prismatic effect of the spectacle-contact lens combination (e.g. up to 5.3° intra-saccadic and 1° post-saccadic divergence for 20° right saccades, and up to 4.4° intra-saccadic and 0.9° post-saccadic right hyperdeviation for 20° upward saccades). These movements occurred with both binocular and monocular viewing. Whereas this adaptation occurred with both horizontal and vertical saccades, on initially exchanging the spectacle-contact lens combination and the normal correction, an appropriate vergence response to the acute prismatic effect was seen only with horizontal saccades.

These results suggest that the CNS learns to preprogram intra- and post-saccadic vergence movements, which, once learned, occur independently of disparity cues.

248.11

VISUALLY-INDUCED CROSS-AXIS PLASTICITY OF POST-SACCADIC EYE DRIFT. Z. Kapoula, D.A. Robinson and L.M. Optican*. Lab. of Sensorimotor Res., NEI, Bethesda, MD 20892.

Post-saccadic eye drift can be induced optically in monkeys and humans by post-saccadic motion of a visual pattern (Optican & Miles, J. Neurophysiol., 54: 940, 1985; Kapoula et al., Soc. Neurosci. Abstr., 13: 392, 1987). We examined the ability of humans to adapt to horizontal post-saccadic pattern motion coupled with vertical saccades.

Five subjects scanned a random-dot pattern projected onto a 2 m hemisphere. A computer detected the end of each saccade and drifted the pattern exponentially, by 25% of vertical saccade size, leftward after up saccades, right after down saccades. At first subjects followed the pattern motion after a delay of 30-93 ms. After 3 hrs of training, vertical saccades were followed by zero-latency horizontal drift, with no horizontal saccade, in the direction of pattern motion. It had an exponential waveform and mean amplitude of 2.1°. For all subjects, the horizontal drift even persisted after purely vertical saccades in the dark (0.6°).

The drift appeared due to a step in horizontal innervation, presumably from the neural integrator which integrates a neural pulse, but how could that occur with no horizontal pulse? Perhaps the coupling from the output of the integrator is changed or a part of the vertical step is coupled to the horizontal system.

248.12

LONG TERM SACCADIC ADAPTATION DOES NOT AFFECT THE SACCADES EVOKED BY ELECTRICAL STIMULATION OF THE SUPERIOR COLLICULUS.

Edmond J. FitzGibbon and Michael E. Goldberg Laboratory of Sensorimotor Research, National Eye Institute, N.I.H., Bethesda, MD 20852.

Stimulation of the superior colliculus (SC) of a monkey whose saccadic system has adapted to visual targets yields saccades identical to those evoked in the unadapted state. To see if this failure to evoke adapted saccades by electrical stimulation were a property unique to the paradigm of short term adaptation we stimulated SC before and after chronic saccadic adaptation.

Horizontal rectus muscles of one eye of two rhesus monkeys were weakened by injection of botulinum toxin, and a microelectrode implanted in the intermediate layers of the superior colliculus. The normal eye was occluded, and the monkeys viewed the world through the weakened eye. After a week the monkeys made more accurate saccades with the weakened eye and hypermetric saccades with the occluded eye. Saccadic gains were increased by over a factor of 2. Electrical stimulation of SC through the fixed microelectrode evoked saccades similar to those evoked before the start of the adaptation process.

These data suggest that both long- and short-term saccadic adaptation occur in neural centers not excited by electrical stimulation of the SC, either in a region before the SC in the processing stream or a region which acts directly on the saccadic centers in the pons and midbrain reticular formation yet is not affected by electrical activation of the SC.

FEEDING AND DRINKING IV

249.1

EFFECT OF HOUSING AND PRE-TEST HANDLING ON THE HYPERPHAGIC AND HYPOTHERMIC EFFECTS OF 8-OH-DPAT. D.V. Coscina and L. Dixon*. Sect. of Biopsychol., Clarke Inst. of Psychiatry University of Toronto, Toronto, ONT, Canada, M5T 1R8.

Considerable research has shown that drugs which stimulate post-synaptic serotonin (5-HT) receptors can reduce food intake. More recent work suggests that agents which stimulate pre-synaptic 5-HT receptors can enhance feeding by suppressing the release of endogenous 5-HT. Work from this lab with one of these agents, 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), has revealed inconsistency in reliably enhancing feeding in sated rats. One difference between our work and that of others who report consistent feeding enhancement is the testing conditions used. We conduct all testing in single wire-mesh homecages while others use plastic tubs for housing, then move rats to new tubs just before and during testing. To determine if such conditions contribute to different findings, we conducted 3 separate studies with adult female rats fed Purina Chow ad lib that were housed and handled both ways, then received 60 ug 8-OH-DPAT vs. saline s.c. In 2 of these studies, 1 hr feeding was enhanced only when rats were housed in tubs. These same rats became hypothermic after 8-OH-DPAT while rats housed in wire-mesh cages became hyperthermic. These findings show that 8-OH-DPAT's ability to modify food intake and body temperature can vary with test conditions. This fact should be considered when attempting to interpret the mechanism of action for this putative 5-HT autoreceptor agonist.

249.2

EFFECT OF DIETARY PROTEIN ON THE ANORECTIC POTENCY OF FLUOXETINE (FLX). E.T.S. Li and S.Q. Luo*. Department of Nutritional Sciences, University of Toronto, Toronto, Ontario, M5S 1A8, CANADA.

Low doses of FLX, a 5-HT uptake inhibitor, selectively suppress carbohydrate (CHO) but not protein (PRO) intake in rats given choices. To investigate further the effect of protein content of the diet on FLX, rats were fed single diets containing 10% PRO- 73.5% CHO, 25% PRO- 58.5% CHO or 40% PRO- 43.5% CHO. The rats received FLX or saline 15 min prior to food access. Compared to saline, FLX decreased 1 hr food intake (mean difference in g given in table,

Casein	FLX (mg/kg, ip)			
%	1	2	2.5	3
10	1.4	6.0*	6.2*	5.9*
25	1.1	5.0*	2.6	5.1*
40	0.2	2.7	3.4*	4.6*

paired t test, *p<0.05). ANOVA followed by Duncan's Multiple Range Test indicate an effect of FLX at 1 mg/kg being weaker than at the other doses (p<0.05). Diet composition was a significant factor (F = 3.47, p<0.037) with the 10% PRO- 73.5% CHO diet different from the 40% PRO- 43.5% CHO diet (p<0.05). We conclude that the anorectic potency of FLX is dependent on the relative proportion of PRO and CHO in the diet.

THE IMPACT OF SEROTONERGIC AGONISTS ON NOCTURNAL PATTERNS OF MACRONUTRIENT SELECTION. G.F. Weiss* and S.F. Leibowitz. The Rockefeller University, New York, N.Y. 10021.

Evidence suggests that brain serotonin (5-HT) plays an important role in the inhibitory control of appetite for specific foods. We have examined the impact of centrally injected 5-HT, d-norfenfluramine (DNF), fluoxetine (FLUOX) and peripherally injected dexfenfluramine (DF), on the natural patterns of macronutrient intake in freely feeding rats.

The results of these studies demonstrate: 1) Injection of 5-HT (0.5-4 µg) directly into the paraventricular nucleus (PVN) selectively suppresses carbohydrate intake. 2) This effect is most potent in freely-feeding animals and occurs during the first hour of the nocturnal feeding cycle. This is precisely when an increase in PVN content of the 5-HT metabolite 5-HIAA is detected using microdialysis procedures (B.G. Stanley et al., 1987). 3) PVN injection of DNF (0.4-12 µg) and FLUOX (1-20 µg), as well as peripheral injection of DF (0.06-0.25 mg/kg), also selectively suppress carbohydrate intake. 4) Cannula mapping studies indicate that this serotonergic effect is anatomically specific, localized to the medial hypothalamus (PVN and ventromedial nucleus), as opposed the lateral hypothalamus or other extra-hypothalamic areas examined.

Additional results show that medial hypothalamic electrolytic lesions produce carbohydrate hyperphagia and obesity, while blocking the feeding suppressive effect of peripherally injected DF. These results strongly support the hypothesis that 5-HT neurons innervating the medial hypothalamus are physiologically active in regulating appetite for carbohydrate-rich foods, particularly at dark onset, and also in mediating the influence of peripherally injected serotonergic drugs on patterns of eating behavior.

MAIN SEROTONINERGIC EFFECTS OF FENFLURAMINE ON FOOD INTAKE MAY NOT INVOLVE CENTRAL APPETITE PATHWAYS. D. A. Booth and B. J. Baker*. Neuroscience Labs., Psychology Dep't, Univ. Birmingham, P.O. Box 363, Birmingham B15 2TT, U.K.

In frequently feeding rats and people, most of the suppression of food intake caused by 5HT actions of the anti-obesity drug dl-fenfluramine (F), including reduced intake of conventional snackfoods between meals, is likely to arise from the retardation of gastric emptying and a consequent prolongation of the appetite-suppressant effect of energy being absorbed from the last meal: peripheral 5HT antagonist xylamidine (3 mg/kg) counters F's effects at 2.5 mg/kg both on gastric emptying rate and on the ratio of meal size to time to the next meal.

In the rapidly eaten first meal by food-deprived rats (the common test for "anorexia") and in a choice between diets differing in texture (as carbohydrates and proteins do), much of the observed suppression of intake or shift in choice can be attributed to F's action on brainstem 5HT synapses within the sensorimotor pattern generators for manipulation, mastication and/or deglutition, and sedation at high doses. F (2.5 mg/kg) alters relative intakes of chow crumbs differing in size (2.5 - 6.5 mm). F's effect on this innate texture preference is modulated by the texture of the nutrient preparation with which the crumbs are mixed (45% casein or calcium caseinate, dextrin or maltodextrin). Furthermore, the previously observed lack of effect of F on the learned protein- or carbohydrate-specific dietary selection cued by odor (Soc. Neurosci. Abstr., 15: 593, 1986) also extends to learned crumb-size cues. We conclude that previous observations attributed to nutrient regulation arose from sensorimotor disruption.

It remains to be shown that any forebrain 5HT action of peripherally administered F affects intake or dietary choice other than via these two sorts of effect on ingestive behavior, i.e. feeding-specific modulation of peripheral satiety signals and non-specific inhibition of central reflexes.

SERTRALINE AND OTHER SEROTONIN (5-HT) UPTAKE INHIBITORS POTENTLY REDUCE NOCTURNAL FREE-FEEDING IN RATS. K. J. Simansky, J. Lemieux* and F.C. Sisk*, Dept. Pharmacol., Med. Coll. PA, Philadelphia, PA 19129.

5-HT is thought to mediate inhibitory control of feeding. Nonetheless, acutely administered, 5-HT uptake blockers have proven equivocal in producing anorexia. We determined the effects of sertraline (SERT), a potent and highly selective inhibitor of 5-HT uptake, on the amount of dry food eaten by male rats under various conditions. When given to nondeprived rats 30 min prior to lights off, SERT (3.3, 10 and 30 umol/kg, IP) reduced feeding during the first h of the dark period by 32, 66 and 93%. SERT also produced anorexia (-15, -46, -70%) during the ensuing 3 h. Tested at night after 24h deprivation, SERT was less effective (+3, -45, -50%) during the first h and ineffective thereafter. Comparing 20 umol/kg SERT in separate groups, the degree of anorexia was: nondeprived rats in the dark > deprived rats in dark > deprived rats eating during the light period. Moreover, ad lib rats never compensated for the initial anorexia whereas deprived rats did. The 5-HT uptake inhibitors fluoxetine (FLU) and zimeldine (ZIM) (20 umol/kg) also reduced intake in ad lib rats during the dark with SERT=FLU>ZIM. A much smaller dose (5 umol/kg) of SERT, FLU and paroxetine decreased feeding from 0-1, not 1-4 h. The anorexic effect of this dose of SERT was completely antagonized by 0.25 umol/kg methiothepin but not by 0.3 umol/kg spiperone. Thus, normal feeding most sensitively detects the anorexic effect of acutely enhancing synaptic 5-HT in rats. Supported by NIMH 41987 to KJS.

MICROSTRUCTURAL ANALYSIS OF FEEDING SUPPRESSION AND OTHER BEHAVIORAL CHANGES INDUCED BY N-0437, A SELECTIVE DOPAMINE D2 AGONIST. I.N. Rusk and S.J. Cooper. Department of Psychology, University of Birmingham, B15 2TT, U.K.

N-0437 (5,6,7,8-tetrahydro-6-propyl[2(2-thienyl)ethyl] amino]-1-naphthalenol)hydrochloride) reduces palatable food consumption in nondeprived rats and mice (Rusk, I.N. and Cooper, S.J., Brain Res. Bull., in press). The present experiment undertook a microstructural analysis of N-0437's effects on feeding behavior, and on associated behavioral categories. Adult male rats were observed after administration of 0.3 - 3.0 mg/kg of N-0437, or vehicle, using a counterbalanced within-subjects design (n=8). The rats were trained to consume a palatable sweet mash in a 30 min test. Responses were recorded on-line using a microcomputer according to 7 categories (feeding, oral activity, sniffing, grooming, locomotion, rearing and immobility). Within each category, total duration, bout frequency and bout duration could be calculated. Food intake and local eating rates were also calculated. N-0437 (0.3 mg/kg) stimulated DA autoreceptors, since it induced immobility and yawning, but had no effect on food intake. However, at 1.0 and 3.0 mg/kg, N-0437 significantly reduced food intake, due to a reduction in eating rate with no change in eating duration. Since d-amphetamine and cocaine reduced food intake through a reduction in eating duration (unpub.observations), N-0437 is quite different in its feeding suppressant effect.
