Neurons in the medial superior temporal area (MST) of extrastriate visual cortex frequently show a directionally selective response to moving stimuli, and many cells in a subregion of this area respond preferentially to motion of a large field patterned stimulus rather than to motion of a single spot. In the present experiments we determined whether these cells also prefer motion at selected depths within the visual field. Awake monkeys were rewarded for fixating on a tangent screen 86 cm in front of them; the positions of both eyes were monitored using the magnetic search coil technique. Disparity within a moving random dot pattern was produced by using a red-green color anaglyph projected onto the screen and viewed by the monkey through a red or green filter over each eye. With stimulation of the central region of the receptive field, many cells had broadly tuned disparity sensitivity. Most cells preferred near stimuli (crossed disparity). These cells also were generally sensitive to stimulus motion viewed monocularly, and the effect of disparity was to reduce the response to motion at certain disparities (mainly for far stimuli - uncrossed disparities). The cells also responded to changing disparity (motion in depth), but for most of the cells studied to date the response has been the same for motion toward and away from the monkey, suggesting that the response is due to the changing disparity stimulus passing through a range of fixed disparities for which the cells are selective.

ANATOMICAL SEGREGATION OF NEURONS SENSITIVE TO FACE EXPRESSION AND IDENTITY IN MACAQUE TEMPORAL CORTEX.
M. E. Hasselmo* and G. C. Baylis. Div. of Biology, Caltech, Pasadena, CA 91125, and Dept. of Psychology, University of California, San Diego, La Jolla, CA 92093.

Neurons which respond to faces have been described in both the superior temporal sulcus and the inferior temporal gyrus of the macaque monkey. These responses may convey information about face identity (Baylis et al., 1985, Brain Res. 342: 91.) or expression (Hasselmo et al., 1986, Neurosci. Lett. 26:S571). Models of human face recognition based on neuropsychological and psychophysical evidence postulate separate processes for the encoding of expression and identity (Bruce and Young, Brit. J. Psych. 77: 305).

To determine if expression and identity are encoded independently by face response neurons, 45 neurons in two macaques were tested on a stimulus set depicting three monkeys with three expressions each. The responses were analyzed with a two-way ANOVA. Of the 45 neurons tested, nine (20%) showed significant differences of response to expression independently of identity, and fifteen (33.3%) showed significant differences of response to identity independently of expression. Only three neurons showed a significant effect of both expression and identity.

Neurons sensitive to expression were found primarily in the cortex in the superior temporal sulcus, while neurons responsive to identity were found primarily in the inferior temporal gyrus. The difference in distribution was shown to be highly significant. Multidimensional scaling is used to describe differences in the representation of expression and identity in the two regions.

85.20

SEPARATE NEURONAL CODING OF STRUCTURE FROM BIOLOGICAL MOTION AND TRANSLATION IN THE MACAQUE TEMPORAL CORTEX.
D.I. Perrett*, M.H. Harries*, A.J. Chitty*, A.J. Mistlin* and P.J. Benson* (SPON: European Brain and Behaviour Society) Dept. of Psychology, University of St Andrews, Scotland.

Neurones within the temporal cortex (area TPO) of the macaque monkey respond selectively to the sight of body movements of other animals (Bruce, C.J., et al., J. Neurophysiol., 46:369, 1981). The sensitivity of such cells was investigated to the form of the body defined through different types of motion. 31% of cells (19/61) selective for body movements under normal lighting continued to discriminate body form under "biological motion" conditions where the only visual information available is the pattern of movements of a small number of lights attached to points of limb articulation. These cells were selective for body view and were less responsive to random moving lights. For the remaining cells insensitive to biological motion stimuli, 73% (14/19) were selective for body form of 3D or 2D stimuli translating without articulation. The study indicates the existence of separate motion pathways for defining structure from translation (common fate) and non-rigid articulation (biological motion). Further evidence was found that descriptions of form, based on static and dynamic visual information, converge on cells within the temporal cortex.

FACE NEURONS AND NEURONS RESPONSIVE TO HUMAN FACES IN THE INFEROTEMPORAL CORTEX OF THE MONKEY.
S. Yamane*, K. Kawano, S. Kaji*, and H. Komatsu. Electrotechnical Lab., Umezono, Tsukubashi 305, Japan

Single neurons were recorded in the inferotemporal cortex (IT) of a monkey trained to discriminate three human faces from other stimulus. We used 30 faces, a square and an ellipse as the discrimination stimuli, and a small green spot, appearing after one of these stimuli, as a response cue for the monkey. We examined 446 single neurons in the anterior and posterior banks of the superior temporal sulcus, and the gyrus of the IT. There were 86 neurons responsive to faces. Most of them also responded to the green spot (41/86), and the square and/or the ellipse (24/86). 21 neurons responded only to the faces, and all of them showed selective responses to the 30 faces. Most of them (18/21) were located in the gyrus of the IT. To know the orign of the selectivity, we analysed the correlation between neuronal responses and facial features. 5 of these neurons showed highly correlated responses to the combinations of distances between facial parts. For example, one neuron showed responses correlated to both the amount of the hair above the left eye and the distance between the eyes and the mouth. Its responses to montaged faces, constructed with two of the 30 faces, confirmed the neuron's preferrence to the combination of facial features. The fact that the neurons detected essential features in faces leads us to call each a face neuron.

SACCADE-RELATED ACTIVITY IN AREA LIP.
S. Barash, R. Andersen, M. Bracewell, J. Gnadt, L. Fogassi. Dept. Brain & Cog. Sci., M.I.T., Cambridge, MA 02139.

Many cells in area LIP, a subdivision of the macaque posterior parietal cortex, are excited by visual stimuli but are also active in relation to saccades. The properties of the saccade-related activity were studied in two tasks in which the stimulus and motor responses were temporally isolated.

In the first task the animal was required to memorize the location of a briefly presented target and make a saccade to that remembered location after a variable time period. Generally saccade activity was found to begin 50 to 150 msec before the initiation of the saccade, to peak within 0 to 50 msec after the peak velocity of the saccade, and to decay exponentially back to baseline 100 to 200 msec after the eye movement. Especially interesting are a subclass of cells that remain active in the dark in the interval between the offset of the visual target and the eye movement, which, in the memory task, can be as long as 2.7 seconds. In previous experiments we have shown that this memory linked activity is coding the direction and amplitude of the impending saccade in motor coordinates and thus represents the intended movement of the animal.

The nature of the intended movement activity was further analysed using a double saccade task. In this paradigm the second saccade was made to a location within the motor field of the neuron without the target light ever falling within the receptive field of the neuron under study. The onset of the intended movement activity was very tightly linked to the first eye movement, generally beginning during the movement. On the other hand, the offset of the intended movement activity decayed relatively slowly, requiring on average 200 msec to return to baseline after the completion of the second eye movement. Interestingly, if a light was turned on at the target location of the second saccade during the interval between the two saccades, the activity of the cells was considerably boosted, and the saccades themselves had higher peak velocities. These results suggest that area LIP is involved in high level visual-motor integration including aspects of motor planning.

NEUROETHOLOGY II

86.1

TEMPORAL ANALYSIS OF HORMONE INDUCED CHANGES IN ELECTRIC ORGANS AND ELECTRIC ORGAN DISCHARGES.
E.G. Freedman, J. Olyarchuk*, M.Marchaterre, and A.H.Bass. Section of Neurobiol. and Behavior, Cornell Univ. Ithaca, N.Y. 14853.

Gonadal steroids have been shown to increase the duration of the electric organ discharge (EOD) and to increase the surface area of the anterior face of the cells responsible for producing the dishcarge (electrocytes). This study followed the time course of the changes in amplitude and duration after testosterone treatment in order to understand the structural basis for the observed changes. Fish (*Brienomyrus sp.*) were implanted intraperitoneally with gonadal steroid hormones (11Keto-testosterone or 17-a-methyl-testosterone), and EODs were monitored for 27 days after treatment. The duration of all three phases of the triphasic waveform began to increase in duration three days after implantation. In treated animals the duration of the first phase increased linearly for about six days after which the duration remained constant. The durations of the second and third phases increased linearly for the duration of the experiment. Changes in surface area of the anterior and posterior faces (the membranes responsible for the second and third phases of the EOD respectively) of the electrocytes were measured. The surface area of both the anterior and posterior faces was found to increase after treatment. Increased surface area suggests an increase in the total capacitance of the anterior and posterior faces of the electrocytes, and such capacitative changes can account for the observed changes in duration of the second and third phases of the EOD. The amplitude of the second phase of the EOD increased as the total duration of the EOD increases; conversely, the amplitude of the third phase of the EOD decreased with increasing total EOD duration. These changes in amplitude may be due to the interaction of currents flowing across the two excitable faces in opposite directions. No change in first phase amplitude was observed. Electrocytes were measured from the outer edge of the anterior face to the outer edge of the posterior face, and their width was found to increase. The increase in electrocyte width and the increase in duration of the first phase of the EOD followed the same time course.

In summary, the way in which the EOD changes after exposure to gonadal steroid hormones is temporally linked with changes in the morphology of the electrocytes. We suggest that these morphological changes are indeed the structural correlates for changes in the EOD.

86.2

PATTERNS OF THE ELECTRIC ORGAN DISCHARGE DURING COURTSHIP AND SPAWNING IN THE MORMYRID, *POLLIMYRUS ISIDORI*.
B.O. Bratton and B. Kramer. Zoologisches Institut, Universitat Regensburg, W. Germany.

The weakly electric, African fish, *Pollimyrus isidori* proved an excellent subject to study 1) the intraspecific, individual variability of electric organ discharge (EOD) pulse characteristics as related to questions of mate recognition; and 2) reproductive behavior and electric signalling by EOD interval patterns. Pulse rhythms were examined in socially interacting fish, including the behaviors of courtship and spawning. Characteristic patterns are also described for resting, hiding, hovering, swimming and aggressive behaviors.

Male and female EOD interval patterns were not found to be sex specific before the time of courtship and spawning. Just prior to the onset of courtship, however, females displayed a "spawning readiness pattern" of a medium uniform rate consisting of fairly regular pulse intervals (8-12 Hz), contrasting with the much more irregular proceeding EOD activities. During the male-female engagement of courtship/spawning the male displayed a similar pattern of regularized intervals (about 10 Hz) for each 15-25 s bout. Between bouts, males displayed a higher rate, variable EOD pattern. The relative timing of EOD interval patterns associated with reproductive behaviors suggest an instrumental function of the EOD with the occurrence of courtship and spawning.

MEASUREMENT OF THE ELECTRIC FIELD OF *GNATHONEMUS PETERSII* AND RECONSTRUCTION OF FIELDS GENERATED DURING EXPLORATORY ACTIVITY. B. Rasnow[1], M.E. Nelson[2], and J.M. Bower[2]. Depts. of Physics[1] and Biology[2], Caltech, Pasadena, CA 91125.

We are investigating the role of body position and the timing of the electric organ discharge (EOD) in exploratory behavior of the weakly electric teleost, *Gnathonemus petersii*. We believe the electric fish is an excellent model system for studying the process of active repositioning of sensory structures during exploration and the possible role of the cerebellum in the control of this process. In order to evaluate the electrosensory consequences of body position and EOD timing in the fish, we have developed a computer-based finite-element simulation which allows us to calculate the fish's self-generated electric fields and the resulting transdermal potentials for arbitrary body positions in complicated environments. The accuracy of the simulation is dependent on the electrical properties of the fish's skin and body and we have calibrated the simulation by measuring the unperturbed fields generated by immobilized fish. To reconstruct the transdermal potential profiles generated during exploratory activity, we provide the simulator with accurate body position and EOD discharge data from real fish. This is obtained from videotape records of the trajectory and spatial orientation of freely moving fish and synchronized analog recording of the firing times of the electric organ in response to novel objects placed in the environment. In this way, we can simulate the sequence of peripheral electrosensory images established by the fish during its active exploration of the environment. (This work supported by the Joseph Drown Foundation and NIH Grant NS22205.)

SENSORY GUIDANCE OF PASSIVE ELECTROLOCATION IN ELECTRIC FISH. C.D. Hopkins, E. A. Davis* and E. Mutisya*. Neurobiology & Behavior, CORNELL UNIVERSITY. Ithaca, New York 14853.

•*Passive electrolocation* occurs when an electroreceptive organism uses exafferent information to locate the source of electric signals from animate or inanimate sources in the environment. It serves an important function in electric communication by orienting and guiding a receiver's responses to electric organ discharges (EODs) from other fish. • We observed territorial *Gymnotus carapo* approaching and attacking artificial EODs played through dipole or bipole electrodes in their home tanks. Six electrode configurations were used to generate different stimulus geometries; the observations were made in the dark with infrared video. Although superimposed paths were different for each electrode geometry, in each case the fish adopted a simple strategy for finding the active electrodes: they aligned their body axis parallel to the axis of the local electric field (a vector), and while swiming forward, maintained a constant alignment until they reached the electrode(s). "Hunting" motions of approximately 30° to the left and right of the electric field axis were common. The fish showed a slight preference for approaching the "head" end of the electric model. When the stimulator is a slowly-rotating horizontal dipole, the fish makes loops to follow the rotating vector. For rapid rotations, the fish follows the mean vector direction. The fish are *not* disoriented by homogeneous electric fields. • We modeled the passive electrical properties of the fish's body interior, its skin, the tank, and the electrodes using a two dimensional resistive mesh and iteratively solved for the DC voltage at each point in the mesh on the Cornell Super Computer. Both elliptical and disk-shaped fish models could use the position of the maximum transepidermal voltage as a cue to the local electric field vector direction. By left to right hunting, elliptical fish models could use the absolute magnitude of the maximum transepidermal voltage. Left side/right side comparison of transepidermal voltage seem a particularly potent cue for alignment of the body axis to the field vector. • Partial support by NIMH grant MH37972to CDH.

86.5

NEURAL ACTIVITY IN THE NUCLEUS EXTEROLATERALIS ANTERIOR (ELa) OF MORMYRID ELECTRIC FISH. S. Amagai*, C.D. Hopkins and G.D. Harned* (SPON: B.R. Johnson). Neurobiology & Behavior, Cornell University, Ithaca, NY 14853

The tuberous Knollenorgan electroreceptors of the Mormyrid electric fish are implicated in detecting the electric organ discharges (EOD) of other fish. The primary afferent terminates ipsilaterally in the nucleus of the electrosensory lateral line lobe (nELLL), and receives a strong inhibition by the electric organ corollary discharge, preventing throughput of reafference from the fish's own EOD. The sole output of the nELLL projects bilaterally to the mesencephalic nucleus exterolateralis anterior (ELa), which is thought to be a processing area for timing information, and terminates on large intrinsic neurons as well as small output neurons which are the only types of cells known in this nucleus (Mugnaini, E. and Maler, L., Anat. and Embryo., 176:313, 1987). Glass microelectrodes were used to make single unit intra- and extracellular recordings from ELa in a pulse Mormyrid, Brienomyrus brachyistius.

Most of the units encountered were spontaneously active and responded to a brief electrical pulse applied transversly across the fish with a single spike at a short latency ranging from 2.5-3.5ms for different units. Variations in each unit's response latencies were typically less than 100μs. Less common were units which fired double or triple spikes, both spontaneously and in response to electrical stimuli. The number of spikes occuring close together usually remained constant for a given unit and was independent of stimulus intensity. Other units had yet more complex characteristics, including bursting, stimulus intensity dependence and loose time-locking.

Post stimulus time histograms for these units were generated from the time of the spinal cord electric organ command discharge. This allowed the presumed inhibition at nELLL to be visualized as silent time periods and was used to identify Knollenorgan inputs. Considerable variation was observed in both the onset and the duration of inhibition, not only for different types of units but also among units which appeared to be similar in their behavior. Supported by NIMH grant MH37972(CDH).

86.6

SUPPRESSION OF THE ELECTRIC ORGAN DISCHARGE BY DESYNCHRONIZATION OF PACEMAKER NEURONS IN THE ELECTRIC FISH HYPOPOMUS. W. Heiligenberg, M. Kawasaki and J. Nissanov. UCSD, La Jolla CA 92093.

The gymnotiform electric fish, Hypopomus, produces pulse-like electric organ discharges (EODs) of up to several tens of Hz. EODs are triggered individually by single command pulses of the medullary pacemaker nucleus. This nucleus contains electrotonically coupled 'pacemaker cells' which generate the rhythm, as well as 'relay cells' which transmit the command signals to the motor neurons of the electric organ. Normally, these two populations of cells fire in synchrony with a phase difference of approximately 1 msec. Iontophoretic stimulation of a brain site close to the prepacemaker nucleus, which projects to the pacemaker nucleus, caused an interruption of the EOD. Simultaneous intracellular recordings in the pacemaker nucleus revealed that while relay cells show high-frequency firing with reduced amplitude, pacemaker cells continue to fire with normal amplitude and a slight reduction in frequency regularity. In contrast to Eigenmannia, a gymnotiform electric fish of higher EOD frequency in which both pacemaker and relay cells cease firing during interruption of the EOD, Hypopomus apparently is able to break the coupling between pacemaker cells and relay cells.

86.7

PACEMAKER MODULATIONS IN THE ELECTRIC FISH STERNOPYGUS. C.H. Keller, M. Kawasaki and W.Heiligenberg, Scripps Institution of Oceanography, UCSD, La Jolla CA 92093

The weakly electric fish, Sternopygus, produces quasi-sinusoidal electric organ discharges (EODs) at a regular rate in the range of 50 to 200 Hz. EODs are commanded by a medullary pacemaker nucleus. This nucleus contains electrotonically coupled 'pacemaker cells' which generate the rhythm, as well as 'relay cells' which transmit the command pulse to the motor neurons of the electric organ. Rapid and transient frequency increases as well as brief interruptions are produced during courtship and aggression. These two distinct forms of discharge modulations can be elicited by iontophoretic stimulation with L-glutamate at separate midbrain sites. Investigations underway demonstrate different changes in firing patterns within pacemaker and relay cells during each form of EOD modulation. Pacemaker cells recorded intracellularly during interruptions in the EODs continued firing at their regular frequency although with increased jitter. Field potentials recorded in the vicinity of the relay cells, however, were greatly reduced in amplitude during EOD interruptions, suggesting that interruptions are generated by either silencing or desynchronization at the level of the relay cell.

86.8

DIFFERENT GLUTAMATE RECEPTORS MEDIATE DISTINCT BEHAVIORS IN A SINGLE BRAINSTEM NUCLEUS IN WEAKLY ELECTRIC FISH. J. Dye, W. Heiligenberg, K. Keller and M. Kawasaki. Scripps Institution of Oceanography, Neurobiology Unit, UCSD A-002, La Jolla, CA 92093.

The weakly electric 'wave-type' fish possess an electric organ which emits a regular, quasi-sinusoidal discharge. They are capable of behavioral modulations for purposes of communication (e.g. brief, transient accelerations in frequency, called 'chirps') and preservation of electrolocating abilities (the jamming avoidance response or JAR: a much slower frequency change). The electric organ is controlled by the medullary pacemaker nucleus.

The pacemaker nucleus of one wave species, Apteronotus, continues to fire rythmically in vitro. It can also be induced to chirp in vitro by stimulation of afferents from the prepacemaker nucleus. Glutamate, aspartate and various agonists of glutamate receptors were found to cause transient accelerations when applied to the in vitro nucleus; among the agonists, kainate and NMDA appeared to be the most potent. Glutamate antagonist, PDA, blocked the chirps in vitro, whereas NMDA antagonist, APV, did not, but in some trials blocked a slow relaxation to baseline seen after trains of stimuli. Examination of the effects of these agents in vivo confirmed that PDA reversibly blocks all frequency modulations in the pacemaker nucleus while APV selectively and reversibly eliminates the JAR.

86.9

ANATOMICAL AND PHYSIOLOGICAL PROPERTIES OF THE PREPACEMAKER NUCLEUS OF EIGENMANNIA. G. Rose, M. Kawasaki, W. Heiligenberg, and L. Maler. Scripps Inst. Ocean., UCSD, La Jolla, CA 92093 and Univ. of Ottawa, Ottawa, Ontario K1H8M5.

Eigenmannia, a weakly electric fish from South America, produces rhythmic electric organ discharges (EODs) for the purpose of spatial orientation and social communication. The EOD rhythm follows that of an electrically coupled group of cells in the medullary pacemaker. This nucleus is innervated exclusively by diencephalic prepacemaker neurons. Abrupt and slow modulations in the EOD frequency occur in the context of social behaviors and can be induced by L-glutamate stimulation of ventrolateral prepacemaker locations, occupied by large cells, and dorsomedial locations, containing small cells, respectively. Accordingly, intracellular recordings show that the large neurons generate abrupt modulations. Extracellular recordings presumed to be from the small cells suggest that they are decision-making units situated at the top of a neuronal hierarchy for the control of the Jamming Avoidance Response. These neurons receive the convergence of phase information required to achieve temporal hyperacuity.

86.10

SINGLE ELECTROSENSORY NEURONS RESOLVE TEMPORAL DISPARITIES OF ONE MICROSECOND. Masashi Kawasaki, Gary Rose & Walter Heiligenberg. Neurobiology Unit, Scripps Institution of Oceanography, University of California at San Diego, A-002, La Jolla, California 92093.

Behavioral studies have revealed that animals are capable of resolving temporal disparities in the microsecond range. Since this resolution is far superior to that of individual receptors, it must be achieved through central neuronal mechanisms. It is unclear, however, whether such sensitivity exists at the level of single neurons, or only at the behavioral level through the collective action of many less sensitive neurons. We have found that single neurons in the prepacemaker nucleus of a weakly electric fish are sensitive to temporal disparities as small as 1 microsecond, the highest temporal sensitivity ever observed at the single-neuron level. The remarkable temporal resolution of these prepacemaker neurons results from a high degree of spatial convergence of afferent inputs. These neurons represent the final elements of a sensory hierarchy and directly control a behavior.

86.11

PHYSIOLOGICAL AND ANATOMICAL CORRELATES OF THE STEROID-SENSITIVE EOD OF *STERNOPYGUS*. A. Mills, H. H. Zakon and A.H. Bass^. Dept. of Zoology, Univ. Texas, Austin, TX 78712; ^Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853.

The electric organ discharge (EOD) of the wave gymnotid *Sternopygus macrurus* is continually produced as a regular series of pulses, resulting in a quasi-sinusoidal waveform. The duration (dur.) of each pulse is longer in fish of lower EOD frequencies (freq.) and shorter in fish of higher freq. The pulse broadens after treatment with dihydrotestosterone (DHT), as freq. lowers. Since the basis of each EOD pulse is the simultaneous action potentials (a.p.s) in the electrocytes of the electric organ, it is likely that a.p. durs. recorded from fish with long pulse durs. are long, and that a.p. dur. increases following DHT treatment. To test the first assumption, intracellular recordings in electrocytes were compared to the externally-recorded EOD. The resting potential ranged from -40 to -104 mV (mean=-71±17mV), and threshold from -10 to -60 mV (mean=-31±13mV). The shape of each intracellularly-stimulated a.p. was very similar to the EOD pulse, with a faster rise to peak; this may be due to the absence of current shunting through acetylcholine channels. A.P. dur. ranged from 4.0 to 11.3 msec in fish with pulse durs. from 4.8 to 9.0 msec, respectively. The dur. of the a.p. was not identical to the pulse dur., but was highly correlated (r=0.88, N=7 fish), with most a.p.s slightly longer (mean a.p. dur. 12% greater than mean pulse dur.). Thus the basis of the DHT-induced increase in pulse dur. is probably an increase in electrocyte a.p. dur. To investigate the anatomical basis for the differences in a.p. dur., we studied the morphology of the tubular-shaped electrocytes using electron microscopy. Transverse sections 0.5-0.65µm thick were studied to determine overall electrocyte size, while longitudinal semi-thin sections were used to examine the surface invaginations characterizing the anterior and posterior faces. Although examination of field-preserved fish indicated a sex difference in electrocyte size (larger in males), DHT-treatment of lab-maintained fish did not induce a significant increase in size in comparison to controls. There also appear to be no significant changes in the extent of invaginations along either face. Supported by NIH grant to AHB and NSF grant to HHZ.

86.12

ULTRASTRUCTURAL ANALYSIS OF SYNAPTIC CONTACTS ON HRP LABELED SPHERICAL-LIKE NEURONS IN STERNOPYGUS. B. Losier* and J.A. Matsubara (SPON: M. Yoon), Dept. Anatomy, Dalhousie University, Halifax, Nova Scotia, Canada.

The weakly electric fish *Sternopygus*, a low frequency wave species, does not possess a JAR and previous physiological recordings in the electrosensory lateral line lobe (ELLL) revealed that certain cells are able to encode moving objects even in the presence of jamming signals. The aim of this study was to characterise the morphology and distribution of synapses on a morphologically unique cell type in the ELLL of *Sternopygus*. This cell is like the spherical cell found in other species in its location in the deep neuropil layer (DNL) and projection to the torus semicircularis (TS). However, it is different in that it possesses an extensive dendritic bush which arborizes in the primary afferent zone of the ELLL. We studied retrogradely labeled, spherical-like neurons at the ultrastructural level. The perikarya consisted of an electron lucent cytoplasm richly endowed by cytoplasmic organelles. Asymmetrical chemical synapses with round vesicles (30-40 nm) were seen on the cell soma and dendrites. Thus, the synaptology of DNL neurons differs remarkably between species, with electrotonic gap junctions observed on spherical cells of *Eigenmannia* and asymmetrical chemical synapses on spherical-like cells of *Sternopygus*. The relationship between the intrinsic organization of the ELLL and the non-jammable electrolocating abilities in *Sternopygus* will be discussed. (This work was funded by NSERC).

86.13

A TECHNIQUE FOR ANALYZING NEWLY-SYNTHESIZED PROTEINS WITHIN THE ELECTRIC ORGAN OF STERNOPYGUS. J. M. Patterson, and H. H. Zakon Dept. of Zoology, University of Texas, Austin, Texas. 78712

Weakly electric fish of South America, the Gymnotiforms, produce a peroidic, quasi-sinusoidal electric field which they use for electrolocation and social behavior. This electric field is generated by synchronous activity of electrocyte cells located in the tail. Previous studies have shown that administration of dihydrotestosterone (DHT) lowers the electric organ discharge (EOD) frequency and increases the pulse duration of the EOD. Since steroids often exert their effect via protein synthesis we have attempted a biochemical analysis of this tissue. We report here a technique for detecting newly-translated proteins within the electric organ, and our preliminary findings using one-dimensional gel electrophoresis.

Electric organ from Sternopygus was obtained by removing a segment of tail posterior to the anal fin, and dissecting away skin and spinal cord. The tissue was transferred to a tube containing 60 uCi ^{35}S-methionine (NEN) in 1 ml. of Hickman's saline and incubated at 25 °C for 1 hr. The organ was then frozen on dry ice, homogenized in an SDS/BME sample buffer, placed in a 100 °C water bath for 3 min., centrifuged at 10,000xG for 5 min., and frozen at -20 °C. Twenty ul./lane of sample was analyzed using 1-D SDS/PAGE. Gels were run at constant voltage (125v. for 4-5 hr.), stained with Coomassie Blue, destained, and treated with PPO phosphor for fluorography. Fluorograms were exposed 10-20 days, and consistently showed 20-30 labelled bands.

We have made several observations in our early work with this technique. 1. Electric organ translates proteins in vitro at a rate comparable to liver tissue measured under the same conditions, and at a much higher rate than skeletal muscle, from which it is derived embyrologically. 2. In vivo injections of labelled methionine confirm that no artifacts are generated by the in vitro procedures. 3. No significant differences between DHT-treated fish and control fish can be detected with the resolution offered by this technique, indicating that DHT induces small changes in protein synthesis, rather than major translational changes. Two-dimensional gel electrophoresis will be required to resolve such differences.

86.14

NEURAL CORRELATES OF MAGNETIC FIELD DETECTION IN THE MARINE MOLLUSC TRITONIA DIOMEDEA. K. J. Lohmann and A. O. D. Willows. Dept. of Zoology, University of Washington, Seattle, WA 98195.

Behavioral experiments have indicated that the nudibranch mollusc Tritonia diomedea can detect the magnetic field of the earth (K. J. Lohmann and A. O. D. Willows, Science, 235: 331-334, 1987). Intracellular recordings from a semi-intact whole animal preparation demonstrated that the large, visually identifiable neuron Left Pedal 5 (L Pe 5) responds with enhanced electrical activity to changes in earth-strength magnetic fields. Responses of L Pe 5 to a periodically imposed magnetic stimulus were characterized by an increase in spiking frequency occurring 6-12 minutes after the first field rotation. The same stimulus fails to elicit a response from L Pe 5 in isolated brain preparations. Cobalt fills and electrophysiological data indicate that neurites project from L Pe 5 through left pedal nerves 2 and 3. The function of L Pe 5 is not currently known. The neuron might be a primary sensory receptor, an interneuron receiving synaptic input from one or more primary receptors, or a motoneuron exerting a subtle, visually undetectable influence on a behavioral (e.g., turning) response to the stimulus.

87.1

COMPARATIVE NEUROPHARMACOLOGY OF IPSAPIRONE, FLUPRAZINE AND (+)-8-HYDROXY-DIPROPYLAMINOTETRALIN. B. A. McMillen, S. M. Scott* and H. L. Williams*, Dept. Pharmacol., Sch. Medicine, East Carolina Univ., Greenville, NC 27858.

The potential anxiolytic aryl-piperazine drugs, ipsapirone and fluprazine, were compared to DPAT for acute effects on monoaminergic neurotransmission. Ipsapirone, 10 mg/kg i.p., caused a small increase in mouse striatal dopamine (DA) metabolism without alterations in frontal cortex. Serotonin (5HT) metabolism decreased slightly (not significant) in both areas. In contrast, anti-aggressive doses of fluprazine or DPAT reduced 5HT metabolism. Both ipsapirone and fluprazine could reduce stimulation of striatal DA autoreceptors by apomorphine in vivo. Ipsapirone or trifluoperazine (TPZ) was added to the rats' drinking water for 6 weeks. Ipsapirone did not alter D2, 5HT2 or β receptor binding. TPZ increased D2 receptor Bmax: an effect that could be reversed by simultaneous infusion of ipsapirone, 1.0 mg/kg/day s.c., for 2 weeks prior to removal of all drugs. These data demonstrate that fluprazine and ipsairone have less pronounced dopaminergic effects than buspirone and more closely resemble gepirone in their pharmacology. Decreased serotonergic activity is the most likely explanation for the anti-aggressive effects of these drugs and possibly for their anxiolytic effects. Whether ipsapirone reversal of antipsychotic-induced increased D2 receptor binding has a therapeutic correlate is unclear.

FOOTSHOCK-INDUCED FREEZING IN RATS AS A MODEL FOR ASSESSING ANXIOLYTICS. L.H. Conti*, C.R. Shaw*, J.W. Rzeszotarski*, M.E. Guzewska*, S. Ellenberger*, J.W. Ferkany and M.E. Abreu* (SPON: L. Steranka). NOVA Pharmaceutical Corp., Baltimore, MD 21224

Soon after receiving electric footshock, rats assume a defensive posture referred to as freezing. We examined whether drugs with known anxiolytic action reduced the amount of time which rats spend in the freeze posture following mild footshock. Rats (male Sprague Dawley, 250g) were given an injection (ip) of a drug or vehicle 30 min prior to testing. Testing was conducted during a 6.5 min observation session during which rats received 2 mild footshocks (.5mA, .5sec). The amount of time which animals spent freezing following the second footshock served as the primary index of anxiety.

Diazepam, CPP (an excitatory amino acid antagonist with an anxiolytic profile), buspirone, and NPC 12626 (a novel excitatory amino acid antagonist) reduced time spent freezing in comparison to controls. Neither CPP, buspirone, nor NPC 12626 stimulated locomotor activity in experiments in which no shock was delivered. In a further control experiment, it was found that amphetamine (0.5mg/kg) did not reduce freezing. These data indicate that the footshock-induced freezing paradigm may be a sensitive method with which to assess anxiolytic potential of drugs with various mechanisms of action.

THE EFFECTS OF BUSPIRONE ON COMPARABLE RATES OF PUNISHED AND NONPUNISHED RESPONDING. C.V. Boley*, S. Izenwasser, S.I. Dworkin (SPON: G.F. Guerin). Dept. of Psychiatry, LSU School of Med., Shreveport, LA 71130.

The effects of buspirone were determine using a procedure that can evaluate the punishment-specific effects of drugs. Seven littermate pairs of male F-344 rats responded under this procedure which generated comparable rates of punished and nonpunished responding. One subject of each pair was maintained on a random-ratio schedule of food presentation. The interreinforcement intervals from this subject were used to generate a yoked variable-interval schedule of reinforcement for a littermate. A random-ratio schedule of electric footshock was then added to the random-ratio schedule of food presentation. The addition of the punishment contingency resulted in similar rates and patterns of responding by both the punished and yoked unpunished rats. The effects of buspirone (0.56-10.0 mg/kg, i.p.) were determined after stable baselines of responding had been obtained.

Chlordiazepoxide increased punished responding in 4 of the 7 rats studied. Maximal effects occurring at the two lowest doses evaluated. There was, however, little effect of the drug on nonpunished responding. These findings suggest the rate increasing effects of buspirone can be punishment-specific.

CALCIUM CHANNEL ANTAGONISTS AND PSYCHOLOGICAL DISORDERS Y.Watanabe*, J.W.Spain*, H.Honda*, S.Emanuel*and T.Shibuya Univ. Ill. College of Medicine, Rockford, IL 61107 and Tokyo Medical College, Tokyo 160 JAPAN

The potential of calcium channel antagonists as a novel treatment of psychological disorders was investigated using the spontaneously hypertensive rat (SHR) exposed to psychological stress. The physiological characteristics, with respect to blood pressure, of the SHR and its normotensive control strain, Wistar Kyoto rat (WKY), have been well documented. Furthermore, there exists several differences in behavioral response to stimuli. We observed significantly higher spontaneous locomotor activity in SHR, when compared to age-matched WKY, during the first 30 min of exposure to a novel environment. Activity counts for SHR were roughly 60% higher than WKY. Both 10 day chronic and acute treatment with nitrendipine (10 mg/kg, s.c.) resulted in a 25% reduction in activity. Chronic treatment ended 24 hr prior to testing, ruling out the possibility of a direct sedative action of nitrendipine causing reduced activity. We suggest that hyperactivity during acclimation to a novel environment may, at least partially, be caused by anxiety resulting from unfamiliarity. In support of this hypothesis, we observe that chronic or acute treatment with a novel anxiolytic derivative of buspirone (SM-3997) produced similar decreases in activity. The results suggest that calcium channel antagonists may be clinically useful in the management of stress-induced anxiety.

87.5

EXPERIMENTAL ANXIETY MODEL EMPLOYING THE INTRASPECIES EMOTIONAL COMMUNICATION: CORTICOSTREONE RESPONSE OF RATS IN THE COMMUNICATION BOX METHOD. N. Ogawa, M. Ishikawa* and C. Hara. Dept. Pharmacol., Ehime Univ. Sch. of Med., Ehime 791-02, Japan.

The communication box (CB) consists of both electric shock (ES) and non-ES compartments. In the CB, the animals placed individually into non-ES compartments (responder; R) could receive emotional cues (EC) from the animals subjected to ES in the ES compartments (sender; S). Therefore, "R" were considered to be in psychosocial anxiety. In order to establish the method as a tool for inducing psychosocial anxiety, the present study examined corticosterone response of "R". Male Wistar strain rats (9 weeks old) were used. They were housed in an air-conditioned room with 12:12 LD cycle (lights on 0700) under free access to food and water. Blood was collected from tail vein before and after the exposure of EC. Corticosterone was assessed by the modified protein-binding radioassay of Murphy. In the daytime and nighttime exposures to EC for 6 hr in the CB, the corticosterone level of "R" increased to have a peak time at 1 hr after the exposure. In the daily exposure to EC for 1hr in the daytime under the condition renewing "S" to intact animals daily, the pre-level of corticosterone of "R" just before the EC exposure progressively increased, and was significantly higher than the initial level of Day-1 on Day-5. These results suggest that the increased pre-level is applicable for a marker of anxiety.

PRECLINICAL PHARMACOLOGICAL STUDIES OF WY-48,624 (ENCIPRAZINE), A NOVEL ANXIOLYTIC AGENT. J.T. Haskins, D.E. Jones*, R. Scerni*, E.A. Muth and T.H. Andree. Wyeth-Ayerst Research, Princeton, NJ 08540.

WY-48,624 (4-(2-methoxypheny1)-α-[(3,4,5-trimethoxyphenoxy)methyl]-1-piperazine ethanol, dihydrochloride was synthesized and tested as an anxiolytic agent and is now in phase II clinical trials. In in vivo behavioral studies the anxiolytic potential of WY-48,624 (ENCIPRAZINE) is predicted in antiagression testing procedures. In these tests Enciprazine is similar in potency to diazepam. In vitro neurochemical studies indicate that Enciprazine has the highest affinity (although weak) for alpha-1 adrenergic receptors (Ki=163 nM), and has little or no affinity for opiate, benzodiazepine, D-2, muscarinic cholinergic, alpha-2 adrenergic, or beta adrenergic receptors. Enciprazine is also weak at inhibiting the uptake of NE, DA, and 5-HT and does not inhibit monoamine oxidase activity. In neurophysiological studies, intravenous injections of Enciprazine, like buspirone, inhibited serotonergic neuronal activity although its effects were weaker than those of buspirone. Enciprazine and buspirone activated noradrenergic neurons although Enciprazine was again weaker than buspirone. Enciprazine, although having an unremarkable neuroreceptor profile, has behavioral effects predictive of anxiolytic activity and also has neurophysiological effects similar to the nonbenzodiazepine anxiolytic buspirone.

87.7

PSYCHOPHARMACOLOGICAL PROFILE OF WY-47,846 - A PUTATIVE NONBENZODIAZEPINE ANXIOLYTIC AGENT. **J. A. Moyer, T. H. Andree, J. T. Haskins, M. Abou-Gharbia and E. A. Muth. Dept. of Experimental Therapeutics, Wyeth-Ayerst Research, Princeton, NJ 08543**

Wy-47,846 (3a,4,4a,6a,7,7a-hexahydro-2-[4-[4-(2-pyrimidinyl)-1-piperazinyl]-butyl]-4,7-etheno-1H-cyclobut [f] isoindole-1,3(2H)-dione), a compound with structural and biochemical similarities to buspirone, was examined in a series of preclinical tests to determine efficacy and side effect potential as a nonbenzodiazepine anxiolytic agent. Wy-47,846 suppressed avoidance responding and increased escape performance in conditioned avoidance procedures at doses which did not cause animal debilitation. As several nonbenzodiazepine agents have similar profiles in this test, these results indicate Wy-47,846 may have preclinical anxiolytic activity. Like most nonbenzodiazepines, Wy-47,846 lacked anticonvulsant activity and anxiolytic activity in anticonflict models. With respect to side effect liability, Wy-47,846 was more potent in antagonizing apomorphine-induced climbing behavior than stereotyped behavior. Wy-47,846 was considerably weaker in producing benzodiazepine-associated side effects (sedation, ataxia, drug interaction effects) than diazepam. These studies indicate Wy-47,846 may have preclinical anxiolytic activity with a favorable side effect profile. Behavioral results will be discussed in terms of neurochemical and neurophysiological effects of Wy-47,846.

87.8

DISCRIMINATIVE STIMULUS PROPERTIES OF GEPIRONE. V. Guanowsky and P.A. Seymour, Central Research Division, Pfizer, Inc., Groton, CT 06355

The anxiolytic buspirone has been demonstrated to possess discriminative stimulus properties in pigeons (Mansbach and Barrett, JPET, 240: 364, 1987), but has been found to produce only a poor discriminative stimulus in rats (Hendry et al., Pharmacol. Biochem. Beh. 19: 97, 1983). This may be due to the fact that doses required to produce effective stimulus control are behaviorally disruptive. Since gepirone appears to be less disruptive, a group of rats was trained to discriminate gepirone (3.2 mg/kg, i.p.) from saline. Following acquisition, administration of gepirone resulted in drug-appropriate responding (ED50 = 1.1 mg/kg). Additional compounds with high affinity for the 5-HT1A receptor were then tested in generalization experiments. The anxiolytic buspirone and the putative anxiolytic, SM-3997, both were found to completely substitute for gepirone (ED50 = 1.32 and .69 mg/kg, respectively). The 5-HT1A agonist, 8-OH-DPAT also completely substituted for gepirone, with an ED50 of .05 mg/kg. These data support recent behavioral and biochemical studies suggesting that 5-HT1A receptors may be involved in mediating the effects of this novel class of anxiolytic agents.

87.9

COMPARATIVE EFFECTS OF ZACOPRIDE, GR38032F (ODANSERIN), BUSPIRONE, AND DIAZEPAM IN THE MOUSE LIGHT/DARK EXPLORATORY MODEL. R. Young and D. N Johnson. Dept. of Pharmacology, A. H. Robins Co., Richmond, VA 23261.

The effects of various anxiolytic agents and putative anxiolytic agents were assessed in mice in the two compartment light-dark chamber (Costall et al., Br. J. Pharmac. 90:257D, 1987). Significant increases in lit area activities (e.g., time spent in the lit area, locomotor activity, rearing behavior) are presumed to be indicative of anxiolytic action. The benzodiazepine, diazepam, the 5-HT1A agonist, buspirone, and the 5-HT3 antagonists, GR38032F and zacopride, produced significant increases in time spent in the lit area, rearing activity, and/or locomotor activity over a tenfold (1-10 mg/kg, IP), threefold (3.16-10 mg/kg, IP), ten thousandfold (.0001-1 mg/kg, IP), and over a one hundred fifty thousandfold (.0001-17.8 mg/kg, IP) range of doses respectively. In addition, buspirone and zacopride were compared for oral potency and for duration of action after IP and PO administration. Buspirone and zacopride produced significant increases in lit area activities over a fivefold (10-56.2 mg/kg, PO) and a one hundred thousandfold (.001-100 mg/kg, PO) range of doses respectively. The time course effect of buspirone was 2-4 hours after IP or PO administration, while zacopride was active for more than 8 hours by either route of administration. The positive results obtained for the three types of compounds suggest that the light-dark test is a useful procedure for identifying known and putative anxiolytic agents.

87.10

THE EFFECTS OF A CANDIDATE COGNITION ENHANCING AGENT, BMY 21502, ON CELL MEMBRANE PROPERTIES AND SYNAPTIC PLASTICITY IN CA_1 NEURONS OF RAT HIPPOCAMPAL SLICES. V.K. Gribkoff, L.A. Bauman*, and C.P. VanderMaelen. CNS Biology, Bristol-Myers Co., Wallingford, CT 06492.

The neuronal actions of a putative cognition enhancing compound, BMY 21502, were assessed with intracellular and extracellular recording techniques in CA_1 neurons of normal, young-adult male rats.

Bath application of BMY 21502 (500 nM-100 μM) did not produce consistent effects on cell membrane properties in intracellularly recorded neurons. Cell membrane potential, membrane resistance, spike frequency adaptation, and burst after-hyperpolarizations appeared to be unaffected by this agent. Synaptic potentials, evoked by Schaffer-collateral stimulation, were reduced in BMY 21502 at concentrations above 30 μM.

Using the population synaptic potential recorded in the apical dendrites as a measure of synaptic efficacy, the effect of BMY 21502 on short-term (1-10 min.) and long-term (15-30 min.) potentiation of these responses was determined following single 100/sec, 1 sec stimulus trains. The identity of the solutions were unknown to the experimenter, and data analysis was performed blind. While BMY 21502 did not have a noticeable effect on short-term potentiation, a moderate enhancement of long-term potentiation was noted in 1.0 and 10 μM, but not in 25 μM BMY 21502.

87.11

SYNTHESIS AND AMNESIA-REVERSAL ACTIVITY OF A SERIES OF NOVEL PYRROLIDINONE DERIVATIVES: IDENTIFICATION OF BMY 21502 AS A POTENTIAL TREATMENT FOR COGNITIVE DISORDERS. Ronald J. Mattson*, Eric P. Loukas*, Joseph P. Yevich, and Michael S. Eison. CNS Research, Bristol-Myers Company, 5 Research Parkway, Wallingford, CT 06492.

Several substituted pyrrolidinones, such as piracetam, aniracetam, and pramiracetam, have been found to reverse electroconvulsive shock-induced amnesia in animals. The initial screening of a series of novel pyrrolidinone derivatives identified an aminal, BMY 20046 (I), which also reverses ECS-induced amnesia in a step down, passive avoidance task. As an aminal, I possesses limited acid stability. The amnesia reversing activity of I could not, however, be explained by the hydrolysis products, since these were inactive in this paradigm. An acid stable analog of I, BMY 20764 (II), was subsequently found to be even more potent in reversing ECS-induced amnesia. A series of heteroaryl analogs of II have been screened for amnesia reversing activity. From the results in these and other tests, BMY 21502 (III) was chosen as a clinical candidate and is currently in Phase I clinical trials as an agent for the treatment of cognitive disorders.

BMY 21502: A POTENTIAL COGNITION ENHANCER THAT IMPROVES MEMORY AND ENHANCES GLUCOSE METABOLISM IN THE AGED HIPPOCAMPUS. S.L. Moon, R.J. Mattson*, F.D. Yocca, D.P. Taylor, J.P. Yevich, M.S. Eison, L.A. Riblet, D.L. Temple, Jr. Bristol-Myers Co., CNS Research, Wallingford, CT 06492.

BMY 21502 is chemically designated 1-(1-(2-(trifluoromethyl)-4-pyrimidinyl)-4-piperidinyl)methyl)-2-pyrrolidinone. It is active in models of learning and memory.

Sites of metabolic alteration were determined through the use of ^{3}H-2-deoxyglucose (2DG) autoradiography. The hippocampal formation of the young untreated rat was characterized by bands of high metabolic activity found in the pyramidal layer and in the dentate gyrus. In the hippocampus of some of the vehicle-dosed aged animals, the activity in CA1 and dentate gyrus was diminished. In the BMY 21502-dosed aged rats, there were bands of high activity in the hippocampal formation, so that the resultant pattern of 2DG in the BMY 21502-treated hippocampus of aged rats resembled the pattern seen in the young adult.

BMY 21502 did not inhibit in vitro binding to any neurotransmitter receptor tested, (cholinergic, aminergic, amino acidic, CCK, μ opiate, sigma). Additionally, BMY 21502 showed no activity at serotonergic and adrenergic reuptake sites, high affinity choline uptake sites, nor calcium channels.

BMY 21502 is a potential cognition enhancer for the therapeutic treatment of disorders that are characterized by learning and memory impairment.

87.13

[3H]TETRAHYDROAMINOACRIDINE BINDING SITES IN RAT CNS MEMBRANES. E. E. Mena, Department of Neuroscience, Central Research Division, Pfizer, Inc., Groton, CT 06340.

Oral administration of 9-amino-1,2,3,4-tetrahydroaminoacridine (THA) is reported to result in significant improvement in cognitive function in patients with Alzheimer's Disease (AD). THA is a potent acetylcholinesterase (AChE) inhibitor. However, since little is known about the complete pharmacological profile of THA, it is possible that effects on other neuronal systems may contribute to these clinical results.

In order to identify other potential actions of THA in the CNS, rat brain membranes were examined for [^{3}H]THA binding sites. [^{3}H]THA binding (5 nM) reached equlibrium after 2 min at 0°C and was rapidly reversed upon the addition of 50µM nonradioactive THA. Analysis of kinetic data (LUNDON software) showed that [^{3}H]THA bound with Kd and Bmax values of 420 ± 56 nM and 42.7 ± 12 fmoles/ mg protein, respectively. The THA binding site was distinct from the AChE enzyme since the relative levels of THA binding and AChE activity in membranes prepared from the striatum, hippocampus, cortex and cerebellum differed greatly. Pharmacological analysis of the binding site revealed that compounds which interact with receptors for monoamines, ACh, glutamate, GABA, diazepam and sigma opiates or bind to Ca^{2+} and K^+ channels were inactive at displacing [^{3}H]THA.

The [^{3}H]THA binding site appears to be a novel CNS binding site distinct from the AChE enzyme and the binding sites of several neurotransmitters/neuromodulators. It is possbile that the function(s) mediated by this site may contribute to the clinical effects of THA.

Acknowledgments: I would like to thank Dr. M. Desai, Department of Medicinal Chemistry, Pfizer, Inc., for generously supplying [^{3}H]THA and Ms. M. F. Gullak for technical assistance.

EVALUATION OF BENZOYL ESTERS OF DOPAMINE AS POTENTIAL PRO-DRUGS FOR DOPAMINE IN THE CNS. **M. Hauptmann*, S.M. Tejani-Butt, A. D'Mello*, A. Frazer, & D.J. Brunswick. Dept. of Psychiatry, Univ. of Pennsylvania & VA Med. Ctr. Phila, PA 19104.**

For a compound to be a useful pro-drug of dopamine (DA) in the CNS, it is necessary that it both penetrate the brain as well as break down to the parent compound once in the brain. In this study the monobenzoyl (MBDA) and dibenzoyl (DBDA) esters of DA were evaluated. These compounds were radiolabelled and their uptake into brain measured. ^{14}C-DBDA penetrated the brain rapidly; 0.28% of the injected dose per gram tissue was taken up into the brain at 5 minutes. However DBDA did not produce measurable increases in DA levels in the brain. ^{14}C-MBDA on the other hand was found not to penetrate the brain, but upon its i.c.v. administration to rats caused DOPAC levels to increase significantly both in the striatum and in the rest of the brain; the increase in the striatum was 3 to 10 fold greater than that seen in the rest of the brain. In rats pretreated with the MAO inhibitor, pargyline, MBDA given i.c.v. caused increases in DA levels in both the striatum and in the rest of the brain with the increase in the striatum about 25 fold greater than that in the rest of the brain. From these results, it is inferred that MBDA is being hydrolyzed in vivo in the brain to form DA which is then taken up into dopaminergic neurons. Given this, it seems likely that an ester pro-drug of DA can be obtained that will have sufficient lipophilicity to penetrate the brain as well as a rate of hydrolysis that will produce increases in DA in the brain. **(Supported by Research Funds from the Vet. Admin. and USPHS grant GM34781).**

EFFECTS OF NICOTINE AND PBA-415 ON CALORIC INTAKE. R.M. Keenan*, M.E. Carroll* and S.T. Lac* (SPON: D. Burkhardt). Dept. of Psychiatry, U. of Minnesota Med. Sch., Minneapolis, MN 55455.

Past research has shown nicotine to be effective as a suppressant of caloric intake. Also, nicotine withdrawal leads to increased caloric consumption. Accordingly, cigarette smokers cite their weight gain after cessation of use as a major factor for relapse. PBA-415 is a nicotine analogue without the undesirable cardiovascular side effects which may help smokers combat nicotine withdrawal during cessation.

Six rats were given i.v. nicotine (12 mg/kg/day), PBA-415 (24 mg/kg/day) and saline for alternating five day periods. Their daily intake of food, glucose plus saccharin solution, total fluids and total calories were monitored. The results show that PBA-415 (in comparison to nicotine) is equally effective in suppressing daily food intake and total daily caloric intake when compared to saline levels ($p<.01$). Water intake was also increased on the PBA-415 days when compared to nicotine and saline days ($p<.01$). There was a significant suppression of glucose plus saccharin intake as a result of removing nicotine ($p<.01$).

The present results showed that i.v. nicotine and PBA-415 are able to suppress caloric intake when compared to saline. From this, it appears that PBA-415 has nicotine-like qualities with respect to caloric intake and may serve as an effective therapeutic agent in the treatment of cigarette smokers.

ELTOPRAZINE, A DRUG THAT REDUCES AGGRESSIVE BEHAVIOR, BINDS SELECTIVELY TO 5-HT$_1$ RECEPTOR SITES IN RAT BRAIN. H.Sijbesma*[1], J.Schipper[1] and E.R.de Kloet[2]. Depts Pharmacology, Duphar B.V., P.O.Box 2, 1380 AA Weesp[1], and Rudolph Magnus Institute, Utrecht[2], Holland

Eltoprazine, a new serenic, specifically reduces aggressive behavior in animal aggression models. The distribution and characterization of [^{3}H]eltoprazine binding sites were studied with in vitro autoradiographic techniques. Specific binding of [^{3}H]eltoprazine was found in many brain areas. The distribution was very similar to that of [^{3}H]5-HT binding sites. However, brain areas enriched in 5-HT$_{1a}$ sites showed relatively more [^{3}H]5-HT binding, whereas in 5-HT$_{1b}$ receptor dense areas [^{3}H]eltoprazine binding was more pronounced. Competition for [^{3}H]eltoprazine by several "selective" serotonergic compounds supported the finding that [^{3}H]eltoprazine selectivity binds to the 5-HT$_1$-receptor type. In addition, the affinity of eltoprazine for the different 5-HT$_1$ receptor subtypes was investigated. Eltoprazine showed relatively high affinity for 5-HT$_{1b}$ > 5-HT$_{1a}$ > 5-HT$_{1c}$ sites. (IC_{50}: 28nM, 37nM and 240nM, respectively). These results indicate that eltoprazine selectively binds to the 5-HT$_1$-receptor subtypes. The binding profile of eltoprazine together with its behavioral properties, strengthen the importance of serotonin in the modulation of aggressive behavior.

87.17

CHANGES IN SOCIAL INTERACTION PRODUCED BY COMPOUNDS WITH SEROTONERGIC SITES OF ACTION. A.L. Johnston* and S.E. File. The School of Pharmacy, University of London, London WC1N 1AX.

The following compounds, which have been proposed as putative anxiolytics, were investigated in the social interaction test of anxiety in the rat: ipsapirone (0.5 - 2 mg/kg, i.p.), a 5-HT$_{1A}$ agonist; ritanserin (0.05 - 5 mg/kg, i.p.), a 5-HT$_2$ antagonist; GR 38032F, BRL 43694 and ICS 205-930 (0.01 - 1 mg/kg, p.o.), 5-HT$_3$ antagonists. Chlordiazepoxide (CDP) (7.5 mg/kg, p.o.) was included as a positive control.

Increases in the time spent in social interaction were displayed by: ipsapirone (1 mg/kg) in a low light unfamiliar and a low light familiar condition; ritanserin (5 mg/kg) in a low light familiar condition; BRL 43694 (1 mg/kg) and ICS 205-930 (0.1 mg/kg) in a high light unfamiliar condition; CDP in a low light unfamiliar and a high light unfamiliar condition. No other treatments significantly affected social interaction.

The increases displayed may indicate anxiolytic activity, however, these were confined to single doses and were often weaker, inconsistent or different in profile from those typically displayed by benzodiazepines.

87.18

THE EFFECTS OF GEPIRONE AND 1-(2-PYRIMIDINYL)-PIPERAZINE ON RAT CORTICOSTERONE LEVELS. G.K. Matheson, D. Guthrie, G. White, J. Rhoades & D. White. Neurobiology Laboratory. Indiana University School of Medicine.Evansville,IN 47714

The major metabolite of gepirone is 1-(2-pyrimidinyl)-piperazine (1-PP). The effects on the hypothalamic-pituitary-adrenal axis (HPAA) produced by gepirone and 1-PP were indicated by changes in plasma corticosterone (CS) concentration. The rats were maintained in a light (on 0600-1800 hrs), temperature and humidity controlled environment. Control levels of CS were 14.1 ± 1.2 S.E. µg/dl (n=43). A greater maximum facilitating effect on CS levels was seen 45 minutes after gepirone administration (+283%; 50 mg/kg, i.p.) than after 1-PP (+211%). Gepirone was also more potent than 1-PP since the ED_{50}'s were 2.6 mg/kg (6.4 µmol/kg) for gepirone and 13 mg/kg (65.4 µmol/kg) for 1-PP. The duration of the effect produced by these agents on the HPAA was determined by measuring the plasma CS levels 1/2, 1, 2, and 4 hours after their administration. At a dose of 10 mg/kg gepirone increased CS levels 244% for a period of one hour, but 1-PP did not produce any measurable change in CS levels over the four hour test period. Animals subjected to a one minute spinning stress (30-60 rpm) 15 minutes before decapitation had stress control levels of 35.6 ± 1.6 µg/dl CS (39). This stress and gepirone's effects were additive increaseing CS levels to 58.3 ± 1.5 µg/dl (14) after one hour of drug treatment.

88.1

DEVELOPMENT OF THE SEROTONERGIC SYSTEM IN THE CENTRAL NERVOUS SYSTEM OF THE TOBACCO HORNWORM MANDUCA SEXTA. N.A. Granger*, W.A. Radwan* and J.M. Lauder (SPON: R. Weinberg). Dept. Cell Biol. and Anat. Univ. of N.C., Sch. Med., Chapel Hill, NC 27599

Development of the serotonergic (5-HT) system in the brain and ventral nerve cord of Manduca sexta embryos, larvae and pupae was studied in whole mounts with an antiserum to 5-HT. Immunoreactivity (IR) was first detected in fibers in the head region at 40-50% of embryonic development prior to differentiation of the brain. 5-HT IR cell bodies were seen at 60% development in both the brain and ventral ganglia. By 75% development, eight IR cell groups (38-40 cells), four commissures, and five regions of arborization were visible in the brain. The same pattern was observed in fifth instar larvae and early pupae. These results indicate that embryonic 5-HT neurons are conserved during development. By 75% development, there were 94 IR neurons in the ventral ganglia, including segmentally homologous pairs of interneurons in each of the thoracic and abdominal ganglia, and efferent neurons in thoracic and posterior abdominal ganglia. Previously intense ganglionic arborizations of IR fibers had regressed by the end of embryogenesis, as did arborizations in the neuropil of metamorphosing larval brain, suggesting that a reorganization of 5-HT innervation had occurred. The early appearance of 5-HT IR in the central nervous system of Manduca suggests that 5-HT may play a role in neurogenesis in this species.

88.2

A SEROTONERGIC SUB/SUPRAEPENDYMAL AXONAL NET IN CONJUNCTION WITH A SUB/SUPRAEPENDYMAL MASS OF MESENCEPHALIC TRIGEMINAL NEURONS OF SHARKS. M.F. MacDonnell. Dept. Biol. Sciences, Rutgers Univ., Box 1059, Piscataway, N.J. 08855.

Light microscopy with silver stains and electron microscopy reveal a sub/supraependymal system of varicose axons in the tectal midline ridge formation of sharks, a region shared by a sub/supraependymal mass of mesencephalic trigeminal (Mes V) neurons in these animals. The relationship of axonal varicosities and terminals to both CSF and to sub-and supraependymal Mes V somas is such as to suggest a largely non-synaptic association. Immunocytochemical experiments show that the sub/supraependymal axonal network seen in the tectum is part of a large serotonergic sub/supraependymal axonal network involving the entire rim of the tecto-tegmental ventricle and arising in the midline tegmentum. The shared topography of the sub/supraependymal serotonergic and the sub/supraependymal mass of mesencephalic trigeminal neurons and the details of their association suggest a nonsynaptic relationship which may serve to modulate the powerful jaw reflexes of the shark.

88.3

SEROTONIN IMMUNOREACTIVE PERIKARYA AND PROCESSES IN THE MEDULLA OF THE NEW WORLD PRIMATE, CEBUS CAPUCINUS: CONTRASTS WITH RODENT, *V.A. Pieribone, E.J. Van Bockstaele, G. Go*, M. Springston* and G. Aston-Jones*, Dept. Biol. & Cntr. for Neural Sci., New York Univ., NY 10003.

Several studies have examined serotonergic perikarya in the medulla of primates using histofluorescence, but few have used the more sensitive and stable immunocytochemical methods. Additionally, there has been only limited study of serotonin immunoreactive (5-HT-IR) fibers and terminals in the primate medulla.

We have examined 5-HT-IR profiles in the medulla of Cebus capucinus using PAP immunocytochemistry followed by a gold-substituted silver procedure that substantially increases staining sensitivity. Sections containing 5-HT-IR structures were compared to adjacent sections stained for Nissl and with complementary sections of the rat medulla similarly processed for 5-HT immunocytochemistry.

Serotonin-positive somata were distributed throughout the midline raphe system, but additional prominent groups were identified in the ventrolateral medulla and within the nucleus of the solitary tract.

Patterns of 5-HT-IR fibers in primate medulla differed in many respects from those in rodent. For example, while the Xth and XIIth nuclei are only moderately innervated in rat, these structures receive heavy, basket-like innervation in primate. Nucleus commissuralis of the solitary tract is densely innervated in rat, but only lightly so in monkey. The inferior olive in rat contains homogeneously light 5-HT innervation, while in monkey this nucleus exhibits marked regional differences in density of innervation.

Distinct classes of 5-HT-IR fibers and termination patterns were identified in the primate medulla. Thick, beaded fibers that provide basket-like innervation of individual neurons were present in some of the cranial nerve nuclei, while thin axons containing numerous punctate varicosities homogeneously innervate subaspects of the inferior olivary complex. Overall, there was greater regional variation in fiber types and innervation patterns in primate compared to rodent. Supported by NINCDS grant NS24698, ONR contract N00014-86-K-0493, and the Air Force Office of Scientific Research.

IDENTIFICATION OF SEROTONIN NEURONS PROJECTING TO THE SUBSTANTIA NIGRA IN THE RAT USING A COMBINED TECHNIQUE OF IMMUNOHISTOCHEMISTRY AND FLUORESCENT RETROGRADE TRACING METHOD. S. Mori* and Y. Sano*(SPON: K. Toyama). Dept. of Anat., Kyoto Pref. Univ. of Med., Kyoto 602, Japan.

The origin of serotonin nerve fibers distributed in the rat substantia nigra was studied by a combined technique of immunohistochemistry using the serotonin antibody and a retrograde fluorescence Fluoro-Gold labeling method on the same tissue sections. After the unilateral injection (0.15 µL) of the Fluoro-Gold (2% solution) into the substantia nigra, the confined appearance of Fluoro-Gold-labeled neurons in the raphe nuclei was demonstrated in the dorsal raphe nucleus. A majority of these labeled neurons (56%) were serotonin-immunoreactive, but the rest (44%) were nonimmunoreactive. Fluoro-Gold-labeled as well as serotonin-positive neurons were localized mainly in the ipsilateral lateral and dorsomedial aspects. Additionally, after chemical axotomy of serotonergic fibers by an intraventricular injection of 5,7-dihydroxytryptamine, the Fluolo-Gold was similarly injected into the substantia nigra. Retrogradely labeled neurons were still observed in the dorsal raphe nucleus, however, a majority of these neurons (94%) were serotonin-negative. These findings indicate that a majority of serotongic fibers projecting to the substantia nigra originate mainly in the ipsilateral lateral and dorsomedial aspects of the dorsal raphe nucleus, and these raphe nigral pathways contain both serotonergic and non-serotonergic fibers.

LOW SYNAPTIC INCIDENCE OF SEROTONIN AXON TERMINALS IN THE FRONTAL, PARIETAL AND OCCIPITAL NEOCORTEX OF ADULT RAT. P. Séguéla, K. C. Watkins* and L. Descarries. Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Québec, Canada H3C 3J7.

PAP-immunocytochemistry with an antiserum against serotonin (5-HT-glutaraldehyde-protein conjugate, kindly donated by M. Geffard) was used to analyze the ultrastructural relationships of 5-HT axon terminals (varicosities) in the frontal (Fr1), parietal (Par1) and occipital cortex (Oc1M-Oc2) of adult rat. One hundred and fourty five immunostained varicosities from Fr1 (54 in layers I-II, 91 in layers V-VI), and 97 each from the upper layers of Par1 and Oc1M-Oc2, were examined in groups of serial thin sections (mean number of sections in series: 3.4 to 7.2). The terminals were of comparable size in all 3 regions, averaging 0.66 ± 0.16 µm (mean ± s.d.) in diameter. Their junctional complexes measured 0.24 ± 0.09 µm. The proportion of varicosities endowed with synaptic junctions was evaluated by linearization of the relationship between the observed junctional frequency and the number of thin sections per varicosity available for examination. Reliability of the sampling was evidenced by high correlation coefficients ($r > 0.9$) in each cortical region. Extrapolated synaptic incidence amounted to 30% in both the superficial and deep frontal cortex, and to 45% and 35% in the superficial parietal and occipital cortex, respectively. The differences between the 3 regions were not statistically significant. These 5-HT synapses were exclusively made with dendrites. They were equally distributed between dendritic spines and shafts in the frontal and the parietal cortex, but appeared more frequent on dendritic spines (71%) than shafts (29%) in the occipital cortex. It may be concluded that the 5-HT input is only partly synaptic throughout the neocortex of adult rat, which reinforces earlier views of a divergent afferent system capable of widespread and perhaps long-lasting influences in this part of the brain. (Supported by MRC grant MT-3544).

REGIONAL DIFFERENCES IN THE SEROTONIN INNERVATION OF RODENT CEREBRAL CORTEX: DIFFERENTIAL DISTRIBUTION OF TWO MORPHOLOGICALLY DISTINCT AXON TYPES. M.E. Blue, B.E. Kosofsky and M.E. Molliver. Dept. of Neurosci. Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205 and Dept. of Neurology, MGH, Boston, MA 02114

Morphologically dissimilar serotonergic (5-HT) axon types in rat cerebral cortex have separate origins in the midbrain: axons from the dorsal raphe (DR) are fine with small, pleomorphic varicosities; median raphe (MR) axons are coarse with large, spherical (beaded) varicosities. In the present study, we show, using 5-HT immunocytochemistry, that fine and beaded 5-HT axons have different regional patterns of distribution. Numerous fine axons are distributed throughout cerebral cortex with regional and laminar differences in density. Beaded axons are much less abundant than fine fibers and are highly concentrated in restricted regions and layers of cortex. In neocortex, higher densities of fine 5-HT axons are found in frontal areas of cortex than in parietal or occipital areas. Somatosensory cortex (SI) exhibits the most highly differentiated laminar distribution of 5-HT axons in neocortex. Although fine 5-HT axons are found in all layers of SI, they are particularly abundant in layer V_a where they form a dense band. Beaded axons appear to be distributed in clusters which are found predominantly in layers I-III and VI of SI. Similar clusters of beaded axons are found in occipital and auditory cortex. Beaded axons form distinctive patches or bands in other cortical areas including posterior cingulate cortex (layer II), hippocampus (the molecular layer of CA1, along the dentate granular layer and in CA3) and in the perirhinal and entorhinal cortex. In contrast, fine fibers are distributed relatively uniformly throughout these areas of cortex. The differential distribution of fine vs beaded axons in each area of cortex demonstrates that there is regional specialization of the 5-HT innervation to areas of cortex that have different cytoarchitecture and function. These results suggest that the 5-HT projection from the DR and MR may exert a different and possibly selective effect in each area of cortex. [Support: NIH NS15199 and HD19920]

THE ANATOMIC ORGANIZATION OF SEROTONERGIC PROJECTIONS TO NEOCORTEX IN THE PRIMATE. M.A. Wilson and M.E. Molliver. Dept. of Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Serotonin (5HT) neurons of the midbrain raphe nuclei project widely upon the cerebral cortex in primates, however, there is evidence of specificity in the organization of this projection. In macaque monkeys, there are differences in the density and laminar distribution of 5HT axons in different areas of the cerebral cortex. In addition, the two classes of 5HT axon terminals which have been described in primates, fine and beaded, vary in density in different areas and laminae of cerebral cortex, and are differentially vulnerable to certain neurotoxic psychotropic drugs.

The present study examines the distribution of neurons in the raphe nuclei which project to selected areas in macaque cerebral cortex. Retrogradely transported fluorescent dyes (or WGA-HRP) were injected into primary motor, somatosensory, or visual cortex or into parietal or frontal association cortex in macaques, and labeled neurons were mapped in the midbrain raphe nuclei. 5HT immunocytochemistry was used to determine whether labeled neurons were serotonergic. After injections in different cortical areas, different, partially overlapping distributions of labeled neurons were observed in the raphe nuclei. For example, cells projecting to motor cortex are found in both rostral and caudal parts of the dorsal raphe nucleus (DR), with few in the median raphe nucleus (MR). Cells projecting to somatosensory cortex are found predominantly in the caudal part of the DR, with few in the rostral part of the nucleus and some in the MR. Neurons projecting to visual cortex are found in the MR and in the caudal part of the DR, with almost none in the rostral part of the DR. Raphe-cortical projections have an intricate organization, with different cortical areas innervated by different, but partially overlapping, sets of raphe neurons. These sets differ in their rostro-caudal distributions, and in their ratios of DR to MR neurons. (Support: NIH NS21011, T32NS07179, and the L.P. Markey Fund.)

SELECTIVE NEUROTOXIC EFFECTS OF (+)FENFLURAMINE UPON 5-HT AXONS IN RAT BRAIN: IMMUNOCYTOCHEMICAL EVIDENCE. D.C. Molliver* and M.E. Molliver. (Spon: E. O'Hearn). Depts. of Neuroscience and Neurology, The Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Fenfluramine - a halogenated amphetamine derivative that is used as an anorectic agent - has been reported to cause lasting decreases in brain levels of 5-HT in the rat. The changes are similar to those of other substituted amphetamines that have neurotoxic effects upon 5-HT projections. In this study, we have used immunocytochemistry to determine whether 5-HT neurons are structurally damaged by fenfluramine and if there is a selective loss of axons similar to that caused by p-chloroamphetamine (PCA) and methylenedioxy-amphetamine (MDA). Rats were given (+)fenfluramine in single or repeated doses (10, 20 or 40 mg/kg s.c. q12h for 4 days) and studied at 5 hours, 2 weeks or 4 weeks after the first dose. At all time points there is a profound loss of 5-HT immunoreactive axon staining, with no change in catecholamine axons. There are regional differences in the effects, with neocortex and striatum most depleted and hippocampus partially spared. Sparing of 5-HT axons is seen in olfactory bulb and basal forebrain. There is little decrease in the brainstem while 5-HT staining is lost in the medial but not lateral hypothalamus with the ventromedial nucleus most affected. In all forebrain regions, fine 5-HT axons are selectively lost while beaded axons that are distinguished by large spherical varicosities are spared. The loss of 5-HT immunoreactive staining at 5 hours indicates massive depletion of 5-HT; the persistent loss at 2 and 4 weeks is indicative of degeneration of 5-HT axon terminals. The results show that in large repeated doses (+)fenfluramine is neurotoxic to one class of 5-HT axons and has the same pattern of selectivity as does PCA and MDA. The regional differences in effect may be due to a selective action of these drugs on fine axons (presumably of dorsal raphe origin). The anorectic action of fenfluramine may be related to release of 5-HT in the ventromedial hypothalamic nucleus. [Support NIDA #DA04431]

CONTRASTING *in vitro* and *in vivo* EFFECTS OF p-CHLOROAMPHETAMINE (PCA) ON 5-HT AXONS: IMMUNOCYTOCHEMICAL STUDIES IN HIPPOCAMPAL SLICES. M.E. Molliver, K. Stratton, P. Carr*, R. Grzanna and J. Baraban. Dept. of Neuroscience, The Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Systemic administration of PCA elicits a profound depletion of brain serotonin associated with degeneration of 5-HT axons. To help define the neurotoxic role of PCA and its metabolites, we have examined the effects of PCA on 5-HT axons *in vitro* by applying 5-HT immunocytochemistry to the rat hippocampal slice preparation. Hippocampal slices, incubated in physiologic buffer, were immersion fixed in paraformaldehyde and frozen sections prepared for 5-HT immunocytochemistry. Slices from control rats, maintained for up to 6 hours *in vitro*, exhibit a dense plexus of 5-HT axon terminals identical to that seen with perfusion fixation. Incubation of slices for 1-2 hours in buffer containing PCA (50 μM) does not induce loss of axonal staining. In slices taken from rats treated *in vivo* with PCA (10 mg/kg i.p.) 2 hours prior to sacrifice and immediately fixed after slicing, profound depletion of 5-HT was observed; fine 5-HT axons were not detected while varicose (drug-resistant) fibers remain intensely stained. Incubation of these depleted slices in standard buffered saline for 1/2-2 hours led to progressive recovery of 5-HT immunoreactivity; nearly all 5-HT axons appear intact with normal morphology. In rats treated with PCA 16 hours prior to slice preparation, there is initial depletion of 5-HT with much less recovery of axon staining after 2 hours *in vitro*. These results indicate that in the early phase of 5-HT depletion following PCA administration, the axons have not degenerated and the terminals initially retain the ability to synthesize and store 5-HT. The additional finding that *in vitro* incubation of slices in PCA does not induce 5-HT depletion supports the hypothesis that PCA itself is not the active, neurotoxic agent, but that a peripheral metabolite of PCA is likely to produce 5-HT depletion and axon degeneration. MORPHOLOGICALLY DISSIMILAR SEROTONERGIC AXON TYPES IN RAT CEREBRAL CORTEX ARE DIFFERENTIALLY VULNERABLE TO THE NEUROTOXIN p-CHLOROAMPHETAMINE (PCA). L.A. Mamounas, C. Mullen* and M.E. Molliver. Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

Morphologically dissimilar types of serotonergic (5-HT) axons have been described in forebrain: fine axons with small, pleomorphic varicosities and coarse axons with large, spherical (beaded) varicosities. Using immunocytochemical methods, we have previously shown that systemic administration of the neurotoxin PCA (10 mg/kg; 2-week survival) produces selective ablation of fine 5-HT axon terminals in forebrain, while sparing beaded 5-HT axons. In the present study, we demonstrate that this differential neurotoxicity is observed over a wide range of doses and survival times. The density of fine axons in cerebral cortex is progressively reduced at doses of PCA ranging from 2-10 mg/kg, with almost no fine axons remaining at 20 mg/kg; in contrast, beaded axons are consistently spared at doses up to 40 mg/kg. Moreover, the differential neurotoxicity of PCA on the two 5-HT axon types is not a transient event: up to five months after PCA administration (10-20 mg/kg), few fine axons are found in cortex, whereas beaded axons remain unaffected. Furthermore, at short survival times (4 hours), PCA causes profound depletion of 5-HT from fine axons but not from beaded axons, reflecting, most likely, differential release of 5-HT from the two axon types. We have recently shown that fine and beaded 5-HT axons arise from separate nuclei in the midbrain - the dorsal and median raphe nuclei, respectively (Kosofsky and Molliver, 1987) and that the dorsal raphe projection to neocortex is selectively eliminated by PCA (Mamounas and Molliver, 1988). Since other psychotropic amphetamines (MDA and MDMA) also affect the same type of 5-HT axons (O'Hearn et al., 1988; Mamounas et al., 1988), we propose that the dorsal raphe projections may function in the regulation of affective state. ELECTRON MICROSCOPIC CYTOCHEMICAL AND IMMUNOCYTOCHEMICAL LOCALIZATION OF TYPE-SPECIFIC MONOAMINE OXIDASE (MAO) IN RELATION TO IDENTIFIED ENTERIC SEROTONERGIC NEURONS M.D. Gershon, J.E. Pintar and D.L. Sherman*. Dept. Anat. & Cell Biol., Columbia Univ., New York, NY 10032.

Intrinsic neurons of the guinea pig gut contain MAO-B, but little or no MAO-A, which is located in extrinsic sympathetic axons. MAO-B-rich neurons have been found to contain neuropeptide Y and calcitonin gene related peptide, but not 5-hydroxytryptamine (5-HT). We have now studied the distribution of MAO at the ultrastructural level in order to examine the possibilities that MAO-A or MAO-B may be present in the terminals of serotonergic neurons or in the post-synaptic elements of serotonergic synapses. MAO-B immunoreactivity was visualized by using a monospecific antiserum and an immunoperoxidase technique. Type-specific MAO activity was also localized by a coupled peroxidation method following preincubation with deprenyl (to inhibit MAO-B) or clorgyline (to inhibit MAO-A). Serotonergic elements were simultaneously identified by radioautography following incubation with tritiated 5-HT. Neither MAO-B immunoreactivity (I) nor activity were found in enteric glia. More neurons and processes were demonstrated immunocytochemically than cytochemically; therefore, either the immunocytochemical technique is more sensitive for the detection of MAO-B or not all of the immunoreactive molecules are enzymatically active. Individual cells varied greatly in the degree of immuno- or cytochemically demonstrable MAO-B, which was most concentrated on the outer membranes of mitochondria. MAO-B-I (but not cytochemical activity) was found on mitochondria in some serotonergic perikarya. In contrast, mitochondria in most serotonergic axon terminals displayed both MAO-B activity and immunoreactivity. Neurites receiving serotonergic synapses often, but not invariably, contained MAO-B-I and activity. It is concluded that serotonergic neurons contain relatively little MAO-B, that it is not present on all mitochondria, and that MAO-B-reactive mitochondria are preferentially located at terminals. DETERMINATION OF THE ACTIVITIES OF THE SUBTYPES OF MONOAMINE OXIDASE WITHIN SEROTONERGIC NERVE ENDINGS OF RAT BRAIN IN VITRO AND EX VIVO. S.S. Shim and R.E. Becker. Dept. of Pharmacology and Dept. of Psychiatry, Southern Illinois Univ., Springfield, IL 62794-9230.

Subtypes of monoamine oxidase (MAO) A and B in 5-hydroxy-tryptamine (5-HT) synaptosomes were determined using clorgyline and l-deprenyl at 100 nM of 14C 5-HT. 90% of the deamination of 14C 5-HT was inhibited by clorgyline at 0.1-30 nM, 10% inhibited by l-deprenyl at 1-30 nM, 90% inhibited by l-deprenyl at 100nM-100 uM, indicating that 90% of 14C 5-HT transported into 5-HT synaptosomes was deaminated by MAO A, 10% by MAO B. Results from ex vivo studies agreed with the in vitro. Deamination of 14C 5-HT was inhibited by increasing concentrations of clorgyline in presence of l-deprenyl at 30 nM. L-deprenyl increased the inhibition of deamination of 14C 5-HT only at concentrations of clorgyline at which 90% of the deamination was already inhibited. We suggest that deamination of 14C 5-HT by MAO B occurs after cytoplasmic concentrations of 14C 5-HT are increased by inhibition of MAO A. It appears that MAO A plays major role for inactivating 5-HT transported into 5-HT synaptosomes. MAO B is active only at high cytoplasmic concentrations of 5-HT due to its low affinity for 5-HT and may prevent excessive accumulation of 5-HT.

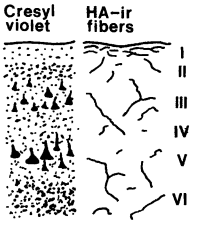
TRYPTAMINE IMMUNOREACTIVITY WITHIN THE RAT CENTRAL NERVOUS SYSTEM. F.TISON*, M.GEFFARD and H.DABADIE* (SPON : F. CLARAC). Lab. Neuroimmuno., CNRS-IBCN, 33077, Bordeaux, France. In order to define chemoanatomy of tryptamine (T) an immunocytochemical procedure was applied using a polyclonal antisera against T (TAS). TAS were raised in the rabbit with T-glutaraldehyde-BSA (T-G-BSA). TAS affinity and specificity tests carried out in competition experiments (ELISA method) showed apparent IC.50 of $2.5_{4}10^{-9}$ M and cross reactivity ratios of 1:50, 1:60 respectively for 5.hydroxy T (5.HT-G-BSA), 5.methoxy T (5.MT-G-BSA) conjugates. A G-mediated histological fixation procedure of Wistar adult rat brains and spinal cords was used. 50 µm thick vibratome transverse and sagittal sections were incubated with TAS (1:10, 000) followed by a peroxydase-anti peroxydase staining method. Sections were also incubated with 5.HT rabbit antisera (5.HT AS) for comparative neuroanatomy. Control sections were : rabbit non immune serum incubation, preadsorption of TAS with T-G-BSA, 5.HT-G-BSA, 5.MT-G-BSA from 10^{-8} to 10^{-9}M. Neurons were observed within the B1 to B9 raphe cell groups of Dahlström and Fuxe. Localisation and morphology of these neurons were comparable with those stained with 5.HT AS and distribution is consistent with L-aromatic-aminoacid decarboxylase localisation (Jaeger, C.B., *Neurosci.*, 11:691, 1984). Neuronal density was however about 30 % less than with 5.HT AS and intra-cellular immunoreactivity about 3 times less seeming to show a sub-cellular fractioning. 5.HT and T containing fibers also showed comparable distribution : strongest staining was seen within the spinal cord (anterior, intermediolateral and posterior horns), area postrema, locus coeruleus, interpedoncular nucleus, caudal substantia nigra and ventral tegmental area, arcuate nucleus, amygdalo-hippocampal structures, paraventricular thalamic nucleus, parts of caudato-putaminal complex and globus pallidus, accumbens, lateral septum, olfactory tuberculs and bulbs and in nearly all levels of median forebrain bundle and supra-ependymal plexus. Control sections showed a good specificity of TAS for T. Our results are comparable with those obtained by [^{3}H]-T binding studies (Mc.Cormack, J.K., *J.Neurosci.*, 6:94, 1986) and show a similar regional chemoanatomy of T and 5.HT.

88.14

HISTAMINE-IMMUNOREACTIVE NEURONS AND NERVE FIBERS IN HUMAN BRAIN. P. Panula, M.S. Airaksinen, U. Pirvola* and E. Kotilainen* Dept. of Anatomy, University of Helsinki, 00170 Helsinki, and Dept. of Neurosurgery, University of Turku, 20520 Turku, Finland.

Distribution of histamine-immunoreactive (HA-ir) nerve fibers was examined in samples of adult human frontal and parietal cortex removed in operations of astrocytoma in 3 patients. Hypothalamic areas were examined in postmortem brains after autopsy. All tissues were fixed with carbodiimide as described earlier (Panula et al., J. Histochem. Cytochem. 36:259-269, 1988). Cortical fibers were also examined after pre-embedding immunocytochemistry electron microscopically. A large number of neurons exhibited HA-ir in the tuberomammillary nucleus of basal hypothalamus. They sent long smooth and varicose fibers arranged as bundles. A widespread network of fibers was seen in the cortex (figure). HA-ir fibers were seen in all layers of the grey matter. They were densest in lamina I, where they ran mostly parallel to the overlying pia mater. The large number of HA-ir neurons in the basal hypothalamus and a well-organized network of fibers in the cerebral cortex suggest that histamine may be involved in the regulation of cortical functions in human brain.



88.15

ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL LOCALIZATION OF HISTAMINE IN CARBODIIMIDE-FIXED GUINEA PIG CNS NEURONS AND ADRENAL MEDULLARY MAST CELLS. M.S. Airaksinen and P. Panula. Department of Anatomy, University of Helsinki, Finland.

The aim of this work was to locate the compartments of histamine immunoreactivity (HA-ir) in the guinea pig hypothalamic neurons, their axon terminals and in the adrenal medullary mast cells by optimizing the effects of fixation and incubation parameters on preservation of antigenicity and ultrastructure. For preembedding electron microscopy (EM) perfusion with carbodiimide, followed by carbodiimide and aldehyde immersion was adequate for vibratome sectioning. PAP-immunocytochemistry was applied with specific HA antiserum on saponin-permeabilized sections, followed by postfixation with glutaraldehyde and osmium. The location of HAir in the cells was dependent on ultrastructural preservation. The reaction product was found in large cytoplasmic granules, but also diffused in the cytoplasm. Many axon terminals containing small HAir vesicles were found in CNS areas like nucleus accumbens, periventricular gray and neurohypophysis. In the adrenal medulla HA-ir was found in the cytoplasm of apparent mast cells around the vessels. HA in these cells may have a local role in liberating catecholamines.

88.16

CNS LEVELS OF HISTAMINE IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS. Edward L.Orr. Dept. Anatomy, Texas College of Osteopathic Medicine, Ft. Worth, TX 76107.

We have postulated that CNS and/or peripheral mast cells may be important in the development of experimental autoimmune encephalomyelitis (EAE). To begin testing this hypothesis, we have measured , using a radioenzymatic assay, the levels of histamine (Hm; a major mast cell product) in the brains and spinal cords of adult Lewis rats inoculated with adjuvant (Control) or adjuvant + guinea pig spinal cord homogenate (EAE). Rats were assessed daily for behavioral signs of EAE, and groups of 5 Control and 5 EAE rats were sacrificed on days 7, 9, 11, and 13 post-inoculation (pi). Compared to Controls, CNS levels of Hm were unchanged until days 11 (and 13) pi, when significantly increased levels of brain and spinal cord levels developed. Behavioral signs of EAE appeared on day 10 or 11 pi. Further, when EAE was attenuated by two/day injections of prazocin (i.p., 2 mg/injection) on days 9-11 pi, the behavioral signs of EAE and the increase in CNS levels of Hm (as seen in saline-treated EAE rats) did not occur in prazocin-treated EAE rats (all rats were sacrificed on day 12 pi). These results suggest that mast cells may be in the development of EAE, and support the report by Hinrichs, et al. (In: **Immune Regulation by Characterized Polypeptides**, 1987, pp.541) that agents which block or attenuate mast cell release, block or attenuate EAE. (Supported by NMSS grant #RG-1914-A-1).

RAPID TURNOVER OF HISTAMINE (Hm) IN RAT BRAIN DEMONSTRATED BY TISSUE FIXATION WITH IN SITU PERCHLORIC ACID (PCA) PERFUSION. W. L. Russell* and D. P. Henry* (SPON: L. Lemberger) Dept. of Pharmacology, Ind. Univ. Sch. of Medicine, Eli Lilly & Co. Indianapolis IN 46202.

A rapid turnover pool of Hm in rat brain has been difficult to examine since rapid tissue fixation by microwave irradiation or liquid nitrogen artifactually elevates brain Hm levels by the liberation of Hm from dural mast cells. Fixation of rat tissue with aldehydes would degradate Hm. We have developed a technique which simultaneously inactives brain enzymes and stabilizes brain Hm. Rats were anesthetized with ether. Next, 20 ml of chilled saline (0-4°C) was perfused to the brain from a cardiac puncture which was followed by the perfusion with 20 ml of PCA (0.1 N, 0-4°C). Rats were then decapitated. Whole brain Hm was unaffected by ether anesthesia or saline perfusion, but was higher after PCA perfusion.

HISTAMINE IN RAT BRAIN AREAS (ng/g tissue)

	Decapitation	PCA Perfusion (mean ± SEM)
Brain Stem	21.0 ± 0.6	24.2 ± 2.5
Hypothalamus	378.9 ± 17.8	484.0 ± 36.3 *p<0.05
Thalamus	106.5 ± 10.9	122.5 ± 12.5
Striatum	48.6 ± 2.7	58.3 ± 7.8

Histaminergic neurons are localized in the hypothalamus. Among all brain regions, PCA perfusion elevated hypothalamic Hm suggesting that the fast Hm turnover was terminated by acid fixation and the low temperature. PCA perfusion may be useful with neurotransmitters with a fast turnover in brain.

88.18

ELEVATED LEVELS OF HISTAMINE METABOLITES IN LUMBAR CSF OF AGING, HEALTHY HUMANS AND OF NEUROLOGICAL PATIENTS. G.D. Prell, J.K. Khandelwal*, R.S. Burns*, P.A. LeWitt* and J.P. Green. Dept. of Pharmacology, Mount Sinai School of Medicine, CUNY, New York, NY 10029 and Section on Experimental Therapeutics, NIMH, Bethesda, MD 20205.

The metabolites of histamine, tele-methylhistamine (t-MH) and tele-methylimidazoleacetic were measured in lumbar cerebrospinal fluid of healthy, normal subjects aged 20-31 (n=4) and 60-72 (n=8) by GC-MS. Mean levels (pmol/ml) of t-MH, t-MIAA and the sum of t-MH and t-MIAA (2.9, 6.4 and 9.4, respectively) were significantly higher in CSF from older subjects than from younger subjects (1.1, 4.5 and 5.5, respectively). Another older subject had yet higher levels of metabolites (6.7, 15.1 and 21.8, respectively). The sum of the levels of the known metabolites of histamine in brain, t-MH + t-MIAA, did not overlap between younger and older subjects. Levels of pros-methylimidazoleacetic acid (p-MIAA), an endogenous isomer of t-MIAA not derived from histamine, did not differ between groups. A larger sample (n=43) of patients and controls aged 20-74, showed significant ($p<0.05$) correlations (Pearson [α=1]) between age and lumbar CSF levels of t-MH, t-MIAA, and the sum of t-MH + t-MIAA, but not p-MIAA. These findings contrast with results of similar studies of metabolites of other transmitters which generally decline with increasing age. (Supported by NIMH grant 31805).

MULTIPLE [^{3}H]-IMIPRAMINE BINDING INHIBITORS IN CALF BRAIN EXTRACTS. A. Strijewski*, J. Chudzik*, D. Helmeste, S. Cheung* and S.W. Tang. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

In order to isolate the endogenous ligand for imipramine (IMI) binding sites in the brain, combined calf caudate and frontal cortex were extracted with acetic acid and then with methanol. Methanol extract was delipidated with chloroform and chromatographed on Bio-Gel P-2 column. The elution profile as measured by inhibition of platelet ^{3}H-IMI binding shows four major distinctly separate peaks (A, B, C,D). None of these fractions contained salt or 5HT. All four fractions also inhibited platelet [^{3}H]-paroxetine binding and [^{3}H]-5HT uptake. Specificity of these fractions was further tested for their inhibition of β-adrenergic (^{3}H-dihydroalprenolol) and dopamine D_2 (^{3}H-spiperone) receptor binding. Fractions A and C had a substantial inhibitory effect on both [^{3}H]-DHA and [^{3}H]-spiperone binding while fraction B inhibited ^{3}H-DHA binding only. Fraction D had no significant inhibitory effect for either type of binding and therefore is the most specific ^{3}H-IMI inhibiting fraction of the four. Further TLC analysis of fractions A and B revealed a complex ninhydrin positive composition. Fraction C did not contain any detectable ninhydrin positive components. Antibodies raised against IMI revealed the possible presence of IMI-like compounds in fraction D while the HPLC results are so far non-conclusive. Further investigation should lead to the purification and identification of the [^{3}H]-IMI binding inhibitors.

TRYPTOPHAN HYDROXYLASE ACTIVITY IN HYPOTHALAMUS AND BRAINSTEM OF NEONATAL AND ADULT RATS TREATED WITH HYDROCORTISONE, FLUOXETINE OR PARACHLOROPHENYL-ALANINE. D.H. Park, H. Paivarinta, A.C. Towle and T.H. Joh. Lab. Mol. Neurobiology, Cornell Univ. Med. Coll., Burke Reh. Ctr., White Plains, NY 10605.

Glucocorticoids have been implicated in the regulation of the activity of tryptophan hydroxylase (TPH), the rate-limiting enzyme in serotonin biosynthesis. In order to understand the mechanisms governing TPH activity in brain and superior cervical ganglion (SCG) of neonatal and adult rats, we determined whether chronic hydrocortisone treatment causes any change in TPH activity in hypothalamus, brainstem and SCG of 7-day-old or adult rats. In addition, the effect of fluoxetine, a serotonin uptake inhibitor or p-chlorophenylalanine (PCPA), a TPH inhibitor, on TPH activity was studied. Our results indicate that 1) hydrocortisone treatment increases only TPH activity in brainstem of 7-day-old rat and has no effect on TPH activity in other brain regions or SCG in neonatal and adult rats; 2) fluoxetine treatment also leads to a significant increase in TPH activity only in the brainstem of neonatal rats; 3) PCPA results in a 50% decrease in activity in SCG and 80-100% decrease, in the brain. Supported by NIH grants, MH 24285 and 1PO1MH 42626-01.

OPPOSITE EFFECTS OF SEROTONIN (5HT) AND CYCLIC ADENOSINE 3',5'-MONOPHOSPHATE (cAMP) ON TRANSFERRIN SECRETION BY ENRICHED EPITHELIAL CELLS OF RAT CHOROID PLEXUS IN CULTURE. M. Tsutsumi*, M.K. Skinner*, and E. Sanders-Bush. (SPON: S.E. Mayer). Dept. of Pharmacology and Psychiatry, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232.

The choroid plexus secretes the cerebrospinal fluid into the ventricles of the brain. Messenger RNA for plasma proteins including transferrin, transthyretin, and ceruloplasmin have been localized in intact choroid plexus. We have previously shown that enriched epithelial cells of the rat choroid plexus in culture synthesize and secrete transferrin based on radioimmunoassay. Using this assay, we examined the effects of 5HT, dibutyrl cAMP and 8-bromo-cAMP on transferrin secretion by epithelial cells. Transferrin secretion increased with increasing concentrations of 5HT while cAMP analogs induced a concentration-dependent decrease. These data suggest that both 5HT and cAMP play a regulatory role in the choroid plexus. The level of transferrin in cells changes in concert with that in the medium, suggesting that the neurohumoral-induced changes in transferrin reflect alterations in the synthesis of the proteins rather than the secretory process. These findings show that choroid plexus synthesizes and secretes nutrients that are essential to the central nervous system, and that this function may be regulated by various neurotransmitters. SENSITIVE HPLC METHOD FOR SEROTONIN IN CEREBROSPINAL FLUID. T.J. Tolliver,* S.J. Huang,* I.N. Mefford,* N.A. Garrick, and D.L. Murphy* (SPON: J.M. Tolliver). LCS, NIMH, Bethesda, MD 20892.

Serotonin (5HT) has been implicated in several psychiatric disorders. To evaluate serotonergic function in human disorders, we developed a method for quantitating 5HT in human lumbar and monkey cervical cerebrospinal fluid (CSF) using a sensitive (10 pg/ml lower detection limit) HPLC procedure with electrochemical detection. Use of a long chain ion pairing agent, sodium dodecyl sulfate (SDS), and high acetonitrile content coupled with microbore technology allowed for the "non-eluting matrix" approach for directly injecting large sample volumes onto the column. N-methyl 5HT was used as the internal standard. The mobile phase was 0.25 m NaH_2PO_4 containing 200 mg/l SDS, 100 mg/l Na_2 EDTA, and 20% acetonitrile. The system consisted of an Applied Chromatography System 400-02 pump, Rheodyne 7125 injector fitted with a 100-µl loop, and a Bioanalytical Systems electrochemical detector with glassy carbon working electrode. The working electrode potential was set at 0.55 V vs. Ag/AgCl. The column was 15 cm x 1.0 mm I.D. packed in house with 3 µm C_{18} ODS Shandon Hypersil. Levels of 5HT in human lumbar CSF ranged from < 10 to 793 pg/ml, with a median value of 16.2 (n = 108). Levels of 5HT in monkey cervical CSF ranged from < 10 to 882 pg/ml, with a median value of 35.9 (n = 223). In most cases, the highest 5HT values were found in CSF samples that appeared blood tinged.

REGULATION OF STRIATAL SEROTONIN AND HIPPOCAMPAL NORADRENALINE RELEASE BY THE LATERAL HABENULA AS STUDIED BY IN VIVO MICRODIALYSIS. P. Kalén*, R.E. Strecker, E. Rosengren* and A. Björklund. (SPON: B.D. Boss) Dept. Med. Cell Res., Biskopsg. 5, S-22362 Lund, Sweden.

Extracellular levels of serotonin (5-HT) and noradrenaline (NA) were monitored with the microdialysis technique in halothane anaesthetized rats. Striatal 5-HT was recovered through a new double-loop probe with a substantially improved recovery rate, with an uptake blocker added to the perfusion medium. NA was collected through a single loop probe implanted in the hippocampus. Samples were collected every 15 min. Electrical stimulation of the lateral habenula (LHb; 15 Hz, 0.5 mA, 0.5 ms) for 15 min increased the 5-HT levels by 70 %. It is suggested that this effect was mediated by a direct excitatory amino acid projection from the LHb to the dorsal raphe nucleus (NRD), and that this projection was modulated by GABA synapses at the raphe level, mainly since: (1) transection of the LHb efferents, but not lesion of the interpeduncular nucleus, abolished the effects of stimulation; (2) NRD injections of kynurenic acid blocked the effect of LHb stimulation, whereas bicuculline injections increased the 5-HT levels by 70 %, and potentiated the stimulation effect by 50 %. In the hippocampus LHb stimulation increased the NA release 3-fold. It is suggested that this effect was specifically mediated by the descending projections of the LHb, but that it was not relayed over the serotonergic component of the rostral raphe nuclei, mainly since: (1) transection of the dorsal bundle, or transection of the LHb efferents, abolished the stimulation effect; (2) no reduction in NA release was seen after neurotoxic lesion of the 5-HT system.

ENDOGENOUS RELEASE OF SEROTONIN AND NOR-ADRENALINE IN THE RAT AS STUDIED BY INTRA-CEREBRAL DIALYSIS. A. Björklund, P. Kalén*, R.E. Strecker, E. Rosengren*, M. Kokaia* and O. Lindvall*. Dept. Med. Cell Res., Biskopsgatan 5, S-22362 Lund, Sweden.

Extracellular levels of serotonin (5-HT), 5-HIAA and noradrenaline (NA) were monitored in the striatum and hippocampus of the rat, and analyzed by HPLC with fluorimetric detection (indols), or a radioenzymatic assay (NA). In awake freely moving animals the steady state output of 5-HT and NA in the hippocampus were 35 and 50 fmole/30 min, respectively, whereas during resting or sleep these levels were reduced by approx. 25 %. Halothane anaesthesia further reduced the output. In 5-HT and NA denervated animals the basal levels were below the limit of detection 2-3 weeks post lesion, but returned to the levels of intact animals after prolonged survival. KCl added to the perfusion fluid substantially increased the 5-HT and NA levels, whereas TTX reduced the output. P-chloroamphetamine and pargyline injected i.p. increased the 5-HT levels, whereas omission of Ca^{++} from the perfusion fluid, or i.p. injections of the 5-HT receptor agonist N,N-dimethyltryptamine, reduced the 5-HT release. Several of these manipulations were found to induce the same percentage changes also when an uptake blocker was added to the perfusion medium in order to increase the extracellular levels of 5-HT and NA, and thereby allow for shorter sampling times.

It is concluded that intracerebral microdialysis provides a useful method for the study of extracellular levels of 5-HT, 5-HIAA and NA, and that changes in extracellular level of 5-HT and NA are closely related to changes in synaptic activity, whereas 5-HIAA primarily reflect intraneuronal metabolism.

COMBINED *IN VIVO* ELECTROCHEMICAL AND ELECTROPHYSIOLOGICAL STUDIES OF MONOAMINE OVERFLOW FROM RAT HIPPOCAMPAL SLICES. Mei-Tsu Su*, Thomas V. Dunwiddie and Greg A. Gerhardt. (SPON: G. Kindt) Depts. of Pharmacology and Psychiatry, U.C.H.S.C., Denver, CO 80262, and VA Medical Center, Denver, CO 80220.

In vivo electrochemical measurements of chronoamperometric recordings from Nafion-coated electrodes were used to investigate monoamine overflow from selected regions of the rat hippocampal slice. Concurrent electrophysiological measurements of CA1 pyramidal cell population spike amplitude were used to characterize changes in the electrical activity of the slice during various treatments. Superfusion with elevated potassium (50 mM, 5 min) elicited consistent increases in the electrochemical response recorded from the dentate gyrus. At the onset of potassium perfusion, there was an initial increase in the population spike response, followed by electrical silence, which usually lasted 5-10 min and required 20-30 min for complete recovery of the response. The electrochemical signal always increased following the decline in the electrophysiological response, suggesting that release occurred only following a high degree of depolarization, and the electrochemical signal usually returned to baseline much before the electrophysiological response (usually within 5 min). Cocaine pretreatment (10-50 uM) caused a dose-dependent augmentation of the electrochemical responses. Local pressure ejection of potassium via a micropipette elicited dose-dependent increases in the electrochemical signals that were of relatively brief duration. The present experiments demonstrate the feasibility of conducting simultaneous electrophysiological and electrochemical experiments in an isolated preparation of brain such as the hippocampal slice.

INHIBITION OF SEROTONIN METABOLISM BY OPENING SODIUM CHANNELS. L.S. Sorkin, M.G. Hughes*, W.D. Willis and D.J. McAdoo, Marine Biomed. Inst. and Dept. of Anat. & Neurosci., Univ. of Texas Med. Branch, Galveston, TX 77550.

We are using dialysis fibers to administer drugs and collect released neurotransmitters within the dorsal horn of the spinal cord of α-chloralose anesthetized cats. Released amines and metabolites are subsequently assayed by high pressure liquid chromatography-electrochemical detection. We found that depolarizing agents caused an increase in 5-hydroxytryptamine (5HT) levels in the extracellular fluid. The same treatments caused a several-fold decrease in the 5HT metabolite 5-hydroxyindole acetic acid (5HIAA). Sodium channel openers veratridine and aconitine both produced 5HIAA decreases that persisted for at least 2 hours. The sodium channel blocker lidocaine prevented the drug-induced decreases in 5HIAA levels. Neither the monoamine oxidase inhibitor pargyline nor the 5HIAA clearance inhibitor probenecid influenced the drug-induced decrease in 5HIAA levels. Lidocaine and parachloroamphetamine caused substantial release of 5HT. Lidocaine by itself appeared to slightly increase 5HIAA levels. Our results suggest that sodium channel activation strongly inhibits 5HT oxidation in the spinal cord.

MEASUREMENT OF THE IONTOPHORETIC RELEASE OF MONOAMINES FROM GLASS MICROELECTRODES USING HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC). I.A.Paterson, B.D.Sloley* & A.A.Boulton. Neuropsychiatric Res.Unit,Univ. of Saskatchewan,Saskatoon,Sask,Canada

The iontophoretic release of monoamines from five-barrelled glass microelectrodes was measured in vitro using HPLC with electrochemical detection. This method allowed reproducible measurements of release with currents as low as 3nA, and allowed the simultaneous measurement of the release of upto five amines in different barrels of the electrode. Measurements were made of adrenaline, dopamine, noradrenaline, *p*- and *m*-octopamine, serotonin, *p*- and *m*-synephrine, tryptamine, *p*- and *m*-tyramine.

There was no correlation between the tip size of the electrode, the resistance of the barrel, the spontaneous efflux of the amine, nor the apparent transport number calculated from Faraday's (Hittorf's) law. There was no correlation between transport numbers of different amines within the same electrode, although there was a positive correlation between the spontaneous efflux of different amines within the same electrode.

The relationship between the iontophoretic ejection of an amine and the iontophoretic current was not linear, and the apparent transport number increased with the size of the current. The transport number increased rapidly with currents of 3-20nA and then increased more slowly with currents of 20-200nA. Measurements of non-iontophoretic transport processes could not account for the increase in the transport number in the low current range. These findings show that Faraday's (Hittorf's) law is not an adequate description of iontophoretic release when using smaller iontophoretic currents. The equations of Purves (R.D.Purves, 1981, Microelectrode methods for intracellular recording and iontophoresis, Pub. Academic Press, London) provide a more accurate description of iontophoretic release.

AMILORIDE, AN INHIBITOR OF Na-Ca EXCHANGE, INHIBITS SEROTONIN MODULATION OF CONTRACTION OF APYLSIA BUCCAL MUSCLE. L.-X. Liu* & J.L. Ram (SPON: I. Montgomery). Dept. of Physiology, Wayne State Univ., Detroit, MI 48201.

Serotonin (5-HT) potentiates acetyl choline (ACh) elicited contraction of Aplysia buccal muscles. Contraction is also potentiated by zero sodium medium (ONa), an effect attributed to Ca influx via Na-Ca exchange (Ram et al., this volume). To test whether 5-HT might similarly potentiate contraction by activating Na-Ca exchange we used amiloride (AMIL), a Na-Ca exchange inhibitor. Enhancement of ACh contraction by 10^{-8} M 5-HT, measured as % increase in the first contraction after 5-HT compared to the preceding contraction, averaged 160 ± 12% (n=54) in the absence of AMIL. In the presence of AMIL the effect of 5-HT was 0% (no var.)*, .3 mM AMIL (n=4); 50 ± 15%*, .1 mM AMIL (n=10); 60 ± 13%*, .03 mM AMIL (n=13); and 210 ± 60%, .01 AMIL (n=3) (*=p<.005). As percent of vehicle controls, unenhanced ACh contractions were 22%*, .3 mM AMIL; 61%*, .1 mM AMIL; 106%, .03 mM AMIL & 92%, .01 mM AMIL. At ≤.1 mM, AMIL had no effect on ACh depolarization, while .3 mM AMIL reduced its magnitude and speed. Thus, .03 & .1 mM AMIL drastically reduced 5-HT enhancement while having a much smaller effect on contractile and membrane potential responses to ACh. These data are consistent with Na-Ca exchange mediating effects of 5-HT; however, since AMIL has other effects on sodium movements, other interpretations are possible. (supported by MDA).

SPECIFIC ANTAGONISM AT ENTERIC NEURONAL 5-HT_{1P} RECEPTORS BY BRL 24924: ROLE OF SLOW EPSPS IN ACTIVATION OF GASTRIC INHIBITORY NEURONS. G.M. Mawe, T.A. Branchek, and M.D. Gershon. Dept of Anatomy and Cell Biology, Columbia Univ. P&S, New York, NY 10032

5-HT_3 receptors on enteric neurons mediate a short-lived depolarization (fast response), associated with an increased Na conductance. Fast responses are antagonized by ICS 205-930 and mimicked by 2-CH_3-5-HT. In contrast 5-HT_{1P} receptors on enteric neurons mediate a long-lasting depolarization (slow response), associated with a decreased K conductance. Slow responses are antagonized by dipeptides of 5-HTP and mimicked by hydroxylated indalpines. 5-HT_{1P}, but not 5-HT_3 antagonists, block slow EPSPs for which 5-HT is the transmitter. The 5-HT_{1P}, but not 5-HT_3 receptors, can be labeled by ^{3}H-5-HT. We have now analyzed the effects of BRL 24924 on guinea pig myenteric neurons by using intracellular microelectrodes. Pressure microejection of BRL 24924 onto type II/AH neurons mimicked neither the fast, nor the slow response to 5-HT. On the other hand, BRL 24924 (0.5-1 μM) antagonized slow responses to 5-HT (15/15 cells). Moreover, BRL 24924 also blocked the slow EPSP in myenteric type II/AH neurons that is mediated by the release of endogenous 5-HT. Both of these actions of BRL 24924 were slowly reversible. The action of BRL 24924 was specific, since the slow response of myenteric neurons to substance P, which is similar to that elicited by 5-HT, was not affected by BRL 24924 in 8/8 cells. These results indicate that BRL 24924 is primarily a 5-HT_{1P} antagonist. Unlike other specific 5-HT_{1P} agonists or antagonists, BRL 24924 did not block the binding of ^{3}H-5-HT to 5-HT_{1P} receptors. BRL 24924 (0.5 mg/kg) was found to increase the rate of emptying of a ^{51}Cr-labeled liquid meal from the stomachs of awake freely moving mice. Since BRL 24924 blocks 5-HT-mediated slow EPSPs, these results imply that intrinsic inhibitory neurons of the murine stomach may be tonically activated by serotonergic axons acting through 5-HT_{1P} receptors. Supported by NIH grants NS12969, NS 07062, and NS 22637.

SEROTONIN EXCITES VISCERAL SENSORY NEURONS BY TWO SEPARATE MECHANISMS. E.P. Christian, G.E. Taylor* and D. Weinreich. Department of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201

Serotonin (5-HT) is known to stimulate afferent fibers of visceral sensory nerves (Douglas and Ritchie, J. Physiol., 138:31, 1957). One mechanism underlying this excitability increase may be a depolarization of afferent terminals, since 5-HT has been shown to depolarize sensory neurons (Higashi, Nature, 267:448, 1977). Here we report that 5-HT produces an additional excitatory effect by blocking a slow spike afterhyperpolarization (AHP_{slow}) that exists in a subpopulation of sensory neurons in the nodose ganglion (Fowler et al., J. Physiol., 365:59, 1985).

Rabbit and guinea pig nodose ganglia were maintained *in vitro* and neurons recorded with standard intracellular techniques. The depolarizing effect of bath applied 5-HT (0.5-10 μM) was blocked by including 10 μM d-tubocurarine in the superfusate (Higashi and Nishi, J. Physiol., 323:543, 1982). Under these conditions, 5-HT reduced or abolished the AHP_{slow} in a concentration-dependent manner. Blockade of the AHP_{slow} was accompanied by a decrease in the accommodative properties of these neurons, whereas 5-HT did not affect accommodation in neurons not exhibiting an AHP_{slow}. Thus the AHP_{slow} represents a distinct locus where 5-HT can act to increase the excitability of these sensory neurons. (Supported by NIH grant NS 22069).

89.4

ELECTROPHYSIOLOGICAL RESPONSES PRODUCED BY AUTACOIDS ON BRONCHIAL PARASYMPATHETIC NEURONS OF THE GUINEA PIG *IN VITRO*. A.C. Myers and D. Weinreich; Dept. of Pharm. and Exp. Ther., Univ. of Md Sch. of Med, Balt, MD 21201.

Bronchial parasympathetic neurons play an important role in the control of bronchial caliber. Both circulating and locally released neuroactive agents may alter the electrophysiological membrane properties of these neurons. The synaptic and membrane properties of guinea pig bronchial neurons were monitored with standard intracellular microelectrode techniques during superfusion of the compounds listed below (values are x ± SD for 6-30 experiments):

Compound		Δ Em (mV)	Δ Gi (%)	Δ fEPSP(%)
Histamine	10^{-5} M	+4 ± 2	+38 ± 15	no effect
5-HT	10^{-6} M	+3 ± 2	+48 ± 9	+41 ± 19
Epinephrine	10^{-6} M	+4 ± 1	no effect	-48 ± 23
Norepi.	10^{-5} M	+1 ± 3	no effect	-64 ± 20
PGD_2	10^{-6} M	+3 ± 1	-50 ± 10	no effect

Of these compounds only PGD_2 (10^{-6} M) decreased accommodation of phasic firing neurons thus mimicking this change induced by *in vitro* antigen challenge (Undem, et al., FASEB J. 2: A1056, 1988). These data suggest that a variety of endogenous neuroactive compounds may alter the synaptic efficacy of these ganglia. (Supported by NIH grants #NS 22069 & NS 25598).

89.5

INVOLVEMENT OF THE SEROTONERGIC SYSTEM IN DEPRESSION OF THE SPINAL MONOSYNAPTIC REFLEX BY PHENCYCLIDINE IN NEONATAL RATS. Y. Ohno and J.E. Warnick. Dept. of Pharmacol. & Exp. Ther., Univ. of MD Sch. of Medicine, Baltimore, MD 21201.

Phencyclidine (PCP) interacts with several neurotransmitter systems including those for serotonin (5-HT), catecholamines, acetylcholine, σ-opioid and N-methyl-D-aspartate (NMDA) in the central nervous system. This study was undertaken to elucidate the mechanism of PCP action in depressing the spinal monosynaptic reflex (MSR) in neonatal rats. Spinal cords were removed from male Wistar rats (6-9 days old), hemisected and superfused with oxygenated physiological solution *in vitro*. Stimulation of an L_{3-5} dorsal root evoked a MSR in the corresponding ventral root. PCP caused a dose-dependent depression of MSR with 50% inhibition at 8 μM. Neither the NMDA antagonists APV (2-amino-5-phosphonovalerate) and AP7 (2-amino-7-phosphonopentanoate) (100 μM) nor the σ-opioid agonist N-allylnormetazocine (30 μM) affected the MSR. The depressant action of PCP was markedly attenuated by simultaneous exposure to the 5-HT antagonists spiperone (5-HT_1 and 5-HT_2) and ketanserin (5-HT_2), but was unaffected by adrenergic (phentolamine and timolol), dopaminergic (chlorpromazine and pimozide) and cholinergic antagonists (atropine and mecamylamine) which by themselves did not affect the MSR. Our results suggest that the depression of the MSR by PCP is mediated by activation of a spinal serotonergic system and does not involve either σ-opioid or NMDA receptors. (Supported in part by USPHS grant DA-02804.)

89.6

SEROTONIN FACILITATION OF SPINAL MOTONEURON EXCITABILITY IS NOT MIMICKED BY THE $5HT_{1A}$ AGONIST, 8-OH-DPAT. D.A. Jackson and S.R. White. Dept. of VCAPP, Washington State University, Pullman WA 99164-6520

The ventral horn of the rat spinal cord is richly innervated with serotonin (5HT) terminals, and several $5HT_1$ receptor subtypes have been identified in the spinal cord (Huang and Peroutka, Brain Res., 436:173, 1987). Although 5HT is known to facilitate spinal motoneuron excitability in rats, the receptor subtype responsible for this facilitation is not known. However, the $5HT_{1A}$ agonist, 8-OH-DPAT, can mimic some of the spinal components of the "serotonin syndrome," suggesting that $5HT_{1A}$ receptors may mediate motoneuron excitability changes caused by 5HT (Tricklebank et al., Eur. J. Pharmacol., 106:271, 1985). In the present study, the effects of 5HT on glutamate-evoked spinal motoneuron activity were compared to the effects of 8-OH-DPAT in urethane-anesthetized rats. Iontophoretically applied 5HT (20 nA, 30-60 sec) consistently produced a marked facilitation of glutamate-evoked motoneuron firing. This facilitation was sometimes, but not always, preceded by very brief inhibition at current ejection onset. In contrast, 8-OH-DPAT (20-100 nA, 30-60 sec) produced only inhibition of glutamate-evoked firing in these spinal motoneurons. We conclude that facilitation of motoneuron excitability by 5HT is not mediated by $5HT_{1A}$ receptors. Supported by NIH grant NS 24388.

89.7

POST-SPIKE AFTER HYPERPOLARIZING POTENTIALS ARE DECREASED BY SEROTONIN AND TRH IN SPINAL MOTONEURONS OF DECEREBRATE CATS. S.R. White and S.J. Fung. Dept. of VCAPP, Washington State Univ., Pullman WA 99164

Serotonin and thyrotropin releasing hormone (TRH) are colocalized in terminal plexuses in the spinal cord ventral horn and both substances facilitate glutamate-induced motoneuron firing One mechanism by which motoneuron firing rates may be increased is by reducing the afterhyperpolarization (AHP) which follows an action potential. Serotonin has been shown to reduce the AHP in lamprey motoneurons (Van Dongen et al., Brain Res., 306:320, 1986) and in hippocampal pyramidal neurons (Andrade and Nicoll, J. Physiol., 394:99, 1987). We have investigated the effects of iontophoretically applied serotonin (5HT) and TRH on the AHP following action potentials evoked by intracellular current pulses in antidromically identified lumbar motoneurons in decerebrate cats. Both 5HT (25-50 nA, 30-60 sec) and TRH (80-115 nA, 90-120 sec) reduced the amplitude of the AHP. This reduction was more clearly seen in the AHP following the second or third spike of a spike train than following the initial spike. The reduction of the AHP developed slowly following the onset of 5HT or TRH ejection and outlasted the ejection period by more than a minute. In addition to reducing the AHP, 5HT and TRH also produced slow, low amplitude depolarizations of the motoneuron membrane and decreased the threshold for spike initiation by a depolarizing current pulse. Supported by NIH, NS24388

NOREPINEPHRINE FACILITATES SPINAL MOTONEURON EXCITABILITY RECORDED INTRACELLULARLY IN DECEREBRATE CATS. S.J. Fung, S.R. White, and C.D. Barnes. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164

Previously we reported that locus coeruleus stimulation produces an adrenoceptor-mediated increase in motoneuron excitability in the lumbar spinal cord of the cat (Fung and Barnes, Brain Res., 216:299, 1981). The concept of an excitatory role for norepinephrine (NE) on spinal motoneurons is, however, in conflict with early reports that iontophoretically applied NE hyperpolarized these cells. In the present study we reinvestigated the effect of NE on spinal motoneurons in decerebrate cats, paying particular attention to slowly developing, long-lasting changes in membrane excitability. In 19 antidromically identified hindlimb motoneurons (spike height > 60 mV), iontophoretically applied NE (30-70 nA, 30-60 sec) consistently produced a slow, long-lasting depolarizing potential with an associated increase in cell excitability. NE application was followed by a decrease in the threshold for action potential production by intracellular depolarizing current. NE also facilitated initial segment to soma dendritic transmission in the motoneurons and decreased the afterhyperpolarization which follows action potentials in the cells. None of these NE effects were mimicked by ejection of hydrogen ions from a pH control solution. We conclude that NE facilitates excitability of lumbar spinal motoneurons in cats. Supported by NIH grant NS 24388.

5-HT AND BIPHASIC CHANGES IN VENTRAL AND DORSAL ROOT MEMBRANE POTENTIALS. A.M. Holohean*, J.V. Vega*, J.C. Hackman and R.A. Davidoff. (SPON: R. Clark). Neurophysiology Lab, VAMC and Dept. of Neurology, Univ. of Miami School of Medicine, Miami, FL 33101.

5-HT receptors are implicated in the modulation of sensory information in the spinal cord, but the nature of the process is unclear. We studied putative 5-HT spinal receptors by means of sucrose gap recordings from ventral (VR) and dorsal (DR) roots of hemisected frog spinal cords superfused with HCO_3^--buffered Ringer's solution (15°C).

5-HT (1nM-1mM), 8OHDPAT (5-HT_{1A} agonist, 1nM-1mM), TFMPP (5-HT_{1B} agonist, 10nM-1mM), and methysergide (mixed agonist/antagonist, 1uM-100mM) produced biphasic effects on the DR and VR membrane potential. Low (nM) concentrations hyperpolarized (0.3-1 mV), while higher concentrations (uM-mM) depolarized (0.2-5 mV) DRs and VRs. 5-HT consistently produced larger VR than DR depolarizations; 8OHDPAT evoked greater DR depolarizations. TTX decreased 5-HT- and abolished TFMPP- and 8OHDPAT-evoked depolarizations. All hyperpolarizations were enhanced in TTX (presumably 2° to reduced depolarizations). The 5-HT_{1A} antagonists spiperone (1-10uM) and spiroxatrine (1-3uM) reduced the 5-HT-hyperpolarizations, while methysergide (1-10uM), mianserin (10uM) and ketanserin (1-10uM) increased hyperpolarizations and reduced depolarizations.

In sum, 5-HT produced biphasic responses in frog motoneurons and afferent terminals with direct 5-HT_{1A}-hyperpolarizations and indirect depolarizations. (Supported by VAMC Funds MRIS #1769 and #3369 and USPHS grant #17577)

5-HT MODULATION OF REFLEXES AND EXCITATORY AMINO ACID RESPONSES IN FROG SPINAL CORD. R.A. Davidoff, A.M. Holohean*, J.V. Vega* and J.C. Hackman. Dept. of Neurology, Univ. of Miami School of Med. and Neurophysiology Lab, VAMC, Miami, FL 33101.

Because the ability of 5-HT to affect reflexes could result from an effect on synaptic transmission mediated by excitatory amino acids (EAAs), we examined the effects of the amine on the changes in potential produced in ventral (VR) and dorsal (DR) roots by specific EAA receptor agonists and on VR (VRPs) and DR (DRPs) potentials evoked by DR stimuli by means of sucrose gap recordings from DRs and VRs in the isolated, hemisected frog spinal cord superfused with HCO_3^--buffered Ringer's solution.

A low concentration (0.1uM) of 5-HT increased VRPs and DRPs by 18%, but increasing the concentration (100uM) reduced the evoked reflexes by 13%. Application of both concentrations of 5-HT produced variable effects on the potential changes produced by 10 s applications of EC_{50} concentrations of quisqualate (3uM), kainate (10uM), NMDA (30uM), L-glutamate (1mM) and L-aspartate (1mM). In contrast, application of 8OHDPAT (a selective 5-HT_{1A} agonist, 0.01uM) shifted concentration-response curves for quisqualate (1-100uM), NMDA (1-100uM), kainate (10-100uM), and glutamate (100uM-2 mM) to the left and increased the slope of the linear portion of each curve.

These results indicate that 5-HT_{1A} receptors are involved in the spinal effects of 5-HT; these receptors may affect the ability of 5-HT to mediate reflexes and EAA responses. (Supported by VAMC Funds MRIS #1769 and #3369 and USPHS grant #17577)

SUPRAOPTIC NUCLEUS (SON) NEURONAL RESPONSES TO HISTAMINERGIC INPUTS RECORDED INTRACELLULARLY *IN VITRO*

G. I. Hatton & Q.Z. Yang, Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Horizontal slices of rat ventral hypothalamus containing the pituitary stalk, SON and tuberomammillary (TM) histaminergic neurons were studied. In some slices, one SON and one TM cell were impaled to study synaptic responses. In single impalements of SON cells, responses to micropressure applications of histamine or H_1 and H_2 agonists and antagonists were studied. 3 of 60 SON/TM pairs were found to be synaptically connected. Each of the 3 SON cells was an AVP neuron and was excited synaptically by depolarizing current injected into the TM cell. In spontaneously firing AVP cells, antidromically activated by stalk stimulation, firing frequency and epsps were increased by histamine or H_1 agonist application, effects that were blocked by H_1 antagonists. Putative OX neurons (n=2) were hyperpolarized by histamine. H_2 agonists were without effect. Silent or hyperpolarized SON cells fired single spikes upon stalk stimulation. Histamine application altered this response so that single stimuli resulted in trains of spikes. Thus, AVP-containing neurons are synaptically excited by input from TM cells, probably through activation of H_1 receptors. OX-containing neurons may be inhibited by histamine. Differential release of AVP and OX may be mediated by this pathway. Supported by NIH grant NS16942.

ELECTROPHYSIOLOGY OF MAGNOCELLULAR (HISTAMINERGIC) TUBEROMAMMILLARY NEURONS (TM) IN SLICES OF RAT HYPOTHALAMUS.

Q. Z. Yang & G. I. Hatton. Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Histaminergic TM neurons project to many brain areas, including cortex and brain stem, and are apparently involved in control of vasopressin release through modulation of supraoptic neurons to which they have direct projections. Intracellular recordings were made from 25 TM neurons in horizontally cut slices of hypothalamus. For positive identification, about 1/2 of the neurons were also injected with Lucifer Yellow, and some were antidromically activated by electrical stimulation of one target area, the supraoptic nucleus (SON). The following membrane properties were determined (means): E(membrane)= -55mV, AP(amplitude)= -63 mV, R(input)= 181 MΩ, Time constant(membrane)= 5 msec. APs were followed by afterhyperpolarization (100-150 msec dur., 10mV ampl.). TM neurons were characterized by fast Na^+ spikes (1.5 msec dur. at 1/ ampl.) and slow, presumed Ca^{2+} spikes (15-40 mV ampl., 12-400 msec dur.). The fast spikes only were abolished by TTX (10^{-5} M). TM neurons were generally silent in the slices, although some fired spontaneously (2-20 Hz). Depolarizing current injections produced a train of 5-12 APs with progressively increasing interspike intervals. Prolonged current injection did not result in continued firing, suggestive of a Ca^{2+}-activated K^+ conductance as one factor in burst termination. Supported by NIH grant NS16942.

SEROTONIN (5-HT) AND NOREPINEPHRINE (NE) INDUCE IPSPs IN PYRAMIDAL CELLS OF THE PIRIFORM CORTEX: EVIDENCE FOR A 5-HT_2 AND $alpha_1$ ACTIVATED INTERNEURON. P. W. Sheldon* and G. K. Aghajanian. Departments of Pharmacology and Psychiatry, Yale University, New Haven, CT. 06510

Pyramidal cells of the piriform cortex are known to have a high level of spontaneous IPSPs. Using intracellular recording with KCl-filled electrodes in an in vitro slice preparation of rat piriform cortex, we found that IPSPs could be induced in 20-30% of the pyramidal cells in layer II by bath application of either 5-HT (100μM) or NE (100μM). Induction of IPSPs by 5-HT was blocked by the 5-HT_2 antagonist ritanserin (5μM). Ritanserin also blocked the direct depolarization associated with 5-HT application, but with much reduced potency. The IPSPs induced by application of NE were blocked by the $alpha_1$ antagonist prazosin (2μM).

Because the IPSPs were blocked by both bicuculline and tetrodotoxin, suggesting that they arose from the firing of a GABAergic interneuron, we searched extracellularly for an interneuron which was activated by both 5-HT and NE. We found a group of such presumed interneurons on the border between layers II and III. 5-HT activation of these interneurons was blocked by ritanserin (1μM) ; NE activation was blocked by prazosin (2μM). The activation by 5-HT is potentiated by application of the putative 5-HT_2 agonist 2,5-dimethoxy-4-methylamphetamine (DOM) (1μM).

It appears that piriform cortex possess a GABAergic interneuron which is activated via 5-HT_2 and $alpha_1$ receptors and whose firing produces IPSPs in layer II pyramidal cells. (Supported by MH 17871 and the State of CT.)

THE EFFECT OF INCREASED CENTRAL SEROTONIN LEVELS ON HIPPOCAMPAL RHYTHMICAL SLOW ACTIVITY AND NEOCORTICAL LOW VOLTAGE FAST ACTIVITY.

B. Robertson*, C.H. Vanderwolf and G.B. Baker.
Dept. of Psychology, Univ. of Western Ontario, London, Ont., Canada, N6A 5C2 (BR & CHV); Dept of Psychiatry, Univ. of Alberta, Edmonton, Alta., Canada (GBB).

Serotonergic activity was increased in rats by treatment with tranylcypromine and tryptophan; HPLC revealed an 80% increase in the neocortex and an 83% increase in the hippocampus. Both hippocampal rhythmical slow activity (RSA) and neocortical low voltage fast activity (LVFA) were produced. Scopolamine-resistant RSA, thought to be dependent on brain serotonin (Vanderwolf, C.H. & Baker, G.B. Brain Res., 374:342, 1986) maintained its normal relation to behavior, occurring during motor activities such as walking and head movements (Type 1 behaviors). Scopolamine-resistant RSA was not present during classical serotonin syndrome behaviors such as forepaw treading and head weaving. Scopolamine-resistant LVFA, also thought to be dependent on brain serotonin (see above ref.), appeared continuously in the neocortex. No evidence was found to support the view that increased serotonin release promotes quiet sleep or cortical deactivation. The present findings support the view that serotonin is involved in cortical activation.

MULTIPLE ACTIONS OF SEROTONIN ON MEMBRANE PROPERTIES OF CEREBELLAR PURKINJE CELLS IN VITRO. H. K. Strahlendorf and J. C. Strahlendorf. Depts. of Physiology and Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

We have reported complex effects of serotonin (5-HT) on the rate and pattern of firing of Purkinje cells (PCs) recorded extracellularly. This study investigates the actions of 5-HT on passive and active membrane properties of PCs. Intracellular recordings were obtained from PCs in sagittal slices of rat cerebellum at 32°-34°C. 5-HT was superfused or applied as a droplet. The resting membrane potential (Vm) of PCs averaged -51mV and the average input resistance (Rm) was 27MΩ. Spontaneous fast and slow spikes were observed. The most consistent effect (75% of PCs) of 100-200μM 5-HT was an increase in Rm that averaged 29%. In 25% of PCs, an average 39% decrease in Rm occurred. 5-HT hyperpolarized 37% of PCs by average of 3mV, depolarized 37% of PCs by an average of 10mV and failed to change Vm in 25% of PCs. Hyperpolarizations were associated with an increase in Rm; depolarizations were accompanied most frequently by an increase in Rm but decreases also were observed. Spiking in response to anodal breaks of hyperpolarizing pulses frequently was enhanced by 5-HT. These preliminary results underscore the complexity of 5-HT actions on PCs and suggest 5-HT may affect a number of ionic conductances in PCs. Supported by NS 19296.

SEROTONERGIC DORSAL RAPHE NEURONS: ALTERED SPONTANEOUS ACTIVITY AND SENSITIVITY TO 5-MeODMT AFTER LONG-TERM AMPHETAMINE. B.A. Heidenreich* and G.V. Rebec (SPON: G.P. Frommer). Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Amphetamine (AMPH) slows the firing rate of serotonin (5-HT) neurons in the dorsal raphe nucleus. Chronic treatment with a high dose of AMPH attenuates this response (Heidenreich et al., Neuropharmacol., 26:719, 1987). We now have examined the effects of long-term AMPH on the spontaneous activity of 5-HT neurons and on their sensitivity to 5-MeODMT, a 5-HT autoreceptor agonist.

Rats received injections of saline or 10 mg/kg d-AMPH twice daily for 6 days. Recordings of 5-HT cells on the next day revealed no effect of AMPH on spontaneous firing rate, interspike interval (ISI) or variability around the mean ISI. However, ISI variability was inversely related to firing rate in AMPH-treated rats, but not controls. Although both groups had comparable sensitivity to 5-MeODMT, the dose needed to inhibit unit activity correlated significantly with firing rate (r=.98) and ISI (r=-.95) only in the AMPH group. Also, a regular firing pattern was associated with lower effective doses of 5-MeODMT in the saline group. In contrast, regular firing patterns in the AMPH group were associated with higher firing rates and larger effective doses of 5-MeODMT. These results suggest that chronic AMPH enhances the importance of 5-HT autoreceptor control of firing rate relative to other mechanisms.

INHIBITION OF SEROTONERGIC DORSAL RAPHE NEURONS BY p-CHLOROAMPHETAMINE (PCA) AND MDMA ("Ecstacy"): EFFECTS OF A SEROTONIN (5-HT) UPTAKE INHIBITOR AND L-TRYPTOPHAN. J.S. Sprouse and G.K. Aghajanian. Dept. of Psychiatry, Yale Univ. Sch. of Medicine, New Haven, CT 06508.

The mind-altering agent, (±)-3,4-methylenedioxymethamphetamine (MDMA), produces neurochemical effects in rat brain which closely resemble those of the serotonergic neurotoxin, PCA. Like PCA, MDMA causes an immediate and a long-term decrease in brain 5-HT. The initial effects may be due to inhibition of 5-HT synthesis and stimulation of 5-HT release; the later effects may be the result of nerve terminal damage. A comparison of the electrophysiological responses of 5-HT-containing dorsal raphe (DR) neurons to PCA and MDMA has not been examined previously.

Extracellular single unit recordings of DR neurons were made in the in vitro rat brain slice preparation. PCA (10-100 μM) or MDMA (3-30 μM) produced a dose-dependent suppression of DR cell firing. Pretreatment with L-tryptophan (30-100 μM), which stimulates 5-HT synthesis, increased the potency of PCA and MDMA. Pretreatment with the selective 5-HT uptake inhibitor fluoxetine (20 μM), which blocks the acute release and long term depletion of 5-HT by PCA and MDMA, blocked the suppressant effects of PCA and MDMA. These electrophysiological responses, consistent with the neurochemical data, suggest that PCA and MDMA act indirectly on DR neurons through release of endogenous 5-HT. SEROTONIN AGONISTS INHIBIT DEPOLARIZING SYNAPTIC POTENTIALS IN THE RAT LOCUS COERULEUS *IN VITRO*. D.H. Bobker* and J.T. Williams. Vollum Institute, Oregon Health Sci. Univ., Portland, OR 97201

Intracellular recordings were made from rat locus coeruleus (LC)neurons *in vitro*. The depolarizing synaptic potential (DSP), elicited by electrical stimulation, was typically 10 - 15 mV in amplitude and is mediated by glutamate and GABA. Superfusion with 5-HT, or the non-specific 5-HT_1 agonist 5-carboxamidotryptamine (5-CT), produced a maximal inhibition of the DSP of 60%. This effect was found to be presynaptic. The EC_{50} for 5-CT was 50 nM, while for 5-HT it was 10 μM. In the presence of cocaine (10 μM), however, the 5-HT concentration-response curve was shifted left and had an EC_{50} of 400 nM. 8-OH-DPAT, the specific 5-HT_{1A} receptor ligand, acted as a partial agonist, producing approximately 60% of the 5-CT response (EC50 = 50 nM). The 5-HT_{1B} selctive ligand, TFMPP, acted as a full agonist (EC50 = 110 nM). None of these agonists had effects on membrane potential or firing rate.

The response to 8-OH-DPAT was antagonized by pretreatment with the 1A specific drug spiroperidol (1μM). The apparent K_D for spiroperidol was 20 nM. At this same concentration, however, there was no effect on the 5-CT induced response. The antagonist LM 21-009 (1B > 1A, 5-fold selectivity) was found to shift the 5-CT response to the right in a parallel manner at doses as low as 100 nM. The apparent K_D was 19 nM. This pharmacologic profile suggests that the presynaptic inhibition of the DSP is mediated by both 1A and 1B receptors. In addition, these results support previous *in vivo* work which demonstrates that 5-HT inhibits sensory evoked LC activity without effecting spontaneous activity.

SEROTONIN SELECTIVELY DECREASES GLUTAMATE-EVOKED EXCITATION OF LOCUS COERULEUS *IN VIVO*. G. Chouvet*, G. Aston-Jones[1], H. Akaoka*, & E. Malekaki*[1] (SPON: F. Strand), INSERM U171, Gif-sur-Yvette, France; [1]Dept. Biol. & Cntr. Neural Sci., New York Univ., NY 10003.

Despite the dense serotonergic input to locus coeruleus (LC), little is known concerning the influence of serotonin (5-HT) on LC physiology. Therefore, we examined the effects of serotonin on spontaneous LC activity and on responses of LC neurons to one of their major afferent transmitters, glutamate (Glu).

Extracellular recordings were obtained from individual LC neurons in 12 halothane-anesthetized rats using a single-barrel micropipette glued onto a 7-barrel iontophoretic micropipette assembly (recording tip extending 12-18 um). Iontophoretic Glu or acetylcholine (ACh) potently activated 91% and 88% of 49 and 25 LC cells, respectively, and NE consistently inhibited LC discharge (95% of 20 cells). However, 5-HT had no consistent effect on LC spontaneous discharge: this agent yielded weak inhibition in 49%, had no effect on 42%, and caused excitation in 9% of LC neurons (N = 49).

Despite weak and variable effects on spontaneous LC discharge, 5-HT consistently suppressed responses of LC neurons to Glu, markedly decreasing Glu excitations (by 60 to 98%) in 83% of 24 cells tested. Such attenuation of Glu-evoked activity by 5-HT was independent of effects of 5-HT on spontaneous activity, occurring in cells whose spontaneous discharge was augmented as well as in those that were inhibited by 5-HT. In addition, this effect of 5-HT was relatively specific to Glu-evoked excitations, as 5-HT did not attenuate (and in some cases enhanced) ACh responses in 10 of 11 neurons. Such effects were also relatively specific for 5-HT: NE, in contrast to 5-HT, suppressed spontaneous more than Glu-evoked activity.

These results indicate a selective filtering or modulatory role for 5-HT in the control of LC activity. As a consequence of 5-HT input, activation of LC neurons by excitatory amino acid afferents would be blunted while tonic, spontaneous discharge and excitation from other inputs (for example, those mediated by ACh) may remain intact. LOCALIZATION OF PHONOLOGICAL PROCESSING IN THE TEMPOROPARIETAL CORTEX BY PET. S.E. Petersen*, P.T. Fox, M.I. Posner and M.E. Raichle, Washington University School of Medicine, St. Louis, MO 63110.

Recent PET blood flow studies have shown activation in left temporoparietal cortex when words are presented auditorily, but not for other types of auditory stimuli, suggesting a role for this area in higher-order auditory, or phonological, processing. This area is not activated during the presentation or repetition of visually-presented words, suggesting that recoding into a sound-based representation is not obligatory during repetition of visual words.

To determine whether temporoparietal cortex is also engaged in phonological processing of visually-presented information, we measured cortical activation during a rhyme monitoring task using averaged PET blood flow subtraction images. Subjects monitored pairs of visually-presented words for rhymes as a phonological task. The control state was simple visual presentation of word pairs. Rhyme monitoring activated left temporoparietal cortex, near the site activated by passive auditory word presentation. This area was not activated during semantic monitoring. These observations strongly implicate the temporoparietal cortex in high-order phonological processing.

90.2

GLUCOSE HYPOMETABOLISM IN STROKE: SPECIFIC OR NONSPECIFIC EFFECT IN APHASIA. E.J. Metter*, W.R.Riege, W.H. Hanson*, C. Jackson*, D. Kempler*, and D. Van Lancker*. NIA, Gerontology Research Center, Baltimore, MD 21224, and VA Med Ctr, Sepulveda, CA 91343.

We examined the distribution of metabolic and structural abnormalities in 45 aphasic subjects studied greater than 1 month post onset in a resting state (eyes and ears unoccluded) with (F18)fluorodeoxyglucose PET, and x-ray CT. Structural damage was most frequent in the parietal and posterior superior temporal areas (67% of subjects). For these same regions, glucose metabolism was abnormal in 82% and 87% of subjects. Aphasia severity had a higher correlation with temporoparietal metabolism than structural measures. Using pathway analysis, regional metabolism had an effect on aphasia which was not accounted for by structural damage. The observations argue that regional hypometabolism in stroke are important in the cause of the aphasia. If metabolic effects were nonspecific (resulting from disruption of projections with no loss of regional function), then the aphasia should show weaker associations with regional metabolism than with structural damage, which was not the case.

90.3

REPRODUCTION OF TEMPORAL INTERVALS BY APHASIC AND NON-APHASIC BRAIN-INJURED PATIENTS. J. Ilmberger, E. Pöppel. Inst. Med. Psychology, Univ. of Munich, Munich, FRG.

Within the continuity of mental processing, successive mental events are usually integrated into coherent patterns forming a gestalt. The temporal limit of this integration process can be measured with different experimental paradigms, for instance temporal reproduction. In reproduction experiments, intervals of approximately 3 seconds are reproduced most accurately; indifference intervals defined in this way are one expression of limits of temporal integration. Indifference intervals possibly refer to language processing, too, as in spontaneous speech pauses are made every two to three seconds. We tested whether disorders of language processing are correlated with disorders of integration time. Time reproduction experiments were performed with aphasic and non-aphasic brain-injured patients and a control-group without brain damage. The results show that aphasic patients have significantly altered auditory indifference intervals. This finding is discussed with respect to possible consequences for language processing.

90.4

EFFECTS OF UNILATERAL TEMPORAL LOBECTOMY ON RECOGNITION MEMORY FOR TEXT AND MELODY IN SONGS. S. Samson* and R.J. Zatorre (SPON: C. Anderson). Montreal Neurol. Inst., McGill Univ., Montreal, Canada H3A 2B4.

The effect of left-temporal lobectomy on verbal memory is well-documented, but less is known about the cerebral structures involved in memory for text sung to a melody, or for the melodic component of songs. The performance of patients who had undergone left (N=21) or right (N=20) temporal lobectomy for the relief of intractable seizures was compared with that of 20 normal control subjects. Unfamiliar songs were presented in a recognition paradigm that permitted independent assessment of memory for text or melody. A significant deficit was obtained after left temporal excision in the recognition of both the text and the melody of songs. By contrast, the performance of subjects with right temporal lobectomy did not differ significantly from that of normal control subjects. The results suggest that the left temporal lobe is involved in the recognition of verbal as well as musical components of songs. Preliminary indications are that excision of Heschl's gyri in the left side exacerbates the deficit while hippocampal resection does not.

90.5

PROCEDURAL MEMORY IMPAIRMENT IN SCHIZOPHRENICS. P.B. Vrtunski, D.M. Simpson*, K.M. Weiss* and H.Y. Meltzer. VA Med. Center and CWRU Sch of Med., Brecksville OH 44141.

Groups of normal and schizophrenic subjects were studied in performance with two choice reaction time tasks with visual (pictures) and auditory (spoken words) high (HF) and low (LF) frequency stimuli. The aim was to establish whether the repetition of stimuli facilitates recognition in schizophrenics in the same manner as it does in control subjects and whether the repetition effect is independent of the stimulus material used. Stimuli were presented once or three times. The principal findings were that a) with both stimulus conditions schizophrenic subjects were significanly impaired; b) The stimulus repetition effect was not observed with pictorial stimuli, but was observed with word stimuli (LF words always having longer latencies); and c) There were significant group differences in latency reduction due to word repetition: whereas the controls showed large decrement in reaction time mostly at second stimulus presentation, response latency of the schizophrenic subjects followed this pattern only with LF words. With HF words no latency reduction was seen until the third presentation. The conclusion reached was that in procedural memory, as seen with high frequency words, stimulus encoding in schizophrenics at first presentation may be only partially executed.

90.6

NORMAL MCCOLLOUGH EFFECT IN ALZHEIMER'S DISEASE AND GLOBAL AMNESIA. R.L.Savoy* and J.D.E.Gabrieli (SPON: S. Kosslyn). Rowland Institute for Science, Cambridge, MA 02142 and Dept. of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139.

The McCollough Effect (ME), a long-lasting pattern-contingent color aftereffect in normal human vision, has often been offered as a candidate for a simple form of human learning and memory. Independent of the as yet unknown mechanisms underlying the ME, it seemed worthwhile to examine the effect in persons with known deficits in memory.

After 5 minutes of staring at a bright ME adapting pattern, normal subjects have measurable color aftereffects at least 1 hour later. We induced such effects in 7 subjects: 2 patients with mild Alzheimer's Disease, H.M. (a patient with global amnesia due to bilateral medial temporal lobectomy who has been studied for the 35 years since his operation), and 4 age-matched control subjects. H.M. and the Alzheimer's patients showed MEs of strength and duration comparable to those of the control subjects.

These results demonstrate an intact visual aftereffect in H.M. and in patients with Alzheimer's disease. Further, the results extend the domain of intact aftereffects in amnesia to a particularly long-lasting effect.

EFFECTS OF OPERANTLY CONDITIONING CORTICAL SOMATOSENSORY EVOKED POTENTIAL (SEP) AMPLITUDE ON THE BLINK REFLEX. R. Dowman. Department of Surgery, University of Alberta, Edmonton AB., Canada T6G 2B7.

Stimulation of the median nerve evokes cortical potentials (SEP) and a blink reflex. The present work investigated the effects of operantly conditioned changes in SEP component P100 amplitude on the blink reflex in humans.

SEPs were evoked in 8 subjects by stimulation of the median nerve and recorded from over the contralateral somatosensory (SI) and frontal cortices, each referenced to the contralateral earlobe. The blink reflex was recorded from above and below the contralateral eye. The SEP conditioning procedure was comprised of baseline, SEP training, and reversal training modes. During the SEP training mode subjects were rewarded (money) when SI cortex P100 amplitude was larger than (uptrain) or smaller than (downtrain) its baseline mode mean. During the reversal training mode the reward contingency was reversed: uptrainers became downtrainers and vice versa. Each training mode lasted 5-10 sessions (1 session/day).

Four of the 8 subjects successfully changed SI cortex P100 amplitude in the direction of training. There were no changes in frontal cortex P100 amplitude. The blink reflex in these subjects was larger during uptraining than downtraining. The small blink reflex relative to P100 and the absence of change in frontal cortex P100 during conditioning suggests that the SI cortex P100 component is not generated by muscle potentials associated with the blink reflex. These results also suggest that P100 conditioning alters descending cortical modulation of the brainstem blink reflex pathways.

EFFECTS OF FOCAL FOREBRAIN INJURY ON FEATURE-BASED VISUAL SEARCH. R. B. Bolster and P. Birk, Dept. of Psychiatry, Fac. of Med., Univ. of Manitoba. Winnipeg, Man. R3E OW3

Visual selective attention in neurosurgical patients was assessed using a computer-based search task modelled after Treisman (1977). Patients with focal forebrain damage were compared to age-matched nonpatient controls on the ability to locate and identify colored-form targets in the presence of nontarget distractor items. The target was a green square, presented for 50 msec amid a 3 x 3 array of colored forms. Two array types were used, a "feature disjunction" array, with red square distractors, and a "feature conjunction" array with red diamond, red square, and green diamond distractors. Patients with dorsolateral frontal damage were selectively impaired on conjunctive arrays, making more errors to distractors sharing one feature with the target. Patients with orbital frontal injury were unimpaired. Patients with right, but not left, temporal lobectomy showed a pattern similar to the dorsolateral frontal group. Parietal patients were also impaired in comparison to normals, but errors were related to the position of the target rather than the features of the distractor items.

90.9

DYSCALCULIA IN PATIENTS WITH VERTIGO. J. Risey* & W. Briner Dpt of Otolaryngology, Tulane Univ. School of Medicine, New Orleans, La. 70112.

Vestibular disturbances have been associated with learning disabilities and other CNS disorders but not with specific disorders of cognition. One author (JR) has noted discrete and nearly identical errors in counting (dyscalculia) by approximately 20% of patients seen for ENG Tests. Patients skipped and displaced decades when asked to count backwards by twos.

8 patients with vertigo and dyscalculia were given the math subtests of the WAIS, counting tasks, visual error recognition tasks, ENG and audiometric exams including Neuroaudiological Tests. This same workup was given to 16 patients without dyscalculia (8 with and 8 without vertigo); all groups were matched for educational level and conventional audiometric results. The patients with dyscalculia exhibited poorer performance than patients from the other groups on the arithmetic and digit span portions of the WAIS and on the Neuroaudiological Tests.

This phenomenon appears not to be an isolated arithmetic anomaly but a dysfunction reflected in other arithmetic abilities. It appears to involve more than just the auditory/speech function; it also involves visual recognition of numerical sequences. The results of the Neuroaudiological tests suggest that the area of dysfunction is not the primary auditory cortex but may be the result of auditory association area dysfunction. Dyscalculia appears to be a common event among adults complaining of vertigo.

IMPAIRED PROBLEM SOLVING IN PARKINSON'S DISEASE (PD): INFLUENCE OF SET-SHIFTING DEFICIT. A. Cronin-Golomb, S. Corkin, and J.H. Growdon. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, and Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114.

PD often is associated with specific cognitive deficits in the absence of dementia, including the inability to suppress inappropriate learned responses. We assessed problem solving ability in 9 nondemented, never medicated subjects with PD ($\bar{X}$ age 63.8, education 14.9 years) and 7 matched healthy control subjects (HCS). The 10 problems required subjects to deduce a 'poisoned food' after study of lists of 3-food meals and their outcomes. Information provided by a single outcome was positive (the diner 'died') or negative ('lived'). All information (meals, outcomes, subject's deduction after each meal) was available at all times. PD subjects' performance was worse than HCS' (PD: $\bar{X}$ 7.4, SD 1.3; HCS: $\bar{X}$ 9.0, SD 1.0; $p<.05$). Most PD errors occurred on negative meals immediately following correct assessment of positive meals. Problems consisting exclusively of negative meals were performed correctly. The results suggest that subjects with PD can develop a learning set within a problem, even after a single trial, and are unable to suppress it on subsequent trials when that set leads to incorrect responses. This dysfunction must be considered when assessing problem solving and other multicomponential cognitive abilities in PD.

90.11

EFFECT OF TESTOSTERONE OR NANDROLONE ON SELF-ESTIMATES OF PERFORMANCE. A.C. Zold*, C.J. Hannan, Jr., K.E. Friedl* and S.R. Plymate* (SPON: R. Aronstam). Clinical Investigation Dept. and Psychology Service, Madigan Army Medical Ctr, Tacoma, WA 98431.

In order to quantify psychiatric changes reported with anabolic steroid use, a battery of psychological tests were administered to male subjects before and after a six week regimen (dosed/wk) of testosterone enanthate (Te) or Nandrolone decanoate (Nan). The standard psychomotor test of peg board rate was supplemented with a measure of the subjects ability to estimate their own performance. At trial 1 subjects were informed of the normal range of response for the task before giving their self-estimate. At trial 2 the subject knew his time for completion of trial 1 before giving his self-estimate. Results in the table are mean changes in seconds ± SE.

Estimate of Peg Board	Hand*	100mg Te n=6	300mg Te n=5	100ng Nan n=6	300ng Nan n=7
Δ Trial 1	D	1.8±5.3	-4.2±4.3	-6.7±3.2	1.9±3.2

FACES AS RELEASERS OF CONTAGIOUS YAWNING: AN APPROACH TO THE NEURAL BASIS OF FACE PERCEPTION. R. R. Provine. Dept. of Psychology, Univ. of Maryland Baltimore County, Baltimore, MD 21228.

The contagiousness of yawns is a non-invasive means of assaying the yawn-evoking potency of various facial features. This is an investigation of face perception and a search for the ethological "releasing stimulus" that triggers the "fixed action pattern" of yawning. The yawn-evoking potency of variations on a 5 min. series of 30 videotaped repetitions of a yawning face were compared with each other and a series of 30 smiles. The yawn variations were: 1) axial orientation, 0°, 90°, 180°, 270°; 2) still image; 3) high contrast; 4) no mouth; 5) no eyes; 6) mouth only; 7) eyes only; and 8) no facial features.

Animate video images of yawning faces in all axial orientations evoked yawns in more subjects than featureless or smiling faces, and no single feature such as the gaping mouth was necessary to evoke yawns. The yawn recognition process was maximally activated by the overall configuration of the yawning face regardless of its axial orientation. A similar lack of feature and axial specificity in many face-specific neurons in the brains of monkeys suggests a related stimulus analysis. These results about yawning and face-specific neurons join those from prosopagnosia (face non-recognition) in brain damaged humans and perhaps facial "imitation" in human neonates, which suggest that special neural mechanisms detect and process information about faces.

90.13

FACIAL EXPRESSION AND THE NEOCORTEX. B. Kolb and L. Taylor*, Univ. of Lethbridge, Lethbridge, Canada, T1K 3M4, and Montreal Neurol. Inst., Montreal, Canada, H3A 2B4

This study examined the relative roles of the left and right frontal and temporal lobes in the production and perception of facial expression. Subjects (Ss) were asked to produce an expression appropriate for a faceless character in real life cartoon drawings, and to mimic the emotional expression portrayed in a series of photos. Subsequently Ss chose the "best match" expression for the faceless character from a series of 6 key photos of people depicting different basic expressions, and also matched the series of photos with the 6 keys. The left frontal-lobe group produced significantly less intense expression on both production tests than any other group. Right temporal Ss performed poorly on both perception tests whereas the left-temporal Ss were normal on the face-matching task. Frontal lobe Ss were also impaired at both tests. Thus, (1) left frontal lobe lesions impair both the production and perception of facial expression, (2) right temporal and right frontal lesions impair the perception of facial expression, and (3) left temporal lesions only affect the perception of emotional expression in context.

KNOWING WITHOUT LEARNING? SEMANTIC CATEGORIZATION BY THE DISCONNECTED RIGHT HEMISPHERE OF INFORMATION KNOWN ONLY BY THE LEFT HEMISPHERE. J. Sergent, Montreal Neurological Institute, McGill University, Montreal (Quebec) H3A 2B4, Canada.

One of the most influential findings in the study of commissurotomized patients concerns the capacity of the right hemisphere to subserve verbal functions such as language comprehension and lexical decision. This finding is of critical importance for the formulation of models of hemispheric specialization, reading, and recovery from aphasia and suggest a specific contribution of the right hemisphere to verbal processes. However, recent evidence of subcortically mediated interhemispheric transfer in commissurotomized patients makes it conceivable that a right-hemisphere correct lexical decision does not indicate that the required information is represented in this hemisphere. Such a possibility was examined in two commissurotomized patients (L.B. & N.G.), using familiar and unfamiliar faces as stimuli. Two preliminary experiments aimed at establishing the nature of the information that can be transferred between the hemispheres, and showed that information about facial identity was not exchanged while information about sex, age, emotion and professional category, was. In the third experiment, the professional category of each unfamiliar face was initially taught to the patients by presenting the faces in the right visual field, such that only the left hemisphere learned semantic information about the faces. A reaction-time categorization task was then conducted on these faces appearing either in the right or the left visual field. Responses were faster and more accurate to right than to left presentations, but they were nonetheless significantly better than chance in the left visual field, even though the right hemisphere had not learned the appropriate association. The results suggest that right-hemisphere responses may not necessarily reflect knowledge and competence of this hemisphere and offer an alternative account of the reported right-hemisphere capacity to perform verbal semantic categorizations and lexical decisions.

90.15

EVIDENCE FOR MISDIRECTED REACHING TO 'PLACES' BUT NOT 'TARGETS' IN PATIENTS WITH RIGHT-HEMISPHERE LESIONS. A. D. Milner* and M. A. Goodale. University of Western Ontario, London, Ontario, Canada. N6A 5C2.

Patients with lesions of the right hemisphere were tested on two visually guided reaching tasks in which the kinematics of their limb movements were recorded optoelectronically (WATSMART). In the first task (Targets), they were asked to reach out and put the index finger of their right hand as quickly and as accurately as possible on a small target that was presented randomly in one of five locations between 20 cm left and right of their body axis. In the second task (Places), two targets were presented 18 cm apart and the subjects were asked to put their index finger on the point midway between the two targets. The spatial locations of the required endpoints in the two tasks were identical. Despite the fact that the patients showed little clinical evidence of visual neglect, they showed a consistent rightward bias in the terminal position of their finger in the Places task as compared to the Targets task. This bias was not present in control subjects. However, the initial heading directions of the reaching movements made by the patients were equivalent in the two tasks and tended to deviate to the right side as compared to reaches made by control subjects. These results suggest that 'recovery' from visual neglect may, in fact, reflect the use of compensatory adjustments to the trajectory of reaching movements as they unfold and that these adjustments are more easily made for reaches to discrete targets than for reaches to places defined by more distal cues.

90.16

HAND PREFERENCE SHIFTS AND SEX DIFFERENCES IN THROWING AND INTERCEPTING. N. V. Watson and D. Kimura. University of Western Ontario, London, Canada N6A 5C2.

In humans, the organization of movements of both upper limbs relies significantly on a left-hemisphere "praxis" system. To the extent that right hand preference reflects this left-hemisphere dependence, a task that maximizes spatial complexity of a target (presumably engaging right hemisphere systems), and minimizes motor programming demands, might yield a diminished disparity between the two hands.

Left and right hand abilities were measured independently for two motor tasks in 48 normal right-handed adults: 1) throwing a dart at a stationary target, 2) using the open hand to block a projectile at varying trajectories and velocities. ANOVA yielded a significant task by hand interaction (F = 17.5, $p < .001$). Left hand performance didn't differ from the right hand for the intercepting task (t = .81, p = .42), but was significantly worse for throwing (t = 5.93, $p < .001$). A sex difference favouring males was evident for both tasks ($p < .001$ for each), which was not reducible to differences in physique or athleticism.

Thus, right-handedness was abolished in the spatially demanding interception task but not in the motorically demanding throwing task. This suggests that hand preference in humans is dynamic, varying with task demands and with the degree of left/right hemisphere processing involved in a given task.

90.17

HUMAN OLFACTORY DISCRIMINATION AFTER FOCAL CEREBRAL EXCISION: MONORHINAL DEFICITS? R.J. Zatorre and M. Jones-Gotman* (SPON: H. Jasper). Montreal Neurol. Inst., Montreal, Canada H3A 2B4.

Olfactory discrimination was studied in 96 patients with unilateral cerebral excision and in 20 normal control subjects. Patients were grouped according to side and site of lesion in the temporal (N=62), frontal (N=26), or parietal (N=8) lobe. Detection thresholds for n-butyl alcohol did not differ across subject groups or across nostrils (Jones-Gotman & Zatorre, Neuropsychologia 26:387-400, 1988), ruling out primary olfactory sensory loss. The discrimination task involved monorhinal presentation of unfamiliar odorants in pairs, which subjects judged as same or different in quality. The results showed: (1) severe impairment after frontal-lobe lesions, with a generally greater deficit on the nostril ipsilateral to the lesion. We interpret this as reflecting the importance of orbitofrontal cortex in olfactory processing. (2) A significant but milder deficit, confined to the ipsilateral nostril, was obtained after temporal-lobe lesions. (3) Normal discrimination was observed after parietal-lobe lesions. (4) Normal subjects performed significantly better with the right nostril, raising the question of hemispheric asymmetry for odor processing.

90.18

COLOR VISION DEFICITS IN ALZHEIMER'S DISEASE (AD). J. Cohen*, A. Cronin-Golomb, J.H. Growdon, and S. Corkin (SPON: B. Vermeire). Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114, and Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

We administered the City University Colour Vision Test to 36 AD patients and 11 age-matched healthy control subjects (HCS). The test consists of 10 plates, each with a target circle of a particular hue surrounded by four circles each of a different hue. Subjects point to the outer circle closest in hue to the target. The AD group made more errors overall than did the HCS group ($p<.05$), and made more tritan (blue-yellow) than protan (red) ($p<.05$) or deutan (green) ($p<.05$) errors. We observed further that a number of AD patients showed marked difficulty in discriminating between blue and green items on the Stroop Test, which requires naming of red, green, and blue stimuli. Of 67 AD patients, 15% made blue-green errors, compared with 6% of the 36 age-matched HCS.

Further studies will be necessary to identify the lesion(s) accounting for color deficits. Damage to extrastriate cortex (area 18) has been associated with dyschromatopsia in humans and in monkeys; this region is often affected in AD. Alternatively, impaired color vision could result from lesions of the retina or optic nerve, which also may be damaged in AD. Our behavioral findings prompt caution in interpreting results from the Stroop Test and other cognitive measures that rely upon preserved color vision.

90.19

ATTENTION ENHANCES TACTILE PATTERN IDENTIFICATION.
K. C. Whang*, H. Burton, G. L. Shulman. Depts. of Anat. and Neurobiol., Neurol. and Neurol. Surg., Washington Univ. Sch. of Med., St. Louis, MO 63110.

Discriminations between patterns of vibration demonstrate attentional effects in touch. Normal human subjects detected patterns of amplitude changes in 250 Hz vibrations applied to the index and middle fingertips of both hands. They were required to determine in which of two choice intervals a target pattern occurred.

During each interval, each finger received two pulses of increased or decreased amplitude from a fixed base level. Within an interval, the 200-ms. pulses could begin at any of four start times spaced apart by 600 ms. each. The target pattern, presented to one of the four fingers during one of the two choice intervals, was an increase followed in time by a decrease. The other pulse patterns presented were all distractors. A tactile cue in each interval indicated the finger at which a target could appear with 80% validity.

Subjects performed significantly better when the target appeared at the cued finger. The results show that spatial attention can improve the accuracy with which tactile temporal patterns can be identified. In other tasks where the target was a single pulse instead of a pattern, no improvements in performance were found with cueing. The single-pulse targets were defined by their amplitudes and durations, and were more difficult to detect than the pulses that constituted the pattern elements.

A spatial pattern task analagous to the temporal pattern task is being investigated. Subjects are cued to the time at which the target pattern, a simultaneous increase to the left of a decrease, is likely to occur.

INFLUENCE OF SENSORY AND MOTOR ATTENTION ON PRECORTICAL RESPONSES TO VISUAL STIMULATION IN HUMANS. R. G. Eason, Marta T. Oakley, and J. M. Harding.* UNC-Greensboro; Los Alamos Nat. Lab.; & Marian Area Couns. Ctr., Inc., Ohio.

We have been investigating the hypothesis that when one selectively attends to a location in space where a task relevant stimulus is expected to appear (relevant location), subcortical neural pathways activated by stimuli appearing at that location are biased by centrifugal influences of cortical origin such that information is preferentially transmitted over them (NS Abstr's., 1985, 1986, 1987).

Using the paradigm of Eason, Harter, & White (Phy. & Beh., 1969), we have new data indicating that: (1) the ERG b-wave is significantly enhanced, as noted in earlier studies, when sufficiently salient evoking stimuli are presented at the relevant (attended) location compared to when that same stimulus is irrelevant; (2) frontally and parietally recorded short-latency VER-deflections (30-40 msec onset) evoked by stimuli too weak to elicit a measurable ERG tend to be more negative for relevant than for irrelevant locations; and (3) the magnitude and polarity of the relevancy effect is greater and more negative when subjects are set to make a finger lift or saccade response to target stimuli than when silently counting the stimuli.

These studies provide further evidence that spatial selective attention can alter sensory transmission precortically at a number of subcortical levels, and that such alteration is dependent on the saliency (size) of the stimulus, and the type of response the subject is set to make.

BEHAVIORAL PHARMACOLOGY: PSYCHOSTIMULANTS

91.1

EFFECT OF CAFFEINE ON SOCIAL BEHAVIOR, EXPLORATION AND MOTOR ACTIVITY: INTERACTION WITH ETHANOL. L.A. Hilakivi, M.J. Durcan and R.G. Lister. Lab. Clin. Stud., NIAAA, DICBR, 9000 Rockville Pike, Bethesda, MD 20892, USA.

The present study examined caffeine's effects in NIH Swiss mice in a test of social behavior and in a holeboard test of exploration and locomotor activity. The interaction of caffeine with ethanol was also investigated. In experiment 1, singly-housed mice were injected i.p. with 0, 15, 30 or 60 mg/kg caffeine and put in pairs into a familiar arena for 7.5 min during which their social behavior was studied. Moreover, group-housed mice were individually tested for 8 min in a holeboard apparatus, with which they were unfamiliar, following similar treatments. Caffeine did not significantly affect the time spent in social interaction (sniffing, following). Motor activity in the social behavior test was increased by 60 mg/kg caffeine ($p<.05$). Caffeine had a biphasic effect on the time spent in aggressive behavior (tail rattling, biting, fighting): 15 mg/kg significantly increased aggression ($p<.02$) and 60 mg/kg decreased it ($p<.03$). The time spent in avoidance-irritability behavior (withdrawing, shrieking, startling) was dose-dependently reduced ($p<.001$). In the holeboard, a dose-related increase in locomotor activity by caffeine was seen ($p<.05$), but there were no significant changes in the time spent head-dipping. In experiment 2, caffeine was given in combination with 0 or 2.0 g/kg ethanol prior to the social behavior and holeboard tests. 30 mg/kg caffeine partly reversed the ethanol-induced reduction in social interaction ($p<.05$), and 60 mg/kg caffeine reversed the ethanol induced increase in locomotor activity, both in the social behavior test ($p<.01$) and in the holeboard test ($p<.01$). Since only the highest dose of caffeine reversed the locomotor stimulant effect of ethanol, this antagonism may be mediated by a non-adenosinergic mechanism.

91.2

AN ANALYSIS OF THE STIMULANT AND HALLUCINOGENIC PROPERTIES OF (+) OR (-) 3,4-METHYLENEDIOXYAMPHETAMINE (MDA). J. Broadbent and J. B. Appel. *Behavioral Pharmacology Lab., Dept. Psychology, University of South Carolina, Columbia, SC 29208 USA.*

Drug discrimination studies (in animals) suggest that one reason for the continuing abuse of MDA may be the similarity of the subjective effects of the (+) and (-) isomers of this amphetamine derivative to those of stimulant and hallucinogenic compounds, respectively. This possibility was examined further in two groups of rats trained to discriminate (+) or (-) MDA (1.25 mg/kg) from saline (N=16/group). The notion that the different isomers of MDA have different stimulus properties was supported to some extent by findings that (+) MDA partially generalizes to both *d*-amphetamine and cocaine while (-) MDA may generalize to mescaline and *d*-LSD. However, the two enantiomers were also found to cross generalize; this suggests that the stimulus properties of MDA must be more complex than previously indicated and that further analysis of the substitution of hallucinogens for (+) MDA and stimulants for (-) MDA is needed.

91.3

DEVELOPMENTAL CHANGES IN OPIATE ANALGESIA IN DEER MICE: SEX AND POPULATION DIFFERENCES. D. G. Innes and M. Kavaliers (SPON: F. S. Tepperman). Div. Oral Biology, Univ. Western Ontario, London, Ontario, Canada.

There is evidence for developmental changes in nociception and opiate-induced analgesia. It has also been shown that there are sex and population differences in nociceptive sensitivity and analgesia. Whether or not sex and population differences exist during the development of opiate analgesia is, however, not clear. Accordingly, in the present study we describe developmental changes in nociception and opiate-induced analgesia in two different populations of male and female deer mice: Peromyscus maniculatus artemisiae from a mainland region and P. m. angustus from small coastal islands. Throughout the course of development (10- 30 days of age) males displayed significantly greater nociceptive responses and levels of mu (morphine) and kappa (U-50,488) opiate-induced analgesia than females. In both sexes there were similar significant differences between the rates of development of mu and kappa opiate analgesia. In addition, throughout the course of development the male and female insular mice displayed significantly greater morphine (mu) and significantly lower U-50,488 (kappa) induced analgesia than the mainland animals. In all cases, maximum sex differences in analgesia were evident at weaning (18- 20 days of age) before sexual maturity was attained.

ANALGESIC SUBSTITUTED AMPHETAMINES. J. M. Beaton, F. Benington*, R. D. Morin*, M. A. Khaled* and J. A. Monti. Neuropsychiatry Research Program and Department of Psychiatry, University Station, Birmingham, Alabama 35294, U.S.A.

We have previously shown that two amphetamine analogues, the alpha-methyl and alpha-ethyl derivatives of methylenedioxymethamphetamine, have potent analgesic properties. We believe that the analgesic action of these agents is due in part to their substituents in the para position. Therefore, a series of amphetamine analogues, substituted in the para position were synthesized and tested for their ability to induce analgesia in mice. The compounds tested were 4-hydroxy-amphetamine (4-HO-AMP), 4-methoxy-AMP (4-MeO-AMP), 4-HO-2,6-dimethyl-AMP, 4-MeO-2,6-dimethyl-AMP and the N-methyl derivatives of four compounds. Analgesia was measured with a tail-flick apparatus. Dose response curves were obtained using groups of five mice for each dose. The doses ranged from 0.75 to 24 μ mol/kg. The animals were tested at 30 min intervals, beginning 30 min after intraperitoneal administration of the compounds in a volume of 0.1 ml/10g. Testing continued until each animal's response time had returned to preinjection control levels. All compounds showed analgesia. In general, the N-methylated compounds were less potent than the nonmethylated equivalent compounds. It is hypothesized that the mode of action of the analgesia is via the mu opiate receptor.
(Supported in part by the Alabama Consumer Research Fund).

EFFECTS OF INTRACEREBROVENTRICULAR (ICV) INJECTIONS OF MORPHINE IN THE HAMSTER. P. Schnur, C. Archuletta* and R. Martinez*. Department of Psychology, University of Southern Colorado, Pueblo, CO 81001.

Subcutaneous (SC) injections of morphine in hamsters produce hyperactivity at low doses and hypoactivity at high doses. Across a range of doses, hypoactivity is followed by recovery and then by hyperactivity. Both effects are naloxone reversible. The present work studied the effects of ICV administration of morphine on locomotor activity in the hamster. In Experiment 1, six doses of morphine were tested (0, 0.5, 2.5, 5, 25 & 50 ug) in a 3 hr test session. Results indicated that the three lowest doses of morphine elicited transient hyperactivity. The higher doses elicited dose-related hypoactivity but no hyperactivity. In Experiment 2, ICV morphine (0, 30 ug) and naloxone (0,1,3,10,30 ug) were administered. Morphine produced hypoactivity but no hyperactivity. Naloxone antagonized morphine-elicited hypoactivity in a dose-dependent manner. Low doses of naloxone (1 & 3 ug) blocked morphine-elicited hypoactivity, though incompletely. High doses of naloxone (10 & 30 ug) not only blocked morphine-elicited hypoactivity but produced hyperactivity in its place. Results are compared to those following SC injections of morphine and naloxone.

AMPHETAMINE INJECTED REPEATEDLY INTO THE VTA OR THE N. ACCUMBENS DOES NOT PRODUCE ENVIRONMENT-SPECIFIC SENSITIZATION OR CONDITIONING OF ITS LOCOMOTOR ACTIVATING EFFECTS. P. Vezina and J. Stewart. C.S.B.N., Dept. of Psychology, Concordia University, Montreal, Canada, H3G 1M8.

Recently, it was shown that repeated injections of amphetamine into the ventral tegmental area (VTA) but not the n. accumbens (NAC) produce a sensitized locomotor response to a subsequent systemic injection of amphetamine or morphine (Kalivas and Weber, Neurosci. Abst.,13: 600, 1987). In the present experiments, the role of amphetamine action in these two sites in the development of environment-specific sensitization and conditioning of the locomotor activating effects of amphetamine was investigated. During training, groups of rats received bilateral injections of amphetamine (2.5 µg/0.5µl saline/side) either into the VTA or the NAC prior to being placed in activity boxes and saline (0.5 µl/side) in their home cages (COND, conditioning groups), saline in the activity boxes and amphetamine in their home cages (PSEUDO, pseudoconditioning groups), or saline in both environments (Control groups). On a subsequent test with morphine (1.0 mg/kg, i.p.), only rats that had received intra-VTA amphetamine showed activity levels that were higher than those of Control animals, replicating the above findings. Further, this sensitized response was evident in both the intra-VTA COND and PSEUDO groups, suggesting that amphetamine action in the VTA is not sufficient to produce environment-specific sensitization. On a separate test with saline, no evidence for conditioned activity was found in either the intra-VTA or the intra-NAC groups. These findings, together with others demonstrating that conditioned activity is produced by intra-VTA morphine, suggest that the action of released DA at other mesocorticolimbic DA neuron terminals may be necessary to produce conditioning.

91.7

EXTINCTION TRAINING DEMONSTRATES THAT DIFFERENT MECHANISMS UNDERLIE THE STIMULUS CONTROL OF THE EXPRESSION OF ENVIRONMENT-SPECIFIC BEHAVIORAL SENSITIZATION PRODUCED BY MORPHINE OR AMPHETAMINE. J. Stewart and P. Vezina. Center for Studies in Behavioral Neurobiology, Dept. of Psychology, Concordia University, Montreal, Canada, H3G 1M8.

The effect of extinction training on previously established environment-specific sensitization of the locomotor activating effects of either d-amphetamine sulfate (1.0 mg/kg) or morphine sulfate (10.0 mk/kg) was compared in two experiments designed to investigate the relation between sensitization and conditioning. During training, groups of animals were administered drug, i.p., prior to being placed in activity boxes, and saline in their home cages (COND, conditioning, groups), drug in their home cages, and saline in the activity boxes (PSEUDO, pseudoconditioning groups), or saline in both environments (Control groups). Evidence for conditioning and environment-specific sensitization was found in both experiments in tests given following training during which all animals were administered saline or drug, respectively. By the last trial of extinction training, during which all animals had received only saline injections and were repeatedly tested in the activity boxes, no behavioral differences between groups were evident. In a final test for environment-specific sensitization given after extinction, it was found that, in morphine-treated animals, behavioral sensitization was still evident in the COND group, but that the PSEUDO group was not different from the Control group, a finding that suggests that the drug reinstated the excitatory control of sensitization by the environmental stimuli. In amphetamine-treated animals, however, behavioral sensitization was evident in both COND and PSEUDO groups following extinction, suggesting that, prior to extinction, the expression of sensitization in the PSEUDO group was under inhibitory control.

91.8

ASSESSING COMPLEXITY OF RAT LOCOMOTOR BEHAVIOR USING INVARIANT MEASURES FROM ERGODIC THEORY. M.P. Paulus*, M.A. Geyer, L.H. Gold and A.J. Mandell. Laboratory of Biological Dynamics & Theoretical Medicine. UCSD Sch. of Med., La Jolla, CA 92093.

The study of complex systems suggests that the understanding of complicated behavior may be facilitated by calculating measures that characterize the amount of information produced per time unit. Ergodic theory provides measures that are invariant under coordinate transformations, e.g. metric and topological entropy, fractal dimensions, and characteristic exponents. In an experimental setting they can be estimated using symbolic dynamics, which transforms a trajectory of a discrete time series into symbol sequences through a "meaningful" partition that can be fixed by the experimenter or generated dynamically according to the result of the recorded trajectory using a "kd-tree". The dynamics are characterized by a shift operating on the sequences, which can be represented as a topological Markov chain. The (largest) Perron Frobenius eigenvalue, spectral decomposition, and the number of periodic orbits approximated by an appropriate zeta function yield information about the underlying dynamical process. Groups of animals that were treated with stimulant drugs (Amphetamine, MDMA, Apomorphine, Scopolamine) and exhibited comparable increases in locomotor activity (photobeam breaks) were analyzed using an individual dynamical partition of the 4-dimensional x-y-t-behavior space. The resultant symbol sequences were analyzed to obtain their mutual information content, the metric and topological entropy. The results indicate that ergodic measures reveal differences in the nature of the hyperactivity elicited by the various drugs studied and emphasizes the value of these techniques to characterize trajectories generated by complex time series.

91.9

MULTIVARIATE BEHAVIORAL ANALYSIS OF AMPHETAMINE (AMPH) CONDITIONED LOCOMOTION. L.H. Gold, G.F. Koob and M.A. Geyer. Research Institute of Scripps Clinic and UCSD Dept. of Psychiatry, La Jolla, CA 92037.

Conditioned locomotion in rats was examined with a computerized Behavioral Pattern Monitor (BPM), a system which provides detailed information regarding amount and qualitative patterning of locomotor activity and investigatory responses. Each BPM chamber consists of a 30.5 x 61 cm black Plexiglas holeboard with a 4 x 8 array of infrared beams to define the X-Y position of the rat and 3 floor holes, 7 wall holes and rearing touchplate to record various facets of exploratory behavior.

Rats were divided into 2 groups and injected SC with saline or 0.75 mg/kg AMPH immediately prior to placement in the BPM chambers for a 2h experimental session. A small dish of peanut butter was placed underneath each chamber to enhance the saliency of the testing environment. Following each conditioning session, rats were returned to their home cages and injected with the alternate solution. Conditioning training lasted 5 days and on the 6th day all rats were injected with saline prior to placement in the BPM. Rats who had been previously injected with AMPH in the BPM exhibited significant increases in horizontal locomotion, rearing and investigatory holepokes on the test day. X-Y plots and statistical measures of the rats' locomotor paths were used to further characterize the nature of the unconditioned (UCR) and conditioned (CR) responses. Such descriptive measures of spatial and temporal patterning of behavior may help to determine whether the increase in motor activity measured on the test day is a CR which resembles the UCR or rather a generalized excitement reflective of cued anticipation of a reinforcing drug.

91.10

PLACE CONDITIONING WITH d-AMPHETAMINE: EVIDENCE OF AN AVERSION. A-M. Wall, R.E. Hinson and A. Streather. Dept. of Psychology, Univ. of Western Ontario, London, Ontario, Canada, N6A 5C2.

In Experiment 1 a dose-response study of place conditioning was conducted. Male, Sprague-Dawley rats receiving one of 0.0, 0.05, 0.1, 0.5, 2.0, 5.0, 7.5, or 10.0 mg/kg of d-amphetamine underwent ten four-day cycles of standard place conditioning. On alternate days, each rat was injected with its designated dose of d-amphetamine while confined to its originally non-preferred end of a three compartment, straight alley-box. On intervening days each rat was injected with saline while confined to its originally preferred compartment. Following each four-day cycle, a choice test was administered in which each rat was allowed 20 minutes access to the entire chamber. Contrary to previous research, no evidence of a preference was found. In fact, doses of amphetamine $\geq$ 0.5 mg/kg induced a significant avoidance of the end in which amphetamine had been administered. In Experiment 2, animals received one of 0.0, 0.5, 2.0 or 5.0 mg/kg of amphetamine and underwent place conditioning procedures identical to animals in Experiment 1. In contrast to Experiment 1, animals were given a single choice test following ten four-day place conditioning cycles. All groups that received amphetamine exhibited a conditioned place avoidance. The observed amphetamine-induced place avoidances may have been due to inhibitory conditioning.

91.11

THE EFFECTS OF ANTIHISTAMINES ON AMPHETAMINE-INDUCED STEREOTYPY. F.Jordan-Palylyk and Ann Robertson. Dept. of Psychology, Univ. of Alta., Edmonton, AB T6G 2M7

It has been suggested that histamine interacts with dopamine (DA) in controlling some behaviors. For example, the H_1 antagonist diphenhydramine reversed haloperidol-induced suppression of self-stimulation (Carey,R.,Pharm.Bio.Behav., 17:851,1982). The present study investigated the DA-histaminic interaction more directly by studying the effects of 2 H_1 antagonists, diphenhydramine HCl (DP) and tripelennamine HCl (TP) on amphetamine-induced (A-I) behaviors in 32 Sprague-Dawley male rats. Different groups of rats received DP (0.0, 1.6, 4.0 or 10.0 mg/kg, IP) or TP (0.0, 5.0 or 10.0 mg/kg IP). All rats were then injected with amphetamine (0.0, 0.5, 1.0, 2.5 and 5.0 mg/kg IP). Behavioral observations were taken for 1 hour. At 2.5 mg/kg amphetamine, stereotyped sniffing and head movements were increased 59% by 1.6 mg/kg DP, 112% by 4.0 mg/kg, and 160% by 10.0 mg/kg. Concomitantly, A-I rearing was dose-dependently decreased. DP alone did not alter behavior, nor did it alter other A-I behaviors. TP had no significant effect on any A-I behaviors. DP's facilitation of A-I stereotypy can be interpreted as evidence for a DA-histaminic interaction;however, the differential actions of DP and TP suggest that DP's effect on A-I stereotypy is not necessarily due to its antihistaminic properties. DP's actions may be due to moderate anticholinergic activity (Kubo et al,Jpn.J.Pharm., 43:277,1987),although DP does not alter scopolamine's behavioral effects (Sansone et al,Psychopharm.,93:155,1987).

SOMATOSENSORY CORTEX I

92.1

LOCAL CONNECTIONS IN MOUSE BARREL CORTEX. K.L. Bernardo*, J.S. McCasland, T.A. Woolsey and R.N. Strominger*. Dept. Neurosurg., Div. Exp. Neurol. & Neurosurg. and McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

We targeted focal extracellular HRP injections into barrel cortex, in vitro, in order to demonstrate the distribution patterns of labeled cells projecting to the labeled site. The distribution of label in the tangentially sectioned hemispheres, with respect to the cortical barrel field, was mapped in one or two ways: 1). A Grinnell image processor with a video camera, connected to a Zeiss computer microscope equipped with a motorized stage, was used to reconstruct regional stain densities from tissue sections. 2). The x,y and z coordinates of individual cells in each section were determined with an Eutectics system.

Results have been analyzed for hemipheres in which the labeling site was confined to supragranular layers (i.e., layers II,III) within barrel cortex. The majority of labeled cells in all cortical layers are related to barrels in the same row as that which was injected. As compared to layer IV, labeled cells tend to be distributed more widely within the supra and infragranular layers. These trends hold true for injections confined to individual barrels, as well as for injections placed between barrels. We conclude that interbarrel connections are most numerous within the same barrel row. This "row tendency" is consistent with and a basis for functional organization of rodent somatosensory cortex.

92.2

BASIC RULES GOVERNING THE SYNAPTIC ORGANIZATION OF THE CEREBRAL CORTEX. E. L. White, A. Keller and E. El-Hanany*. Dept. of Morphology, Ben Gurion Univ. Sch. Med., Beer Sheva, Israel.

Investigations on the quantitative aspects of synapses between identified pre- and postsynaptic elements in mouse SmI cortex has provided the basis for the formulation of a set of rules governing cortical synaptic relationships: Rule 1: Every neuron within the target region of a projection receives input from the projection. Corollary to Rule 1: Axon terminals from any extrinsic or intrinsic source synapse onto every morphological or physiological neuronal type within their terminal projection field. In practice this means that a pathway will form synapses with every element in its target region capable of forming the type of synapse normally made by the pathway (i.e., asymmetrical or symmetrical). Rule 2: Different dendrites of a single neuron form similar synaptic patterns, i.e., the numbers, types, proportions and spatial distribution of synapses is similar, provided the dendrites are exposed to similar synaptic inputs. Corollary to Rule 2: Axonal pathways form similar synaptic patterns onto all the dendrites of a single neuron provided the dendrites occur within the target region of the axonal pathway. Rule 3: Neuronal types receive characteristic patterns of synaptic connections; the actual numbers, proportions and spatial distribution of the synapses formed by each neuronal type occur within a range of values. Corollary to Rule 3: Different extrinsic and intrinsic synaptic pathways form specific proportions of their synapses with different postsynaptic elements (spines vs. dendrites, one cell type vs. another). Comparisons with data from other studies suggest these rules can be used to predict synaptic relations in all areas of the cortex and in all species. Supported by NIH grant NS20149-05.

92.3

SOMATOTOPIC ORGANIZATION AND THALAMIC CONNECTIONS OF THE SECOND SOMATOSENSORY AREA, S-II, IN SQUIRREL MONKEYS. C.G. Cusick and M.M. Manning. Dept. of Anatomy, Tulane Univ., New Orleans, LA 70112.

The location and somatotopic organization of the second somatosensory area was studied using microelectrode mapping techniques in five squirrel monkeys anesthetized with ketamine hydrochloride. S-II was found on the upper bank of the lateral sulcus, and responded predominantly to low threshold stimuli on the contralateral body surface. Receptive fields were typically larger than in area 3b. For example, receptive fields on the hand sometimes included large areas of the palm and the entire glabrous surface of two or more fingers. Within the hand area in S-II, the palm was represented mainly caudally and the digits rostrally. Ulnar surfaces tended to be more deeply placed in the sulcus than radial surfaces. The representation of the teeth and tongue in S-II was rostral to that of the hand. The foot area in S-II adjoined the hand caudally, and was more deeply placed in the sulcus. A representation of the trunk and limbs was found deep to the hand and foot regions.

WGA-HRP was injected into physiologically identified hand and mouth representations in S-II. Labeled cells and terminations were identified in the ventroposterior inferior nucleus, and less dense in the ventroposterior nucleus proper, posterior nucleus, and anterior pulvinar. Supported by NIH Grant DE07695.

92.4

SPATIAL ORGANIZATION OF CORTICOTHALAMIC CELLS IN THE RAT SmI VIBRISSA/BARREL CORTEX. J. Chmielowska*, G.E. Carvell* and D.J. Simons. Depts. of Physiology and Physical Therapy, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Horseradish peroxidase (HRP) was used to examine the distribution of corticothalamic projection cells in the whisker representation of the SmI cortex. Under physiological control using double-barreled pipettes, HRP was iontophoretically deposited in the vibrissa area of the thalamic ventrobasal complex (VB) of normal adult rats. Labeling in the cortex had a columnar appearance. Dense patches of anterogradely labeled axons formed a barrel-like pattern in lower layer III and layer IV; supragranular labeling was densest and extended most superficially, to laminae I/II, over the center of the barrel. Retrogradely labeled neurons were observed in lower layer V and layer VI. Their density/area was $\sim$1.5X greater in the regions deep to the barrels than in the regions below the interbarrel septa. Extensive axonal ramifications were not observed in upper layer V, suggesting that if axon collaterals of corticothalamic cells were labeled, these terminated locally and/or superficially in the thalamic recipient zone. The vibrissal column thus appears to contain a core zone that is intimately associated with the thalamic barreloids. Supported by NIH NS 19950.

92.5

VELOCITY-DEPENDENT RESPONSE PROPERTIES OF NEURONS IN LAYERS II-IV OF THE CAT PRIMARY SOMATOSENSORY (SI) CORTEX. J.D. Greenspan. Dept. of Physiology and Dental Research Center, Univ. of North Carolina, Chapel Hill, NC 27514.

Many SI cortical neurons are responsive to surface-parallel movements across the skin's surface. Some of these movement sensitive units generate greater responses with certain parameters of stimulation than with others. In this study, single-unit recordings were made in the cat SI cortex, while cutaneous, brushing stimuli of various velocities and directions were presented.

Units recorded in layer IV gave regular, excitatory responses to brushing stimuli, while units recorded in layers II-III gave simple excitatory responses, excitatory responses followed by post-stimulus inhibition, or inhibitory responses. Units could be classified as rapid brush, slow brush, or very slow brush, based on the stimulus velocity that produced the greatest response. Rapid brush units, commonly encountered in layer IV, gave greater responses to stimuli ≥10cm/s, and little or no response to stimuli ≤1cm/s. Slow brush units, commonly encountered in layers II-III, gave reliable responses to stimuli 0.5-1.0cm/s, greater responses at 5-10cm/s, and little or no response to stimuli 50-100cm/s. Very slow brush units did not respond to stimuli ≥10cm/s, and gave greater responses to stimuli at 1cm/s than at 5cm/s. (Supported by NIH grant NS-20159).

92.6

PROJECTIONS FROM SIV AND ADJACENT CORTEX TO PRIMARY SENSORY AREAS IN THE CAT. D. Minciacchi*, A. Granato*, A. Antonini*, G. Tassinari* and L. Zanolli*. (SPON: European Brain and Behavior Society). Inst. of Neurology and Anatomy, Catholic Univ., Rome and Inst. of Physiology, Univ. of Verona, Italy.

We have previously described the lack of topographical organization in the visual and somatosensory representations of the cat's anterior ectosylvian sulcal cortex (AES) (Minciacchi, D. et al., Brain Res. 410: 21, 1987). The present study was aimed at analyzing the anatomical organization of AES efferents to primary sensory cortices. A multiple retrograde tracing technique was here employed. Four different fluorescent tracers were injected under electrophysiological control in four cortical regions: the face (SIfa) and forepaw (SIfp) representation fields of the first somatic sensory area, the vertical meridian (V1vm) and periphery (V1pe) representations of the first visual area.

SI projecting cells were observed throughout AES: SIfa neurons were more numerous in the rostral part of AES and SIfp neurons were preferentially located in its caudal part. In the rostral part of AES SIfa cells were segregated in the dorsal bank of the sulcus while SIfp cells were placed in the ventral bank. In the caudal part of AES labeled cells were observed almost exclusively in the dorsal bank of the sulcus in which SIfa and SIfp neurons were located respectively in its outer and inner part. Neurons projecting simultaneously to SIfa and SIfp by means of axonal branches were extremely rare. Scattered neurons were labeled from the V1 injections thus confirming the weakness of AES projections to V1.

The present evidence of a clear topography in the AES projections to SI is in contrast with the lack of topographical organization of both somatosensory and visual representations in this area. These data suggest that AES is a high order associative area in which the processing of multisensory informations requires a strict topographic interrelation with SI.

92.7

SII IN NEW WORLD MONKEYS DEPENDS UPON INPUTS FROM SI FOR ITS ACTIVATION. P.E. Garraghty, T.P. Pons, and J.H. Kaas. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

Cortical somatosensory areas SI and SII do not have the same relationship to each other and the thalamus in all mammals. Most notably, these two cortical areas are independently activated by thalamic inputs in cats (Burton et al., Neurosci. Abstr., 13:75, 1987), but are arranged hierarchically with SII depending on SI for its activation in Old World monkeys (Pons et al., Science, 237:417, 1987). This difference in dependence on thalamic or cortical inputs of a presumably homologous area led us to study the relationship of SI and SII in two species of New World monkeys, marmosets and owl monkeys. During our experiments, we first mapped SII cortex, and then demarcated the extent of the representation of a particular body part (e.g., the hand) in area 3b and adjacent parts of areas 3a, 1, and 2), which we then lesioned by aspiration. We then immediately remapped SII. Since we had recorded the locations of recording sites from our first map on a photograph of the brain, we were able to relatively precisely reposition the electrode to sample the same cortex. We found that the part of SII which had initially been responsive to stimulation of the body surface whose representation was lesioned in SI was now silent. This effect was not due to a general depression of cortex since parts of SII cortex adjacent to the silent zone could be activated, as could parts of SI cortex within 100 μm of the lesion.(Supported by NS16446.)

92.8

THALAMUS-EVOKED SYNAPTIC RESPONSES OF INHIBITORY INTERNEURONS OF MOUSE SMI (BARREL) CORTEX IN VITRO A.Agmon and B.W.Connors, Neurology Dept., Stanford Univ. Sch. of Med., Stanford, CA 94305 and Brown Univ., Providence, RI 02912.

Using our previously described thalamocortical slice preparation (Soc. Neurosc. Abstr. 13:247, 1987) we have extended our survey of intrinsic firing properties and VB-evoked synaptic responses in mouse barrel cortex neurons. As described, responsive regular-spiking (pyramidal) neurons were encountered in all cellular layers and were usually strongly inhibited at a disynaptic latency. In about half of these cells the IPSP was preceded by a monosynaptic EPSP which was seldom strong enough to fire the cell. In contrast, fast-spiking neurons were encountered mainly in layers IV and the V/VI border, which are known to be the thalamocortical afferents' termination layers. Consistent with their position, they were ususally strongly excited at a monosynaptic latency and would fire upon VB stimulation when their membrane potential was held close to threshold. Fast-spiking neurons are believed to be GABAergic interneurons. We conclude that inhibitory interneurons are major recipients of thalamocortical input and serve an important role in sensory information processing in the neocortex.

92.9

CALLOSAL CONNECTIONS IN THE FORELIMB ZONE OF SII AND SIV IN CATS. P. Barbaresi, S. Bernardi, T. Manzoni. Institute. of Human Physiology, University of Ancona, Ancona (Italy).

HRP and microelectrode recording techniques were used to study in the cat the callosal connections in the forelimb zones of SII and SIV. Tracer was injected in electrophysiologically identified sites of SII or SIV body map. Subsequently, receptive fields of neurons in the homologous area of the contralateral side were mapped with microelectrodes. The topographical distribution of HRP labelled callosal neurons in relation to the body representation was studied on planar cortical maps reconstructed with a computer from TMB-processed serial sections cut from the anterior ectosylvian gyrus. Callosal neurons were present in the digit, hand and arm zones of SII but they were unevenly distributed: each zone contained randomly distributed sub-zones in which callosal neurons were either numerous or rare. In callosal and relatively acallosal sub-zones receptive fields were similar. In SIV callosal neurons were distributed homogeneously throughout the forelimb zone. Labelled neurons of heterotopical callosal afferents to SII and SIV were in SI and in a cortical region lying in the lower and upper banks of the anterior suprasylvian sulcus.

INTRACORTICAL MICROSTIMULATION IN SOMATOSENSORY CORTEX IN ADULT RATS AND OWL MONKEYS RESULTS IN A LARGE EXPANSION OF THE CORTICAL ZONE OF REPRESENTATION OF A SPECIFIC CORTICAL RECEPTIVE FIELD. G.H. RECANZONE* and M.M. MERZENICH, Coleman Laboratory, Departments of Physiology and Otolaryngology, Univ. of CA, San Francisco, S.F., CA 94143

Intracortical microstimulation (ICMS) has been commonly used in experiments defining movement representations in motor cortex. It has recently been demonstrated that ICMS can itself alter movement representations in the motor cortex of adult rats (Nudo, R.J. and Merzenich, M.M., *Soc. Nsci. Abstr.*, 1987; also see Brown and Sherrington, *Proc. Roy Soc. B* 85, 1912). In the present study, we investigated the consequences of localized ICMS within the body surface representation of the somatosensory koniocortical field in rats (SM1) and owl monkeys (area 3b).

Primary somatosensory cortex was exposed in Nembutal-anesthetized animals. Multi-unit cutaneous receptive fields were carefully defined with fine-tipped glass probes or von Frey hairs using glass micropipettes introduced at multiple sites in very fine grain within a limited sector of this cortical field. A stimulating microelectrode was then placed in the center of this cortical zone to a depth of 700-850μm. Charge-balanced monophasic pulses were delivered for up to 6 hrs. (3-7μA, 200 μsec pulses, 300pps bursts for 40 msec delivered 1/sec). At variable post-stimulation times, receptive fields were defined throughout the same cortical zone, and in many cases at the identical cortical sites.

Among the results were the following: 1) The specific receptive field defined at the stimulation site came to be represented at many penetration sites up to more than 600μm away from the stimulation location. 2) This expansion progressed throughout the course of stimulation. 3) Driven activity at the stimulation site was reduced during the stimulation period, but recovered following the stimulation period.

These results support the hypothesis that input coincidence plays an important role in cortical "functional minicolumn" formation and demonstrate that cortical neurons can select a new subset of driving inputs over a short time course.

VASCULAR PATTERNS IN MOUSE AND RAT BARREL CORTEX. T.A. Woolsey, J. Christensen*, N. Hunt*, R. Kohn*, J. Matter* and R. Strominger* (SPON: W. Landau). Division of Experimental Neurology & Neurosurgery and McDonnell Center for Studies of Higher Brain Function and A.D.R.C., Washington University School of Medicine, St. Louis, MO 63110.

The angioarchitecture of the brain is as distinctive as its neuronal architecture. There are brain region specific patterns of blood vessels. Patel (Brain Res., **289**:65-70, 1983) showed a relationship between capillary density and the whisker barrels in the rat by careful reconstruction from semithin sections of rat cerebral cortex. We have extended these observations with a variety of vascular and neuronal marking techniques. All approaches show patterns of capillary networks which are specific for individual barrels in layer IV of the rodent somatosensory cortex. This relationship is being quantified and a number of different images will be shown. The barrel specific capillary networks suggest a closer relationship between the development of functional neuronal groups and their vascular supply than previously suspected. The somatosensory cortex of the rodent offers an especially favorable site to study the relationship between the dynamic properties of functional groups of neurons and their blood supply. 92.12

METABOLIC PLASTICITY FOLLOWING NEONATAL CORTICAL BARREL-FIELD INFARCTION. W.D. Dietrich, O. Alonso, R. Busto*, B.D. Watson*, and M.D. Ginsberg. Cerebral Vascular Disease Research Center, Department of Neurology, University of Miami, School of Medicine, Miami, FL, 33101.

Abnormal metabolic patterns of cortical field activation induced by whisker stimulation are observed in adult rats after chronic cortical barrel-field (BF) infarction (Dietrich et al, Soc. Neurosci. Abstr., 12:1168, 1986). To characterize the metabolic consequences of brain infarction in the immature brain, 20-day old male Wistar rats (n=7) underwent photochemically-induced BF infarction of the right SmI cortex. 60 days later, patterns of activation-induced increased glucose utilization were assessed with quanitative ^{14}C-2-deoxyglucose autoradiography. Unilateral whisker stimulation activated contralateral cortical regions anterior and lateral to the BF infarct. Lateral to the infarct, a single region of stimulation-induced increased glucose utilization (162% of control) was apparent, which extended more laterally than the normal SmII BF region. Subcortically, depressed rates of glucose utilization were documented within several thalamic nuclei underlying the infarcted zone. A decreased capacity to activate the contralateral ventrobasal thalamus in response to whisker stimulation was demonstrated. Ipsilateral to whisker stimulation, abnormal patch-like aggregates of increased glucose utilization (161% of control) within somatosensory cortex were detected. Thalamic nuclei (Posterior, Lateroposterior) also demonstrated abnormal metabolic responses to whisker stimulation (159% of control). Although similar patterns of stimulation-induced increased glucose utilization are observed following either neonatal or adult BF infarction, abnormal patterns are more pronounced following neonatal BF infarction. Supported in part by NIH grant NS05820; WDD is an Established Investigator of the AHA.

92.13

BARREL-FIELD CIRCUIT ACTIVATION IN THE NEONATAL RAT. O. Alonso, W.D. Dietrich, R. Busto*, and M.D. Ginsberg. Cerebral Vascular Disease Research Center, Department of Neurology, University of Miami, School of Medicine, Miami, FL, 33101.

In adult rats, unilateral whisker stimulation combined with ^{14}C-2-deoxyglucose autoradiography results in the metabolic activation of the major relay stations of the whisker-barrel circuit. This study was designed to document the metabolic activation patterns in rats ranging from 20-23 days of age. Male Wistar rats were briefly anesthetized with halothane and restrained in a plaster body cast. In 7 rats, all the large whiskers on one side of the face were stroked 2-3 times/sec with a brush for 5 min before and 40 min following a pluse injection of 2DG. In nonactivated rats (n=8), local cerebral metabolic rate of glucose (lCMRglu) was significantly depressed in most grey matter regions compared to values obtained in nonactivated adults (4 months). Unilateral whisker stimulation resulted in highly-focal regions of increased glucose utilization occupying the BF regions of contralateral SmI and SmII. Percentage difference between activated and nonactivated BFs was 124% in neonates compared to 36% in young adults. In addition to these focal alterations in lCMRglu, widespread elevations in lCMRglu were detected in brain regions outside the BF circuit. For example, within the ipsilateral frontal cortex, whisker stimulation increased lCMRglu by 42% over nonactivated values. In contrast, widespread metabolic consequences were not detected in activated young adults. These metabolic consequences to the physiological activation of this well-defined somatosensory circuit in the neonatal rat are consistent with a lack of inhibition at this stage of neuronal development. Supported in part by NIH grant NS05820; WDD is an Established Investigator of the AHA.

92.14

THE DEVELOPMENT AND TOPOGRAPHIC ORGANIZATION OF THE SOMATOSENSORY CORTICES OF THE NEONATAL PIG. R.H. Ray and S.L. Craner.* Dept. of Physiology, East Carolina University, Greenville, N.C. 27858

The perinatal ontogenesis of electrical activity and the topographic organization of the somatosensory cortices was determined in domestic pigs ranging in age from 7 days preterm to 60 days postnatal. Somatosensory evoked potentials (SEPs) and single and multiunit activity were used to determine 1) the details of the topographical representation in primary (SI) and secondary (SII) somatosensory areas and 2) whether SI and SII show evidence of differing rates of functional maturation. Standard histological techniques were used to examine the cytoarchitectural development of the somatosensory cortices in animals across all age groups. Complete topographical representations of SI and SII were present in all animals studied, including piglets 7 days preterm. The body map in SI was oriented similarly to that of other mammals, however, multiple representations of the rostrum, face and mouth were present including a separate ipsilateral face representation. The pig SII cortex had a "strip-like" orientation of the limb representations and an inverted trunk orientation. Multiple face regions were also found in SII. Response properties, including waveforms, latencies, and frequency-following capacities of SEPs, suggested that functionally the pig SI matures more rapidly than SII. Cytoarchitectural studies supported this conclusion.

CELLULAR AND MOLECULAR SUBSTRATES FOR CRITICAL PERIOD-DEPENDENT ALTERATIONS IN SOMATOTOPY. N. G. F. Cooper and D. A. Steindler. Dept. of Anatomy and Neurobiology, University of Tennessee, Memphis, TN 38163.

The somatosensory barrel field cortex of mice contains a distinctive neuronal pattern that can be observed in Nissl-stained sections. The cell aggregates of layer IV neurons are the cortical representations of vibrissae present in the face, and the pattern of cell aggregates mirrors the pattern of vibrissae. Pertubation of vibrissae and their underlying nerve fibers in early postnatal animals leads to the development of altered patterns of Nissl-stained cell aggregates seen in the cortex. On the other hand, pertubation of vibrissae at later times does not lead to such changes. Presumably the substrates, necessary for the neuronal rearrangements are only present in the first postnatal week. In this study, the middle rows of vibrissae were cauterized in anesthetized neonatal animals. The animals were anesthetized several days later and cardiac perfused with aldehyde fixative. Sections of the cerebral cortex were cut on a vibratome and washed with a tris-buffered saline (TBS) and incubated in the peroxidase conjugated lectin, peanut agglutinin, which binds to the galactosyl carbohydrate residues of glycoconjugates. After incubation in the lectin-conjugate, sections were washed in TBS and reacted with hydrogen peroxide in the presence of the chromogen, diaminobenzidine. The distribution of peroxidase reaction product in sections was observed with a light microscope and compared to control sections of somatosensory cortex from animals that had no cautery treatment. The data demonstrates that cauterization of vibrissae leads to altered lectin- binding patterns in the cortex. Specifically, carbohydrate-rich boundaries between individual barrels in rows that represent the cauterized vibrissae were missing. It is suggested that the lectin-positive boundary regions contain molecules that help move the neurons into their characteristic patterns. Interactions between afferents and glial-rich boundaries (Cooper and Steindler,Brain Res., 380:341,1986) are responsible for shaping neuronal cytoarchitecture.The transient boundary regions it is argued, form the basis of the critical period. Support-NIH:NEI EY02708 (NGFC).

93.1

MALE AND FEMALE RATS ARE AFFECTED DIFFERENTLY BY NEONATAL STRESS: AUTONOMIC AND IMMUNE SYSTEMS RESPONSES. L.L. Ross, C.E. Taylor*, A. Seggos* and B. Weston*. Departments of Anatomy and Microbiology and Immunology, Med. College of Pennsylvania, Philadelphia, PA 19129.

We have shown that the adrenomedullary-sympathetic nervous system is permanently altered by stress administered during the neonatal period and that this alteration results in a modified response to stress administered to the adult. Further, males and female rats are affected differently by neonatal stress. In the present study, we expand on these findings and include data on the influences of neonatal stress on the immune system.

Beginning on P1 rat pups (Sprague-Dawley, VAF) were subjected to two forms of stress for 1 hour daily for 10 days: immobilization and maternal separation. At 40 or 60 days of age, representative groups of animals were immunized with a polysaccharide antigen and then immobilization stressed 5 days later. Others were stressed without prior immunization. These animals and appropriate controls were sacrificed and assayed for catecholamine content of adrenal glands and plasma and for the numbers of antibody-producing plaque forming cells specific for the antigen administered.

For adrenal and plasma catecholamines, the neonatally-stressed females showed a heightened response compared to the males, the latter being more like the control, unstressed animal. While neonatally stressed animals of both sexes showed a suppression of the immune response, the males had a greater degree of suppression.

93.2

LYMPHOID TISSUE MONOAMINE CONTENT AND IMMUNE RESPONSIVENESS IN CHICKS TREATED IN OVO WITH 6-HYDROXYDOPAMINE. H.M. Brown-Borg and F.W. Edens*. Dept. of Poultry Science, North Carolina State University, Raleigh, NC 27695.

An existing hypothesis suggests that the sympathetic nervous system influences the immune response. Studies were conducted to determine the effects of in ovo general sympathectomy on catecholamine content of lymphoid tissues in chicks. Anti-sheep red blood cell (SRBC) antibody production and delayed-type hypersensitivity response to phytohemagglutinin (PHA) were measured concurrently. Eggs were injected with either 100 mg/kg 6-hydroxydopamine (6-OHDA) or water (CON) at d18 incubation. At 3.5 weeks of age, chicks were challenged intravenously with SRBC and bled on days 0,2,4,6,8 and 10 post-challenge. Bursae and spleens were removed on the same days and norepinephrine (NE), epinephrine (E), dopamine (DA) and serotonin (5HT) were determined using HPLC-EC. A intradermal injection of PHA (100ug) in the wing web was given to 10 birds in each group and the site of injection was measured at 0, 12 and 24 hours post injection. Antibody titers were significantly increased in the 6-OHDA birds on days 6,8 and 10 when compared to controls ($P<.05$). Splenic NE and DA increased with increasing antibody titers. Splenic DA was significantly increased in the 6-OHDA birds on day 6 which coincided with the peak in antibody titers ($P<.05$). No significant differences were found in cell-mediated immunity. These data indicate that the catecholamines are involved in the immune response in birds.

93.3

PRESENCE OF BETA-ADRENERGIC RECEPTORS ON DEVELOPING SPLEEN CELLS AND ALTERATIONS IN IMMUNOLOGIC REACTIVITY FOLLOWING NEONATAL SYMPATHETIC DENERVATION K.D. Ackerman, S.Y. Felten, D.L. Felten, and S. Livnat Depts. of Neurobiol. & Anat., Psychiatry, and Microbiol. & Immunol. Univ. of Rochester, Sch. of Med., Rochester, NY 14642

Previous studies from our laboratory have shown that noradrenergic sympathetic nerves are present within specific compartments of the spleen at the earliest stages of postnatal development. Norepinephrine produced by these nerves may play a functional role in the development of both lymphoid and non-lymphoid cells, provided that these cells have adrenergic receptors and can respond to adrenergic signals. In this study, neonatal rat spleens were examined for the presence of beta-adrenergic receptors and changes in immunologic reactivity following neonatal sympathectomy.

The presence of beta-adrenergic receptors was measured on spleen cells from 1 to 90 days of age using the ligand iodocyanopindolol. Scatchard analysis revealed a Kd of 8-13 pM in all age groups, consistent with a high affinity beta receptor. Bmax was 400-500 sites/cell from 1-7 days, rising to 1000-1200 sites/cell at 21 days, and then declining to 600-700 sites/cell at 90 days.

Spleen cells from 10 day old rats, sympathectomized with 6-OHDA at birth, showed decreased spontaneous proliferation, reduced ConA-induced suppression of the background proliferation, and diminished NK cell activity. In contrast, by 41 days of age, spleen cells showed increased NK cell activity but control levels of spontaneous and ConA-induced proliferation. These findings suggest that at the earliest stages of postnatal development, splenocytes possess beta-adrenergic receptors and demonstrate altered responsiveness following chemical sympathectomy.

93.4

PATTERN AND TIME COURSE OF RE-INNERVATION OF NORADRENERGIC FIBERS INTO THE SPLEEN FOLLOWING DENERVATION WITH 6-HYDROXYDOPAMINE. D. Lorton, D.L. Bellinger, D. Hewitt, S.Y. Felten, and D.L. Felten. Dept. of Neurobiol. & Anat., Univ. of Rochester, Sch. of Med., Rochester, NY.

The time course and pattern of reinnervation of noradrenergic (NE) nerve fibers into the spleen following chemical sympathectomy with acute treatment of 6-hydroxydopamine (6-OHDA) was examined in young adult male Fischer 344 rats. On 1, 3, 5, 10, 21, and 56 days after 6-OHDA treatment, NE nerve fibers in the spleen were examined with glyoxylic acid fluorescence histochemistry. 6-OHDA treatment resulted in almost complete NE denervation, sparing only a small number of fibers at the hilar region at day 1 after treatment. Sprouting of fibers into the spleen was apparent by day 5 and continued to increase between 10 and 56 days after treatment. NE reinnervation first appeared at the hilar region by day 5, largely associated with the vasculature. The density of NE fibers increased in a radial fashion from the hilus with increasing post-lesion times. At 10 and 21 days after treatment, NE fibers coursed along the blood vessels in the hilar region, continued into the spleen with the vasculature, and extended into the parenchyma of the white pulp in regions near the hilus. Regions distal to the hilus, remained denervated. By 56 days post-treatment, NE fibers had reinnervated a vast portion of the spleen; however, sprouting NE fibers did not extend to regions extremely distal to the hilar region. Regions of splenic white pulp near the hilus appeared to be hyperinnervated. In all 6-OHDA treated spleens, the compartmentation of sprouting NE fibers was similar to that in saline injected controls, but the density differed according to the distance from the hilus. Supported by grants N0014-84-K-0488 from ONR, RO1 MH42076 from NIMH, RO1 NS25223 and T32 MH18260 from NIH.

NORADRENERGIC SYMPATHETIC NERVE FIBERS ARE ASSOCIATED WITH IMMUNE COMPARTMENTS BUT NOT SMOOTH MUSCLE DURING EARLY NEONATAL DEVELOPMENT OF THE RAT SPLEEN. D.L. Felten, K.D. Ackerman, S.Y. Felten, J.A. Olschowka, and S. Livnat. Depts. of Neurobiology & Anatomy, Psychiatry, and Microbiology and Immunology, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

In the adult rat spleen, sympathetic noradrenergic (NE) nerve fibers form neuroeffector junctions with both smooth muscle cells and lymphocytes. We investigated whether the development of innervation in these different compartments occurred in parallel or followed separate time courses. Light and EM immunocytochemical observations of the spleen at days 1 and 3 revealed tyrosine hydroxylase-positive (TH+) nerve fibers in the periarteriolar lymphatic sheath (PALS) in a periarteriolar location, with lymphocytes present between these fibers and the central artery, and macrophages present distally. The TH+ fibers did not contact central arteriolar smooth muscle cells; only later, at day 7, were vascular plexuses of TH+ nerve fibers routinely present. We also found ß-adrenergic receptors on splenocytes at 1 day of age. We suggest that NE nerves communicate with cells of the immune system as their principle targets during early neonatal development of the spleen, and may influence development of the compartmentation of the splenic white pulp and subsequent immune competence.

GUANETHIDINE SYMPATHECTOMY ENHANCES T-CELL RESPONSE IN NEONATAL BUT NOT ADULT RATS. T.T. Nguyen*, D.K. Nelson*, C.J. Krco* and V.L.W. Go* (SPON: B. Guthrie). Mayo Clinic, Rochester, MN 55905.

Acute chemical sympathectomy (SX) by 6-hydroxydopamine (6-OHDA) and surgical SX have both been shown to enhance T-cell function in the neonatal animal, but not in the adult. We examined the effect of chronic chemical SX using guanethidine, which selectively destroys peripheral sympathetic neurons. Methods: Adult (n=14) and neonatal (n=8) rats were injected (5 wks ip, and 3 wks sc, respectively) with either guanethidine (40 mg/kg/d) or vehicle and sacrificed 1 wk after cessation of treatment. Degree of SX was determined by dopamine-B-hydroxylase (DBH) assay of peripheral nerve. T-cell mitogen-induced lymphocyte (mesenteric lymph nodes) proliferation was measured by ^{3}H-thymidine incorporation in the presence of Concanavalin A (ConA). Results: Guanethidine-treated animals showed 90% depletion of DBH. Treated neonatal rats showed a significant increase in T-cell activation over controls (48 and 64% with 2.5 and 1.25 µg/ml ConA, respectively; $p<0.002$). However, treated adult rats showed no significant difference ($p=.292$) in their T-cell response to ConA over controls. Conclusion: Guanethidine SX enhanced T-cell mitogen response in the neonate, but not in the adult. This differential effect on the immature and mature immune systems is similar to that seen following surgical and 6-OHDA SX. These data support the importance of neural input to the developing immune system.

93.7

INTERACTION OF SECOND MESSENGER SYSTEMS LINKED TO THE ß-ADRENERGIC AND T CELL RECEPTORS ON HUMAN T LYMPHOCYTES. S.L. Carlson and T.L. Roszman* Dept. Microbiology and Immunology, Univ. Kentucky College of Medicine, Lexington, KY 40536

The sympathetic nervous system innervates lymphoid tissues, with fibers extending into the parenchyma, particularly into T cell zones. The neurotransmitter norepinephrine (NE), which is released from these fiber terminals, interacts with lymphocytes through binding to the ß-adrenergic receptor (ß-AR) expressed on the lymphocyte surface. Many studies have shown that NE or ß-adrenergic agonists are capable of modulating lymphocyte function. In particular, ß-adrenergic agonists have been shown to inhibit T cell activation stimulated through the T cell receptor (TCR). The mechanism responsible for such effects of ß-adrenergic activation is not known. It is important, therefore, to examine the transmembrane signalling induced by stimulation of the ß-AR in T cells, particularly in relation to intracellular signals necessary for T cell activation.

We are examining the interactions at the second messenger system level, between the ß-AR and the TCR. The ß-AR is linked to the cAMP system, and the TCR to the phosphotidylinositol (PI) system. Stimulation of human T cells with 10^{-5}M isoproterenol, a ß-adrenergic agonist, causes a rapid increase in cAMP, which begins to decline by 10-15 minutes. Stimulation of the TCR with a monoclonal antibody to the TCR (anti-T3 mAb) alone has no effect on cAMP. Simultaneous stimulation with isoproterenol and anti-T3 mAb causes a potentiation of the cAMP response. This suggests that a component of the PI system has a potentiating effect on the ß-AR-linked cAMP system. In addition, we are examining the effect of ß-AR stimulation on the TCR-linked activation of the PI cycle through measuring IP3 production, Ca2+ fluxes, and PKC activity. Understanding how the second messenger systems linked to the ß-AR and the TCR interact and modulate one another will aid in understanding the physiological role of the sympathetic nervous system in modulation of T cell activation in response to antigens.

HIGH AFFINITY DOPAMINE BINDING TO MOUSE THYMOCYTES AND MYTILUS EDULIS (BIVALVIA) HEMOCYTES: HEMOCYTE MONOAMINERGIC INTERACTION. G. B. Stefano, X. Zhao*[1], D. Bailey*, M. Metlay* and M.K. Leung. Center for the Study of Aging, SUNY/ Old Westbury, Old Westbury, N.Y. 11568.

The present report demonstrates that both mouse thymocytes and Mytilus edulis hemocytes contain a novel type of DA receptor. Scatchard analysis of these data revealed a single class of high-affinity binding sites with an affinity constant (K_d) of 6.6 nM, and a binding site density (B_{max}) of 141 pmol/g protein in mice and a K_d of 7.6 nM and a B_{max} of 66 pmol/g protein for the hemocytes. In older Mytilus the K_d was the same and the B_{max} was reduced (48 pmol/g protein; P>0.05; not evident for the mice cells). Displacing specifically bound DA was investigated and the catecholamines (NE > E) and the DA agonist epinine were the most potent and apomorphine and butaclamol were of moderate potency. This indicates that DA binding site is different from D_1 and D_2 sites. The hemocytes appear to be of two types, cells with a granular and agranular cytplasm. Other studies reveal that a group of granulocytes contain serotonin. The study suggests that vascular and neural interactions also exist in invertebrates indicating further their establishment early in metazoan evolution. Grants NIH-MBRS 08180 & ADAMHA-MARC 17138

THE ORIGIN OF ACETYLCHOLINESTERASE-POSITIVE NERVE FIBERS IN THE SPLEEN OF YOUNG ADULT RATS. D.L. Bellinger, S.Y. Felten, and D.L. Felten. Dept. of Neurobiol. & Anat., Univ. of Roch., Sch. Med., Rochester, N.Y.

The source of acetylcholinesterase-positive (AChE+) nerve fibers in the spleen of young adult male Sprague-Dawley rats was examined using a modified thiocholine method for specific AChE with nickel-3,3'-diaminobenzidine enhancement following surgical and 6-hydroxydopamine (6-OHDA) denervation procedures. AChE+ staining in all control groups was present in several populations of lymphoid cells, including small follicular cells, small grainy lymphocyte-appearing cells in the marginal zone, and large macrophage-like cells with AChE+ granules, throughout the spleen. AChE+ neural-like profiles were present along the vasculature, in the trabeculae, and to a lesser extent, in the white pulp, near the capsule, and in the follicles. Complete superior mesenteric-celiac ganglionectomy resulted in a total loss of noradrenergic (NE) as well as AChE+ fibers, and an expected loss of AChE staining in all lymphoid cells. No loss of AChE+ fibers was seen following bilateral subdiaphragmatic vagotomy. Treatment with 6-OHDA resulted in almost complete NE denervation, and loss of a majority of AChE+ fibers in all compartments 1 day after treatment, without apparent loss of AChE staining in lymphoid cells. This was followed by a progressive increase in AChE staining in neural profiles, as NE fibers subsequently reinnervated the spleen between 10 and 56 days following 6-OHDA treatment. The distribution of AChE+ neural profiles closely overlaps the distribution of NE fiber in the spleen, suggesting co-localization; however, some AChE profiles appear to be present in non-NE nerve fibers as well. Supported by grants N00014-84-K-0488 from ONR, RO1 NS25223 from NIH, RO1 MH42076 and T32 MH18822 from NIMH.

NOVEL MUSCARINIC RECEPTOR ON B CELL LINE UP REGULATED BY GLUTAMINE. T. Radojcic and K. Bulloch(T. Melnechuk, spon.) Neuroimmune Physiology Lab, Helicon Foundation/ Depts. Psychiatry and Pediatrics, Univ. of Cal San Diego, CA 92093

Recent studies indicate that cholinergic agonists directly influence T cell function and development. Other reports suggest that humoral immunity may also be effected by cholinergic mechanisms but do not indicate at what level cholinergic transmission exerts its effect. In this study we report the presence of a novel muscarinic receptor on a cloned murine B cell line L10 A2J that is up regulated by glutamine. In radioligand binding assays, these cells specifically bind ^{3}H-QNB at two affinities (Kd 1-2nM, 1mM). The specific binding could be displaced by 70-100uM atropine. Similar affinities are observed on lymphocytes. The number of muscarinic receptors of L10.2J was up-regulated by l-glutamine. Cells grown in glutamine depleted culture media did not bind QNB, whereas the number of receptors doubles when the concentration of glutamine is raised from 10-50mM. Supported by:grant #N00014-85K-0528 ONR and a grant from the Joan B. Kroc Foundation of Psychoneuroimmunology

FUNCTIONAL LOCALIZATION OF MAST CELLS IN DIFFERENT BRAIN AREAS. A.D. Konstantinidou*, N. Flaris*, M. Lambracht-Hall*, and T.C. Theoharides. Dept. of Pharmacology, Tufts University School of Medicine, Boston, MA 02111.

Mast cells have been identified in the brain histologically only. We examined their differential distribution in the brain using their secretory characteristics. We used a custom-made perfusion system with four wells so that we could simultaneously study the following areas labelled with ^{3}H-serotonin: thalamus, hypothalamus, cortex and cerebellum. Mast-cell release was induced by the classic mast cell secretagogue, compound 48/80, and the perfusate was assayed for ^{3}H-serotonin, histamine, β-hexosaminidase (a secretory granule enzyme) and LDH. There was no substantial release of LDH in any of the areas tested. The prevalence of mast cells in different areas was estimated from the extent of mediator release as follows: hypothalamus >> thalamus > cortex. There was insignificant release from cerebellum (without meninges), in accordance with previous anatomic studies, thus permitting us to use it as a negative control. This is the first study demonstrating the differential distribution of brain mast cells based on functional criteria. Release of important mediators from brain mast cells could influence neuronal secretion with possible effects on behavioral and neuroimmune disorders.

ANTIBODIES TO THE m1 MUSCARINIC ACETYLCHOLINE RECEPTOR. S.J. Wall, G.R. Luthin, and B.B. Wolfe. Dept. of Pharmacology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

Cloning and sequence analyses of rat muscarinic cholinergic receptor (MAChR) genes have demonstrated the existence of at least four distinct receptor subtypes. Rabbit polyclonal antibodies (m1 Abs) were raised against a synthetic 17 amino acid peptide conjugated to KLH. The peptide sequence corresponded to the C-terminal of the rat m1 MAChR. Initial screening with a solid phase radioimmunoassay indicated that the antisera had a high titer directed against the m1 peptide. The m1 MAChR is recognized with high affinity by pirenzepine (PZ), an antagonist possessing differential selectivity for MAChR subtypes. Uniform labelling of MAChR can be observed with the nonselective antagonist QNB. The m1 Abs were able to precipitate successfully QNB and PZ binding activities solubilized from several brain regions, but not from heart. Precipitation of binding activity was reversed in the presence of m1 peptide but not in the presence of C-terminal peptides of the m3 or m4 MAChRs. The m1 Abs precipitated QNB binding from Chinese hamster ovary (CHO) cells transfected with cDNA for the m1 MAChR, but not from CHO cells containing cDNA for the m2 MAChR. Together, these data indicate that the m1 Abs exhibit selectivity for the m1 MAChR subtype and may be suitable for immunoaffinity enrichment and tissue level quantitation of m1 MAChRs. PROPERTIES OF M1 AND M2 MUSCARINIC ACETYLCHOLINE RECEPTORS IN AFFINITY PURIFIED PREPARATIONS. Ramon Diaz-Arrastia and Stanley H. Appel, Department of Neurology, Baylor College of Medicine, Houston, Texas 77030.

To investigate the molecular basis of muscarinic acaetylcholine receptor (MAchR) subtypes, the properties of receptors from porcine heart and forebrain were studied in native membranes, after detergent solubilization and affinity purification, and after reconstitution with purified G proteins. Affinity chromatography was carried out on ABT-agarose (JBC 260:7927, 1985). The purification procedure yielded highly enriched MAchR, approximately 15-20% pure, and resolved from endogenous G proteins. Membrane bound receptors from the two tissues differed in kinetic rates of binding to classical antagonists, equilibrium binding affinities for pirenzipine, and equilibrium binding affinities for carbachol. Crude soluble receptors differed only in kinetic rates of binding to classsical antagonists--affinities for pirenzipine and carbachol were indistinguishable. Affinity purified receptors were identical in all parameters tested. Affinity purified receptors were reconstituted with purified Gi. MAchRs purified from both tissue sources interacted with Gi in identical fashion as determined by the ability of muscarinic agonists to stimulate the GTPase activity. This research was supported by grants from the John A. Hartford Foundation and the Helen C. and Robert J. Kleberg Foundation.

SELECTIVE ANTAGONISTS BLOCK ^{3}H-PROPYLBENZILYLCHOLINE MUSTARD BINDING TO MUSCARINIC RECEPTIVE PROTEINS OF DIFFERENT MOLECULAR WEIGHT. S. McLeskey*, W. Wojcik. FGIN, Georgetown Univ., Washington D.C. 20007.

Four distinct muscarinic receptive proteins, m-1 through m-4 have been reported. The m-3 receptive protein has a higher MW (90 KD) than the m-1, m-3 and m-4 proteins which have a MW of about 66 KD. ^{3}H-propylbenzilylcholine mustard (^{3}H-PBCM) can affinity label these muscarinic receptive proteins and, after SDS-PAGE with subsequent autoradiography, two bands (90 KD, 66 KD) of labeled proteins can be seen. In studies of selective muscarinic antagonists, pirenzipine and (-)QNX were found to be slightly selective in blocking the muscarinic mediated stimulation of phosphotidylinositol hydrolysis (M-PI) over the muscarinic mediated inhibition of adenylate cyclase (M-AC). Methoctramine was 600 times more selective at the M-AC than at the M-PI. In displacement studies of these three antagonists against ^{3}H-PCBM, both pirenzipine and (-)QNX completely prevented ^{3}H-PCBM binding to the 90 KD protein (m-3?) with a slight loss in binding to the 66 KD band of protein (m-1, m-4 ?). Methoctramine selectively blocked the ^{3}H-PCBM binding to the lowest MW portion of the 66 KD band (m-2?).

SHIFT OF THE PREDOMINANT Mr FORM OF THE AVIAN RETINA mAChR IN VITRO. **A.F. Skorupa*, J.S. Aguilar*, M.I. Fonseca*, and W.L. Klein (SPON: D. Gibbs). Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208.**

Muscarinic acetylcholine receptors (mAChR) exist in developing chick retina in two molecular weight (Mr) forms (86KD and 72KD), whose relative proportions shift during synaptogenesis in vivo (Large et al., PNAS, 82: 8785, 1985). We have used aggregate and monolayer cultures to study a possible role for cell-cell interactions in the shift. Embryonic day 9 (E9) retinas were grown in high density monolayer cultures (10^{6} cells/cm^{2}) on poly-L-lysine-coated dishes for 2 to 8 days (C8). mAChR Mr profiles were obtained from 3H PrBCM-labeled broken membranes and intact cells using SDS-urea-PAGE. The predominant mAChR Mr form changed from 86 to 72KD between E9C2 and E9C8. Membrane mAChR Mr profiles from E9C8 low density retina cultures (10^{5} cells/cm^{2}) are less shifted than those from high density cultures, suggesting a role for cell-cell interactions. Cells grown in aggregates have similar membrane mAChR Mr profiles to high density monolayers. Receptor activity is not involved in the shift, as growing aggregates with 0.1 uM atropine does not influence the predominant Mr form.

94.5

IDENTIFICATION OF MUSCARINIC ACETYCHOLINE RECEPTOR KINASE (mAChRK) IN THE RAT BRAIN SYNAPTIC MEMBRANE, A.K. Ho*, Y-J Zhang*, Q-L Ling* and R. Duffield* (Spon: J. Stewart), Dept. Basic Science, U. of Ill. Coll. of Medicine-Peoria.

Phosphorylation has been suggested as a possible mechanism for receptor desensitization. Purified muscarinic acetylcholine receptor (mAChR) can be phosphorylated by cAMP-dependent protein kinase (cAMP-PK) (Ho et al. BBRC, 137, 142, 911, 1987) and by protein kinase C (Haga et al. TIPS Supp. 1988). We present here preliminary findings to demonstrate the possible existence of an agonist activated mAChR kinase which was co-purified with the mAChRs from rat brain synaptic membranes by ABT-affinity and hydroxyapatite chromatographies. Purified mAChR was phosphorylated by this crude kinase in the presence of [γ-^{32}p]-ATP and Mg^{2+}. The enzyme activity was increased by one to four-fold in the presence of either carbachol (0.1 to 1mM) or acetylcholine (ACh 50-100 μM). This effect was blocked by atropine. SDS-PAGE radioautography showed the presence of the heavily labeled band indicating the ^{32}P-mAChR ($\simeq$70 Kd) and two other labeled bands of M.W. 62 and 58 Kd respectively. Since phosphorylation of mAChR occurred in the absence of cAMP-PK, cAMP, or Ca^{2+} phospholipid and in the presence of EGTA and was activtated by either carbachol or ACh, we tentatively conclude that a mAChR kinase may be present in the synaptic membrane. MOLECULAR COMPONENTS OF A MUSCARINIC RECEPTOR-G PROTEIN COMPLEX ISOLATED FROM RAT HEART. G.R. Luthin, D.R. Manning*, V. Kamath*, L. Schretzman*, and B.B. Wolfe. Dept. of Pharmacology, Univ. of PA. Sch. Med., Philadelphia, PA 19104-6084.

High-affinity agonist binding to muscarinic acetylcholine receptors (MAChRs) is believed to reflect an interaction of the agonist-occupied receptor with a guanine nucleotide-binding (G) protein. We have solubilized and isolated MAChR-G protein complexes from rat heart and identified the molecular components of the complex. Heart membranes were incubated with ^{3}H-oxotremorine-M (oxo-M) or ^{3}H-QNB, then solubilized in digitonin/cholate. Receptors were enriched by chromatography over wheat germ agglutinin (WGA)-agarose, then were immunoprecipitated using a monoclonal antibody to the cardiac MAChR (Luetje et al., Biochemistry 26:6892, 1987). Immune pellets were dissolved and subjected to SDS-PAGE and Western blotting, using antibodies of general specificity for G_{α} and G_{β} subunits. In the presence of oxo-M, a 39 kD protein was identified in the Western blots. Levels of the protein were much reduced or absent when QNB-labelled receptors were used, or when a control ascites was used in the immunoprecipitation. Using antibodies of more defined specificity for G_{α} subunits, we have tentatively identified the 39 kD protein as the α-subunit of G_{o}. These data suggest that oxo-M promotes a physical interaction of the cardiac MAChR with the α-subunit of G_{o}. (Supported by NS23006, GM31155, and CA 39712).

94.7

LOW-K_M GTPASE AS A MEASURE OF TOTAL MUSCARINIC RECEPTOR ACTIVITY IN BRAIN AREAS. S. Ghodsi-Hovsepian*, W.S. Messer, Jr., Z. Mazloum*, B. Shankar* and W. Hoss (Spon: C.L. Hinman) Dept. of Medicinal and Biological Chemistry, Univ. of Toledo, College of Pharmacy, Toledo, OH 43606

A family of structurally similar receptors mediates a number of muscarinic responses in the CNS. G-proteins couple the various receptors to their effector systems in brain. The pharmacology of muscarinic responses has been examined by the action of subtype-selective agonists and antagonists on biochemical and electrophysiologic responses. These studies do not however, address the fraction of total muscarinic receptors in a given brain region that may be associated with a particular response. Receptor-mediated low-K_m GTPase stimulated by full agonists such as acetylcholine or carbachol is a measure of the total muscarinic activity for a particular brain region. Previous studies (Ghodsi-Hovsepian et al., *Soc. Neurosci. Abstr.* 13:1374, 1987) indicate differential coupling between muscarinic receptors and G-proteins comparing different brain regions.

Oxotremorine-M is a full agonist for some responses, e.g., phosphoinositide (PI) turnover, whereas oxotremorine is a weak partial agonist for PI turnover but is effective for inhibition of acetylcholine release at presynaptic receptors. We have compared the ability of oxotremorine-M and oxotremorine to stimulate low-K_m GTPase in the rat cortex and hippocampus. Both agonists stimulated low-K_m GTPase activity in cortex and hippocampus with EC_{50} values in the low-to-submicromolar range, generally more potent than carbachol. Oxotremorine produced a significant but partial response in both areas. Oxotremorine-M produced a full response in the hippocampus, but only a partial response in the cortex. The data indicate that a significant fraction of receptors in both cortex and hippocampus as well as other areas (e.g., pons-medulla) are responsive to oxotremorine and therefore, not associated with PI turnover. These data are consistent with the finding (Dutar and Nicoll *Soc. Neurosci. Abstr.*. 13:152, 1987) that three of four electrophysiologically measured responses in the hippocampus can be elicited by oxotremorine, whereas both carbachol and oxotremorine-M activate all four responses. Supported by NS23929 and DA04068

SELECTIVE INACTIVATION OF G PROTEINS ASSOCIATED WITH MUSCARINIC RECEPTORS BY HEAT. R.L. Dennison, W. Boswell*, N. Harmer*, E. Wright*, T.K. Narayanan, and R.S. Aronstam Dept. Pharmacol. & Toxicol., Medical College of Georgia, Augusta, GA 30912.

The influence of heat on muscarinic receptors-G protein interactions was investigated in neural membranes from rat brainstem. A suspension of membranes was immersed in a water bath at 50°C for 1-30 min. This treatment lowered the proportion of receptors which displayed high affinity agonist binding from 64 to 21% without affecting the number or affinity of antagonist binding sites. The half time of this effect was less than 5 min. To test the possibility that this change reflected a specific inactivation of receptor-associated G proteins (receptors coupled to G proteins display high affinity agonist binding while uncoupled receptors display low affinity binding), we determined the influence of heat on two G protein functions, guanine nucleotide binding and GTPase activity. Both the binding of [^{35}S]GTP and the hydrolysis of alpha-[^{32}P]GTP were inhibited by exposure to heat with a half time of 2-3 min. These findings suggest that exposure of neural membranes to low heat for a short period of time selectively inactivates receptor-associated G proteins without affecting the receptors. This treatment may be useful in removing functional G proteins in reconstitution procedures. (Supported by GM-37948, AA-07698 and the Georgia Heart Association).

94.9

GLANDULAR M_2 MUSCARINIC RECEPTORS MEDIATE INHIBITION OF CYCLIC AMP FORMATION IN MOUSE NEUROBLASTOMA CELLS. C.L. Amrhein*, W. Surichamorn and E.E. El-Fakahany. (SPON: O.H. Choi). Dept. of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

The effects of M_2-selective muscarinic receptor antagonists on receptor-mediated inhibition of cyclic AMP formation (an M_2 response as defined by pirenzepine) were investigated in mouse neuroblastoma cells (clone N1E-115). This response was measured using 25 μM forskolin in the absence or in presence of the muscarinic agonist carbamylcholine. For comparison, we also determined the potency of these antagonists in inhibiting muscarinic receptor-mediated increases in cyclic GMP synthesis and phosphoinositide (PI) hydrolysis, responses which are triggered by M_1 receptors. AF-DX 116, a cardioselective M_2 muscarinic antagonist, was less potent at blocking muscarinic receptor-mediated inhibition of cyclic AMP formation than the cyclic GMP or PI responses. In contrast, the glandular M_2-selective antagonist, hexahydro-sila-difenidol, exhibited the reverse selectivity, being > 100 fold more potent than AF-DX 116 in blocking the cyclic AMP response. According to the known rank order of potency of these two antagonists at the M_1 and the two M_2 receptor subtypes, these data provide evidence that inhibition of cyclic AMP levels in this neuronal clone is mediated by the glandular M_2 muscarinic receptors. (Supported in part by NIH grants NS-24158, AG-07118 and AG-00344)

PREFERENTIAL COUPLING OF SUBTYPES OF MUSCARINIC RECEPTORS TO SPECIFIC SECOND MESSENGER SYSTEMS: THE m1 RECEPTOR PREFERS PHOSPHOINOSITIDE BREAKDOWN WHILE THE m2 RECEPTOR PREFERS INHIBITION OF ADENYLATE CYCLASE. Min Li* and Barry B. Wolfe. U. PA Sch. Med., Phila. PA 19104. Spon: (P. Salzman)

Recently, several genes have been cloned that code for proteins having the properties of muscarinic cholinergic receptors. Chinese hamster ovary (CHO) cells normally not expressing muscarinic receptors were transfected with a plasmid containing DNA coding for either m1 (CHO-m1) or m2 (CHO-m2) receptors (Peralta et al., EMBO J. 6: 3923, 1987). These cells (a gift to us from Dr. D.J. Capon, Genentech Inc.) were used to examine the relationship between two specific, defined, receptor subtypes and two second messenger systems, inhibition of adenylate cyclase activity and stimulation of phosphoinositide breakdown. CHO cells expressing m2 receptors had a much higher (10 x) density of (^{3}H)-QNB binding sites than cells expressing m1 receptors. Never the less, using equal numbers of cells per assay tube, cells expressing m1 receptors demonstrated a 10-fold increase in inositol phosphate production in response to 1 mM carbachol while cells expressing m2 receptors had less than a 2-fold response. On the other hand, in agreement with Ashkenazi et al. (Science 238: 672, 1987), carbachol strongly inhibited adenylate cyclase activity in cells expressing m2 receptors but not in cells expressing m1 receptors. Thus, these receptor subtypes demonstrate a preferance for coupling to a given second messenger system. This preferance does not seem to be absolute but rather depends on the density of receptors per cell. Supported by GM31155.

INHIBITION OF MUSCARINIC RECEPTOR STIMULATED PHOSPHOINOSITIDE TURNOVER IN SK-N-SH NEUROBLASTOMA CELLS BY AGENTS REPORTED TO INCREASE INTRACELLULAR cAMP. M. Akil*, S.K. Fisher. Neuroscience Laboratories, University of Michigan, Ann Arbor, MI 48104.

The effects of agents known to increase intracellular cAMP on muscarinic receptor stimulated phosphoinositide turnover (PPI) in the human neuroblastoma cell line SK-N-SH was examined. Intact SK-N-SH cells were first prelabeled with [^{3}H]Inositol for 45 min at 37°C and then exposed to carbachol for 45 min in the presence or absence of the agents of interest. Release of total inositol phosphates (IP), phospholipid labeling and cAMP concentrations, were determined. Forskolin inhibited the PPI response to carbachol significantly in a dose and time dependent fashion (50% at $5x10^{-5}$ M and 40 min), without influencing basal IP release. cAMP was increased 200-300% under these conditions. The effects of dibutyryl cAMP, theophylline, and isobutyl methylxanthine on stimulated IP release and cAMP were similar to those of forskolin. Chronic (24 hr) treatement of cells with cholera toxin also inhibited the PPI response, but in the absence of detectable increase in cAMP concentration. Prostaglandin E1, on the other hand, increased cAMP concentrations dramatically (2500-3000%) in the presence of a diesterase inhibitor, but did not have a significant effect on stimulated IP release. These results point to the complexity of interaction between these two second messenger systems and suggest, furthermore, that their interrelationship is unlikely to be a simple quantitative one. (Supported by NIMH grant MH 42652).

94.12

DESENSITIZATION OF MUSCARINIC INCREASES IN NEURONAL FIRING RATES MAY BE RELATED TO INOSITOL LIPID HYDROLYSIS.

N.J. Pontzer* and F.T. Crews. Dept of Pharmacology, Univ. of Florida College of Medicine, Gainesville, FL 32610.

We have studied a series of muscarinic agonists which have varying intrinsic activity for stimulation of phosphoinositide (PI) hydrolysis in hippocampal slices. The ability to stimulate PI hydrolysis was compared to the stimulation of extracelluler firing rates in CA1 hippocampal neurons. All of the muscarinic agonists studied produced large increases in firing rate in contrast to their differences in intrinsic activity at stimulation of PI hydrolysis. At higher concentration firing rates decreased for all drugs except oxotremorine, the weakest partial agonist at stimulation of PI hydrolysis we studied. A comparison of the two dose response curves suggested that the decreases in firing rate occurred at a threshold for PI stimulation. Oxotremorine did not produce desensitization and not reach the PI threshold. Full PI agonists caused a pronouced concentration dependent decrease in firing. Partial agonists, which only approached the PI threshold, slowly desensitized. Carbachol stimulated PI hydrolysis and firing rate desensitization are reduced in the presence of oxotremorine. These studies suggest that threshold levels of PI hydrolysis decrease muscarinic stimulated firing rates.

To further test this hypothesis lithium was used to deplete neuronal PI stores reducing the ability of agonists to stimulate PI hydrolysis. Lithium pretreatment appeared to increase firing rates and reduce desensitization of firing rates by high concentrations of carbachol. (Supported by NIH grant #AG06660.)

MUSCARINIC STIMULATION OF PI TURNOVER AND NOREPHINEPHRINE RELEASE IN PC12 CELLS OCCUR VIA INDEPENDENT MECHANISMS. A. Takashima* and J. G. Kenimer. Lab. of Cellular Physiology, CBER, FDA, Bethesda, MD 20892.

PC12 cells, preloaded with ^{3}H-NE or ^{3}H-myo-inositol, were used to quantitate the effects of methacholine on PI turnover and NE release. Methacholine stimulation resulted in a biphasic increase in IP_3 levels and in NE release. In both cases there was a rapid increase for the first 3 min to levels which remained stationary, or slightly increased, over the next 12 min. IP_2 and IP levels were each shown to increase over the entire 15 min test period. Pertussis toxin pretreatment of the cells resulted in parallel dose dependent inhibitions of both PI turnover and NE release suggesting that both events are dependent upon G-protein participation. These results are consistant with previous suggestions that muscarinic-stimulated PI turnover and NE release are coupled events. To further investigate this hypothesis we performed release and PI turnover experiments under conditions designed to discriminate between these events. Under Ca^{2+}-free conditions methacholine-stimulated release was inhibited but PI turnover was unaffected. In contrast, pretreatment with phorbol dibutyrate abolished methacholine-stimulated PI turnover without inhibiting stimulation of NE release. In addition, treatment of cells with AlF_4^- or vanadate was shown to stimulate PI turnover without significantly affecting the release of NE. These results demonstrate that methacholine-stimulated NE release can occur under conditions in which PI turnover is not stimulated and that, conversely, stimulation of PI turnover can occur without release of NE. We interpret these results to indicate that these two muscarinic-dependent events are stimulated via independent mechanisms. We are currently investigating whether different muscarinic receptor subtypes and/or different pertussis toxin sensitive G-proteins are involved.

AF-DX 116 (MUSCARINIC M2) BINDING SITES IN RAT BRAIN: PRE-SYNAPTIC MODULATION OF ACETYLCHOLINE RELEASE. P.A. Lapchak, D.M. Araujo, R. Quirion and B. Collier. Depts. Pharmacol.& Psychiat., McGill University, Montreal, Canada, H3G 1Y6.

The present study characterized the binding of the muscarinic antagonist (ant) [3H]AF-DX 116 to muscarinic receptors in rat brain, and tested the effect of AF-DX 116 on acetylcholine (ACh) release from rat brain slices.

The results show that [3H]AF-DX 116 binds saturably and specifically to two apparently distinct classes of sites in rat forebrain homogenates (kd= 2.63 nM & 63.3 nM). [3H]AF-DX 116 also bound specifically to homogenates from cortex, striatum and hippocampus. The ligand selectivity pattern of these sites indicated that AF-DX 116, atropine, and (-)QNB potently competed for [3H]AF-DX 116 binding sites, whereas pirenzepine (M1 ant) was a poor competitor. AF-DX 116 (10 uM) increased K+ evoked (25 mM) ACh release from cortex (43.6%), striatum (41.0%), and hippocampus (58.0 %). Atropine and (-)QNB (non-selective ant, 10 uM) also increased the K+ (25 mM) evoked release of ACh from the three brain areas (34-54%). This effect was not shared by pirenzepine (M1 ant) or 4-DAMP (M3 ant). In summary, [3H]AF-DX 116 specifically binds to two populations of muscarinic receptors in rat brain; some of these binding sites are located presynaptically on cholinergic terminals where they mediate positive feedback modulation of ACh release when activated. REGULATION OF ACETYLCHOLINE RELEASE BY M_2 AUTORECEPTORS T. Scranton* and W. Hoss (Spon: A. Iannone) Department of Medicinal and Biological Chemistry University of Toledo College of Pharmacy Toledo, Ohio 43606

Both biochemical and behavioral data have suggested the existence of presynaptic muscarinic receptors that regulate acetylcholine release in the CNS. In order to characterize these receptors in a direct manner, the effects of muscarinic ligands on acetylcholine release from cortical nerve endings were investigated. Synaptosomes prepared from rat cerebral cortex were preloaded with [^{3}H]-choline and release of [^{3}H]-acetylcholine was stimulated by incubation at 37° in the presence of 25 mM K^+ and 10μM hemicholinium-3 for 5 min.

The muscarinic agonist oxotremorine inhibited acetylcholine release in a dose-dependent manner, reaching a maximal value of 30% at 10μM. The nonselective antagonist atropine as well as the M_2-selective antagonists gallamine and AFDX-116 restored release to the control level in a dose-dependent manner. The M_1-selective antagonist pirenzepine was, however, ineffective. None of the antagonists affected unstimulated release.

These data indicate that presynaptic autoreceptors of the M_2 subtype inhibit the release of acetylcholine from nerve endings in the cerebral cortex of the rat brain.

STIMULATION OF CENTRAL MUSCARINIC RECEPTORS: PROSTAGLANDIN SYNTHESIS, A REQUIREMENT FOR PHARMACOLOGICAL ACTION. J.J. Buccafusco, V. Magri, D.P. Daly, R.G. Owen and D.K. Parker (SPON: W.J. Jackson). Dept. Pharmacology and Toxicology, Medical College of Georgia and Vet. Admin. Med. Ctr., Augusta, Georgia 30912.

Stimulation of central muscarinic receptors can result in profound increases in arterial blood pressure (BP) in several species, including human. Our earlier studies indicated that the vasoconstrictor response to acetylcholine in the isolated rabbit lung, in situ, was mediated through the release of prostaglandins (PG) (Catravas, et al., J Pharmac Exp Ther, 231:236, 1985). The purpose of this study was to determine whether the pressor response to intracerebroventricular (icv) injection of carbachol (C) in conscious rats was dependent upon brain PG synthesis. Icv injection of 5μg of C produced an immediate increase in BP which became maximal (41mmHg) by 5-10 min after injection and remained elevated for more than 30 min. Pretreatment with either 0.3 or 3μg of indomethacin (IN) 15 min earlier resulted in a dose-dependent inhibition of the C-induced pressor response. The 3μg dose completely eliminated the response. In contrast, the pressor response (up to 36mmHg) to icv injection of nicotine was not altered by IN pre-treatment. Thus, stimulation of muscarinic, but not nicotinic, receptors involved in central BP regulation requires PG synthesis for the expression of its pharmacological response. ACETYLCHOLINE RECEPTOR (AChR) IN A MUTANT MUSCLE CELL LINE ACCUMULATES IN THE ENDOPLASMIC RETICULUM. Y. Gu*, C. Murphy-Erdosh* and Z. W. Hall. Dept. of Physiology, Univ. of California, San Francisco, CA 94143-0444.

Using a replica technique, we have previously isolated a variant of the C2 mouse muscle cell line, T^-, whose myotubes make a normal amount of the AChR, but express a reduced amount on the surface (20-25% of wild-type). The remainder is accumulated in an internal pool that is 3-5 times normal levels. Pulse-chase experiments and the kinetics of transfer of internal AChR to the surface after inhibition of protein synthesis suggest that internal T^- AChR consists of two independent populations: ca. 25% is transported to the surface with normal kinetics; and the remainder is not transported to the surface and turns over slowly.

SDS-PAGE and Western blotting of the AChR subunits in T^- myotubes shows that alpha and beta subunits are normal, but that gamma and delta subunits have faster than normal mobilities. Treatment with endoglycosidases H and F shows that gamma and delta subunits of T^- AChR contain only high mannose sugars rather than the normal mixture of high-mannose and complex sugars. Subcellular fractionation of T^- variants demonstrates that internal AChR is not accumulated in the Golgi apparatus, but most likely remains in the endoplasmic reticulum. Our results thus suggest that the primary defect in the T^- variant is either a defect in N-linked glycosylation or a defect in transport.

CALCITONIN GENE-RELATED PEPTIDE REGULATES PHOSPHORYLATION OF THE NICOTINIC ACETYLCHOLINE RECEPTOR IN RAT MYOTUBES K. Miles, P. Greengard and R. Huganir (SPON:S.Halpain) The Rockefeller University, New York, N.Y. 10021

The nicotinic acetylcholine receptor (nAcChR) is a ligand activated ion channel which mediates synaptic transmission at the neuromuscular junction. The Torpedo nAcChR has been shown to be a substrate for protein kinase C, cAMP-dependent protein kinase and a tyrosine specific protein kinase. Forskolin and cAMP analogues each increased the phosphorylation of the nAcChR in intact cells suggesting that cAMP-dependent protein kinase regulates phosphorylation of the nAcChR. Phosphorylation of the nAcChR by cAMP-dependent protein kinase has been shown to increase the rate of receptor desensitization. Calcitonin gene-related peptide (CGRP) is a 37 amino acid neuropeptide localized presynaptically at the neuromuscular junction which has been shown to increase the synthesis of nAcChR. We report that CGRP increases phosphorylation of the nAcChR in rat myotubes. After exposure to 10^{-7}M CGRP, phosphorylation of the nAcChR δ subunit reached maximal levels within 5-10 minutes whereas phosphorylation of the α-subunit reached maximal levels after 20 minutes. β subunit phosphorylation decreased after CGRP treatment. The time course and specificity of nAcChR phosphorylation induced by CGRP is comparable to that obtained with forskolin. CGRP may be a physiological regulator of nAcChR desensitization at the neuromuscular junction.

A NON-AGONIST ACTIVATOR OF THE NICOTINIC ACETYCHOLINE RECEPTOR. G. Escalona de Motta, J.A. Prieto*, J.A. Lasalde*, R.M. Hann*, P.A. Ferchmin, and V.A. Eterović. Dept. Biochemistry, Univ. Central del Caribe, Inst. Neurobiology and College of Pharmacy, Univ. of Puerto Rico Med. Sci. Campus, and Dept. Chemistry, Univ. of Puerto Rico at Río Piedras, Puerto Rico, USA

N-tris(hydroxymethyl)methyl-2-aminoethane sulfonic acid (TES) was dissolved in acetonitrile with triethylamine and reacted with acetic anhydride. The resulting monoacetyl-TES (MAT) was not a cholinergic agonist, yet it increased the amplitude of miniature end-plate potentials in frog sartorius muscle, without affecting the time-course of miniature end-plate currents. MAT (10^{-7} to 10^{-5} M) also increased the amplitude of ACh-induced tension in frog rectus abdominus muscle. MAT did not appear to alter receptor desensitization produced by repetitive applications of ACh. In other experiments performed on purified receptor from electric organ of Torpedo californica, MAT did not affect the equilibrium binding of [^{3}H]ACh or receptor affinity state transitions induced by preincubation with carbamoylcholine. Therefore, either MAT acts directly at the level of the ion channel without affecting the binding parameters or this compound affects muscle but not electric organ.

MODULATION OF THE ACTIVITY OF THE NICOTINIC ACETYLCHOLINE RECEPTOR BY A SUBSTANCE ISOLATED FROM *TORPEDO* ELECTROPLAQUE.. B.A. Coleman, G.A. Weiland, & R.E. Oswald. Dept. of Pharmacology, Cornell University, Ithaca, NY 14852.

A substance isolated from *Torpedo* electroplaque was found to modulate the activity of the nAChR. Extracted tissue was applied to C18 columns, washed and eluted with acetonitrile. Eluents were lyophilized and resuspended in water. These eluents inhibited agonist-potentiation of PCP binding to the high affinity site for noncompetitive blockers on the nAChR of *Torpedo* receptor-rich membranes, but had no effect on PCP binding in the absence of agonist. The eluents also inhibited α-bungarotoxin (αBgt) binding to the membranes. Control eluents (treated and extracted columns without tissue) showed little or no effect. By measuring the effect of test eluents on the time-dependence of the inhibition of the initial rate of [^{125}I]αBgt binding by carbamylcholine the eluent appeared to increase the rate of desensitization. No increase in the extent of desensitization at equilibrium was observed at the concentrations tested. Furthermore, test eluents inhibited carbamylcholine stimulated ^{22}Na flux into both reconstituted, purified nAChR vesicles and PC12 cells.

The inhibitory activity was acid and heat stable and was dialyzable through 6,000-8,000 MW dialysis tubing. High concentrations of test eluent inhibited acetylcholinesterase activity, though it is not yet known if the test substance is hydrolyzed by the enzyme. Block of PCP binding and competition for αBgt binding is not affected by 3 mM EDTA suggesting that the substance is not a divalent cation. These studies suggest that a substance(s) may be present in the *Torpedo* electroplaque which is capable of interacting with a binding site(s) on the nAChR. Similar results have been reported for substance P (J. Neurochem. 49:253; Molec. Pharmacol. 32:625). We are currently examining the possibility that this inhibitory activity might be substance P or a structurally-related tachykinin.

LOW CONCENTRATIONS OF TETRAHYDROAMINOACRIDINE AND PHYSOSTIGMINE BLOCK SODIUM FLUX IN PC12 CELLS. M.T. Edge, G.E. Kemp, and R.J. Bradley, Neuropsychiatry Research Program, University Alabama at Birmingham, Birmingham, AL 35294.

We have studied the effects of two anticholinesterases used in the treatment of senile dementia of the Alzheimer type (SDAT) on the carbachol-induced sodium flux in PC12 cells. This line of cells from a rat pheochromocytoma expresses a ganglionic receptor which exhibits a cholinergic pharmacology. These cells are then particularly well suited for studying, *in vitro*, the drugs used in the treatment of this disease which results in a diminished cholinergic activity in the brains of its victims. Cells were plated onto poly-L-lysine coated dishes and then preincubated with concentrations of physostigmine or 1,2,3,4-tetrahydro-9-aminoacridine (THA) for up to 30 minutes at 37°C in a controlled atmosphere. Sodium flux was initiated by the addition of 600μM carbachol in the presence of 0.7μCi $^{22}Na^+$ for 30 seconds either with or without the anticholinesterase being present. Significant reductions in flux were observed after preincubation with either anticholinesterase. Some reduction in flux was observed with co-introduction of the anticholinesterases and carbachol but without prior incubation. Physostigmine and THA produced similar reductions in flux at high concentrations with > 80% reduction at 50μM physostigmine or THA. Neither anticholinesterase at concentrations of up to 5mM produced appreciable flux in the absence of carbachol. We hypothesize that the reductions in flux observed here are due to desensitizing effects of the anticholinesterases. Although the concentrations of the anticholinesterases used in these experiments were low, it is unclear if they are physiologically relevant. The pharmacological implications of these observations are uncertain at this time as they pertain to the palliative effects such drugs exert in the treatment of SDAT.

INTERACTIONS OF ALLOSTERIC ANTAGONISTS WITH NICOTINIC ACETYLCHOLINE RECOGNITION SITES IN BRAIN. H. Takayama*, M.D. Majewska and E.D. London (SPON: B. Gold). Neuropharmacol. Lab., NIDA ARC, Baltimore, MD 21224.

Noncompetitive blockers (NCBs) of the nicotinic acetylcholine receptor (NR) interact primarily with the associated cationic channel. We investigated how these and other potential NCBs or effectors of NR interact with nicotinic binding sites in rat forebrain membranes using [^{3}H]-methylcarbamylcholine (MCC), a NR ligand. MCC bound with high affinity to NR receptors (Kd = 1.1 nM, Bmax = 27 fmol/mg protein). Among NR agonists, the order for inhibition of MCC binding was as follows: l-nicotine >> d-nicotine > carbamylcholine >> acetylcholine. Atropine was inactive up to millimolar concentrations. Several NCBs which block the NR-operated cationic channel also affected MCC binding. Local anesthetics, phencyclidine, mecamylamine and hexamethonium inhibited MCC binding at micromolar concentrations. Among NCBs, chlorpromazine (CPZ) had a unique effect (biphasic): CPZ potentiated MCC binding (50 - 80%) below concentrations of 100 μM, and reduced binding at higher concentrations. Enhancement of binding reflected both an increase of affinity and the density of sites, and the decrease was due to apparently competitive displacement of MCC binding. The anesthetic steroid, alphaxalone, also affected MCC binding in a biphasic manner, similar to CPZ. The data suggest that NCBs represent a heterogeneous group of substances which interact with NR by various mechanisms.

95.7

MODULATION OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR FUNCTION BY THE THYMIC PEPTIDE FRAGMENT THYMOPENTIN. R. Afar*, J. M. Trifaro* and M. Quik. Dept. of Pharmacology, McGill Univ., Montreal, Que. and Univ. of Ottawa, Ottawa, Ont., CAN.

Thymopoietin affects α-bungarotoxin binding in Torpedo electric organ and impairs function at the neuromuscular nicotinic acetylcholine receptor. Using the biologically active 5 amino acid thymopoietin fragment, thymopentin (TP-5), we sought to assess whether this peptide could also alter nicotinic activity in neuronal cells. To determine this, the effect of TP-5 was studied on the release of ^{3}H-noradrenaline (^{3}H-NA) from bovine adrenal chromaffin cells in culture. TP-5 (10^{-5}M to $3x10^{-4}$M) resulted in a concentration dependent decrease in acetylcholine stimulated ^{3}H-NA release, while basal release was not affected. This decline in stimulated release was optimal after a 20 min exposure of the cells in culture to TP-5. TP-5 (10^{-5}M) decreased overall acetylcholine stimulated ^{3}H-NA release by 22% ($p<0.05$). This decrease in release was more pronounced for the second and third stimulation periods with acetylcholine than for the first. TP-5 inhibited nicotine (3μM) and acetylcholine ($3x10^{-5}$M), but not high potassium (56mM), evoked amine release. Thus, TP-5 appears to selectively inhibit nicotinic sensitivity in adrenal chromaffin cells. These findings indicate that TP-5 may modulate neuronal nicotinic receptor function.

KAPPA-BUNGAROTOXIN ANTAGONIZES THE ACTIONS OF NICOTINE IN PURKINJE CELLS OF THE RAT CEREBELLUM. **R. de la Garza, Y. Chiappinelli*, B.J. Hoffer, and R. Freedman. Univ. of Colo., Health Sci. Ctr., Dept. of Pharmacol. C236, 4200 E. 9th St., Denver, CO 80262 and Denver VAMC. * St. Louis Univ., St. Louis, MO.**

Recent studies from our laboratory have shown the heterogenous electrophysiological actions of nicotine in the rat cerebellum. The specific NMJ blocker α-Bungarotoxin (α-BTX), antagonized the actions of nicotine on cerebellar interneurons but not on Purkinje cells. To further explore the selectivity of nicotine actions on these cell populations, the snake toxin k-Bungarotoxin (k-BTX), which is selective for ganglionic nicotine receptors, was tested.

The inhibitory actions of nicotine, applied by micro-pressure or microiontophoretic ejection, on Purkinje cells were blocked by K-BTX. The extent of blockade, however, differed depending on the mode of nicotine application. k-BTX produced a small, but significant, 39% reduction in the actions of pressure ejected nicotine (p. 0.01), but a larger 80% reduction in the actions of iontophoretic nicotine (p. 0.001). The present data support the hypothesis of multiple nicotinic sites of action in mammalian brain. The data also suggests that snake toxins may be used to characterize putative functional nicotine receptors.

95.9

PROPERTIES OF NEURONAL NICOTINIC RECEPTORS FROM CHICK RETINA. R.H. Loring[1], E.Aizenman[2], S.A. Lipton[2] and R.E. Zigmond[1]
Depts. of Pharmacology[1] and Neurology[2], Harvard Med. School, and Div. of Neuroscience[2], Children's Hospital, Boston MA 02115

Neuronal bungarotoxin (NBT, 100 nM; also known as bungarotoxin 3.1, toxin F or kappa-bungarotoxin) antagonizes a nicotinically mediated depolarization recorded from intact chick retina, while the neuromuscular blocker α-bungarotoxin (BGT, 10 μM) does not. Receptor function in retina is blocked by treatment with the reducing agent, dithiothreitol, and function is restored by oxidizing with dithiobisnitrobenzoic acid, as has been shown for nicotinic receptor function in muscle and autonomic ganglia. In the presence of 1 μM BGT, ^{125}I-NBT binds to homogenates of chick retina with a k_d of 3 nM and this binding is displaceable by nicotinic drugs. However, unlike immunopurified nicotinic receptors from chick brain (e.g. Whiting & Lindstrom, 1986 J. Neurosci. 6:3061), which have high affinity for nicotine (k_d=3 nM), ^{125}I-NBT binding in chick retina is displaced with low affinity by nicotine (k_i=400 nM). Chick retina does have high affinity ^{3}H-nicotine binding (k_d<20 nM), but this binding is not displaced by 1 μM NBT. Low affinity ^{3}H-nicotine binding is partially displaced by NBT. Thus, the class of functional nicotinic receptors recognized by NBT in chick retina appears to have low affinity for nicotinic agonists. Detergent solubilization by cholate, CHAPS, CHAPSO or Triton X-100 causes alteration of NBT binding sites such that nicotinic ligands no longer displace specific ^{125}I-NBT binding to solubilized sites detected on DEAE-cellulose columns. Since these same detergents readily solubilize muscle nicotinic receptors without pharmacological impairment, neuronal nicotinic receptors from chick retina appear to be more easily denaturable. ISOLATION OF A cDNA CLONE CODING FOR A NEW NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR a-SUBUNIT. D. McKinnon*, J. Boulter*, E. Wada*, S. Heinemann and J. Patrick. (SPON: G. Lemke). Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92138.

A family of neuronal nicotinic acetylcholine receptor subunit genes has been described in rat and chicken which now includes the genes alpha2, alpha3, alpha4 and beta2. The initial basis for classification of these receptor subunits as either alpha or beta subunits was the presence or absence of two cysteine residues at positions corresponding to positions 192 and 193 of the *Torpedo* electric organ and skeletal muscle a subunit. This classification scheme has been given considerable validity by the demonstration that each of the alpha subunits can form a functional nicotinic receptor when expressed in *Xenopus* oocytes in combination with the beta2 subunit (Boulter et al., 1987, P.N.A.S. 84:7763; Wada et al., 1988, Science 240:330). We have recently cloned another member of the neuronal nicotinic AChR gene family from rat hippocampus and PC12 cDNA libraries. The deduced amino acid sequence of this newly identified subunit has two cysteine residues at positions corresponding to amino acids 192 and 193 of the skeletal muscle a subunit. For this reason the new subunit has provisionally been named alpha5.

Using *in situ* hybridization, the presence of mRNA coding for the alpha5 gene has been demonstrated in the cingulate cortex, endopiriform nucleus, subiculum, layer IV of the isocortex, substantia nigra pars compacta and interpeduncular nucleus of rat brain. The pattern of expression of alpha5 RNA is different from that of the previously identified neuronal nicotinic AChR subunit RNAs. We have also shown that the alpha5 subunit is expressed in both PC12 cells and adrenal chromaffin cells.

While the alpha5 subunit has significant amino acid sequence homology with other neuronal alpha subunits, it is not yet clear whether it is a functional homologue.

IDENTIFICATION OF A cDNA ENCODING A NEW SUBUNIT OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS

E.S. Deneris*, J. Boulter*, J. Patrick, and S. Heinemann. Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138

We identified a family of genes encoding nicotinic acetylcholine receptors (nAchR) expressed in the brain. To determine the extent of neuronal nAchR diversity, brain cDNA libraries were screened at low stringency with probes made from previously characterized cDNAs. A radiolabelled cDNA encoding the alpha3 subunit of neuronal nAchRs was used to screen a cDNA library prepared from mRNA isolated from the diencephalon of the rat. Screening a half million plaques resulted in the isolation of a clone containing an insert of 2.2kb that encodes a 53kd protein similar to but different than previously reported nAchR subunits. The encoded protein has the hallmarks of neurotransmitter-gated ion-channel superfamily subunits including two cysteine residues homologous to cysteines 128 and 142 of the Torpedo alpha subunit. Absent from the deduced primary structure are cysteine residues corresponding to cysteines 192 and 193 of the Torpedo alpha subunit. The greater amino acid sequence identity to the neuronal nAchR subunits relative to the $GABA_A$ or glycine subunits leads us to place this subunit in the neuronal nAchR subunit family. Thus, in view of the absence of two adjacent cysteine residues, we have named the encoded protein neuronal non-alpha2 (non-alpha1 corresponds to beta2). Hybridization in situ has shown that the non-alpha2 gene is expressed in the central nervous system. However, unlike the beta2 gene, mRNA hybridizing to the non-alpha2 probe is found in only a few regions. Strong signals are found in the medial habenula, the substantia nigra pars compacta, and reticular thalamic nucleus.

STRUCTURAL DETERMINANTS OF FUNCTIONAL DIFFERENCES BETWEEN SUBTYPES OF NICOTINIC ACETYLCHOLINE RECEPTORS. J.G. Connolly*, J. Boulter*, S.W. Rogers*, A. O'Shea*, J. Patrick and S. Heinemann. (SPON: P.D. Gardner). Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138.

We have isolated cDNAs coding for subunits of mouse muscle, (alpha1, beta1, gamma and delta), and rat brain (alpha2, alpha3, alpha4 and beta2) nicotinic acetylcholine receptors (nAchRs). Functional receptors were expressed following injecting combinations of RNAs derived from these clones into Xenopus oocytes, and their electrophysiological responses to a variety of pharmacological reagents were tested. Preliminary data suggest that below 0.01 mM agonist, equal concentrations of acetylcholine and nicotine give approximately equal responses for the alpha2+beta2 and alpha4+beta2 receptors. However, for the alpha3+beta2 and mouse muscle receptors, more than a ten-fold higher concentration of nicotine is required to reproduce the response to acetylcholine. The neuronal receptors were not blocked by alpha-bungarotoxin, but were ,with the exception of the alpha2+beta2 combination, blocked by 3.1 toxin. Thus these homologous receptors are pharmacologically distinct. It is now important to localise the structural bases of these and other receptor properties. We have begun this work by functionally expressing chimaeric receptors in which the extracellular domains of the alpha2 and alpha4 subunits have been reciprocally exchanged.

95.13

CLONING OF GENOMIC SEQUENCES ENCODING SNAKE ACETYLCHOLINE RECEPTOR. D. Neumann*, D. Barchan*, M. Horowitz*, M. Souroujon*, E. Kochva* and S. Fuchs. Dept. of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel, and Dept. of Zoology, Tel Aviv University, Tel Aviv, Israel.

The acetylcholine receptor (AChR) at the neuromuscular junction of Elapid snakes binds cholinergic ligands but unlike other muscle AChRs, does not bind α-bungarotoxin (α-BTX). Administration of α-BTX in concentrations several orders of magnitude higher than its LD_{50} for other species did not result in snake death. To characterize snake AChR α-subunit, DNA and RNA were isolated from Natrix tesselata. In Southern blots of snake DNA digested with several restriction enzymes we detected DNA fragments which reacted with a ^{32}P-labeled cDNA probe of the mouse AChR α-subunit. A genomic library of DNA fragments in the range of 4-6 Kb, obtained by EcoRI digestion, was constructed. The library was probed with the mouse AChR α-subunit cDNA and a positive clone containing an insert of 4.3 Kb was isolated and characterized. Partial sequence analysis of this clone revealed a fragment of 530 bp, obtained by PstI digestion, which contains a stretch of 185 bp homologous to the mouse α-subunit cDNA. This stretch corresponds to bases 448-633 of the mouse AChR α-subunit cDNA and codes for amino acid residues 96-157. Using the 530 bp fragment as a probe, a single snake AChR mRNA of approximately 3.7 Kb was detected on Northern blots.

95.14

MAPPING OF MAIN IMMUNOGENIC REGION ONTO THE NICOTINIC ACETYLCHOLINE RECEPTOR SEQUENCE. W. H. M. L. Luyten and J. Lindstrom. Molecular Neurobiol. and Receptor Biol. Labs, Salk Institute, San Diego CA92138.

The nicotinic acetylcholine receptor (nAchR) at the neuromuscular junction is the target of an auto-immune response in the human disease myasthenia gravis. The majority of antibodies in myasthenia patients are directed against a single set of closely-linked conformationally-sensitive epitopes, named main immunogenic region (MIR). The location of the MIR on the primary structure of the nAchR (recently obtained for several species using recombinant DNA techniques) is important for understanding the pathogenesis of myasthenia gravis and for developing a treatment. Ratnam et al. (Biochemistry 25, 2621-2632) found that only three out of 50 MIR monoclonal antibodies (mabs) (at 10-100 nM) bind to *Torpedo* α-subunit (~2 μg) on blots. Barkas et al. (Science 235, 77-80) reported many more MIR mabs binding (at 50-200 nM) to a series of mouse nAchR α-subunit fragments (10-40 μg) expressed from the corresponding cDNA clone as fusion proteins in bacteria; they concluded that the MIR mapped to two distinct epitopes within α6-85. Under similar conditions, however, we could demonstrate binding of MIR mabs to a *Torpedo* α87-208 fragment and even to abundant bacterial proteins, suggesting at least some aspecific binding. Using a number of control and anti-nAchR mabs with known epitopes, we established that more specific immunoreaction was obtained at lower mab (20 nM) and antigen concentrations, and by using 5% nonfat dried milk rather than gelatin or tween as quenching agent. Under these conditions only two MIR mabs (198, 210) reacted specifically with *Torpedo* α-subunit fragments expressed in bacteria. These mabs probably recognise the same epitope since they compete with one another for binding to *Torpedo* α-subunit on blots, but mab210 has the higher affinity on blots (K_D ~5 nM); its epitope lies within α46-92.

ANTIBODIES AGAINST AN α-BUNGAROTOXIN-BINDING PEPTIDE OF THE α-SUBUNIT OF THE ACETYLCHOLINE RECEPTOR. D. L. Donnelly-Roberts* and T.L. Lentz, Department of Cell Biology, Yale University Sch. Medicine, New Haven, CT 06510.

A 32 amino acid synthetic peptide (32 mer) comprising residues 173-204 of the α-subunit of the Torpedo acetylcholine receptor (AChR) was shown previously to bind α-bungarotoxin (α-Btx) with the same affinity as isolated α-subunit (PNAS 82:8790,1985). Polyclonal and monoclonal antibodies were raised against the 32 mer and tested for their ability to inhibit binding of α-Btx to the 32 mer. This region of the receptor appears to be relatively nonimmunogenic and thus far has yielded only IgMs. The polyclonal antibodies inhibited 42-54% of toxin binding; the most effective monoclonal antibody, 37%; and pooled monoclonal antibodies, 48%. To map the epitopes of the antibodies, their reactivity against shorter peptides comprising portions of the 32 mer was tested. The antibodies that were most effective in inhibiting binding of toxin were directed against residues 185-191. These antibodies also reacted with native receptor, either in membranes or affinity purified and detergent solubilized. The failure of any of the antibodies to completely inhibit toxin binding indicates toxin-binding determinants are not restricted to a single antibody epitope on the 32 mer. Efforts are now underway to obtain high affinity antibodies (IgGs) for testing in other functional assays. Support by NSF grant BNS 85 06404 and NIH grant NS 21896.

A PROPOSED MODEL FOR INTERACTIONS AT THE AGONIST-BINDING SITE OF LIGAND-GATED RECEPTOR ION-CHANNELS V.B.Cockcroft*, G.G.Lunt, E.A.Barnard*†, D.J.Osguthorpe* Depts. of Biochemistry and Chemistry, University of Bath, Bath, BA2 7AY, U.K. †MRC Unit of Molecular Neurobiology, Hills Road, Cambridge, CB2 2QH

Ligand-gated receptor ion-channels are a super family of proteins in the nervous system of vertebrates and invertebrates. Members of the family include receptors for acetylcholine, GABA, glycine and glutamate. In the nAChR of Torpedo electroplax the region 128-142 of the αsubunit has been implicated in the binding of agonists. This region contains a disulphide bridge and is highly conserved in all members of the super-family. Previous models proposed that the region forms a β-hairpin loop with a type VIa turn. Using computer modelling, we present a general model for ligand recognition in which a formal positive charge on a sp^3 nitrogen atom of the ligand results in an electrostatic interaction with the invariant aspartate residue close to the proposed turn. Specificity is determined by the type of residue on the opposite strand that faces the aspartate and by the residue preceding the cis-proline of the turn. In particular we account for the differences in the stereoselectivity and the potency of a range of compounds that recognise the nicotinic acetylcholine receptor. (We are grateful to Shell Research Ltd and the SERC for their generous support.)

LEARNING AND MEMORY: HIPPOCAMPUS

96.1

BEHAVIORAL EFFECTS OF HIPPOCAMPAL AND DIENCEPHALIC LESIONS IN RHESUS MONKEYS. H. Mahut, M. Moss and W. Grisham*, Psychol. Dept., Northeastern Univ., Boston, MA 02155

Selective ablations of the hippocampal formation in monkeys are necessary and sufficient to impair memory and object-reward association learning (Mahut et al., Neuropsychologia, 19:201,1981; Mahut et al., J. Neurosci. 2: 1214, 1982). But ablations of dorsal-medial thalamus also impair memory in monkeys (Aggleton and Mishkin, Neurosci. Abstr. 7: 1981). In comparing the two post-operative profiles in the same project we found that 1. Monkeys in both operated groups were severely and equally impaired in object recognition (DNMS with 10-130 sec delays and lists of 3-10 items). However, 2. Only hippocampectomized monkeys were impaired in learning object-reward associations (concurrent discrimination between members of 8 pairs of objects). This can be accounted for by the greater sensitivity to inter-item interference on the list version of the DNMS task shown by hippocampectomized monkeys. Finally, 3. Monkeys in both operated groups showed equally rapid rates of forgetting at 10 min, 1 and 24 hr intervals.

These findings suggest that the hippocampal formation and the dorsal medial thalamus share important aspects of mnemonic functions. They also suggest that the precise nature of the distinctions between bitemporal and diencephalic amnesias remains to be specified.

96.2

THE HIPPOCAMPUS AND PLACE MEMORY IN RHESUS MONKEYS. S.J. Angeli*, E.A. Murray and M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

An earlier study (Parkinson et al., J. Neurosci., in press) found that hippocampectomized (but not amygdalectomized) monkeys failed each of two trial types of a spatial memory task: (1) "object-place" trials, requiring one-trial memory for the association of an object and its location; and (2) "place" trials, a version of spatial delayed response requiring one-trial memory for location only. To determine whether the monkeys in that experiment failed the "place" trials because of interference from a strategy needed to remember the more difficult "object-place" trials, we trained naive monkeys on "place" trials only. First the monkey was required to displace two sample objects, each covering an unbaited well on a 3-well test tray; six seconds later the monkey was given a choice between one of the samples and a duplicate, one covering the well it covered previously (now baited, i.e. correct place) and the other covering the previously unused well (unbaited, i.e. incorrect place). Preoperatively, the monkeys scored 85% correct responses, whereas following bilateral hippocampectomy they achieved only 60% correct. The results indicate that a) impairment on the "place" trials in the earlier study was not due to interference from the "object-place" trials, and b) performance on this version of spatial delayed response, unlike performance on the classical version, depends critically on the hippocampus, despite the use of very short intratrial delays.

96.3

GABA-ERGIC NEURONS IN THE RAT HIPPOCAMPAL FORMATION: ULTRASTRUCTURAL CHARACTERIZATION AND SYNAPTIC RELATIONS WITH CATECHOLAMINERGIC TERMINALS. *C.E. Bacon*, C. Abate and T.A. Milner (SPON: D.A. Fischman).* Div. of Neurobiology and Molecular Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

The ultrastructural morphology of neurons containing γ-aminobutyric acid (GABA) and their relation to catecholaminergic terminals exhibiting immunoreactivity for the catecholamine synthesizing enzyme tyrosine hydroxylase (TH) were examined in the rat hippocampal formation (HF) using dual immunoautoradiographic and peroxidase anti-peroxidase labeling methods to simultaneously localize antisera from two different species. By light microscopy, GABA-ergic perikarya and processes co-distributed most noticeably with TH-containing processes in the hilus of the dentate gyrus and in strata lucidum, radiatum and lacunosum-moleculare of the CA3 region of the hippocampus. Thus, these regions were examined further by electron microscopy. GABA-like immunoreactivity (LI) was detected in neuronal perikarya, dendrites and axon terminals. The GABA-containing perikarya were large, ovoid (20x40μm) and contained abundant cytoplasm and an indented nucleus with one nucleolus. Synaptic junctions on perikarya and dendrites with GABA-LI were both symmetric and asymmetric with 63% (55 out of 88) of the pre-synaptic terminals unlabeled. The remaining terminals were immunoreactive for GABA (11%) or TH (26%). Terminals with GABA-LI (0.5-1.6μm) contained numerous small clear and 1-3 large dense-core vesicles. Of the synapses formed by GABA-ergic terminals, 29% (42 out of 143) were with unlabeled perikarya and dendrites; whereas 9% were with perikarya and dendrites containing GABA-LI. Additionally, 23% of the GABA-ergic terminals were in direct apposition with TH-labeled terminals and 14% contacted the same perikarya or dendrite as a TH-containing terminal. The remaining 25% of the terminals with GABA-LI were without any apparent synaptic relations. The results suggest that GABA-ergic neurons can be modulated by both GABA and catecholamines. Moreover, GABA-ergic terminals either alone or in conjunction with catecholaminergic terminals can regulate pyramidal cells and granule cells as well as interneurons in the HF. (Supported by NIH grant MH42834.)

96.4

EFFECT OF FIMBRIA/FORNIX, HIPPOCAMPAL, AND HIPPOCAMPAL/AMYGDALA LESIONS ON PERFORMANCE OF 8-PAIR CONCURRENT OBJECT DISCRIMINATION, OBJECT REVERSAL, AND T-MAZE ALTERNATION IN RATS. C.G. Wible and D.S. Olton. Department of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

Experiments with rats and monkeys lead to conflicting conclusions about the relative contribution of the fimbria/fornix, hippocampus, and amygdala to the memory deficit in amnesia. However, the two species have usually been tested on different tasks and after different types of lesions. The present experiment tested rats in two tasks that have been used previously with monkeys (an 8-pair concurrent object discrimination and an object reversal) and a task that is commonly used to test rats (the T-maze alternation). Lesions of the fimbria/fornix, hippocampus alone, and the hippocampus combined with the amygdala differentially impaired choice accuracy. This experiment will contribute to a resolution of the apparent conflicts between conclusions based on data from rat models and monkey models of amnesia.

96.5

HIPPOCAMPAL MOSSY FIBRE DISTRIBUTION IN RELATION TO TESTS OF SPATIAL MEMORY IN MICE. J. M. Lassalle*. Lab. d'Ethologie, U. de Tours, France, B. Bulman-Fleming and D. Wahlsten. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Inbred BALB/cWah and C57BL/6J mice and their reciprocal F_1 hybrids were derived from grafted ovaries and then fostered to surrogate mothers to assess effects of maternal environment. After 8 weeks of age, each mouse was tested for water escape learning, memory for spatial arrangement of objects in an open field, and learning of an 8-arm Olton radial maze. At 100 days of age, mice were perfused with sodium sulfide and horizontal sections were stained using the Timm's method to reveal mossy fibres. Measures of hippocampus included a) percent of the area of CA3 and CA4 occupied by the intra- and infrapyramidal mossy fibres, and b) percent of CA3 and CA4 occupied by pyramidal cells below the anomalous intrapyramidal mossy fibre termination typically seen in BALB/c. Both measures of hippocampus showed intermediate inheritance, whereas measures of learning and memory showed either complete dominance or overdominance. Neither measure correlated with behavioral differences within a strain. No maternal environment effects on behavior or hippocampus were detected.

Supported in part by grant 4878 from the Natural Sciences and Engineering Research Council of Canada.

96.6

HIPPOCAMPAL AND MEDIODORSAL THALAMIC INTERACTION IN MEMORY. K. A. Stokes* and P. J. Best, Dept. Psych., Univ. of Virginia, Charlottesville, VA 22901.

Separate memory systems may exist in the medial and basolateral limbic systems. Both hippocampal (HIPP) and mediodorsal thalamic (MD) lesions impair radial maze performance in rats. If these structures operate as two independent systems, then damage to both should impair performance additively. Rats with MD & HIPP damage showed no improvement on a radial maze task, whereas animals with MD lesions alone showed some improvement over later trials. On two additional tasks requiring an explicit discrimination of extramaze cues, combined lesion of MD & HIPP impaired performance more than MD lesion alone, but not in a directly additive manner.

Although a mass action hypothesis may obtain, we believe that additional hippocampal damage may enhance response perseveration (which may in turn increase errors); however, the hippocampus does not appear to contribute a totally independent mnemonic capacity which is dissociable from the contribution of MD in these tasks. MD and the hippocampus may be part of two interdependent systems, such that lesion of either impairs performance in mnemonic tasks, but for somewhat different reasons.

96.7

HIPPOCAMPAL ANATOMY AND BEHAVIORAL COVARIATION IN CHIMERIC MICE. I. M. Bär*, W. E. Crusio*, and H. Schwegler* (SPON: A. M. Lefcourt). Institute of Human Genetics, University of Heidelberg, Federal Republic of Germany.

We investigated covariation between behavior and hippocampus anatomy in a population of 35 aggregation chimeras between the inbred mouse strains C57Bl/6J and BALB/ cJ. Factor analysis showed a positive association between learning and activity in a water-maze and the size of the intra- and infrapyramidal mossy fiber (iip-MF) terminal field. A similar relationship of the iip-MF with measures of activity, but not with other exploratory variables, was found in an open-field. These results are partly at variance with results obtained earlier using inbred and hybrid mice [Crusio, W. E., and Schwegler, H., *Behav. Brain Res.* **26**, 153 (1987)]. It is hypothesized that the different results are caused by the albino allele carried by BALB/c mice.

We also examined the hippocampal lamination patterns in the chimeric animals. Adjacent to patterns intermediate between those seen in the donor strains, several MF-distribution patterns not occuring in the inbred strains were observed.

96.8

Hippocampal Inactivation Effects on spatial memory. Edwin J. Barea, Michael R. Hickey* and Douglas C. Smith, Dept. of Psychology, Southern Illinois Univ., Carbondale, IL 62901.

Though it is widely held that the hippocampus (HPC) is involved in memory, the specific role of this structure is still unknown. Olton et al.(1979) proposed that the HPC is involved in "working memory" (WM, information useful only for a given trial), but not "reference memory" (RM, information constant across trials), whereas Rawlins proposed that the HPC is involved in processing all types of mnemonic information whenever the stimuli to be associated are temporally discontiguous (Rawlins, 1985).

We now report the effects of reversible inactivation of the HPC vs the amygdala (AMY) on a working/reference memory task in a 12 arm-radial maze. Long Evans rats learned to retrieve food from 8 WM arms and not to visit 4 unbaited RM arms (Olton & Papas, 1979). Following criterion attainment, Ss were implanted with bilateral cannulae in the HPC (n=11) or the AMY (n=10) and then retrained to a criteria of 7 out of 8 correct for 10 consecutive days. The following day, they received bilateral infusions of 1 µl lidocaine, a Na+ channel blocker. The results expressed as mean number of WM and RM errors pre-, during, and post-lidocaine were: HPC-WM, 0.25, 3.75, and 0.42: HPC-RM=0.42, 1.0, and 0.17. For the AMY-WM mean errors were 0.09, 0.36, and 1.0, while AMY-RM=0.36, 0.45, and 0.55. These findings indicate the HPC but not the AMY must be functional for WM. Animals are now in testing on a delayed nonmatching to sample task and these results will also be presented.

96.9

EFFECTS OF HIPPOCAMPAL LESIONS ON ACQUISITION AND EXTINCTION OF TRACE EYE-BLINK CONDITIONING IN RABBIT. J.R.Moyer,Jr., R.A.Deyo* and J.F.Disterhoft, Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Reports of single and multiple neuron activity have demonstrated hippocampal plasticity during eye-blink conditioning in rabbits (Berger & Thompson,PNAS, 75: 1572-1576, 1978). Biophysical studies of hippocampal slices have correlated postsynaptic reductions of a Ca^{++}-mediated potassium current with acquisition of the CR (Disterhoft et.al., PNAS, 83: 2733-2737, 1986). Hippocampal lesions do not impair acquisition of a short-delay eyeblink task in rabbits, but they do affect extinction of delay conditioning (Akase and Disterhoft, 1987). Conflicting reports exist regarding the effects of hippocampal lesions on trace conditioning (in which the CS and UCS are discontiguous).

Subjects were 13 young adult male albino rabbits. Aspiration lesions removed either a) the hippocampus plus overlying neocortex (N=4) or b) overlying neocortex only (N=5). There were 4 sham-operated controls. Rabbits were habituated and then trained using a trace conditioning paradigm employing: a 100ms tone CS, a 300ms trace period (neither CS nor UCS) and a 150ms corneal air puff UCS. All rabbits were trained to a behavioral criterion of 2 consecutive sessions of at least 80% CRs. 24 h later, 3 extinction sessions (CS but no UCS) were begun. Analysis of the last 2 days of training indicated no differences between the groups in trials to criterion, %CRs, CR or UCR amplitudes. During extinction, however, hippocampal lesioned rabbits showed significantly more responses ($F(2,10)=4.12$, $p<.05$) and larger response amplitudes ($F(2,10)=3.09$, $p<.029$). Lesioned rabbits also showed no change in mean response latency while the other groups progressively increased in latency ($F(2,10)=3.99$, $p<.05$), so that by the 3rd day, the response latency for both control groups was nearly twice that of the lesioned group. None of these differences between the groups were seen during acquisition, so they must be related to the extinction process. These results suggest that the hippocampus may be involved in an inhibitory modulation of brainstem/cerebellar circuitry during extinction of trace conditioning. Further studies are being conducted to test acquisition and retention of more difficult conditioning tasks. These should provide additional information as to the role of hippocampal plasticity in associative learning.

ELECTROPHYSIOLOGY OF CORTICAL-HIPPOCAMPAL CONNECTIONS. A. M. Borroni, R. L. Berry, and T. J. Teyler. Dept. of Neurobiology, NE Ohio Univ. College of Medicine, Rootstown, Ohio 44272.

A recent theory of hippocampal function, the "Memory Indexing Theory" (Teyler & DiScenna, 1985, Neurosci. Biobehav. Rev.,9, 377-89), proposes that the hippocampus indexes cortical sites associated with a given experience and, by later reactivating these sites, allows recall of the experience. To test this theory, the present study investigates the electrophysiology of cortical-hippocampal connections.

Adult male Long Evans rats anesthetized with urethane were placed in a stereotaxic apparatus and the cerebral cortex exposed. The cortex was electrically stimulated at 1 mm intervals and field potentials recorded in the dentate hilus, yielding electrophysiological maps of the cortical projection to the hippocampus. Responses in the septal hippocampus were maximal when anteromedial cortex was stimulated. Current source density analysis of these responses revealed current sinks (50 msec latency) located in the dendritic fields of the dentate gyrus granule cells, suggesting a multisynaptic pathway through the entorhinal cortex. Data obtained from different hippocampal locations will be presented. Supported by ONR grant #86K0664.

96.11

FIMBRIA-FORNIX LESIONS IN RATS IMPAIR CHOICE ACCURACY IN AN OBJECT DELAYED MATCH-TO-SAMPLE DISCRIMINATION. A.L. Markowska* and D.S. Olton. Dept. of Psychology, The Johns Hopkins Univ., Baltimore, MD 21218.

Memory in primates has been studied extensively with non-spatial visual discriminations. In order to conduct parallel research in rats, this experiment reports the effect of fimbria-fornix damage in rats upon performance of a delayed-match-to-sample task with objects. The usual procedures of a sample, delay, and choice were followed in a water maze. The objects were hung in two different locations; a hidden platform was placed below the water beneath the correct object. The choice accuracy of control rats was about 80%, demonstrating that this technique is useful to teach rats object discriminations. Postoperatively, the fimbria-fornix rats performed at chance, showing that the fimbria-fornix in rats is required for object-relevant / space-irrelevant memory.

96.12

HIPPOCAMPAL AND PARIETAL CORTEX LESIONS IMPAIR STONE-MAZE ACQUISITION IN RATS. R. F. Berman[1], R. P. Kesner[2], and H. J. Altman[3]. [1]Dept. Psych., Wayne State Univ., [2]Dept. Psych., Univ. of Utah, [3]Dept. Psychiatry, Lafayette Clinic, Detroit, MI.

The Stone-maze is a 14-arm sequential T-maze which rats learn to traverse for food reward. It has been used to assess learning deficits in aged rats, but little has been reported concerning the effects of specific brain lesions on acquisition of this maze task. Therefore, we have compared Stone-maze acquisition in young rats with either hippocampal, parietal, medial prefrontal or dorsolateral frontal cortex lesions with that of sham-lesioned and unoperated control animals. Hippocampal lesions were made electrolytically, all cortical lesions were made by aspiration, and all lesions were made bilaterally. Rats with hippocampal or parietal cortex lesions were significantly impaired in the acquisition of the Stone-maze compared to control animals. In contrast, the maze acquisition of medial prefrontal and dorsolateral frontal cortex lesioned animals was not impaired. These results demonstrate differential involvement of specific cortical areas in maze learning. The results also suggest a parallel involvement of the hippocampus and parietal cortex in maze learning, and thus are similar to previous findings obtained from studies using other complex maze tasks (e.g., water maze). (Supported by NIH Grant RR-08167).

96.13

PROPOSITION OF A NEW CONCEPT CONCERNING TO THE THREE-DIMENSIONAL NEURONAL CIRCUITRY IN THE RAT HIPPOCAMPUS. N. Tamamaki* and Y. Nojyo* (SPON: K. Yoshida). Dept. of Anatomy, Fukui Medical School, Fukui 910-11 Japan.

On the basis of physiological data, the excitatory pathways in the hippocampus has been said to be lamellarly organized. However, the neuroanatomical data, up to this time, did not support enough the existence of such organization. In this study, granular cells and pyramidal neurons in the serial hippocampal fields of rat brains were intracellularly labeled with HRP under anesthetia (pentobarbital 50 mg/kg i.p.), and the axonal projection patterns of these neurons were analyzed in three dimensions with computer graphics.

Caudally directed axon branches of CA1 pyramidal neurons were parallel to the alvear fibers. Most projection fibers of CA2 and CA3 pyramidal neurons to field CA1 were also arranged parallel to the alvear fibers, while these pyramidal neurons had wide spreading association fibers. Therefore, pyramidal neurons generally seemed to form lamellae parallel to the alvear fibers. On the other hand, the mossy fibers originating from the granular cells did not run parallelly to the alvear fibers along their full length. Therefore, the granular cells in the dentate gyrus seemed to form lamellae in the regio inferior intercrossing with the lamellae formed by pyramidal neurons. This study revealed that the serial excitatory pathways in the hippocampus can not be confined within a section of several hundred micrometers thickness.

96.14

INTERTRIAL INTERVAL AND SINGLE-ALTERNATION LEARNING IN INFANT RATS WITH LESIONS OF HIPPOCAMPUS OR OF HIPPOCAMPUS AND AMYGDALA. A. Amsel, P.L. Greene, N.J. Lobaugh, and T. Nick. Dept. Psychology, Univ. Texas, Austin, TX 78712.

These experiments were designed to investigate the role of the developing hippocampus and amygdala in long intertrial-interval (ITI) patterned (single) alternation (PA) in the infant rat. PA is a kind of go/no-go learning that produces differential responding on alternating reward and nonreward trials in the absence of differential external cues. In these experiments, rats were given two bilateral, electrolytic hippocampal lesions (HPPX) or sham surgeries (SHAM) at 10 or 11 days of age, and were trained 6 days later in a straight runway. In Experiment 1, rats received 120 trials in one day, with 8, 15, or 30-sec ITI. PA learning occurred in both HPPX and SHAM pups at the 8 and 15-sec ITIs, but only in SHAMs, to a reduced degree, at the 30-sec ITI. In Experiment 2, training was extended to 240 trials over two days, with 30 or 60-sec ITIs. Both SHAM and HPPX pups showed PA at the 30-sec ITI, while only the SHAMs showed PA learning at the 60-sec ITI. In Experiment 3, pups with combined hippocampal and amygdala lesions were trained at 8-sec ITI. The combined lesion significantly delayed the emergence of PA. The results of these experiments argue for a role of the hippocampus in single-alternation learning with long intertrial intervals and suggest that even at 16 days of age and an 8-sec ITI, the effects of combined hippocampal+amygdala lesion are stronger than hippocampal lesions alone.

96.15

SCOPOLAMINE AND FIMBRIA-FORNIX LESIONS IMPAIR CHOICE PERFORMANCE OF F-344 RATS IN A NEW COMPLEX SHOCK-MOTIVATED SIX DETOUR MAZE.

E. Bresnahan, P. Wiser*, N. Muth*, and D. Ingram*. Essex Community College, Baltimore, MD 21237 and Gerontol. Res. Center, NIA, Baltimore, MD 21224.

A new complex maze task is used for within-subject assessment of various cholinergic manipulations. Seven 6-mo male F-344 rats were trained to high active avoidance (AA) performance levels in the white straight runway portion of the maze. Next with the AA contingency still enforced, rats were required to learn different combinations of black alleyways representing detours from the straight path but leading to the goal. Additional brief shock was given for errors, entries into blocked alleyways. They were trained for 3 mo with one problem/day from a set of six 1-detour and twelve 2-detour problems, using a learning set approach (2 sample and 10 choice trials). Next using a 2/3 correct choice-trial criterion, performance was evaluated for 1 mo on 3 problems/day from the same 18-problem set. When all rats achieved criterion within 3 trials (weekly average), experimental manipulations were provided with this procedure. First, in a counterbalanced design, rats received 0.3 or 1.0 mg/kg scopolamine hydrocholoride (S) during 2 wks. Compared to 3 no-drug wks, S increased errors and trials to criterion in a dose-dependent manner ($p's < 0.01$). Using a more difficult problem set (2-detour only) in a second 5-wk period, 0.1 and 0.3 mg-Kg doses of physostigmine (P) did not affect errors or trials to criterion but did increase run-times ($p < 0.05$). Next, after 1-wk baseline performance using the original 18-problem set, rats received bilateral electrolytic fimbria-fornix (FF) lesions with the objective of interrupting septal-hippocampal cholinergic systems. Following 2 wks of recovery, testing continued for 6 wks. A deleterious effect of FF lesions ($p's < 0.001$) was observed on all performance measures. Recovery of function as observed in several measures was noted beginning with wk-4 of retest and clearly was evident by wk-6. Thus, this maze paradigm can be used to assess involvement of cholinergic systems in this flexible memory task utilizing a within-subjects design.

96.16

HIPPOCAMPUS, AMYGDALA, AND CROSS-MODAL ASSOCIATIONS. R. J. Sutherland, R. J. McDonald* and J. W. Rudy. Dept. of Psychol., Univ. of Lethbridge, Lethbridge, Canada, T1K 3M4 and Dept. of Psychol., Univ. of Colorado, Boulder, CO, 80309.

We propose that the hippocampal formation is necessary for acquiring and storing configural associations but not simple associations. Configural associations must be acquired to solve tasks in which prediction of a reinforcer requires an appreciation of the relationship among cues.

As a test of this idea we used a nonmatching-to-sample task for rats similar to one developed by Aggleton et al (1986). Three pairs of boxes contained distinct visual cues (white, black or striped walls) and olfactory cues (almond, patchouly or cheap aftershave, respectively). For each choice the rats were presented with two boxes, one identical to the box they had just exited and one that was different; they were rewarded for choosing the different one. Preoperatively, all rats solved the bimodal version and solved both unimodal versions. Half of the rats received hippocampal lesions; the other half received amygdala lesions. Postoperatively, all rats solved the bimodal and both unimodal problems. Hippocampal lesion rats failed to solve either cross-modal version (visual-olfactory or olfactory-visual). Amygdala lesion rats solved both cross-modal problems.

The results imply that the hippocampus is essential for solving tasks that require the animal to acquire configural associations among cues.

96.17

THE ROLE OF THE HIPPOCAMPUS IN THE ACQUISITION AND RETENTION OF CONFIGURAL ASSOCIATIONS. J.W. Rudy and R.J. Sutherland Psych Depts, University of Colorado, Boulder Colorado 80309, University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

The negative patterning discrimination problem can be arranged by reinforcing the animal for bar pressing when either a light or tone is presented (L+/T+) but nonreinforcing the response when the compound stimulus consisting of the light and tone is presented (TL-). To solve this problem, the animal must be able to construct a unique configural representation of the compound (<TL>) that can be distinquished from the representations of the individual elements (T and L). We have proposed (Sutherland & Rudy, under review) that the hippocampal formation is essential for the acqusition and retention of associations involving configural representations. Consequently, our position predicts that animals with hippocampal damage will not solve the negative patterning problem and that damage to the hippocampal formation of animals who previously solved the problem will result in their failure to retain the solution. The results of two separate experiments support our position. Animals with hippocampal-formation damage neither acquired nor retained the negative patterning discrimination. These animals, however, were able to solve a simple discrimination in which they were rewarded for responding in the presence of a light but nonrewarded for responding in the presence of a tone.

96.18

HIPPOCAMPAL SIZE IN FOOD-STORING BIRDS. D.F. Sherry*, A.L. Vaccarino, K. Buckenham* and R. Herz*. (SPON: C. Thinus-Blanc). Department of Psychology, University of Toronto, Toronto, Ontario Canada M5S 1A1.

Black-capped chickadees (Parus atricapillus) recover their scattered caches of stored food by remembering the spatial locations of caches. Bilateral hippocampal aspiraton disrupts cache recovery in these birds without affecting the storing of food or the intensity of search for caches. Hippocampal birds search for caches they have made but search in the wrong places. The disruption is due to impairment of both memory for places and working memory (Sherry, D.F. & Vaccarino, A.L. Behav. Neurosci. in press).

Some species of birds cache food, but most do not. Volume of the hippocampus and telenchephalon were determined from serial brain sections for 29 species of birds from 9 taxonomic families. Sections were stained, enlarged and digitized to determine sectional areas and volumes of hippocampus and telencephalon. Three families that are predominantly food-storing, Paridae, Sittidae, and Corvidae, had a larger hippocampus relative to telencephalon volume and body weight than did non-storing families. Natural selection on memory capabilities, arising from food-storing behaviour, may have resulted in greater relative hippocampal size in food-storing birds.

INTRADENTATE COLCHICINE-INDUCED IMPAIRMENT OF REFERENCE MEMORY: SPATIAL VS. NONSPATIAL. Kevin P. Nanry*, William R. Mundy, and Hugh A. Tilson (SPON: Ronnie L. McLamb). National Institute of Environmental Health Sciences, P. O. Box 12233, Research Triangle Park, North Carolina 27709.

Male, Fischer-344 rats received bilateral injections of 2.5 µg of colchicine/site in the dorsal and ventral hippocampus. Intradentate colchicine preferentially destroyed dentate granule cells. Subsequent behavioral studies showed that three weeks after dosing, colchicine impaired the acquisition of a spatial, reference memory task in the Morris water maze. In a second group of rats which were trained in the water maze prior to dosing, intradentate colchicine impaired retention of this task when rats were tested three weeks later. The acquisition of nonspatial reference memory task, an autoshape response in an operant chamber, was facilitated by prior administration of colchicine. Facilitative effects of colchicine were seen if delays of 0, 4, or 6 sec were interposed between response and presentation of food reinforcement. If rats were trained on an autoshape response with either a 0 or 4 sec delay between response and reinforcement, intradentate colchicine had no effect on retention of the response 3 weeks later. These data are in accord with the conclusion that the dentate gyrus plays an important role in the acquisition of new information and retrieval of previously learned material and is an integral neural substrate for spatial, reference memory in the rat.

INTRADENTATE COLCHICINE IMPAIRS ACQUISITION OF A TWO-WAY ACTIVE AVOIDANCE RESPONSE IN A Y-MAZE. W. R. Mundy, R. L. McLamb, and H. A. Tilson. LMIN, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709

The present experiment was designed to test the hypothesis that increased two-way avoidance responding after hippocampal damage may be related to a nonassociative process. Male Fischer-344 rats received bilateral injections of colchicine (2.0 ug/site) into the dorsal and ventral hippocampus to destroy dentate gyrus granule cells. Acquisition of a brightness discrimination, active avoidance task in a Y-maze was measured in 120-trial sessions given once weekly for three or four weeks. Colchicine lesions impaired the ability of rats to learn the task. If rats were trained prior to intradentate colchicine, significant effects on performance were not observed. In a third experiment, rats were tested in a modified procedure in which only the tone CS and light cue were presented; shock was not presented. Colchicine-treated rats showed a response bias under these conditions, entering the unlighted arm with greater frequency than the lighted arm when the tone and light were activated. These data are consistent with other reports indicating that rats with hippocampal lesions are impaired in the acquisition of a simultaneous discrimination if a response bias exists to one of the choices.

ROLE OF A G-PROTEIN IN THE REGULATION OF BINDING TO THE NMDA RECEPTOR COMPLEX. A.I. Sacaan, L.D. Snell* and K.M. Johnson. Dept. Pharmacol. & Toxicol., Univ. Texas Med. Br., Galveston, TX 77550.

We have recently reported that glutamate (GLU) and glycine (GLY) increase the affinity of the phencyclidine (PCP) receptor associated with the N-methyl-D-aspartate (NMDA) ionophore. To determine whether these receptor changes involve guanine nucleotides, we examined the effects of guanosine 5'-O-3-thiotriphosphate (GTPγS) on binding at this receptor complex. GTPγS potentiated GLU-induced ^{3}H-TCP binding while it inhibited GLY-induced ^{3}H-TCP binding. GTPγS decreased the binding of NMDA-specific ^{3}H-GLU and ^{3}H-GLY. The IC_{50} values of GLU and the selective NMDA receptor antagonist 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) for displacing ^{3}H-GLU were shifted to the right by the presence of 10µM GTPγS suggesting a decrease in the affinity of the NMDA receptor. The IC_{50} of GLY for displacing ^{3}H-GLY binding was not significantly altered by GTPγS, whereas that of CPP was shifted to the right. Since the CPP displacement of ^{3}H-GLY binding probably occurs via an indirect modulation of the glycine site by action at the NMDA receptor, these data suggest that GTPγS inhibition of GLY-induced ^{3}H-TCP binding and ^{3}H-GLY binding are also mediated through a decreased affinity at the NMDA receptor. Our data point to the possible involvement of a G-protein in the function of the NMDA/PCP/glycine receptor complex. DA-02073.

HIGH AND LOW AFFINITY SITES FOR ^{3}H-MK801: ALLOSTERIC EFFECTS OF GLUTAMATE AND GLYCINE ON RECEPTOR PROPERTIES. N. R. Mason, and L. G. Mendelsohn Lilly Research Labs., Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285

Electrophysiological studies have demonstrated modulation of excitatory amino acid receptors of the NMDA-type by phencyclidine (PCP) and MK801. Biochemical data provides further evidence of direct coupling between the NMDA receptor, PCP/MK801 receptor, and the non-strychnine sensitive glycine (GLY) receptor. These interactions suggest that drugs which act through these mechanisms may have utility in the treatment of diseases involving the excitatory amino acids, e.g. ischemia, epilepsy, psychosis, cognitive disorders and neural degeneration. We have established a receptor binding assay for the PCP/MK801 receptor using ^{3}H-MK801, in order to further study these phenomena. Rat forebrain membranes were characterized with respect to the effect of repeated washings to remove endogenous glutamate (GLU) and GLY, the effect of addition of GLU and GLY, and the interaction of a variety of drugs with the MK801 site. Repeated washing of forebrain membranes resulted in a decrease in the radioactivity of ^{3}H-MK801 bound to the receptor. The addition of GLU (100 µM) increased the amount of ^{3}H-MK801 associated with membrane receptors. Concentration response curves using GLU, GLY or the two together showed a greater than additive stimulation of binding. Competitive binding studies using unlabeled MK801 or PCP and well washed membranes produced biphasic displacement curves. Analysis with LUNDON software resolved two binding sites: a high affinity component (KD, 30 µM) and a low affinity site (Kd, 5 µM). GLU or GLY increased the affinity of MK801 for the high affinity site (Kd 3nM) with no affect on the low affinity site. Concentration response studies with CPP, D-AP5, and PCP showed that PCP could fully displace MK801 at both receptors. The NMDA blockers were ineffective at the low affinity site even at 100 µM although they are effective (non-competitive) blockers at the high affinity site. The results suggest that this second site is not coupled to the NMDA-type of glutamate receptor and that binding of MK801 or PCP is not affected by GLU or GLY agonists or antagonists at this site.

97.3

SCHILD PLOT ANALYSIS OF THE INTERACTIONS OF GLYCINE AND KYNURENIC ACID AT THE N-METHYL-D-ASPARTIC ACID RECEPTOR. Linda M. Pullan and Julie A. Cler*. Searle R & D/Monsanto, CNS Diseases Research, St. Louis, MO 63198.

Glycine and D-serine enhanced N-methyl-D-aspartic acid (NMDA) stimulated ^{22}Na flux from rat hippocampal slices. Glycine was slightly more effective than equimolar D-serine. The potentiation by glycine was concentration dependent and apparently not competitive to NMDA, with a maximal effect (30% enhancement) near 200μM. Glycine also reversed the kynurenic acid inhibition of NMDA stimulated ^{22}Na flux, increasing the flux several fold. The glycine potentiation was not competitive to kynurenic acid. Kynurenic acid was not competitive to NMDA with a Schild plot slope with an absolute value significantly different than 1. Addition of glycine resulted in a slope with an absolute value closer to 1. These results imply that kynurenic acid interacts at both the glycine recognition site and the NMDA recognition site of the NMDA receptor complex.

97.4

D-CYCLOSERINE EXHIBITS PARTIAL AGONIST CHARACTERISTICS FOR THE N-METHYL-D-ASPARTATE COUPLED GLYCINE RECEPTOR. W.F. Hood, R.P. Compton and J.B. Monahan. Searle CNS Diseases Research & Development, Chesterfield, MO 63198.

Using synaptic plasma membranes, we report that D-cycloserine displaces strychnine-insensitive [^{3}H]glycine binding (K_i=2.33μM) to a recognition site having properties consistent of a N-methyl-D-aspartate (NMDA) receptor modulatory site. Like glycine, D-cycloserine is a positive modulator of the NMDA receptor as shown by its dose-dependent enhancement of [^{3}H]1-(1-(2-thienyl)cyclohexyl) piperidine ([^{3}H]TCP) binding (EC_{50}=12.6μM). Further examination of this enhancement indicates that the maximal stimulation of [^{3}H]TCP binding by D-cycloserine is lower than that produced by other compounds acting at the glycine modulatory site (glycine and D-serine). Consequently, D-cycloserine can be shown to antagonize glycine stimulation. Hence, the stimulation of [^{3}H]TCP binding induced by D-cycloserine in the presence of various concentrations of glycine results in a family of dose response curves that asymptotically converge to 40-50% of the maximal glycine stimulation. These results are consistent with D-cycloserine acting as a partial agonist at the glycine modulatory site of the NMDA receptor complex.

97.5

KYNURENIC ACID UNMASKS GLYCINE MODULATION OF NMDA-EVOKED [^{3}H]NEUROTRANSMITTER RELEASE FROM RAT BRAIN SLICES. R.W. Ransom. Merck Sharp & Dohme, West Point, PA 19486.

Kynurenic acid (KYN) has been shown to be an antagonist at the glycine modulatory site associated with the NMDA receptor. The present experiments were designed to determine whether KYN can be used to detect glycine regulation of NMDA receptor activation in rat brain slices in vitro. NMDA-stimulated release of [^{3}H]norepinephrine (NE) was noncompetitively blocked by KYN (IC_{50} = 102 μM). Glycine, D-serine, L-serine, D-alanine, and L-alanine were able to reverse this inhibition with potencies that correlated with their abilities to displace strychnine-insensitive [^{3}H]glycine binding to rat cortex membranes. Glycine and D-serine had no effect on the inhibition of NMDA-stimulated [^{3}H]NE release by D-AP5, MK-801, or Mg^{2+}. Also, neither amino acid modified KYN inhibition of kainic acid-induced [^{3}H]NE release. Rat striatal slices were used to study NMDA-stimulated [^{3}H]acetylcholine and [^{3}H]dopamine release. KYN inhibition of the release of both neurotransmitters was prevented by low concentrations of either glycine or D-serine. These experiments confirm that, 1) KYN possesses glycine antagonist behavior at the NMDA receptor and, 2) the NMDA receptors mediating hippocampal [^{3}H]NE release and striatal [^{3}H]acetylcholine and [^{3}H]dopamine release are regulated by endogenous glycine.

97.6

GLYCINE REQUIREMENT FOR ACTIVATION OF N-METHYL-D-ASPARTATE RECEPTORS IN XENOPUS OOCYTES. **N.W. Kleckner* and R. Dingledine (SPON: B. Pallotta). Dept. of Pharmacology, University of North Carolina, Chapel Hill, NC 27599.**

Strychnine-insensitive glycine binding sites that co-localize with with N-methyl-D-aspartate (NMDA) binding sites in the brain are thought to be responsible for potentiation of NMDA receptor responses by glycine. We showed previously that rat brain mRNA injected into Xenopus oocytes encoded NMDA receptors that were regulated by glycine. Now we have found that glycine is required for NMDA receptor activation in oocytes. Xenopus oocytes were voltage clamped with one or two microelectrodes. At a holding potential of -60 mV in nominally Mg-free medium, application of NMDA by perfusion (300 μM) or brief pressure ejection (10 mM) elicited inward currents in the presence of glycine (66±13 nA and 5.1±0.7 nA, respectively), whereas in the same cells the NMDA-induced current in the absence of added glycine was negligible (0.6±0.3 nA and 0.04±0.02 nA, respectively). Dose-response curves for glycine at a fixed NMDA concentration (100 μM) showed an EC_{50} of 670 nM and a Hill slope of 1.35. The estimated current induced by NMDA in the absence of glycine was not significantly different from zero. D-serine and D-alanine mimicked the action of glycine while several other analogs did not. The obligatory nature of glycine at the NMDA receptor suggests that 1) its mechanism of action may more closely resemble that of essential cofactors of enzymes than of allosteric modulators of other neurotransmitter receptors, and 2) glycine uptake and perhaps glycinergic synapses may be important in NMDA receptor function.

97.7

POTENTIATION BY GLYCINE OF N-METHYL-D-ASPARTATE INDUCED EXCITOTOXICITY IN RAT CORTICAL CELL CULTURE. D. McNamara* and R. Dingledine. (SPON: R. Meeker). Dept. Pharmacol. Univ. North Carolina, Chapel Hill, NC 27599.

Glycine is known to potentiate current flow through NMDA channels. To determine whether glycine regulates the excitotoxic effect of NMDA, high density dissociated cultures prepared from E19 rat cortex were challenged on day 11 with 100 μM NMDA in the presence of 0-1000 μM added glycine or its analogues. The exposure period was limited to 5 min to minimize the effect of endogenous glycine released by the cells, after which cells were incubated overnight in fresh growth medium plus 100 μM D-APV to prevent toxic effects of residual NMDA. The degree of cell death was judged by the amount of lactate dehydrogenase (LDH) activity released into the medium, and was expressed as a fraction of the maximum amount of LDH released by exposure to NMDA plus 100 μM glycine for 1 hr. In the absence of added glycine, 100 μM NMDA released 12% of the releasable LDH pool; however, a few μM glycine was detected in the medium by HPLC after a 5 min incubation. Added glycine potentiated the toxic effect of NMDA, with an EC50 of 24 μM (95% CI 6-81). D-APV (100 μM) abolished the toxic effect of NMDA plus 100 μM glycine, but 5 mM Mg was without effect. Glycine by itself (1000 μM) was not toxic. Several glycine analogues, including D-serine and D-alanine, were ineffective. Thus the excitotoxic effect of NMDA is less sensitive to glycine and Mg than is the activation of NMDA receptors in oocytes or excised patches of membrane. It is possible that NMDA modulatory sites are themselves regulated in intact tissues.

GLYCINE POTENTIATES NMDA RECEPTOR MEDIATED QUINOLINIC ACID NEUROTOXICITY IN RAT STRIATUM

Kenton J. Swartz, Joseph B. Martin and M. Flint Beal

Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Boston, MA. 02114 and Department of Biochemistry, Boston University School of Medicine, Boston, MA. 02118.

Johnson and Ascher [Nature, 325, 5 (1987)] demonstrated that the putative amino acid neurotransmitter glycine allosterically potentiated the NMDA response in vitro. In the present experiments we examined whether glycine can potentiate excitotoxin lesions acting at the NMDA receptor in vivo. Glycine was co-injected at concentrations of 120 nmol, 240 nmol and 480 nmol with quinolinic acid (120 nmol) into the anterior striatum of the rat. All injections were made in a total volume of 1.0 ul. Controls consisted of quinolinic acid (120 nmol) alone, glycine (960 nmol) alone and 0.9 % saline alone. GABA and substance P-like immunoreactivity (SPLI) were measured as markers for medium-sized spiny striatal neurons and somatostatin-like immunoreactivity (SSLI) and neuropeptide Y-like immunoreactivity (NPYLI) were measured as markers for medium-sized aspiny striatal neurons. Quinolinic acid (120 nmol) lesions resulted in a 20.5 % decrease in GABA and a 23.0 % decrease in SPLI while co-injection of quinolinic acid (120 nmol) and glycine (480 nmol) resulted in a decrease of 37.8 % in GABA ($p < 0.01$) and a 52.2 % decrease in SPLI ($p < 0.01$). Increasing doses of co-injected glycine resulted in dose-dependent increases in the excitotoxin lesions as evaluated by decreases in GABA and SPLI. Saline and glycine (960 nmol) injected controls resulted in no significant change in the content of GABA and SPLI. SSLI and NPYLI were spared with all of the quinolinate lesions. Glycine therefore potentiates NMDA receptor mediated quinolinate neurotoxicity in vivo. This raises the possibility that a defect in glycine metabolism and/or neurotransmission could result in excitotoxic mediated neurodegeneration.

97.9

GLYCINE REGULATION OF THE NMDA RECEPTOR COUPLED CHANNEL IN HIPPOCAMPAL MEMBRANES: STRUCTURE/ACTIVITY RELATIONSHIPS. L.A. Skaryak*, D.W. Bonhaus and J.O. McNamara. Duke Univ. and V.A. Med. Ctr. Durham, NC 27705.

Glycine, an inhibitory neurotransmitter in the spinal cord, markedly potentiates NMDA evoked currents in cultured neurons and in frog oocytes injected with rat MRNA. We tested whether glycine also potentiates NMDA dependent channel activation in hippocampal membranes from adult rat. Using the apparent association rate constant of [3H]N-(1[thienyl]-cyclohexyl) piperidine (TCP) as an index of NMDA dependent channel opening, we found that: 1) glycine dose dependently increased NMDA dependent channel activation; 2) this response was strychnine insensitive; 3) D-serine, D-alanine, L-serine, L-alanine and B-alanine were all equally efficacious at activating the NMDA receptor coupled channel; 4) the rank order of potency of these glycine agonists in activating the channel matched their potency in displacing [3H]glycine from membranes derived from rat cortex (Kishimoto et al. 1981).

a.a.	gly	d-ser	d-ala	l-ser	l-ala	b-ala
EC50 (uM)	0.31	0.42	0.74	26.7	68.7	894.0

These results support the idea that a stereoselective glycine receptor, as part of the NMDA receptor/channel complex, regulates NMDA evoked currents in hippocampus.

97.10

RADIOHISTOCHEMICAL DEMONSTRATION OF NMDA/GLYCINE RECEPTOR COUPLED ION CHANNEL ACTIVATION. D.A. Hosford, D.W. Bonhaus & J.O. McNamara, Depts. Medicine(Neurology) & Pharmacol., Duke Univ. and V.A. Med. Ctrs., Durham, NC, 27705.

Kinetic analyses indicate that NMDA and glycine regulate ^{3}H-TCP binding to hippocampal membranes by controlling its access to a "guarded" binding site (Bonhaus, D.W. et al., this vol.), presumably within the NMDA channel. The intent here was to extend these findings from isolated membranes to slide-mounted sections of rat brain by using a radiohistochemical method.

Sections were preincubated in 50 mM Tris-HCl; incubated in 5 mM Tris-HCl with 2 nM ^{3}H-TCP and combinations of glycine, NMDA, PCP and other drugs; washed; dried; exposed to ^{3}H-sensitive film; analyzed with RAS/R1000 image analysis system (Loats). Specific ^{3}H-TCP binding was enhanced by NMDA (D-APV-blockable) and glycine (strychnine-insensitive) but not by AMPA or kainate. NMDA and glycine greatly (300 %) enhanced binding in dentate stratum moleculare and strata radiatum/oriens of CA1/CA3 of hippocampus but not in cerebellar granule cell layer. This parallels electrophysiologic studies that show NMDA channel activation in CA1 but not in adult cerebellar granule cells, and further validates the use of NMDA/glycine-regulated ^{3}H-TCP binding as a molecular marker of NMDA channel activation. This radiohistochemical method is a powerful tool that permits in situ functional analysis of the NMDA receptor/channel complex in discrete neuronal populations in physiologic and pathologic states. (funded by V.A. Merit Review & NIH grants)

97.11

AGONIST ACTIVATION OF THE NMDA RECEPTOR COUPLED CHANNEL IN HIPPOCAMPAL MEMBRANES: MEASUREMENT WITH [3H]N-(1[THIENYL]-CYCLOHEXYL) PIPERIDINE (TCP). D.W. Bonhaus and J.O. McNamara. Duke Univ. and V.A. Med. Ctr. Durham, NC 27705.

Phencyclidine and structural analogs (ketamine, MK-801) are uncompetitive NMDA antagonists (UCA). Numerous laboratories have shown that NMDA agonists increase [3H]UCA binding in membrane preparations. Electrophysiologic data suggest that UCA bind in the lumen of the receptor coupled channel and that access of UCA to the binding site requires opening of the channel. These findings raise the possibility that [3H]UCA can serve as biochemical markers of channel activation. We used a kinetic approach to test this idea. We found that NMDA receptor agonists increased both the apparent association and apparent dissociation rate constants for binding of the phencyclidine analog TCP. APV virtually eliminated both the association and the dissociation of the ligand. The effect of NMDA agonists and antagonists on both rate constants was of equivalent magnitude resulting in no change in the kinetically determined Kd. These results are consistent with the idea that NMDA regulates UCA binding by controlling access of the ligand to a binding site in the channel. The results are not consistent with NMDA increasing the affinity or number of TCP binding sites. Thus these results validate the use of [3H]UCA binding as a biochemical marker of channel activation.

97.12

GLYCINE MODULATION OF THE NMDA RECEPTOR: ANALYSES OF STOICHIOMETRY AND LIGAND SELECTIVITY. M. Benedict*, K. Thedinga* & G.E. Fagg, Research & Development Dept., Pharmaceuticals Division, CIBA-GEIGY Ltd., 4002 Basel, Switzerland. (SPON: P.L. Herrling)

Recent evidence indicates that glycine allosterically regulates the activity of the NMDA (N-methyl-D-aspartate) receptor complex in brain neurons. Here, we show that ^{3}H-glycine bound to a Triton X-100-treated synaptic membrane fraction from rat telencephalon with K_d 213 nM and B_{max} 17.0 pmol/mg protein. In the same membrane preparations, L-^{3}H-glutamate (NMDA-sensitive), ^{3}H-CPP and ^{3}H-MK-801 bound with K_d's of 102, 130 and 12 nM, and with B_{max}'s of 9.3, 6.8 and 8.1 pmol/mg protein, respectively. For all ligands, Hill coefficients were close to unity. These data suggest that the NMDA receptor complex comprises transmitter, glycine and channel units either in the ratio 1:2:1 or, if L-glutamate and CPP binding sites represent distinct but interconvertible states of the transmitter binding site (as recently proposed by Cotman's group), then in the ratio 2:2:1. However, dose-response curves for the stimulation of ^{3}H-MK-801 binding (a marker for channel opening) by glycine and L-glutamate were each characterized by Hill coefficients of unity.

Analyses of the ligand selectivity of the ^{3}H-glycine binding site indicated that it was strychnine-insensitive, but was inhibited by D-serine>D-alanine>L-alanine>L-serine (IC_{50}'s 0.4-40 μM). Cycloserine, HA-966 and kynurenic acid were also potent inhibitors (IC_{50}'s 2-10 μM), whereas a number of kynurenic acid analogues were inactive. Based on ^{3}H-MK-801 binding, D- and L-serine, D- and L-alanine and cycloserine were characterized as agonists at the glycine regulatory site (i.e., they increased MK-801 binding), whereas HA-966 and kynurenic acid antagonized the stimulatory effects of glycine.

97.13

GLYCINE INDUCES SPREADING DEPRESSION IN AREA CA3 OF RAT HIPPOCAMPAL SLICES THROUGH AN NMDA RECEPTOR-DEPENDENT MECHANISM. A.C. Bragdon, H. Kojima* and W.A. Wilson. Veterans Administration Medical Center, and Depts. of Medicine (Neurology) and Pharmacology, Duke University Medical Center, Durham, NC 27705.

Glycine was recently discovered to potentiate a variety of NMDA receptor-mediated actions in membranes and single neurons through a strychnine-insensitive mechanism. Reports of comparable effects in brain slices have been lacking. We now report that glycine induces spreading depression (SD) in area CA3 of rat hippocampal slices through an NMDA receptor-dependent mechanism. (We have also reported that glycine induces epileptiform bursting, Am Epilepsy Soc, 1988.)

Hippocampal slices from male Sprague-Dawley rats were studied submerged in a chamber perfused with ACSF (including K^+ 3.3 mM, Ca^{++} 1.2 mM, Mg^{++} 1 mM; 33°C). Extracellular potentials were recorded from s. pyramidale and stimuli were delivered to s. radiatum of area CA3. All drugs were bath-applied.

Glycine induced SD at concentrations ranging from 4-7 mM with an EC_{50} of 6 mM (N = 8 slices). Identical results were obtained in the presence of 10 uM strychnine (N=6) suggesting the effect was not mediated through the classical glycine receptor. The NMDA receptor antagonist D-APV at 50 uM prevented SD induced by 10 mM glycine when applied prior to glycine (N=6) and reversed SD when applied during glycine exposure (N=6). In medium lacking the channel blocker Mg^{++} SD occurred at 3 mM (N=4), a significant (P<0.005) reduction. D-serine, L-serine and beta-alanine also caused SD at similar concentrations; mannitol (5-30 mM) and glycerol (5-30 mM) had no effect. 10 mM KCl-induced SD was unaffected by D-APV.

These results suggest the NMDA receptor plays an important role in glycine-induced SD, but not in SD from all causes. The high amino acid concentrations required may reflect the presence of active uptake processes or an endogenous antagonist. Whether glycine acts through the NMDA receptor-associated glycine receptor or another mechanism awaits development of a selective antagonist.

LOW MAGNESIUM EPILEPTIFORM ACTIVITY IN THE DEVELOPING NEOCORTEX: LACK OF MODULATION BY ZINC AND GLYCINE.
J. J. Hablitz, E. Hegstad* and I. A. Langmoen*. Sect. of Neurophysiol., Baylor Col of Med., Houston, TX 77030 and Dept. of Neurosurgery, Rikshospitalet, Oslo, Norway.

Spontaneous epileptiform activity was induced in neocortical slices from rats 9-14 days old by perfusion with salines containing no added magnesium. It consisted, in extracellular recordings, of spike discharges superimposed on a slow negative field potential. Such events were 40-70 sec long, recuring every 4-5 min. Bath application of the NMDA receptor antagonist DL-AP7 (4-10 μM) completely suppressed spontaneous and evoked epileptiform activity (N=5). Addition of zinc (50-100 μM; N=10) produced no change in the frequency, amplitude or duration of discharges. Possible modulation by glycine was examined in three ways: (1) addition of glycine (100-500 μM), (2) blockade of glycine uptake by methylmalonic acid (.5-1.0 mM) and (3) blockade plus exogenous glycine. None affected epileptiform activity. The present results indicate that long duration paroxysmal bursts are observed in the developing neocortex following removal of extracellular magnesium. Involvement of NMDA receptors was indicated by the sensitivity to DL-AP7. Using this slice preparation, we were unable to demonstrate a modulatory effect of zinc or glycine. This may result from an immature state of the NMDA receptor during development or point to differences in synaptic vs nonsynaptic NMDA receptors. Supported by NS18145 and NS2373.

98.2

MULTIPLE EFFECTS OF CHANGES IN $[Mg^{2+}]_0$ ON RAT NEOCORTICAL NEURONS IN VITRO.
B. Sutor* and J. J. Hablitz. (SPON: A. C. Coats), Sect. of Neurophysiol., Dept. Neurol., Baylor Col. of Med., Houston, TX 77030.

Intracellular recordings were obtained from neurons in slices of rat frontal cortex using single-electrode current and voltage-clamp techniques. Following a decrease in $[Mg^{2+}]_0$ from 1.3 mM to a nominal 0 mM, the resting membrane potential (RMP) depolarized (3-5 mV), the input resistance (R_N) increased (15-25%) and the rheobase current decreased (50-60%). Simultaneously, graded EPSPs and IPSPs disappeared and were replaced by prolonged, spontaneous, all-or-none epileptiform bursting activity. The responses to iontophoretically applied NMDA were simultaneously enhanced. However, the NMDA-induced depolarization was still associated with an apparent increase in R_N. Upon return of 1.3 mM Mg^{2+} to the bathing solution, all effects were reversible. Following an increase in $[Mg^{2+}]_0$ to 3 mM, opposite effects, including hyperpolarization of the RMP, decreases in R_N, and direct excitability, depression of postsynaptic potentials and reduction in NMDA-induced responses were observed. The present results indicate that changes in $[Mg^{2+}]_0$ affect not only the neuron's response to NMDA, but in addition, intrinsic membrane properties and NMDA-independent synaptic transmission.

HIPPOCAMPAL SLICES EXPOSED TO QUISQUALATE SUBSEQUENTLY DEVELOP INTERICTAL ACTIVITY THAT IS INTENSIFIED BY AP4 AND AP6.
E.W. Harris, Dept. Pharmacology, Pharmaceutical Div., Pennwalt Corp., Rochester, NY 14603

It was recently reported (Robinson et al., Brain Res. **381**, 1986, 187; Harris et al., Brain Res. **418**, 1987, 361) that the glutamate analog quisqualate induces in hippocampal slices an atypical sensitivity to the otherwise innocuous glutamate analogs 2-amino-4-phosphono butyrate (AP4) and 2-amino-6-phosphonohexanoate (AP6). This report describes epileptiform activity that develops after bath application of quisqualate.

Bathing hippocampal slices briefly in 10uM quisqualate reduces extracellularly recorded synaptic responses by depolarizing postsynaptic neurons. Synaptic responses return 3-5 minutes after wash-out, by which time sensitivity to AP4 or AP6 is evident. Unexpectedly, spontaneous interictal discharges appear 20-30 minutes after quisqualate treatment. Upon re-application of quisqualate, AP4, or AP6, spontaneous discharge rate increases, culminating in a prolonged ictal discharge. The spontaneous interictal activity and elicitable ictal discharges persist for over 2 hours. Several ictal discharges can be elicited after each quisqualate treatment. The epileptiform activity has been observed in slices of septal and temporal hippocampus, but is always more pronounced in region CA3 than CA1.

98.4

DIFFERENTIAL ACTIONS OF ANTITUSSIVES: I. EFFECTS OF DEXTROMETHORPHAN AND CARAMIPHEN ON EPILEPTIFORM ACTIVITY AND NMDA RESPONSES IN PYRIFORM CORTEX SLICES.
J.P. Apland, S. Sparenborg and D.J. Braitman*, Neurotox Br, US Army Med Resrch Inst of Chem Defense, APG, MD 21010

The centrally acting non-narcotic antitussives dextromethorphan (DM) and caramiphen (CM) are potent anticonvulsants (Tortella and Musacchio, Fed.Proc, 46:708, 1987). DM blocks epileptiform activity by blocking NMDA receptors (Wong et al., Neurosci. Ltrs, 85:261, 1988). Here we report that, while DM blocks NMDA-induced epileptiform activity and responses in pyriform cortex brain slices, these responses were not blocked by the more potent antitussive anticonvulsant caramiphen.

Tangential slices of guinea pig olfactory (pyriform) cortex were placed in a total submersion chamber at 32° C in normal oxygenated Ringer's for extracellular recording. DM (100-300 uM) blocked responses elicited by NMDA as well as epileptiform activity evoked by Mg^{++} free medium, but had little effect on field potentials evoked by stimulation of the lateral olfactory tract (LOT). NMDA responses were blocked long after cessation of exposure to DM. In contrast, CM (100-300 uM) depressed LOT-evoked field potentials but did not block NMDA responses nor epileptiform activity in the short or long term. These results indicate that the antitussives dextromethorphan and caramiphen exert their anticonvulsant actions through different mechanisms.

DIFFERENTIAL ACTIONS OF ANTITUSSIVES: II. PROTECTION AGAINST SEIZURES INDUCED BY THE CHOLINESTERASE INHIBITOR SOMAN.
S. Sparenborg and D.J. Braitman*. Neurotox. Br., US Army Med. Res. Inst. Chemical Defense, APG, MD 21010

The antitussive dextromethorphan (DM) blocks epileptiform activity and NMDA responses (Wong et al., Neurosci. Let., 85:261, 1988). Since MK-801, a specific NMDA antagonist, blocks convulsions ,and seizures induced by soman (Braitman et al., SN Abstr. 1988), we tested DM and two other anticonvulsant antitussives, carbetapentane (CBP) and caramiphen (CM), for their efficacy against soman. Guinea pigs were surgically prepared under general anesthesia for chronic ECoG recording. One week later, they were pretreated with pyridostigmine and either CM edisylate (100 mg/kg), CBP citrate (100 mg/kg), DM HBr (30, 60 or 100 mg/kg), or saline, then were given 2 x LD_{50} soman, and treated with methylatropine and pralidoxime chloride. All saline control subjects exhibited severe convulsions and seizures within 15 min after receiving soman. DM attenuated seizures at 60 and 100 mg/kg, but death occurred within one hr after soman. CBP, and low dose DM, offered only slight protection against seizures and convulsions. In contrast, CM blocked ECoG seizures and provided substantial protection against convulsions and lethality, but CM does not appear to block NMDA responses (Apland et al.,SN Abstr., 1988). Although DM blocks NMDA responses, its anticonvulsant properties are inferior to those of the NMDA-blocker MK-801, and to CM, when used as a pretreatment for soman.

INVOLVEMENT OF THE NMDA RECEPTOR IN ABNORMAL DISCHARGES PRESENT IN HIPPOCAMPAL BRAIN SLICES FROM EPILEPTIC PATIENTS.
Leona M. Masukawa, Masato Higashima, Jung Kim and Dennis Spencer. Sections of Neuroanatomy, Neuropathology and Neurosurgery, Yale University Medical School, New Haven, Ct. 06510.

Hippocampal tissue was obtained from epileptic patients who underwent enbloc surgical resections of temporal lobe structures for the treatment of intractable epilepsy. These patients had complex partial seizures that were localized unilaterally to the hippocampus as determined by depth electrode placement along with neurological and neuropsychological testing. Structural abnormality was confirmed by neuropathological examination. The hippocampi were atrophied, sclerotic and displayed dramatic cell loss.

Conventional brain slice recording techniques were used on 450 um thick slices from these human hippocampi. Abnormal discharges were characterized by multiple population spikes (PS's) that were evoked in the dentate gyrus during stimulation of the perforant path (0.1Hz) in normal ACSF. Control rat brain slices generated only one PS at the same intensities. Excitability of the human dentate field response was potentiated by 1 Hz stimuli. The number of PS's was increased 4-5 times after 15 stimuli at this frequency. Multiple PS's were blocked by 5-100 uM APV and the effect was reversable for orthodromic stimuli at 0.1 Hz and 1 Hz. The potentiation at 1 Hz could be mimicked in rat brain slices by lowering Mg to 0.2 mM. These data suggest the involvement of NMDA receptor activation in the abnormal discharge of human epileptic brain slices. Suppported by NIH NS23077 to LMM and NIH NS06208-22 to DS and JK

THE EFFECTS OF EXTRACELLULAR CALCIUM ON THE EPILEPTIFORM ACTIVITY AND NMDA RESPONSES ARE DIFFERENT IN MATURE AND IMMATURE HIPPOCAMPAL SLICES. R.J. Brady and J.W. Swann, Wadsworth Ctr. for Labs and Res., NYS Dept. of Health, Albany, NY 12201.

The number of afterdischarges in penicillin-treated hippocampal slices from an immature rat 9-19 days old can be modulated by changing the concentration of extracellular calcium ([Ca]o) while holding the magnesium concentrations ([Mg]o) constant. Lowering [Ca]o increased the number of afterdischarges produced. Intracellular recordings in TTX-treated CA3 pyramidal cells investigated the effect of changing [Ca]o on the NMDA iontophoretic response. The result of changing [Ca]o paralleled that seen above, lowering [Ca]o increased the response.

The effects of changing [Ca]o on these parameters were also investigated in hippocampal slices taken from mature rats. In contrast to the previous results, changes in [Ca]o had little or no effect in mature slices. Lowering of the [Ca]o has been shown to decrease the voltage sensitivity of the NMDA response in immature but not mature CA3 cells. Since all investigations took place in constant [Mg]o it is likely that the immature NMDA receptor-channel complex is less sensitive to Mg and more sensitive to Ca than its mature counterpart. It is possible that this change in divalent cation sensitivity could underlie the observed developmental differences. **Supported by grants NS-23071 to RJB and NS18309 to JWS from NINCDS-NIH.**

CGS-19755: An NMDA antagonist in drug discrimination and catalepsy in pigeons. Baron, S.P.*, France, C.P.*, Hartman, J.* and Woods, J.H. Departs. Psychology and Pharmacology, Univ. of Michigan, Ann Arbor, Michigan 48109.

Separate groups of White Carneaux pigeons were trained to discriminate between i.m. injections of either 0.32 mg/kg phencyclidine (PCP) or 5.6 mg/kg N-methyl-D-aspartate (NMDA) and saline. The discriminative stimulus and cataleptic effects of the purported competitive NMDA antagonist 1-(cis-2-carboxypiperidine-4-yl)methyl-1-phosphonic acid (CGS-19755) were compared to the behavioral effects of other competitive and non-competitive NMDA antagonists. CGS-19755 produced catalepsy in all subjects and was three times less potent than PCP. CGS-19755 also failed to completely substitute for the PCP discriminative stimulus effects up to doses which suppressed responding, but did attenuate the discriminative stimulus effects of NMDA. Thus, antagonism of NMDA appears not to be sufficient for producing PCP-like discriminative effects in pigeons. In light of the reported neuroprotective effects of NMDA antagonists in animal models of hypoxic-ischemia, the present results suggest that CGS-19755, while sharing some behavioral effects with PCP, might function as an important therapeutic agent without producing the same subjective effects as PCP. This research was supported by NIDA grant DA/AG-05325-01.

NMDA RECEPTOR AFFINITY DETERMINES THE ANTICONVULSANT ACTIVITY OF NMDA ANTAGONISTS IN EPILEPTIC FOWL. S.C.J. Pedder, R. Wilcox, J.M. Tuchek and D.D. Johnson. Dept. of Pharmacology, Univ. of Saskatchewan, Canada S7N OWO.

The high seizure susceptibility in epileptic fowl is due to an autosomal recessive mutation. Epileptiform seizures can be evoked in homozygotes (epileptics) by intermittent photic stimulation (IPS) but not in heterozygotes (carriers). N-methyl-D-aspartate (NMDA) receptor antagonists have been shown to possess anticonvulsant properties in many animal models of epilepsy. However a correlation of *in vivo* activity to *in vitro* affinity has not been shown due to poor specific binding when using [^{3}H] glutamate as the radioligand. Recently a NMDA selective [^{3}H] glutamate radioligand binding assay has been described (Monahan and Michel, J. Neurochem., 1987). Using this procedure we have achieved NMDA specific binding levels of >90%. NMDA receptor antagonist (3-(±)-2-Carboxy-piperazin-4-yl)-propyl-1-phosphonic acid (CPP), 2-Amino-7-phosphonoheptanoic acid (2-AP7), 2-Amino-5-phosphonovaleric acid (2-AP5), ∝-Aminoadipic acid (∝AA), and ∝, ε-Diaminopimelic acid (DPA) were tested for their ability to protect against IPS-evoked seizures in epileptic chickens and to displace [^{3}H] glutamate from synaptic membranes. In both experiments the same order of potency was established, CPP=2-AP7>2-AP5>> ∝AA=DPA. These data provide evidence that NMDA receptor antagonism can be correlated with anticonvulsant effectiveness in a hereditary model of epilepsy. Supported by the MRC.

IN VIVO PHARMACOLOGICAL PROFILE OF NPC 12626 A PUTATIVE NMDA ANTAGONIST. **S.A. Borosky*, B.E. Jones, M.E. Guzewska*, S. Ellenberger*, W.J. Rzeszotarski*, and J.W. Ferkany. Div. Drug Discovery, Nova Pharmaceutical Corp., Baltimore, MD 21224.**

Evidence suggests that systemically active NMDA antagonists may be useful as anticonvulsants, anxiolytics and neuroprotective agents. The novel compound NPC 12626 [2-amino-4,5-(1,2-cyclo-hexyl)-7-phosphonoheptanoic acid] was synthesized and tested for NMDA antagonist effects. Administered ICV, NPC 12626 (ED_{50} = 0.72 nmoles) was 2- and 24-fold more potent in preventing NMDA-induced convulsions than CPP and AP7, respectively. NPC 12626 and CPP were equipotent (ED_{50} = 0.18 and 0.15 nmoles) in the PTZ test. Likewise, systemic administration of NPC 12626 prevented NMDA (ED_{50} = 43 mg/kg) and PTZ-induced (ED_{50} = 47 mg/kg) convulsions. Subchronic injections of NPC 12626 (100 mg/kg; 8 days; b.i.d) did not alter the profile or potency of the compound as an anticonvulsant. Like MK-801 and CPP, NPC 12626 was effective in attenuating damage to CA_1 neurons in the gerbil model of ischemia. Preliminary studies (L. Conti, this meeting) indicate an anxiolytic effect of NPC 12626 (6.25 mg/kg; i.p.). Injected at up to 3000 mg/kg (i.p.) no fatalities were observed in test animals. Similarly, subchronic administration of high doses (10days; 250 mg/kg; b.i.d.) were nonlethal to rats.

The data suggest NPC 12626 is a systemically active NMDA antagonist *in vivo*.

DEXTRORPHAN AND DEXTROMETHORPHAN ACT AS NMDA ANTAGONISTS IN VIVO: BLOCKADE OF NMDA CONVULSIONS IN MICE. J. Sepinwall, M. Smolen* ,S.S. Furman* and E. Mohacsi Research Division, Hoffmann-La Roche Inc., Nutley, NJ 07110

Several studies suggest that the neuronal degeneration seen in Huntington's Disease and after cerebral ischemia may be prevented by compounds acting as antagonists at the NMDA subtype of glutamate receptors. Morphinans, such as dextrorphan (DX), can bind to a high affinity site on the NMDA receptor channel complex, distinct from the NMDA recognition site (Wong et al., J. Neurochem. 50:274, 1988). DX and dextromethorphan (DM) can also prevent glutamate-induced neurotoxicity in neuronal cultures (Choi, Brain Res. 403:333, 1987). To determine whether DX and DM act as NMDA antagonists in vivo, we examined their ability to block convulsions induced by NMDA (175 mg/kg i.p.) in male CF1 mice. The known NMDA antagonist ketamine (K) (active between 30 and 100 mg/kg i.p.), DX (10-30 i.p.) and DM (20-30 i.p.) all blocked both the clonic and tonic convulsions induced by NMDA. MK-801 (0.03-1 i.p. or 0.3-1.6 p.o.) only blocked tonic convulsions; any possible anticlonic activity was obscured by MK-801 induced twitches, tremors and clonic seizures. In contrast to DX, DM and K, neither diazepam (1-30 p.o.) nor phenytoin (10-100 i.p.) blocked clonic convulsions although they did prevent the tonic seizures. Thus reversal of clonic seizures can be a selective endpoint for identifying NMDA antagonists. DX and DM should be pursued further as NMDA antagonists that may be useful as neuroprotective agents.

BEHAVIORAL AND EEG EFFECTS OF MK-801, AND NMDA RECEPTOR ANTAGONIST. R.G. Fariello and D. Garant*. Neurological Sciences, Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612

MK-801 is a recently synthesized non-competitive NMDA receptor antagonist(Woodruff et.al. Neuropharmacology 26, 93.1987). We have studied the behavioral and EEG effects of MK-801 administered to cats. After 0.1 mg/kg MK-801 ip the animal assumes an abnormal posture with extensional ridigity of the neck and forepaws and squatting of the hindpaws. There is loss of postural reflexes and ataxia, with response to sudden auditory or tactile stimuli with massive myoclonic jerks. EEG from cortex and depth structures consisted of spike, polyspike and slow wave discharges with long periods of high voltage rhythmic slowing at 2-4 Hz. At 0.5 mg/kg the animal becomes totally unresponsive and presents erratic myclonic twitches. Bursts of polyspikes and electrographic seizures appear from cortical leads, whereas high voltage rhythmic waves and bursts of spikes and polyspike-and-wave are seen from cortical regions. After several hours the tracing turns into a burst surpression pattern, and then to severely depressed low voltage activity. Recovery is seen after 16-20 hours at 0.1 mg/kg and after 3-5 days after 0.5 mg/kg. There are some analogies between the effects of MK-801 and ketamine.

PAROXYSMAL DISCHARGES IN THE DENTATE GYRUS BLOCKED BY KETAMINE AND MK-801. J.L. Stringer and E.W. Lothman. Dept. of Neurology, Univ. Va. Med. Ctr., Charlottesville, VA 22908.

The NMDA sub-class of glutamate receptors is thought to be involved in events that depend on repetitive activation of neurons. Previous electrophysiological studies on the cellular and synaptic responses to activation of NMDA receptors have been restricted to *in vitro* systems. This study describes *in vivo* responses of the hippocampal formation to 30 sec trains of low intensity stimulation to the CA3 region. A distinct paroxysmal response, consisting of bursts of large amplitude population spikes (30-40 mV), was generated in the dentate gyrus but not in CA1. This dentate response was associated with a secondary rise in the extracellular potassium level and a negative shift of the DC potential. This paroxysmal dentate response was blocked by the NMDA antagonists ketamine and MK-801 in a dose dependent manner. However, the blockade by MK-801 developed only after activation of the paroxysms in the presence of the drug - a demonstration of use-dependence. These studies show that NMDA receptors are activated by repetitive, low intensity stimulation of hippocampal circuits to produce epileptiform discharges in the dentate gyrus. Supported by NIH grants, NS 21671, NS 07199, and NS 25605.

MK-801 PROTECTS AGAINST SEIZURES AND BRAIN DAMAGE INDUCED BY THE CHOLINESTERASE INHIBITOR SOMAN. D.J. Braitman*, N.K. Jaax* and S. Sparenborg (SPON: S. McMaster), Pathophysiology Div, U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Grounds, MD 21010

Excitatory amino acids (EAA) have been shown to be involved in several models of epilepsy and brain damage (Meldrum, Clin. Sci., 68:113, 1985). We present evidence that the NMDA class of EAA receptors is involved in seizures and brain damage induced by the irreversible organophosphorus cholinesterase inhibitor soman. Guinea pigs were chronically instrumented for electrocorticogram recording under general anesthesia. One week later, each group of nine animals received i.p. injections of either MK-801 (LO, 1 mg/kg; HI, 5 mg/kg) or saline vehicle, and pyridostigmine. Thirty minutes later each subject received 2 X LD_{50} soman and was treated with atropine methylnitrate and pralidoxime chloride. All control subjects exhibited convulsions and seizure activity shortly after soman. LO MK-801 greatly attenuated and HI MK-801 completely blocked seizure activity. MK-801 treated animals did not convulse but were prostrate. Animals pretreated with MK-801 recovered faster and had a much greater probability of surviving for 48 hrs after soman exposure than did controls. Also, MK-801 reduced the severity of soman-induced brain damage. This is the first demonstration of the involvement of the EAA neurotransmitter system in seizures, convulsions, and brain damage induced by a cholinesterase inhibitor.

THE "MUSSEL TOXIN", DOMOIC ACID, PRODUCES ITS NEUROTOXIC EFFECT THROUGH KAINATE RECEPTOR: CLINICAL AND ELECTROPHYSIOLOGICAL STUDIES. G. Debonnel, J. Teitelbaum*, S. Carpenter*, L. Beauchesne*, J. Antel, A.N. Cashman and C. de Montigny. Institut P. Pinel and McGill University, Montréal, Québec, Canada.

Domoic acid (DOM), an excitatory amino acid structurally related to kainate (KA), was identified as being responsible for the toxic syndrome produced by mussels grown in Prince Edward Island (Canada). The main neurological symptoms were: memory deficits, confusion, altered state of consciousness and seizures. Six months later, patients still present severe neurological deficits. Two post-mortem examinations revealed extensive neuronal loss in the hippocampus, spotty loss in the thalamus (maximal in the dorso-medial nucleus), in the amygdala and the accumbens.

Unitary recordings were obtained in CA_1 and CA_3 regions of the rat dorsal hippocampus to compare the effect of DOM applied by microiontophoresis to those of KA, quisqualate (QUIS) and N-methyl-D-aspartate (NMDA). In both CA_1 and CA_3, the activation induced by DOM was three fold greater than that by KA. Both DOM and KA were 20 times more potent in CA_3 than in CA_1, whereas there was no such regional difference for QUIS and NMDA. These results provide strong evidence that DOM is an extremely potent agonist of KA receptors. Given the well-known neurotoxicity of KA, this finding is fully consistent with the clinical features of DOM intoxication in humans.

98.16

INHIBITION OF N-METHYL-D-ASPARTATE (NMDA)-INDUCED [^{3}H] NOREPINEPHRINE (NE) RELEASE FROM RAT HIPPOCAMPAL SLICES. **S. Leventer*, D. Giacomo*, S. McArthur*, and G. Metcalf. Wyeth-Ayerst Research, Princeton, NJ 08543**

Excitatory amino acids (EAA's) have been implicated in the pathology of several neurodegenerative diseases. EAA antagonists may be of benefit in such diseases. The purpose of this study was to test compounds for their ability to inhibit NMDA-induced [^{3}H]NE release from rat hippocampal slices as a test of NMDA antagonism.

Hippocampal slices (0.5mm) were preincubated for 30 min in Krebs-Ringer bicarbonate buffer (KRB) containing 10μM pargyline and 1mM ascorbate. Next, the slices were incubated in KRB containing 0.1μM [^{3}H]NE. Thirty min later, the slices were transferred to tubes with 0.5ml Mg^{+2}-free KRB containing 50 μM corticosterone and 10μM desipramine to minimize NE reuptake. At 5 min intervals, 250μl samples were analyzed for [^{3}H] and were replaced by fresh buffer. After 75 min, test drugs were added, and were present for the remainder of the experiment. Fifteen min later, NMDA was added for a 5 min period. After 125 min, the slices were homogenized and assayed for [^{3}H].

NMDA (30μM-3mM) caused a concentration-dependant increase in [^{3}H]NE release. $MgCl_2$ (1.25mM), as well as NMDA antagonists such as MK-801 (20nM), (±)-CPP (10μM) and (±)-AP-7 (100μM) inhibited the release induced by NMDA (300μM). These data support the use of this test for the determination of functional NMDA antagonism.

98.17

AMPA-INDUCED CONVULSIONS IN MICE: COMPARISON TO NMDA AND KAINATE INDUCED CONVULSIONS. **T. A. Emrey*, R. R. Notvest. (SPON: K. L. Keim) Department of Experimental Therapeutics, Wyeth-Ayerst Research, Princeton, NJ 08543**

The NMDA-induced convulsion model is an effective *in vivo* test for evaluating excitatory amino acid antagonists (EAAA) (Croucher, et al., 1982). Kainate (KA)-induced convulsion models have also been developed (Ben-Ari, 1985). This report characterizes a quisqualate receptor-mediated convulsion induced by administration of the quisqualate agonist, alpha-amino-2,3-dihydro-5-methyl-3-oxo-4-isoxazolepropanoic acid HBr (AMPA), and compares it to NMDA- and KA-induced convulsions.

Male Swiss albino mice were habituated for 30 minutes to individual chambers (4 sq. in. plexiglass), treated with AMPA (50-175 mg/kg, i.p.), and observed for 30 minutes. Responses to 50-80 mg/kg doses included circling (ipsi- and contralaterally), tonic rigidity and tremors. Doses of 90-150 mg/kg also produced catatonia and catalepsy, generalized myoclonus and mortality. The AMPA-induced convulsion does not include hind limb scratching which is observed in both NMDA- and KA-induced convulsions.

Systemic administration of AMPA induces a distinctive and reproducible motor convulsive response which may be useful as a model for identifying EAAA acting at the quisqualate receptor.

98.18

EFFECT OF PROTOTYPE ANTICONVULSANT AGENTS ON QUISQUALIC ACID (QA)-INDUCED SEIZURES IN MICE. N.A. Singh*, E.A. Swinyard*, and H.S. White* (SPON: R.P. Tuckett). Dept. of Pharmacol. and Tox., Univ. of Utah, S.L.C., UT 84112.

Previous investigations have demonstrated that the QA antagonist glutamic acid diethyl ester (GDEE) and selected prototype anticonvulsants partially attenuate QA-induced tonic-extension seizures. The present investigation was designed to assess further the effect of phenytoin (PHT), carbamazepine (CBZ), phenobarbital (PB), valproate (VPA), ethosuximide (ETS), and clonazepam (CLZ) on forelimb tonic extension (FTE) induced by intracerebroventricular administration of QA. Groups of 5 to 14 CF #1 mice were injected i.p. with increasing doses of each anticonvulsant and at the predetermined time of peak effect challenged with the convulsive dose 97 of QA (42 μg/5 μl). Animals that did not display FTE within 30 min were considered protected. The effective dose 50 (ED50) was calculated by probit analysis. Except for ETS, all of the anticonvulsants tested were more effective in blocking QA-induced FTE than the QA antagonist GDEE. For example, CLZ was the most potent, followed by PHT, CBZ, PB, VPA, and GDEE (ED50's: 0.119, 6.05, 6.25, 6.41, 138.4, and 736.5 mg/kg, respectively). ETS was ineffective in minimally neurotoxic doses of 600 mg/kg. These results suggest that QA-induced FTE is blocked by preventing spread from a seizure focus. (Supported by NIH training grant GM07579 and NIH contract NO1-NS-4-2361).

98.19

QUISQUALATE ANTAGONIZES THE CONVULSANT ACTION OF KAINATE IN AREA TEMPESTAS. P. Zhong* and K. Gale (SPON: K. Woodbury). Department of Pharmacology, Georgetown University Medical Center, Washington, DC 20007.

Area tempestas (AT) is an epileptogenic zone within the deep prepiriform cortex from which clonic seizures are elicited by focal injections of GABA antagonists, NMDA receptor agonists, as well as kainic acid (KA). The present study examined the effect of quisqualate (QA), an agent that causes excitatory effects via receptors other than those activated by NMDA or KA.

QA was microinjected unilaterally into AT in freely moving, awake rats. Generalized clonic convulsions characterized by repeated facial and forelimb clonus, rearing and falling, were induced in 100% of the rats receiving 2500 pmol QA. These seizures were comparable to those obtained with 100 pmol KA in AT. QA, 500 pmol, produced convulsive responses in only 15% of the rats and these responses were very transient and mild, while QA, 250 pmol, was without convulsant effect.

Following 15 min pretreatment with QA (250 or 500 pmol) in AT, seizures induced by KA (100 pmol) in AT, were prevented. When the same rats were tested 24 hr later with KA alone in AT, a full convulsive response was obtained. Following 15 min pretreatment with QA (500 pmol) in AT, there was no modification of the convulsant effect of bicuculline (100 pmol) in AT, indicating that the anticonvulsant effect of QA is selective for seizures evoked by activation of KA receptors. These data support the in vitro observations of Wroblewski et al. (Fed. Proc. 46: 848, 1987) who found QA to be a non-competitive antagonist of KA receptor function in cultured cerebellar granule cells.

N-METHYL-D-ASPARTIC ACID (NMDA)-INDUCED CONVULSIONS: AN IN VIVO MODEL TO IDENTIFY NMDA ANTAGONISTS. L. C. Johnson* and V. J. DeNoble (SPON: S. W. Tam). E. I. duPont de Nemours & Co., Inc., Wilmington, DE 19898.

NMDA receptors can mediate the neurotoxic actions of excitatory amino acids. Compounds that block NMDA receptor binding or prevent the resulting calcium ion influx prevent NMDA-induced cell death. Research has focused on in vitro studies to investigate the mechanism of cell death. This study was designed to develop an in vivo model of NMDA receptor activation useful in finding compounds that block NMDA-induced cell death. Such a model should be sensitive to NMDA antagonists, PCP receptor binders, and calcium channel blockers, while insensitive to anticonvulsants. Intravenous administration of NMDA to mice produces behavioral excitement leading to clonic convulsions. The ability of different pharmacological agents to block NMDA-induced convulsions in comparison to their ability to block electroshock-induced convulsions (ECS) was studied. Competitive NMDA antagonists (AP7, CPP) and PCP-like drugs (PCP, MK801) blocked NMDA and ECS convulsions at similar doses. Verapamil, a calcium channel blocker, blocked NMDA convulsions but was inactive against ECS. Anticonvulsants (phenobarbital, phenytoin) were either inactive or blocked NMDA convulsions only at doses higher than those active against ECS, while diazepam and valproate showed similar antagonist activity against NMDA and ECS convulsions. These data suggest that NMDA-induced convulsions can be used as an in vivo model of NMDA receptor activation.

TURNOVER OF MUSCARINIC CHOLINERGIC RECEPTORS IN GH_3 CELLS. C.P. Bolden and S.P. Baker. Department of Pharmacology, University of Florida, College of Medicine, Gainesville, FL 32610.

The recovery of muscarinic receptor (M-R) binding and function was determined after irreversible blockade with N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ). Pretreatment of near confluent GH_3 rat pituitary tumor cells with 100 μM EEDQ plus 1 mM glycine ethyl ester decreased specific [^{3}H]quinuclidinyl benzilate ([^{3}H]QNB) binding 85-90% with no change in K_D of ([^{3}H]QNB) binding for the receptors left. This treatment had no effect on forskolin-stimulated adenylate cyclase activity, cell viability or cellular protein synthesis. Associated with the receptor loss was a 90% reduction in the maximal M-R mediated inhibition of forskolin-induced cAMP production. In addition, the carbachol dose-response curve for inhibition of cAMP production was shifted rightward about 5-fold. Recovery of receptor binding ([^{3}H]QNB) was a first-order process, the control levels being achieved within 24 hr and was blocked by the protein synthesis inhibitors cycloheximide and puromycin. In contrast, the maximum response (carbachol inhibition of forskolin-stimulated adenylate cyclase) fully recovered within 6 hr. The data suggests the half-life of the M-R in GH_3 cells is relatively short (approximately 7 hr) and a high coupling efficiency between the receptor and response is present.

99.2

IN VIVO ASSESSMENT OF THE COMPARTMENTALIZATION OF DOPAMINE IN STRIATAL NERVE TERMINALS G.W. Arbuthnott, I.S. Fairbrother, S. Butcher. (Spon: European Neurosciences Association) MRC Brain Metabolism Unit and Department of Pharmacology 1 George Square, Edinburgh EH8 9JZ, UK.

In rats anaesthetised with Halothane we have examined the release of dopamine (DA) into the perfusate passing through a dialysis fibre implanted into the neostriatum. The actions of various releasing agents including K^+, amphetamine, veratrine, ouabain and tyramine have been studied. The amount of DA release is altered to different extents by pretreatment of the animals with reserpine, or α-methyl-p-tyrosine (αmpt), according to the releaser administered. Similarly the drugs show markedly different sensitivities to EGTA or to TTX applied through the probe. Veratrine and K^+ cause release from a pool which is exquisitely sensitive to TTX, EGTA and αmpt. Tyramine results in release which is little affected by TTX, or by EGTA. Amphetamine and ouabain share an intermediate position.

The amount of DOPAC in the dialysate is also differently altered by the various releasing agents. At doses that cause the release of DA, K^+ causes a marked reduction of DOPAC, whilst tyramine does not.

Thus release in vivo seems to derive from different nerve terminal pools with differing sensitivities to pharmacological manipulations.

99.3

INFLUENCE OF SYMPATHETIC INNERVATION ON CATECHOLAMINE METABOLISM IN RABBIT CAROTID BODY. A. Gomez*, C. Gonzalez, B. Dinger and S. Fidone, Dept. of Physiol., Univ. of Utah, Salt Lake City, UT 84108

The present experiments examined the influence of sympathetic innervation on stimulus evoked ^{3}H-dopamine (^{3}H-DA) and ^{3}H-norepinephrine (^{3}H-NE; synthesized from ^{3}H-tyrosine) release from the carotid body superfused in vitro by media equilibrated with 10% O_2 or containing nicotine (10^{-4} M). In one group of animals, superior cervical ganglionectomy was performed 10 to 14 days prior to experimentation to eliminate the sympathetic innervation to the carotid body. The stimulus evoked release (stimulus minus basal release in 100% O_2-media) of each ^{3}H-catecholamine (^{3}H-CA) was expressed as a percent of the ^{3}H-DA or ^{3}H-NE remaining in the tissue. The ^{3}H-CA release evoked in low O_2-media, which is primarily ^{3}H-DA, increased 20.4x after sympathectomy, and likewise the nicotine evoked release of ^{3}H-CA (mostly ^{3}H-NE) averaged 4.9x that released from normal carotid bodies. These differences suggest that sympathetic fibers in normal carotid bodies decrease the sensitivity of type I glomus cells to natural and pharmacological stimuli. Alternatively, noradrenergic sympathetic fibers may participate in the uptake of catecholamines released from type I cells. (Supported by USPHS Grants NS12636 and NS07938).

MDMA AND MBDB POTENTIATE PHORBOL ESTER-STIMULATED CATECHOLAMINE RELEASE FROM PC-12 CELLS. J.A. Monti, J.M. Beaton, F. Benington*, R.D. Morin*, and S.T. Christian. Neuropsychiatry Research Program and Department of Psychiatry, University Station, Birmingham, Alabama 35294, U.S.A.

We have previously shown that MDMA (Ecstasy) and its congener MBDB, stimulated catecholamine release from PC-12 cells. The S(+) stereoisomer of both compounds is most potent in stimulating catecholamine release and MDMA appears to preferentially stimulate the release of NE as compared with DA. Phorbol dibenzoate stimulates NE and DA release from PC-12 cells with an EC_{50} ~200 nM. Phorbol didecanoate is inactive in stimulating catecholamine release. The release of NE and DA from PC-12 cells was measured (HPLC-EC) using increasing concentrations of Phorbol dibenzoate in the presence of 200 μM racemic MDMA or MBDB. Catecholamine release induced by the combination of Phorbol dibenzoate and racemic MDMA or MBDB was greater than that induced by the phorbol ester alone, and in the presence of MDMA or MBDB, the dose-response curves for Phorbol ester-stimulated catecholamine release were shifted to the left. Dose-response curves for Phorbol dibenzoate + MBDB-stimulated release of NE and DA were monophasic with EC_{50} ~50 nM, as was the dose-response curve for Phorbol dibenzoate + MDMA-stimulated release of DA (EC_{50} ~60 nM). However, the dose-response curve for Phorbol dibenzoate + MDMA-stimulated release of NE appeared to be biphasic with EC_{50}'s of 2 and 30 nM, respectively. Potentiation of Phorbol ester-stimulated catecholamine release of MDMA and MBDB was stereospecific with the S(+) isomer of each compound being more potent. Catecholamine release in the presence of S(+) MDMA or MBDB and Phorbol didecanoate was less than that induced by MDMA or MBDB alone. These data suggest the possibility that MDMA and MBDB-stimulated release of catecholamines from PC-12 cells may be mediated by protein kinase-C.

ATP-DEPENDENT UPTAKE OF GABA BY RAT BRAIN SYNAPTIC VESICLES. J.A. Near and W.J. Chang*. Medical Sciences Program and Department of Pharmacology, Indiana University School of Medicine, Bloomington, IN 47405.

A number of small neurotransmitters are sequestered in synaptic vesicles by transport systems coupled to a proton translocating ATPase. In order to determine if a similar uptake system for GABA exists in the mammalian CNS, association of [^{3}H]-GABA with a crude preparation of synaptic vesicles from rat brain was examined. ATP and GTP both supported the apparent transport activity, whereas other nucleotides and nucleosides were ineffective. Agents that disrupt proton electrochemical gradients, such as ammonium ion and CCCP, inhibited ATP-dependent activity. The activity was dependent on time, temperature, external pH, vesicle protein concentration and GABA concentration, with an apparent K_m of 13mM for GABA. Although plasma membrane transport systems for GABA are sodium dependent, the activity described here was not. Similarly, agents that are known to interact with GABA and glutamate receptors, synaptosomal and glial uptake systems for GABA or glutamate, and the vesicle catecholamine uptake system were all ineffective at relevant concentrations. These results suggest that a specific uptake system for GABA exists in synaptic vesicles from mammalian brain.

HIGH-AFFINITY UPTAKE OF L-KYNURENINE IN MOUSE BRAIN ASTROCYTES. K. Hares*[1], C. Speciale[1], R. Schwarcz[1] and N. Brookes[2] (SPON: F. Du). [1]Maryland Psych. Res. Ctr., Baltimore, MD 21228 and [2] Dept. Pharmacol. Exptl. Therap., Univ. Maryland Sch. Med., Baltimore, MD 21201.

L-kynurenine (KYN), the bioprecursor of the neuroactive brain metabolites quinolinic and kynurenic acid, can be taken up into rat brain slices by two processes, one Na^+-dependent and the other Na^+-independent (Soc. Neurosci. Abstr. 13:1675, 1987). Here, primary astrocyte cultures derived from the cerebra of newborn mice were equilibrated for 30 min in HEPES-Tris buffer (pH 7.4, 34.5°C) before addition of ^{3}H-L-KYN (8.9 Ci/mmol). Saturation curves for the initial velocity of KYN uptake conformed to a one-component saturable system with a K_m of a 32 μM and a V_{max} of 2.1 nmol/mg protein/ min. The KYN transporter did not recognize aspartate, GABA or taurine. However, the large neutral amino acids leucine, tryptophan and phenylalanine were accepted with somewhat higher affinity than KYN. In Na^+-free buffer, KYN uptake was equal to or greater than in the presence of Na^+. The spontaneous efflux of label from cultures loaded with ^{3}H-L-KYN was suppressed at 4°C, and was accelerated by the presence of unlabeled KYN or Na^+ in the buffer. KYN was notably concentrated by the astrocytes. After addition of 1 μM ^{3}H-L-KYN to the cultures, the steady-state (20-30 min) distribution ratio of labeled species was estimated to exceed 100-fold. (Supported by USPS grants NS 16102 and ES 03928).

ENHANCED KYNURENIC ACID SYNTHESIS IN CORTICAL AND HIPPOCAMPAL SLICES FROM AGED RATS. R. Schwarcz, W.A. Turski and J.B.P. Gramsbergen. Maryland Psych. Res. Ctr., Baltimore, MD 21228.

In aging, nerve cell loss may occur in particularly vulnerable brain areas, such as cortex and hippocampus. Kynurenic acid (KYNA), a regular brain constituent, has been shown to display neuroprotective properties. Therefore we have examined KYNA production and liberation of KYNA in brain slices of rats of different ages.

KYNA production and liberation from brain slices was examined upon exposure to 50 μM kynurenine (cf. Turski et al., this meeting). Experiments were performed with young adult (3 months), mid adult (1 year) and old (2 years) rats (N = 6 per group). After incubation, KYNA content (per mg slice protein) in medium of cortical and hippocampal slices from 1 and 2 year old rats was about twice as high as that from young animals ($p<0.05$). KYNA production in slices obtained from striatum, thalamus, cerebellum and liver was similar in all age groups. In urine, KYNA content decreased with increasing age (from 27±7 pmol/ μl at 3 months to 7±2 pmol/ μl at 2 years; $p<0.05$).

Our data show that large differences exist at all ages in the capacity of different organs and brain regions to synthesize and liberate KYNA. The specific increase in cortical and hippocampal tissue in the aged brain may be of relevance for an understanding of neuronal loss in advanced age.

DIFFERENTIAL REGULATION OF DOPAMINE AND NEUROTENSIN IN COLOCALIZED AND NON-COLOCALIZED NEURONAL POPULATIONS. A.J. Bean, T.E. Adrian*, I.M. Modlin*, and R.H. Roth. Depts. of Pharmacol. & Psychiat., Yale Univ. Sch. Med., New Haven, CT, and VA Med. Ctr., West Haven, CT.

The demonstration of coexistence of dopamine (DA) and neurotensin (NT) within a subset of ventral tegmental area neurons has prompted us to examine the regulation of DA and NT storage in colocalized (prefrontal cortex; PFC, and nucleus accumbens; NAS) and non-colicalized (striatum; CP, and periaqueductal grey; PAG) neuronal populations. We investigated the effects of reserpine (RES), alpha-methyl-p-tyrosine (AMT), and gamma-butyrolactone (GBL) on DA and NT content within the same sample of each brain region. RES (0.5-5.0 mg/kg i.p. -6, -18. -48 h) dose-dependently depleted DA in all brain regions at the 6 and 18 h time points and levels returned to control values by 48 h. NT levels dose-dependently declined in the PFC (18, 48 h), increased in the CP (6, 18 h), and NAS (18, 48 h) and were not altered at any time point in the PAG. AMT (200 mg/kg i.p. -4 h) reduced DA in all regions without altering NT. GBL (750 mg/kg i.p. -2 h) induced increases in PFC DA and NT which were reduced by RES. GBL-induced increases in CP and NAS DA, and decreased CP NT, effects which were reversed by RES. Thus, RES may increase NT synthesis and/or decrease NT release in NAS and CP. Furthermore, these data indicate that DA and NT may be co-stored in some PFC terminals in RES-sensitive vessicles. Supported by MH-14092, NIGMS-GM 07324, and the Veterans Administration.

STIMULATION-DEPENDENT RELEASE OF ATP FROM HIPPOCAMPAL SLICES. A. Wieraszko, G. Goldsmith, T. Seyfried, Biology and Physics Depts. Boston College, Boston, MA 02167

ATP is known to be released from K^+-stimulated rat brain synaptosomes (White, Nature 267: 67, 1977) and may act as a neuromodulator in the CNS. Here we demonstrate the release of ATP from hippocampal slices following the electrical stimulation of Schaffer collaterals. The slices were stimulated with bursts of pulses (300Hz for 50ms, 2 sec intervals) for 30 sec which caused a stable increase in the size of the population spike (LTP). The release of ATP was measured with a luciferase-luciferine system and the light emitted was recorded with a photomultiplier placed beneath the slice chamber. ATP release was observed shortly after the start of stimulation. No ATP release was detected in a Ca^{+2} free solution or after low frequency stimulation (1Hz). Glutamate (2 mM) applied without electrical stimulation did not evoke ATP release. Kynurenic acid (10 mM), which blocks population spike, did not block ATP release. We conclude that ATP is released from electrically stimulated hippocampal slices from presynaptic nerve terminals in a calcium-dependent fashion and may play a role in the modulation of synaptic efficiency.

UNIQUE BIOCHEMICAL PROPERTIES OF DOG BRAIN MAO-A. P.W. Scates* and H.L. White. Dept. of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Monoamine oxidase occurs as two distinct enzyme forms, MAO-A and MAO-B. Both forms are found in brain mitrochondrial preparations, as characterized by substrate specificities and effects of selective inhibitors. Although MAO of Beagle dog brain can be classified as A and B using these criteria, certain properties of dog brain MAO-A distinguish it from the enzyme of other species. MAO-A in mitochondrial preparations from dog brain was inhibited by A-selective inhibitors. However, it was about 10-fold less sensitive to inhibition by clorgyline and pargyline than was MAO-A of human brain. After solubilization by nonionic detergent, dog brain MAO-A became much less sensitive to inhibition by clorgyline, harmine, and pargyline, while the Km with serotonin as substrate was increased approximately 15-fold. No such effects were observed with human or rat brain MAO-A in similar experiments. Solubilization of MAO-B of dog brain did not change its Km with phenethylamine as substrate. In addition, dog brain MAO-A was particularly sensitive to inactivation by trypsin under conditions which did not affect MAO of human or rat brain enzyme. These and other results reveal species differences in the structure and/or membrane microenvironment of MAO-A.

IMMUNOBLOT ANALYSIS OF HUMAN MAO A AND B FROM TISSUES CONTAINING WIDELY DIFFERENT RATIOS OF A TO B ACTIVITY.

L. A. Riley*, M. A. Waguespack*, R. M. Denney, Department of Human Biological Chemistry and Genetics, Graduate School of Biomedical Sciences, University of Texas Medical Branch, Galveston, TX, 77550.

Monoamine oxidases (MAOs; EC 1.4.3.4) oxidize important biogenic and xenobiotic amines. Previously, we reported an immunoblotting assay for MAO A using the monoclonal antibody MAO A-4D3 (Riley et al., Soc. Neurosci. Abs., 1987). Using the same system, the MAO B-specific antibody, MAO B-1C2 (Denney et al., Molec. Pharm. 22:500, 1982) immunoblots human MAO B. Binding of antibodies to MAO A or B on nitrocellulose is enhanced by the presence of Tween-20 in the primary antibody incubation. Both antibodies retain their specificities after antigen denaturation and apparent epitope regeneration. Neither antibody binds detectably to other proteins in placental mitochondria or platelets. Human placenta, widely reported to contain primarily MAO A, contains significant MAO B protein and activity [deprenyl-sensitive β-phenylethylamine (PEA) and benzylamine oxidizing activity]. In contrast, much more MAO B than MAO A protein was detected in liver, even though the rates of tyramine oxidation by A and B are approximately equal. These observations suggest that MAO A has a higher molecular activity than MAO B for many substrates, including shared substrates like tyramine and the reportedly MAO B-selective substrate, PEA. (Supported by grant NS19453.)

TIME- AND NH_4^+- DEPENDENT CHANGES OF AMINO ACID CONCENTRATIONS IN MEDIUM FOR ELECTROPHYSIOLOGICAL RECORDING FROM PRIMARY CULTURES OF CEREBELLUM.

J.E. Madl*, D.H. Smullin, S.R. Skilling*, A.A. Larson, and W.A. Raabe. Depts. Vet. Biol. and Neurology, Univ. of Minnesota and VA Med. Ctr., St. Paul, MN 55108.

Amino acids in the electrophysiological recording medium (ERM) used for tissue culture may affect membrane currents (e.g., effect of glycine on NMDA-activated channels). NH_4^+ depolarizes neurons and perturbs amino acid metabolism. We therefore studied the concentrations of glutamate (Glu), aspartate (Asp), glycine (Gly), taurine (Tau), glutamine (Gln) and asparagine (Asg) in ERM and ERM with 5mM NH_4Cl added. Primary monolayer cultures of the cerebellum were grown in 35 mm dishes. After discarding the growth medium, each dish was rinsed six times with ERM and sampled. By 60 min, the concentrations of Glu and Asp decreased to 30% and 15% of their original values, repectively. The concentrations of the other amino acids increased to 4-20 times their original concentrations within 30 min and remained stable thereafter. Addition of NH_4^+ to ERM resulted in an increase of all amino acids, including an 8-fold increase of Glu. These data indicate that after exposure of cultures to ERM, amino acid concentrations in ERM undergo significant changes within the first 30-60 min. In addition, agents affecting amino acid metabolism and neuronal function, such as NH_4^+, may produce significant changes in amino acids concentrations in ERM. Supported by NS 01105, DA 04090, DA 04190, DA 00124 and the Veterans Administration.

FUNCTIONAL INTRACELLULAR GLUTAMINASE ACTIVITY IN DIBUTYRYL C-AMP TREATED ASTROCYTES.

H.R. Zielke* and J.T. Tildon* (Spon: K.A. Gregerson). Pediatric Research, University of Maryland, Baltimore, MD 21201.

The functional intracellular glutaminase activity measured by the release of ^3H_2O from L-(2-^{3}H)-glutamine is 5-10% of the activity measured in extracts of DiBcAMP treated and untreated astrocytes. The V_{max} was 181 nanomol/mg protein/h for untreated cells and 581 nanomol/mg protein/h for treated cells. The $K_{m(app)}$ for untreated and treated cells were similar: 169 and 132 nanomol/mg protein, respectively. Addition of glutamate to the medium inhibits intracellular glutaminase activity. However, a residual 30% of the enzyme activity was uninhibited. The $K_{i(app)}$ for glutamate was independent of DiBcAMP treatment, approximately 150 nanomol/mg protein. The glutamate inhibition curve as well as the calculated kinetic constants are consistent with published results for purified enzyme. After 4 h in the presence of increasing extracellular glutamine (0.2 to 6.4 mM), intracellular glutamine increased from 40 nanomol/mg protein and plateaued at about 140 nanomol/mg protein in untreated cells and increased from 20 nanomol/mg protein to 60 nanomol/mg protein in DiBcAMP treated cells. With increasing extracellular glutamate (40-200 M), intracellular glutamate concentration increased linearly to 600 nanomol/mg protein. These data indicate that glutaminase activity is regulated intracellularly by glutamine and glutamate as well as by additional effectors. (NICHD-16596)

IN VIVO METABOLISM OF 6-[^{18}F]-L-FLUORODOPA AND [^{3}H]-L-DOPA: DOUBLE LABEL EXPERIMENTS.

W.P. Melega, A. Luxen*, M. Perlmutter*, C. Nissenson*, M.E. Phelps and J.R. Barrio*. Division of Nuclear Medicine, UCLA School of Medicine, Los Angeles, CA 90024.

To validate the assumption that 6-[^{18}F]-L-fluorodopa (FD) cerebral kinetics reflect the functional integrity of the endogenous dopamine (DA) system, we designed experiments with [^{3}H]-L-DOPA (HD), and FD.

Sprague-Dawley rats (275-325g) (jugular cannulae 1 day prior to the experiment) were pretreated with Carbidopa (5 mg/kg., s.c.) 60 min before i.v. injection of FD (400 μCi) and HD (50 μCi). Animals were sacrificed by decapitation at 15, 30, and 60 min. The striata and vermis were removed and were prepared for HPLC analysis (C-18 reverse phase column, 80% 0.1 M Na_2HPO_4, 2.6 mM OSA, 0.1 mM EDTA; 20% MeOH, pH 3.3); the metabolites were identified with authentic standards.

The striatum/cerebellum (s/c) total activity increased for ^{18}F and ^{3}H (2.0, 60 min); the metabolite profiles differed when expressed as a fraction of total radioactivity. [^{3}H]-Dopamine (HDA) and 6-[^{18}F]-fluorodopamine (FDA) were detected exclusively in striatum; none in plasma or in cerebellum. The FDA (striatum)/FD (plasma) ratio increased from 0.95 (15 min) to 3.2 (60 min); the HDA (striatum)/HD (plasma) ratio increased from 0.7 (15 min) to 1.0 (60 min). The relative plasma levels of HD remained higher than the FD levels, whereas there was an increase in the relative rate of O-methylation of FD when compared with HD. Both 3-O-MeFD and 3-O-MeHD rapidly appeared in the plasma, but the 3-O-MeDopa/Dopa ratio differed at 60 min (3-O-MeFD/FD is 6.5, 3-O-MeHD/HD is 1.0). The s/c ratio for 3-O-MeFD, and for 3-O-MeHD was approximately one at 15, 30 and 60 min. These data indicate that a quantitative correlation between 6-[^{18}F]-L-fluorodopa kinetics and cerebral DA metabolism can be established.

99.15

EFFECTS OF POLYMYXIN B AND SPHINGOSINE, PROTEIN KINASE C INHIBITORS, ON CATECHOLAMINE SECRETION FROM INTACT AND DIGITONIN-PERMEABILIZED ADRENAL MEDULLARY CELLS.

E. Tachikawa, S. Takahashi*, C. Shimizu*, N. Ohstubo*, and T. Kashimoto*. Department of Pharmacology, School of Medicine, Iwate Medical University, Morioka 020, Japan.

The effects of polymyxin B (PMB) and sphingosine, inhibitors of protein kinase C (PKC), on catecholamine (CA) secretion from intact and digitonin-permeabilized adrenal medullary cells were examined. Acetylcholine (ACh), 56 mM K^+, veratridine, Ca^{2+}-ionophore ionomycin or 12-O-tetradecanoylphorbol-13-acetate (TPA) induced the secretion of CA from the intact cells. PMB (0.1-100 μM) decreased the secretion of CA induced by these secretagogues in a concentration-dependent manner. Sphingosine (5-400 μM) also diminished the secretion of CA induced by ACh or veratridine but did not affect TPA- and ionomycin-induced CA secretion. Both PMB and sphingosine inhibited the rise in the intracellular free Ca^{2+} concentration ($[Ca^{2+}]_i$) stimulated by ACh, 56 mM K^+ or veratridine. The degrees of both inhibition of ACh-, 56 mM K^+- or veratridine-induced rise in $[Ca^{2+}]_i$ and CA secretion by PMB or sphingosine were similar. PMB also reduced CA secretion from the digitonin-permeabilized cells evoked by an addition of free Ca^{2+} (1 μM) to the medium. Sphingosine had no effects on this Ca^{2+}-dependent secretion. These results suggest that an activation of PKC is involved in Ca^{2+}-dependent CA secretion from bovine adrenal medullary cells. Further, the inhibitory effects of PKC inhibitors on ACh-, 56 mM K^+- or veratridine-induced CA secretion can be considered as a result of blocking the influx of extracellular Ca^{2+} into the cells stimulated by these secretagogues.

99.16

EFFECTS OF MPP^+ ON THE RELEASE OF SEROTONIN AND 5-HYDROXYINDOLEACETIC ACID FROM RAT STRIATUM BY BRAIN DIALYSIS.

H. Miyake*, R.M. Cohen*, and C.C. Chiueh, Clinical Brain Imaging, LCM, NIMH, Bethesda, MD 20892.

In addition to the well documented parkinsonism inducing effects, high dose of MPTP causes acutely a serotonin syndrome. It is postulated that MPP^+, the major metabolite of MPTP in the brain, may increase 5-HT neurotransmission by blocking reuptake, inhibiting MAO and/or releasing 5-HT. Thus, an in vivo brain dialysis procedure was employed to investigate the effects of MPP^+ on the release of 5-HT and 5-HIAA in rats. Sprague-Dawley rats (280-300g) were anesthetized with chloral hydrate (400 mg/kg, i.p.) and then Carnegie Medicin microdialysis probes were inserted into the striatum. The brain was perfused with Krebs-Ringer solution (1μl/min). MPP^+ (1mM) was applied through the dialysis tubing for 60 min. Perfusates were collected every 20 min and assayed simultaneously for monoamines and their metabolites by HPLC-EC. MPP^+ caused a 30-fold increase in the release of 5-HT which peaked within 30 min and lasted for more than 3 hours after the MPP^+ infusion. 5-HIAA decreased from 3.7 ± 0.4 to 2.0 ± 0.3 ng/20μl perfusate. In addition, MPP^+ increased dopamine level 55-fold and caused a concomitant increase in the release of 3-MT. While it decreased HVA and DOPAC. This MPP^+-induced increase in 5-HT release may be responsible for the acute 5-HT syndrome after MPTP.

FLUCTUATION OF STRIATAL DOPAMINE UPTAKE SITES DURING THE ESTROUS CYCLE: COMPARISON WITH BIOGENIC AMINE METABOLISM. M. Morissette*, A. Bélanger* and T. Di Paolo (SPON: M. Colonnier). Dept of Molecular Endocrinology, Laval University Medical Center, Québec, G1V 4G2 and School of Pharmacy, Laval University, Québec, G1K 7P4, CANADA.

Striatal dopamine (DA) uptake sites labelled with [^{3}H]GBR-12935 binding and biogenic amines concentrations measured by HPLC-EC were investigated during the rat estrous cycle and compared to ovariectomized (OVX) rats. Plasma prolactin concentrations peak in the afternoon of proestrus (PPM) while estradiol levels increase gradually to reach a peak on the day of proestrus. Progesterone concentrations are more phasic with one peak the day of diestrus I (DI) and one on PPM. In the striatum, DA levels increase in the morning of proestrus (PAM) compared to rats in estrus (E), DI, diestrus II (DII), PPM and OVX, the DA content being similar in the latters. Striatal DOPAC levels and the ratio DOPAC/DA increase in PAM ($p < 0.01$ vs E, DI, DII and OVX) with a minimum in E while HVA levels and the ratio HVA/DA remain unchanged. Striatal DOPAC levels during the estrous cycle were higher than in OVX rats ($p < 0.01$). Striatal 5-HT levels are decreased in E ($p < 0.01$ vs DI, DII, PAM, PPM) while no variation of 5-HIAA and 5-HTP, were observed. Density of striatal [^{3}H]GBR-12935 binding increases gradually to reach a maximum in PAM ($p < 0.05$ vs E, DI, PPM) while no variation of the dissociation constant were observed. In the striatum, both the maximum density of the DA uptake sites as well as DA and DOPAC levels peak in PAM, when estradiol levels are increased suggesting a causal-effect relationship although the primary site of action of estradiol and/or other hormones is yet to be determined. Thus, physiological hormone fluctuations, as occur during the estrus cycle, can influence DA uptake and biogenic release and metabolism in the striatum. Supported by the MRC.

VASOPRESSIN (VP) FUNCTION IN THE SEPTUM (S) AND HIPPOCAMPUS (H) OF ADULT MALE RATS.

J.D. Vincent, V.D. Ramirez*, F. Rodriguez*, C. Poncet*, N. Ramirez* and R. Bonhomme*. INSERM U.176, Rue Camille Saint-Saëns, 33077 Bordeaux Cédex, France.

Different evidence indicate that vasopressin neurons (VPn) play an important modulatory role in various CNS functions. Herein, we describe the in vivo and in vitro functions of VPn innervating the S or H of adult male rats. Higher VP levels in the S (8.1 ± 1.4 pg/mg wet tissue, $\bar{X}$ ± SE, n=6) than in the H (0.32 ± 0.04, n=6) were determined with a sensitive and specific RIA for VP (0.1 pg/tube at 90% binding). However, in freely moving rats bearing a miniaturized push-pull cannulæ (PPC) in the lateral S detectable levels of VP were not measured (n=6). In contrast rats with PPC in the dorsal H released VP (1.45 ± 1.2 pg/10 min, n=6) in a pulsatile manner. Interestingly, pulsatile VP release was measured from S as well H fragments superfused in vitro. When VP was added either in vitro to S or H fragments or perfused directly into the lateral S or dorsal H of awake rats marked difference in the recovery of exogenous VP was found (31.8 ± 2.5%, n=6 vs 78.3 ± 5.6, n=5, respectively). In two experiments recovery of VP perfused through the PPC system was 89.5 and 86.8%. The data demonstrate that in spite of higher amounts of VP in the S than in the H it is only from the hippocampus that VP is released in a pulsatile manner in freely behaving rats.

NATURALLY OCCURING LIGAND INHIBITS BINDING OF [3H]-IMIPRAMINE TO HIGH AFFINITY RECEPTORS. T. Hauser*, K.G. Walton, J. Glaser* and R.K. Wallace. Departments of Physiology and Chemistry, Maharishi International University, Fairfield, IA 52556.

Numerous studies have suggested the role of serotonergic activity in various behavior such as depressive illness, anxiety, learning and memory. Our laboratory has been investigating possible endogenous and exogenous modulators of serotonin uptake in platelets. We have recently begun to look at specific herbal preparations known to influence mood which come from the traditional system of medicine of India known as Ayurveda.

An aqueous extract of one particular Ayurvedic preparation (Maharishi Amrit Kalash #5) yielded a factor that demonstrates striking inhibition of [3H]-imipramine binding to human blood platelet membrane receptors by Scatchard analysis. An ethanol extract was about an order of magnitude less effective at inhibiting [3H]-imipramine binding. The factor in the aqueous extract was concentrated using a reversed phase CYANO extraction column (Baker-10 SPE), eluting with methanol. Preliminary analysis using a Lineweaver-Burk plot indicates that inhibition is at least partially competitive. Characterization of the nature of the inhibition and purification of the factor are currently in progress.

Since an endogenous ligand for the imipramine receptor has never been clearly defined, and since the preparation under investigation has been demonstrated in previous human studies to influence mood and well-being and to contain ligands for other important neuro-receptors, it is possible that if a ligand can be isolated from this herbal formulation, it may prove to have imipramine-like effects on mood and behavior.

99.20

NICOTINIC AND MUSCARINIC RECEPTOR STIMULATION OF THE PHOSPHOINOSITIDE CYCLE IN CHROMAFFIN CELLS WITH ACCUMULATION OF INOSITOL TETRAKISPHOSPHATE. B.B. Sanborn*, O.E. Harish* and A.S. Schneider (SPON: R.A. Ferrari). Dept. Pharm. & Tox., Albany Med. Coll., Albany, N.Y. 12208.

Muscarinic or nicotinic stimulation of cholinergic receptors on adrenal chromaffin cells results in catecholamine secretion. Both receptor subtypes appear to interact with the phosphoinositide (PI) cycle, but by different mechanisms, and the resultant products (inositol phosphates and diacylglycerol) may be important in the mechanism of neurohormone secretion. Muscarine was found to cause a rapid breakdown of polyphosphoinositides (PIP_2, PIP, PI) with accumulation (in the presence of LiCl) of the corresponding inositol phosphates including inositol tetrakisphosphate (IP_4) (detectable within 10 sec). 2,3-DPG, a specific inhibitor of IP_4 and IP_3 monoesterase, should enhance accumulation of IP_4 and IP_3, and in cells pretreated with DPG prior to muscarinic stimulation, IP4 increased 42% and IP_3 224% above control. The nicotinic agonist, DMPP, stimulated IP, IP_2 and IP_3 production at 15 min, and the Ca^{2+} dependence of this effect was determined. The data suggest that elevated cytosolic calcium, secondary to nicotinic receptor stimulation, activates the PI cycle, whereas muscarinic stimulation of the PI cycle is receptor-linked. Calcium activation of the PI cycle may be relevant to the mechanism of calcium-mediated exocytosis.

UPTAKE OF PROLINE, PIPECOLIC ACID, LYSINE AND GLYCINE BY PC-12, C-6 AND CHO-K1 CELLS. M. Cordero*, O. Torres* and J.G. Ortiz. Dept. of Pharmacology, Univ. of Puerto Rico Medical School, San Juan, Puerto Rico 00936

The transport of proline (PRO), hydroxyproline, pipecolic acid (PA) and glycine (GLY) has been considered to be mediated by a common uptake system, (Wellner and Meister, 1980).

In PC-12 cells, preincubation of the cells in a salts/glucose medium resulted in a marked decrease in PRO uptake; moderate decreases in GLY and LYS uptake and essentially no change in PA uptake. PRO and LYS uptake were not altered by the preincubating C-6 cells in the salts/glucose medium, while the uptake of PA and GLY were significantly increased. On the other hand, in CHO-K1 cells, only the uptake of PRO was significantly reduced by the preincubation in the salts/glucose medium.

The results of these experiments are not consistent with the presence of a common uptake system for PRO, PA and GLY, nor with the existence of common regulatory mechanism(s) as evidenced by the differential effects of preincubation in a salts/glucose is medium. Detailed examination of the uptake process(es) necessary in order to determine the relative contribution of the different cell types to the endogenous levels of these compounds, as well as, their possible role in disorders of peroxisomal function(s). (supported by NIH/MBRS)

LOCALIZATION OF TYPE II CALCIUM/CALMODULIN-DEPENDENT KINASE IN CELLULAR LAYERS OF HIPPOCAMPUS. G.K. Feussner* and M.L. Vallano. (SPON: R.B. King). Dept. of Pharmacology, SUNY/Health Science Center, Syracuse, NY 13210.

Type II calcium/calmodulin-dependent protein kinase (CaM kinase II) is concentrated in brain and has been implicated in synaptic transmission, plasticity, and cytoskeletal function. The predominant form of the holoenzyme in cerebrum is 560-730 kDa containing two subunits of 50 kDa and 58-60 kDa in a molar ratio of 3-4:1, respectively. CaM kinase II appears to be present in all neuronal cell types, but its regional distribution and molar ratio of subunits comprising the holoenzyme are variable. CaM kinase II is particularly enriched in hippocampus where it represents ~2% of the total protein. The lamellar organization of the hippocampus maintained in the in vitro slice has provided a useful model for numerous structure/function studies. To ensure discrete sampling and to minimize post-mortem alterations, neuronal areas from freeze-dried tissue sections from rat brain frozen in situ were free hand dissected and assayed for CaM kinase II activity. The specific activity of CaM kinase II was 2-3 fold greater in area CA1, compared to areas CA3 and dentate gyrus. In addition, the dentate gyrus contained a distinct isozymic form of CaM kinase II compared to the pyramidal cell layers examined. These data provide a basis to examine differential regulation of CaM kinase II expression and activity within the hippocampus.

ALTERATION OF THE HIPPOCAMPAL CA1 RESPONSE TO CA3 INPUT BY SEPTAL STIMULATION. P.G. Newlon*, S.J. Goldberg, S. Miyazaki* and R.L. Hayes. Div. Neurosurg. & Dept. Anat., Med. Coll. of Va.-VCU, Richmond, Virginia, 23298.

Stimulation of the Schaeffer Collateral/Commissural path (SCC) from the CA3 region of hippocampus produces a characteristic field potential in CA1 which increases with stimulus intensity. We studied the effect of high frequency patterned stimulation of the septum on this CA1 response. Field potentials were recorded from the dorsal CA1 pyramidal layer with glass micropipettes (2-5 MOhm) in male rats anesthetized with urethane. Bipolar stimulating electrodes were placed in the ipsilateral CA3 region and the septum. CA1 field potentials were obtained from a range of stimulus intensities prior to, and 10, 30, and 60 min after a septal series of ten, 400 Hz trains (5 pulses/train; 200 msec intertrain interval). Septal stimulation reduced the CA1 population spike (PS) threshold by 30-40%. Lateral septal stimulation potentiated the PS amplitude while medial septum suppressed it. These effects persisted up to one hour. The influence of septal stimulation on the development of hippocampal long term potentiation is presently being investigated. This work was supported by NS-21458 and NSF BNS-8507610.

POSTSYNAPTIC TARGETS OF THE SEPTO-HIPPOCAMPAL GABAERGIC PROJECTION IN THE RAT. T.F.Freund* and M.Antal*(SPON:C.Beaulieu) MRC Anatomical Neuropharmacology Unit, Dept. of Pharmacology, Oxford OX1 3QT, United Kingdom.
The cholinergic component of the septo-hippocampal pathway has been pharmacologically, physiologically and anatomically well characterised, but much less is known about the role of the GABAergic component. Small injections of PHAL were delivered into the medial portion of the medial septum and diagonal band, where most of the noncholinergic septo-hippocampal cells are located. Two distinct populations of fibres were labelled in the hippocampus. One had small boutons, terminating mainly in the proximal dendrite-cell body region of both pyramidal cells and granule cells, whereas the other had large terminals, and formed numerous multiple basket-like synaptic connections with nonpyramidal cell somata and dendrites in all regions. The latter type of afferents as well as most of their postsynaptic targets were shown to be GABAergic by postembedding immunogold staining for GABA. Postsynaptic dendrites negative for GABA were also found. The GABAergic neurons surrounded by GABAergic septal baskets were further characterised by immunostaining for calcium binding proteins parvalbumin and calbindin D-28k (antisera kindly provided by Dr. K. G. Baimbridge), by which the dendritic tree of these cells were also visualised. Occasionally, more than 30 terminals of single septal axons were seen in contact with dendrites and perikarya of single target cells. GABAergic interneurons immunoreactive for calbindin in CA3 were far the most frequent targets. These target cells are likely to have extensive local axon arborisations controlling the activity of large groups of pyramidal and granule cells. The GABAergic component of the septo-hippocampal projection may thus have a crucial role in the septal induction of hippocampal rhythmic slow activity, by synchronising large populations of principal neurons via strong GABA-GABAergic disinhibition.

MODIFICATION OF EVOKED HIPPOCAMPAL DENTATE INHIBITION BY DIAZEPAM AND THREE ANTAGONISTS. **T.E. Albertson and R.M. Joy. U.C. Davis Medical Center, Sacramento, CA 95817**

Urethane anesthetized rats with perforant pathway stimulating electrodes and recording electrodes in the dentate gyrus of the hippocampus were exposed to increasing doses of either the agonist diazepam (DZP) or a benzodiazepine antagonist (PK-11195 (PK), CGS-8216 (CGS) and RO15-1788 (RO)). None of the four compounds significantly altered the excitatory postsynaptic potentials. The population spike (PS) threshold demonstrated minimal but significant increases after exposure to DZP and the central antagonists RO and CGS, but not to the peripheral antagonist PK. PS amplitude was reduced after exposure to RO, CGS and DZP, but not PK. DZP significantly increased early paired pulse $GABA_A$-mediated inhibition greater than it reduced later facilitation. The antagonist RO also significantly increased early $GABA_A$-mediated inhibition without altering later facilitation. Neither CGS nor PK altered early PS inhibition or later facilitation. The marked increases in $GABA_A$-mediated inhibition and smaller reductions in later facilitation seen with DZP was reversed by a second treatment with either RO, CGS, but not with PK, the vehicle control or DZP. When given first, both CGS and RO, but not PK prevented any further increase by DZP in $GABA_A$-mediated inhibition. These data point to the importance in vivo modulatory role of the benzodiazepine receptor on overall granule cell sensitivity and early presumed $GABA_A$-mediated PS inhibition.

VARIATIONS IN PHYSIOLOGY AND MORPHOLOGY OF HIPPOCAMPAL CA3 PYRAMIDAL CELLS. D.K. Bilkey* and P.A. Schwartzkroin (SPON: J.S. Lockard). Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Cajal (1893) reported that hippocampal pyramidal cells vary in morphology depending on their location in the inferior or superior regions of stratum pyramidale (s.p.). We have attempted to determine whether these differences in morphology and location are correlated with particular electrophysiological characteristics. In vitro hippocampal slices were prepared from male guinea pigs. Intracellular recordings were obtained from pyramidal cells in area CA3a-c. Membrane potential, input resistance and firing characteristics were measured, and the cells were subsequently injected with the dye Lucifer Yellow. Preliminary data confirm that cells in the superior edge (i.e., s.p./str. oriens border) of s.p. have smaller soma, and also suggest that these cells have a longer time constant and are more likely to produce high frequency trains of action potentials followed by slow spikes. At the present time it is unclear whether this represents clear differences in electrophysiology between superior and inferior cells, or whether it is due to the greater probability of recording from the apical dendrites of cells in the superior region.

These studies were supported by NIH,NINCDS grant NS18895.

ULTRASTRUCTURE OF INTRACELLULAR LABELLED MOSSY CELLS IN THE RAT DENTATE GYRUS. D.D. Kunkel, H.E. Scharfman and P.A. Schwartzkroin. Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Mossy cells of the rat dentate hilus are large, distinctive cells with extensive dendrites bearing complex spines (thorny excrescences), and an axon that projects ipsilaterally and contralaterally to the dendritic layer of granule cells. To investigate the circuitry of the region, we examined the morphology of mossy cells and other hilar neurons.

Mossy cells were recorded from transverse hippocampal slices maintained in vitro. Mossy cells were first identified physiologically and then injected intracellularly with Lucifer Yellow. These studies showed that mossy cell axons arborize profusely within the hilus. Subsequently, HRP was used to intracellularly label and then examine mossy cells ultrastructurally. Large terminals filled with small, round vesicles contacted mossy cell thorny excrescences. Elaborate cup-shaped spines were contacted by smaller terminals containing fewer, larger vesicles. HRP-positive synaptic contacts by mossy cell terminals were seen on a variety of hilar cell types. These terminals also appeared to be involved in axo-axonic contacts. Studies are ongoing to examine the relationship of HRP-filled mossy cells to hilar neurons immunoreactive with the antibodies to gamma-aminobutyric acid (GABA) and somatostatin (SRIF).

EFFECT OF CHOLINERGIC AGONISTS ON LACUNOSUM-MOLECULARE INTER NEURONS IN RAT HIPPOCAMPUS. L.J. Reece and P.A. Schwartzkroin. Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Stratum lacunosum-moleculare (L-M) interneurons have been described in the guinea pig and rat hippocampus. Compared to other types of hippocampal interneurons, L-M interneurons have a low spontaneous firing rate and longer action potentials, in addition to differences in passive membrane properties. These L-M cells receive cholinergic innervation from the medial septum-diagonal band complex as evidenced by choline acetyltransferase and acetylcholinesterase histochemistry, and by degeneration studies after fimbria-fornix lesions. In order to evaluate the effect of this innervation, we applied acetylcholine and the cholinergic agonist carbachol to L-M cells while recording intracellularly from these cells in the *in vitro* hippocampal slice preparation. Drugs were applied iontophoretically near the cell soma or by the microdrop method to the surface of the slice. All cells were depolarized upon exposure to cholinergic agents. Unlike basket cells, which we have found to be extremely sensitive to these compounds, the responses of L-M cells were slow; despite large changes in membrane potential, cells did not begin discharging spontaneously or increase baseline firing rate.

These studies were supported by NIH NINCDS grants NS 15317 and NS 18895.

VIDEOMICROSCOPY AND SYNAPTIC PHYSIOLOGY OF CULTURED HIPPOCAMPAL SLICES. A.H. Ganong, D.E. Stevens* and T.H. Brown. Div. of Neurosciences, Beckman Research Institute, City of Hope, Duarte, CA 91010.

Culture of slices from postnatal vertebrate brains offer advantages including a high degree of organotypic cellular organization, the ability to visualize single neuronal somata and processes, and accessibility of neurons for recording electrodes and pharmacological manipulations. We have used a variation of the roller tube slice culture technique (B.H. Gahwiler, *J. Neurosci. Meth.*, 4:329, 1981) to culture 250-300 μm thick slices of rat hippocampus on collagen-coated coverslips.

During the first 1-2 weeks following plating many of the cells died leaving a thinner slice which still had recognizable pyramidal and granule cell layers. Slices that were damaged during the preparation often had large gaps or holes. The pyramidal cell layer was typically 3-8 cells thick in intact cultures after about 3 weeks in vitro. Individual neuron somata were difficult to discern in the thicker cultures using phase contrast optics. However, differential interference contrast optics (40X), especially when coupled with a video camera with adjustable contrast gain and offset, allowed for clear visualization of neuronal somata, nuclei, and nucleoli throughout individual cultures.

Intracellular recordings using potassium acetate electrodes were obtained from CA3 pyramidal neurons in cultures after 3 weeks *in vitro*. The neurons showed resting potentials in the range of -55 to -75 mV, overshooting action potentials, and input resistances in the range of 50-120 MΩ. When the cultures were superfused with Hank's salts (with 5.8 mM K^+, 0.9 mM Mg^{2+}, and 1.26 mM Ca^{2+}) spontaneous EPSPs and IPSPs could be recorded. Both the spontaneous IPSPs and evoked IPSPs had a reversal potential near -70 mV. The presence of 10 μM picrotoxin in the recording medium eliminated the ipsps, but also resulted in paroxysmal depolarizing shifts. This epileptiform bursting could be reduced in medium with 2 mM K^+, 4 mM Mg^{2+}, and 3 mM Ca^{2+}. The use of this medium coupled with low intensity stimulation allowed the study of excitatory synaptic events in isolation from the large inhibitory components present in these cultures. *(Supported by the AFOSR).*

HILAR NEURONS: GATEKEEPERS OF THE DENTATE GYRUS B.Y. Wong and D.A. Prince. Dept. of Neurology Stanford University, Stanford, CA 94305-5300.

Dentate hilar cells (HCs) are postulated to inhibit dentate granule cells (DGCs) by excitation of intermediary GABAergic interneurons. We therefore performed experiments to determine whether HC discharges are associated with DGC inhibition.

Intracellular HC recordings were obtained from longitudinal guinea pig hippocampal slices. Nearly continuous spontaneous EPSPs were observed in all neurons. Stimulus trains delivered to the hilus evoked large (>20 mV, 1.0 sec) bursts of summated EPSPs, followed by >25 mV post-burst hyperpolarizations which lasted up to 20 sec. In about 25% of slices, spontaneous bursts occurred after stimulation. Responses were associated with hilar field potentials. Using Anti-Lucifer Yellow immunocytochemistry we identified neurons with these electrophysiological properties as large cells with spiny dendrites whose morphology is consistent with the mossy cell as seen in Golgi studies of the hilus.

In other experiments, we found that spontaneous hilar field potential bursts were associated with large inhibitory synaptic events in DGCs. Since HCs have long associational and commissural hippocampal projections, they may have a critical role in gating information flow through the dentate by amplifying excitatory inputs and collectively activating potent local inhibition of DGCs. Supported by NIH grants NS01179 and NS06477.

IN VIVO ELECTROPHYSIOLOGICAL EVIDENCE FOR MONOSYNAPTIC INPUT FROM THE ENTORHINAL CORTEX TO PYRAMIDAL CELL REGIONS OF THE HIPPOCAMPUS M.F. Yeckel, G. Barrionuevo and T.W. Berger, Depts. of Behavioral Neuroscience and Psychiatry, Univ. of Pittsburgh, PA 15260

Efferent fibers of the entorhinal cortex (EC) project to the molecular layer of the fascia dentata (FD), where they can initiate a sequential excitation of the dentate granule cells, CA3 pyramidal cells, and CA1 pyramidal cells. Serial propagation through this tri-synaptic pathway traditionally has been regarded as a fundamental characteristic of intrinsic hippocampal physiology. However, anatomical evidence also indicates a monosynaptic projection from the EC to the molecular layers of CA3 and CA1, suggesting simultaneous rather than sequential activation of these cell regions.

We investigated this possibility using electrical stimulation to the angular bundle of halothane anesthetized rabbits while recording from FD, CA3, and CA1. Antidromic responses due to reciprocal pyramidal cell projections to EC were identified and dissociated through high frequency stimulation and knife transections of the alveus. Latencies to orthodromic activation of single units and population spikes were 4-6ms and 6-7ms in FD (medial and lateral perforant path, respectively), 4-6ms in CA3, and 5-7ms in CA1.

These data demonstrate that input from EC can activate all hippocampal subfields nearly simultaneously, and suggest that FD and CA3 provide feedforward modulation of EC-driven CA1 activity. Supported by NSF, NIMH, ONR.

GABAERGIC CONTRIBUTION TO NONLINEAR REPSONSE PROPERTIES OF THE IN VIVO DENTATE GYRUS. R.L. Port, T.A. Blanpied*, R.J. Sclabassi, and T.W. Berger. Departments of Behavioral Neuroscience, Psychiatry, and Neurosurgery, University of Pittsburgh, Pittsburgh, PA 15260.

GABAergic interneurons provide feedforward and feedback inhibition in all regions of the hippocampal formation. The role of GABA in determining nonlinear response properties of dentate granule cells was examined in the rabbit. Systemic manipulations were used to alter GABA throughout all hippocampal regions: 3-mercaptopropionic acid (3-MP; 16 mg/kg, i.p.), a GABA synthesis inhibitor and aminooxyacetic acid (AOAA; 30 mg/kg, i.p.), a GABA aminotransferase inhibitor. Local pressure injection of bicuculline (BMI; 1 mM) was used to antagonize GABAergic effects primarily in the dentate gyrus. Perforant path (PP) input to granule cells was activated using random impulse train stimulation. The relationship between interstimulus intervals (ISIs) of the train and evoked population spike amplitude was determined through computation of first and second order kernels.

First order kernels represent the average population spike amplitude to all impulses, and were slightly reduced by AOAA (1.5 mV vs. 1.6 mV in control preparations) and were increased by 3-MP (2.1 mV). Second order kernels reflect the modulatory influence of a preceding stimulus as a function of ISI. Control preparations exhibited suppression of spike amplitude to ISIs of 10-50 ms, and facilitation to ISIs of 60-400 ms. Spike suppression was reduced by 3-MP, and eliminated totally by local injection of BMI. Facilitation was reduced by AOAA, and occurred to ISIs <40 ms after BMI. Supported by ONR and NIMH.

100.12

GABAERGIC CONTRIBUTION TO NONLINEAR RESPONSE PROPERTIES OF THE IN VITRO HIPPOCAMPAL DENTATE GYRUS. T.P. Harty, T.W. Berger, R.J. Sclabassi, and G. Barrionuevo. Depts. of Behavioral Neuroscience, Psychiatry and Neurological Surgery, Univ. of Pittsburgh, Pgh., PA 15260

Using random impulse train stimulation and nonlinear systems analytic procedures, we previously have compared the nonlinear response properties of the in vivo and in vitro dentate gyrus. Second order kernel analyses showed that in vivo granule cell population spikes evoked by perforant path stimulation display a marked decrement in amplitude when inter-stimulus intervals (ISIs) in the train are short (10-50 ms). Longer ISIs (50-400 ms) lead to a facilitation of spike amplitude. In contrast, in vitro population spikes are facilitated rather than suppressed when ISIs are short. This facilitation occurs over a shorter range of intervals (10-150 ms) than in vivo facilitation.

The lack of suppression of in vitro preparations to short ISIs may reflect the transection of GABA-containing dentate interneurons during slicing. Consistent with this hypothesis, the GABA antagonist bicuculline (5-20 uM) had minimal effects on dentate nonlinearities. The GABA agonists pentobarbital (10-100 uM) and alphaxalone (1-5 uM) produced a suppression of population spike responses to short ISI's, thus restoring inhibition to in vivo levels. However, facilitation similar to the in vivo preparation (i.e. to ISI's of 50-400 ms) was not observed, suggesting that this component of dentate network properties is mediated by connectivity with other hippocampal subfields. Supported by ONR, NIMH, and NIH.

100.13

AN INPUT/OUTPUT MODEL OF THE HIPPOCAMPAL FORMATION. R.J. Sclabassi, D. Krieger, J. Solomon*, S. Levitan*, G. Barrionuevo, and T. Berger. Departments of Electrical Engineering, Behavioral Neuroscience, Neurosurgery, and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15213.

We are utilizing an integrated theoretical and experimental approach to characterize the functional properties of the hippocampal formation through the use of an input/output neural network model. We conceive of this network as a set of interconnected elements or nodes, each of which may be characterized by its own input/output function. We have established that nonlinear input/output characteristics of each network element can be measured experimentally by recording electrophysiological responses to random impulse train stimulation and expressing the relationship between input signal and node output as the kernels of an orthogonalized functional power series expansion. The kernels are estimated experimentally by cross-correlation techniques for Poisson-distributed point process inputs. The resulting functions may be interpreted physiologically as generalized recovery functions and theoretically as n^{th} order impulse responses. N^{th} order convolution integrals are computed on transputer elements which represent populations of neurons interconnected according to known anatomical relationships. This paper will report the result of three different simulation studies: the closed-loop system, the partially closed system, and the open-loop system.

OPTICAL RECORDING OF NEURONAL ACTIVITY IN ORGANOTYPIC SLICE CULTURES

T. Knöpfel*, H.J. Kasper*, B. Kohler*, Z. Zglinski*, L. Zeller* and B.H. Gähwiler; Brain Research Institute, University of Zürich, CH-8029 Zürich (Switzerland)

Previously, multi-site recordings of neuronal activity using voltage-sensitive fluorescent dyes have been obtained from a variety of preparations. We report here the application of this technique to organotypic cultures of rat hippocampus and cerebellum. These cultures offer unique opportunities since optical signals with a high signal-to-noise ratio could be recorded from single neurons which were integrated in complex synaptic networks.

For optical mapping with high temporal resolution (0.2 ms), a 10 x 10 photo-diode array was used. With this detector, we recorded synaptically evoked activity from single cerebellar Purkinje cells and population responses from the more densely packed hippocampal pyramidal neurons using dye RH 414.

Optical imaging with high spatial resolution (256 x 244 points) was achieved with a charge coupled device (CCD). At present, the temporal resolution of our CCD detector is too low (20 ms) to resolve single action potentials. The CCD allows, however, mapping of slow synaptic potentials, while their time course could be recorded with the diode-array.

This work shows that using a combination of diodes and a CCD allows recording with high temporal, as well as spatial, resolution neuronal activity in organotypic slice cultures.

100.15

Compartmental modelling of hippocampal neurones. J.E.Chad, H.M.Cole *, E.W.Stockley *, H.V.Wheal * and T.R.Harris *. Dept. of Neurophysiology, University of Southampton, SO9 3TU and IBM Scientific Centre, Winchester, UK.

We have created a database structure that enables us to accurately represent the three-dimensional morphology of individual neurones. The description of membrane surfaces within the database is used to generate a compartmental model. This model is analysed by a circuit simulator, allowing us to predict the electro-physiological properties of these neurones. Our model is being refined by recursive testing against the experimentally measured properties of the digitised cells. We have analysed pyramidal neurones both in, or dissociated from adult rat hippocampal slices. The simplified morphologies of dissociated cells enable a more accurate determination of their electrophysiological properties due to the improved space clamp. These neurones have a greatly increased input resistance (300-400 Mohms) compared to intact cells (30-40 Mohms), presumably due to the removal of many dendritic processes. Thus far the model can predict the relative contributions of the soma and the dendritic system to the passive properties of the cells. We are using this system to study the relative contributions of distal and proximal synaptic inputs to cell function.

100.16

SHAPE AND AREA OF HIPPOCAMPUS/PARAHIPPOCAMPUS IN SCHIZOPHRENIC, SUICIDE AND CONTROL BRAINS. L.L. Altshuler*. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892. M. Casanova*, N. Sachder*, T.E. Goldberg*, J. Kleinman (SPON: J. Stevens). NIMH Neurosciences Center at St. Elizabeths Hospital, Washington, D.C. 20032.

Anatomic abnormalities of limbic system structures have been demonstrated in schizophrenia by neuroimaging and postmortem studies. Postmortem reports reveal smaller volumes of the hippocampus proper and parahippocampal cortex as compared to controls. The present study was undertaken in an attempt to replicate these findings using a method that minimizes shrinkage due to fixation and paraffin embedding. Coronal sections were made at the level of the mammillary bodies (pes hippocampi) in 18 schizophrenic, 17 non-schizophrenic suicide and 17 non-psychiatric control brains, matched for sex and age at death. The tissue blocks were then photographed and digitized with a LOATS computer image analysis system. The illumination and resolution were maximized and the area measurements calibrated. Sections were evaluated for total area (mm^2) and for shape (harmonic) with LOATS. Analysis for shape in the dominant harmonic revealed no statistical differences between the groups in either the hippocampus (H) or parahippocampal cortex (PH). However, analysis for area revealed significant differences between groups in the PH (ANOVA $F=5.23$, $P<.02$). By post hoc t-test the schizophrenic PH area was significantly smaller than suicide ($p<.05$) and control ($p<.05$) PH. No significant differences in hippocampal area were found.

Our positive findings are consistent with previous studies and further support the existence of structural pathology in schizophrenia.

100.17

MEASUREMENT OF THE SOMATIC SHUNT IN HIPPOCAMPAL GRANULE CELLS. D. Durand and G.Yuen. Applied Neural Control Laboratory, Dept of Biomedical Engineering, School of Medicine, Case Western Reserve University, Cleveland, OH. 44106.

Intracellular recordings in neurons have revealed the presence in some neurons of a shunt at the soma. This shunt could be caused by injury from electrode penetration or by a lower membrane resistance at the soma compared to the membrane resistance in the dendrites. Theoretical derivations of the equation for the electronic parameters of cell with a somatic shunt have allowed not only the measurement of this shunt but have also shown that electrode penetration cannot solely be responsible for the shunt.

Intracellular recordings were obtained from hippocampal granule cells. A short hyperpolarizing current pulse (.5ms, 1 to 7nA) was injected in the cells and the resulting voltage filtered, averaged and digitized. Peeling analysis and least-square non-linear fit methods were used to extract the coefficients and the time constants of the multiexponential decay. A computer program was then used to solve numerically the shunt model equations and to determine the best fit the data.

The results from 13 cells show that the ratio of the somatic time constant to the dendritic time constant was equal to .32 $\pm$ .22. This ratio normally assumed to be equal to 1, suggests that, on average, the granule cells have a dendritic membrane resistance equal to three times the somatic membrane resistance (assuming that the membrane capacitance is constant). The presence of this shunt could be important for the interpretation of the measurements of electrotonic parameters in granules cells.

MODELLING THE EFFECT OF EXTERNAL APPLIED ELECTRIC FIELDS ON THE EXCITABILITY OF HIPPOCAMPAL CELLS. E. Warman and D. Durand, Applied Neural Control Lab., Dept. of Biomedical Engineering, Case Western Reserve University, Cleveland, OH. 44106

Recent studies have shown that electrical fields applied to the cerebellum and hippocampus can modulate the excitability of the neurons provided that the electrical field is properly oriented with the dendritic structure. We have studied the effect of applied extracellular fields on the excitability of hippocampal granule and pyramidal cells using computer simulations.

Both cells were modeled as compartmental cylinders with active channels at the soma compartment. The extracellular intercompartment voltages were set by calculating the product of the constant electric field applied and the intercompartmental distances. In the presence of the applied field, the new steady-state transmembrane potentials were calculated and the cell response to stimulation was tested.

The results indicate that in the presence of a constant field it is possible to modify the somatic steady state potential. This induced membrane potential can lead to a change in the excitability of the cells. A 10mV/mm field changed the rheobase current by 11% in granule cells and 14% in pyramidal cells. Preliminary studies indicate that the effect of the electric field is dependent on the morphology of the cell models. The contribution of dendritic length, branching and variations in dendritic diameter are currently under investigation.

Supported by NSF grant #ECS-8406861, NSF Presidential Young Investigator Award to the author and the Whitaker Foundation.

EIGENFUNCTIONS OF THE CHARGING CURVE IN MULTIPOLAR NEURONS OF NONUNIFORM DENDRITIC LENGTH.

L.L. Glenn, B.G. Samojla, and P.J. Rebeta*. *Department of Physiology, Ohio College of Podiatric Medicine, Cleveland, Ohio 44106-3082.*

A general solution to the cable equation (Rall, Biophys. J. 9:1483, 1969) describes the voltage response of a passive membrane cylinder to current stimulus as

$$V = C_0 \exp(-t/\tau_0) + C_1 \exp(-t/\tau_1) + \ldots + C_i \exp(-t/\tau_i) + \ldots$$

We present below the equations for the C_i and τ_i of a multipolar cylinder model with cylinders of nonuniform electrotonic length, when the stimulus is a step of current applied or withdrawn at t=0.

$$C_0 = \frac{\Sigma G^{\infty}_j \tanh L_j}{\Sigma G^{\infty}_j L_j} \qquad C_i = \frac{2\ \Sigma G^{\infty}_j \tanh L_j}{(1 + \alpha_i^2)\ \ \Sigma G^{\infty}_j L_j \sec^2 \alpha_i L_j}$$

where L_j is the electrotonic dendritic length for the j^{th} dendrite, G^{∞}_j is the input conductance that the j^{th} dendrite would have if it were semi-infinite, and the α_i and τ_i are obtained from

$$\Sigma G^{\infty}_j \tan \alpha_i L_j = 0 \qquad \tau_i = \tau_0 / (1 + \alpha_i^2)$$

The significance of these equations is that the charging curve for a current step can be calculated for all t in multipolar neurons with dendrites of arbitrary number and length.

LEARNING AND MEMORY: PHARMACOLOGY II

101.1

MK-801 IMPAIRS OLFACTORY DISCRIMINATION LEARNING IN 16-DAY-OLD RATS. M.E. Stanton and K.F. Jensen. Neurotoxicology Division, U.S. EPA, Research Triangle Park, NC 27711.

NMDA receptors are thought to play a special role in neural processes associated with development, learning, and neurotoxicity (TINS,10[7],1987). These receptors are widely distributed in a variety of forebrain regions, including the olfactory system and hippocampus. Here we report that administration of MK-801, a potent non-competitive antagonist of the NMDA receptor, impairs olfactory discrimination performance in 16-day-old rat pups.

Pups were taken from their nest, injected i.p. with MK-801 (.1 mg/kg) or saline vehicle, and 40-70 min later, were tested on an odor-aversion task (see Kucharski and Spear, Dev. Psychobio, 1984, 17, 465-479 for details). Rat pups were trained with two odors (lemon and methyl), one (CS+) paired with footshock and the other (CS-) not, and then given a simple preference test involving the two cues. MK-801 treated animals showed less of an aversion to CS+ than did those treated with saline. Control experiments indicated that this impairment did not reflect general anosmia and/or motor effects of MK-801.

These findings suggest a role for the NMDA receptor in early learning.

101.2

NMDA ANTAGONISM AND WORKING MEMORY PERFORMANCE. M.J. Pontecorvo and D.B. Clissold* NOVA Pharmaceutical Corporation, Baltimore, MD 21224

Although recent data suggest that N-methyl-D-aspartate (NMDA) sensitive glutamate receptors may be in important for learning and memory, their particular contribution to memory processes remains to be delineated. Therefore, we trained rats to perform a two choice continuous non-matching to sample working memory task.

A variable number of trials with one stimulus (tone) alternated with trials with the second stimulus (light). The rats were reinforced for responding on one lever if the present stimulus was the same as the previous(match), and the second lever when the present stimulus differed from the previous (non-match). Thus, the rats had to remember across the intertrial interval (retention intervals: 2.5, 10 and 20 sec) which stimulus was presented most recently.

After achieving asymptotic levels of accuracy the rats received either saline, 3(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP), a direct acting NMDA antagonist, or MK801, a non-competitive antagonist that acts through the PCP site. Although high doses of CPP disrupted response accuracy, these effects were accompanied by a marked reduction in response probability. In contrast, MK801 reduced accuracy at doses that did not produce a reduction in response probability. Interestingly, the reduction in accuracy following MR801 was evident across all retention intervals and resulted primarily from an increase in false alarms (non-match choices on match trials), rather than from a change in both hits (correction-match responses) and false alarm, or a selective reduction in hits, as has previously been observed in this test with other amnestic treatments. We believe this pattern of results indicates that disruption of NMDA transmission produces a general disorientation rather than a specific failure of working memory.

101.3

EFFECTS OF MK 801, AN ANTAGONIST OF THE N-METHYL-D-ASPARTATE TYPE OF EXCITATORY AMINO ACID RECEPTOR, IN TWO-TRIAL MEMORY TESTS. N.Venable*and P.H.Kelly. Preclinical Research, Sandoz AG, CH-4002 Basel, Switzerland

The effects of the N-methyl-D-aspartate (NMDA) type receptor antagonist, MK 801, in passive avoidance learning and in a new test, described below, were examined. Systemic administration (0.03-0.3 mg/kg) to mice (i.p.) or rats (s.c.) shortly before a single step-through passive avoidance training trial did not significantly affect step-through latencies on the training day, but resulted in a dose-dependent reduction of latencies in the retention test performed 24 hr later. In parallel experiments in mice the substance slightly reduced the threshold for shock-induced vocalization, suggesting that the impairment of passive avoidance was not due to drug-induced analgesia. In the second test rats were placed in a swimming pool for a short (3-5 min) swim in order to assess the pattern of their exploratory activity on two consecutive days. Animals received drug (0.1 mg/kg s.c.) or vehicle shortly before the first swim only. On the first day animals initially swam predominantly around the perimeter, and then spent an increasing proportion of time in the central region. This increase was less in the drug-treated group. On the second day, during the first minute of the test, animals which had received vehicle spent a much higher proportion of time in the central region than they had spent in the first minute of their first swim. In contrast, animals which had received drug before their first swim spent only the same low proportion of time in the central region during the first minute of their second swim as they had during the first minute of their first swim. These results suggest that in both tests memory formation was impaired under the influence of MK 801, and thus are consistent with either a direct or indirect role of NMDA receptors in memory formation.

101.4

A BEHAVIORAL EFFECT OF MK801 MIMICS A DEFICIT ASSOCIATED WITH HIPPOCAMPAL DAMAGE. G. Robinson*, G. Crooks*, P. Shinkman, and M. Gallagher. Dept. Psychology, Univ. North Carolina, Chapel Hill, NC 27599.

N-methyl-D-aspartate (NMDA) receptors appear to play an important role in the induction of long-term potentiation in the hippocampal formation. The anticonvulsant compound MK-801 {(+)-5-methyl-10,11-dihydro-5*H*-dibenzo[a,d]cyclo- hepten-5,10-imine maleate} belongs to a class of antagonists that bind to phencyclidine (PCP) sites and block activation of NMDA receptors. This experiment examined the effects of systemically administered MK-801 on a spatial learning task that is sensitive to hippocampal dysfunction.

All animals received an habituation session (90 sec) during which they were allowed to swim in a pool of tepid, opaque water. Rats were then trained for 3 daily sessions (6 trials each) to locate an escape platform submerged 1 cm below the water surface in the pool. During this "place" training, the platform remained in the same position across trials. A final session consisted of a free swim (60 sec) to analyze the search pattern with the platform removed from the pool. This trial was immediately followed by 6 "cue" training trials during which animals were allowed to escape to a visible platform that was positioned in different locations from trial to trial. Animals received subcutaneous injections (0.00, 0.01, 0.05, or 0.08 mg/kg MK-801) prior to each session.

At the 0.08 mg/kg dose of MK801, a general performance decrement was evident on both the place and cue tasks. At the 0.05 mg/kg dose, rats were impaired in place, but not in cue learning. The latter results parallel the effects of damage to the hippocampal formation. Other behavioral tests are currently underway to assess the range of learning/memory tasks that are sensitive to low-dose MK-801 administration.

101.5

GLYCINERGIC COMPOUNDS FACILITATE MEMORY FORMATION AND RETRIEVAL IN RATS. G.E. Handelmann, L.L. Mueller, and A.A. Cordi*. CNS Diseases Research, G. D. Searle and Co., St. Louis, MO 63198.

Glycine and other neutral amino acids (e.g. serine) have been shown to potentiate neuronal responses to N-methyl-D-aspartate (NMDA; Johnson and Ascher, Nature, 325: 529, 1987), and to bind to a recognition site in rat brain which has the pharmacological characteristics (Monahan et al., FASEB J., 2:A1401, 1988) and anatomical distribution (Bristow et al., Eur. J. Pharmacol., 126:303, 1986) consistent with an NMDA-receptor coupled modulatory site. As the NMDA receptive neural pathways in the forebrain are believed to play a role in processes of learning and memory (Collingridge, Trends Pharmacol. Sci., 6:407, 1985) glycinergic neurotransmission may be expected to enhance these functions. We studied the effects of two glycinergic compounds on performance of a shock-motivated passive avoidance task in rats. Milacemide, a prodrug which increases brain glycine concentrations (Christophe et al., Life Sci., 33:533, 1983), enhanced memory consolidation and retrieval at 10 mg/kg i.p. D-cycloserine, which binds with high affinity to the glycine receptor (Monahan et al., submitted), was effective at 3 mg/kg. These studies suggest the importance of the glycine neurotransmission in cognitive processes.

101.6

THE DIHYDROPYRIDINE CALCIUM CHANNEL AGONIST BAY K 8644 ENHANCES WORKING MEMORY IN THE RAT AND MOUSE. D.G. Spencer, Jr. and J. Traber*. Neurobiology Dept., Troponwerke (Bayer AG), Neurather Ring 1, 5000 Köln 80, FRG.

BAY k 8644 (1,4-dihydro-2,6-dimethyl-3-nitro-4-(2-trifluoromethylphenyl)-pyridine-5-carboxylate) has high affinity for the dihydropyridine site on calcium channels, whereupon it exerts agonistic effects, enhancing calcium ion flux. This mechanism is associated in the periphery with vasoconstriction and positive inotropic effects, while facilitation of neurotransmitter release and of long-term potentiation in the hippocampus have been observed in the central nervous system. In the present study, the effects of BAY k 8644 on rat and mouse memory performance were studied. Rats were trained to select arms without repetition in a conventional 8-arm radial maze, with an interval of 1 or 4 hours between the first 6 and last 2 arm choice opportunities. BAY k 8644 (1.25 mg/kg i.p.) injected during the interval consistently and significantly improved post-interval arm choice accuracy. BAY k 8644 at 0.64 and 1.25 mg/kg i.p. also significantly antagonized scopolamine-induced deficits in passive avoidance retention performance in mice. These data support on a behavioral level the hypothesis of calcium channel activity involvement in the neurobiology of memory.

101.7

Physostigmine, Tetrahydroacridine, and 3,4-Diaminopyridine protect against hypoxia-induced passive avoidance retention deficit: Comparison of safety margins. V. J. DeNoble, K. Strek*, L. Johnson*, and L. Cook. E. I. DuPont de Nemours & Co., Med. Prod. Department, Wilm., DE 19898.

The applicability of acetylcholinesterase (AChE) inhibitors for intervention of a cholinergic deficit is limited by the imbalance between acetylcholine (ACh) and the absence of AChE at the synapse. DAP is a compound that releases ACh in vitro without effects on AChE. In this experiment post training administration of two AChE inhibitors and DAP on hypoxia-induced amnesia was evaluated. During PA acquisition, rats were placed in a lighted compartment and given access to a dark compartment. Ten sec after entering the dark side rats were given two, three sec foot shocks (1.5 mA). Retention (300 sec max) was tested four hr later. At 21% O_2 retention latencies were at max, however, exposing rats to 6.5% O_2 for 30 min prior to PA training reduced median retention latencies to less than 30 sec. All three compounds produced a dose related increase in retention latencies. The compounds were evaluated in an overt side effects test battery. A comparison of the peak effective dose in hypoxia and minimum dose which produced tremors revealed the following ratios. DAP had a safety margin of 5, Ph 1, and THA 2. The results suggest that DAP, a compound that induces non-stimulated release of ACh offers no safety advantage over AChE inhibitors.

101.8

Comparative Effects of Putative Cognitive Enhancing Compounds. G. P. Alberici and G. F. Steinfels. E. I. Dupont de Nemours & Co., Med. Prod. Dept., Wilmington, DE 19898 USA.

Electroencephalographic (EEG) activity in man and animals has been shown to change with age and pathological states, such as Alzheimer's Disease. Generally this change consists of a shift in EEG spectral power with a relative decrease in the high frequencies (alpha and beta) and a relative increase in the low frequencies (delta and theta). This decrease in the alpha and beta bands is believed to be involved with a deterioration of vigilance and is correlated with deficits in cognitive performance. It is thought that a compound that would reverse this shift would also improve cognitive performance. Tetrahydroacridine (THA), amphetamine, physostigmine and aniracetam have been shown to improve some elements in the cognitive process. In this study the cortical EEG profile of these compounds in the Long Evans rat was examined. The profiles place the compounds into two general groups; those that increase alpha (aniracetam and amphetamine) and those that increase beta (THA and physostigmine) relative power. Amphetamine and physostigmine produced an inverted U-shaped dose response curve for relative change in spectral power in the alpha or beta bands. The highest doses of amphetamine (1.0 mg/kg) and physostigmine (1.0 mg/kg) decreased relative power in all bands except theta, which increased. These profiles suggest that differences among the compounds may reflect the relative degree of pharmacological efficacy.

101.9

SELECTIVE EFFECTS OF N-methyl-D-aspartate (NMDA) ON ACQUISITION OF A PASSIVE AVOIDANCE RESPONSE IN RATS. K.W. Jones*, C.L. Schaeffer*, G. Steinfels, G. Alberici, and V.J. DeNoble (SPON: W.K. Schmidt). E.I. duPont Medical Products Dept., Wilmington, DE 19898.

The NMDA receptor is suspected to play an important role in learning and memory. In the following studies the function of NMDA in learning a passive avoidance (PA) task was assessed. During acquisition male CD rats were placed in the illuminated side of a two compartment apparatus. When they went into the dark side, they received two three sec .75 mA footshocks. Retention testing occurred 24 hr later. The rat was placed in the illuminated side and the latency was recorded (≤300 sec). Administration of NMDA 30 min prior to acquisition resulted in significant amnesia at doses of 3, 10, 30, and 50 mg/kg s.c. When administered immediately after acquisition NMDA had no effect on memory and the same doses given 30 min prior to retention testing had no effect on recall. An increase in low frequency EEG was found following 15-48 mg/kg s.c. NMDA, indicating a direct effect on brain function. The 30 mg/kg NMDA-induced amnesia was not blocked by the NMDA antagonist 3-((+)-2-Carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) at doses of .001 to .05 mg/kg. The results suggest that NMDA can interfere with the acquisition of a PA task, but not consolidation of memory or recall for the task.

101.10

INFLUENCE OF AP5 ON MEMORY FORMATION IN THE CHICK. T.A. Patterson, K. Scharre, E.L. Bennett, & M.R. Rosenzweig. Brain Research Group, Open University, Milton Keynes, MK7 6AA England and Department of Psychology, University of California, Berkeley, CA 94720.

Several experiments examined the influence of AP5, a NMDA receptor antagonist, on memoryin chicks using a one-trial taste-avoidance task.

To determine the dose response function for AP5, chicks were given bilateral injections into the medial hyperstriatum ventrale (MHV) of either saline or different doses of APV, 5 min before training. Chicks were tested 24 hr after training. Results show that 250 picogram to 25 microgram (dose per brain) AP5 produced significant amnesia.

Experiment 2 examined the pre- and post-training susceptiblity gradients of AP5. Groups of chicks were given bilateral injections into the MHV of either saline or AP5 (250 nanogram per brain) at various times before and after training, and the chicks were tested 24 hr after training. The results indicate that AP5 produced amnesia when given between 60 and 5 min before training, but was not amnestic when given after training.

The time course of amnesia development following pretraining injection of AP5 (250 nanogram per brain) was determined. Chicks were given 5 min pretraining bilateral injections into the MHV of either saline or AP5, and groups of chicks were tested at various times after training. The results show that AP5 produced permanent amnesia that developed between 10 and 30 seconds after training.

These results indicate that NMDA receptor activation plays a role in memory formation in the chick. The results suggest that activation of NMDA receptors may be important for either acquisition, or formation of a very early stage of memory. Experiments are in progress to decide between these possibilities.

101.11

A COMPARATIVE STUDY OF THE LPO AND MHV IN MEMORY FORMATION IN THE CHICK BRAIN. P.A. Serrano, S.J. Ramus*, E.L. Bennett and M.R. Rosenzweig. Department of Psychology, University of California, Berkeley, CA 94720.

The medial hyperstriatum ventrale (MHV) of the chick brain is involved with memory formation (Gibbs and Ng, 1977). When injected into the MHV, glutamate (GLU), ouabain (OUAB), and emetine (EME) are effective in disrupting the formation of short-term, intermediate-term (ITM), and long-term memory, respectively (Patterson et al., 1986). These agents were injected into another area of the chick brain, the lobus parolfactorius (LPO), which showed increased [^{14}C]2-deoxyglucose uptake in chicks after training on a one-trial taste avoidance task (Rose, et al. 1986). Injections of 50mM GLU, .027 mM OUAB, 2.25mM EME or saline (10µl per hemisphere) were given bilaterally into the LPO or MHV. Five min after injection, the chicks were trained on a one-trial taste avoidance task and then tested 24 hr later. Chicks injected into the MHV showed significant amnesia for all three drugs ($p<.05$). Only chicks injected with OUAB in the LPO showed significant amnesia ($p<.05$). The results show that a depolarizing agent (GLU) or a protein synthesis inhibitor (EME) are not effective at producing amnesia, whereas the Na+/K+ ATPase inhibitor OUAB does produce amnesia. The LPO may be an area primarily involved with ITM formation, suggesting that not all areas are involved with the three stages of memory formation. To test this further, we are determining comparative time courses for the appearance of amnesia when OUAB is injected into the MHV or LPO. Effects of other ITM inhibitors are presently being studied in the LPO, and other brain regions are being investigated.

Supported by NSF grant BNS-86-06938.

MEMORY FOR A ONE-TRIAL PASSIVE AVOIDANCE TASK IN CHICKS GIVEN ANISOMYCIN IS NOT STATE DEPENDENT. D.W. Lee, A. M. Perlmutter*, E.L. Bennett and M.R. Rosenzweig. Dept. of Psychology, Univ. of California, Berkeley, CA, 94720.

Research has shown that drugs such as glutamate, ouabain, and anisomycin inhibit the formation of short-term, intermediate-term, and long-term memory, respectively (Gibbs & Ng, 1977; Patterson, et al., 1986). The experiment described here investigates the possibility of state dependency of amnesia caused by the protein synthesis inhibitor anisomycin (ANI). Further experiments will examine both glutamate and ouabain.

Two-day-old XCell white leghorn cockerels were trained in a one-trial passive avoidance task. Bilateral injections (10µl per hemisphere) of saline (SAL) or ANI (3.0 mg/ml) were made into the medial hyperstriatum ventrale 5 min pretrain and 5 min pretest. Training consisted of one 10 sec exposure to a 3mm metal bead dipped in either methylanthranilate (M), a bitter tasting liquid, or water (W). Chicks peck readily at the bead lure during this 10 sec period. Twenty-four hours later, testing consisted of one 10 sec exposure to the same dry bead. Retention for this task was measured as the avoidance of the M bead during test; animals given the water bead during training were expected to peck during test. Six groups were formed: SAL-W-SAL, SAL-M-SAL, ANI-W-ANI, ANI-M-ANI, ANI-W-SAL, ANI-M-SAL (pretrain drug - training bead - pretest drug). As expected, ANI-M-SAL chicks showed significant amnesia; ANI-M-ANI chicks did not. However, the ANI-W-ANI group also showed significantly higher rates of avoidance of the water bead when compared to that of controls. These findings suggest that ANI administration results in generalized avoidance behavior but not necessarily state dependency. The design and interpretation of state dependency tests of ANI will be discussed.

POSTTRAINING INJECTION OF GABAERGIC ANTAGONISTS ENHANCE RETENTION OF AVERSIVELY MOTIVATED TASKS: ROLE OF THE AMYGDALOID GABAERGIC SYSTEM.

J.D. Brioni*, A.H. Nagahara* and J.L. McGaugh. Ctr. Neurobiol. Learning and Memory & Dept. Psychobiol., U. C. Irvine, CA 92717.

The effect of sub-convulsive doses of GABAergic antagonists on the retention of two aversively motivated tasks, inhibitory avoidance and Y-Maze discrimination, was investigated in adult CFW mice. Posttraining IP injections of picrotoxin (0.1-3.0 mg/kg) and bicuculline (0.1-3.0 mg/kg), but not bicuculline methiodide (BMI) (1-30 mg/ kg), induced a dose-dependent increase in retention of both tasks. Neither picrotoxin nor bicuculline affected testing latencies when the animals were trained in the absence of footshock punishment in the inhibitory avoidance task.

The participation of the GABAergic system in the amygdala was also examined. Adult Sprague-Dawley rats with bilateral implanted amygdala cannulae were trained in the inhibitory avoidance task and tested 48 hr later. Rats that received posttraining injections of BMI (0.1-1.0 nmoles per cannula) showed a significant increase in retention as compared to control animals.

Our results indicate that GABAergic antagonists enhance the retention of aversively motivated tasks through central mechanisms, and suggest the involvement of the intrinsic GABAergic system of the amygdala in memory consolidation.

DIAZEPAM AND LONG-TERM HABITUATION OF THE ACOUSTIC STARTLE RESPONSE IN RATS. B. J. Young*, F. J. Helmstetter, and R. N. Leaton. Department of Psychology, Dartmouth College, Hanover, NH 03755.

It is well known that fear increases the amplitude of the acoustic startle response. This effect is usually shown in a potentiated startle paradigm following explicit fear conditioning (e.g., Davis, 1978). We have shown significant correlations between freezing (a behavioral index of fear) and startle amplitudes in a potentiated startle paradigm (Leaton & Borszcz, 1985), and without explicit fear conditioning we have found increased freezing over the early trials in acoustic startle habituation paradigms (Borszcz,Cranney,& Leaton, 1988). Fear occurring over the early trials of habituation training may mask the appearance of long-term habituation (LTH), and we have shown that manipulations that reduce fear, lesions of the amygdala (Leaton & Supple, 1987) or of the central gray (Borszcz, et al.), appear to facilitate the rate of LTH. We now report that diazepam, a widely used benzodiazepine with marked anxiolytic properties, appears to facilitate LTH. Rats tested daily for 4 days (10 trials/day, 60-sec ISI, 125-dB, 100-ms white noise stimulus) following 2.5 mg/kg of diazepam showed significantly greater rates of habituation from Day 1 to Day 2 than vehicle injected controls. Diazepam reduced overall response levels, but the significant rate of decrement was accompanied by a larger absolute response decrement. Diazepam injections represent still another procedure for reducing fear and producing what appear to be increased rates of LTH.

101.15

ENHANCING EFFECT OF A β-CARBOLINE ON MULTIPLE-TRIAL LEARNING IN MICE. P. Venault*, M.J. Raffalli-Sebille*, R.H. Dodd** and G. Chapouthier*. Départ. de Psychophysiologie, Lab. de Physiologie Nerveuse* and Inst. de Chimie des Substances Naturelles**, CNRS, Gif-sur-Yvette, France.

In contrast to diazepam (DZ), which impairs memory processing, methyl β-carboline-3-carboxylate (β-CCM), administered before the training session, has an enhancing effect on performance in the retention test (Venault et al., Nature, 1986, 321, 864). However, this action of β-CCM has been demonstrated only in single trial or single session learning protocols. The present report confirms these results in a multiple trial learning procedure in mice (brightness discrimination in a T maze, with negative reinforcement). The animals were trained for 10 trials per day for 6 consecutive days. The sessions during the first 3 days took place after a subcutaneous injection of β-CCM (0.3 mg/kg), DZ (2.5 mg/kg) or saline. Performance was improved by β-CCM and impaired by DZ in the first 3 sessions as well as in the 3 final sessions (no further treatment). These results provide evidence that the opposite effects of β-CCM and DZ observed in single trial learning protocols, during the retention test, are already observable during the drug treatment. They confirm that both drugs have an action on the acquisition (learning) side of memory processing rather than on retention (memory) itself. These effects being suppressed by the coadministration of Ro 15-1788 (15 mg/kg, s.c.), our results suggest a specific role for benzodiazepine receptors in learning.

101.16

ENHANCEMENT OF LEARNING AND MEMORY IN MICE BY CGS 8216, A BENZODIAZEPINE RECEPTOR ANTAGONIST.

H. Lal, B.A. Kumar* and M.J. Forster. Dept. of Pharmacology, Texas Coll. of Osteopathic Medicine, Fort Worth TX 76107-2690.

Benzodiazepine receptor antagonists are known to reverse diazepam-induced amnesia, but may also improve learning and memory when administered alone (Lal, H. et al. *FASEB J.* 2, 1988, in press). Based on these findings it was proposed that diazepam-like endocoids may exert a tonic inhibitory influence over learning/memory processes. In order to further test this hypothesis, the present study examined the mnemonic effects of CGS 8216, a benzodiazepine antagonist with a chemical profile different from flumazenil. Mice pretreated with CGS 8216 (2.5, 10, or 40 mg/kg, i.p.) were tested for acquisition and retention of a discriminated escape response in a T-maze (Forster, M.J. et al. *Drug Dev. Res.* 11:97, 1987). All CGS 8216-treated groups required fewer trials to reach the acquisition criterion than controls. When the mice were tested for retention one week later (without further treatment), the previously CGS 8216-treated mice had greater difficulty reversing the maze habit than controls and showed improved first-trial recall. The effects of CGS 8216 on retention were dose-dependent and similar to the memory-enhancing effects reported previously for flumazenil. These findings suggest that the enhancement in learning and memory seen after CGS 8216 and flumazenil are mediated specifically via an antagonism of benzodiazepine receptors. [supported by a Grant from CIBA-GEIGY Corp. (H.L.) and NIH grant AG06182 (M.J.F.)].

101.17

Ro 15-4513 ENHANCES DISCRIMINATION LEARNING AND MEMORY IN MICE. B.A. Kumar*, H. Lal and M.J. Forster. (SPON: I.M. Korr).Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

The benzodiazepine receptor antagonist, flumazenil, was previously shown to facilitate acquisition and retention in mice (Lal H. et al., *FASEB J.*, 2, 1988, in press). The memory-enhancing effect of this drug was proposed to be mediated via antagonism of diazepam-like endocoids. In the present study, we investigated the mnemonic effects of Ro 15-4513, an anxiogenic drug (Harris, C.M. & Lal, H. *Neuropharmacol.*, 26:1545-1547, 1987) with inverse agonist properties at benzodiazepine receptors (Harris, C.M. & Lal H. *Drug Dev. Res.*, 13, 1988, in press). Mice received Ro 15-4513 (2.5 and 10 mg/kg, i.p.) 15 min prior to training under a T-maze, discriminated escape paradigm described previously (Forster, M.J. et al. *Drug Dev. Res.*, 11:97, 1987). All mice were tested for retention one week later without additional treatment. Ro 15-4513 resulted in a dose-dependent decrease in the number of trials required for initial acquisition of the maze habit. In retention tests, the Ro 15-4513-treated mice had better first-trial recall and required more trials to reverse the previously acquired habit than controls. These findings are consistent with the hypothesis that memory processes could be modulated by endogenous ligands acting on benzodiazepine receptors.

101.18

REVERSAL OF CHLORDIAZEPOXIDE-INDUCED IMPAIRMENT IN DISCRIMINATION PERFORMANCE BY RO 15-1788. S.O. Cole*(SPON: J.L. Falk). Dept. of Psychology, Rutgers University, Camden, NJ 08102.

Chlordiazepoxide (CDP) 10 mg/kg, administered on 6 weekly sessions, impaired the performance of a previously-learned go-no go successive discrimination in male, Sprague-Dawley rats. The impairment was accompanied by an increase in responding during no go periods of the task, indicating that CDP-drugged animals have difficulty withholding incorrect responses. The benzodiazepine (BDZ) receptor antagonist Ro 15-1788 (5 and 10 mg/kg) reversed the impairment in discrimination performance on sessions 2-6 (but not session 1) when co-administered with CDP. While the reversal of impairment by Ro 15-1788 was not dose-dependent, it was accompanied by a significant reduction in responding during no go periods of the task. These findings suggest that the impairment in discrimination performance produced by CDP is mediated by central BDZ receptor sites. When administered alone, Ro 15-1788 10 mg/kg (but not 5 mg/kg) produced a mild BDZ-like impairment in discrimination performance and increase in no go period responding. These findings suggest that Ro 15-1788 may have some intrinsic action of its own which needs to be assessed independently of its use as a mediational research tool.

101.19

NEUROCOGNITIVE FEATURES OF MIDAZOLAM INDUCED AMNESIA. J. French, E.F. Domino, R. Pohorecki*, C.F. Galus*, and S.K. Pandit*. Department of Pharmacology, University of Michigan, Ann Arbor, MI 48109-0626.

Subhypnotic doses of midazolam were evaluated in healthy adult volunteers using a neurocognitive assessment battery. Volunteers were assigned randomly to medicated and control groups (10 subjects each). Midazolam HCl in a dose of 0.02 mg/kg was injected i.v. three times at 15 min intervals after obtaining baseline electrophysiological recordings and memory test results.

The incidence of EEG beta activity from the frontal lead F_3 was increased while alpha activity from the occipital O_1 lead was decreased by midazolam in a dose dependent manner. The amplitude of the P300 component of the auditory evoked potential progressively decreased with increasing doses of midazolam as did the accuracy of counting the number of rare tones. The N100 data was progressively augmented. Twenty four hr after midazolam, the treated subjects were impaired in their ability to recall memory cards presented, particularly following the second and third dose. The ability to recall misplaced objects was impaired relative to baseline. The results support the conclusion that midazolam induced amnesia is better correlated with an attention deficit than gross sedation.

101.20

ROLE OF CHOLINERGIC AND GABAERGIC NEURONAL SYSTEMS IN CYCLOHEXIMIDE-INDUCED AMNESIA IN MICE. T. Nabeshima, Y. Noda*, K. Itoh* and T. Kameyama*. Dept. of Chemical Pharmacology, Fac. of Pharmaceutical Sciences, Meijo Univ., Nagoya, 468 Japan.

The role of cholinergic and GABAergic neuronal systems on the cycloheximide (CXM)-induced amnesia was investigated using the step-down type passive avoidance task in mice. CXM (7.5 - 120 mg/kg, s.c.) given just after the training caused amnesia (indicated by short latency to step down from the platform on the gride floor) in the retention test conducted 24 hr later in a dose dependent fashion. In the CXM (60 mg/kg)-treated mice, a choline esterase inhibitor, physostigmine (PHY; 0.125 and 0.25 mg/kg, i.p.), or GABA agonists, muscimol (1 and 2 mg/kg, i.p.) and baclofen (6 and 12 mg/kg, i.p.) given just after training markedly prolonged step down latency (SDL), indicating reversal of amnesia. The antiamnesic action of PHY (0.125 mg/kg) was almost completely antagonized by a central acetylcholine antagonist, scopolamine (3 mg/kg, s.c.), but not by a peripheral acetylcholine antagonist, butylscopolamine (3 mg/kg, s.c.). Furthermore, the antiamnesic action of muscimol (2 mg/kg) was reversed by GABA antagonists, picrotoxin (0.5 mg/kg, s.c.) and bicuculline (0.5 mg/kg, s.c.), while the effect of baclofen (12 mg/kg) was reversed by picrotoxin (0.5 mg/kg), but not by bicuculline (0.5 mg/kg). These results suggest that the dysfunction of cholinergic and GABAergic neuronal systems play an important role in the CXM-induced memory impairment on the passive avoidance task.

EPILEPSY II

102.1

MUSCARINIC ACETYLCHOLINE RECEPTORS IN THE GENETICALLY EPILEPSY-PRONE RATS (GEPRs) by P.C. Jobe, R. Duffield* and A.K. Ho*. Department of Basic Sciences, Univ. of Illinois College of Medicine at Peoria, Peoria, IL 61605

The possible role of the central muscarinic receptors (AChRs) in seizure predisposition was studied in the GEPRs under phosphorylating conditions. Brain homogenates and synaptic membranes were prepared from naive and acoustically screened GEPRs of the moderate (GEPR-3) and severe (GEPR-9) seizure types. Results obtained showed that the specific [^{3}H]-QNB binding sites were significantly decreased in the naive GEPR-3 and GEPR-9 brain when compared with the controls, with GEPR-9s ($p<0.01$) showing significantly greater reduction than the GEPR-3s ($p<0.05$). Total binding sites remained significantly lower in GEPR-9 brain during seizures and 1 hour after seizures. Under phosphorylating conditions, both the controls and GEPR-3s showed a reduction in binding in the range of 20% approximately whereas in the GEPR-9 brain [^{3}H]-QNB binding showed no significant reduction. The number of [^{3}H]-pirenzepine binding sites were significantly higher in the GEPR-9 than the GEPR-3 and the controls. Binding under phosphorylating conditions showed little or no effect on the [^{3}H]-pirenzepine binding in the GEPRs. These findings suggest an abnormal response of the GEPRs to phosphorylation and a differential effect on the M_1 and M_2 receptor subtypes. [Supported in part by BRSG, University of Illinois, AFAR and a grant from the NIH (NS 16829).

102.2

APAMIN-SENSITIVE POTASSIUM CHANNEL AND CHOLINERGIC INFLUENCES ON INFERIOR COLLICULAR SEIZURE ACTIVITY. **Thomas J. McCown and George R. Breese Univ. of North Carolina Sch. Med. Chapel Hill, N.C. 27599-7250.**

The role of apamin-sensitive potassium channels, as well as nicotinic and muscarinic cholinergic function, on neural excitability was investigated within the inferior collicular cortex. Inferior collicular microinjection of apamin(21 pmol) significantly reduced the stimulation current necessary to elicit seizure activity from the inferior colliculus, yet higher doses did not cause spontaneous seizure activity. Likewise intermediate doses of d-tubocurarine (0.22 umol), gallamine(1.7 umol) or α-bungarotoxin(0.33 nmol) reduced the threshold current, while higher doses caused spontaneous seizure activity. Conversely, atropine caused a dose-related increase in the seizure threshold. However, atropine pretreatment totally blocked seizure threshold reduction effects of α-bungarotoxin, partially attenuated d-tubocurarine or gallamine effects, yet did not alter the actions of apamin. Thus, both apamin-sensitive potassium channels and cholinergic function significantly influence seizure activity. (Supported by USPHS HD-031110).

MATHEMATICAL MODELLING OF THE HUMAN EPILEPTIC SPIKE COMPLEX IN MAGNETOENCEPHALOGRAPHY. C.Baumgartner* (1,3), S.Di* (1,2), W.W.Sutherling (1) and D.S.Barth (1,2) (SPON: C.H.Markham). Dept. of Neurology (1) and Psychology (2), Univ. of California, Los Angeles, CA 90024, Neurological Univ. Clinic, Vienna, Austria (3).

The interictal spike complex in epileptic patients is often difficult to interpret because of its origin in different brain regions and a substantial spatial and temporal overlap of the generated potentials. This poses a major problem for the localization of the abnormally discharging neuronal populations by non-invasive measurements as scalp-EEG and magnetoencephalography (MEG).

We therefore developed new methods of computer-based analysis of the epileptiform MEG using both physical models and multivariate statistical methods to investigate spatially and temporally overlapping extracranial neuromagnetic fields over the entire course of the interictal spike complex. These methods were applied to MEG measurements from five patients with partial seizures. We could estimate the localization of several different brain regions which generated the epileptic spike discharges and were active simultaneously.

It is concluded that with the help of these new models the investigation and localization of epileptic discharges from several different brain regions overlapping both in space and time can be performed by non-invasive measurements. These methods of analysis should also readily be applicable to data from scalp-EEG.

102.4

NEUROBIOLOGICAL BASES OF EPILEPSY IN MAGNETOENCEPHALOGRAM (MEG). S.Di*, C. Baumgartner*(1) and D.S.Barth. (SPON: W.W. Sutherling). Dept. of Neurology and Psychology, Univ. of California, Los Angeles, CA 90024. (1).Neurological Univ. Clinic, Vienna, Austria.

The magnetoencephalogram (MEG) is a recently developed method of localizing and studying the synchronized cellular currents produced by epileptic paroxysms in animal and man. Clinically, MEG is a potential tool to noninvasively localize human epileptic foci for neurosurgical treatment of seizures. However, based on the theoretical prediction that neuromagnetic fields are induced predominantly by intracellular currents, MEG animal studies may also provide valuable insights into the electrophysiological mechanisms of seizure disorders.

The present study uses a penicillin model of epilepsy in rat cortex to explore the neurogenesis of epileptiform magnetic fields in man. Laminar electrical recordings of rapid and slow cellular currents were obtained from 5 rats using glass microelectrodes and analyzed by current source density (CSD) method. MEG measurements were done on the same animals. combining MEG with CSD maps from detailed electrical recording, a qualitative relationship has been established between recorded neuromagnetic field and the spatial-temporal characteristics of the electrical activity of the underlying neural structures.

RAT STRAIN DIFFERENCES IN KAINIC ACID NEUROTOXICITY. G.T. Golden, T.N. Ferraro, G.G. Smith*, J.H. Kulp* and P.F. Reyes*. VA Medical Center, Coatesville, PA 19320 and Thomas Jefferson Medical College, Phila., PA 19107.

Genetic factors may influence the neurotoxic effect of Kainic acid (KA). Sanberg (1979) reported that the neostriatum of Wistar rats is more sensitive to intrastriatally injected KA than that of Sprague-Dawley rats. Systemic administration of KA elicits multifocal seizures and causes biochemical changes and neuronal loss. Here we report behavioral, EEG and biochemical data indicating strain differences in sensitivity to KA and, in addition describe a strain of rats which reliably and consistently demonstrate electrographic and behavioral status epilepticus to a 10 mg/kg, sc dose of KA. Male Sprague-Dawley (SD, n=11), Wistar-Furth (WF, n=10) and Long-Evans (LE, n=10) rats had electrodes implanted in the hippocampus and cortex for chronic EEG recordings. Ten days after recovery rats received a sc injection of 10 mg/kg KA. Behavior and EEG were monitored for 240 min. The # of subclinical (only EEG) and electroclinical seizures, # of wet dog shake episodes (WDS), the total time in ictal activity and latency to onset of status epilepticus were compared in the three strains. Results showed that WF strain demonstrated the most consistent and least variable response to systemically administered KA. WF rats had the shortest latency to onset of status epilepticus, spent the greatest amount of time in seizure activity and had more behavioral and electrographic seizures. (Supported by VA funds.)

102.6

EFFECTS OF REPEATED AUDIOGENIC SEIZURES (AGS) ON SEIZURE SEVERITY AND EEG IN TWO SUBSTRAINS OF THE GENETICALLY EPILEPSY-PRONE RATS (GEPRs) D.K. Naritoku*, L.B. Mecozzi*, and C.L. Faingold. (SPON: J.R. Couch) So., IL Univ. Sch. Med., Depts. Neurol. and Pharmacol., Springfield, IL.

GEPRs show increased susceptibility to seizures induced by numerous stimuli. GEPR-9s exhibit wild running, clonus, and tonic seizures with hindlimb extension (HLE) in response to loud sounds. AGS in GEPR-3s do not include HLE. Effects of daily AGS induced by electrical bell sound (110 dB SPL) were studied in both substrains. Behavior and EEG were simultaneously recorded in unrestricted animals. All GEPR-9s uniformly developed prolonged seizures and cortical spike-wave EEG abnormalities by day 3. GEPR-3s showed an erratic response to daily AGS. Most GEPR-3s developed prolonged seizures and spike-wave abnormalities; however, spike-wave onset varied from day 3 to 10 and seizure behaviors were inconsistent. GEPR-3s with prolonged AGS exhibited clonic activity which differed from the usual running clonic seizures, and profound postictal states. Tonic seizures with HLE were never seen in the GEPR-3. These data demonstrate increased seizure severity following repeated AGS in GEPR substrains which have distinctly different behavioral seizure patterns. This suggests that mechanisms of AGS propagation from brainstem initiation sites may be dissimilar in the two substrains despite increased severity. Seizure propagation to cortex appears to be induced by repeated AGS in the GEPR.

ACCELERATED KINDLING IN THE MUTANT EPILEPTIC MOUSE El R.C. Green, B.J. Elizondo, T.N. Seyfried Department of Neurology and Division of Neuroscience, The Children's Hospital and Harvard Medical School and Department of Biology, Boston College, Boston, MA 02115

The El mouse carries an autosomal dominant mutation on a ddY inbred backround. Homozygous mutants (El/El) develop generalized motor seizures after 2 months of age when tossed in the air. El/El mutants (n=7) and non-epileptic ddY +/+ controls (n=6) were implanted with bipolar electrodes in the left olfactory bulb and kindled with daily stimulations through six consecutive stage 5 seizures. All mice were kindled at 4-6 weeks of age, prior to the development of any inherent seizure activity in El.

Kindling to first stage 5 seizure required 14.1 ± 1.223 stimulations in the epileptic El mice versus 19.5 ± 0.764 stimulations in the ddY mice (mean ± SEM, $p < .005$). The kindling rate to the sixth consecutive stage 5 seizure was similarly accelerated in El. The mean afterdischarge (AD) duration at the initial stage 5 seizure in the El mice (23.3 ± 1.085 seconds) was significantly shorter than that of the non-epileptic controls (38.7 ± 2.14 seconds) (mean ± SEM, $p < .0001$). The shorter AD duration was entirely accounted for by a shorter mean latency to onset of motor seizure in the El mice ($p < .005$).

These results demonstrate that there is accelerated electrical kindling in the El mouse in comparison to ddY controls, at an age prior to the development of motor seizures in El.

102.8

SOUND-INDUCED SEIZURE RESPONSIVENESS OF THE MODERATE SEIZURE COLONY OF THE GENETICALLY EPILEPSY-PRONE RAT. **C.E. Reigel, P.K. Mishra, J.W. Dailey and P.C. Jobe. Dept. of Basic Sci., Univ. of Ill. Col. of Med. at Peoria, Peoria, IL 61656.**

The moderate seizure genetically epilepsy-prone rat (GEPR-3) has been bred to exhibit generalized clonic convulsions following a single running episode in response to sound. Such a convulsion receives an audiogenic response score (ARS) of 3 according to the method of Jobe and coworkers (J. Pharmacol. Exp. Ther. 184: 1-10, 1973). The GEPR-3 colony currently reflects 25-28 generations of brother-sister inbreeding for this characteristic clonic seizure. This has resulted in a highly consistent degree of seizure responsiveness in the progeny of the GEPR-3 colony. The purpose of the present report was to document the seizure characteristics of the recent GEPR-3 colony. Routine seizure assessments of eleven generations of GEPR-3s spanning a 3 year period were examined. The majority of GEPR-3 progeny are sound stimulated at 3 weekly intervals to confirm their seizure responsiveness and for the selection of new breeders. Latencies to the onset of wild running and convulsion are recorded in addition to the ARS score. Collectively, the GEPR-3s tested exhibited a 99.5 percent incidence of sound-induced seizures on the first test. Over 86 percent of the GEPR-3s exhibited seizures rated at an ARS of 3 on the first test. Latencies to running and convulsion decreased and incidence of ARS of 3 increased in the second and third tests, suggestive of an experiential effect on seizure severity.

102.9

CLASSICAL GENETIC ANALYSIS OF KINDLED SEIZURE SUSCEPTIBILITY IN DBA/2J AND C57BL/6J MICE. C. Applegate, S. DiFazio*, K. Spanknebel*, J. Burchfiel and P. Neumann*. Dept. Neuroscience, The Children's Hospital, Boston, MA 02115.

We examined the susceptibility of DBA/2J (D2) and C57Bl/6J (B6) inbred strains of mice to kindling stimulation of the olfactory bulb. The kindled seizure phenotypes of F_1 (N=14) and F_2 (N=19) hybrids and offspring of backcrosses (D2xF1; N=16; B6xF1; N=14) also were defined.

In comparison with B6 (N=18) mice, D2 (N=10) animals required significantly fewer stimulations to elicit the first generalized seizure, exhibited significantly longer afterdischarge durations at all kindled seizure stages and exhibited significantly longer motor seizure durations. F1 hybrids represented an intermediate seizure phenotype on these measures.

Phenotypic distributions in F2 and backcross generations were inconsistent with a single gene hypothesis suggesting that 2 or more genes are responsible for strain differences in kindled seizure susceptibility. We are currently defining seizure phenotypes in BXD recombinant inbred strains to determine the mode of inheritance of susceptibility to kindling and to identify and map the genes involved.

102.10

CHRONOBIOLOGICAL VARIATIONS IN THE CONVULSIVE EFFECT OF MONOSODIUM GLUTAMATE (MSG) WHEN ADMINISTERED TO ADULT RATS. R. Gutiérrez-Padilla*, F. Alfaro*, G. Tapia-Arizmendi* and A. Feria-Velasco. Unidad de Investigación Biomédica de Occidente, I.M.S.S. Guadalajara, Jalisco. MEXICO.

The convulsive effect of MSG administered intraperitoneally (i.p.) to various animals is well known and the convulsive pattern varies according to animal age. This work was designed to know whether the convulsive effect of MSG in rats would vary when the drug is given at different day times. Three groups of rats were given i.p. 4mg/g MSG at 7 am, 3 pm and 11 pm, whereas 15 rats were injected with NaCl (eqNaCl) equimolar to MSG solution at 7 am, 3 pm and 11 pm in groups of 5 as controls. Animal behavior was recorded in all experiments. Results from both groups were compared to those from similar groups of rats injected i.p. with isotonic saline solution (ISS). No convulsions appeared in animals injected with ISS or eqNaCl at the 3 times studied. With MSG, no variations were seen in the latency period when data from the 3 times studied were compared among them. Duration of convulsive period when rats were injected at 7 am was shorter (88.5$^+$27 min) than those obtained at 3 (199.4$^+$4) and 11 pm (203.5$^+$5). No significant variations were seen in total number of convulsive episodes in the 3 groups, but the number of seizures per hour and their intensity were significantly greater when animals were injected at 7 am than those seen when rats were studied at 3 and 11 pm. Nearly 70% of animals of the group injected at 7 am died in status epilepticus, whereas no deaths were recorded in animals injected at 3 or 11 pm. Results could be explained in terms of variations of physiological processes at both, the brain and extracerebral tissues involved in MSG metabolism related to circadian rhythms. Whether the behavioral variations correlate with variations of brain biochemical parameters related to the production of convulsions in the MSG model is unknown.

102.11

INDUCTION OF STATUS EPILEPTICUS IN NAIVE RATS BY ELECTRICAL STIMULATION OF VENTRO-LATERAL FOREBRAIN. J. Rick, J. Heitzner, G.O. Ivy, and N.W. Milgram. Div. of Life Sciences, Univ. of Toronto, Toronto, Ontario, M1C 1A4.

In an attempt to induce status epilepticus using electrical stimulation in experimentally naive rats, we implanted electrodes in a variety of limbic and cortical structures and stimulated continuously for up to 2 hours, using bursts of pulses delivered at 3Hz at progressively higher intensities. Thus far, status epilepticus was produced in 80% (4/5) of a group of animals with electrodes placed in the ventrolateral forebrain, adjacent to or in the endopiriform nucleus. In contrast, recurrent seizures persisting after the offset of stimulation developed in 13% (1/6) of the rats stimulated in the perforant path, and in none of the animals with neocortical electrodes. Histological analysis using both cell stains and immunocytochemical markers of astroctye reactivity revealed relatively widespread patterns of damage which was largely unilateral in the animals with endopiriform nucleus electrode placements. In contrast, the damage produced by stimulation of perforant path was bilateral and symmetrical. These findings support the claim of a unique seizure sensitive system in the pyriform cortex. Supported by NSERC.

3D ANALYSIS OF SEIZURES PATHWAYS IN CORTICALLY-KINDLED RATS

E.M. Santori, A.W. Toga and R.C. Collins
Department of Neurology, UCLA, Los Angeles, CA 90024-1769

In control and electrically kindled subjects, the metabolic responses to bicuculline-induced focal cortical seizures were studied. These experiments were undertaken to determine whether kindling of forelimb cortex alters its functional anatomy.

Rats were kindled within the forelimb sensorimotor cortex. Over a two month period experimental subjects received 39 to 50 stimulations; controls underwent afterdischarge testing at the start and end of experiment but were not stimulated during the kindling period.

Four hours prior to 14C-2-deoxyglucose administration, electrode headsets were replaced with epidural wells. Metabolic traces were obtained on experimental subjects and non-kindled controls while focal cortical seizures were induced by the topical application of (-) bicuculline methiodide (1 mg/ml).

The autoradiographic data were reconstructed to 3 dimensions. Each of 600 coronal sections was assigned a value corresponding to its rostral-caudal position. Geometric reassembly was performed in accurate 3-space. Anatomic surfaces were rendered to orient the viewer and statistics computed on metabolic data. Isodensity contours were established at several metabolic rates and volumetric measurements taken.

No striking differences between the kindled and control patterns of metabolic activation were observed. A more detailed analysis of the topology and volume of these metabolic effects is being performed and will be presented.

102.13

ELECTROGRAPHIC KINDLING IN AN ISOLATED PYRIFORM BLOCK IN A CHRONIC PREPARATION. M. Mosher and R. J. Racine. Dept. of Psychology, McMaster Univ., Hamilton, Ontario, CANADA, L8S 4K1.

Previous work has shown that pyriform lobe structures are heavily involved in the kindling process, regardless of which sites are kindled (Kairiss, E.W., et al. Brain Res. 1984, 322, 101-110). It is still not clear, however, whether the pyriform lobe structures require participation of other structures for these changes to develop. To test the ability of the pyriform cortex and amygdala to develop a chronic epileptogenic response pattern, we isolated a block of tissue containing a portion of the pyriform cortex and amygdala. These blocks retained a blood supply and remained viable for the duration of the experiment. An electrode was implanted into the center of the block. Kindling stimuli were then applied via this electrode while the electrographic response was monitored. We have found that these blocks support normal looking epileptiform afterdischarges (AD's) and that these discharges develop in strength in much the same way as in the intact preparation. The AD's increased in duration, the AD spike frequency increased, the AD spike amplitudes increased and the AD spike morphology became more complex. Spontaneous interictal spike activity also appeared within the isolated blocks. These changes were long-lasting. Also of some interest was the finding that convulsions would develop (though more slowly) in animals in which the isolation was not complete, indicating that propagation to outside structures required only a small bridge of tissue.

102.14

INFERIOR COLLICULUS (IC) UNIT ACTIVITY AND AUDIOGENIC SEIZURES (AGS) IN BEHAVING GENETICALLY EPILEPSY-PRONE RATS (GEPRs). C.L. Faingold and C.A. Boersma Anderson*, Dept. Pharmacol., Southern IL Univ., Springfield, IL 62794-9230

The GEPR displays AGS in response to intense acoustic stimuli. Recording neuronal activity during seizures is difficult, but microwire electrodes have been used recently during kindling. In this study microwires were implanted into the IC of GEPRs under anesthesia. At least one week later, multiunit and single unit activity were recorded in unrestrained GEPRs during acoustic stimulation. Responses were examined to acoustic stimuli (12 kHz tone bursts, 60-100 msec at 2/sec) that initiate AGS in the GEPR with high intensities. The number of action potentials in the response initially increased as acoustic intensity was increased, and an afterdischarge-like response was observed at the offset of the tone as AGS threshold was approached. The afterdischarge resulted from increased firing of the unit and recruitment of additional units. The overall responses of many units decreased with higher sound intensity [(non-monotonicity (NM)] as observed in normal animals. GABA is implicated in NM in normal IC neurons. However, NM in the GEPR was often overcome with further intensity increases. This reduced effectiveness of NM may be another manifestation of the reduced efficacy of GABA observed in GEPR IC neurons. Neuronal responses after AGS were greatly reduced reversibly during the post-ictal depression of behavior. (Support: NIH NS 13849; NS 21281).

102.15

NONCONVULSIVE STATUS EPILEPTICUS IN KINDLED RATS: 2-DG UPTAKE & NEUROPATHOLOGY. G.G. Buterbaugh, B.E. Jones, J.S. Kiefer* and G.M. Hudson*. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

Pilocarpine (20 mg/kg)-facilitated status epilepticus (pfSE) was evoked by amygdala stimulation of amygdala kindled rats. All rats (N=14) remained upright and immobile to the onset (55.4 ± 2.4 min) of slow leftward circling continuing through 2 hrs with generalized EEG seizures when pfSE was terminated. Three weeks later, histology showed enlarged ventricles and bilateral cell loss, especially in the substantia nigra pars reticulata (SNpr) and the paleolimbic cortex; hippocampal regions were relatively spared. Other rats received i.v. ^{14}C-2-DG after 2 hrs pfSE, 45 min before decapitation; brains were frozen sectioned for autoradiography. 2-DG uptake showed a uniform hypometabolic pattern (relative to rats after 10 min of pfSE), most notable in SNpr and paleolimbic regions. These results support a relationship between diminished 2-DG uptake and regional brain damage in a model of nonconvulsive SE. Moreover, dorsal hippocampal kindled rats (2 hrs pfSE) showed similar behavior and brain damage as amygdala rats and supported generalized seizures and pfSE three weeks post-pfSE. Since pfSE continues for 4-6 hrs if not terminated, the results also question the role of SNpr and paleolimbic regions in the support of long duration pfSE.

102.16

FLASH EVOKED POTENTIALS (FEP) FOLLOWING PROLONGED STATUS EPILEPTICUS IN KINDLED RATS. L.M. Mayo*, R. Gussio*, G.A. Young, C.U. Eccles and G.G. Buterbaugh. Department of Pharmacology, University of Maryland, School of Pharmacy, Baltimore, MD 21201.

Amygdala-kindled male Sprague-Dawley rats were subjected to pilocarpine-facilitated status epilepticus (pfSE) for one or two hrs duration. FEP's were then obtained at three day intervals for four weeks. Three days post-pfSE, FEP waveform patterns were grossly altered with markedly diminished amplitudes. These changes were related to the duration of pfSE. Consequently, the six conventional positive-negative waveform components could not be identified. For several weeks following pfSE, temporal changes in waveform pattern and amplitude varied between rats. A predominant positive peak transiently emerged in all animals. Preliminary signal analysis suggests frequency modulation of the general FEP waveform. In the 1 hr pfSE rats, FEP's resembling pre-pfSE waveforms appeared after 2-3 weeks. Histological examination (at 4 weeks) revealed widespread bilateral gliosis and cell loss which was more severe in 2 hr pfSE rats. These results suggest alterations in the FEP after pfSE are, like cell damage, related to seizure duration. They are compatible with the reports of transient blindness following SE and support the use of FEP's as a tool to monitor seizure induced brain damage and the effect of potential cytoprotective agents.

102.17

DECREASE IN CEREBELLAR IODOCYANOPINDOLOL BINDING SITES IN 31-DAY-OLD GENETICALLY EPILEPSY-PRONE RAT. S. Razani-Boroujerdi, D.Y. Tso-Olivas and D.D. Savage. Dept. Pharmacol., U. New Mexico Sch. of Medicine, Albuquerque, NM, 87131.

Studies from other laboratories have revealed deficits in neurochemical and electrophysiological indicators of noradrenergic neurotransmission in the cerebellum of the Genetically Epilepsy-Prone (GEPR-9) rat. For example, the ability of norepinephrine to potentiate GABA-mediated inhibition of Purkinje cell firing is decreased in GEPR-9 rats compared to non-epileptic controls. One possible explanation for this observation is a decrease in the number of GEPR-9 rat Purkinje cell β-adrenergic receptors. To test this hypothesis, ^{125}I-iodocyanopindolol (CYP) binding to monoaminergic receptor binding sites was measured in horizontal sections of cerebellum in non-epileptic control and GEPR-9 rats using *in vitro* autoradiography.

CYP binding was measured in the absence and presence of 1 μM propranolol to determine the total amount of specific CYP binding. In addition, sections were incubated with CYP in the presence of 22 different concentrations of the β_2-adrenergic antagonist ICI118,551 to discriminate CYP binding to β_2-adrenergic receptors and serotonin 5HT$_{1B}$ receptors. The number and affinity of β_2-adrenergic and 5HT$_{1B}$ subtypes of CYP binding sites in the cerebellum was determined by analysis of the displacement of binding data using the non-linear curve fitting program LIGAND. The results indicated a significant decrease in total CYP binding in the stratum moleculare of cerebellar cortex in GEPR-9 rats compared to control. LIGAND analysis of the displacement of CYP binding data indicated a 25% decrease in the number of β_2-adrenergic binding sites with no change in the number of 5HT$_{1B}$ binding sites or the affinity of CYP for either subtype of CYP binding site. (Supported by NIH-RR08139).

TARGET-SPECIFIC REQUIREMENTS OF IMMATURE AXOTOMIZED CNS NEURONS FOR SURVIVAL AND AXONAL ELONGATION AFTER INJURY
B.S. Bregman, M.B. Clark, and H.W. Muller. Dept. Anatomy, Univ. Maryland Sch. Med., Baltimore, MD 21201

This study examined the degree to which the requirements of immature axotomized neurons for survival and axonal elongation are target specific. Following spinal cord hemisection at T6 in rat pups <48 hours of age, transplants of embryonic target (spinal cord) or non-target (cortex, hippocampus, cerebellum, astrocytes and Schwann cells) tissue were placed into the lesion site. We used neuronal cell counts in the red nucleus (RN) to assay for cell survival and the serotonergic (5-HT) raphe-spinal projection for the analysis of axonal elongation at acute (7 days post-operative, dpo) and chronic (30 dpo) survival times. Target and non-target transplants survived within the cord at both 7 and 30 dpo. At 7 dpo, both target and non-target transplants rescued immature axotomized RN neurons. In contrast, at 30 dpo, only target specific transplants (spinal cord) supported the survival of axotomized RN neurons. At 7 dpo, immature 5-HT axons grew into both target and non-target tissue, but only the spinal cord transplants maintained the projection. These results suggest that components contained within a variety of immature tissues can substitute for the loss of the normal target immediately after injury, but permanent survival and maintenance of axonal projections are dependent upon target specific factors. Supported by NIH NS19259, NS01249, March of Dimes and NATO.

103.2

TWO MECHANISMS MAY CONTRIBUTE TO THE NEURONAL SURVIVAL-PROMOTING ACTION OF VIP: NEUROTROPHIC FACTOR RELEASING ACTIVITY AND GLIAL MITOGENESIS.
D.E. Brenneman, Lab. of Develop. Neurobiology, NICHD, Natl Institutes of Health, Bethesda, MD 20892

Vasoactive intestinal peptide (VIP) has been shown to increase neuronal survival by an action involving non-neuronal support cells in CNS cultures (Brenneman, D.E., J. Cell Biol. 104:1063, 1987). We now present evidence that low concentrations of VIP can produce an increase in the number of astroglia and a rapid increase in the availability of neurotrophic material in conditioned medium from nonneuronal spinal cord cultures. A combination of GFAP (glial fibrillary acidic protein) immunocytochemistry and ^{3}H-thymidine autoradiography was used to assess the astroglial population. Compared to controls, a 20-30% increase in the number of astroglia was observed during a five day test period. In addition, nonneuronal cultures from fetal mouse spinal cord tissue were incubated with 0.1 nM VIP for 30 min. High molecular weight (>30 kD) substance(s) were found to be released into the incubation medium that significantly increased the survival of spinal cord neurons during a critical period of development in cultures. Conditioned medium from nonneuronal cultures that were not stimulated with VIP had no detectable neurotrophic activity. These data suggest both a long term (glial mitogenesis) and a short term (trophic factor releasing activity) regulatory role for VIP during development.

103.3

INTERACTION OF SCHWANN CELLS AND TRIGEMINAL NEURONS IN LONG-TERM COCULTURE. K.Y. Chan and J.H. Chang*. Dept of Ophthalmology, University of Washington, Seattle, WA 98195.

Previous studies in this laboratory have shown that trigeminal neurons (TN) of rabbit are induced to extend neurites and remain viable in culture conditions by a neurono-trophic factor (ENF) secreted from corneal epithelial cells (innervated target). In this study, the trophic relation between TN and Schwann cells (SC) was investigated using LM, EM and immunocytochemistry (IC). Neonatal TN were mechanically dissociated and cultured in serum-free medium containing ENF for 5 days. During this period TN extended a profuse network of neurites. Subsequently the cultures were maintained in culture medium containing 2% serum for several months. Within 1 wk, SC enveloping the TN migrated to the substratum and proliferated slowly. These stellate cells associated spatially with the soma and neurites of TN. During the following weeks some SC aligned themselves along the neurites which gradually increased in diameter and ran a linear course instead of wavy pattern. After 4 wks of coculture, myelin layers were detected around the neurites by EM. IC studies showed that NGF receptor was expressed in both TN and SC. Neurofilament was identified in the neurites only. Vimentin was expressed by both SC & fibroblasts (when present). Thus, differentiated TN enhanced the survival and proliferation of SC, which depended on neuronal contact to initiate myelination. This in vitro model would be useful for studying cellular interaction during corneal nerve regeneration. (NIH EY04538)

Cyclic AMP Analogs and Cortical Astrocyte Conditioned Medium Increase [^{125} I] Tetanus Toxin Binding in Mouse Hippocampal Cultures. Ralph F. Alderson. (SPON: J.D. Clements). Lab. Developmental Neurobiol., NICHD, NIH, Bethesda. MD 20892.

Basic fibroblast growth factor (bFGF) and analogs of cyclic AMP; 8-bromo-cAMP (8Br-cAMP), and 8-(4-chlorphenylthio)-cAMP (CPT-cAMP), promote neuron survival in the hippocampus (Walicke et.al., PNAS, 83:3012, 1986), or sympathetic and sensory neurons in culture (Rydell&Green, PNAS, 85:1257, 1988) respectively. Tetanus toxin (TT), a discrete early marker for neurons in culture was iodinated and used in a celisa assay to evaluate the potential survival or neurite promoting effects of the cAMP analogs and conditioned medium on hippocampal cells in culture. These effects were compared to those produced by bFGF.

Dissociated cell cultures were prepared from the hippocampi of E18 mouse embryos. The cells were grown in defined medium and treated with the various ligands for 48 hours. B-FGF (Collaborative Research) at a dose of 100 ng/ml produced a 60% increase in TT binding (3535.5 dpm/well) as compared to the vehicle treated controls (2215.2 dpm/well). 8Br-cAMP at a dose of 10 or 1 uM increased TT binding by 36 and 53%, respectively. A similar dose response curve was obtained with CPT-cAMP. When the hippocampal cells were treated with 16.4 ng of defined medium conditioned by purified cortical astrocytes, TT binding was enhanced by 80% (2888.10 dpm/well) as compared to the vehicle treated controls (1607.9 dpm/well). The active factor(s) in conditioned medium are now under investigation.

HIPPOCAMPAL NON-NEURONAL CELLS INCREASE CHOLINE ACETYLTRANSFERASE ACTIVITY IN BASAL FOREBRAIN CULTURES. M. Yokoyama, C.F. Dreyfus, and I.B. Black. Div. Devel. Neurol., Cornell Univ. Med. Coll., N.Y., N.Y. 10021.

To define the role of central targets in development of the basal forebrain (bf)-hippocampal system, we grew bf from embryonic day 17 (E-17) rat as dissociated cultures in a fully defined system. Maturation of bf cells grown alone was compared to development in co-cultures with the appropriate hippocampal or the inappropriate cerebellar target. Cholinergic development was monitored using the activity of choline acetyltransferase (CAT), the acetylcholine biosynthetic enzyme.

Control bf cultures grown alone exhibited a significant increase in CAT activity over 10 days in culture, the longest period studied. Addition of the hippocampus elicited a 5-fold increase in CAT activity over the control cultures grown alone, and a 2-fold increase above the bf-cerebellar cultures. The increase in CAT activity was reproduced in co-cultures of bf neurons with hippocampal non-neuronal cells. CAT activity in these cultures was significantly higher than that observed in co-cultures with cerebellar or basal forebrain non-neuronal cells.

Our study suggests that target, hippocampal non-neuronal cells may stimulate development of bf cholinergic neurons. Future studies will be directed to further characterization of target influences. (supported by NS 20788, HD 23315, and the Alzheimer's Disease and Related Disorders Assoc., Inc.)

EVIDENCE THAT THE LOSS OF A RETROGRADELY TRANSPORTED MUSCLE-DERIVED FACTOR INITIATES THE AXON REACTION. B.G. Gold and C. Dark* Neurotoxicology Labs., Rutgers College of Pharmacy, Piscataway, NJ 08854

The mechanism whereby the response of the neuronal perikaryon to axonal injury (axon reaction) is initiated is unknown. Somatofugal axonal atrophy represents one readily quantifiable component of the axon reaction arising from a selective reduction in neurofilament synthesis and delivery to the axon. In the present study, colchicine (5 mM) was unilaterally applied (30-40 min) to the sciatic nerve using soaked cotton balls to determine whether this is a sufficient alteration to produce somatofugal axonal atrophy. This protocol was shown to impair the retrograde axonal transport of wheat germ agglutinin-horseradish peroxidase to dorsal root ganglia (DRG) cells without producing extensive (<1%) axonal degeneration. Rats were perfused with 5% glutaraldehyde at two weeks for quantitative morphometry. A significant ($p<0.05$) reduction in axonal area of dorsal root fibers in the L5 DRG was demonstrated compared with contralateral controls. Neurofilament number was also reduced for axonal perimeter in these atrophic fibers. Preliminary studies indicate that the atrophy is not as marked following application of homogenized muscle to the proximal stump of a transected nerve. These studies suggest that a muscle-derived factor is required for normal neurofilament synthesis.

103.7

NEURON-SUPPORT CELL INTERACTIONS INCREASE DOPAMINERGIC (DA) CELL NUMBER IN THE SUBSTANTIA NIGRA (SN). E.K. O'Malley, C.F. Dreyfus, and I.B. Black. Div. Devel. Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021.

To examine local interactions regulating SN development we have been growing dissociated SN under a variety of conditions. Tyrosine hydroxylase (TH), a dopamine biosynthetic enzyme, was used to monitor SN development.

Initially cells were plated at low (1x), medium (2x), and high (4x) densities in serum-containing media. After 7 days increased density increased TH activity per culture suggesting that high density fosters DA cell development. The number of Neuron Specific Enolase (NSE)-positive cells, a measure of total neuron number, increased linearly with increased cell density. Conversely, the number of TH immunopositive cells rose disproportionately, suggesting a selective effect on the DA subpopulation.

To define specific cellular interactions virtually pure neuron cultures were compared to neuron-support cell cultures in serum-free medium. In pure neuron cultures TH^+ cell number increased proportionally to plating density. In marked contrast, neuron-support cell cultures reproduced the disproportionate rise in TH^+ cell number noted previously. Our observations imply that neuron-neuron interactions specifically increase TH activity per cell, while neuron-support cell interactions selectively increase DA cell number. INJURY-DEPENDENT UPREGULATION OF CHOLINE ACETYLTRANSFERASE IN RAT BASAL FOREBRAIN BY EXOGENOUS NERVE GROWTH FACTOR. L.R. Williams, K.S. Jodelis*, and M.R. Donald. CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

After transection of the rat fimbria/fornix (F/F), treatment with Nerve Growth Factor (NGF) is reported to increase choline acetyltransferase (ChAT) activity in dissections of the "septal area"; dissections that included both right and left forebrain (Hefti et al., 1984). In the present report, accurate microdissections of the right and left forebrain were analyzed separately for ChAT activity 2 weeks following unilateral aspiration of the right F/F and continuous infusion with 2.5s NGF (1.2 μg/day). Although there was a small, 40% stimulation of activity by NGF on the uninjured left side (compared to untreated animals), there was a larger, previously unidentified, 2-fold stimulation of ChAT on the axotomized right side.

ChAT Specific Activity according to Fonnum (1975)
(n) (pmole ACh/μg protein/min, Avg. ± S.D.)

	Left	Right
Untreated (8)	1.9±0.2	1.5±0.2
NGF-treated (8)	2.7±0.2*	3.9±0.3**

These results indicate that neuronal injury triggers a sensitization to exogenous NGF that results in, and is requisite for, the larger stimulation of ChAT activity. Such stimulation may be mediated by an upregulation of NGF receptor.

103.9

PLASTICITY OF NGF RECEPTORS IN THE RAT BASAL FOREBRAIN FOLLOWING AXOTOMY AND EXOGENOUS NGF TREATMENT. H. Yip and L.R. Williams. Department of Anatomy, Univ. Utah, School of Medicine, Salt Lake City, Utah 84132, and CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Exogenous NGF infusion into the rat brain is known to prevent the death of basal forebrain cholinergic neurons after axotomy and to stimulate choline acetyltransferase activity (ChAT), particularly in injured neurons. We tested the hypothesis that such upregulation of ChAT activity was mediated via an upregulation of NGF receptor in basal forebrain neurons. Rat brains were frozen 2 wk after unilateral right fimbria/fornix transection and continuous NGF infusion (2.5s, 1.2 µg/day, Williams et al. 1986). Coronal sections were cut through the basal forebrain and prepared for quantitation of NGF receptor by receptor binding autoradiography using both ^{125}I-NGF and ^{125}I-anti NGF receptor antibody as markers (Yip et al. 1987). A significiant decrease of receptor density (33%) was observed in the forebrain on the side of axotomy in untreated animals. However, in NGF-treated animals, the receptor density was at least equal to that of uninjured neurons, indicating survival of the axotomized neurons by the NGF treatment. In some animals there is a 50% increase in receptor density, indicating an upregulation of NGF receptors. These results suggest that the observed stimulation of basal forebrain ChAT by NGF is mediated by an upregulation of NGF receptor.

NGF-MEDIATED NGF RECEPTOR RE-EXPRESSION AND CHOLINERGIC NEURONAL HYPERTROPHY IN THE DAMAGED ADULT NEOSTRIATUM. F.H. Gage, P. Batchelor,* K.S. Chen,* D. Chin,* S. Deputy,* T. Shaw,* M. Rosenberg, W. Fischer,*[2] and A. Bjorklund[2]. Dept. of Neurosciences, UCSD, La Jolla, CA 92093, USA, and [2]Department of Histology, University of Lund, Lund, Sweden.

Adult cholinergic interneurons of the neostriatum are not immunoreactive for monoclonal antibodies to NGF receptor (courtesy of E. Johnson), whereas the developing neostriatum is immunoreactive to this same antibody. Chronic NGF infusion to the adult neostriatum results in hypertrophy to some of the cholinergic interneurons. NGF infusion and chronic damage to the adult striatum also results in re-expression of the NGF receptor such that many cholinergic interneurons become immunoreactive for NGF receptor. Infusion of anti-NGF, will partially inhibit the re-expression of these NGF receptors. Infusion of the NGF will dramatically increase the size and ChAT-immunoreactivity of these same cholinergic neurons.

These findings distinguish two separate trophic mechanisms in the damaged adult neostriatum. 1) Developmentally expressed NGF receptors are once again re-expressed in response to damage as a result of the release of trophic factors including NGF. 2) Cholinergic interneurons which are upregulated to express NGF receptor immunoreativity, as well as those that do not show NGF receptor immunoreactivity, will show a robust hypertrophy in response to NGF. Additional evidence supports the contention that damage to the striatum results in availability of trophic factors in addition to NGF.

MIXED SUSPENSIONS OF CRYOPRESERVED FETAL MIDBRAIN TISSUE AND C6 GLIOMA: ENHANCED DOPAMINE NEURON VIABILITY IN CULTURE AND NEURAL GRAFTS. T.J. Collier, J.E. Springer, M.F.D. Notter, C.D. Sladek, M.J. Gallagher, B.F. Daley and J.R. Sladek Jr. Departments of Neurobiology and Anatomy and Neurology, University of Rochester School of Medicine, Rochester, N.Y. 14642.

Cryopreservation provides a convenient method for storage, transportation and viability-testing of fetal brain tissue to be used in cultures and neural grafts. However, our experience with cryopreservation of the developing dopamine (DA) neurons of the ventral midbrain indicates that this procedure yields fewer cells than fresh tissue (Brain Res. 436:363, 1987; Soc. Neurosci., 13:784, 1987). In particular, immunocytochemical analysis of cultures for the glial marker GFAP, indicates that a large glial population is lost during cryopreservation. In response to the accumulating evidence for important trophic support provided by glia, we assessed whether the viability of frozen-stored DA neurons could be improved by addition of C6 glioma cells (derived from a rat astrocytoma) to DA neuron cultures and grafts. Cultures stained for the neuronal marker, neuron-specific enolase, and the DA neuron marker tyrosine hydroxylase (TH) indicated that the addition of C6 glioma cells enhanced process outgrowth from TH-positive neurons, and appeared to promote neurite fasciculation. Our initial observations in mixed suspension grafts of cryopreserved fetal rat DA neurons and C6 glioma placed into the denervated striatum of adult rat hosts also suggest improved yield of grafted neurons and enhanced TH fiber staining in the adjacent striatum. However, the findings in vivo are as yet equivocal: it is unclear whether the enhanced fiber staining is related to graft-derived or host-derived neurites. Taken together, these findings support the view that supplementation of glial-derived factors enhance the viability of cultured and grafted cryopreserved DA neurons. TARGET DEPENDENCE OF HYPOGLOSSAL MOTOR NEURONS DURING DEVELOPMENT AND IN MATURITY. S. Thanedar* and W. Snider (spon: C. Hunt). Dept. of Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The extent to which somatic motor neurons in maturity depend on connections with skeletal muscle for survival is controversial. We have reinvestigated this issue using the hypoglossal nucleus of rats as a model system. The peripheral projections of these neurons via the hypoglossal nerve were interrupted, deflected, and prevented from reinnervating their normal target for periods up to one year. We then counted large neurons in the hypoglossal nucleus and myelinated profiles in the cranial nerve XII rootlets.

After transection of the nerve and prevention of reinnervation in early postnatal life, approximately 60% of hypoglossal motor neurons die and surviving neurons are markedly atrophic compared to contralateral controls. In maturity there is also substantial neuronal atrophy and death (approximately 30%) after this procedure, but the majority of neurons survive for periods of up to one year. The adult response is present by three weeks of age. We also investigated the time course of neuronal atrophy and death after permanent target deprivation in adult animals. One month after the hypoglossal nerve was deflected, there was marked axonal atrophy and some degree of cell death, although somatic atrophy was minimal. By three months after the procedure, substantial neuronal atrophy and cell death were apparent. There was little change between three and six months.

We conclude that hypoglossal motor neurons are influenced by connections with their targets in postnatal life. Even in maturity, neurons require target connections for maintenance of somatic and axonal morphology. However, the majority of motor neurons in adult animals can survive target deprivation for prolonged periods.

NGF INDUCED INCREASES IN THE EXPRESSION OF CELL SURFACE GLYCOPROTEINS IN PC12 CELLS ARE DIFFERENTIALLY MODULATED BY INCREASED INTRACELLULAR cAMP. P. Doherty, D.A. Mann* P. Seaton* and F.S. Walsh. Dept Neurochem, Inst Neurology, Queen Square, London WC1N 3BG, England.

Specific antibody reagents have been used to quantitate the relative expression of the NGF-receptor (NGF-R), the neural cell adhesion molecule (N-CAM) and the Thy-1 and L1 antigens for PC12 cells grown in SATO media in the presence of NGF and/or cholera toxin (see Doherty et al, 1987, J Neurochem 49:1676-1687). Whereas NGF treatment induced transcription dependent increases in the cell surface expression of all four glycoproteins, treatment with cholera toxin specifically increased the expression of L1. Over the first few days of culture cholera toxin acted synergistically with NGF in both promoting neuritic outgrowth and an increased synthesis and cell surface accumulation of the 140 and 180Kd subunits of N-CAM. In contrast, over the same time period, cholera toxin fully inhibited the NGF induction of its own receptor, and partially inhibited the induction of both L1 and Thy-1. Over longer periods of culture (3-5d) cholera toxin inhibited the NGF induction of N-CAM and neurite outgrowth. This longer term inhibition may be directly related to the shorter term inhibition of NGF-R expression. A similar pattern of synergistic and inhibitory responses were observed when differentiation was induced by FGF, rather than NGF.

103.14

EFFECT OF TESTOSTERONE IMPLANT ON SURVIVAL OF MOTONEURONS FOLLOWING AXOTOMY IN MALE CASTRATED RATS. W.H.A. Yu. Dept. of Anat. Sci., CUNY Med. Sch., New York, NY. 10031.

It was shown previously that axotomy-induced neuronal loss in motor nuclei of cranial nerves was more severe in females and male castrates than in male rats (Yu, W.H.A., Anat. Rec., 218:152A, 1987). In order to test the hypothesis that androgens promote survival of motoneurons, this study was made whereby neuronal loss in castrated males was compared to castrated males given androgen replacement therapy. Twelve male Sprague-Dawley rats weighing 160-180 g were orchidectomized bilaterally under light ether anesthesia. Eleven days later, these rats were anesthetized with chloral hydrate, subjected to unilateral transection of the hypoglossal and facial nerves, and received either subcutaneous implant of 2 or 4 testosterone-filled Silastic capsules (each measuring 10 mm in length and 2.0 mm in diameter), or no replacement therapy as control (n=4 for each group). Neuronal population in the respective motor nuclei were quantified 12 weeeks after axotomy on serial paraffin sections cut through the extent of the motor nuclei and stained with cresyl violet. Total number of neurons in the motor nucleus of the axotomized side was expressed as a percentage of the contralateral, intact side. Results indicated that the percent neuronal loss in the two replacement therapy groups did not differ from each other nor from that of male castrated control. In view of the previous finding that injection of testosterone to gonad-intact females was effective in attenuating neuronal loss (Yu, W.H.A., Anat. Rec. 219:152A, 1987), it is postulated that gonadal substance(s) facilitated effects of androgens on motoneurons. This possibility is being tested on ovariectomized females receiving testosterone implants.

INSULIN-LIKE GROWTH FACTOR 1 AND INSULIN DECREASE CHOLINE ACETYLTRANSFERASE ACTIVITY AND INCREASE GLUTAMIC ACID DECARBOXYLASE ACTIVITY IN CULTURES OF RAT STRIATAL NEURONS. B.J. Brass* and J.N. Barrett. Dept. of Physiology & Biophysics, Univ. of Miami School of Medicine, Miami, FL 33101.

Neuron-rich cultures were prepared from the striata of embryonic rats (day 15-16). Exposure to insulin-like growth factor 1 (IGF 1) or insulin for 1-3 weeks produced up to a 40% decrease in the activity of choline acetyltransferase (ChAT), the rate-limiting enzyme for acetylcholine synthesis. In the same cultures the hormones produced up to a 40% increase in the activity of glutamic acid decarboxylase (GAD), the rate-limiting enzyme for GABA synthesis. The hormonal effects were dose-dependent; half-maximal reductions of ChAT activity were observed with 1 nM IGF 1 and 22 nM insulin. The magnitude of the hormonally induced reduction of ChAT and its speed of onset increased with cell density. This suggests that the effects of IGF 1 and insulin on cholinergic neurons may be indirect, possibly mediated by secreted molecules or cell-to-cell contact that would be more prevalent in denser cultures. In contrast, the hormonally induced increase in GAD activity was not cell density dependent. IGF 1 and insulin are both present in the brain, and these results suggest that they may play a role in regulating the balance between cholinergic and GABAergic transmitter systems. Supported by NIH grant NS 12207.

103.16

INVOLVEMENT OF NERVE GROWTH FACTOR (NGF) IN GLIOMA-INDUCED ANGIOGENESIS S.E. Kennedy (*), M. S. Fiandaca, J.H. Kordower, M.F.D. Notter, and J.E. Springer (SPON: R. Herndon) Dept. of Neurobiology and Anatomy, University of Rochester Med. Ctr., Rochester, New York 14642.

Neovascularization is a hallmark of many central nervous system (CNS) gliomas. This angiogenic response is critical for the development and growth of the glioma, and has been attributed to the presence of a tumor-derived soluble factor(s). We now report the possible involvement of NGF in glioma-induced angiogenesis, and suggest a mechanism by which this soluble factor may direct the growth of newly formed vessels via specific NGF receptors. C6 gliomas (derived from rat CNS and obtained from the American Type Culture Collection) were injected as a 1 µl suspension (20,000 cells/µl) into the hippocampal formation of the rat. At 2-4 weeks following surgery, animals were perfused, and 30 µm brain sections prepared for NGF receptor (NGFR) immunocytochemistry. C6 gliomas grown as monolayers in culture were also analyzed for the presence of NGFRs. Both cultured and transplanted C6 cells exhibited a wide range of NGFR immunoreactivity (NGFRI) across cells, and may reflect the differential expression of NGFRs at different developmental phases of cell mitosis. Following transplantation, NGFR-positive cells (presumably gliomas) appeared to form tube-like structures, some of which extended into the tumor mass from blood vessels in the surrounding brain parenchyma. Electron microscopic analysis revealed NGFRI in cell membranes closely associated with endothelial cells. A similar pattern of NGFRI was observed in centrally-derived human gliomas. There is evidence to indicate that one of the factors secreted by rat C6 gliomas, and possibly human gliomas, has a biological activity identical to NGF. From these results, it is proposed that glioma-derived NGF may bind to elements associated with migrating endothelial cells as well as NGFRs located on NGF-secreting tumor cells, thus providing a mechanism for directing and maintaining the proliferation of glioma-induced neovascularization. JES is an NRSA postdoctoral fellow. Supported by a grant from the American Federation for Aging Research (JES).

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CIRCUITRY AND PATTERN GENERATION II

104.1

NONSPIKING INTERNEURONS IN THE VENTILATORY CENTRAL PATTERN GENERATOR OF THE SHORE CRAB. R. A. DiCaprio. Dept. of Zoological & Biomedical Sciences, Ohio Univ., Athens, OH 45701.

The central pattern generator controlling ventilation in Crustacea was originally thought to consist of a single nonspiking neuron driving scaphognathite levator and depressor motor neurons (Mendelson, M., Science 171:1170, 1977).

This study describes eight nonspiking interneurons which are elements of the crab ventilatory CPG. The membrane potential of all CPG interneurons oscillated in-phase with the extracellularly recorded ventilatory motor pattern and this oscillation ceased during ventilatory pauses. In all cases, a rhythmic phase-locked modulation of the membrane potential was also present during periods of reversed ventilation. Injection of intracellular current pulses into these interneurons caused a resetting of the ongoing rhythm, indicating that they are a part of the ventilatory central pattern generator. Structurally, all of the interneurons were restricted to a single hemiganglion and perturbation of these cells with intracellular current only effected the motor output of the hemiganglion containing the interneuron.

104.2

PATTERN GENERATING NEURONS SWITCH BETWEEN DIFFERENT NEURAL CIRCUITS. P. Meyrand*, J.M. Weimann*, and E. Marder. Biol. Dept., Brandeis Univ., Waltham, MA 02254.

The crustacean stomatogastric ganglion (STG) produces two different rhythmic outputs, the pyloric rhythm and the gastric rhythm. It has been thought that these two rhythms were generated by two independent groups of neurons, and that weak interactions exist between these two different neural circuits. However, in the crab, Cancer borealis, components of the pyloric and gastric networks can switch among a variety of output patterns. Specifically, three classes of neurons considered part of the gastric network, the Lateral Gastric (LG), Medial Gastric (MG), and Lateral Posterior Gastric (LPG) neurons are sometimes part of the pyloric circuit when the gastric system is inactive. At other times they participate in the gastric rhythm. The Ventricular Dilator (VD) and Inferior Cardiac (IC) neurons of the pyloric network, take on gastric rhythm properties under some conditions. We are currently investigating the mechanisms controlling the switch of these neurons between different motor outputs. These data argue that many neurons of the STG can be used to form part of several, operationally distinct neural circuits, and that the composition of the circuits is defined by modulatory neural inputs to the ganglion. PATTERNS OF SPONTANEOUS ACTIVITY IN CULTURED NETWORKS OF HIPPOCAMPUS AND SEPTAL REGION NEURONS. M.Siebler*, H.Koeller*, C.Schmalenbach*, H.W.Mueller, H.J.Freund, Dept. of Neurology, University of Duesseldorf, FRG

Dissociated cultured neurons from the hippocampus and septal region of embryonic rat (E18) developed neuritic networks under the trophic influence of spatially separated astrocytes. In hippocampal neurons at 3 - 6 days in vitro (DIV) network driven postsynaptic potentials (psp) as well as action potentials (ap) appeared. The interspike intervals varied randomly from ms up to minutes. The impulse rate increased during development and after 8 - 10 DIV some neurons displayed combined firing patterns with two preferred impulse intervals: 20-100 ms and 200 - 400ms, frequently interrupted by long silent periods. Septal neurons or mixed cultures of dissociated hippocampal and septal neurons showed no spontaneous activity prior to 7 DIV and nor did impulses exhibit a preferred frequency between 200 - 400 ms within 20 DIV. Fast impulse rates were associated with regenerative firing during psps while low frequencies could be a phenomenon of inhibition specific for hippocampal neurons. During reversible blockade of spontaneous activity by tetrodotoxin miniature-psps could be registered, suggesting that mpsps are driving force behind spontaneous activity in neuronal networks.

ENHANCEMENT OF RECURRENT EXCITATION OF THE EARTHWORM MEDIAL GIANT FIBER BY SLOWLY CONDUCTING PROJECTIONS WITHIN THE VENTRAL NERVE CORD. J.L. Johnson. Dept. of Physiol. and Pharm., USD School of Medicine, Vermillion, SD 57069.

In the earthworm, head end escape is centrally programmed by the medial giant fiber (MGF). While action potentials are initiated in the MGF by segmental mechanoreceptive inputs, the recurrent excitatory effects exerted upon this giant interneuron remains to be adequately appreciated. The data obtained in this study suggests that the interneuronal tract fibers within the cord that are activated by segmental sensory inputs markedly enhance recurrent excitatory affects exerted upon the MGF. When the slowly conducting intersegmental projections were activated, recurrent excitation of the MGF was enhanced for a time period of 79 ± 3 msec (M ± SEM) after a conduction latency of 16 ± 1 msec (M ± SEM; conduction distance = 10 mm). Thus the ability of sensory inputs to induce MGF discharge may depend, in part, upon the ability of the sensory input to facilitate excitatory recurrent feedback effects exerted upon this command cell. This indicates that, besides initiating MGF discharge, afferent inputs may enhance self-excitation of this giant interneuron through recurrent feedback circuits.

DIFFERENTIAL EFFECTS OF NEUROMODULATORS ON PATTERNED MOTOR ACTIVITY IN THE BUCCAL GANGLIA OF HELISOMA. A.Don. Murphy, J.E. Richmond and K. Lukowiak. Dept. of Biol. Sci., University of Illinois at Chicago, Chicago, Illinois. 60680

We have recently established that buccal motor output in Helisoma is driven by three pattern generating sub-units (S1, S2 and S3) within the buccal ganglia. Previously we have shown that several neurotransmitters can initiate patterned activity in buccal motor neurons based on observations of only one of these subunits, the S2 or cyberchron group. We can now monitor all three subunits whilst recording from only two neurons. Our present aim has been to assess the effects of individual neurotransmitters on the subunits of this central pattern generator (CPG). Our preliminary data suggests that differential patterns result from bath application of various transmitters. Specifically, dopamine at relatively high concentrations ($2x10^{-6}$M) phase locks all three subunits; S1,S2 and S3 in the standard pattern. At a concentration of 10^{-8}M , serotonin phase locks S2 and S3 but S1 activity is variable. GABA most prominently turns on the S2 subunit and causes high rates of activity in S1 follower neurons whereas octopamine can activate S1 in the absence of S2 and S3. These neurotransmitters will be useful tools for manipulating the CPG to produce various motor patterns.

104.6

SLOW-WAVE AMPLITUDE AND PATTERN STABILITY IN GASTRIC MILL CIRCUIT OF LOBSTER STOMATOGASTRIC SYSTEM

Norman Herterich, Dept. of Biology, U.C. San Diego

The lobster gastric CPG produces a coordinated pattern of activity in efferent nerves. CPG cells undergo slow voltage oscillations and communicate via graded release and gap junctions. If they coordinate their activity by entraining each others' activity, one might ask if increasing the amplitude of oscillations in one cell, which could increase its postsynaptic effect, could make that cell more effective in determining the timing of the pattern. Here I report on experiments that alter the amplitude of oscillations in the LG cell (which synapses on all other cells in this CPG) by injecting current intracellularly. Injection is triggerred to the ongoing activity of the LG cell. Those manipulations which increase the oscillation amplitude make the pattern more regular, while manipulations which decrease amplitude destabilize the pattern. These manipulations must be affecting the timing cues which coordinate activity. These results are consistent which the hypothesis that the amplitude of a cells' activity is related to its ability to entrain the activity of other cells.

104.7

ALL NEURONS IN THE PYLORIC PATTERN GENERATOR OF THE LOBSTER ARE CONDITIONAL OSCILLATORS. T.Bal*, F.Nagy and M.Moulins. Lab. Neurobiol. CNRS. 33120 Arcachon, FRANCE.

The regenerative properties of the 14 pyloric neurons in the stomatogastric ganglion (STG) of the lobster, Jasus lalandii, were examined after isolating each neuron from its counterparts in the pyloric network (photoinactivation and pharmacological blockade of presynaptic neurons). Under these conditions, every pyloric neuron manifests voltage-dependent oscillations in membrane potential and rhythmic bursts of spikes. The temporal characteristics of oscillation are different for each type of isolated pyloric neuron. Two groups of these neurons can be recognized: 1) a group of relatively fast oscillators (the interneuron AB and the dilator motor neurons PD, VD), among which AB is the only one whose oscillations are not modified by isolation; 2) a group of slow oscillators (the constrictor motor neurons LP, PY, IC) whose oscillations are rhythmical plateaus with long-lasting and variable period and duration.

When the STG is disconnected from anterior ganglia (axonal conduction blockade of the input nerve), the oscillatory capability of all pyloric neurons is abolished. This capability is durably restored by brief electrical stimulation of the input nerve. In conclusion, the pyloric network is a set of conditional oscillators, requiring the appropriate modulatory inputs to express their rhythmic activity.

PHASE ENTRAINMENT OF A NEURONAL OSCILLATOR IN THE LOBSTER STOMATOGASTRIC GANGLION. T.Kiemel*(SPON: A.J.Tierney), Center for Applied Math, Cornell Univ., Ithaca, NY 14853.

The response of a neuronal oscillator in the stomatogastric ganglion (STG) of the spiny lobster, *Panulirus interruptus*, to periodic hyperpolarizations was studied and the results understood in terms of phase transition curves (PTCs).

With descending inputs from the oesophageal and commissural ganglia intact, 5μM picrotoxin was applied to the STG. Under these conditions, the anterior burster (AB) and two pyloric dilator (PD) neurons of the STG, which are strongly electrically coupled, function as a single neuronal oscillator with one active phase, undergoing synchronous rhythmic bursting (T~1sec) with little or no feedback from other cells in the ganglion. Steps of hyperpolarizing current (3-5nA, 100-600msec) were injected into one PD cell. PTCs and the response of the cell to periodic (T=.5-1.5sec) current injections were obtained.

Three types of responses to periodic current injections were seen in the PD cell: 1) 1:1 phase entrainment in which every hyperpolarization was followed by exactly one PD burst, 2) entrainment at a ratio other than 1:1, and 3) a chaotic response in which the pattern of PD bursts never repeated. The type of response observed varied depending on the duration and frequency of the current injection with the occurrence of 1:1 entrainment increasing as the duration of current pulses increased. Although current injection could produce either a phase advance or a phase delay, it was not possible to achieve 1:1 entrainment of the oscillator at a frequency much faster than its natural frequency. The above results were precictable based on the PTCs measured and the general properties of the PTCs were in turn consistent with the Fitzhugh-Nagumo model for a neuronal oscillator.

Work was supported by a NSF graduate fellowship. Special thanks to Ron Harris-Warrick for the use of lab facilities and for advice along the way.

MODULATION OF TRIGEMINAL MESENCEPHALIC NEURONS DURING FICTIVE MASTICATION. A. Kolta*, J.P. Lund and S. Rossignol. Cent. Res. Sci. Neurol., Univ. de Montréal, Montréal, Canada, H3C 3J7.

In most rhythmic motor systems, there appears to be phasic modulation of transmission in sensory pathways. Work on fictive locomotion indicates that presynaptic mechanisms may be implicated, because phase locked fluctuations of dorsal root potentials and rhythmic antidromic discharges of some afferents have frequently been observed. We have begun to look for similar phenomena in mastication. The experiments were conducted on anesthetized and paralysed rabbits. Cuff electrodes were placed around the XII nerves to monitor fictive mastication evoked by electrical stimulation of the masticatory area of the cerebral cortex. Neurons were recorded from the V mesencephalic nucleus (Vmes.) and V ganglion with glass-coated tungsten microelectrodes. The Vmes. neurons were identified by their brisk responses to stretch of the jaw closing muscles and by pressure on the masseter and temporalis muscles. The majority could be made to fire tonically by fixing the jaw in an open position. Fictive mastication was then induced and changes in firing rate were calculated. The activity of the majority of Vmes neurons was phasically modulated during fictive mastication, but approximately 25% were unaffected. In contrast, skin and hair afferents from the face did not appear to fire antidromically during mastication.

PHASE COUPLING DURING ENTRAINMENT OF FICTIVE LOCOMOTION IN LAMPREY SPINAL CORD. K.A. Sigvardt and T.L. Williams* (SPON: A. Davies). Univ. of California at Davis, VAMC, Martinez, CA 94553 and Physiology Dept., St George's Hospital Medical School, London SW17 0RE, UK.

In the isolated spinal cord/notochord of the lamprey, fictive locomotion can be entrained by rhythmic lateral bending. This is mediated by intraspinal mechanoreceptors (edge cells). We have investigated the phase relations between the movement and the ventral root activity near the point of bending and up to 40 segments more rostral or caudal. We show that if the point of bending is in the caudal half of the cord then the mechanical-neural phase coupling at that point is near the value seen in the intact swimming animal, when the feedback loop is unbroken. If, however, the bending is in the rostral half, the phase relationship is more labile. We have also investigated the effects of length of spinal cord, rostral vs. caudal segments, and rostral vs. caudal bending upon the neural-mechanical coupling, the frequency range of entrainment, and the intersegmental phase coupling in order to test predictions of coupled-oscillator theory.

THE ROLE OF PUTATIVE NEUROTRANSMITTERS OR MODULATORS ON JAW OPENER MOTONEURONAL DISCHARGE DURING CORTICALLY INDUCED RHYTHMIC JAW MOVEMENTS. S.H. Chandler and N. Katakura*. Dept. of Kinesiology and the Brain Research Institute, UCLA, L.A. CA, 90024

Repetitive stimulation of the masticatory area of the cortex induces rhythmical jaw movements (RJMs) in the anesthetized guinea pig. Underlying these RJMs are rhythmical synaptic and spike potentials in both jaw opener and closer motoneurons. At the present time there is no information as to the nature of the neurotransmitters(NT) or modulators(NM) contributing to the rhythmical activity of these cells during RJMs. The purpose of the present study was to elucidate the role(s) of selected putative NTs/NMs in the production of cortically induced RJMs utilizing classical extracellular single unit recording and microiontophoretic techniques.

In ketamine/urethane anesthesized, and paralyzed guinea pigs, repetitive stimulation (30-40Hz) of the masticatory area of the cortex was used to evoke RJMs. Extracellular recordings of digastric motoneurons (DIG MNs) were made through the central barrel of seven-barreled microelectrodes. Responses of neurons during RJMs were challenged with either L-glutamate, N-methyl-D-aspartate (NMDA), D-2-amino-5-phosphonovalerate (APV), kynurenate (KYN), noradrenalin (NA) or 5-Hydroxytryptamine (5HT). Rhythmical field potential and spike activity were monitored by metal microelectrodes inserted into the contralateral DIG MN pool.

The results are summarized as follows: 1) Application of glutamate or NMDA facilitated spike discharge during RJMs whereas application of the specific NMDA antagonist APV or the broad spectrum amino acid antagonist KYN suppressed rhythmical spike activity. KYN was more effective than APV. Application of NA or 5-HT (<20nA) produced a predominate facilitation of DIG MNs discharge during RJMs which lasted up to 10min following termination of the ejection current. The effects of NA and 5-HT antagonists are currently being examined. The results suggest that excitatory amino acids, 5-HT, and NA may be involved in activation and/ or modulation of rhythmical discharge of DIG MNs during RJMs. Supported by NIH grant DE 06193.

GRASP FORCE RESPONSE IN MAN MATCHES THE CHARACTERISTICS OF PULLING LOADS. R.R. Riso, C. Hägar*, R.S. Johansson and G. Westling*. Dept. of Physiology, University of Umeå, S-901 87 Umeå, Sweden.

Subjects were seated with there arm abducted and supported up to wrist. The S's were instructed to use their thumb and index fingers to grasp an instrumented object that consisted of two parallel 30mm dia. disks spaced 25mm apart and connected to a servo controlled puller. Strain gages mounted on the object allowed independent registration of the grip (normal) and load (tangential) forces imposed on the finger tip skin. The studies utilized two different sets of load force stimuli each consisting of up to 34 consecutive "ramp and hold" trials. In one series the rate of rise of the load force was pseudorandomly varied and the amplitude was held constant. In the other series, the rate was held constant but the amplitude of the load force was varied.

Analysis of the grip responses to the ramp pull showed that the latency (typically 80-120ms) was shorter for the trials involving the higher rate load forces, and the rate of development of the grip force was clearly graded from its onset to match the rate of rise of the load force stimulus. The subject's automatically modulated the grasp force in response to the rises and decays of the load force ramps. Changing the direction of application of the tangential load forces showed no qualitative differences in the grip responses. It was concluded that somatosensory information acquired during the initial onset of the stimulus (ca. 50-100ms) was utilized in programming the grip force response. When the fingers were anesthetized, the modulation of the grip force was drastically reduced, implying that the "automatic" regulation of the grip response is dependent on cutaneous input.

Signals in tactile afferent units are now being analyzed using the technique of human microneurography.

NEURAL NETWORK MODEL WITH APPLICATIONS TO PLEUROBRANCHIA. V. Bedian*, F. Zhang*, J.F. Lynch* and M.H. Roberts (SPON: G. Felsten) Depts of Biology, and Math and Computer Science, Clarkson Univ., Potsdam, NY 13676

A computer model of neural networks was formulated to simulate behavior and learning in simple systems. Each neuron has a firing threshold, time constant, absolute and relative refractory periods, and reversal potentials for excitatory and inhibitory inputs. The network is defined by connection strengths between neurons, and neurons and external inputs. Connections have associated delays to represent variable transmission times.

Feedback circuits in the nervous system of the carnivorous gastropod Pleurobranchia produce a typical bursting strike-bite feeding response, and competition between feeding and withdrawal responses. We constructed an 18 neuron model of this system. Simulation results reproduce the bursting strike-bite response to chemo-sensory stimuli, and withdrawal response to tactile stimuli. Mixed stimuli show transition from strike-bite to withdrawal separated by a narrow range of no response. Inhibiting peripheral feedback from the feeding circuit does not abolish the oscillatory behavior between feeding command and central inhibitory neurons. The network model should be useful in simulating behavior in this and other organisms, providing testable predictions, and simulating learning by addition of modification rules for time constants, connections, and/or thresholds.

A CONSTANT-NOISE MECHANISM FOR ENHANCING LEARNING IN NEURAL NETWORKS AND ITS COMPARISON TO SIMULATED ANNEALING. R. M. Burton and G. J. Mpitsos. Mathematics Department, Oregon State Univ., Corvallis, OR 97331, and the Hatfield Marine Science Center, Oregon State Univ., Newport OR 97365.

Variability in neural and behavioral responses can arise from sources that follow some deterministic law such as chaos, and from nondeterministic processes such as random noise. There is evidence for the first type in the sea slug Pleurobranchaea (e.g., Mpitsos et al., In: Dynamic Patterns in Complex Systems, J. A. S. Kelso, A. J. Mandell, & M. F. Shlesinger, eds., World Scientific Pub., Singapore, 1988). Using simulated "temperature" annealing procedures to avoid local minima in searching for optimal solutions, the role of random noise has been shown in computational systems. Biological systems, however, do not necessarily seek optimizations as long as success is achieved using responses arising from local minima, and it is quite unlikely that temperature-dependent annealing occurs in brain function. Using backpropagating networks (Mpitsos et al., these proceedings), we have devised noise-enhancement methods (NE) that are simpler than simulated annealing (SA), do not require control of temperature schedules, and whereas SA requires constants for both the noise level and for the rate of temperature reduction, NE requires only one constant relating to noise level. In one method, learning is a function of a Hebbian rule plus a noise term proportional to the amount of error in the backpropagating algorithm. In behavioral terms the network "anneals" itself by making the constant noise appear smaller when the response is "successful", but larger when the response is less "successful". This noise could arise from random processes or from variability in chaos. SA is as effective as NE during the acquisition of learning to the first of a sequence of different situations. But having learned one task, SA has used up its temperature range, and must be reset by another process that must perform the difficult problem of distinguishing between simple variations in executing the same task and variations relating to the appearance of a new task. In contrast, by requiring no temperature schedules, NE automatically adjusts to all errors and does not have to distinguish between normal variations in doing a particular task or those that appear when a new task has to be learned. NE may occur naturally in brain function during learning, in selection of unlearned responses, and may be useful in generating robotic adaptive responses. Supported by AFOSR-86-0076 to G. J. M. CAN CHAOS PROVIDE READABLE INFORMATION SIGNALS IN NEURAL NETWORKS? G. J. Mpitsos, R. M. Burton, H. C. Creech, and S. O. Soinila. Mark O. Hatfield Marine Science Center, Oregon State University, Newport OR 97365.

Our neurophysiological studies provide evidence showing that patterned neural activity relating to behavior may be generated by dynamical processes attributable to chaos (Mpitsos et al., In: Dynamic Patterns in Complex Systems, J. A. S. Kelso, A. J. Mandell, & M. F. Shlesinger, eds., World Scientific Pub., Singapore, 1988). The inherent unpredictability of chaos, however, could pose difficulties in information transfer in brain function. Because biological systems are not sufficiently controllable, we used a simple connectionist, error-backpropagating network, consisting of 1 input, 1 output, and 4 intermediate units, to determine whether a chaotic signal originating in one part of the network could be identified and transmitted by another part. We used the Rössler attractor, and the 3.60 and 3.95 logistic equations as inputs to train the network, and compared the output of the network to each input. We found that: (1) The network could learn to distinguish different chaotic signals. (2) The parametric values of the outputs were significantly different from the input values, but (3) the circuit accurately transmitted the dynamical qualities of the inputs. (4) Having learned a particular dynamical quality, the circuit could immediately identify other, previously unlearned signals, using the same set of connections and synaptic weights; i.e., the circuit was multifunctional by generalization through dynamical qualities common to different test stimuli. Thus, chaos can provide an appropriate information signal through transmission of dynamical qualities. This is consistent with our findings of variability and chaos in neural and behavioral activity in our experimental animal, the marine mollusc Pleurobranchaea.

HOW SYNAPTIC NOISE MAY AFFECT CROSS CORRELATIONS. G. Midroni and P. Ashby. (SPON: B. Nixon) Playfair Neuroscience Unit, Toronto Western Hospital, Toronto, Ont. M5T 2S8.

Cross-correlations between input and output spike trains of repetitively firing neurons are used to derive the characteristics of the underlying postsynaptic potentials (PSP).

In the present study a computer simulation was used to explore the effects of synaptic noise on the PSP cross-correlation relationship.

We conclude: 1) In the presence of synaptic noise the cross-correlation profile tends toward representing PSP shape directly but will never do so under physiological conditions. 2) There is no reason to view the cross-correlogram as the sum of 2 terms, proportional to the PSP and to it's derivative. 3) Peak area provides the best estimate of PSP amplitude. 4) Synaptic noise decreases peak area and lead to an underestimate of PSP amplitude. The results of this study correlate with experimental findings.

WHY "GRANDMOTHER'S FACE" AND "COMMAND" NEURONS ARE RARE (Answer: the fireworks finale). William H. Calvin, University of Washington, Biology NJ-15, Seattle WA 98195.

Thomas Young's 1802 patterning principle (for trichromaticity) has been called many things by its reinventors: population codes, parallel processing, distributed functions, ensemble coding, and across-fiber pattern. Whether something tastes salty, bitter, acid, or sweet seems to be a matter of irreducible combinations; there are no labeled-line specialists in one taste or another in your tongue. And there need not be any later in the brain.

The most fundamental reason why labeled lines aren't needed in sensory processing is that all actions require a motor program that orchestrates **many** motorneurons. Triggering this ensemble into action need not require a single "command neuron"; it only requires a committee of interneurons active in some characteristic pattern. A **many-to-many transformation** from sensory-to-motor should suffice without the bottleneck of **many-to-one-to-many**. Perhaps only motor programs with the simplest spatiotemporal patterns can get by with the single command neuron approach to orchestration, e.g., Mauthner cells. The appropriate trigger for most motor programs is likely a key-like combination; indeed, it will probably be just as important which cells are inactive as which are active. And unlike a spatial pattern such as key notches, it will be a spatiotemporal pattern like the fireworks finale, the order in which various neurons are activated, as well as which neurons are activated, being the adequate stimulus.

IDENTIFICATION OF FIRING PATTERNS IN MULTIPLE SPIKE TRAINS USING A NEURAL NETWORK EMPLOYING THE BACK-PROPAGATION ERROR CORRECTION LEARNING ALGORITHM. D. C. Tam and D. H. Perkel. Theoretical Neurobiology Facility, Department of Psychobiology, University of California, Irvine, CA 92717 USA.

A parallel-distributed processing (PDP) network using the back-propagating error-correction algorithm is used to compute the temporal correlation of firing patterns among many simultaneously recorded spike trains. The spike trains are analyzed by a multi-layer PDP network with each hidden layer computing the time-shifted pattern of activity between the input and output. The activity of each of the N input neurons is treated as a separate input channel to the PDP network and the activity of each of the M output neurons is treated as the expected output of the PDP network during training. After training, the n-th hidden layer computes the correlation of input patterns with the n time-step shifted output patterns. Once the PDP network is trained to produce the observed set of M output spike trains in response to the N input spike trains, the correlations among neurons at different lag times can be represented by the connection weights among the network units at different hidden layers. These weights may be displayed graphically in a 3-dimensional histogram form, providing an easily interpretable form of the input/output relationship. Simulation results show that the temporal correlation characteristics among different neurons are revealed by this technique.

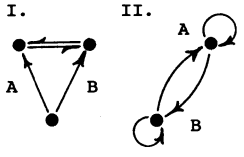
EMERGENCE OF MULTICOMPONENT RHYTHMS, T.K. Leen and G. McCollum, Robert Dow Neurol. Sciences Institute, Portland, OR 97209.

Different rhythmic patterns of biological activity are distinguished primarily by the relative timing of marker events within each pattern (e.g. motor neuron bursts). The relative timing between markers of different interacting components determines a spatio-temporal pattern among the components.

A minimal description of such patterns can reveal the principles of connected components participating in a rhythmic process. Connectivity of the components is linked to the stability of the particular patterns. This link is explored mathematically through coupled circle maps. These maps possess graphical counterparts depicting connectivity (I) and the corresponding flow of timing influence (II). This flow, along with the connection strengths, determines stability of the patterns formed.



The approach illuminates the fundamental relation between component connectivity and the emergence of temporal patterns.

A COMPARISON BETWEEN DIFFERENT NEUROPHYSIOLOGICAL MODELS OF RHYTHMIC MOTOR CONTROL USED TO DRIVE A SIMPLE DAMPED PENDULUM. S. F. Giszter* (SPON: E. Bizzi) Dept. Brain and Cognitive Sciences, M. I. T., Cambridge MA 02139.

Planning and control of movement may be thought to reside in both the central neural and in the peripheral mechanical systems. The neural portion may be thought of as comprising three components of (1) central pattern generator (CPG), (2) reflex corrections, (3) phaselocking properties of the reflexes. What are the roles of these in determining the range of frequencies and amplitudes in which a simple rhythmic movement is successfully generated? To examine this question, models utilizing some or all of these different components were compared when connected to a simple damped pendulum.

It is known that 'chaotic' non-linear behavior can occur in the sinusoidally forced simple damped pendulum. In fact a pure central pattern generator control scheme fails to generate predictable rhythmic behavior in the simple damped pendulum for some parameters and types of forcing functions. I tested the hypothesis that 'reflex' interactions increase the range of controlled cyclic motions of the pendulum which are possible and the parameter regions in which these can be generated, by shaping and phase adjusting the forcing function in response to pendulum behavior.

Simulations show that closing one type of first order feedback loop (which gives a phaselocking response of the forcing function to the pendulum motion) generates a control operating in limit cycles over a wider range than the open loop forcing. For appropriate parameters this phaselocking controller can operate at the frequencies and amplitudes of forcing where chaotic behavior was found in the pure central pattern generator model. A more flexible control is therefore possible using this scheme. However pure CPG control is adequate over a smaller range of values.

This work was supported by NIH grants NS09343 and AR26710.

A GENERAL PURPOSE NEURAL NETWORK SIMULATOR FOR IMPLEMENTING REALISTIC MODELS OF NEURAL CIRCUITS. M.A.Wilson*, U.S.Bhalla*, J.D.Uhley*, J.M.Bower, Division of Biology, Caltech, Pasadena CA 91125 (SPON: P. Monaghan)

Rapid improvements in the speed and power of computers readily available to neurobiologists has made possible the construction of computer simulations of neural networks that are complex enough to provide data relevant to the organization and function of real neural networks (c.f. Wilson and Bower, NIPS, AIP Press 1988). To facilitate the design of such detailed, realistic biologically-based models we have developed a general-purpose network simulator, written in C, running under the Unix operating system. A graphics based front end using the X windowing system allows rapid interactive specification of network circuitry and parameters. The simulator is capable of generating output in the form of spike activity, EEGs, intracellular potentials and field potentials to facilitate the comparison of modeled results to physiological measurements. The simulator currently runs on conventional serial machines but has been designed for use on parallel computers to provide greater computational power. The hierarchical representation of components used by the simulator is designed to be sufficiently general to support simulations ranging from detailed single cell models to large networks of simple or complex cells. Current models developed under this system include mammalian olfactory cortex, invertebrate neural structures, and high end cognitive/connectionist level simulations. A library of simulations performed on the system is being established, and several of these will be presented. (work supported by NSF grant EET-8700064, and the Lockheed corporation)

MODEL OF RHYTHMIC NEURONAL POPULATION OSCILLATIONS IN THE LONGITUDINAL CA3 HIPPOCAMPAL SLICE. R.D. Traub, R. Miles and R.K.S. Wong. IBM Research Div., T.J. Watson Res. Ctr., Yorktown Heights, NY 10598 and Dept. of Neurology, Columbia Univ., New York, NY 10032.

A long-standing question in cortical neurophysiology and EEG concerns how a population of interconnected neurons can generate rhythmical extracellular waves (derived from correlated synaptic currents in the population), even when the correlation is small between the actual firing of any given neuron and the extracellular potential. How do the functional parameters, such as synaptic strengths and cellular excitability, determine the amplitude and frequency of rhythmic activity? We propose a solution to this problem, presented as a 9900-cell computer model, based on our physiological studies of the longitudinal CA3 slice. Critical features of this system are these: (1) excitatory cells generate intrinsic bursts with long hyperpolarizing afterpotentials; (2) excitatory cells are interconnected with each other by a sparse network of powerful excitatory synapses; (3) the outputs of any particular excitatory cell are spatially restricted; (4) both fast and slow IPSPs are activated by local recurrent circuitry. Even with locally random connections, and with a random distribution of firing properties for the individual cells, this model produces rhythmic waves of activity, reflected as periodicity in time in the number of cells firing and in average synaptic currents; but the firing of individual cells appears random. The amplitude and period of population activity are determined, in part, by the strength of inhibition (in a way that agrees with experiment, i.e. less inhibition leads to larger amplitude and lower frequency), by excitatory synaptic strength, and by cellular excitability. Oscillations are coherent over distances long compared with the spatial distribution of synapses from any given neuron. This model provides considerable insight into the rhythmic behaviors available to isolated cortex.

105.1

KINEMATIC ANALYSIS OF SCRATCHING IN CHICKS. M.B. Smith and A. Bekoff. Dept. EPO Biology, University of Colorado, Boulder, CO 80309.

We have previously analyzed EMG recordings obtained during scratching (Smith, M.B. et al, Soc. Neurosci. Abstr. 13: 355, 1987). The current investigation extends the study by characterizing the limb movements that occur during scratching. Kinematic analysis was carried out in 1- to 7-day old chicks. Black dots were placed on the lateral aspect of the right hip, knee, ankle and mid-tarsus. A stimulus was then applied near the right external ear and the resulting behavior was videotaped. Frame-by-frame analysis of the right limb trajectory was accomplished using a computer program to digitize the joint markers.

A typical scratch sequence consists of an initial positioning movement of the limb, followed by several cycles of rhythmic flexion and extension, and then a return to baseline. During the rhythmic flexion and extension cycles, the knee joint motion preceded the ankle. Both knee and ankle joints showed greater excursions than the hip. Supported by NIH grant NS 20310.

105.2

CHARACTERIZATION OF SCRATCHING IN NORMAL CATS. P. Carlson-Kuhta and J. L. Smith. Laboratory of Neuromotor Control, Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Hindlimb scratching at 2-5 cycles/s in the decerebrate cat has asymmetrical flexor and extensor muscle activities, with the flexor phase occupying about 85% of a scratch cycle (Deliagina *et. al., Brain Res.* 100: 297, 1975). This muscle synergy has been used to model the central pattern generator (CPG) for scratching, but studies of kittens (Bradley & Smith, *Dev. Brain Res.* 38: 69, 1988) suggest that the neuromuscular patterns in normal cats may differ from those described for decerebrate cats.

The purpose of this study was to characterize the muscle activity during scratching in normal cats. Fine-wire bipolar electrodes were surgically implanted under anesthesia and aseptic conditions in uniarticular flexor (TA, IP) and extensor (LG, SOL, VL, ABF, GM) hindlimb muscles in three cats. Scratching was elicited by water or a small tapeball placed in the ear canal.

Cats varied their posture greatly during different scratch responses, ranging from lying to standing. The majority of responses had cycle periods between 5 and 7 cycles/s. There were symmetrical flexor and extensor phases. Some muscles varied in activity during different scratch responses. A muscle had either rhythmical bursting, tonic activity, or no activity. These differences may be due to the variations in postures for scratching which change the orientation of the scratching hindlimb with respect to the head.

The differences in cycle period and the flexor-extensor muscle symmetry between decerebrate and normal cats suggests that the decerebrate preparation may not be an appropriate model to study the CPG for scratching. Funded by NIH NS19864.

105.3

KINEMATICS OF BACKWARD AND FORWARD TREADMILL WALKING IN NORMAL CATS. J. A. Buford, J. L. Smith, and R. F. Zernicke. Laboratory of Neuromotor Control, Department of Kinesiology, UCLA, Los Angeles, CA. 90024-1568 (USA).

Grillner (1981) cited backward walking (BWD) to illustrate the facultative nature of a unit burst generator, since BWD purportedly resulted from a 0.5 phase shift between the output of hip and knee extensor units. However, EMG data from bipeds (Thorstensson, 1986; Bekoff, 1987) do not support this mechanism for BWD.

Three cats (Felis domesticus) were filmed for four speeds BWD (0.3-0.6 m/s) and one forward (FWD) (0.6 m/s). As BWD speed increased, stride length increased 24% (27 to 34 cm), and cycle period (650 to 460 ms) as well as stance duration (460 to 300 ms) decreased 44%. At 0.6 m/s, stride length (49 cm) was 44% greater and cycle period (750 ms) was 75% greater for FWD. The cats crouched with spinal ventroflexion during BWD, with hindlimb trajectories limited to a smaller range and shifted rostrally under the center of mass as compared to FWD.

During BWD stance, the knee extended greatly while the hip flexed slightly. But during FWD stance, the hip extended greatly while the knee slightly yielded and then extended. With a slightly greater range during FWD, the ankle moderately yielded and then extended during stance. For both directions, swing began with flexion at all three joints. During BWD swing knee flexion dominated, but during FWD swing hip flexion dominated. During BWD swing, each joint reversed from flexion into extension: first the hip, then the ankle, and finally the knee. But during FWD swing the hip flexed only, and the knee extended before the ankle.

Thus, to explain differences between FWD and BWD, we suggest different functional roles: propulsion from knee extension during BWD *vs.* propulsion from hip extension during FWD. We expect further analyses to show that the BWD movement patterns optimized BWD propulsion and minimized changes needed to produce BWD from the FWD motor program. Preliminary EMG supports this with extensors active during stance and flexors during swing at all three joints. Funded by NIH NS19864.

105.4

IMMUTABILITY OF ANKLE MUSCLE ACTIVITY DURING PAW-SHAKE RESPONSES. G.F. Koshland and J.L. Smith. Dept. of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Our previous studies of kinematic and kinetic analyses of paw-shake responses suggest that ankle muscles are preprogramed without regard to limb dynamics, predicting that ankle muscles are not influenced by motion-dependent feedback. In this study, details of the EMG pattern of ankle muscles (lateral gastrocnemius, LG and tibialis anterior, TA) were examined in 4 chronic spinal cats after motion-dependent feedback was perturbed by casting the ankle (115°) and by wrapping a lead cuff (46 gm) around the paw segment. Under all conditions, responses were elicited by applying tape to the paw, and a total of 225 cycles from 25 responses were analyzed for each condition.

During control responses, cycle period averaged 90 ms with 9 cycles/response, and cycle periods increased linearily over consecutive cycles within individual responses. Burst durations of the LG were short (33 ms) and remained constant over consecutive cycles. In contrast, TA burst durations were longer (59 ms), and onsets and durations of the TA increased over consecutive cycles. During all cycles, a constant period of cocontraction (15 ms) occurred between the TA offset and LG onset of the subsequent cycle. After ankle-casting and paw-weighting, cycle characteristics, as well as the durations and timing of TA and LG muscle activities were unaltered, supporting the prediction that recruitment of ankle muscles is immutable with altered motion-dependent feedback.

In another study of responses after partial deafferentation of the hindlimb (L3-S1), however, the timing and durations of the TA were altered, while LG recruitment did not change. These results suggest that although recruitment of the LG appears fixed, recruitment of the TA may be modulated by temporal proprioceptive information that was available during casting and weighting of the limb, but eliminated after deafferentation. Supported by NS 19864.

105.5

MODULATION OF THE FLEXION REFLEX IN HUMAN LOCOMOTION. J. Duysens, V. Dietz and G.A. Horstmann. Dept. Med. Physics, K.U.N., Geert Grooteplein N. 21, 6525 EZ Nijmegen, The Netherlands and Dept. Clin. Neurology & Neurophysiology, Univ. of Freiburg, Hansastr. 9, D-7800 Freiburg, F.R.G.

The sural nerve of a series of human volunteers was stimulated electrically at two intensities which were 20 and 40% above the flexion reflex threshold respectively. These shocks were given either at 4 fixed points in the step cycle while the subjects walked on a treatmill at 4 km/hr or when they were at rest and imitated the postures at these 4 phases of the qait. The EMG responses were compared with the pain ratings of the subjects.

Ipsilaterally a response with a latency of 70-90 ms appeared in biceps femoris (BF) for stimuli in early and mid stance. For each subject the modulation patterns were identical during real and simulated stepping and for the two stimulus intensity levels. The changes in reflex amplitudes were largely independent of the pain ratings which exhibited little variation throughout the step cycle.

It is concluded that the modulation of the flexion reflex during locomotion reflects a type of gating which has no perceptual equivalent and which depends on limb position information.

WHAT ARE THE RELATIONSHIPS BETWEEN WALKING AND AIRSTEPPING IN CHICKS? R.M. Johnston* and A. Bekoff. Dept. of EPO Biology, University of Colorado, Boulder, CO 80309-0334.

A previous kinematic study showed many differences between walking and airstepping in chicks (Johnston, R.M. and A. Bekoff, *Soc. Neurosci. Abstr.*, 13:356, 1987). To determine if the differences were due to differences in cycle periods we compared kinematic data taken from cycles which fell within the range of overlapping cycle periods. In addition, we compared airstepping to data based only on the swing phase of walking to determine if the previously observed differences result from the presence of stance in walking.

We videotaped walking and airstepping in 1- to 7-day old chicks. Recordings were made when the chick walked on a runway and airstepped while suspended. Hip, knee and ankle joint markers on the lateral aspect of the limb were digitized. A cycle was defined from peak ankle flexion to peak ankle flexion.

Many differences between walking and airstepping remain when data from overlapping cycle periods are compared. However, when airstepping is compared to data based only on the swing phase of walking, several of the differences between the behaviors are decreased or eliminated. That is, duration versus period relationships for flexion and extension at each joint approach those observed for airstepping. In addition, the percent swing flexion and extension at the knee or the ankle in walking do not differ from airstepping. Thus the presence of stance in walking accounts for some of the major differences between walking and airstepping. This supports the idea that airstepping may be generated using a less modulated version of the output of a basic pattern generating circuit for leg movements. Supported by NIH grant 20310.

VISUAL CONTROL OF STEP LENGTH DURING OVERGROUND LOCOMOTION. A.E. Patla, M. Samways, C. Robinson, *C.J. Armstrong*
Neural Control Laboratory, Dept. of Kinesiology, Univ. of Waterloo, Waterloo, Ontario, N2L 3G1,

In this study, we have examined how the step length changes made during overground locomotion to avoid obstacles or provide proper placement of the foot occur, by directly measuring the ground reaction forces and temporal information. Subjects (n=20) were required either to walk or run on a long walkway. Lights placed at distances corresponding to short, normal, and long step were selectively triggered by trigger mats placed before or over the force plate. Subjects were required to place their contralateral foot on the appropriately lighted mat. The results demonstrate that depending on when the cue to alter step length is given, the strategies adopted were different. Overall to modulate step length, subjects increased or decreased the pushoff and/or the braking impulse. In late cue subjects did not alter the impulse, rather they made changes during the free flight phase. During the experiment subjects slowed down: although in the early cue conditions they were able to better maintain the average velocity of progression. In contrast to results of Warren et al. (1986), the results of this study suggests that adapting the locomotor synergy, to accomodate different step lengths, is a complex phenomena requiring more than just changes in the vertical impulse.

FOOT TRAJECTORIES OF DIFFERENT GAIT POPULATIONS: GROSS OR FINE MOTOR CONTROL? B.J. McFadyen and D.A. Winter*, Gait Laboratory, University of Waterloo, Waterloo, Ontario, N2L 3G1.

The swing phase of walking involves a number of degrees of freedom within the linked system of the contralateral support limb, pelvis and ipsilateral swing limb. Yet, during normal walking, the average minimum ground clearance is less than a centimeter (x=.88 cms.) at a point in time when the toe is at its peak horizontal velocity of approximately 4.5 m/s. During continued forward progression, the foot re-establishes gentle contact with the ground by reducing heel velocities to near zero. These end-point trajectories during level gait can only be the result of finely tuned motor control in spite of the involvement of gross musculature and larger limbs.

Different populations from the gait laboratory data base, including normals at different cadences, normals jogging, the elderly (between the ages of 61 and 82) and below-knee amputees, were compared with respect to toe and heel trajectories during level walking. The results showed differences which were dependent upon age, cadence and degree of disability, but all suggested the existence of fine motor control. The lowest toe clearances occurred during natural cadences in normals. The results are discussed with respect to joint kinetics.

TENDON STRETCH IN CAT GAIT ESTIMATED FROM MUSCLE SPINDLE FIRING IN ACTIVE AND PASSIVE MOVEMENTS. A. PROCHAZKA, J. ELEK, M. HULLIGER, S. VINCENT & V. WALDON. Dept. of Physiol. University of Alberta, Edmonton, AB, CANADA.

Tendons undergo large tension variations in normal movement. The resultant stretch must contribute to external muscle length (l_{ext}), but there is debate over how large this effect is. The issue is important, as muscle spindles might "see" length changes very different from l_{ext}. The CNS would be faced with controlling movements of inertial loads through compliant "springs".

In the cat step cycle, E_2 phase, ultrasonic data suggested that while l_{ext} increased, active muscle fibres actually shortened at the expense of tendon (Griffiths & Hoffer, Soc.Neurosci.Abstr.13,1214, 1987). Inexplicably, fibre shortening was also registered at swing onset: increasing l_{ext}, muscle silent. Ultimately spindles themselves best monitor local length change. In anesthetized cats, we recorded the responses of l.gastroc. spindles to step cycle length variations with distributed ventral root stimulation (fusimotor action avoided) modulated to replicate step cycle tensions: 20N peak. Spindle firing in trials without stimulation was then matched to active trials by iterative changes of the length profile. Small differences in active and passive length profiles suggested reduced muscle fibre lengthening in active E_2, and slightly advanced lengthening at swing onset. Thus tendon compliance effects were detectable but modest.

LOCOMOTOR NEUROCONTROL PATTERNS IN SPINAL CORD INJURY SUBJECTS. A. M. Sherwood, M. R. Dimitrijevic, W. J. Eaton* and L. Verhagen Metman*. Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, TX 77030.

Gait is characterized by a high degree of automaticity, integrating many complex tasks in a seemingly effortless fashion. In contrast to fictive locomotion in spinal cat, thus far it has been impossible to elicit stepping in primates with cord transection. Ambulatory spinal cord injury (SCI) subjects with incomplete recovery walk with diminished supraspinal influence and hence with altered neurocontrol patterns. We will present data on the patterns of neurocontrol of ambulation in 16 traumatic SCI subjects, all spastic, all incomplete. A brain motor control assessment (BMCA) protocol was employed to study segmental reflexes and suprasegmental control of single and multi-joint movements in a supine position, and gait. The BMCA employed multiple pairs of surface electrodes over the lower extremities. For gait, footswitches were used to denote foot position. We found that gait patterns were different from those in healthy subjects, were dependent on suprasegmental control, and were idiosyncratic though stable patterns. The residual volitional control was both directly expressed and through influence on segmental reflexes. Features of altered gait will be presented, and their implications for restorative intervention discussed.

KINEMATIC GAIT ANALYSIS IN THE QUANTIFICATION AND ELUCIDATION OF GERIATRIC GAIT DISTURBANCES. R.J. Elble, S. Sienko Thomas* and C. Moody*. Southern Illinois Univ. School of Medicine, Springfield, IL 62794-9230.

Gait kinematics and lower extremity EMG patterns were recorded from five elderly patients (ages 72-87) with symmetrical gait disturbance of central nervous system (CNS) origin ("senile gait"). Two patients exhibited the clinical triad of normal pressure hydrocephalus (NPH), and one fulfilled the clinical criteria of multi-infarct dementia. Both patients with NPH responded to ventriculoperitoneal cerebrospinal fluid (CSF) shunting. The etiology in two patients remained obscure despite exhaustive clinical evaluation. The abnormal kinematic and EMG data of each patient were compared with control data obtained from 14 healthy elders, ages 70-84 (mean 74.4, S.D. 4.7). In general, the kinematic parameters of the five patients were 3 to 10 standard deviations from the mean control values. CSF shunting in the two NPH patients resulted in normalization or near-normalization of most kinematic parameters. However, the gait characteristics of our patients were qualitatively similar, regardless of etiology. Thus, standard kinematic gait analysis is useful for quantifying disability in elderly patients with symmetrical gait disturbances of CNS origin but provides little if any insight into the underlying pathophysiology.

THE EFFECTS OF TREADMILL SPEED ON SPASTIC PARAPARETIC GAIT. M. Visintin* and H.Barbeau. School of Physical and Occupational Therapy, McGill Univ., Montreal, PQ, H3G 1Y5

The aim of this preliminary study is to investigate the effects of speed on the EMG, kinematic and temporal distance parameters of spastic paraparetic gait. Three spinal cord lesioned subjects walked on a treadmill at their relative minimal and maximal speeds (LR:0.1 & 0.3 ms^{-1}; MB:0.2 & 0.6 ms^{-1}; BP:0.2 & 0.6 ms^{-1}). EMG activity of trunk and lower limb muscles were recorded simultaneously with kinematic and temporal distance data. A decrease in % stance (LR:69.4→66.4%; MB:75.5→64.3% & BP:83.5→67.7%) was noted in all subjects at the higher speeds. The kinematic changes seen were an increase in trunk flexion (LR:7°→14° & BP:10°→14°) and total hip angular excursion (LR:22°→34° & MB:36°→43°) throughout the gait cycle. LR and MB demonstrated an increase in knee flexion during initial ground contact (9°→16° & 22°→32° respectively). BP walked with a straighter knee (18°→6°) at foot-floor contact, however a 10° yield was seen during initial loading of the limb. Plantarflexion range during push-off increased for MB (4°→12°) and BP (6°→10°). EMG data on the muscles investigated demonstrated an increase in peak burst amplitude at the higher speeds in the 3 subjects. LR and MB showed an increase in co-activation for Vastus Lateralis (VL) and Medial Hamstrings during the loading phase. BP showed a stretch induced activation in VL following knee flexion at initial loading at 0.6 ms^{-1}. The important changes evidenced in the distal muscles for the three subjects were an increase in duration and amplitude of clonus in Gastrocnemius at the higher speeds. All 3 subjects demonstrated an increase in amplitude of the early stretch activation in Soleus (SOL) following initial foot floor contact. An increase in the burst amplitude was seen in SOL for MB and BP and was related to an increase in plantarflexion at the ankle during push-off. The prolonged duration of activity during stance in the proximal muscles, increase in clonus and early stretch activation seen at the higher speeds support the concept that walking speed is an important factor contributing to the spastic features of paraparetic gait. CONTROL OF LOWER LIMB INTERSEGMENTAL DYNAMICS DURING SPONTANEOUS KICKING IN 3-MONTH-OLD HUMAN INFANTS. K. Schneider*, R. F. Zernicke, B. D. Ulrich*, J. L. Jensen*, and E. Thelen. Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568 and Department of Psychology, Indiana University, Bloomington, IN 47405.

One important component of skill acquisition is the harnessing of joint forces which may be generated not only by muscle actions, but by passive reactions related to movements of the limb segments or by gravity. Here we ask about the control of these intersegmental dynamics in involuntary, cyclic leg movements in young infants (n=3; age=0.21 + 0.02 years) while in a supine position. To calculate joint torque for infants, accurate estimates are needed of the limb's anthropometric parameters, which we determined for upper and lower extremities (n=18; age=0.18-1.5 years) by modifying a 17-segment model of the human body (Hatze, J. Biomech., 13, 1980). Using inverse dynamics (Hoy & Zernicke, J. Biomech., 19, 1986), we calculated the contributions of muscular, interactive, and gravitational torque components to the net joint torque at the hip, knee, and ankle from three-dimensional limb kinematics. The analysis of the intersegmental dynamics of spontaneous supine infant kicking revealed a counterbalancing effect of muscular and passive forces for controlling coordinated movement. For example, the kicking action was initiated at the hip joint by a muscle flexor torque. In the course of the movement a motion-dependent torque related to leg angular acceleration generated knee flexion, which was counteracted by a knee muscle extensor torque. Supported by grant NIH HD22830.

POSTURE-RELATED CHANGES IN LOWER-LIMB INTERSEGMENTAL DYNAMICS IN SPONTANEOUS KICKING IN 3-MONTH-OLD INFANTS. J. L. Jensen*, B. D. Ulrich*, E. Thelen, K. Schneider*, and R. F. Zernicke. Department of Psychology, Indiana University, Bloomington, IN 47405 and Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

A systems-functionalist approach to early skill development (Thelen, Kelso, & Fogel, Devel. Rev., 7, 1987) views coordinated behavior as emerging from the self-organizing properties of the neuromuscular system acting within a task context and the maturational constraints of the organism. Analysis of the intersegmental dynamics of spontaneous supine infant kicking (Schneider, et al., Soc. Neurosci. Abstr., 18, 1968) showed an interplay of active and passive forces to control movement. Here we ask about the task-sensitivity of these self-organizing processes by calculating joint torque components as a function of infant posture. Although lower limb movements in 3-month-olds are spontaneous and involuntary, our analysis revealed that they are sensitive to intersegmental dynamics and self-organize to control forces generated by movement and gravity. In all postures (supine, upright, 45°), at the hip, flexion was initiated by a muscle flexor torque. In the course of the movement the hip muscle flexor torque counterbalanced extensor torques related to gravity and leg and thigh angular acceleration. As the posture became more upright, the torque related to the thigh angular acceleration became more important. At the knee as the body's posture became more upright, gravitational torques became less significant and motion dependent torques became more pronounced. Supported by NIH grant HD22830.

MYOTATIC REFLEXES AND GAIT: RELATIVE ROLES IN EARLY DEVELOPMENT AND SUCCESSFUL AGING. BM Myklebust, GL Gottlieb, MA Tomski, JB Myklebust. Laboratory of Sensory-Motor Performance, Zablocki VA Medical Center & Medical College of Wisconsin, Milwaukee, WI 53295 & Rush Medical College, Chicago, IL 60612.

Our current understanding about normal human gait fails to define an explicit role for the myotatic reflex. The stretch reflex is not evoked in rthythmic locomotion. The implicit role of the monosynatpic reflex in error correction (*i.e.*, stepping over objects and avoidance of trips and falls) may operate in concert with polysynaptic pathways and central pattern generators of the spinal cord.

Studies of myotatic reflexes and gait in early childhood, aging, and neurologic disease have identified the following: [1] Locomotor skills in normal children do not develop until the normal adult-like pattern of reciprocal inhibition is seen in the tendon jerk reflex, and reciprocal excitation is absent. [2] A child, whose stretch reflexes did not disappear until age 4, has a gait pattern which is grossly unimpaired. A second child, whose stretch reflexes were absent from the time of birth, has failed to develop normal rthythmic locomotor skills by the age of 6. [3] Children and adults with hyperexcitable stretch reflexes and/or reciprocal excitation have aberrent gait patterns (*i.e.*, abnormal joint angle and velocity profiles). [4] "Successfully aging" adults (*e.g.*, those individuals who are physically active and who are not known to have neurologic or orthopedic disease) do not have definitive gait abnormalities. Tendon jerk reflex studies evoke a range of responses, from absence of the myotatic reflex, to reflex EMGs like those in normal young adults.

These results suggest that the development of spinal cord connections which allow the normal adult-like myotatic reflex pattern may be a fundamental requirement for the acquisition of normal locomotor skills. The presence of the myotatic reflex may not be a necessary requirement for the persistence of normal gait patterns in childhood and adulthood. Excessive levels of reflexly-evoked agonist and/or antagonist EMG activity may play a contributing role in modulating the patterns of gait with respect to the available joint range of motion, speed of movement, or performance of complex flexion-extension synergies.

THE COMBINED EFFECT OF CLONIDINE AND CYPROHEPTADINE WITH INTERACTIVE LOCOMOTOR TRAINING ON SPASTIC PARAPARETIC GAIT. J.Fung, J.E.Stewart* and H.Barbeau, Sch. of P.& O.T., McGill University, Montreal, Quebec H3C 1Y5

The locomotor pattern of incomplete spinal cord injured (SCI) subjects is often impaired by spasticity as manifested by clonus, hyperactive stretch reflexes and spasms. An integrated drug and locomotor training approach, combining the action of the noradrenergic agonist clonidine and the serotonergic antagonist cyproheptadine with an interactive gait training program, incorporating both progressive body weight support (BWS) and treadmill stimulation, has been proposed. This study examined the effectiveness of such an approach in 2 chronic, wheelchair-bound SCI subjects (SQ: T_{4-7}, SH: C_{7-8}). The experimental design consisted of a double-blind crossover drug trial, followed by the gait training program. Kinematic, temporal distance and EMG data were collected during treadmill locomotion before and after each intervention. Functionally, neither subject was capable of independent ambulation in the placebo period due to spasticity. They required at least 50% BWS and maximal manual assistance to advance the limbs on the treadmill. With medication, SQ could walk unassisted at 20% BWS, and SH at 0% BWS. After locomotor training, both could walk independently at 0% BWS with greater endurance. SQ also achieved a 30% increase in speed. Kinematically, the excessive flexion of the hip (SQ:90°, SH:70°) and knee (SQ:104°, SH:92°) in midswing due to flexor spasms was diminished by medication (hip:(SQ)90°→22°, (SH)70°→17°; knee: (SQ)104°→56°, (SH)92°→52°). A more normal midstance position of the hip (SQ:20°→0°, SH:-10°→-3°) and knee (SQ:20°→0°, SH:4°→0°) were further achieved by training. The EMG activity, initially characterized by clonic discharge and abnormal timing, became phasically more appropriate with less clonus following medication. This improvement was retained with training. Thus, the combined medications modulated the neural output at the spinal level, as reflected by EMG and kinematic changes. The subsequent interactive gait training with progressive BWS further optimized the locomotor pattern. (Supported by MRC, FRSQ, Boehringer-Ingelheim and Merck Frosst)

INFLUENCE OF HEAD TILT ON THE REGULATION OF STANCE AND GAIT. V. Dietz*, A. Horstmann* and W. Berger*. (SPON: F.B. Horak) Dept. of Clinical Neurology and Neurophysiol., Univ. of Freiburg, D7800 Freiburg.

Sudden tilts of the head to the front or rear were induced during stance, balancing, gait and during perturbations of gait. The most prominent repsonse in the leg muscle electromyogram (e.m.g.) to head tilt occurred in the tibialis anterior muscle (latency about 55 ms) following a backwards head tilt induced during balancing. During stance and gait, the e.m.g. activity related to head tilt was only a minor component of the leg muscle activity normally occurring during gait. When the head tilt was induced shortly after a perturbation of gait (treadmill acceleration impulse), the compensatory reaction in the leg muscles did not significantly differ from that seen after the gait perturbation alone. In addition the rate of acceleration of the head was tested against the compensatory e.m.g. responses: No correlation or influence could be discerned.

The results indicate that sudden head tilts and the resulting head acceleration have little influence on the e.m.g. pattern that occurs during gait and perturbations of gait. It is assumed that these patterns are regulated by central programs, and that the compensation for leg perturbation is achieved mainly by spinal reflex mechanisms. It is discussed whether the lack of head tilt responses is the result of an antagonistic vestibular-neck interaction, or whether its indicates a reduced effectiveness of vestibulo- and cervico-spinal reflexes during gait.

VENTRAL MIDBRAIN TRAJECTORY OF FIBERS REQUIRED FOR LOCOMOTION ELICITED BY LATERAL HYPOTHALAMIC STIMULATION IN THE ANESTHETIZED RAT. D. I. Levy* and H. M. Sinnamon. Neuropsych. Lab., Wesleyan University, Middletown, CT 06457.

Unilateral procaine injections (70 sites in 46 rats were tested for their ability to reversibly block stepping elicited by 75-uA pulses (10 to 160 Hz) to the lateral hypothalamus. In Differential blocks, procaine (0.5 ul or less) blocked stepping elicited by ipsilateral but generally not contralateral stimulation. In Nondifferential blocks, locomotion initiated by ipsi and contra stimulation was impaired equally. Procaine into the posterior dorsal tegmentum was ineffective. Differential blocks were characteristic of injections into the anterior ventral tegmentum. Both Differential and Nondifferential blocks were produced by injections into the posterior ventral tegmentum as dorsal as the superior cerebellar peduncle. In the posterior ventral region, both types of sites were widespread and they were intermixed with each other and ineffective sites. Locomotor initiation involves interdependent midbrain tegmental systems that, in some cases, must integrate bilateral information to produce a patterned output.

105.19

EFFECT OF NEMBUTAL ON LOCOMOTION ELICITED BY HYPOTHALAMIC STIMULATION IN UNRESTRAINED VS. RESTRAINED RATS. (SPON: D.B. Adams) B. Sklow* and H.M. Sinnamon. Laboratory of Neuropsychology, Wesleyan Univ., Middletown, CT 06457.

Locomotor stepping elicited by hypothalamic stimulation can be studied in rats anesthetized by Nembutal and restrained in a stereotaxic apparatus. We determined if this method selected against Nembutal-sensitive locomotion by comparing the effects of Nembutal on locomotion of chronically prepared rats tested either awake in a runway or anesthetized in a stereotaxic apparatus. For 27 hypothalamic sites, hourly maintenance anesthetic injections (7 mg/kg) transiently slowed or in some cases blocked locomotion initiation of restrained rats. The depression was less for sites that in the runway had low predrug latencies which were lowered even more by 14 mg/kg. The lowest latencies in the stereotaxic apparatus were similar to predrug latencies in the runway. If head movement was completely restrained by the use of earbars (accompanied by Xylocaine injections), the lowest latencies in the stereotaxic apparatus were actually less than runway latencies. The factors responsible for this facilitation are not yet known. The anesthetized and restrained rat seems to provide a method at least as sensitive as the awake and unrestrained rat.

ANALYSIS OF PREMOVEMENT EMGS OF THE SPINAL FROG DURING WIPE AND FLEXION REFLEXES. J.L.Schotland and W.Z. Rymer. Neuroscience Program and Dept. of Physiology, Northwestern University Medical School, Chicago, Il. 60611.

In the wipe reflex of the spinal frog, information about target location in sensory coordinates is transformed into motor output resulting in a coordinated movement of the multijoint hindlimb to the target location in space. It has been reported that the complexity of this task is reduced by the hindlimb assuming an initial flexion posture common to all target locations (Berkinblitt, et al., 1986). If, as suggested by Easton (1972), spinal circuitry underlying simple reflexes is used during more complex tasks, this common initial flexion posture should utilize the same pathways involved in the flexion reflex.

We investigated these possibilities by recording intramuscular EMGs in the spinal frog during flexion and during wipe to two distinct target locations -- one on the forelimb (FW) and one on the hindlimb (HW). We focused our analysis on the premovement EMGs to reduce feedback related effects. EMGs were sampled at 200 Hz, band-pass filtered, and stored on computer. Normalized EMGs were characterized by 1) peak amplitude and 2) areas for the 100 (Area3), 350-250 (Area2), and 750-650 (Area1) msec prior to movement onset (MVON).

Different EMG patterns were evident for each of the three behaviors. During the flexion reflex, all muscles were activated simultaneously. In contrast, onset times were staggered for different muscles during both forms of the wipe. During FW, tensor fascia latae (TFL) peaked pre-MVON, while all other muscles were still increasing in amplitude. Cruralis, peroneus, and plantaris were usually coactivated, and in any one frog showed a consistent temporal relation to the activity of other muscles.

Many muscles exhibited significantly different magnitudes between behaviors ($P<.006$). The amplitude of TFL was smaller during flexion than FW or HW and smaller during HW than FW. The amplitude of sartorius, which was similar during flexion and FW, was much smaller during HW. Iliofibularis is activated more strongly in flexion and the HW than in the FW. The magnitude of gracilis is much greater in flexion than in the FW or HW, but does not differ significantly between the two forms of wipe.

These results suggest that different neural organizations underly the initial flexion for different target locations, and furthermore that this circuitry may not be uniformly shared with the flexion reflex.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: POSTURE AND MOVEMENT IV

106.1

ENDOGENOUS RELEASE OF 5-HT MODULATES FICTIVE LOCOMOTION IN LAMPREY SPINAL CORD BY ALTERING THE INPUT-OUTPUT RELATION OF INDIVIDUAL NEURONS. P. Wallén*, J. Christenson*, S. Cullheim* and S. Grillner. Depts. of Neurophysiology and Anatomy, Karolinska Institute, S-104 01 Stockholm, Sweden.

The lamprey spinal cord contains serotonergic (5-HT) neurons forming a dense plexus, as well as descending 5-HT fibers. Exogenously applied 5-HT markedly affects fictive locomotion induced in the in vitro spinal cord preparation, - burst duration and intensity increases and burst rate decreases. We have investigated (1) effects of endogenously released 5-HT, (2) a specific effect of 5-HT on the afterhyperpolarization (AHP) in motoneurons and interneurons, and (3) the ultrastructural correlate of the 5-HT action: (1) L-Baclofen (500 μM) in combination with the 5-HT uptake blocker Zimelidine (10-20 μM) induces changes in the fictive locomotor pattern analogous to those evoked by 5-HT application. That this is due to an endogenous release of 5-HT was confirmed using HPLC analysis of the perfusate. (2) Local application of 5-HT selectively reduces the late phase of the AHP caused by Ca^{2+}-dependent K^+-channels, without affecting resting membrane properties or action potential shape. This potentiates the response of the neurons to a given excitatory input, and may explain the effects on the locomotor pattern. (3) A combined immunohistochemical and ultrastructural analysis revealed 5-HT varicosities close to dendrites and cell bodies, but no synaptic specializations, suggesting that the 5-HT systems exert their action by volume transmission.

106.2

EXCITATORY AMINO ACID AND GABA TRANSMISSION TO RETICULOSPINAL NEURONS IN THE LAMPREY. R. Dubuc, Y. Ohta* and S. Grillner. The Nobel Institute for Neurophysiology, Karolinska Institutet, S-104 01 Stockholm, Sweden.

During fictive locomotion, reticulospinal (RS) neurons within the posterior rhombencephalic reticular nucleus (PRRN) show membrane potential fluctuations which depend upon spinal cord inputs (Dubuc, R.and Grillner, S. Acta Physiol.Scand., 1988, 132, 34A). RS neurons receive polysynaptic EPSPs from the ipsilateral spinal cord, IPSPs from the contralateral side, and EPSPs and/or IPSPs from several cranial nerves. This study describes the putative transmitters involved in mediating these responses. In the in vitro brain-spinal cord preparation, kynurenic acid markedly depresses intracellularly recorded EPSPs evoked by microstimulation of spinal cord fasciculi and cranial nerves. NMDA transmission is involved since an AP5-reversible prolongation of the responses occurs in Mg-free ringer. Moreover, RS neurons have NMDA receptors since they are depolarized by NMDA in TTX. Bicuculline markedly depresses inhibitory responses evoked by contralateral spinal cord stimulation. Moreover, an AP5-sensitive inhibitory response is unveiled in Mg-free ringer, suggesting the involvement of NMDA in the initial part of the polysynaptic inhibitory pathway. It is concluded that excitatory amino acids and GABA are important in the transmission of spinal cord and cranial nerve inputs to RS neurons. R.D. receives a fellowship from FRSQ.

106.3

STRYCHNINE-SENSITIVE COMPONENTS OF THE SPINAL MODULES FOR HINDLIMB LOCOMOTION IN THE CAT. D.J. Kriellaars*, P. Fortier, L.M. Jordan. Dept. of Physiology, University of Manitoba, Winnipeg, Canada, R3E 0W3.

The hyperpolarized phase of motoneurnal locomotor drive potentials is due to inhibitory synaptic input as evidenced by the fact that it is blocked by strychnine (Pratt & Jordan, J. Neurophysiol., 57:50-71, 1987) and is reversed by chloride injection (Orsal et al, Exp. Brain Res., 64:217-224, 1986). Quantitative analysis of the phase relationship between the onset and termination of the hyperpolarized phase with the excitation of antagonist motoneurones reveals a strong correlation (Kriellaars et al, Soc. Neurosci. Abstr., 13:875, 1987). These observations have allowed the derivation of a neural circuit responsible for strict alternation between flexor and extensor motoneurones, termed the locomotor reciprocity module. This module is composed of last order excitatory interneurons which projects to agonist motoneurones and interneurons which inhibit antagonist motoneurones and last order antagonist excitatory interneurons. Previous studies indicate that the inhibitory interneurons should be blocked by strychnine which should result in disorganization of locomotor activity. During fictive locomotion in the mescencephalic cat we administered strychnine intravenously and observed overlapping flexor and extensor activity. This observation may represent a strychnine-induced failure of the inhibitory components of the reciprocity module. The failure could conceivably occur at the inhibitory interneurons directly projecting to the motoneurones or at inhibitory interneurons projecting to the antagonist excitatory interneurons.

MAPPING OF LUMBAR CORD POTENTIALS EVOKED BY STIMULATION OF THE MESENCEPHALIC LOCOMOTOR REGION (MLR) IN THE CAT. P. Fortier, D. Kriellaars and L. Jordan. Dept. Physiology, Univ. Manitoba, Winnipeg, CANADA, R3E 0W3.

This study was based on the hypothesis that an examination of the distribution of lumbar cord potentials, evoked by stimulation of the MLR, would permit the localization of the interneurons that have been postulated (Shefchyk & Jordan, J. Neurophysiol. 53:1345, 1985) to be interposed between the volley descending from the brainstem to lumbar motoneurons involved in locomotion. Monopolar potentials were recorded along the 4th to 7th lumbar segments (L4-L7) during stimulation of an MLR-site that could produce fictive stepping in the mesencephalic cat. Potentials recorded over the dorsal surface of the cord typically showed 4 positive waves (P1-P4) which varied in amplitude along the lumbar segments. P1 may reflect the descending volley from the brainstem and P2 could result from the action of this volley on lumbar interneurons with subsequent waves resulting from the chain of events leading to rhythmical locomotor activity. The largest P2 wave was found in the region of L5. Isopotential mapping within this segment revealed steep gradient fields localized, among other regions, in the dorsal part of the ventral horn. This region overlaps the distribution of transneuronally labelled interneurons active during MLR-evoked locomotion (Noga et al., Soc. Neurosci. 13:826, 1987). These results suggest that the interneurons involved in the generation of locomotion may extend along the caudal lumbar segments with an important assembly within L5 since locomotor activity is abolished following transections in this segment (Grillner & Zangger, Exp. Brain Res. 34:241, 1979). Research funded by Canadian MRC.

TAIL-PINCH-INDUCED AKINESIA IN MEDIAN RAPHE'-LESIONED RATS. Rebecca M. Chesire. Psychology Dept., Univ. Hawaii-Manoa, Honolulu, HI 96822.

Electrolytic lesions of the median raphe' nucleus (MRN) of rats produced excessive, rapid relatively straightforward locomotion and loss of lateral head orienting in the absence of a stimulus applied to the head, snout, or encountered during unrestrained locomotion; 1). Undamaged animals showed normal forward locomotion and head orienting. When tail-pinch or a tail clamp was applied (30s-1m), MRN-damaged rats immediately became completely akinetic, stopping in a forward locomotion posture (1, cf.2) until the clamp was removed or the pinch ceased. They then resumed forward locomotion. Undamaged rats ran forward, but within 20s oriented toward the tail, often twisting their forequarters arear toward the spine and over the opposite hindquarter. They kicked using the rearquarters, boxed and scratched using the forepaws, bit the clamp or the tail and vocalized.

Tail-pinch can inhibit the excessive release of forward locomotion produced by MRN damage. Thus, the arousing effects of tail-pinch are not limited to those that release behaviors inhibited by damage (3,4). Such arousal might serve to release any of several excitatory or inhibitory behaviors that reduce or are incompatible with the predominant symptom produced by the particular form of neurological damage.

ACTIVITY OF MIDLUMBAR GROUP II INTERNEURONS DURING BRAINSTEM EVOKED FICTIVE LOCOMOTION IN THE MESENCEPHALIC CAT. S. Shefchyk, D. McCrea, D. Kriellaars, L. Jordan, and P. Fortier. Depts. Med. & Physiol., U. Manitoba, Winnipeg, CANADA R3E 0W3.

Edgley and Jankowska (J. Physiol. 389:647, 1987) have described a population of interneurons (INs) in the midlumbar segments which receive group II afferent input and project monosynaptically to lower lumbar motoneurons. This study describes the activity of a subpopulation of these midlumbar group II neurons which are rhythmically active during fictive locomotion produced by electrical stimulation of the MLR (details in Shefchyk & Jordan, J. Neurophysiol. 53:1345, 1985). Midlumbar interneurons were examined using extra- or intracellular recordings and identified according to criteria described by Edgley and Jankowska (1987) which included their projection to caudal motonuclei. All rhythmically active INs examined to date displayed activity coincident with activity in ipsilateral tibialis anterior (flexor) muscle nerve or, in the case where the tibialis anterior neurogram was not available, out of phase with ipsilateral extensor neural activity. Experiments are in progress to determine the synaptic actions of rhythmically active group II neurons on motoneurons using the sucrose gap technique as well as confirming our initial observations that these cells are primarily active during the flexion phase of the fictive step cycle. This information will be important for an understanding of the contributions of the L4 group II INs to the pattern of activity of motoneurons during fictive stepping. Supported by the Canadian Paraplegia Association and the Medical Research Council of Canada.

LOCOMOTION ON AN INCLINED PLANE BEFORE AND AFTER SPINALISATION IN THE SAME CAT. M. Bélanger, T. Drew, J. Provencher* and S. Rossignol. Cent. Rech. Sci. Neuro., Univ. de Montréal, Qué, Canada.

This study compares the adaptation of the hindlimb walking pattern (EMG and Kinematics) to inclined planes (15deg uphill, 10deg downhill, 20deg roll) before and after spinalisation in a chronically prepared cat. Before spinalisation, walking uphill or downhill induced predictable changes in step length and EMG activity. The leg length changed appropriately to maintain the body close to the horizontal plane. After spinalisation, minor modifications were observed in the EMG activity during walking uphill or downhill as compared to level. The step length was increased for uphill walking. The leg length, on the other hand, did not change to compensate for the slopes. It should be mentioned, however, that here the cat walked with the forelimbs on a board so that the whole body was parallel to the treadmill. Before spinalisation, walking with the treadmill rolled to one side produced a restructuration of the walking cycle on both sides. After spinalisation, such changes were also seen when the cat was manually held vertically. Unaided, the cat could adapt only to a few degrees of roll. Thus, the spinal cat can partly adapt the locomotion of its hindlimbs provided the rest of the body is stabilized to compensate for the loss of vestibular function. (supported by MRC and NSCERC).

106.8

MODULATION OF EVOKED DORSAL ROOT POTENTIALS BY CUTANEOUS AND MUSCULAR STIMULATION DURING FICTIVE LOCOMOTION IN THE CAT. J.P. Gossard and S. Rossignol, Ctr. Rech. Sci. Neuro., Univ. de Montréal, Qué, Canada.

Previous studies on fictive locomotion in decorticated curarised cats have shown that the dorsal roots, at the lumbo-sacral cord level, are depolarised twice per locomotor cycle (Locomotor DRPs). The largest depolarisation occurs during flexor activity and terminates at the onset of extensor activity. To examine the possible functional role of these spontaneous locomotor DRPs, other DRPs or reflex responses were evoked by stimulating muscle nerves (flexor and extensor) or cutaneous nerves through cuff electrodes. For all nerves stimulated, the evoked DRPs were strongly modulated throughout the locomotor cycle, being maximally depressed during the flexor phase and enhanced during the extensor phase. The exact timing and depth of this modulation could vary depending on the rootlet recorded and the nerve stimulated. Moreover, the modulation of short latency excitatory responses evoked in Sartorius nerve by cutaneous stimulation paralleled the modulation of the evoked DRPs during flexion. These results suggest that, during locomotion, there is a centrally generated phasic modulation of the transmission in pathways involved in primary afferent depolarisation, as well as in other reflex pathways, and that the locomotor DRPs may partly reflect the underlying mechanisms. (Supported by the MRC)

106.9

INFLUENCE OF PROPRIOCEPTIVE INPUTS ON FICTIVE LOCOMOTION OF THE FORELIMB OF THE CAT. P.Saltiel and S. Rossignol. Cent. Rech. Sci. Neuro.,Univ. de Montréal, Qué, Canada.

This a study on the effects of manually imposed protractions or retractions of the shoulder on the fictive locomotor rhythm. Cats were decorticated, curarized and spinalised at T13. Locomotion was recorded with cuff electrodes placed on the nerves to the extensor, triceps (Tri), and the flexor, cleidobrachialis (ClB), on both sides (ipsi= i; contra= co). The elbow joint was fixed and the shoulder angle was monitored with a potentiometer. Sustained retractions had little effect on the overall locomotor frequency. However, the iTri and coClB bursts were shortened and decreased in amplitude while the coTri and iClB bursts were lengthened and increased in amplitude. Correspondingly, brief retractions applied during iTri reduced the burst duration and amplitude and shortened the corresponding contralateral silence. Brief retractions in the opposite phase prolonged the silence between iTri bursts and increased the duration and amplitude of the coTri burst. Protractions, brief or sustained, essentially had the opposite effect of retractions except for a variable change in the amplitude of the coTri burst. Thus proprioceptive inputs markedly influence the fictive locomotor pattern and may be expected to contribute significantly to the adaptation of real locomotion. (Supported by the MRC).

106.10

SEGMENTAL AND SUPRASEGMENTAL EFFECTS ON THE LOCOMOTOR RHYTHM IN INTACT CATS. T. Drew and S. Rossignol. Université de Montréal, Montréal, Québec, CANADA

To determine how different inputs may interact with the normal locomotor rhythm, trains of stimuli (300Hz, 200ms duration, 0.2ms pulse duration, 2-3XT for eliciting a muscle response) were applied either to the motor cortex (MC), the medullary reticular formation (MRF), or to the superficial radial nerve (SRn) of chronically implanted, intact cats walking on a treadmill.

Stimulation of all three pathways during the swing phase of locomotion caused large changes in limb trajectory and EMG activity. While stimulation of the MC and the MRF affected mainly the activity of flexor muscles, stimulation of the SRn evoked a complex pattern of activity in both flexor and extensor muscles.

During stance, stimulation of the MC frequently curtailed extensor activity and reinitiated the swing phase, while stimulation of the MRF more often prolonged the stance period. Phase changes from stimulation of the SRn in stance were infrequently seen but, when present, were similar to those evoked by MC stimulation.

These results show that different pathways may affect locomotion similarly in one phase but differently in another, suggesting that each pathway may interact very specifically with the locomotor generating networks. (Supported by the FRSQ and the Canadian MRC)

106.11

SELECTIVE RECOVERY OF DIFFERENT TYPES OF LOCOMOTION IN DEAFFERENTED CAT HINDLIMB. M. E. Goldberger and K.L. Ziegler.* Medical College of Pennsylvania, Phila, PA 19129.

Previous studies suggested that, after hindlimb deafferentation, some spinal pathways were more important than others for recovery of locomotor functions. In the present study,cats were trained preoperatively 1) to walk on a 30.5 cm-wide runway (conditioned unrestricted overground locomotion) 2) to walk on a 5 cm-wide runway (accurate locomotion) 3) to walk on a treadmill (reflex quadrupedal locomotion) 4) to stand on a platform with forelimbs while hindlimbs walked on a treadmill (reflex bi-pedal locomotion). Unilateral hindlimb deafferentation (L1-S2 dorsal rhizotomy/ganglionectomy) impairs all types of locomotion but to different extents. Recovery of unrestricted conditioned overground locomotion is rapid but recovery of accurate locomotion is delayed. Quadrupedal locomotion is also delayed and does not recover to the extent of overground locomotion. Bipedal locomotion does not recover; the control limb hops on the treadmill with little movement of the deafferented limb. This order of recovery is specific for deafferentation and is not seen after hemisection or partial deafferentation. Since, after deafferentation, descending systems are essential for overground but not reflex locomotion, (Goldberger, 88) the results suggest a differential or hierarchical access to spinal circuitry for locomotion by descending supraspinal (conditioned overground locomotion), propriospinal (quadrupedal locomotion) and crossed segmental (bipedal locomotion) systems that is established or released soon after deafferentation.

HIP FLEXION IN HEMIPLEGIC GAIT IMPROVED BY FUNCTIONAL ELECTRICAL STIMULATION (FES) VIA IMPLANTED ELECTRODES J.Elek, M.G.A. Llewellyn, A.Prochazka, L.A.Davis, B.Dolphin and V.Waldon. (SPON: A. French) Dept. of Physiol., University of Alberta, Edmonton, Alta, CANADA.

Hip movements are often severely reduced in hemiplegia, and orthoses for this do not exist. We are assessing FES of hip flexor and abductor muscles as a possible solution. After pilot studies with surface stimulation, we implanted a percutaneous wire electrode into psoas muscle in a stroke patient (18 months post-CVA). The specialized coiled wire, with a nylon retaining barb, was inserted transcutaneously. Judging by muscle responses to stimulation, the wire has stayed in place in the muscle for 6 months without complications.

Goniometry and electromyography (EMG) were used to assess gait and optimize the FES control signals. Without stimulation, psoas EMG was deeply modulated, but delayed by about 500 ms on foot-off. FES of psoas, modulated by a signal from a force transducer under the sound foot, produced earlier, faster swing and increased walking speed. It did not elicit useful knee flexion reflexly as we had hoped. Knee control was improved by physiotherapy and on one occasion by FES of biceps femoris short head. We are optimistic that FES of proximal muscles will improve gait usefully in a small proportion of ambulatory stroke patients, but it is important that criteria for patient selection be adequately developed.

CHANGES IN MEMBRANE PROPERTIES OF CAT ANKLE EXTENSOR MOTONEURONS AFTER CHRONIC SPINALIZATION. S. Hochman* & D McCrea Dept Physiology, U. of Manitoba, Winnipeg CANADA, R3E 0W3.

The present study compares the electrical properties of medial (MG) & lateral gastrocnemius (LG), soleus (SOL) and plantaris (PL) motoneurons between unlesioned and chronic spinal barbiturate anesthetised cats (6 weeks, L1-L2 lesion). Only cells with action potentials greater than 80 mV were accepted. In the first analysis, data from all 4 motoneuron species were pooled. Amongst other changes, there was a 16% decrease in mean input resistance (Rin) and a 17% increase in rheobase current after chronic transection ($p > .025$). Although mean calculated rheobase voltages (Rin * rheobase current) were similar in the two preparations, measured rheobase voltage increased about 14% in the chronic spinal preparation ($p > .025$). However, the most notable change was a 20% decrease in membrane time constant ($p > .001$) without any corresponding change in equivalent cylinder electrotonic length.

These changes following spinalization were not uniform across the four motoneuron species examined. For example, the percentage decrease in Rin was greatest in LG (LG > PL > MG > SOL) whereas rheobase current increased the most in PL (PL > MG > LG > SOL). This illustrates that membrane properties of even close synergist motoneuron species may be affected differently by chronic cordotomy. Generally, no membrane property changes were found in chronic spinal animals that would promote a hyperreflexive state. This is in agreement with previous findings for SOL (Cope et al. J. Neurophysiol. 55:1202-1220, 1986) and MG motoneurons (Munson et al. J. Neurophysiol. 55:619-634, 1986). Supported by the MRC of Canada and the Manitoba Health Research Council.

CHANGES IN MUSCLE MECHANICAL PROPERTIES IN SPASTIC HEMIPARESIS. R.F. Kirsch and W.Z. Rymer Northwestern University Medical School and Rehab. Instit. of Chicago, Chicago, IL 60611.

Spastic hemiparesis due to stroke or head trauma is often accompanied by changes in muscle tissue, with normal contractile tissue being replaced by collagen-based tissue. In extreme cases, this tissue limits the range of motion of the joint. We have begun to compare the mechanical (compliance) properties of the elbow joints of spastic-paretic subjects to normal joints in an effort to determine the extent of this fibrosis when no loss of range of motion is present.

A torque motor was used to apply controlled angular perturbations to the elbow joint. Joint angle and joint torque were sampled by a computer during a perturbation using appropriate sensors, amplification, and filtering. The elbow joint was set to a mid-flexion (90°) position and a small (±1°), bandlimited random perturbation was applied while the subject maintained some degree of background flexion torque either voluntarily or augmented with primitive reflexes released in spastic hemiparesis. As large a range of torque levels as possible was collected from each elbow joint. The dynamic relationship between the torque and angle records was quantified by estimating the compliance impulse response (CIR) of the joint via a correlation-based identification algorithm. The form of the CIRs was quite similar to that of a second order mass (I)- spring (K)- damper (B) mechanical system, so a model of this form was fitted to the CIRs. The I parameter is not of interest since it reflects only the mass of the forearm. Thus, the K and B parameters succinctly summarize the mechanical state of the muscles of the joint.

Three hemiparetic spastic subjects with no loss of range of motion have been examined to date. In all three cases, the elastic stiffness K of the spastic elbow joint was significantly elevated above that of both the unaffected contralateral elbow joint and that of normal subjects, while the viscous stiffness B was essentially unchanged. It is unlikely that the increase in K is due to hyperactive stretch reflexes or co-contraction since these mechanisms would be expected to effect K and B in parallel. These results suggest significant, early, and hitherto unrecognized changes in muscle properties in spastic hemiparesis that may call for early therapeutic intervention.

MOVEMENTS AND MUSCLE ACTIVATIONS DURING TRUNK FORWARD BENDING AND EXTENDING IN LOW BACK PAIN PATIENTS. N. Paquet*, F. Malouin, C.L. Richards, Lab. of Neurobiology and Dept. of Physiotherapy, Fac. of Med., Laval University, Québec, Canada.

We studied the relative contribution of dorso-lumbar (D-L) spine and hip movements (MVTS) and muscle activation patterns of trunk and leg muscles during sagittal trunk MVTS. D-L spine (T8-S1) and hip MVTS were measured with 2 electrogoniometers while surface EMG was recorded bilaterally from the external oblique (EO), erector spinae (ES) and hamstrings (H) in 6 low back pain (LBP) male patients and 4 normal men. In normals, the contribution of the D-L spine was greater in the first 2/3 of forward bending (FB) of the trunk while hip MVTS predominated at the end of the MVT. During EX of the trunk, the mirror image occurred with hip MVTS predominating at the beginning of the MVTS. Preliminary results indicate that 3 LBP patients displayed abnormal trunk FB MVT patterns, whereas abnormal EX MVT patterns were observed in only one patient who already had an abnormal FB MVT pattern. The activation of ES muscles in these 3 patients was maintained throughout the FB MVTS, while in the normals a relaxation of ES occurred before completion of trunk FB. This lack of ES relaxation was associated with a delayed H activation in the early phase of the trunk EX MVT. These abnormal muscle activation patterns, however, were also seen when MVT patterns were not markedly disturbed and this especially for trunk EX MVTS. These results suggest that disturbances in activations of ES and H muscles are usually associated with abnormal MVT patterns during FB and that EX MVT patterns may remain normal despite abnormal activation patterns in these two muscles. This work was supported by IRSST.

POTENTIAL MECHANISMS UNDERLYING THE VOLUNTARY SUPRESSION OF INVOLUNTARY MOVEMENTS IN TARDIVE DYSKINESIA M.P. Caligiuri and J.B. Lohr VA Medical Center, San Diego, CA 92161

It is often observed that patients with neuroleptic-induced tardive dyskinesia (TD) supress involuntary choreo-athetoid movements during voluntary actions involving the affected region. The goal of the present study was to evaluate voluntary control over two muscle variables: force and length. Patients with TD and normal controls were studied in order to gain insight into potential mechanisms which contribute to the supression of involuntary dyskinesia. Two tasks were employed to assess the ability to control steady-state force (isometric condition) and position (isotonic condition). It was hypothesized that patients with marked TD would perform better on the isotonic task than the isometric task on the basis that fusimotor reflex pathways may be utilized to gain control over disruptions in position. Because TD is primarily an orofacial phenomenon, all tasks involved jaw control. Strain gauge force and position transducers were used to record isometric and isotonic stability, respectively. Analyses were made of the magnitude of instability over multiple 2-second intervals. The standard deviation of the steady-state force or position array served as the index of instability. Results indicated that TD patients exhibited significantly greater instability on the isometric condition relative to the isotonic condition in comparison with normal controls. The findings support the hypothesis that TD patients utilize afferent information about muscle length and/or joint position during voluntary action to supress involuntary movements. These results suggest further that TD patients exhibit difficulty on the isometric task because the length servomechanism is disabled during isometric activity.

A CASE STUDY OF MOTOR OVERFLOW FOLLOWING RIGHT HEMISPHERE CVA. E. Roy, J.L. Starkes and J. Charlton* (SPON: C. Riach). Dept of Kinesiology, Univ. of Waterloo, Waterloo, Ontario N2L 3G1.

Motor overflow was examined in the contralesional left hand of a 62 year old, right-handed female, following right hemisphere CVA affecting posterior frontal and anterior-superior parietal areas. Force generation and tapping tasks were performed by the ipsilesional index finger and motor overflow recorded in the contralesional index finger. Force transducers recorded distance moved and simultaneous forces generated in both hands. In a series of force conditions, the subject generated maximum flexion force for 10 sec as well as forces at 25, 50, and 75% maximum. In a similar series of tapping conditions maximum speed tapping was performed for 10 sec, followed by 25, 50, and 75% maximum. The dependent measure for force trials was relative force generated by each hand. For tapping trials cycle time, flexion vs. extension time and forces were determined. The results indicated that even under direction to relax the contralesional hand, motor overflow was present when force was generated by the opposite hand. Degree of overflow was not related to target force. For tapping, a tonic as well as phasic (synchronous) component was seen in overflow. Fast Fourier transform analyses revealed that the exact frequencies of tapping by the ipsilesional hand were embedded within the overflow response by the contralesional hand. No such overflow was found in an age and gender-matched control subject.

LONG-LOOP RESPONSES IN PATIENTS ON CHRONIC NEUROLEPTIC MEDICATIONS. D.J. Beckley*, M.P. Remler, and J. Singh*. Lab of Neurophysiology. Dept. of Neurology-VAMC; Martinez, CA 94553.

Recent studies have demonstrated increased middle latency responses in the stretched gastrocnemius muscles in patients with Parkinson's disease. Primates rendered toxic on phenothiazine medication have also exhibited enlarged middle latency responses. The purpose of our study was to determine if patients on chronic neuroleptic medication, without clinical evidence of parkinsonism, could be shown to have abnormal long-loop responses. EMG recordings were obtained from 3 muscles in the right leg from 10 male patients on chronic moderate dosage phenothiazine therapy and from 10 age-matched male normal controls. Stimuli consisted of 15 trials of sudden toe-up ramp movements supplied by a moveable forceplate platform. The phenothiazine patients showed no increase in size of the middle latency response when compared to normal controls. We concluded that, in the absence of clinical signs of parkinsonism and at the usual therapeutic dosages, patients on phenothiazines cannot be differentiated from normals on the basis of the size of their middle latency responses.

106.19

CEREBRAL GLUCOSE UTILIZATION AND IMMUNOHISTOCHEMICAL EVALUATION OF IDPN-INDUCED CERVICAL DYSTONIA IN THE RAT. S. Caldecott-Hazard, J.S. Schneider, K. Thompson and S. Stopes. UCLA School of Medicine, Los Angeles, CA 90024.

Injections of 3-3-iminodipropionitrile (IDPN) into rats produce a permanent dystonic syndrome consisting of cervical dystonia, locomotor hyperactivity, and occasional choreothetoid head movements. Additional information about this syndrome was obtained by studying cerebral glucose metabolism and immunohistochemical profiles in these rats. Sprague Dawley rats were injected with 150 mg/kg of IDPN daily for 7-10 days or with saline. The frequency of dystonic head movements was quantified. Only animals in which neck dystonia was the most prominent feature of the syndrome were studied. IDPN and saline-treated rats were given 14C-2-deoxyglucose (2DG) (20 uCi/100 g, IV). Resultant autoradiograms revealed reduced glucose utilization in the medial caudate nucleus and locus coeruleus as compared to controls. However, immunohistochemical studies to date have not demonstrated any significant loss of dopaminergic substantia nigra neurons, serotonergic (5-HT) dorsal raphe neurons, or noradrenergic locus coeruleus (LC) neurons. Other putative transmitter and peptide systems are being assessed. While several lines of evidence may point to involvement of the LC and/or 5-HT system in dystonia, the present data suggests that at least in this dystonia model, the primary defect does not involve loss of these neurons. ABNORMAL rCBF RESPONSE TO VIBROTACTILE STIMULATION IN DYSTONICS. L.W. Tempel* and J.S. Perlmutter, Washington Univ. Sch. Med., St. Louis, MO 63110

The purpose of this study was to determine if patients with dystonia have an abnormal response to sensory stimulation. We studied 11 patients with predominantly unilateral dystonia and 13 normals. PET and $H_2{}^{15}O$ were used to measure rCBF at rest and during vibrotactile stimulation of one or both hands. The stimulation produced a consistent increase in rCBF in somatosensory cortex contralateral to hand stimulation in normal subjects (L brain response = 9.6 $\pm$ 2.3; R brain response = 12.0 $\pm$ 2.9 ml/(min $\cdot$ 100g)). In contrast, the comparable rCBF responses to vibration of the affected or unaffected hands in dystonic patients were significantly reduced (7.9 $\pm$ 2.0, $p<.05$; 8.4 $\pm$ 2.3, $p<.002$ respectively). Vibration induced a dystonic hand cramp in 6 patients, but not in any normals. To determine if co-contraction could attenuate the rCBF response, 5 of the normals were studied with vibration and voluntary hand co-contraction, as well as vibration alone. Vibration with voluntary co-contraction produced a greater response than vibration alone ($p<.05$). This differed from the diminished response seen in dystonics with vibration-induced co-contraction. These data suggest that patients with predominantly unilateral dystonia have an abnormal response to vibrotactile stimuli of either hand.

106.21

NEUROPEPTIDE-INDUCED POSTURAL DESTABILIZATION: A POTENTIAL STATE VARIABLE FOR RATE OF ONSET OF BARREL ROTATION. C. D. Balaban*, V.P. Starcevic* and W. B. Severs. Depts. of Anat., Surg. and Pharm., Penn State U., Hershey, PA 17033

Intracerebroventricular (i.c.v.) somatostatin (SRIF) and arg-vasopressin (AVP) can elicit barrel rotation (BR), convulsions and lethal pulmonary edema [Brain Res., 365 (1986) 21-41; 445 (1988) 117-129)]. This report summarizes BR latency data from 16 groups of rats given either i.c.v. SRIF or AVP alone or SRIF with either AVP or the AVP antagonist, Peninula Labs #8109 (mcAVP). Hazard plots of BR latencies were used to estimate the instantaneous rates of BR onset from a 2 parameter exponential model. ANOVA/Scheffe analysis of values of the hazard parameter (θ^{-1}) revealed four discrete states of risk of BR onset across 16 conditions ($p<0.05$): State 4 θ^{-1} (range, %/sec)=2.4-4.47; State 3 θ^{-1}=0.88-1.1; State 2 θ^{-1}=0.46-0.62; State 1 θ^{-1}=0.05-0.14; State 0 no BR. There are distinct patterns of state shifts after injections of SRIF versus AVP. Whereas i.c.v. SRIF (20 or 40 μg) pro-duced serial state transitions from 0 to 2 or 3 to 1 to 0, AVP (0.5 μg) in sensitized rats produced a transition series of 0 to 4 to 2 to 0. Combined doses of SRIF and either AVP or mcAVP produced transitions from 0 to 2-4 to 1 to 0. Thus, endogenous neuropeptides may affect discrete states of postural stability. As BR is not prevented by labyrinthectomy, it may serve as an animal model for central vestibular dysfunction. (RCDA NS00891 [C.D.B.] & Fogarty TW03743 [V.P.S.]).

106.22

EFFECTS OF ARGININE-VASOPRESSIN (AVP) ON SOMATOSTATIN (SRIF)-INDUCED BARREL ROTATION (BR) AND CONVULSIONS IN RATS. V. Starcevic, C.D. Balaban and W.B. Severs. (SPON: J.D. Connor). Depts. Anat., Surg. & Pharm., Penn State U., Hershey, PA 17033.

Intracerebroventricular (i.c.v.) injections of SRIF and AVP produce motor symptoms which include BR and convulsions associated with lethal pulmonary edema, via partially independent mechanisms [Brain Res. 365:21-41; 445:117-129]. Cerebellar Purkinje cells also degenerate in SRIF-treated rats. Alert, adult male SD rats received an i.c.v. bolus of a combined dose of 20 μg SRIF and either 1 μg AVP (SRIF+AVP-1) or 1 μg of a V1 antagonist, Peninsula Labs #8109 (SRIF+mcAVP). These experiments were compared with our cumulative data base for responses to 20 μg SRIF alone or 20 μg SRIF+0.5 μg AVP. BR incidence increased ($p<0.05$) in the SRIF+0.5 μg AVP group vs. SRIF-AVP-1; no other differences were significant. Mortality was elevated after SRIF+AVP-1 vs. SRIF or SRIF+mcAVP ($p<0.05$), but mortality after SRIF+0.5 μg AVP was greater than all other groups ($p<0.05$). Hazard analysis of BR latencies indicated that the initial phase instantaneous probability of BR onset (θ^{-1}) was lower for SRIF+mcAVP (0.49$\pm$.10) and SRIF 20 μg (0.62$\pm$.11) than for SRIF+AVP-1 (0.88$\pm$.12) or SRIF+AVP 0.5 μg (3.32$\pm$.23). Purkinje cell death appeared in all groups. These data imply that endogenous AVP contributes to motor symptoms elicited by i.c.v. SRIF. (NS00891 (CDB) & Fogarty TW03743 (VPS)).

107.1

EFFECTS OF CHRONIC SECOND MESSENGER AND CHOLINERGIC LIGAND EXPOSURE ON THE CELL SURFACE EXPRESSION OF NICOTINIC ACETYLCHOLINE RECEPTOR BINDING SITES BY THE TE671 HUMAN MEDULLOBLASTOMA CLONAL LINE. A. M. Joy*, M. Bencherif*, H. N. Siegel and R. J. Lukas (SPON: I. Westenberg) Division of Neurobiology, Barrow Neurological Institute, 350 W. Thomas Rd., Phoenix, AZ 85013.

The CNS-derived cell line, TE671, expresses a class of nicotinic acetylcholine receptors (nAchR) that are functionally sensitive to blockade by alpha-bungarotoxin (Bgt). Previous studies in this laboratory have demonstrated that chronic exposure (24-48 hr) of TE671 cells in situ to nicotinic agonists induces an up-regulation of binding sites for radiolabeled toxin (I-Bgt) on cellular membrane fractions, while chronic treatment with di-butyryl cyclic AMP induces a down-regulation. By contrast, chronic agonist exposure induces a loss of functional nAchR expressed on the surface of TE671 cells. This study concerns the effects of drug treatments on I-Bgt binding site expression on the cell surface of TE671 cells maintained in situ. Chronic exposure to carbamylcholine results in upregulation of I-Bgt binding sites at the cell surface, while the antagonist d-tubocurarine decreased the number of I-Bgt binding sites. The concentration dependence of the upregulation by agonist has a similar profile as receptor activation by agonist. Possible mechanisms for receptor upregulation will be discussed.

107.2

NICOTINIC ANTAGONISTS AND PHORBOL ESTERS UP-REGULATE α-BUNGAROTOXIN BINDING SITES VIA DISTINCT MECHANISMS. S. Geertsen*, R. Afar*, J.M. Trifaró* and M. Quik. (SPON: P. Braun). Depts. of Pharmacology, McGill Univ., Montreal, Que. and Univ. of Ottawa, Ottawa, Ont., CAN.

Incubation of adrenal chromaffin cells in culture with 4β-phorbol 12-myristate 13-acetate (PMA) for 2-3 days resulted in a marked increase in α-bungarotoxin (α-BGT) binding. The PMA induced increase in α-BGT binding occurred in a dose dependent manner, with 100 nM PMA resulting in a maximal 15 fold increase. Inactive phorbol esters, such as 4α-PMA and 4α-PDB (4α-phorbol 12,13-dibutyrate) resulted in only a minimal increase in binding. Additionally, the protein kinase C inhibitor, polymyxin B, completely inhibited the up-regulation of toxin sites produced by PMA. These results suggest that PMA increased α-BGT binding through the activation of protein kinase C. Previous results had shown that the nicotinic antagonist d-tubocurarine also resulted in a marked increase in α-BGT binding to adrenal chromaffin cells in culture (Quik, M. et al., Mol. Pharmacol. 31:385, 1987). However, polymyxin B did not affect the d-tubocurarine induced increase in α-BGT binding.

These results show that activation of protein kinase C can result in an up-regulation of the α-BGT sites in chromaffin cells in culture. Furthermore, this appears to be distinct from the nicotinic antagonist induced increase in the α-BGT sites.

107.3

EFFECTS OF PREGANGLIONIC DENERVATION AND POSTGANGLIONIC AXOTOMY ON ACH AND GABA RESPONSES OF CHICK CILIARY GANGLION NEURONS. A.E. McEachern[1], M.H. Jacob[2], and D.K. Berg[1]. [1]Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093 and [2]Worcester Foundation for Exptl. Biology, Shrewsbury, MA 01545.

Chick ciliary ganglion neurons have nicotinic acetylcholine receptors (AChRs) that mediate chemical transmission through the ganglion, and $GABA_A$ receptors of unknown significance. We report here that preganglionic denervation of the neurons produces a small decline in ACh sensitivity and a larger decline in GABA sensitivity. Postganglionic axotomy has a different effect, reducing ACh sensitivity dramatically while leaving GABA sensitivity unchanged. The results suggest that cell-cell interactions regulate the ACh and GABA responses of ciliary ganglion neurons, and the regulation involves different mechanisms for the two types of receptors.

Ciliary ganglia in newly hatched chicks were either denervated or axotomized by transecting the appropriate nerves, and later removed and enzymatically dissociated to yield single cells. Intracellular recording was used to measure changes in the membrane conductance of the cells caused by ACh or GABA pressure applied from nearby micropipettes under standard conditions. Five days after axotomy the mean ACh sensitivity of the neurons had fallen to 13 ± 3% (n=28) of that observed for neurons from unoperated contralateral ganglia from the same chicks. GABA responses were not altered by axotomy (n=32). Ten days after denervation mean ACh and GABA sensitivities had declined to 71 ± 12% (n=32) and 41 ± 12% (n=32), respectively, of the values observed for neurons from normal and unoperated contralateral ganglia. The declines could not be accounted for by changes in cell size or cholinesterase levels. The decline in ACh sensitivity after axotomy is similar in magnitude to the large decline in total ganglionic AChRs measured with an anti-AChR monoclonal antibody in detergent extracts. The decline after denervation, however, is not as great as that observed for total ganglionic AChRs with the antibody under the same conditions. (Supported by NS12601 and NS21725)

EFFECT OF CHRONIC DFP TREATMENT ON ACUTE NICOTINE RESPONSE IN MICE. J.L. van de Kamp* and A.C. Collins (SPON: W.E. Hahn). Instit. for Behav. Genetics, Univ. of Colorado, Boulder, CO 80309

Costa and Murphy (JPET 226: 392-397) have reported a decrease in [^{3}H]-nicotine binding and reduced sensitivity to the antinociceptive effect of nicotine in rats chronically treated with disulfoton. Previously, we demonstrated that chronic treatment with diisopropylfluorophosphate (DFP) for two weeks resulted in significant cross tolerance to nicotine on one measure (heart rate) in DBA mice and a decrease in the number of [^{3}H]-nicotine binding sites in cortex. In the present study, DBA male mice were injected with DFP or saline every other day for one month. The animals were subsequently challenged with one of several doses of nicotine. Heart rate, body temperature, Y-maze activity and rearing were recorded. DFP-treated mice exhibited more robust cross-tolerance to nicotine on only one measure (heart rate) and decreases in [^{3}H]-nicotine binding sites were observed in the cortex and midbrain. Some of the chronically treated mice were challenged with an acute dose of 1,1-dimethyl-4-phenylpiperazinium (DMPP), a nicotinic agonist that does not cross the blood-brain barrier. There was no significant cross-tolerance observed in the measures recorded (heart rate and body temperature). (Supported by DA-03194.)

EFFECTS OF COLD STRESS ON CHOLINERGIC RECEPTORS IN THE RAT ADRENAL GLAND. L.L. Miner*, A.P. Baruchin, and B.B. Kaplan (SPON: E.Weisberg). Molecular Neurobiology Program, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

Previously we demonstrated that chronic cold stress resulted in 2-to-4-fold increases in rat adrenomedullary tyrosine hydroxylase (TH) mRNA levels. These changes could be greatly attenuated by the administration of chlorisondamine, a cholinergic antagonist. Conversely, the chronic administration of cholinergic agonists elevated adrenomedullary TH mRNA levels. To further explore the involvement of the cholinergic system in the adaptive response to cold stress, we assessed the effects of cold exposure on adrenomedullary nicotinic and muscarinic receptors. Nicotinic and muscarinic receptors were estimated by radioligand binding assays using α-bungarotoxin (BTX) and quinuclidinylbenzilate (QNB), respectively. After 4 and 7 days of cold exposure BTX binding increased by 150-170%, whereas QNB binding was 25-35% of control levels. Scatchard analysis indicated that these differences were due to changes in the number of binding sites rather than changes in receptor affinity (BTX, .14 nM; QNB, 144 pM). No differences in receptor binding were observed prior to 4 days of cold exposure. These results indicated that the adaptive response to chronic cold stress involve reciprocal changes in adrenomedullary cholinergic receptors.

CONTRACTILE ACTIVITY REGULATES BLADDER MUSCARINIC RECEPTORS AND RESPONSE M.R.Ruggieri*, S.Kitada*, K.E.Whitmore*, A.J.Wein* and R.M.Levin* (SPON: K.Williams) Div. Urology, Univ of PA and Graduate Hospital, Phila., PA 19104.

Previous studies have shown that in the pineal gland, receptor density can be modulated within hours by neuronal activity. The current study investigates whether stimulation of the urinary bladder can alter muscarinic receptor density and response.

Transducer tipped catheters were used to monitor intraabdominal and intravesical pressure in male New Zealand white rabbits. Reflex bladder contractions were induced with a suture tied tightly around the catheterized penis. Control rabbits did not have the external tie. After 4 hours half the bladder was used for muscle bath study and half was used for muscarinic receptor assay. There was no relationship between intraabdominal and intravesical pressure. The bladders were not overdistended after 4 hr (mean volume = 35 ml). The contractile activity of the bladder in-vivo induced by penile ligation could be completely blocked by iv hexamethonium. Penile ligation reduced the maximal response to field stimulation and bethanechol to 45±5% and 46±3% respectively of the response of strips from control animals. Penile ligation reduced the muscarinic receptor density from 34±3 to 22±3 fmole/mg protein.

The effect of repetitive intermittent field stimulation on the contractile response and muscarinic receptor density of bladder strips from untreated rabbits was also investigated. Similar to in-vivo stimulation, intermittent in-vitro field stimulation (30 sec on, 30 sec off for 2 hr) resulted in a moderate (25%) reduction in contractile response to field stimulation and bethanechol and reduced the muscarinic receptor density from 29±2 to 18±2 fmol/mg protein.

In both cases, there was no change in the contractile response to KCl, indicating that there was no deficit in the contractile apparatus over the course of the experiment. Clinically, this process of downregulation may help explain the presence of voiding dysfunctions in patients showing a high degree of uninhibited bladder contractions.

REGULATION OF MUSCARINIC RECEPTORS BY INTRAHIPPOCAMPAL ADMINISTRATIONS OF GALLAMINE. W.S. Messer, Jr. and B.R. Ellerbrock*, Dept. of Medicinal and Biological Chemistry, College of Pharmacy, University of Toledo, Toledo, OH 43606

Long-term intrahippocampal injections of gallamine, a cholinergic antagonist, impair learning of a representational memory task. To determine if the behavioral deficits are due to an alteration in the binding properties of muscarinic receptors, we utilized quantitative autoradiographic techniques to measure the number of muscarinic receptors and the affinity for gallamine, pirenzepine and carbachol.

Animals were injected bilaterally with either saline or 5 µg of gallamine in 0.5 µl saline (10 µg total) daily for 22 days. Animals were sacrificed 24 h following the last injection by cardiac perfusion with 0.1 % formaldehyde in 40 mM phosphate buffer. Muscarinic receptors were localized in 12 µm rat brain sections using 0.06 - 4.0 nM [^{3}H]-l-quinuclidinyl benzilate ([^{3}H]-l-QNB) in phosphate buffer and the binding of gallamine, pirenzepine and carbachol was determined through inhibition of 0.2 nM [^{3}H]-l-QNB binding. Binding properties were examined in several brain regions through quantitative autoradiographic techniques.

The binding properties of muscarinic receptors did not differ when comparing whole slices, but regional analyses of autoradiograms revealed some striking differences. The number of muscarinic receptors was increased (13.5 to 17.4 % over saline controls) throughout all cortical layers in gallamine-treated animals, reaching significantly higher levels ($p < 0.05$) in the deep layers of the cerebral cortex. No differences were noted in the CA1 region of the hippocampus or the dentate gyrus. Significant increases (19.4 %, $p < 0.05$) in receptor number also were noted in the superior colliculus for gallamine-treated animals. Supported by NS 25765.

REGULATION OF MUSCARINIC RECEPTORS IN CULTURED EXPLANTS OF RAT HIPPOCAMPUS BY CHOLINERGIC INNERVATION, AGONISTS AND ANTAGONISTS. K. Rimvall*, F. Keller and P.G. Waser*, Inst. Pharmacol., Univ. Zurich, CH-8006 Zurich, Switzerland.

Agonist induced decreases in receptor number ("down-regulation") represent an in vivo mechanism for the regulation of receptor response to physiological stimuli. In the present study the relationship between the number of muscarinic acetylcholine receptors (mAChrs) in the hippocampus and its cholinergic innervation was investigated. Such studies are difficult to perform in vivo - hence, we used an in vitro approach. Explants of rat hippocampus and septum were cultured on cover slips in rotating test tubes. MAChrs were characterized in binding studies (Rimvall K. et al., Neuropharmacology, 25:221, 1986). Hippocampal explants were cultured either alone (Hal) or with septal explants (Hco). Hal is a deafferented structure devoid of cholinergic transmission whereas Hco is innervated by cholinergic fibers from co-cultured septal explants (Rimvall K. et al., Develop. Brain Res., 19:267, 1985). Septal but not hippocampal explants contain a high-affinity uptake system for choline and release ACh upon depolarization. Cultured explants were incubated with atropine or carbachol for 48 h before the binding experiment. Such pretreatment of Hal with carbachol caused a dose-dependent down-regulation of mAChr numbers (max. 30-40% of control) which was totally inhibited by the simultaneous addition of atropine. Atropine alone had no effect on the number of mAChrs in Hal. Receptor content in non-treated Hco was of the same magnitude as in Hal treated with carbachol. Carbachol pretreatment of Hco caused a down-regulation of mAChrs whereas atropine induced a up-regulation of mAChrs to levels comparable to the ones found in non-treated Hal. Thus, co-culture conditions, i.e. cholinergic (re)innervation of Hco and subsequent influence by septal acetylcholine, cause mAChrs to be sensitive to the down-regulating actions of atropine and also mimic the effects of pretreatment of Hal with carbachol. In conclusion, our findings definitely connect a cholinergic (re)innervation of hippocampal explants with a down-regulation of mAChr number. Our report also provides "reverse evidence" for a compensatory up-regulation of receptor number after cholinergic denervation.

ATROPINE-INDUCED UP-REGULATION OF MUSCARINIC BINDING SITES AND PHOSPHOINOSITIDE HYDROLYSIS IN RAT BRAIN: EFFECTS OF LITHIUM. R.H. Lenox, D.D. Hendley*, and J. Ellis. Neuroscience Research Unit, Dept. of Psychiatry, Univ. of VT Coll. of Med., Burlington, VT 05405.

The effects of chronic atropine administration on muscarinic systems of the rat CNS were studied with and without ongoing lithium treatment (achieving clinically relevant levels in the brain). Atropine was continuously infused via subcutaneously implanted osmotic pumps at the rate of 10 mg/kg/day for 6 days. Twenty-four hours following removal of the pumps, slices and membranes were prepared from the hippocampus and cortex. The binding of labeled quinuclidinyl benzilate, N-methylscopolamine, pirenzepine, and oxotremorine-M was determined. The muscarinic phosphoinositide response was assessed at concentrations of carbachol that produce maximal (1mM) and half-maximal (40µM) responses. Atropine treatment yielded an increase in Bmax of approximately 20% for each of the ligands. The degree of up-regulation was not diminished by concomitant administration of lithium. Atropine treatment also increased the muscarinic phosphoinositide response by about 20% at both carbachol concentrations. This effect of atropine was prevented by concomitant lithium administration. It therefore appears that the muscarinic phosphoinositide response is enhanced by up-regulation and that lithium may act beyond the receptor to prevent the enhancement of the response. MODULATION OF M1 AND M2 mAChR's IN WILD TYPE AND KIN 8 ADRENAL CARCINOMA Y1 CELLS. N.M. Scherer,* R.A. Shapiro,* and N.M. Nathanson. (SPON: S.D. Hauschka) Pharmacology Dept., SJ-30, Univ. of Washington, Seattle, WA 98195.

Wild type and a variant clone (Kin 8) of Y1 adrenal carcinoma cells were transfected with the mouse M1 and pig M2 mAChR's. Y1 cells lack endogenous mAChR's. The Kin 8 clone contains a mutant gene for the regulatory type 1 subunit of cAMP-dependent protein kinase A (PrK A) and is resistant to the effects of cAMP.

In Y1 cells both the M1 and M2 receptors are internalized as a result of exposure of the cells to the agonist, carbamylcholine. Treatment with phorbol 12-myristate 13-acetate (PMA) results in internalization of M1 receptors, suggesting the involvement of Prk C. The effect of PMA is not as great or as rapid as that seen with carbamylcholine, suggesting that activation of Prk C cannot fully replicate the agonist effect. In contrast, treatment with PMA does not result in internalization of M2 receptors. Increasing cAMP levels in Y1 cells does not alter the number of either receptor.

In Kin 8 cells carbamylcholine-induced internalization of the M1 receptor is greatly reduced; in contrast, loss of M2 receptors is greater than in wild type cells. Thus, Prk A is likely to be necessary but not sufficient for internalization of the M1, but not M2, receptor. Treatment of Kin 8 cells with PMA does not result in internalization of M1 or M2 receptors. The ability of PMA to induce internalization of M1 in wild type, but not Kin 8, cells suggests that both Prk C and Prk A are necessary for internalization of the M1 receptor. Neither Prk A nor Prk C appear to be involved in internalization of the M2 receptor. Supported by NIH grant HL30639 and HL07312. N.M.S. is a fellow of the American Heart Assoc., Wash. Affiliate.

REGULATION OF MUSCARINIC RECEPTOR EXPRESSION IN CULTURED SYMPATHETIC NEURONS. K.E. Smith, N.E. Kremer, V. Wong, and J.A. Kessler. Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Muscarinic receptor expression was examined in cultured sympathetic neurons of the neonatal rat superior cervical ganglion. Sympathetic neurons in culture contained abundant ^{3}H-QNB binding sites (2-3 pmoles/mg protein after 2 weeks in culture) and substantial levels of M2 muscarinic mRNA (detected by Northern blot analysis using an M2 muscarinic receptor cDNA provided by E. Peralta, Genentech). Muscarinic receptor numbers were decreased by treatment either with a 29 kD membrane associated molecule isolated from rat spinal cord (Wong and Kessler, PNAS, 84:8726, 1987) or with a soluble factor present in rat fibroblast conditioned medium. Similar decreases in ^{3}H-QNB binding were observed after chronic agonist (carbachol or muscarine) treatment or potassium-induced membrane depolarization. Despite the similar effects of MANS and RFCM on receptor numbers, effects on M2 muscarinic mRNA differed strikingly. MANS treatment decreased M2 mRNA levels whereas levels of the mRNA were unchanged after treatment with RFCM. Thus these two factors, which have similar effects on receptor numbers, act at least in part through different mechanisms. Both factors also promote cholinergic and peptidergic neurotransmitter expression by cultured sympathetic neurons, suggesting that transmitter and receptor expression may be regulated by the same environmental signals. Although mechanisms underlying the effects of MANS and RFCM are unknown, chronic treatment with phorbol myristate acetate (PMA) also decreased both ^{3}H-QNB binding and M2 receptor mRNA. Thus PMA mimicked the effects of MANS, raising the possibility that protein kinase C mediates effects of the membrane associated factor.

POSTNATAL DEVELOPMENT AND SEX DIFFERENCES OF MUSCARINIC ACETYLCHOLINE RECEPTOR CHARACTERISTICS IN RAT CEREBRAL CORTEX SLICES. F. van Huizen [1]*, C. Shaw [1]*, M. Wilkinson [2] and M. Cynader [1] (SPON: R.M. Douglas) [1] Dept. of Ophthalmology, University of British Columbia, Vancouver, B.C., Canada V5Z 3N9 and [2] Dept. of Physiology and Biophysics, Dalhousie University, Halifax, N.S., Canada.

We have shown previously that muscarinic acetylcholine receptor characteristics could be assessed in 'living' slices of rat cerebral cortex (*Soc. Neurosci. Abst. 13, 727*). In this study we examined the possible changes in these receptor characteristics during postnatal development. Fresh cerebral cortex slices of male and female rats (4-100 days old) were incubated in increasing concentrations of [^{3}H]-NMS to yield saturation binding curves. From these curves, K_d and B_{max} values could be calculated. A sharp increase in both Kd and Bmax was found for both males and females, peaking at about 30 days postnatal. Following this peak (12.8 $\pm$ 1.4 nM and 2148 $\pm$ 187 fmol/mg protein, resp.) , Kd and Bmax dropped to a lower level in adult male rats, but in female rats the values were quite varied. This appears to be due to the stage of the ovarian cycle. The peak in Kd and Bmax values at 30 days postnatal coincides with the peak in synapse number. Displacement studies revealed sharp increases in the IC_{50} for pirenzepine and oxotremorine (M_1 and M_2 mAChR) but only a slight increase for NMS during development with a consecutive drop to adult values. Downregulation of the receptor after agonist stimulation is greater in adult rats (-23.8 $\pm$ 2.7%) than in rats younger than 30 days (-8.0 $\pm$ 4.1%).

EFFECTS OF TESTOSTERONE AND ESTRADIOL ON MUSCARINIC RECEPTOR BINDING IN RAT CEREBRAL CORTEX SLICES. D. March[1*], J. Simmons[2*], F. van Huizen[1*], and C. Shaw[1*]. (SPON: P. Bawa), [1]Dept. of Ophthalmology, UBC, Vancouver, Canada; [2]Dept. of Biology, Trinity College, Hartford, CT 06106

Recent studies have characterized the muscarinic acetylcholine receptor (mAChR) in living slices of rat cerebral cortex (van Huizen et al. 1987). In the present study the effects of testosterone (T) and estradiol (E_2) on [^{3}H]-N-methyl-scopolamine ([^{3}H]-NMS) binding to the mAChR was investigated. Prepubescent rats (25 days old) were gonadectomized then sacrificed after 96 hours. Littermates were sham-operated and similiarly sacrificed, creating four distinct groups: orchiectomized males (ORM), sham males (SHM), ovariectomized females (OVF), and sham females (SHF). Cortical slices (400μm) were preincubated for 3 hours at 37°C alone, with 10^{-5}M T or 10^{-7}M E_2. Slices were incubated for 2 hours at 4°C with [^{3}H]-NMS. Bmax and Kd values were determined for each condition (see Table).

Both Bmax and Kd decrease in ORM and return to normal levels with the addition of T. Preliminary evidence in females suggest that increases are seen in Bmax and Kd in OVF, but no significant changes occur when E_2 is added. The present results support a role for gonadal hormones in the development of mAChR characteristics in rat cerebral cortex. Further, hormonal regulation of the mAChRs may be very rapid (hours) as shown by the recovery to normal values after the addition of T.

Group	Control(Bmax*,Kd ^)		+T (Bmax,Kd)		+E_2 (Bmax,Kd)

PHORBOL 12,13-DIBUTYRATE REGULATES MUSCARINIC RECEPTOR BINDING IN RAT CORTICAL SLICES BY ACTIVATING PROTEIN KINASE C. W.-G. Jia, C. Shaw*, F. van Huizen*, M. Cynader. Dept. of Ophthalmology, UBC, Vancouver, Canada, V5Z 3N9.

Stimulation of muscarinic receptors (mAChR) elicits phosphatidyl-inositol turnover , which yields inositol phosphates (InsP) and diacyl-glycerol (DG); the latter activates a second messenger, protein kinase C (PKC). Activating PKC with phorbol esters inhibit mAChR agonist stimulated phosphoinositide hydrolysis and InsP production (Labarca,R. et al. Biochem. Biophys. Res. Commun. 123:707-709,1984). A possible mechanism of this inhibition may be down- regulation of mAChR by PKC. In the present work, rat cortical slices were preincubated with phorbol 12,13-dibutyrate (PDBu) followed by binding assays for [^{3}H]-quinuclidinyl benzilate (QNB) or [^{3}H]N-methyl scopolamine (NMS). Binding of both ligands was reduced after pretreatment with PDBu. This binding loss was dose-dependent in the range of 10^{-9} to 10^{-7}M PDBu and started within 5 min of treatment. After 60 min of pretreatment with 10^{-7}M PDBu, binding of [H^3]-NMS and [H^3]-QNB was reduced by 18.8% ($P<0.01$) and 19.9% ($P<0.02$) respectively. In addition, binding of [^{3}H]-pirenzepine (PZ) or [^{3}H]-oxotremorine-m (OX-m) ($<10^{-9}$M), which selectively bind to M_1 or M_2 mAChR subtypes, was reduced after the PDBu pretreatment (-16.8% for PZ , $P<0.01$ and -20.9% for OX-m, $P<0.001$). Moreover, pretreatment with 1-oleoyl-2-acetyl-rac-glycerol, a synthetic DG, caused the same reduction (-17.8% at 10^{-6}M DG) in [H^3]-QNB binding. These results suggest that activation of PKC may cause "down-regulation" of mAChR and mimic a negative feedback mechanism that exists in mAChR stimulated phosphoinositide hydrolysis.

EVIDENCE AGAINST THE INVOLVEMENT OF PROTEIN KINASE C IN AGONIST-INDUCED DESENSITIZATION OF MUSCARINIC RECEPTORS. W.S. Lai and E.E. El-Fakahany. Dept. of Pharmacology and Toxicology, Univ. of Maryland. Sch. of Pharmacy, Baltimore, MD 21201.

Preincubation of mouse neuroblastoma N1E-115 cells with muscarinic agonists results in rapid down regulation of cell surface muscarinic receptors and in desensitization of receptor-mediated cyclic GMP (cGMP) synthesis. In contrast, short-term exposure of these cells to phorbol esters diminished carbamylcholine (CBC)-induced cGMP and inositol phosphates accumulation without affecting binding of the muscarinic antagonist [^{3}H]N-methylscopolamine ([^{3}H]NMS). CBC, however, added after short-term incubation with phorbol ester still caused down-regulation of [^{3}H]NMS bindings. In addition, long-term (24 hrs) pretreatment of cells with phorbol-12, 13-dibutyrate (PDBu) abolished [^{3}H]PDBu bindings without altering the dose-response curve of CBC-induced down-regulation of [^{3}H]NMS binding. Under the latter condition where protein kinase C is desensitized, CBC preincubation caused a time-dependent desensitization of cGMP response similar to that observed in control cells. These results suggest that protein kinase C may not play an important role in agonist-mediated desensitization of muscarinic receptors. (Supported in part by NIH grants NS-24158, AG-07118 and AG-00344.)

107.16

PHOSPHORYLATION OF PURIFIED CHICK BRAIN MUSCARINIC CHOLINERGIC RECEPTOR BY Ca/CALMODULIN (TYPE II) PROTEIN KINASE. **J.S. Aguilar*, J.P. Sullivan*, A.F. Skorupa*, S. Chan*, A. Routtenberg and W.L. Klein. Neuroscience Program. Northwestern University. Evanston IL. 60308.**

Receptor phosphorylation may play an important role in the regulation of acetylcholine muscarinic receptors (mAChRs) as is the case for the nicotinic and adrenergic receptors. The muscarinic agonist carbamylcholine reduces the number of mAChRs and stimulates their phosphorylation in the heart. Also, phosphorylation of brain and heart mAChRs by cyclic AMP dependent protein kinase causes receptor inactivation. To assess the role of phosporylation in receptor regulation, we evaluated mAChRs as substrates for other key protein kinases. For this, we purified the receptor from chick brain to about 2000 pmol 3H-QNB binding sites per mg of protein by affinity chromatography in ABT-agarose. These prepartions of mAChRs were used as substrate for phosphorylation by protein kinases. Ca++/CM dependent protein kinase (Type II) phosphorylates a polypeptide with the same Mr as the 3HPrBCM labelled mAChR as determined by SDS-polyacrylamide electrophoresis. This observation suggests that Ca++/CM dependent protein kinase may phosphorylate mAChRs in vivo. In contrast, Protein kinase C causes no phosphorylation of purified mAChRs. We are now evaluating the role of Ca++/CM in the regulation by studying the binding properties of the phosphorylated mAChRs.

CELL ADHESION MOLECULES IN THE DEVELOPING EIGHTH NERVE OF CHICKEN EMBRYOS. Sharon G. Hemond[1], Urs Rutishauser[2] and D. Kent Morest[1]. [1]Ctr. Neurological Sciences, Anatomy Dept., Univ. of Conn. Health Ctr., Farmington, CT 06032; [2]Case Western Reserve University, Cleveland, OH 44106.

In the maturation of the cochleovestibular ganglion, cellular interactions may play a role in the generation of specific innervation patterns of different auditory and vestibular endorgans. To address this, we are studying CAMs at the time of ganglion formation and early central and peripheral innervation, E2-E7, and report on two studies. First, immunocytochemistry with antibodies directed against NCAM and AxCAM(G4) shows that NCAM is found in the ganglion and its processes during early innervation and G4 is observed in the forming ganglion associated with initial process outgrowth and is maintained in processes during innervation. Second, we have developed an in vitro system in which neuroblasts, associated with the immature otocyst, extend processes which fasciculate. Aggregation of neurons is apparent. Immunocytochemistry of 2-3 day cultures shows that G4 is expressed by neurons; NCAM data are also suggestive of its expression on neurons.

The temporal and spatial expression of CAMs in situ suggests a functional role in the generation of specific innervation. The in vitro system is being used to assess this possibility. (Supported by NIH grants NS14354 and T32 NS07299)

108.2

NCAM POLYSIALIC ACID CAN REGULATE CELL-SUBSTRATE ADHESIVITY **J.L. Sunshine* and U. Rutishauser Case Western Reserve Univ. School of Medicine, Cleveland, OH**

Explants from embryonic day 7 chick spinal cord produce a fasciculated pattern of neurite outgrowth on a laminin substrate. The NCAM on the outgrowing neurites has a high content of polysialic acid (PSA), a unique carbohydrate moiety associated with modulation of NCAM function. Surprisingly, specific enzymatic removal of the PSA from NCAM during outgrowth resulted in substantial defasciculation of the neurites, although this had been expected to enhance NCAM-mediated fasciculation based on previous studies using DRG explant cultures. Furthermore, the defasciculation was unaffected by anti-NCAM Fab fragments, and was reversed by antibodies to the laminin substrate. Taken together, these data suggest that PSA can influence growth cone-to-substrate adhesion independently of NCAM function.

108.3

REGULATION OF L1 FUNCTION BY NCAM POLYSIALIC ACID ON DRG X NEUROBLASTOMA HYBRID CELLS A. Acheson, J. Dodd, T. Jessell and U. Rutishauser Case Western Reserve University School of Medicine, Cleveland, OH and Columbia University, New York, NY.

E17 rat DRG neurons X murine N18TG2 neuroblastoma hybrid cells express NCAM with a high content of polysialic acid (PSA) as well as the L1 cell adhesion molecule. Treatment of cells with endoneuraminidase N specifically removes PSA from NCAM without affecting L1, as assessed by immunostaining and immunoblot analysis. The presence of both cell adhesion molecules and PSA on the cell surface allows direct assessment of a potential hierarchy of function among these components. Untreated cells show little aggregation after 30 min at 37 °C. However, after specific enzymatic removal of PSA from NCAM, the aggregation rate increased (55% decrease in particle number), and half of the resultant aggregation was inhibited by anti-L1 Fab fragments. These data support the hypothesis that NCAM's PSA moiety can independently regulate the function of other cell adhesion molecules.

EXPRESSION OF THE CYTOPLASMIC DOMAIN OF 5B4/NCAM-180, VIA ITS cDNA, IN HETEROLOGOUS CELLS. Leland Ellis and Purita Ramos, HHMI and Dept.of Biochemistry, UTSWMC, Dallas, Tx.

Monoclonal antibody 5B4 recognizes a large (~185-255 kd) developmentally regulated membrane glycoprotein, whose expression on fetal rat neurons is coincident with neuronal sprouting. The primary sequence of the transmembrane and cytoplasmic domains of the 5B4 antigen, deduced from the nucleotide sequence of λgt11 cDNA clones which encode 5B4, reveals significant identity (75%) with the sequence reported by Edelman and collegues for chick NCAM-180. The cytoplasmic domain (391 aa; M_r 39284) has an unusual amino acid composition (52% proline, alanine, serine and threonine) with little predicted α or β secondary structure, and is of unknown function. To test the feasibility of expressing this domain independently as a soluble protein, with the goal of ultimately exploring the physical properties and interactions of this unusual molecule, we have engineered an expression plasmid designed to encode such a derivative. In Cos cells transfected with this 5B4 cDNA under the transcriptional control of a viral promotor, mAb 5B4 specifically recognizes a protein which migrates anomolously (M_r ~80000) on SDS-PAGE under denaturing and reducing conditions. The successful expression of the 5B4 cytoplasmic domain in heterologous cells now provides an experimental approach with which to assess the phenotype(s) of cells and animals which express this domain autonomously.

MONOCLONAL 12F8 ANTIBODY IDENTIFIES A SUBCLASS OF NCAM ACTIVE IN PROMOTION OF NEURITE OUTGROWTH. C. Lagenaur, J. Yip, and V. Lemmon. Depts. of Neurobiology, Anatomy & Cell Science and Physiology, Sch. of Med., Ctr. for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Rat Mab 12F8 recognizes a neuraminidase sensitive epitope on mouse and chick NCAM. Purified 12F8 antigen is an effective substrate in the nitrocellulose based neurite outgrowth assay described by Lagenaur and Lemmon, PNAS, 84:7753-7757, 1987. 12F8 attaches neurons from P6 mouse cerebellum and promotes fasciculated neurite outgrowth. We have compared the distribution of the 12F8 epitope with total NCAM recognized by Mab 1A6 in developing chick. The distribution of 1A6 and 12F8 are initially similar but by stage 44 12F8 becomes most prominently expressed in sympathetic ganglia while 1A6 is widespread throughout the nervous system. Unlike 1A6, 12F8 is never found in notochord. The developmental distribution of 12F8 epitope containing NCAM may represent the appearance of sites favorable for axon outgrowth. cDNA SEQUENCE ANALYSIS OF GRASSHOPPER FASCICLIN II PROTEIN: HOMOLOGY WITH IMMUNOGLOBULIN SUPERFAMILY. A.L. Harrelson and C.S. Goodman, Dept. of Biochem., Univ. of California, Berkeley, CA, 94720.

To elucidate the mechanisms that control cell recognition during neuronal development, we have been studying the developing nervous system of insects. Previous studies identified three different surface glycoproteins, called fasciclins, which are expressed on subsets of axon fascicles and whose distribution suggests a possible role in labeling developing axon pathways. One of these proteins, fasciclin II, is expressed on the surfaces of longitudinal axon fascicles in the grasshopper embryo. We isolated and sequenced a 3.5 kb cDNA which encodes for nearly the complete fasciclin II protein. The deduced amino acid sequence of the protein contains a putative transmembrane domain with a C-terminal cytoplasmic domain of about 100 amino acids. The most interesting feature of fasciclin II is the presence of five repeated domains in the extracellular region, each containing cysteine and other amino acid residues in a precise spacing similar to that seen in the immunoglobulin superfamily. In particular, fasciclin II has highest amino acid homology to the neural cell adhesion molecules in this family, including N-CAM, MAG, and L1/Ng-CAM/NILE (Schachner et al., in press). Seeger and Kaufman (unpublished) have shown that the amalgam gene in Drosophila encodes a protein with IgG-like domains which is expressed in the developing CNS. The finding of this 2nd IgG-like molecule in the developing insect CNS raises the issue of whether the initial evolutionary role for such proteins was in adhesion and cell recognition, and moreover, raises the question of how many such proteins are present in the developing insect nervous system. To begin a genetic analysis of these proteins, we are presently searching for the Drosophila homologue of fasciclin II.

TEMPORAL EXPRESSION OF TAG-1 AND L1 GLYCOPROTEINS ON CENTRAL AND PERIPHERAL NEURONS IN VITRO. D. Karagogeos*[1,2], J. Dodd[1] and T.M.Jessell[1,2] (SPON: J. Wood). Center for Neurobiology[1] and Howard Hughes Medical Institute[2] Columbia University, New York, NY 10032

The axons of developing vertebrate neurons express several surface glycoproteins that have been implicated in axon extension and fasciculation. Studies in the developing rat spinal cord have shown that two of these proteins, TAG-1 and L1, are segregated spatially and temporally on sensory, motor and commissural (C) neurons (Dodd et al. 1988, Neuron 2). The initial expression of TAG-1 precedes that of L1 on these neurons. TAG-1 expression is transient whereas L1 expression persists throughout development but appears on restricted domains of motor and C axons.

The regulation of TAG-1 and L1 expression on spinal axons may be cell autonomous or influenced by the environment of the developing axon. To investigate the factors that regulate TAG-1 and L1 we have examined their expression on sensory and spinal neurons in dissociated cell culture. About 40-50% of E13 dorsal spinal cord neurons express TAG-1 on their surface when plated on astrocyte monolayers or on laminin. Expression of TAG-1 decreases with time in culture and by 72 hrs in vitro TAG-1 is not detectable. In contrast,most of E13 dorsal spinal cord neurons do not express L1 for the first 24 hrs in vitro although the protein is detectable on the majority of neurons by 72 hrs and expression is maintained with time in culture. In vivo, C neurons stop expressing TAG-1 by E16-17. Neurons dissociated from the dorsal spinal cord of E19-P2 rats regenerate processes in vitro but do not appear to express TAG-1 although L1 is expressed soon after plating. TAG-1 expression by C neurons therefore appears to be confined to the phase of initial axon extension and does not reappear on re generating axons. In contrast, DRG neurons that have stopped expressing TAG-1 in vivo re-express the protein on regenerating axons in vitro, suggesting that there are differences in the regulation of TAG-1 expression on central and peripheral neurons .

108.8

DISRUPTION OF COMMISSURAL AXON GUIDANCE IN THE ABSENCE OF THE MIDLINE FLOOR PLATE. P. Bovolenta, T. M. Jessell[1] and J. Dodd. Center for Neurobiology and [1]Howard Hughes Medical Institute, Columbia University, New York, N.Y. 10032.

Recent studies have suggested that floor plate epithelial cells of the embryonic rodent spinal cord can influence the guidance of commissural axons by: 1. releasing a diffusible factor(s) that promotes directed growth of commissural axons (Tessier-Lavigne et al., Placzek et al., this meeting). 2. regulating glycoprotein expression on commissural axons (Dodd et al. 1988, Neuron 1). 3. providing an adhesive substrate for axons joining the ventral funiculus (Dodd et al., ibid).

To examine further the contribution of the floor plate to commissural axon guidance in vivo we have studied the trajectory of commissural axons in mouse mutants in which the floor plate is abnormal or absent. In one such mutant, Danforth's short tail (Sd), the first observable abnormality is the absence of the notochord in caudal regions. At segmental levels in which the notochord is not detected, the floor plate of the overlying spinal cord is also absent. In regions of the spinal cord where the floor plate is missing , commissural axons project ventrally via a lateral route that contrasts with the medially directed trajectory observed in unaffected segments of the spinal cord or in normal litter mates. The growth cones of commissural axons arriving at the ventral limit of the spinal cord do not appear to cross the midline but project out into the surrounding ventral mesenchyme. At later developmental stages, these axons form a large fascicle, which may also contain misrouted motor axons. Axons within the fascicle continue to express the glycoprotein TAG-1. In normal embryos TAG-1 expression ceases on commissural axons as they cross the midline and enter the ventral funiculus. In mutant embryos the ventral funiculus is perturbed in affected regions of the spinal cord. Immunocytochemical studies indicate that the basal lamina is also disrupted at the ventral midline of affected neural tube segments.

These results support the idea that floor plate epithelial cells contribute to the guidance of commissural axons.

ANTI-IDIOTYPE ANTIBODIES TO THE LIMBIC SYSTEM ASSOCIATED MEMBRANE PROTEIN (LAMP) RECOGNIZE SEVERAL PROTEINS IN THE DEVELOPING BRAIN.

P. Levitt, S. Fisher*, A. Zacco*. Dept. Anatomy, Med. Coll. Pa., Philadelphia, Pa. 19129

The limbic system associated membrane protein (LAMP) is a developmentally regulated 64kd protein that mediates, in part, the ability of axons from limbic neurons to recognize and innervate appropriate targets. The molecular components that may interact with LAMP to perform this function are unknown. In order to identify potential LAMP receptors or interactive molecules, we used an anti-idiotype strategy to generate a series of monoclonal antibodies against anti-LAMP that theoretically could be used to identify such receptor molecules. Three of 45 anti-LAMP positive clones cross-reacted with brain. Western blot analysis, performed on fresh preparations in the presence of protease inhibitors, revealed that one antibody recognized many protein bands ranging from 15-200kd. The other monoclonals recognize only 2 of these protein bands, at approximately 75 and 65kd. Immunocytochemical staining of rat hippocampal cultures revealed that cells with neuronal morphology (including their processes) are immunoreactive. Double staining with anti-LAMP demonstrated that a subset of cells expressed both proteins. Ongoing immunoaffinity purification of these newly identified proteins will allow direct testing of binding between these molecules and LAMP. Supported by NSF grant BNS8519647, March of Dimes Research Grant 1-919.

CHARACTERIZATION OF THE P8-4 ANTIGEN, A NOVEL NEURAL CELL ADHESION MOLECULE.

W. Chuang and C. Lagenaur. Dept. of Neurobiology, Anatomy and Cell Science, Ctr. for Neuroscience, Univ. of Pittsburgh, Sch. of Med., Pittsburgh PA 15261.

Adhesive properties of isolated neural cell surface molecules can be assessed using a recently described technique that immobilizes proteins on nitrocellulose coated petri plates. (Lagenaur, C. and Lemmon, V., PNAS, 84:7753-7757, 1987). Using this method, cell surface antigen P8-4, isolated from mouse brain membranes has been identified as a new neural cell adhesion molecule. Immunoaffinity purified P8-4 contains three proteins of 200, 80, & 60 kD. P8-4 is not cross reactive with N-CAM, L1/NILE, and does not bear the HNK-1 epitope. This antigen is found on cultured cerebellar neurons and a subclass of unidentified flat cells. P8-4 is not found on oligodendrocytes or GFAP positive astrocytes. In the cell adhesion assay, P8-4 attached neurons and promoted neurite outgrowth. Glial cell attachment was also observed. Monoclonal anti-P8-4 detects antigen only in the floor plate of mouse embryonic spinal cord from E9 to P1. Beginning at P2, P8-4 becomes widely expressed throughout the CNS and is retained throughout adulthood. Our data suggest that P8-4 is a novel adhesion molecule that may be important in the early CNS development. Supported by: Basil O'Connor grant, March of Dimes; Culpepper Fellowship.

MONOCLONAL ANTIBODY 8A2 RECOGNIZES A CLASS OF *O*-ACETYLATED GANGLIOSIDES IN THE CHICK RETINA THAT PARTICIPATE IN AXON OUTGROWTH.

M. Pierce*, J. Drazba* and V. Lemmon. Dept. of Anatomy and Cell Biology, Univ. of Miami, Miami, FL 33101 and Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Monoclonal antibody 8A2 binds to axons in the chick nervous system (Soc. for Neurosci. Abs. 385.2, 1987). Using TLC-immunostaining techniques, the antigens in E10 retina display solubilities similar to those of gangliosides, and upon DEAE-Sephadex chromatography, elute almost entirely in the disialylated fraction. TLC-immunostaining of this fraction after HPLC using a NH_2-LiChrosorb column demonstrates binding to 1 major band. Treatment of the fraction with alkali abolished binding to all bands while periodate did not. This suggests that a common structural feature of these gangliosides is a sialic acid residue which is *O*-acetylated, probably at the 9-position. We are using high resolution NMR to complete structural analysis of the epitope. Using a cell culture system described in another abstract (Drazba and Lemmon) we have found that the addition of this antibody to culture medium inhibits neurite outgrowth on laminin and glia. Supported by NIH EY06968 and EY05285 and MOD 1-979.

ALTERED NEURITE OUTGROWTH IN MUTANT PC12 CELLS WITH REDUCED LEVELS OF SPECIFIC NEURONAL SURFACE GLYCOPROTEINS.

M.F. DeFreitas, W.V. Bleisch,* W.D. Matthew,+ and P.H. Patterson. Biology Div., Calif. Inst.Technol., Pasadena, CA 91125 and +Neurobiology Dept., Harvard Med. Sch., Boston, MA 02115.

As an alternative to the antibody perturbation approach in the study of the function of neuronal surface proteins, we have used specific mutagenesis to produce mutant cell lines deficient in NILE (also known as L1 and Ng-CAM). Mutagenized PC12 cells were selected for NILE deficiency by using complement-mediated lysis in conjunction with an anti-NILE monoclonal antibody, ASCS4. 14 clonal cell lines isolated from this selection were examined for their levels of NILE and several other surface proteins by immunocytochemistry and immunoprecipitation and SDS-PAGE. Three classes of mutants with low levels of ASCS4 binding were found: i) 1 mutant with an altered form of NILE, present at normal levels, ii) 8 mutants with low levels of NILE and normal levels of other proteins, and iii) 5 mutants with low levels of NILE and altered levels of N-CAM. Eight of 9 mutants examined grow processes in response to NGF or FGF. The mutant of the first class grows long, thin neurites similar to normal PC12 cells. Mutants of the second and third classes, however, grow neurites that are much shorter and thicker than wild type cells. These results suggest that NILE may be important in determining morphology. It is also interesting that alterations in N-CAM levels frequently occur when NILE is reduced.

108.13

LAMININ PROMOTES AXONAL BUT NOT DENDRITIC GROWTH IN RAT SYMPATHETIC NEURONS IN VITRO.

P.J. Lein and D. Higgins. Dept. Pharm., State Univ. of N.Y., Buffalo, NY 14214

We have characterized the effects of laminin on the morphology of neurons from embryonic rat superior cervical ganglia. Neurons were grown on polylysine-coated coverslips with or without substrate-bound laminin in the absence of serum and nonneuronal cells. In short-term ($\leq$24 hr) culture, laminin has a potent neurite-promoting effect, inducing increases in the number of neurites/cell and in the length and branching of processes. Data from long-term studies ($\geq$2 wk) indicate that these laminin-induced increases in the number of processes/cell and in branching are maintained.

The identity of the neuronal processes induced by laminin was determined in long-term cultures. Axons were distinguished from dendrites on the basis of intracellular dye injections, ^{3}H-norepinephrine uptake, and the immunocytochemical localization of dendrite-specific (microtubule associated protein 2, dephosphorylated M subunit of neurofilaments) and axon-specific antigens (synaptophysin, phosphorylated form of the M and H subunits of neurofilaments). The majority (> 75%) of neurons grown on laminin extend only axons. In contrast, when sympathetic neurons are grown for the same time period in the presence of a basal lamina extract, all neurons (100%) form both axons and dendrites. Thus, the neurite-promoting activity of laminin appears to be axon-specific. (Supported by March of Dimes Predoctoral Fellowship and NSF grant BNS 851960).

NEURITOGENESIS ON DIFFERENT COLLAGEN SUBSTRATA.

NG Carri, K Rubin*and T Ebendal* Departments of Developmental Biology (NGC, TE) and Medical and Physiological Chemistry (KR), Biomedical Center, S-751 23, Uppsala, Sweden.

We have earlier demonstrated that soluble macromolecules extracted from the visual areas are essential for trophic support of retinal neuritogenesis. In the present experiments we studied collagen types I-IV in combination with full trophic support stimulation. Neurite outgrowth from retinal explants (White Leghorn, E6) grown on collagenous substrates was studied. The substrata were prepared (native or denatured in 100 µl drop, overnight at 4°C) in the centre of the plastic dishes. Collagen types I, II and III were also studied as hydrated matrices in the centre of the dish. The explants were cultured with optic lobe at a protein concentration of 500 µg/ml. The cultures were then incubated for 4 days in a CO_2 incubator at high humidity and outgrowth controlled every~24 h in phase contrast in an inverted microscope. The behavior shown by explants was different in each case. Attachment and survival(studied by Trypan Blue exclusion) of the retinal explants were good on all types of collagen including the denatured (30 minutes at 56°C) forms. However, neurite formation occurred only on layer of collagen I and III and profound elongation occurred on these types of collagen in their hydrated forms. No outgrowth was present on collagen types II and IV. From the behavior observed on collagen types I and II it can be suggested that a receptor mechanism is involved here.

MENINGEAL CELLS FROM EMBRYONIC RAT SECRETE AN AUTONOMOUS PATTERN OF COMPLEXED OR FREE LAMININS AND FIBRONECTINS WITH DIFFERENT NEURITE PROMOTING ACTIVITIES. H.P. Matthiessen*, C. Schmalenbach*, and H.W. Müller. Molecular Neurobiology Laboratory, Department of Neurology, University of Düsseldorf, F.R.G. (SPON:S. Thanos)

In order to characterize the vigorous neurite outgrowth promoting activities (NPA) in meningeal cell conditioned media (M-CM) from embryonic rat we separated serum free hormone supplemented M-CM by FPLC on the anion exchange column Mono Q and tested the NPA of the polylysine binding fraction in a quantitative bioassay using hippocampal neurons from embryonic rat. We could determine two main activity peaks. Using antibodies against the substrate adhesion molecules laminin (LN) and fibronectin (FN) we could correlate a smaller NPA eluted at 250-350 mM NaCl with the highest immunoreactivity for free FN and a smaller one for free LN. The major activity peak, however, always coincided with the highest anti-LN and a smaller anti-FN immunoreactivity. This material which was highly sulfated was eluted at about 1 M NaCl and possibly consisted of proteoglycan complexes with LN or FN, respectively. It is noticeable that we could exclusively detect the ß-chains of LN within both peaks of NPA. The distribution of LN and FN in free or complexed forms is different in CM of meningeal cells and astrocytes, respectively. Supported by the DFG (Mu 630/3-1). C.S. is recipient of a fellowship from BMFT.

108.16

ANTIBODIES TO LAMININ AND THE 140KD FIBRONECTIN RECEPTOR UNCOUPLE NEURITE OUTGROWTH FROM CLOCKWISE GROWTH. Y. Tseng* and P. Grant, Institute of Neuroscience, University of Oregon, Eugene, Oregon 97403.

As Xenopus retinal ganglion cell axons mature during development, they begin to express clockwise growth between stages 37 and 50, when grown in serum free media containing laminin or fibronectin. To explore the neurite-substrate interactions responsible for the development of neurite growth patterns, a commercially available monoclonal antibody to laminin and a polyclonal antibody to a putative 140kd fibronectin receptor (generously supplied by Dr. K. Yamada) were employed. Dilutions of the antibodies were added to wells in culture dishes coated with polylysine, in a medium containing laminin or fibronectin (20-30 ug/ml). As controls, dilutions of mouse ascites fluid or rabbit Igg were used. Fragments of stage 25 optic vesicles (whose neurites never express clockwise growth) and stage 50 tadpole retinas were explanted and the patterns of neurite outgrowth and clockwise growth were assayed over six days. For both antibodies, dilutions were obtained which exhibited no, or only a modest inhibition of neurite outgrowth at both stages, while completely inhibiting clockwise bundle patterns in stage 50 neurites. The results suggest that more than one domain on ECM substrate molecules may be involved in retinal neurite outgrowth. (Supported by NSF grant BNS-85 16317).

LAMININ MEDIATES AGGREGATION OF PC12 CELLS ON A 3-DIMENSIONAL RECONSTITUTED BASEMENT MEMBRANE. J. Keshmirian* and S. Carbonetto, McGill Univ. Centre for Research in Neuroscience, 1650 Cedar Ave., Montreal, Canada H3G 1A4.

During development neural crest cells migrate through an extracellular matrix which strongly influences their aggregation into dorsal root and sympathetic ganglia. PC12 cells (a neural crest derivative) seeded on a reconstituted basement membrane (RBM) gel form aggregates interconnected by process-bearing cells. By 3 days these networks coalesce into large aggregates, which in the presence of NGF, extend a halo of nerve fibers and resemble dorsal root ganglia in culture. PC12 cells, when seeded onto gel of LAM alone behave essentially the same, whereas crude COL gels fail to induce aggregation. The extent of aggregation depends on cell density and is enhanced by NGF. Antisera to LAM or 3A3, a monoclonal antibody against a LAM/COL receptor (Turner et. al, J. Cell Biol. 105:137a, 1987) inhibit the REM gel-mediated aggregation in a dose-dependent fashion. Time-lapse studies indicate that cell movement leading to aggregation on RBM gel is accompanied by extensive blebbing as well as extension of processes (5-10 µm) that attach and pull together neighbouring cells.

Our results suggest that polymerized LAM in RBM is responsible for aggregation of PC12 cells. This homogenous cell line may prove a useful model for analyzing the cellular and molecular events in neural cell aggregation.

GLIAL-ASSOCIATED PROTEOGLYCAN 5B12 IS EXPRESSED UPON SUBSETS OF NERVE PROCESSES IN THE EMBRYONIC AND ADULT INSECT. M.R. Meyer*, P. Brunner*, and J.S. Edwards (SPON: R.M. Longley). Department of Zoology, NJ-15, University of Washington, Seattle, WA 98195.

Monoclonal antibody (MAb) 5B12 recognizes a M_r 185 kD chondroitin sulfate-like proteoglycan in the adult cricket that is associated with glial cells of the glial lacunar system (Meyer et al., *Soc. Neurosci. Abstr.* 13:1143, 1987) and glia which juxtapose sensory neurons in the periphery. In the embryo, 5B12 is expressed peripherally as a component of the basal lamina and upon processes of glial cells located in cercal sensory appendages. In both the embryonic periphery and adult glial lacunar system, antigen 5B12 is localized within the extracellular matrix (ECM).

In addition to the glial and ECM distribution of the antigen, we observe 5B12 in close association with distinctly neuronal elements in the embryonic and adult nervous system. In the early embryonic CNS, MAb 5B12 binds in a segmentally repeated fashion to both anterior and posterior commissural tracts. However, by ca. 50% development, expression is highly restricted to only a small subset of nerve fibers located at the ventro-anterior margin of the anterior commissures where 5B12 may be localized on the neuronal cell surface.

The adult nervous system contains distinct peripheral and central 5B12-immunoreactive fiber tracts. In the terminal abdominal ganglion, 5B12 is expressed in sensory, but not motor nerves, and labelling is associated with discrete neural elements within ganglionic commissures. We are correlating 5B12 expression with identity of specific embryonic and adult neurons in order to determine the role of the proteoglycan in the organization of the nervous system. Supported by NIH #NS-07778.

SCHWANNOMA CELL DERIVED INHIBITOR OF THE NEURITE-PROMOTING ACTIVITY OF LAMININ. D.Muir*, E. Engvall*, S. Varon, M. Manthorpe. (Spon: C. Wiley) Dept. of Biology, M-001, Univ. of Calif. at San Diego, La Jolla, CA. 92093

We have previously reported (J. Neurochem. 37:759-767,1981) that medium conditioned by rat RN22 schwannoma cells contains a polyornithine-binding neurite promoting activity (NPA) as well as another activity that interfered with neuritic growth. We and several other groups have demonstrated that the NPA of conditioned media is due to the glycoprotein laminin (LN). Here we have undertaken a study of the inhibitor of neuritic growth. Medium from radiosulfate-labeled RN22 cultures was fractionated by ion-exchange chromatography and the fractions and their western blots examined for NPA, LN and entactin immunoreactivities and for radioactivity. NPA was always associated with LN which co-eluted with entactin. We found fractions containing significant amounts of LN and entactin that were devoid of NPA. These inactive fractions also were inhibitory when mixed with isolated rat RN22 LN or yolk sac LN. The peak inhibitory fractions are highly anionic, heavily sulfated, have a high buoyant density and their inhibitory activity is destroyed by heparitinase. The inhibitor is also prevented from inactivating LN by; a) a monoclonal anti-LN antibody (2E8) which binds to the cross region of the LN molecule and does not block NPA,and b) polyclonal antibodies against entactin (a protein known to bind near the cross region of LN) also which do not block NPA. We propose that the NPA of LN is subject to regulation through association with entactin and proteoglycan. Supported by NSF BNS86-17034.

A *XENOPUS* GLIAL CELL LINE PRODUCES AN EXTRACELLULAR MATRIX WITH NEURITE OUTGROWTH PROMOTING ACTIVITY. D.S. Sakaguchi, C.R. Coffman*, and W.A. Harris, Dept. of Biology, B-022, UCSD, La Jolla, CA 92093

A glial cell line (XR1 cell line) isolated from *Xenopus* retinal neuroepithelium serves as an excellent substrate for neurite outgrowth from embryonic retinal explants. XR1 conditioned cell-free substrates were prepared to examine whether outgrowth-promoting activity was also associated with the extracellular matrix (ECM). Substrates of XR1 cells grown on collagen were still capable of promoting outgrowth following hypoosmotic shock and chemical extraction with Triton X-100. Collagenase and trypsin were used to examine the proteolytic sensitivity of components of the ECM and the promotion of neurite outgrowth. Both enzymes were effective in eliminating the outgrowth promoting activity of the XR1 conditioned substrates. Thus, although collagen alone was ineffective in supporting outgrowth, it may play an indirect role by acting as an effective support for attachment of other ECM components. Immunological and biochemical studies suggest that neither fibronectin nor laminin plays a role in this ECM promoted outgrowth. To identify molecules which mediate growth cone-glial cell interactions, polyclonal antibodies were generated against membrane components of the XR1 cells. An antiserum (NOB1) blocked neurite outgrowth on conditioned XR1 substrates in a dose dependent fashion. Identification of the active components associated with the neurite outgrowth promoting activity is currently being attempted using affinity depletion of the NOB1 antiserum and the production of monoclonal antibodies.

PATTERNS OF 2-DEOXYGLUCOSE UPTAKE REFLECT THE NEURAL PROCESSING OF LORDOSIS-INDUCING TACTILE STIMULI IN HAMSTERS. O. R. Floody and R. D. Lisk*. Dept. of Psychology, Bucknell Univ., Lewisburg, PA 17837 and Dept. of Biology, Princeton Univ., Princeton, NJ 08544.

Semi-quantitative [^{14}C]2-deoxyglucose (2DG) autoradiography was used to map the neural responses of female hamsters to lordosis-inducing flank stimuli. Specifically, the manual stimulation of one flank was used to maintain estrous females in lordosis for 20 min after an i.v. injection of 200 μ Ci/kg of 2DG. Hemispheric differences in 2DG uptake then were sought in brain nuclei previously implicated in the programming of lordosis, or in the processing of somatosensory or hormonal influences on this response.

The responses to lateralized flank stimulation included reliable contralateral elevations in 2DG uptake in the tectum, the dorsal mesencephalic central gray (dCG), and the ventral posterior lateral nucleus of the thalamus (VPL). The first two of these effects are consistent with much previous evidence implicating these areas in the mediation of somatosensory influences on lordosis and suggesting that these influences are strongly lateralized until at least this stage of neural processing. In contrast, elevated activity on the part of the VPL probably is not crucial for lordosis. Nevertheless, this effect, together with the absence of lateralized 2DG uptake by the gracile nuclei, suggests that lordosis-controlling somatosensory inputs to the brain traverse the anterolateral, not dorsal, spinal columns. On the other hand, the ability of dorsal column lesions to disrupt lordosis (Rose et al., Physiol. Behav., 31: 801, 1983) suggests that lordosis draws upon both of these systems, perhaps shifting from a reliance on dorsal column to anterolateral projections as lordosis duration increases. (Supported by MH-08070 and MH-33191 from the N.I.H. and by PCM-7812582 from the N.S.F.).

109.2

INHIBITION OF LORDOSIS IN INTACT FEMALE RATS FOLLOWING ADMINISTRATION OF SCOPOLAMINE. C. S. Menard and G. P. Dohanich. Tulane Univ., New Orleans, LA 70118.

Cholinergic antagonists, such as scopolamine (SCOP) and atropine, have been found previously to inhibit lordosis in ovariectomized rats, primed with estrogen and progesterone. The present study further examines this effect using intact cycling female rats. Cycling was determined by daily monitoring of sexual behavior and vaginal cytology. In Experiment 1, 19 female rats received, during natural estrous, bilateral ventricular infusions of either .5 ul saline solution, 10 ug SCOP/.5 ul saline solution, or 20 ug SCOP/.5 ul saline solution. Administration of both levels of SCOP was found to significantly inhibit lordosis behavior ($p < .0001$). In Experiment 2, 14 animals received, during natural estrous, IP administration of either .2 ml saline solution or 1 mg SCOP/.2 ml saline solution. Likewise, systemic administration of SCOP was found to significantly inhibit lordosis behavior ($p < .0001$). These results lend further support for the cholinergic regulation of sexual behavior. They also suggest that lordosis behavior induced in ovariectomized rats may be equivalent to that seen in intact females.

109.3

LORDOSIS RELEVANT PATHWAYS NEAR THE VENTRAL TEGMENTUM IN FEMALE HAMSTERS. E. Kouri* and J.F. DeBold. Department of Psychology, Tufts University, Medford, MA 02155.

In addition to the ventromedial nucleus of the hypothalamus, the ventral tegmental area (VTA) is an important site of progesterone action in the control of sexual receptivity in estrogen-primed female hamsters.

We investigated the connections of the VTA that are critical for progesterone's behavioral action by disrupting neural pathways with stereotaxically placed 4mm knife cuts. We used three different types of knife cuts: 90° horizontal cuts dorsal to the VTA, coronal cuts anterior to the VTA and cuts bi-lateral to the VTA in the sagittal plane. After an eight-day recovery period ovx. animals that did not show motor side-effects or weight loss were injected with 10 ug EB and then 500 ug P. The total lordosis duration (TLD) of experimental animals was compared to that of animals with appropriate sham cuts.

Knife cuts placed just dorsal to the VTA had the greatest inhibitory effect on TLD. The coronal cuts anterior to the VTA caused a moderate decrease in TLD, but there was no significant effect of the sagittal bi-lateral cuts.

The dorsal cuts disrupted dorsal afferents and efferents including those from the habenula and deep tectum. These connections may be required for the integration of sensory and hormonal stimuli that lead to the lordosis response.

Differential Roles of Alpha-1 and Alpha-2 Noradrenergic Receptors in Regulation of Lordosis Behavior in Guinea Pigs. P. A. Vincent, J. E. Thornton, H. H. Feder. Inst of Animal Behav, Rutgers Univ, Newark, NJ 07102

We examined whether blockade of alpha-1 and alpha-2 noradrenergic receptor subtypes has differential effects on hormone-facilitated lordosis behavior. All animals were given free estradiol (E2) at hr 0 and hr 28, followed by progesterone (P) at hr 39. Experiment 1: Animals were given a single injection of either the alpha-1 antagonist prazosin or the alpha-2 antagonist idazoxan (5 mg/kg, s.c.) 30 min before the E2 at hr 0, 30 min before the E2 at hr 28 or 30 min before E2 injection at hr 0 and hr 28. Prazosin, but not idazoxan, significantly blocked lordosis under each condition. Experiment 2: When idazoxan was given as repeated injections (i.e., 30 min prior to and 60 and 120 min after both of the E2 injections) blockade of lordosis still did not occur. Experiment 3: When idazoxan was given as a single injection to estrogen-primed guinea pigs at hr 38 (1 hr prior to the P) or at hr 44 (5 hr after P) lordosis was blocked only in those animals that received idazoxan at hr 44 (hr 44 coincides with the usual time of onset of lordosis). These data suggest that noradrenergic transmission through alpha-1 receptors mediates the hormone-priming process leading to lordosis facilitation. Apparently, transmission through alpha-2 receptors is not involved in the hormone-priming process but may mediate sensory input to hormone-primed neurons.

Identification of Cholinergic Cell Groups that Facilitate Sexual Behavior in Female Rats

Lynwood G. Clemens and David A. Brigham*
Dept. of Zoology and Neuroscience Program
Michigan State University, East Lansing, MI 48824

Estrogen facilitation of sexual receptivity in the female rat depends, in part, upon cholinergic stimulation of muscarinic receptors in the hypothalamus and/or the midbrain central gray. In the present study we provide evidence to suggest that the cells which produce the endogenous acetylcholine for this neuro-behavioral system are located in the laterodorsal tegmental nucleus (LDT) and in the pedunculopontine tegmental nucleus (PPT). Electrolytic lesions in either region completely abolished estrogen-progesterone induced receptivity. However, cholinergic agonists (eserine or oxotremorine), microinjected into the lateral ventricles, restored lordosis behavior in lesion females given low doses of estrogen. Both the LDT and PPT have been shown to contain choline acetyl transferase (CAT) staining cells (Satoh, et.al. 1983, Brain Res. Bull.). It is possible that these cell groups provide the cholinergic input necessary for estrogen facilitation of sexual behavior.

HYSTERECTOMY COUPLED WITH CERVIECTOMY SUPPRESSES RECEPTIVITY FOLLOWING ESTRADIOL BENZOATE PLUS PROGESTERONE IN RATS. J.A. Witcher*, C.F. Donahue*, W. Michener*, and N.T. Adler. Dept Psych, Univ Pennsylvania, Philadelphia, PA 19104

This study investigates how the female reproductive tract may interact with the dose-dependent, facilitatory actions of the ovarian steroids to permit receptivity. The female reproductive tract was altered in three surgical groups; (1) ovaries were removed sparing the uterine horns and cervix (OVX), (2) ovaries and the uterine horns were removed while sparing the cervix (HYS), and (3) the ovaries, the uterus, and the cervix were removed (CVX). Three weeks after surgery, rats were treated with a range of estradiol benzoate (EB) doses plus progesterone (P4). For 5 consecutive weeks females were treated with a 4-day regimen: EB on days 1-3, plus P4, on day 4. During weeks 1-5; 0.175, 0.175, 0.35, .5 and 1.0 ug EB respectively, were administered. On day 4, P4 (0.5 mg) was injected 4-6 hr before testing for receptivity. During behavioral testing a male was allowed 10 mounts while incidence of lordosis was observed, and a lordosis quotient (LQ) was calculated. All groups displayed a dose-dependent response in LQ to the range of EB doses used. CVX rats displayed a lower LQ than OVX and HYS rats following 0.35 ug EB priming. Since all groups displayed an EB dose-dependent response of receptivity, the suppressed LQ in CVX rats indicates a possible regulatory role for the cervix. Following ovarian hormone exposure the cervix may act as a "filter" for the CNS by modulating reproductively relevant somatosensory stimulation. (Support NIH HD04522 to NTA)

ELECTRICAL STIMULATION OF THE MIDBRAIN ELICITS SHORT- AND LONG-LATENCY PROCEPTIVE PRESENTING IN THE FEMALE MONKEY. S. Aou*, Y. Oomura, A. Takaki*, E. Okada* and Y. KOYAMA* (SPON: K. Yamaguchi). Natl. Inst. Physiol. Sci., Okazaki 444, Japan.

Recently we have reported that single train electrical stimulation (50 Hz, 2.5 sec) of the ventromedial nucleus of the hypothalamus elicits proceptive presenting (active solicitation to a male partner) with latency ranged from 1.3 to 17.7 s in the female monkey (Koyama, Y. et al. Brain Res., 446: 199, 1988). The midbrain central gray and the adjacent tegmentum are known to have close connection with the hypothalamus. Since they are involved in regulation of sexual behavior in various mammalian species, we studied effects of midbrain electrical stimulation (0.2 ms, 50 Hz, 2.5 sec, 50-500 μA) on sexual behavior. Two ovariectomized, estrogen-treated female rhesus monkeys and their male partners were kept and used in accordance with the NIH Guide (1985). Two types of presenting responses were evoked after stimulation of the ventral part of the central gray and the adjacent tegmentum. One was elicited with short-latency (≤15 s) and was similar to that in case of hypothalamic stimulation. The other, with longer latency (>15 s), included long-lasting period of repetitive presenting. The present study suggests that at least two neural components are involved in regulation of proceptive presenting in the midbrain of the female monkey.

109.8

FACILITATION OF FEMALE SEXUAL BEHAVIOR BY THE PROGESTIN RECEPTOR ANTAGONIST RU 38486. E.T. Pleim*, P.J. Cailliau*, M.A. Weinstein*, A.M. Etgen[1], and R.J. Barfield. Dept. Biol. Sci., Rutgers Univ., Piscataway NJ and [1]Albert Einstein Coll. Med. Bronx NY

The progestin receptor antagonist RU 38486 (RU 486) was tested for facilitative effects on female receptive behavior in 44 ovariectomized Long-Evans rats primed (sc) with a low dose (2 μg) of estradiol benzoate. 0, 0.5, 1.6, or 5.0 mg of RU 486 (sc) was administered 48 hours after estrogen priming. Lordosis quotient (LQ) and lordosis score (LS) were assessed 4 hours after RU 486 administration in a 10 mount test with stud male rats. 5 mg RU 486 acted as a weak facilitator of female sexual behavior. Lordosis measures were elevated above control levels in a dose-dependent manner, but subjects did not display the high levels of proceptive behavior seen with progesterone (P) facilitated receptivity.

Because in previous studies of RU 486 inhibition of P facilitated receptivity RU 486 facilitation was not seen, we tested 5 mg RU 486 *vs* vehicle pretreatment followed after one hour by 500 μg P or sesame oil (replicating RU 486 inhibition studies) or a no-injection, no handling condition (as in the dose-response study). In all RU 486 pretreatment conditions, considerable receptivity was seen, though lordosis measures were lower in the RU 486 + P group than in the vehicle + P condition, and little proceptive behavior was seen.

These studies indicate that although an excess of RU 486 diminishes P facilitation, the progestin receptor antagonist has significant facilitating properties of its own. Further study of P *vs* RU 486 induced receptivity and proceptivity, and the interaction of these steroids with neuronal steroid receptors, may help elucidate the mechanism(s) through which progesterone acts to affect female sexual receptivity.

109.9

GABA MEDIATION OF LORDOSIS IN THE RAT. M.M. McCarthy, K.F. Malik (SPON: Jennifer Swann) Institute of Animal Behavior, Rutgers University, Newark, NJ 07102.

The role of GABA in mediating lordosis in the rat remains unclear. Conflicting reports suggest that enhanced GABAergic activity in the HYP may increase, decrease or have no effect on lordosis. We report here that GABA does play a role in mediating lordosis and has differential effects in the VMN and POA. Adult, ovx'd female Sprague-Dawley rats were bilaterally cannulated into the VMN or POA. After priming with EB (10ug;48hr) and P (1.0mg;4hr) females were pretested with a male for 10 mounts. Females with an LQ>60% were then infused with saline or bicuculline (BI) in the VMN (10ng/.25ul/cannula) or POA (10ng/.5ul/cannula). There was a significant decrease in LQ in females receiving BI into the VMN at 10 and 30min post-inj. (LQ=0% at 10', LQ=40% at 30', t-test;$p<.01$). Females receiving BI in the POA did not show a significant decrease in LQ post-inj.In a second experiment, females in EB-induced heats (30ug/day for 5 days) received BI in the VMN (10ng/.25ul/cannula) and showed a similar pattern of inhibition (LQ at 10'=8.8%; 30'=48%, $p<.01$). In a third experiment, females in EB+P heats received muscimol in the POA (25ng/.25ul/cannula) resulting in significant inhibition of lordosis (LQ at 10'=34%;$p<.01$:LQ at 30'=73%;$p<.05$). These results indicate that high GABAergic activity in the VMN facilitates lordosis, whereas high GABAergic activity in the POA inhibits this behavior. INHIBITION OF LORDOSIS IN RATS AND HAMSTERS BY MUSCARINIC ANTAGONISTS. G. Dohanich, R. Holland*, M. McMullan*, A. Piazza*, and D. Cada*. Dept. of Psychology, Tulane Univ., New Orleans, LA 70118.

Hormonal control of lordosis may be mediated by central neurotransmitter systems including acetylcholine. In a series of experiments, muscarinic receptor blockers were infused bilaterally in 0.5 ul volumes of saline into the lateral ventricles of ovariectomized rats and hamsters that had been induced into behavioral receptivity by treatment with estradiol benzoate and progesterone.

Scopolamine, a lipophilic muscarinic antagonist, inhibited the frequency of lordosis in rats (5, 10, and 20 ug/cannula) and reduced the duration of lordosis in hamsters (10 and 20 ug/cannula) 15 min. after infusion. Pirenzepine, a hydrophilic muscarinic M1 antagonist, did not inhibit the frequency of lordosis in rats (5, 10, and 20 ug/cannula). Methylscopolamine, a hydrophilic muscarinic antagonist, inhibited lordosis as effectively as the lipophilic scopolamine following intraventricular infusion (5 and 10 ug/cannula) despite differences in the lipid solubility and receptor affinity of the compounds.

Results indicate that muscarinic antagonists inhibit the display of lordosis in female rats and hamsters. The effectiveness of muscarinic antagonists appear to be related to subtype specificity but not lipid solubility.

INTRACRANIAL IMPLANTS OF DILUTED ESTRADIOL: INDEPENDENT EFFECTS ON FEEDING AND REPRODUCTIVE BEHAVIORS P.C. Butera & R.J. Beikirch*. Dept. of Psychology Niagara University, NY 14109

This study examined the effects of central implants of diluted estradiol (E2) on feeding, body weight, and sexual behavior in ovariectomized rats. Thirty-three adult females were implanted with bilateral double-walled cannulae in either the paraventricular nucleus (PVN), medial preoptic area (MPOA), or posterior hypothalamus (PH) and stimulated unilaterally with cholesterol (CHOL) and E2. Females that received PVN implants were stimulated with either undiluted E2, a 3:1, or 10:1 mixture of CHOL and E2. Animals in the other groups received undiluted E2.

Compared to CHOL implants, undiluted E2 in the PVN reduced food intake and body weight. More importantly, diluted E2 implants in the PVN significantly lowered food intake and body weight. In contrast, undiluted E2 in the MPOA, PH, or VMH had no significant effects on feeding or body weight. Analysis of variance revealed a significant main effect of implant location on lordosis quotients. A Newman-Keuls test indicated that diluted E2 implants in the PVN produced lordosis quotients that were significantly lower than those obtained with undiluted E2 in the VMH.

These findings suggest that the effects of E2 on food intake are mediated by its actions in the PVN, whereas effects on reproductive behavior involve actions of E2 in the VMH. (Supported by NIMH MH42127)

RAPID, LOCAL EFFECTS OF PROGESTERONE ON THE ACTIVITY AND SENSORIMOTOR PROPERTIES OF SUPERIOR COLLICULUS NEURONS RECORDED IN BEHAVING HAMSTERS DURING THE HORMONAL INDUCTION OF LORDOSIS. J. D. Rose. Department of Psychology, University of Wyoming, Laramie, WY 82071.

Research in this laboratory has shown that systemic progesterone (P) administration to estrogen-primed golden hamsters initiates cumulative changes in the activity level and sensorimotor function of superior colliculus (SC) neurons over the 2-4 h prior to the emergence of lordosis responses. In the present study, crystalline P was applied directly to the SC with a removeable cannula, near an array of chronically-implanted microwire electrodes. This method was used to identify direct, as opposed to anatomically remote, actions of P on the dorsal midbrain. P implantation produced changes, within seconds or minutes, in the activity level, movement-related firing and somatosensory responsiveness of SC neurons near the implant. P effects on these neurons entailed either suppression or enhancement of activity and sensorimotor function and were thus similar to effects previously seen with systemic P injection. However, the local effects of P were sometimes antagonized by subsequent systemic P. These results demonstrate that P can act locally on midbrain neurons to alter their sensorimotor function. The rapidity of some of the P implant effects suggests a non-genomic mechanism. Supported by NIH Grant NS13748.

IODOACETAMIDE ENHANCES TRANSMISSION AT PERFORANT PATH AND SCHAFFER COLLATERAL-COMMISSURAL SYNAPSES IN THE GUINEA-PIG HIPPOCAMPAL SLICE BY A POST-SYNAPTIC MECHANISM. J. Waalen* & P. Lipton (SPON: D. Gilboe). Dept. of Physiol., Univ. of Wisc., Madison, WI 53706.

The sulfhydryl reagent iodoacetamide (IAM) profoundly enhances synaptic transmission in hippocampal dentate granule cells and CA1 pyramidal cells prior to inhibiting glycolysis.

Paired pulse inhibition studies show IAM's excitatory effect is not due to blockade of inhibitory transmission. Paired stimuli were applied to the perforant path and population spikes were measured in the dentate granule cell layer. IAM increased the size of the first spike but decreased the size of the second spike; this contrasts with the effect of GABA blockade by 10μM bicuculline which causes a large increase in the size of the second spike.

Extracellular and intracellular recordings show that IAM increases excitability of the post-synaptic cells. Extracellularly, IAM enhances the evoked population spike without changing the size of the field EPSP. Intracellularly, IAM increases the probability of evoked spike generation in CA1 pyramidal cells while decreasing the associated EPSP; it decreases both input resistance and the ability of injected depolarizing current to generate a spike. Thus IAM specifically enhances the spike-generating capability of synaptically evoked EPSP's.

GENERATION OF A NOVEL SLOW EPSP IN THE FROG SYMPATHETIC GANGLIA. Parviz Yavari* (SPON: M. Shelanski). Dept. Physiol & Cell. Biophys., Columbia Univ. CPS, New York, NY 10032.

Several electrophysiologically interesting postsynaptic potentials (PSP) can be elicited in the frog sympathetic ganglion by suitable stimulation of the preganglionic inpu ts (Weight, F. Autonomic Ganglia:309, 1983). These include the nicotinic fast excitatory PSP (EPSP), muscarinic slow EPSP and slow inhibitory (IPSP), and the peptidergic late slow EPSP. Here I describe a slow synaptic excitation in the bullfrog Rana catesbeiana 9th or 10th paravertebral sy mpathetic ganglia which appears to be distinct from the pre viously known PSPs in this ganglion (recorded by the sucro se-gap method). It is generated by tetanic stimulation (w/ trains at as low a freq. as 7 Hz) of the sympathetic chain between the 6th & 7th ganglia with stimuli supramaximal (normally at twice the strength) for the B fiber pathway activation. The macroscopic slow EPSP generated by such sti muli has an early fast-rising component (the muscarinic sl ow EPSP) which overlaps with a slowly-rising, long-lasting component-- a second hump (a non-cholinergic slow EPSP sin ce it persists in Ringer containing curare and high doses of atropine or pirenzepine). The transmitter/pathway for the novel EPSP is not known at present, but it may involve the Substance P- or CGRP-containing fibers seen in the frog S. chain recently (Jan&Jan, J. Physiol 327:219,1982; Horn & Stofer, SN 13:297,1987). The pathway and neurotransmitter for novel slow EPSP is being studied by intracellular reco rding and the use of peptidergic agents.

110.3

CHARACTERISTICS OF MINIMAL FEED-FORWARD IPSPs IN GUINEA PIG CA1 PYRAMIDAL NEURONS. D.A. Turner. Neurosurgery, Univ. of Minnesota and VAMC, Minneapolis, MN 55455.

Stimulation of stratum radiatum (SR) afferents evoked intracellular synaptic responses (<1 mV), many of which were hyperpolarizing and inhibitory. Response ensembles showing clear separation of the hyperpolarizing IPSPs from EPSPs were analyzed for time to onset, waveform parameters and stationarity (n=39 ensembles in n=69 CA1 neurons).

Time to onset of the SR IPSP following the stimulus artifact ranged from 1.4 to 7.5 ms and averaged 3.20±1.53 ms (mean±SD). Responses evoked from proximal SR, distal SR or antidromic stimulation (DA Turner, J. Physiol. 295:419) were not different in terms of amplitude (0.49±0.27 mV) or 10-90% risetime (7.88±6.40 ms). The distal halfwidth was longer than the proximal: 52.0±36.0 ms and 38.1±21.3 ms, compared to a typical antidromic response with halfwidth of 28.9 ms. Response ensembles less than 1.0 mV in magnitude showed no trends in peak amplitude or waveform parameters at stimulation rates of 1.0 or 2.0 Hz.

The minimal stimulation intensity (no detectable field potential), rapid time to onset, hyperpolarizing polarity and long time course all strongly suggest that these responses are direct, feed-forward IPSPs onto CA1 pyramidal neurons. The divergence of proximal SR, distal SR and antidromic evoked waveforms indicates the probable recruitment of a different group of feed-forward interneurons for each site. Supported by a VA Research Service award and a B.S. Turner Foundation award.

LTP AND PAIRED-PULSE FACILITATION AFFECT DIFFERENTIALLY THE NMDA RECEPTOR MEDIATED COMPONENT OF SYNAPTIC RESPONSES. D. Muller and G. Lynch. Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

A significant component of the synaptic responses evoked in field CA_1 of hippocampal slices can be identified as reflecting currents through NMDA receptor associated channels when using low magnesium concentrations (10-50 μM), the selective antagonist D-2-amino-5-phosphonovalerate (D-AP5), and a "priming" paradigm to suppress the fast IPSPs that usually truncate synaptic responses in hippocampus. "Priming" was accomplished by stimulating one of two groups of afferents to a common dendritic field 200 ms prior to stimulating the second test input. Under these conditions application of D-AP5 (50-125 μM) caused in 19 experiments a 28 ± 1% reduction in area of field EPSPs. When two pulses separated by 50 ms were delivered to the test input, the size of the second response was 57% larger than that of the first response, an effect referred to as paired-pulse facilitation and that results from increased transmitter release. Interestingly, the NMDA receptor mediated component of the facilitated response then represented a greater percentage of the total area of the EPSP (32 ± 1%; n=13), thereby indicating that facilitation affected to a greater degree NMDA than non-NMDA components of synaptic responses. In contrast, LTP, which in 14 experiments resulted in a 51% increase in response area, was not accompanied by a similar change. The D-AP5 sensitive component represented only 22 ± 1% of the area of the potentiated response, indicating that potentiation affected to a greater degree non-NMDA than NMDA components of synaptic responses. These results considerably restrict the number of possibilities concerning the mechanism of long-term potentiation and strongly argue against the idea that the potentiation effect might be related to increased transmitter release.

EXTRACTION OF QUANTAL INHIBITORY EVENTS FROM SYNAPTIC NOISE IN HIPPOCAMPAL NEURONS. N. Ropert and H. Korn. Lab. Neurobiologie Cellulaire, INSERM, Institut Pasteur, Paris.

Spontaneous activity was recorded intracellularly from CA_1 pyramidal cells In Vitro in order to characterize inhibitory quantal events which contribute to build up synaptic noise in central neurons. In such conditions IPSPs were unlikely to be contaminated by excitatory potentials or large field effects. Fluctuating unitary IPSPs were easily distinguished; their frequency and amplitudes were reduced by TTX, which eliminated large responses, leaving only small depolarizing potentials of about equal size, presumed to represent inhibitory quantal events. Indeed these miniature potentials shared common properties with larger IPSPs, such as the unitary ones or the alveus-evoked population IPSP: 1) they had comparable time courses, 2) they were Cl^- dependent and abolished by picrotoxin, and 3) their apparent reversal potentials were the same. Using the latter to assess E, the driving force for Cl^-, the quantal conductance was calculated from the relation: $g_{ipsp}=(V/E)*G_m$, were V and G_m stand for the recorded potential and the input conductance of the cell. Values of 0.5 to 1 nS were found; if each open Cl^- channel has a conductance of 25 pS, no more than 20 to 40 channels should be involved in such a quantal response.

CONDITIONING-LIKE OPERATIONS ARISING FROM SIMULATION OF VOLTAGE-DEPENDENT ADAPTIVE PROPERTIES OF A NEURONAL MEMBRANE CURRENT. R.G. Pay and C.D. Woody, UCLA Medical Cntr, Los Angeles, CA 90024.

Some neuronal mechanisms underlying conditioning are supported by modifications of membrane ion currents (Alkon, Science, 1979). Earlier simulations of conditioning have emphasized operations of adaptive networks. We tested the hypothesis that conditioning-like operations could be accomplished by means of a single element with adaptive properties resembling those of an ionic conductance. Adaptation based on changes in a rapidly activated and inactivated, voltage-dependent current, much like an A-current, resulted in selective enhancement of signal transmission analogous to that found in cortical neurons following conditioning (Woody and Black-Cleworth, J. Neurophysiol., 1973;Woody et al., Soc. Neurosci. Abstr., 1987). An important feature of the simulation was that adaptation did not depend on modifying a passive resistance in the signal path but on varying a local current that responded to fluctuations about a reference potential. The current was activated by depolarization, inactivated by sustained depolarization, and potentiated by preceding hyperpolarization. The voltage-dependent operations were expressed by current-voltage curves of general exponential form. Simulated CS-US presentations yielded a learning curve analogous to that found with mammalian conditioning. Efficacy of conditioning varied with interstimulus interval with an optimum between 150-300 ms. Conditioning did not occur when the US preceded or coincided with the CS. Conditioning was more efficacious as CS amplitude increased. Outcomes of the simulation demonstrated enhancements of postsynaptic potentials elicited by the CS.

110.7

NMDA RECEPTOR-MEDIATED BURSTING IS INCREASED BY ELEVATED $[K^+]_O$ AND K-CHANNEL BLOCKADE. N.P. Poolos and J.D. Kocsis. Dept. of Neurology, Yale University and Center for Neuroscience and Regeneration, West Haven VA Hospital, West Haven, CT 06516.

We investigated the response of rat CA1 hippocampal pyramidal cells to single and paired orthodromic stimuli under conditions of elevated extracellular potassium ($[K^+]_O$) and K-channel blockade by TEA to assess the influence of NMDA receptor-mediated conductances on the EPSP and burst firing. EPSP amplitude was assessed before and after application of the selective NMDA blocker DL-APV (50-100 μM).

Elevated $[K^+]_O$ (4-9 mM) revealed an NMDA receptor-mediated component of the EPSP following a single stimulus which increased with higher $[K^+]_O$. EPSP facilitation and burst firing could be induced by paired stimuli. Facilitation and bursting became more prominent and increasingly sensitive to blockade by APV in elevated $[K^+]_O$. With normal $[K^+]_O$ (3 mM), TEA (1 mM) produced a facilitated EPSP following a single stimulus that was not sensitive to APV; however, following paired stimuli, the resultant burst firing was greater than in normal solution, and significantly reduced by APV. These results show that NMDA receptor-mediated postsynaptic activity in hippocampal pyramidal cells is sensitive to small changes in $[K^+]_O$ and TEA-sensitive repolarization, both of which may occur during repetitive activity.

110.8

MEMANTINE MIMICS THE EFFECTS OF PHENYTOIN, BUT NOT OF BACLOFEN IN SPINAL CORD NEURONS IN CULTURE. R.Netzer*, R.Koch*, H.Bigalke* (SPON: P. Sonderegger). Dept. Pharmacol. Toxicol., Med. School Hannover, 3000 Hannover 61, FRG, R.K. Merz & Co., 6000 Frankfurt 1, FRG.

The antiepileptic agent phenytoin blocks repetitive firing in spinal cord neurons by a use-dependent block of Na^+ channels (McLean, M.J. et al., J.of Pharmacol. and Experimental Therapeutics,Vol. 227: 779, 1983), whereas baclofen, an antispastic agent, inhibits pre- and postsynaptic events (Howe, J.R. et al., J.Physiol. 384:539, 1987). The mode of action of memantine, used in the treatment of spasticity from different sources, is widely unclear. We have compared effects of the three drugs on the bursting activities in cultured spinal cord neurons.

Convulsants, like strychnine, tetanus toxin and picrotoxin elicited burst- like activities in mouse spinal cord cultures similar to hyperactivities of seizure-producing nerve cells. The membrane potential depolarized by about 30 mV, accompanied by rapid firing of action potentials. Pressure perfusion of the cells with memantine (10 - 100 μM) decreased the duration of bursts from 1,3 s to 0,4 s and the firing rate from 30 Hz to 10 Hz. The onset of the effects were fast and reversible. The drug did not have any effects on the firing pattern and spontaneous synaptic activity in cultures not treated with convulsants. Phenytoin (1 - 10 μM) mimicked the block of action potentials in the bursting cells, whereas baclofen (10μM) decreased the frequency of the burst from 11/min to 4/min, leaving its duration and the frequency of action potentials within the bursts unaffected. Memantine, similar to phenytoin, thus appears to curb mainly hyperactive neurons, probably by an interference with the sodium channel.

110.9

ANALYSIS OF THE ANTIEPILEPTOGENIC ACTION OF BACLOFEN. ***B. Ault and C.M. Wang. Dept. of Pharmacology, Burroughs Wellcome Co., RTP, NC 27709, U.S.A.**

The $GABA_B$ receptor agonist baclofen inhibits bicuculline (BIC)-induced epileptiform activity in the CA3 region of the hippocampal slice at sub-micromolar levels. While micromolar doses of baclofen increase a potassium conductance and hyperpolarize hippocampal pyramidal cells, the mechanism of action at lower doses is unclear. We have now examined the effect of baclofen upon CA3 pyramidal cells at antiepileptogenic concentrations.

Submerged transverse hippocampal slices of 425 μ thickness were superfused with Elliott's medium (K^+ 5mM; Ca^{2+} 1.3 mM) containing 50 μM BIC. Intracellular and extracellular recordings were made of population burst discharges in area CA3. Application of 0.1 μM baclofen inhibited bursting by 68 ± 8% (N = 9) with no measurable change in V_m or R_m. As the frequency of bursting decreased, the burst duration increased: a similar effect was noted with varying rates of electrical stimulation. Baclofen (0.1 μM) did not significantly affect (i) the duration of stimulation-evoked bursts, (ii) the burst AHP or (iii) spike firing during a 250 ms depolarizing pulse. 1.0 μM Baclofen hyperpolarized CA3 neurons and reduced all of the above measures.

Since baclofen can inhibit burst discharges without altering passive or active pyramidal cell properties measured at the soma, the site of this action is likely to be the distal dendrites or presynaptic terminals.

110.10

EFFECTS INDUCED BY VALPROIC ACID ON THE IONIC CURRENTS IN CULTURED RAT CORTICAL NEURONS. C. Zona, G. Pirrone*, M. Avoli. Lab. Fisiologia Umana, Università "Tor Vergata", Roma, Italy and MNI, Montreal, Canada.

The effects induced by the antiepileptic drug valproic acid (VPA) were studied in rat neocortical neurons in culture by using the whole cell patch clamp technique. VPA was applied by pressure ejection. When the inward currents were selectively blocked by the addition of TTX (5 uM) and Cd (200 uM) in the bath, the application of VPA (1 - 5 mM) had no effect on the remaining outward currents. Instead, when K currents were blocked (Cs and TEA in the electrode, 4-AP (2 mM) in the bath), VPA (1 mM) modified the inward currents evoked by depolarization commands. The early component which was sensitive to TTX and therefore was carried by Na ions, was decreased by VPA. On the contrary, the late inward component which was blocked by Cd, was increased by VPA. These results demonstrate that the antiepileptic drug VPA affects selectively the inward currents in rat neocortical cells in culture.

110.11

SYNAPTIC POTENTIATION AND EPILEPTOGENESIS IN THE CA3 REGION OF THE IN VITRO HIPPOCAMPUS. W.H. Griffith and L.Taylor*. Dept of Medical Pharmacology and Toxicology, College of Medicine, Texas A & M University, College Station, TX 77843.

Short-term excitatory synaptic potentiation was studied in hippocampal CA3 neurons using single electrode voltage-clamp (SEVC) techniques in the rat in vitro slice preparation. Mossy fiber excitatory postsynaptic currents (EPSC) were studied in the presence of 10 μM picrotoxinin (2.5 mM Ca^{2+}, 4 mM Mg^{2+}). Repeated trains of electrical stimulation of the mossy fibers (100 Hz for 0.5 - 1 sec) produced episodes of posttetanic potentiation (PTP) that eventually led to paroxysmal depolarizing shift (PDS) firing. Characteristics of PTP of the mossy fiber synapses included potentiation of 100-150% with a time constant of decay (τ_d) between 50-70 sec. The τ_d of individual EPSCs did not change after PTP and were 90-110% of the control value (n = 5). After high frequency stimulation spontaneous EPSCs were sometimes observed that were not recorded before PDS development. The range of τ_d of spontaneous EPSCs was 1.5 - 3 ms at membrane potentials near rest (-60 to -80 mV). Conversion of single synaptic responses to network-driven synchronization may involve, in part, presynaptic mechanisms that recruit populations of cells to fire in unison.

110.12

FUNCTIONAL IMPLICATIONS OF BURST FIRING IN MAMMALIAN NEURONS. Hilarey R. Feeser and David A. McCormick. Section of Neuroanatomy, Yale Univ. School of Medicine.

Neurons in the mammalian brain often display two basic firing patterns: single spike or burst activity. The functional consequences of neuronal burst firing on the responsiveness of neurons to synaptic inputs was investigated through intracellular recordings of relay neurons in the guinea pig lateral geniculate slice, maintained in vitro. Intracellular injection of short (2.5-5 msec) depolarizing current pulses or the local activation of EPSPs with the cell at Vms negative to -70 mV resulted in bursts of 3-6 action potentials (Jahnsen and Llinas, J. Physiol. 349:205-247). The amplitude and duration of the low threshold Ca^{++} spike underlying these bursts declined in response to increased frequency of activation such that the output of the neuron fell to near zero with inputs of greater than 6-10 Hz. In addition, during periods of artificially imposed rhythm generation, activation of EPSPs was relatively ineffective in generating additional neuronal action potential output. These limitations appear to be due to the kinetics of the major currents (e.g. t-current) underlying burst firing. In contrast, at Vms positive to -60 mV, the same inputs could generate action potentials faithfully at frequencies of up to 200 Hz. These results help to explain why rhythmic burst firing in vivo (such as during slow wave sleep) is associated with a decrease in the faithfulness with which synaptic inputs are transferred to target neurons.

A SLOW REGENERATIVE DEPOLARIZING POTENTIAL IN CELLS IN DEEP LAYERS OF RAT PIRIFORM CORTEX. G.-F. Tseng and L.B. Haberly, Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706

Cells in layer III of piriform cortex and the underlying endopiriform nucleus were studied in 500μm thick slices cut perpendicular to the surface. When deep cells were held at depolarized membrane potentials, a slow depolarizing potential could be triggered by subthreshold depolarizing current pulses. When current pulses were of brief duration, the depolarizing potential grew in amplitude after current offset, thus revealing a regenerative nature. Addition of 2mM Ba^{2+} with 1μM TTX to the bathing medium greatly accentuated the slow depolarizing potential. In the presence of Ba^{2+} and TTX, the slow depolarizing potential triggered long duration spikes. Co^{2+} blocked the slow regenerative potential in both normal bathing medium and Ba^{2+}. In cells with a weak Ca^{2+} activated K^+ conductance, the depolarizing potential was sustained for up to 20s. These results suggest that the regenerative potential is mediated by a high threshold, non-inactivating Ca^{2+} conductance (see Constanti et al, Pflügers Arch.404:259). Injection with Lucifer Yellow revealed that this conductance is present in both deep pyramidal and multipolar cells. Slow regenerative potentials were not observed in layer II pyramidal cells (n=25). In recordings with Lucifer Yellow-containing pipettes, the regenerative potential was increased in amplitude and duration, apparently as a consequence of an increase in input resistance and membrane depolarization that were consistently observed following leakage of the dye and Li_2SO_4 electrolyte into the cell. In these recordings, the regenerative potential could evoke action potentials at a latency up to 250ms following the triggering current pulse or 'SP.

The slow regenerative potential may explain, in part, the long latency, very high amplitude paired shock facilitation displayed by deep cells (Tseng & Haberly, Soc. Neurosci. Abs. 13:156) and the long latency, all-or-none EPSP induced by bursting (W.H. Hoffman & L.B. Haberly, this vol.). Supported by grant NS19865 to LBH.

110.14

THE DEEP PIRIFORM CORTEX IS THE SITE OF GENERATION FOR LONG-LATENCY EPSPS INDUCED BY BURSTING ACTIVITY. W.H. Hoffman* and L.B. Haberly (SPON: A. Berman) Neurosci. Training Prog. and Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

Bursting activity in slices of rat piriform cortex induces long-latency EPSPs in layer II pyramidal cells that can persist for the duration of experiments (up to 10 hr) (W.H. Hoffman & L.B. Haberly, Soc. Neurosci. Abs. 13:1101). These EPSPs occur in all-or-none fashion with a discrete threshold, but are variable in amplitude within a narrow range. Studies of properties of layer II pyramidal cells failed to reveal changes that could underlie development of late EPSPs. The hypothesis was therefore tested that cells in the deep layers of piriform cortex (layer III and the endopiriform nucleus) contribute to generation of bursting-induced, late EPSPs. Standard intracellular recording methods were employed. Bursting was induced by 10-25 min of perfusion with 0 Mg^{2+}; experiments were begun 5-15 min after return to normal bathing medium. Findings in support of the hypothesis include the following: 1) Late EPSPs still occurred after isolation of piriform cortex from adjacent cortical and subcortical structures. 2) Late EPSPs occurred in deep cells, were higher in amplitude than in layer II cells, and consistently evoked action potentials. 3) In small vertical segments of cortex, late EPSPs could occur in deep cells, but not in layer II cells. 4) Microinjection of 10mM Co^{2+} into deep layers could block late EPSPs in layer II cells without affecting the strength of monosynaptic EPSPs evoked by association fiber stimulation. This evidence indicates that bursting-induced late EPSPs are generated by deep cells and synaptically transmitted to layer II pyramidal cells. It can be postulated that the delay in the late EPSP is a consequence of the slow regenerative depolarizing potential in deep cells (G.-F. Tseng and L.B. Haberly, this volume). Supported by NINCDS grant NS19865 to LBH.

POSTSYNAPTIC MECHANISMS II

111.1

ACTIONS OF PUTATIVE NEUROTRANSMITTERS IN THE HUMAN CEREBRAL CORTEX, IN VITRO. Anne Williamson, Dennis Spencer and David A. McCormick. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

The ionic actions of some putative neurotransmitters were investigated using the in vitro slice technique on cerebral cortical tissue removed from patients for the treatment of intractable epileptic seizures. Local stimulation of synaptic inputs to presumed pyramidal neurons resulted in an EPSP followed by two phases of IPSP. The early IPSP was brief in duration, displayed a substantial increase in membrane conductance (65 nS), was mimicked by application of GABA, reversed polarity at -69 mV (which was very sensitive to intracellular injection of KCl), and was blocked by the $GABA_A$ antagonist bicuculline. The late IPSP, in contrast, was longer in duration, displayed a smaller increase in membrane conductance (14 nS), reversed near presumed E_K (-94 mV) and was substantially reduced by local application of the $GABA_B$ antagonist phaclofen. Application of ACh or the muscarinic agonist MCh resulted in a hyperpolarizing, depolarizing sequence which showed all of the properties reported previously for guinea pig cerebral cortex. NE caused a reduction in the slow AHP and/or a slow depolarization. Glutamate caused rapid depolarizations which did not display prominent voltage dependence. These results indicate that actions of classical neurotransmitters in the human cerebral cortex are similar to those previously reported in lower mammals.

111.2

VOLTAGE-CLAMP STUDY OF RAT CHROMAFFIN CELLS (CCs) AND THEIR RESPONSE TO MUSCARINE. A. Neely*+ & C.J. Lingle. Dept. Anesthesiol., Wash. Univ. Sch.Med., St. Louis, MO 63110; +Dept. Biol. Sci, FSU, Tallahassee, FL 32306.

We are interested in the basic electrophysiological properties of rat adrenal CCs and their possible modulation by secretagogues. Muscarine appears to induce secretion from rat CCs by releasing Ca^{+2} from intracellular stores following phosphoinositide breakdown (Malhorta et al., J.Biol.Chem., 5:2123).

Whole-cell patch clamp recording of primary cultures of rat CCs reveals a prominent Na-current and one, sustained component of Ca-current. Outward currents are dominated by voltage-dependent, Ca-activated K-currents. Single-channel recording reveals at least 3 types of voltage-dependent K-channels. Muscarine suppresses spontaneous action potentials in these cells. 0.5-50 μM muscarine induces a slow outward current. This response persists in 5 mM $CoCl_2$. Voltage ramps during the response show that the major conductance increase is voltage independent and reverses around E_K. This is consistent with activation of a voltage-independent, Ca-dependent, outward K-current subsequent to the muscarine-induced increase in intracellular Ca. (supported by AHA & DK-37109)

111.3

PRETREATMENT WITH THE PARTIAL AGONIST DECAMETHONIUM (C_{10}) ENHANCES CARBACHOL-INDUCED DESENSITIZATION. L.M. Coniglio* and R.L. Parsons (SPON: W. Pendlebury). Department of Anatomy and Neurobiology, University of Vermont, Burlington, Vermont 05405.

Brief exposure to a conditioning dose of carbachol (10uM) accelerates the desensitization produced by subsequent exposure to higher doses of carbachol (162-756uM) (Fiekers et al., J. Physiol. 391: 109-124, 1987). The present study was done to test whether pretreatment with other nicotinic agonists, especially partial agonists, also accelerates carbachol-induced desensitization. Carbachol-induced desensitization was studied in snake twitch muscle fibers maintained in a isotonic potassium propionate solution and voltage-clamped to +50mV. Carbachol induced a transient outward current which peaked within a few seconds and then slowly decayed toward the baseline. The time course of current decay, which developed with two exponential components, was used to estimate the time course of desensitzation onset. A 30 second pretreatment with 10uM C_{10} accelerated 216uM carbachol-induced desensitization by decreasing the time constant of both the fast and slow components. C_{10} pretreatment also decreased the peak EPC_{carb} amplitude. Application of 10uM C_{10} alone produced no outward current; measurable outward currents occurring only with concentrations above 350uM. Supported by a grant from the MDA.

111.4

ADENOSINE INCREASES K^+ CONDUCTANCE OF RAT LOCUS COERULEUS NEURONS. W.J. Pan, S.S. Osmanovic and S.A. Shefner, Department of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

We have previously shown that adenosine causes a dose-dependent inhibition of firing and hyperpolarization of locus coeruleus (LC) neurons which is blocked by theophylline. In the present study, the mechanism of adenosine effects on LC neurons was studied with intracellular recording in a submerged rat brain slice preparation. LC neurons showed the usual regular pattern of spontaneous firing at rates of 0.25-3.0 Hz. Bath application of adenosine (100 μM) reversibly decreased the firing rate in 80% of spontaneously active LC neurons (n=20). With current clamp recording, adenosine (100 μM) caused hyperpolarizations (2-7 mV) in 73% of the LC neurons tested (n=22). These hyperpolarizations were accompanied by increased input conductance (11±2%). The reversal potential for the adenosine-induced hyperpolarization was calculated from the intersection of voltage-current curves under control conditions and in the presence of adenosine. The mean adenosine reversal potential was -116 mV (n=13), very similar to the K^+ equilibrium potential as estimated from the reversal potential of the afterhyperpolarization which follows a train of action potentials. Adenosine caused a small outward current in 3 LC neurons tested under voltage-clamp conditions. These data indicate that adenosine-induced hyperpolarization of LC neurons is due to an increase in K^+ conductance. GRANT SUPPORT: US PHS AA 5846.

PROCTOLIN-SENSITIVE CA^{2+} CHANNELS IN ISOLATED CRAYFISH TONIC FLEXOR MUSCLES. M.E. Krouse*, C.A. Bishop and J.J. Wine, Department of Psychology, Stanford University, Stanford, CA 94305

The pentapeptide proctolin is a cotransmitter in 3 of 6 identified motoneurons and, although it has no observable effect on resting muscles, its release greatly potentiates depolarization-induced tension by acting at multiple sites in the excitation-contraction pathway (Bishop, *Neuro. Abst.*,1988). We have used the patch-clamp technique to investigate the possible effects of proctolin on membrane channels. Isolated muscle fibers were treated with collagenase IA for 20 min (2.2 mg/5ml saline) and were then placed in a bath containing 137 mM $BaCl_2$, 1 mM $CaCl_2$, 2.6 mM $MgCl_2$, and 10.1 mM Trizma (pH 7.0). The pipet solution contained 200 mM Na-Gluconate, 2.6 mM $CaCl_2$, 2.6 mM $MgCl_2$, and 10.1 mM Trizma (pH 7.0). Experiments were performed at 21°C on inside-out patches. In the absence of proctolin, 4 channel types were observed: two linear Cl^- channels (8 pS and 24 pS in 280 mM Cl^-) which were activated by hyperpolarization and then remained active, and 2 Ca^{2+} (137 mM Ba^{2+}) channels. Activity of the Cl^- channels was unchanged by the presence of proctolin. However, the Ca^{2+} channels, which showed outward rectification and had chord conductances of 20 and 80 pS at +50 mV, became more active during depolarizations when the muscles were bathed in $5x10^{-9}$ M proctolin; the effect was especially pronounced for the 80 pS channel and was due to a sharp decline in the mean closed time. This voltage-activated increase in channel opening rate is consistent with tension experiments where the cells must first be depolarized for proctolin to increase tension. Also consistent are the results at desensitizing concentrations of proctolin (10^{-8} M), where the 80 pS channel was detected in only 1 of 4 patches (compared to 4 out of 5 patches in $5x10^{-9}$ M proctolin) and its activity was confined to bursts separated by long closed periods of several seconds. 111.6

SUBSTANCE P-INDUCED INWARD CURRENT IN GUINEA-PIG SYMPATHETIC NEURONS. T. Miyazaki*and N. J. Dun (SPON:R.S.Schmidt). Loyola Univ. Med. Ctr., Maywood, IL 60153

Inferior mesenteric ganglion (IMG) neurons were voltage clamped using a single electrode voltage clamp method. At the holding potential of -40 mV, pressure application of substance P (SP) induced an inward current associated with increase (type I), decrease (type II) or no appreciable change (type III) of membrane conductance in different IMG neurons. In type I response, the SP-induced current became larger on membrane hyperpolarization, and the extrapolated reversal potential was about -25 mV. While SP did not appreciably affect the slow inward current induced by hyperpolarizing command pulse, it increased instantaneous transient current at the start and end of command pulse. In type II response, the SP-induced current was nullified at about -70 mV in a portion of the cells, whereas it became larger on hyperpolarization in a few cells. The slow inward current as well as the instantaneous currents were reduced by SP. In type III response, the SP-induced current was accompanied by little or no change of membrane conductance. In a portion of the IMG neurons the slow inward current reduced by SP was also sensitive to muscarine, Co and Cd, suggesting that it probably reflects a Ca-dependent K current. The results suggest that SP induced an inward current in IMG neurons either by increasing membrane conductance to Na and/or Ca, or by decreasing a Ca-dependent K current and leakage current. (Supported by NS18710)

111.7

A CALCIUM-DEPENDENT SLOW AFTERDEPOLARIZING POTENTIAL (s-ADP) RECORDED IN RAT DORSOLATERAL SEPTAL NEURONS IN VITRO. H. Hasuo*, K.D. Phelan, M.J. Twery, and J.P. Gallagher, Dept. of Pharmacol. & Toxicol., University of Texas Medical Branch, Galveston, Texas 77550.

Intracellular recording of action potentials (APs) in rat dorsolateral septal nucleus (DLSN) neurons revealed several types of spike afterpotentials: a fast afterhyperpolarization, a fast depolarizing afterpotential, a slow afterhyperpolarization, and a slow afterdepolarizing potential (s-ADP). In the present study, we investigated the ionic mechanism of the s-ADP. A typical s-ADP, could be evoked by a single AP, was associated with a decreased input resistance, and had a duration of several seconds. Often bursts of APs were triggered on top of the 2 to 10 mV in amplitude s-ADP when recorded at normal resting potential levels (-60 to -70 mV). The s-ADP was not affected by tetrodotoxin, but was markedly reduced by sodium replacement with choline. The s-ADP was abolished by cadmium (0.2 mM) or by a low calcium solution. Changing extracellular chloride did not affect the s-ADP. The s-ADP was voltage clamped following directly-evoked spikes and a plot of its current versus membrane potential was linear between -50 to -90 mV and had an extrapolated reversal potential of -30 mV.

We conclude that this s-ADP in rat DLSN neurons may be mediated by a calcium-activated non-specific cation channel. This potential may underlie some bursting patterns recorded from rat DLSN neurons. (Supported by DAMD-17-86-C-6032)

111.8

SYNAPTIC TRANSMISSION AND PASSIVE MEMBRANE PROPERTIES OF NEURONS IN RAT DORSOLATERAL SEPTAL NUCLEUS ARE AFFECTED BY SOMATOSTATIN IN VITRO. M. J. Twery and J. P. Gallagher, Dept. of Pharmacology and Toxicology, Univ. Texas Med. Br., Galveston, TX 77550.

Immunohistochemical studies indicate somatostatin (SS) may act as a neurochemical messenger in septal nuclei. The present study used intracellular recording techniques to investigate effects of SS-14 on neuronal membranes and orthodromically evoked postsynaptic potentials in a submerged rat brain slice preparation containing the dorsolateral septal nucleus (DLSN). Membrane hyperpolarization was the predominant response to superfused SS (0.001-1 μM) or SS (50-100 μM) applied by pressure ejection from a micropipette. Hyperpolarization (2-14 mV) inhibited spontaneous activity and was associated with an apparent increase in K^+ conductance. Neither bicuculline (10 μM), TTX (0.5 μM), nor low Ca^{++}/ high Mg^{++} media blocked SS-induced hyperpolarizations. Depolarizing responses (1-2mV) to SS were observed infrequently and were blocked by superfusion of a low Ca^{++}/high Mg^{++} medium. All membrane potential (Vm) changes were slow in onset (0.5-5 min) and recovery (2-10 min). SS also decreased the amplitude of GABA-mediated inhibitory postsynaptic potentials (IPSPs) evoked by electrical stimulation of the medial septum. The effect on IPSP amplitude occurred with a slower time course than the changes in Vm and were variable with repeated application of the peptide. Repeated or continuous application of SS resulted in "desensitization".

The results indicate that SS has potent actions at pre- and post-synaptic neuronal membranes in the DLSN. These findings suggest that SS could serve as an inhibitory transmitter and synaptic modulator in this nucleus. (Supported by NIMH Grant MH-39163).

NICOTINIC RECEPTOR ACTIVATION OF RAT DORSOLATERAL SEPTAL NUCLEUS (DLSN) NEURONS RECORDED IN VITRO. Linda A. Wong* and Joel P. Gallagher (SPON: O.S. Steinsland). Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

Our previous studies suggested that carbachol and pyridostigmine act on nicotinic receptors in rat DLSN (*Soc. Neurosci. Abstr.* 13:268). To characterize further the mechanisms of central nicotinic receptor activation and possible nicotinic-modulation of GABA inhibition in DLSN, we investigated the actions of two specific nicotinic agonists: nicotine and DMPP (dimethylphenylpiperazinium). When applied by superfusion (1-10 μM) or pressure ejection (10mM, 10-300 mS, 5-10 psi) both drugs acted in a concentration-dependent manner to hyperpolarize the resting membrane potential (4-14 mV; n=19). This hyperpolarization was long lasting (minutes); associated with an increase in K^+ conductance; persisted in TTX or low Ca^{2+}/high Mg^{2+} solutions; and was reversibly blocked by mecamylamine (50 μM; n=3) but not by α-bungarotoxin (0.5 μM; n=3). Single electrode voltage clamp studies revealed a drug-induced outward current (150-180 pA; n=2). Both drugs consistently depressed GABA-mediated synaptic responses, and evoked delayed effects which altered the normal rhythmic firing pattern of DLSN neurons.

We conclude that nicotinic receptor activation leads to a multiplicity of effects that may result from: (1) direct postsynaptic alteration of intrinsic neuronal properties; (2) presynaptic modulation of GABA release; and (3) possible second-messenger mediated effects on action potential profile. (Supported by DAMD-17-86-C-6032).

111.10

A TRANSIENT INWARD CALCIUM CURRENT IN CAT AND RAT THALAMIC CELLS. V.Crunelli, C.E.Pollard* and J.W.Hynd*. Pharmacol. Dept., St.George's Hosp. Med. Sch., London SW17 ORE, U.K.

Low threshold Ca^{++} spikes are central to the oscillatory activity displayed by thalamic relay cells. The current responsible for their generation has been studied with the single electrode voltage clamp technique in brain slices of cat and rat dorsal lateral geniculate nucleus bathed at 25°C in a medium containing 1mM Ca^{++}, 3mM Mg^{++}, 0.5μM TTX and 3mM CsCl. From a holding potential (V_h) of -100mV, depolarising voltage steps positive to -70mV activated a transient, inward current (I(t)), the size of which was very voltage sensitive between -65mV and -55mV. I(t) was completely inactivated positive to -70mV but the inactivation was removed as V_h approached -100mV. The removal of inactivation was time dependent with the maximal current only being achieved after a 1 sec hyperpolarisation to -100mV. I(t) decayed exponentially with a time constant of 65 - 75ms when fully activated at -50mV. Deactivation was studied by activating I(t) maximally and returning to a V_h of -100mV at the current peak. The tail currents generated decayed exponentially with a time constant of around 5ms. I(t) was relatively resistant to 0.5mM Cd^{++} but was abolished by 0.5mM Ni^{++} or by using 8mM Mg^{++} as a competitive antagonist. I(t) characteristics suggest the involvement of T-type Ca^{++} channels. Because of the narrow voltage activation range of I(t), even small changes in membrane potential will strongly influence the size of low threshold Ca^{++} spikes.

111.11

GABA$_B$ RECEPTOR MEDIATED SYNAPTIC TRANSMISSION IN THE CAT LATERAL GENICULATE NUCLEUS. I. Soltesz*, S. Lightowler*, N.Leresche*, J.W.Hynd* and V.Crunelli (SPON: L.Valzelli). Pharmac.Dept., St.George's Med. Sch., London SW17 ORE, UK.

In projection neurons of the cat dorsal LGN, recorded in a brain slice that did not contain the perigeniculate nucleus, the "classical" EPSP-GABA$_A$ IPSP sequence evoked by electrical stimulation of the optic tract was always followed by a long latency (30-45msec), long duration (200-300msec) IPSP. This IPSP was K^+ dependent and blocked by phaclofen (0.5-1mM), indicating that it represents a GABA$_B$ IPSP. Its amplitude decreased by about 25% at stimulation frequencies higher than 0.05Hz. Bicuculline (10-50μM) and picrotoxin (25μM) blocked the GABA$_A$ IPSP but invariably increased the amplitude of the GABA$_B$ IPSP. GABA$_B$ IPSPs could be recorded from cells located in lamina A, A$_1$ and C, and whose morphology, analyzed following intracellular injection of HRP, was very similar to that of X, Y and W cells. We suggest that the physiological role of the GABA$_B$ receptors in the LGN is to mediate a late, long lasting IPSP that could be involved in the subcortical processing of information in all three main visual channels. Thus in the rat ventral LGN, where no long lasting inhibition had been observed in vivo, optic tract stimulation evoked GABA$_A$ but not GABA$_B$ IPSPs. Finally, the possibility of an increase in GABA$_B$ receptor mediated synaptic transmission should be carefully considered when using bicuculline as a selective blocker of GABA$_A$ mediated inhibition.

111.12

ROLE OF NMDA RECEPTORS IN THE GENERATION OF RHYTHMIC THALAMIC ACTIVITY. N. Leresche*, M. Haby*, D. Jassik-Gerschenfeld*, I. Soltesz*+ and V. Crunelli+ (SPON: European Neuroscience Ass.). Dept. Neurosciences de la Vision, Institut des Neurosciences, Univ. Paris VI, France and +Dept. of Pharmacol., St. George's Hosp. Med. Sch., Cranmer Terrace, London SW17, Great Britain.

Intracellular recordings from projection cells in rat and cat lateral geniculate and ventrolateral posterior nuclei were performed in a slice preparation. In control medium containing 2mM Ca++, 2 mM Mg++, no spontaneous activity was observed. However, removal of Mg++ from the perfusion medium produced rhythmic depolarizations (15-20 mV amplitude, 210-230 ms duration, 0.5-2.5 Hz frequency). Each depolarization could reach threshold for firing and evoked a burst of 1-7 action potentials. This rhythmic activity was voltage dependent (observed only between -65 and -75 mV), and could be more consistently observed in the presence of 3-4 mM Ca++. TTX (1 μM) abolished the bursts of action potentials but had no effect on the underlying depolarizations. This activity was reversibly abolished by (+-)2-amino-5-phosphonovaleric acid (20-50 μM), ketamine (10 μM), Mg++ (50-200 μM) and 8-Br-cyclic-AMP (1 mM) and was unaffected by bicuculline (1-50 μM), strychnine (20 μM), phaclophen (0.5-1 mM) and atropine (10 μM).

Our results suggest that thalamic projection cell in vitro are capable of rhythmic membrane potential oscillations that are similar to those observed during thalamic synchronization and that require the activation of NMDA receptors.

111.13

TRANSDUCTION MECHANISM FOR MUSCARINE-INDUCED CURRENTS IN FROG SYMPATHETIC NEURONES. P.A. Smith, J.A. Zidichouski* and A.A. Selyanko*, Dept. Pharmacol., Univ. Alberta, Edmonton, Canada and Bogomoletz Inst. Physiol., Kiev, U.S.S.R.

Muscarinic outward currents in C-neurones (I_{MO}) and muscarinic inward currents (I_{MI}) in B-neurones were studied in Rana pipiens sympathetic ganglia using the whole cell patch-clamp technique. Inclusion of 100μM cyclic AMP or the protein kinase C inhibitors, H-7, (50μM) or gold sodium thiomalate (GST, 50μM) failed to antagonize either response although both were prolonged by the non-hydrolysable GTP analogue, GTP-γ-S (50μM). I_{MO} was antagonized rather than mimicked by the protein kinase C activator, phorbol-12-myristate-13-acetate (PMA, 2-5μM). Although PMA also produced an inward current as a result of M-current supression in both B- and C-cells and antagonised I_{MI}, this effect was not antagonized by H-7 or GST, suggesting that protein kinase C is not involved in the effects of PMA. Although the inclusion 1μM Ca^{2+} in the patch pipette failed to mimic I_{MO} or steady state I_{MI}, the latter current was supressed by 0.5mM IP_3. Thus, neither adenylate cyclase inhibition, nor the second messengers Ca^{2+} or diacylglycerol seem to mediate G-protein-coupled muscarinic responses in frog sympathetic neurones. However, a Ca^{2+}-independent role for IP_3 in the generation of I_{MI} cannot be excluded.

111.14

OUTWARD AND INWARD CURRENTS PRODUCED BY ADRENALINE AND MUSCARINE IN FROG SYMPATHETIC NEURONES. A.A. Selyanko*, J.A. Zidichouski* and P.A. Smith. (SPON: D.P.J. Boisvert). Dept. Pharmacol., Univ. Alberta, Edmonton, Canada and Bogomoletz Inst. Physiol., Kiev, U.S.S.R.

The effects of adrenaline and muscarine on neurones dissociated from Rana pipiens sympathetic ganglia were studied using the whole cell patch-clamp technique. The larger B-cells exhibited a fast, transient outward current (A-current) which was not present in the smaller C-cells. Drug responses were more readily observed when 100μM cyclic AMP ± 100μM GTP was included in the patch pipette. 10μM muscarine suppressed the M-current in all 16 B-cells tested and thereby produced an inward current (Adams et al., J. Physiol., 330, 537, 1982). A similar effect of 10 or 100μM adrenaline was seen in 5 of these 16 cells. In contrast, muscarine and adrenaline produced outward currents in 15 and 14 out of 22 C-cells respectively (cf. Dodd & Horn, J. Physiol., 334, 271, 1983). This current reversed at E_K and displayed marked inward rectification. Luteinizing hormone releasing hormone (10μM) suppressed the M-current in all B- and C-cells tested. Outward currents produced by muscarine and adrenaline were not additive and both agonists produced > 50% inhibition of the M-current. These data indicate that muscarine and adrenaline share the same potassium channels to generate either an inward current in B-cells or an outward current in C-cells. Supported by MRC and AHFMR.

111.15

GTPγs MIMICS THE EFFECTS OF CARBACHOL ON CAT SPINAL MOTONEURONS. L. Zhang and K. Krnjević. Departments of Anaesthesia Research and Physiology, McGill University, Montreal, Quebec H3G 1Y6, Canada.

We investigated the effects of carbachol and their intracellular mediation in cat spinal motoneurons in situ, by using intracellular recording and iontophoresis. Cats were fully anaesthetized with sodium pentobarbital. Intracellular iontophoresis was made by triple-barrelled electrodes. For extracellular iontophoresis, the injecting barrel was glued to recording one. Extracellular injection of carbachol caused a depolarization with increase in input resistance, reduced the afterhyperpolarization (AHP), and prolonged the spike duration. The effects are probably due to blockade of K conductance. To test if a G protein is involved, we used GTPγs, a non- hydrolyzable analog that causes prolonged activation of G protein. Intracellular injection of GTPγs induced a depolarization with rise of input resistance, depressed the AHP and IPSP, and slightly increased the spike duration. The effects of GTPγs are quite similar to those of carbachol, suggesting the possibility that G protein may be involved in coupling of ACh receptors to K conductance. Further experiments are necessary to examine whether blockade of G protein prevents the effects of muscarinic agents. Supported by Medical Research Council of Canada.

111.16

PROPERTIES OF THE POTASSIUM CONDUCTANCE DECREASED BY REAL AND PUTATIVE NEUROTRANSMITTERS IN SUBMUCOUS PLEXUS NEURONES. K-Z.Shen* and A.Surprenant. Vollum Institute, Oregon Hlth.Sci.Univ., Portland, OR. 97201.

Slow excitatory synaptic potentials (sEPSPs) are a dominant feature of submucous plexus neurones; the peptide and non-peptide projections to these neurones are now well established. We used single-electrode voltage-clamp methods to study the inward current associated with the slow EPSP and the responses produced by application of substance P, 5-HT, muscarine, VIP and forskolin. All agonists produced identical responses in a single cell, responses which were identical to the sEPSP in the same cell. These responses could be mimicked by intracellular injection of ATP-γ-S but not GTP-γ-S and were pertussis toxin insensitive. In 50% of cells this response consisted of a voltage-independent (between -40 to -130 mV) K conductance (gK) decrease. In the other cells, an inward current and decreased gK was observed between -40 to -75 mV; there was an inward current only without associated conductance change from -80 to -130 mV. Ion replacement studies showed that a concomitant cation conductance increase was not responsible for this behaviour. However, when noradrenaline or somatostatin, which appear to increase a separate gK at somatic sites only, were present, the response became a voltage-independent gK decrease.

111.17

GDP RELEASE FROM RAT SYNAPTIC MEMBRANES IS STIMULATED BY RECEPTORS LINKED TO BOTH ACTIVATION AND INHIBITION OF ADENYLATE CYCLASE. T.K. Narayanan and R.S. Aronstam. Department of Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA 30912.

The binding of agonists to many neuronal receptors facilitates their association with transducer G proteins, thereby promoting the release the GDP from the G protein. This release is the rate limiting step in the G protein transduction cycle. To measure this release we incubated rat cortical and striatal membranes with alpha-[^{32}P]GTP under conditions which favored GTP hydrolysis. Following extensive washing of the membranes at 4°, [^{32}P]GDP release was measured in an assay medium containing 25 mM Tris-HCl, pH 7.4, 1 mM EDTA, 0.5 mM DTT, 0.1 M NaCl, 5 mM $MgCl_2$ and 0.2 mM Gpp(NH)p in a volume of 200 ul. Released nucleotides were separated by thin layer chromatography on polyethyleneimine cellulose plates using 1.5 M LiCl. Both histamine and carbamylcholine caused a dose-dependent release of GDP which was blocked by receptor antagonists. Both transmitters (100 uM) increased release 1.5 to 2 fold. Release was linear for 7 min and plateaued after 10 min. Inclusion of either agonist during the labelling period increased the [^{32}P]GDP content of the membranes. Thus, GDP release is mediated by receptors which are coupled to adenylate cyclase in both stimulatory and inhibitory manners. (Supported by GM-37948, AA-07698 and the Georgia Heart Association.)

AUTOPHOSPHORYLATION OF Ca^{++}/CaM-DEPENDENT PROTEIN KINASE II IN RAT BRAIN POST-SYNAPTIC DENSITIES. D.P. Rich* and T.R. Soderling (SPON:T.Inagami). Department of Molecular Physiology and Biophysics and Howard Hughes Medical Institute, Vanderbilt University, Nashville, TN 37232.

CaM Kinase II comprises 30-50% of the protein in the post-synaptic density (PSD), thus placing it in a strategic locale for exerting effects on post-synaptic responses. Ca^{++}/CaM-dependent autophosphorylation of PSD CaM Kinase II caused generation of 50-70% Ca^{++}-independent activity within 1-2 minutes. Subsequent addition of excess EGTA to the autophosphorylation reaction resulted in loss of stimulation of CaM Kinase II by Ca^{++}/CaM. Autophosphorylation of PSD CaM Kinase II at 4°C incorporated phosphate into both 50 and 60 kDa subunits (50kDa:0.024 pmol ^{32}P/μg PSD protein, 73% P-Thr, 27% P-Ser; 60kDa:0.021 pmol ^{32}P/μg PSD protein, 60% P-Thr, 40% P-Ser). HPLC peptide mapping of CNBr ^{32}P-peptides showed Thr-286 to be a major site of autophosphorylation. Kinetic analysis of the autophosphorylated PSD enzyme using Syntide-2 as substrate gave a Km= 12μM and Vmax= 2.77μmol/min/mg compared to a Km= 17μM and Vmax= 5μmol/min/mg for the Ca^{++}-dependent, nonautophosphorylated PSD enzyme. A synthetic peptide corresponding to a putative inhibitory sequence near the CaM binding region of the 50kDa subunit gave inhibition (IC_{50}=10-12μM) of the Ca^{++}-independent form of the PSD kinase. All these results indicate that CaM Kinase II in the PSD is regulated very similarly to the purified cytosolic kinase (Hashimoto et al.(1987) JBC 262,8051;Schworer et al.(1988) FASEB J 2,A992;Colbran et al.(1988) FASEB J 2,A992).

ENDOCRINE CONTROL AND DEVELOPMENT I

112.1

PRENATAL STRESS ALTERS THE DORSOLATERAL NUCLEUS OF THE SPINAL CORD. W. Grisham, M. Kerchner* & I. L. Ward. Dept. Psych., Villanova Univ., Villanova, PA 19085

The dorsolateral nucleus (DLN) of the spinal cord is sexually dimorphic and innervates the ischiocavernosus muscles. These penile muscles are responsible for aspects of copulatory behavior in male rats. Many male rats stressed prenatally fail to mate, a phenomenon attributed to altered patterns of plasma testosterone during fetal ontogeny. We examined the DLN in prenatally stressed and control rats, screened for their ability to ejaculate or not ejaculate.

Regardless of behavior, DLN cells from stressed males had smaller somal ($\bar{x}$ = 876 μ^2, $p < .005$) and nuclear ($\bar{x}$= 167 μ^2, $p < .036$) areas than controls ($\bar{x}$ = 974 μ^2 and $\bar{x}$ = 185 μ^2, respectively). Cell number in copulators tended to be asymmetric, with more cells in the left ($\bar{x}$ = 329) than right ($\bar{x}$ = 315, p = .056) DLN. Since there are no differences in the weight of the IC/BC muscle complex of stressed and control rats, we conclude that the differences in DLN neuron dimensions are not related to peripheral target organ size. (Supported by 2R01 HD-04688 from NICHHD and 2K05 MH00049 from NIMH.)

112.2

SEIZURE-INDUCED DELAY OF PUBERTY IN FEMALE RATS: EFFECTS OF AGE AND OPIOID ANTAGONISTS. R. Carson* and M. Wilkinson. Physiol. & Biophys., Dalhousie U., Halifax, Canada B3H 4H7

We have shown that pre- and post-pubertal female rats are sensitive to seizures. For example, daily convulsions commencing at age 24 days delay puberty (Exp. Brain Res. 56 32, 1984). Here we examine the effect of seizures at various ages. In addition, because opioid peptides are implicated in regulating puberty onset and are activated by convulsions, we also investigate the effect of opioid antagonists in the seizure-induced delay of puberty.

A single daily electroshock (ECS) was given for 10 days to neonatal (days 2-10), infantile (days 15-24) and juvenile (days 21-31) rats. The treatment delayed vaginal opening (VO) in juvenile rats. Neonatal and infantile rats were unaffected. VO is also delayed by daily ECS for only 5 days in the late juvenile (days 27-31) period. The opioid receptor antagonists naloxone and nalmefene (2.5mg/kg 10 mins before and 20 mins after single daily ECS) were unable to block this effect of ECS on VO. To examine whether the effect of ECS is related to stress, we examined several stressors known to induce opioid-mediated alterations in gonadotropin secretion. Footshock, immobilization and ether stress administered in the juvenile period (days 27-31) did not affect timing of VO. In addition, rats anaesthetized with halothane, and then given ECS, still showed a delay of VO. These data demonstrate that rats in the late juvenile stage of development are most sensitive to convulsions. We also suggest that opioids are not critical to the mechanism by which the ECS disturbs puberty and that ECS elicits its effect seemingly independent of the convulsive stress.

112.3

PRENATALLY-STRESSED FEMALE RATS AND FERTILITY AND FECUNDITY: INVOLVEMENT OF POSTCOITAL PROLACTIN SURGES. C.H. Kinsley, P.E. Mann & R.S. Bridges, L.H.R.R.B., Harvard Medical School, Boston, MA 02115

Prenatally-stressed (P-S) female rats exhibit reduced fertility and fecundity. Such females also show dampened prolactin (Prl) secretion following stimulation by estradiol. Since coital-induced Prl is involved in both fertility and fecundity, we examined P-S female rats for altered Prl surges following coitus. Pregnant rats were exposed to a thrice-daily regimen (Days 14-21) of heat and restraint stress; Controls were unhandled. As adults the female offspring (P-S & Controls) were mated on the evening of proestrus and sex behavior was observed and recorded. 24 hours following mating all P-S and Control females were fitted with intra-atrial cannulae. Blood sampling began 48 hours after mating with samples being taken at 2-hour intervals beginning at 2200h and continuing until 0600h (lights on 0500h-1900h) for a total of 3 days. Plasma Prl was determined by RIA. Fewer P-S females became pregnant or carried a pregnancy to term. Of those P-S females who delivered, litter size was smaller than that of Controls. No differences were found in these early (post-coital Days 2, 3 & 4) nocturnal Prl surges. Thus, the deficits in fertility and fecundity in P-S female rats do not appear to be tied directly to alterations in coital-induced Prl secretion during early pregnancy. Other potential factors, however, may include reduced sensitivity to Prl and/or changes in gonadal steroid secretion/sensitivity.

112.4

INHIBITION OF HIPPOCAMPAL CELL PROLIFERATION BY STRESS IN DEVELOPING RATS. P.J. Gutierrez* and J.S. Meyer. Dept. of Psychology, Univ. of Massachusetts, Amherst, MA 01003.

Developing rats and mice display a relative stress-nonresponsive period (RSNP) during which adrenocortical responses to stress are greatly attenuated. Because high doses of glucocorticoids inhibit a variety of brain growth processes including cell proliferation, the RSNP has been thought to protect the developing brain from the deleterious effects of elevated steroid levels. However, there is little evidence that stress-induced increases in corticosterone (CS; the endogenous glucocorticoid) can cause retardation of brain development. In the present study, young rats were stressed by several s.c. injections of histamine over the course of 2 days. Mitotic activity was then assessed in hippocampus, a major CS target area, and cerebellum by measuring the activity of thymidine kinase (TK). Compared to untreated controls, stressed rats showed significant reductions in hippocampal TK both during (days 11 and 13 postnatal) and near the end (day 18) of the RSNP. No effect was found in the cerebellum. When 10-day-old animals were adrenalectomized and implanted with CS-containing minipumps to hold circulating CS concentrations constant, subsequent histamine treatment failed to inhibit hippocampal TK activity measured on day 13. These results support the hypothesized role of the RSNP by showing that even small elevations in CS can alter the timing of developmental events in the hippocampus.

AGE-RELATED EFFECTS OF HANDLING, DIAZEPAM EXPOSURE, AND GONADECTOMY ON CORTICOSTERONE RESPONSE TO STRESS IN THE RAT. R. Guillet* and C.K. Kellogg. (SPON: M. Mangiapane). Dept.of Psychology, Univ. of Rochester, Rochester, NY 14627.

The effects of handling and acute diazepam (DZ) exposure on the corticosterone (CS) response to a novel environment are dependent upon pubertal age and can be modified by prepubertal gonadectomy (GDX). Male Long Evans rats were left intact or gonadectomized at 21 days of age, then examined at 28, 42, or 70 days of age. Beginning one week prior to experimentation, one half of these rats were handled daily, one half left undisturbed. Within each group one half of the rats then received DZ (2.5 mg/kg, i.p.)and one half vehicle (DMSO) at t=0. They were moved to a novel environment at t=30 min, and were sacrificed by rapid decapitation at t=45 min. Trunk blood was collected and assayed for CS. Additional cohorts of intact rats were treated similarly except that they were not exposed to a novel environment. At all ages examined, the CS response to a novel environment was the same in the unmanipulated rat. At 28 days, the CS response was decreased by 25% by either DZ and/or handling in the intact state, but only by DZ in the GDX state. At 42 days, either DZ or handling (but not both together) decreased the response in the intact state; conversely, only DZ plus handling decreased the response in the GDX state. At 70 days, the CS response was not decreased by manipulations in the intact state and was increased in all cases by 75% in the GDX state. Injection alone (without novel environment) resulted in no increase over baseline CS at 45 min. These results suggest that: 1. the effects of handling and of DZ on CS response to stress are dependent upon pubertal age; 2. handling and DZ may affect this response via different mechanisms; 3. the effect of prepubertal GDX on the stress response is manifested differently depending on the age at testing; and 4. the gonadal axis may interact with the adrenal axis in the adult rat to influence stress-responsiveness. Thus, we hypothesize that the CS response to stress is mediated via multiple systems and that these systems are still evolving during puberty. Furthermore, manipulation of the gonadal axis in the prepubertal rat influences the evolution of these systems. Supported in part by Grant No. MH 31850.

PUBERTAL-RELATED INFLUENCES ORGANIZE NEURAL MECHANISMS UNDERLYING SOCIAL INTERACTION IN RATS AND THE EFFECTS OF DIAZEPAM THERE ON. R. Primus and C.K. Kellogg. Dept. of Psychology, Univ. of Rochester, Rochester, NY 14627.

The social interaction test of anxiety demonstrated that the organization of this behavioral response to a novel environment occurs during puberty. The impact of a novel environment and the influence of diazepam (DZ) and prepubertal gonadectomy (GDX) on social interaction was examined in 28, 35, and 60 day old male rats in order to demonstrate that changes during puberty organize the behavioral respone to a novel environment. In the social interaction test, 60 Long Evans rats from each age group received five days of pretreatment with either DZ (1.0 or 0.5 mg/kg/day) or vehicle (tween 80 & saline) and were then tested in one of two environmental conditions, familiar or unfamiliar. The amount of time spent in active social interaction was scored. At 35 and 60 days, vehicle treated rats exhibited the characteristic decreased interaction in the unfamiliar condition. This decrease was not evident in 28 day old rats. Social interaction was differentially affected by DZ depending on the rat's age. At 28 days, DZ treatment increased interaction in both conditions whereas at 60 days DZ increased interaction in the unfamiliar condition only, the typical effect of an anxiolytic compound. At 35 days, DZ had no effect on interaction in either condition. GDX at 19 days of age diminished the impact of the environment at each age (N=24/group). Overall, GDX decreased interaction in both conditions. Furthermore, at 35 and 60 days, there was no effect of the unfamiliar environment on interaction (the typical response of intact rats at 28 days). And finally, prepubertal GDX altered the effect of DZ on social interaction. In summary, social interaction and the ability of DZ treatment to affect interaction depends on pubertal-related influences. Thus, the change in the behavioral response to a novel environment that occurs during puberty reflects organization of the neural mechanisms underlying this response. Supported by Grant No. MH31850.

CORTICOSTEROIDS SUPPRESS EXPRESSION OF GAP-43. H.J. Federoff*, E. Grabczyk*, and M.C. Fishman. Howard Hughes Medical Institute and Medical and Neurology Services, Massachusetts General Hospital, Boston, MA

The hormonal milieu is one important determinant of neuronal structure. For example, corticosteroids can perturb neuronal development (Bohn, Neurosci. 5:2003-2012, 1980) and diminish sprouting (Scheff, et al. Exp. Neurol. 68:195-201, 1980). The GAP-43 gene is one of a set of genes regulated during neuronal growth and remodeling and hence a potential target for the corticosteroid effect. We are investigating the effects of nerve growth factor and glucocorticoids on the regulation of GAP-43 gene expression in the clonal PC12 cell line. We have found the following: 1) glucocorticoids diminish GAP-43 expression in a dose-dependent fashion; 2) nerve growth factor stimulates the accumulation of GAP-43 mRNA (Karns, et al., Science, 236: 597-600, 1987); 3) glucocorticoids suppress the NGF effect when they are added concurrently; 4) both the NGF and glucocorticoid effects are primary, that is they do not require de novo protein synthesis; 5) nuclear run-on experiments reveal that the glucocorticoid effect is predominantly transcriptionally regulated; 6) glucocorticoids similarly reduce GAP-43 mRNA in cultured neurons of the superior cervical ganglion. We are at present identifying the regions of the GAP-43 gene involved in this regulation.

Prenatal nicotine administration decreases testosterone levels in male neonatal rats. A.C.Segarra, A.Mauro*and F.L.Strand. Biology Department.New York University. Washington Square, New York, N.Y. 10003.

Our previous studies indicate that prenatal nicotine administration decreases sexual behavior and testosterone plasma levels in adult male rats (Segarra & Strand, in press). To extend these studies we investigated the effect of pre-(0.25 mg/kg 2X/day) or postnatal (0.25 mg/kg/day) administration of nicotine on various neonatal parameters. Anogenital distance and body weight of newborn rats was assessed. At 6 days of age, the animals were sacrificed, the testes weighed, trunk blood collected and testosterone assayed by RIA. Prenatal nicotine decreased plasma testosterone levels and anogenital distance in 6 day old pups when compared to controls. Postnatal nicotine treatment had no effect on either of these parameters. There were no differences in body nor testes weights following pre- or postnatal nicotine administration. These results extend our previous findings and suggest that the decreased sexual behavior in males treated prenatally with nicotine is correlated to decreased testosterone levels in male neonates. Nicotine appears to exert an organizational effect during the critical period of sexual differentiation of the brain; it's effect on testosterone seems to be confined to prenatal development. NICOTINE MAY REQUIRE ENDOGENOUS ACTH TO ACCELERATE NEUROMUSCULAR DEVELOPMENT IN RATS. K.J. Rose and F.L. Strand. Center for Neural Science.New York University. Washington Square, New York,N.Y. 10003.

A prenatal critical period exists for the neuromuscular acceleratory developmental effects of the noncorticotropic fragment of adrenocorticotropic hormone (ACTH 4-10), and for nicotine in the Sprague-Dawley rat, this period being gestational (G) days G3-G12 (Rose, K.J. and F.L. Strand. 1988. Synapse. [in press]; Rose K.J. et al. 1987. Soc. Neurosci. Abs. 13[3]:1521). Nicotine triggers the endogenous release of ACTH from the pituitary (Cam, G.R. et al., 1979. Arch. int. Pharmacodyn. 237:49-66). We show that two-week-old postnatal pups from pregnant dams that had received orally the ACTH-blocker betamethasone on G8-G9 [20 ug/ml; 17:00 h - 17:00 h] and nicotine [0.25 mg/kg/2x day] on G9 had significantly slower extensor digitorum longus (EDL) muscle contractile times compared to saline controls, pups treated with vector and betamethasone, or with nicotine alone. We conclude that the acceleratory effects of nicotine on neuromuscular development may require endogenous ACTH. (Supported by The Council for Tobacco Research.)

TIMECOURSE OF ADRENAL STEROID RESPONSE TO ETHER STRESS OR CRF IN FIFTEEN DAY OLD CHEMICALLY HYPOTHYROID RATS. L.A. Meserve and L.M. Juarez.* Dept. Biological Sciences, Bowling Green State Univ., Bowling Green, OH 43403-0212.

In earlier studies, thiouracil-induced hypothyroidism has caused delayed pituitary-adrenal stress response. The present study determined the influence of chemical hypothyroidism on corticosterone levels 15, 30, and 45 min after ether stress or injection of corticotropin-releasing factor (CRF) in 15 day old rats. Thiouracil (0.25%) was given in the maternal diet from day 1 of pregnancy, and pups were either exposed to ether fumes (1 min), or were injected i.p. with CRF (10 ng/g) or with injection vehicle. Young were decapitated before or 15, 30 or 45 min after stimulation, and serum thyroxine (T_4) and corticosterone levels, and hypothalamic CRF content, were determined by RIA. Thiouracil depressed body and adrenal weights while producing goitrous thyroid glands and reducing T_4 levels by 80%. Basal corticosterone levels were not modified by thiouracil, but response to ether stress was half of normal at each time point. Thiouracil depressed hypothalamic CRF content, but not response to CRF injection. Indeed, it appeared that hypothyroid animals were better able to distinguish mock and CRF injections than were controls. This study supports hypothalamic modification of pituitary-adrenal response in hypothyroidism. (Supported by the Faculty Research Committee, BGSU).

112.11

ONTOGENY OF PROOPIOMELANOCORTIN IN THE ANTERIOR AND INTERMEDIATE PITUITARY LOBES: mRNA QUANTIFICATION AND PEPTIDE CONTENT. D.M.Vazquez* and H. Akil (SPON: N. Alessi). Mental Research Institute, University of Michigan, Ann Arbor, MI 48109.

The proopiomelanocortin (POMC) producing cells present in the anterior lobe (corticotrophs) and the intermediate lobe (melanotrophs) of the pituitary are derived from a common primordium originating in the Rathke's pouch. However, in the adult rat, these cells exhibit tissue specific post-translational processing, differential regulation of peptide secretion and gene expression. Unlike the adult pituitary where the anterior and intermediate lobe POMC products are distinct, the developing pituitary lobes have similar POMC products. A definite adult pattern is not achieved until at least the twenty-first day of life. To our knowledge, patterns of POMC gene expression as reflected by mRNA levels have not been described in the developing animal, especially during the first two weeks of life when the adrenocortical response to stress is greatly reduced. For this reason, anterior and intermediate lobes of rats ranging between 1 and 21 days of age were extracted separately using the proteinase K extraction method (LET). The homogenized lobes were used to quantitate POMC mRNA by Northern gel analysis and peptide content by RIA (ACTH, βE, NAcβE and αMSH). Plasma samples were likewise assayed for peptide content using RIA. We will report on the POMC mRNA levels present in the anterior and intermediate lobe of rats 1 to 21 days old and its relation to pituitary peptide content and secretion during this time.

NEURONAL OXYTOCIN MRNA REGULATION BY GONADAL STEROIDS IN DEVELOPING AND ADULT RATS. F.D.Miller, R.J. Milner, and F.E. Bloom, Div. Preclinical Neurosci., Research Inst. Scripps Clinic, 10666 N. Torrey Pines Rd., La Jolla, CA 92037.

Gender dependent differences in neuronal structure and innervation patterns have been largely restricted to neurotransmitter systems arising from sexually dimorphic nuclei of the preoptic region.. Vasopressin immunoreactive neurons are more numerous in the male bed nucleus of the stria terminalis (van Leeuwen et al, J. Comp. Neurol. 233: 236,1985), but no comparable data exist for oxytocin (OXY). During studies of genes expressed in developing rat brain (Miller et al, 1988 J. Neurosci.7:2433,1987), we employed *in situ hybridization* (ISH) to determine the location, number, intensity, time course and hormonal sensitivity of brain OXY mRNA. Anti-sense single stranded RNA probes labeled with S^{35} were generated from a genomic clone of the rat oxytocin gene (Gift of H. Schmale, University of Hamburg). ISH gave sensitive, readily discriminable neuronal signals for mapping and quantitative comparisons. OXY mRNA was expressed in far more neurons in adult males than in females. In female rats, OXY mRNA was largely restricted to the supraoptic nucleus and perimeters of the paraventricular nucleus; sparser, but significant numbers of neurons in males were detected in several other nuclei between the anterior preoptic area and the zona incerta. In some regions, e.g., retrochiasmatic portion of the supraoptic nucleus, neurons were 1-2 fold richer in in male rats. Expression of OXY mRNA within positive sites of female rats can also be regulated. Although OXY mRNA expressing neuron numbers did not change in females post-natally, the intensity of the ISH increased approximately 2 fold per neuron and returned to prepubertal levels 3 weeks after ovariectomy. These data indicate that gonadal steroids regulate both number and magnitude of neurons expressing OXY and suggest that gender-dependent differences in OXY expression can exist within neuronal systems not otherwise considered sexually dimorphic. NEUROGENESIS IN THE SEXUALLY DIMORPHIC AREA OF THE GERBIL HYPOTHALAMUS. C. Ulibarri and P. Yahr. Department of Psychobiology, Univ. of California, Irvine, CA 92717.

The sexually dimorphic area (SDA) of the Mongolian gerbil is a complex of hormone-accumulating cells on the border of the preoptic area and anterior hypothalamus. The lateral SDA (lSDA) is connected dorsally to the medial SDA (mSDA) by a bridge of darkly staining cells. This gives the male SDA a hooked shape, but the female SDA is more ovoid and diffuse. The most dimorphic portion of the SDA, the SDA pars compacta (SDApc), is present bilaterally in most males and absent in most females. The SDApc is present in both sexes at birth and is maintained in males by androgens. In females, the SDApc disappears within three weeks of birth. Females injected with testosterone neonatally retain their SDApcs as adults. In males, ^{3}H-thymidine autoradiography shows that neurogenesis occurs over a short time course in all parts of the SDA except the SDApc. Neurogenesis begins in the lSDA on embryonic day 13 (E13), (E1 = day of conception), and ends on E15. Cells in the bridge of the SDA are born on E19. Neurogenesis occurs in the mSDA on E18 and E19. The cells in the area under the hook are born on E15 and E16. In contrast, neurogenesis continues in the SDApc for five days (E17-E21). These patterns of neurogenesis are being compared to those found in normal and neonatally androgenized females.
This research was supported by NIMH Grant MH-26481.

113.2

SPECIFIC PROTEINS IN THE SEXUAL DIMORPHIC NUCLEUS (SDN) OF THE RAT DURING THE NEONATAL PERIOD. J.F. RODRIGUEZ-SIERRA, W.E. HEYDORN, R.P. HAMMER and D.M. JACOBOWITZ. Dept. Anatomy, Univ. Nebr. Med. Ctr., Omaha, NE 68105, Merrell-Dow Research Inst., Cincinnati, OH 45215; Dept. Anatomy and Reprod. Biol., Univ. Hawaii School Medicine, Honolulu, HI 96822; Lab. Clinical Sci., NIH-NIMH, Bethesda, MD 20892.

The development of the SDN in the medial preoptic area of the rat hypothalamus has been linked to several sexually dimorphic traits in this species. Opiate receptors appear very rapidly in the SDN of the female rat, from day 3 to day 6 of life, while male rats do not show this. We used the technique of 2-dimensional gel electrophoresis and spectrophotometry of the separated proteins to determine the amount of protein. We compared male and female rats at 1 and 6 days of age. Our results show that very few proteins were significantly greater on Day 1 of age than on Day 6 for either sex. The greatest effect was observed in the number of protein spots that showed a significant increase from Day 1 to Day 6 in the female rats (19 spots), while the males did not show this dramatic effect (only 2 spots). Our results suggest that during the development of the SDN, the males suppress the formation of a number of specific proteins in this area. (Sponsored by the NIH HD 13219 and HD19951 and funds from the Univ. Nebr. Med. Ctr.).

113.3

HORMONE-DEPENDENT SEXUAL DIFFERENTIATION IN DEVELOPING RAT HYPOTHALAMUS. S.A. Tobet and T.O. Fox. Prgm Neuroscience, Harvard Med. Sch. and Dept of Biochemistry, E.K. Shriver Ctr. for Mental Retard., 200 Trapelo Rd. Waltham, MA 02254.

Morphological sex differences in adults can result from differential gonadal steroid exposure during critical perinatal periods. We are developing molecular markers to study mechanisms of sexual differentiation of brain structure and function. One hypothesis is that certain transient molecular events during development are hormone dependent, leading to sexual dimorphisms. Antibody AB-2 (Tobet et al., Endo.120[Suppl]:235,1987) detected immunoreactive cellular elements, including radial glia, transiently during the perinatal period. Peak reactivity in radial glia was on embryonic day 19 (E19) in males and on postnatal day 1 (P1) in females. On P1, AB-2 immunoreactivity in radial glia was 2-fold greater in females than in males. Activity detected in males was localized more on one side of the brain than the other (2- to 4-fold, depending on the region). Exposure of females to testosterone propionate on E18 resulted in lower levels of AB-2 immunoreactivity in radial glia on P1 relative to control females. The pattern was bilaterally asymmetric, approaching that of males. Whether these differences are in levels of antigen or in detection of antigen, reflecting another brain difference that is hormonally regulated, is being investigated. As a marker AB-2 demonstrates that the sequence of events during development can be influenced by gonadal steroids. (HD07251-SAT, HD20327-TOF, HD04147-MR)

113.4

RELATIONSHIP BETWEEN MALE SEXUAL BEHAVIORS AND DORSAL MEDIAL SPINAL NUCLEUS IN ANDROGEN-INSENSITIVE *Tfm* MICE. K.L. Olsen, C.K. Wagner and L.G. Clemens. Dept. Psychiatry, SUNY-Stony Brook, NY 11794; Neurosci. Prog.& Dept. Zoology, Michigan State Univ., East Lansing, MI 48824.

In testicular feminized (*tfm*) rats, the spinal nucleus of the bulbocavernous (SNB) is markedly reduced (Breedlove & Arnold,'80;81) although they can mount (Olsen,'79). The *Tfm* mutation is characterized by defects in the androgen but not estrogen receptor systems suggesting that masculinization of the SBN morphology and behavior are independent and mediated by different hormones. In contrast, *Tfm* mice display little or no male sexual behavior and the present data reveal that the mutants and their female siblings have less volume and fewer cells in the dorsal medial (DM) spinal nucleus than wild-type males. *Tfm* mice can be induced to display the ejaculatory pattern by various neonatal and/or adult hormone treatments. This study examines the morphology of the DM spinal nucleus in these mice.

At birth, mice were exposed to either testosterone propionate (TP), dihydrotestosterone (DHT), R1881, or estradiol benzoate (EB). When adult, these mice were gonadx, injected daily with TP or DHT+EB and given six weekly 1 hr tests for male sexual behavior. Other adult gonadx *Tfm* mice were given EB (10 μg) for the three days prior to testing.

Androgen-insensitive mice exposed neonatally to DHT (250 ug/2 days) but not to TP (500 μg) or to EB (10 μg) exhibit the ejaculatory pattern. *Tfm* mice given EB in adulthood also eventually display this response. Thus, the potential of the *Tfm* mice to show ejaculatory behavior can be dissociated from neonatal exposure to exogenous androgen. The effect of these treatments on morphology are being analyzed. These data will provide information about the relationship between male sexual behaviors and the sexual dimorphic DM spinal nucleus.

113.5

BRAIN AROMATASE ACTIVITY OF FETAL AND ADULT GUINEA PIGS. P.B. CONNOLLY*, C.E. ROSELLI, J.A. RESKO* (Spon: H. Spies). Physiology Dept, Oregon Health Sci U, Portland, OR 97201, Oregon Reg Primate Res Ctr, Beaverton OR 97006

Conversion of androgens to estrogens by aromatase activity (AA) may be important for organizing nervous tissues that mediate sexual behavior or gonadotropin release. Although testosterone (T) is a definite effector of androgen action in the guinea pig (GP), the role of in situ conversion to estradiol in sexual differentiation of the brain is less clear. We undertook a study to characterize and localize microsomal AA in brains of fetal, neonatal and adult male GP. Hypothalamic tissues from 50-day fetuses and adult males contained AA with an apparent Km of 19.6 and 16.6 nM, respectively. Fetal and neonatal brain AA showed significant ($p<0.01$) between tissue differences (amygdala [AMG]>preoptic area [POA]> basal hypothalamus≥septum>cortex); no sex difference was apparent. AA was highest at 40-days gestation, declined ($p<0.01$) with gestational age (50 and 60 days) and was lowest at 5-days post-partum. Adult male brains showed a similar distribution of AA to fetus with greatest activity in AMG and POA. AA in adults was greater ($p<0.01$) than in neonates. Castration (2 weeks) had no effect on AA in adult brains. These data demonstrate the existence of AA in fetal, neonatal and adult GP brain and suggest that AA in the brain of this species may not be androgen dependent. Supported by HD-07133 and HD-16022.

SEX AND AGE-RELATED DIFFERENCES IN NUCLEAR ESTROGEN BINDING CAPACITY AND PROGESTIN RECEPTOR INDUCTION IN THE RAT BRAIN T.J. Brown, N.J. MacLusky, E.E. Jones and F. Naftolin. Dept. of Ob/Gyn, Yale Univ. Medical School, New Haven, CT 06510

Previous studies have suggested parallels between the mechanisms underlying sexual differentiation and age-related loss of reproductive cyclicity in the female rat. Both appear to involve the actions of estrogen on the brain; and are associated with a reduction in hypothalamic estrogen sensitivity. The present studies were performed to directly compare the effects of sex and aging on cell nuclear estrogen receptor (ERn) capacity and cytosol progestin receptor (PRc) induction in the rat brain and pituitary gland. Young (2.5 mo) and middle-aged (8-10 mo) male and female, and old (19 mo) female rats were gonadectomized and adrenalectomized two weeks before use. ERn capacity and estrogen induction of PRc were measured in the pituitary (PIT), periventricular preoptic area (PVPOA), medial preoptic area (mPOA), bed nucleus of the stria terminalis, arcuate-median eminence region, ventromedial nucleus (VMN) and corticomedial amygdala. RESULTS: ERn levels and PRc induction were lower in the PVPOA, mPOA and VMN of the male as compared to the female. In the female, although the level of PRc induction in the PIT and the six different brain regions was unaffected by age, ERn capacity in the mPOA, VMN and PIT was significantly lower at 19mo than at either 2.5 or 8-10mo. ERn capacity in the PVPOA was identical in young and old animals. CONCLUSIONS: These results demonstrate that the effects of sexual differentiation and aging on the hypothalamus involve similar, but not identical, region-specific reductions in ERn binding capacity. The consequences of these reduced ERn levels in terms of the PRc response to an estrogen challenge are, however, different in male as compared to old female rats. FETAL ETHANOL EFFECTS ON AROMATASE ACTIVITY IN THE HYPOTHALAMIC-PREOPTIC AREA IN THE MALE NEONATAL BRAIN. P.K. Rudeen, J.A. Creighton*, W. Kelce* and V.K. Ganjam*. Depts. of Anatomy and Vet. Biomed. Sci., Univ. of Missouri School of Medicine and College of Vet. Medicine, Columbia, MO 65212.

The fetal ethanol induced demasculinization of the sexually dimorphic nucleus of the preoptic area in male rats may be due to the inhibition of fetal testosterone synthesis by a 50% reduction of 17α-hydroxylase activity. This study was conducted to determine the effects of fetal ethanol exposure on aromatase activity in the anterior hypothalamic-preoptic area of neonatal male rats. Estrogen formation in individual brains was assayed in vitro using the stereospecific production of ^3H_2O from (1β-3H)- androstenedione as a measurement of aromatase activity. Aromatase activity was significantly higher ($p< 0.05$) in the fetal ethanol exposed animals compared to enzyme activity in animals whose mothers were given the chow diet (92.2 ± 7.5 and 61.1 ± 6.4 pmoles/hr/mg protein, respectively). Animals exposed to the pair fed diet had intermediate enzyme activity. The increase in aromatase activity in FEE animals may be due to a compensatory increase in enzyme activity due to reduction in the availability of testosterone from fetal testes. (Supported by Grants AA05893 and AA00107).

DEVELOPMENTAL CHANGES AND SEX DIFFERENCES IN THE ACTIVITY OF TESTOSTERONE- METABOLIZING ENZYMES IN THE BRAIN OF THE ZEBRA FINCH. A. Vockel*, E. Pröve* and J. Balthazart, Dept. Ethology, Univ. Bielefeld, FRG and Lab. Gen. and Comp. Biochemistry, Univ.Liège, Belgium.

Many effects of testosterone (T) in the zebra finch (*Taenopygia guttata*) can be mimicked by T metabolites, mainly oestradiol and 5α-dihydrotestosterone. We have therefore characterized T-metabolizing enzymes and studied their neuroanatomical distribution by means of the Palkovits punch technique combined with radioenzyme assay in the brain of adult and young male and female zebra finches. The kinetic parameters (Km, Vmax) of the aromatase, the 5α- and 5β-reductase were first determined in the hypothalamus of birds of both sexes at different ages between 5 and 100 days post-hatch. We observed a large decrease of the Vmax and Km of the 5β-reductase and a substantial decrease of the Km of the aromatase with increasing age. No significant sex difference in these parameters was detected. The activity of these enzymes was then studied by a one point assay in 4 nuclei of the song system (*X, RA, ICo, HVc*), 2 nuclei of the visual system (*ectostriatum*, *n. rotundus*) and in limbic and hypothalamic areas. Very noticeable was the presence of a very high not sexually dimorphic aromatase activity in the hippocampal region and in the *nucleus taeniae* and the absence of this enzyme in *ICo*. We found a higher aromatase activity in male than female preoptic area-anterior hypothalamus and a higher 5α- but lower 5β-reductase activity in *RA* of males compared to females. Many age-related metabolic differences were also detected but these do not have a clear interpretation since the Km of these enzymes also changes with age. Extremely low levels of 5β-reductase activity were found in the nuclei of the visual system in adult birds while this enzymatic activity was very high in young birds. The function of this change with age remains obscure. Correlations are thus observed between the neuroanatomical distribution of T-metabolizing enzymes and of androgen and estrogen receptors with the important exception of *ICo* which has no aromatase but contains high concentrations of estrogen receptors. T-metabolizing enzymes are however also present in areas which are not known as steroid targets.

ESTROGEN STIMULATES THE INCORPORATION OF NEW NEURONS INTO AN AVIAN SONG NUCLEUS DURING ADOLESCENCE. E.J. Nordeen and K.W. Nordeen. Psychology, U. Rochester, Rochester, NY, 14627.

The avian song nucleus hyperstriatum ventralis pars caudalis (HVc) contains more neurons in adult males (who sing) than in females. In part, this sex difference develops because HVc neurons born during song learning are added in greater numbers in young males than in females. We report here that estradiol (E2) masculinizes HVc by stimulating the addition of these newly-generated neurons.

Two days after hatching, female zebra finches received silastic implants of E2. Beginning 20 days after hatching, these females and normal males and females were injected with ^{3}[H]-thymidine daily for 20 days. On day 25, the E2-treated females were implanted with either empty or dihydrotestosterone (DHT)-filled silastic tubes. Birds were killed at 64 days of age and coronal sections (10um) were processed for autoradiography.

In females, early E2 treatment increased the addition of HVc neurons born after 20 days of age. Exposure to DHT during the juvenile period did not augment this increase. The percentage of labeled HVc neurons in males (19.9%), E2-treated females (23.4%) and E2+DHT-treated females (19.0%) was greater than in normal females (11.9%). These data suggest that sex differences in HVc neuron number arise because in males, early E2 exposure promotes the production or survival of HVc neurons born during the period of song learning.

113.10

EFFECT OF HVC LESIONS ON ESTRADIOL-INDUCED MASCULINIZATION OF ZEBRA FINCH SONG SYSTEM. K. Herrmann* and A.P. Arnold (SPON. S.C. Lee) Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The song system of male zebra finches is much larger than in females. Early treatment with estradiol (E2) can masculinize female song areas by increasing both the number and size of neurons. The mechanism by which this masculinization occurs is unknown. One hypothesis is that E2 acts transsynaptically by first masculinizing one nucleus which then masculinizes the development of other song regions. We tested this idea by lesioning HVc (caudal nucleus of the ventral hyperstriatum) unilaterally in 20 day old female zebra finches which were implanted with a 200 ug E2 pellet. At day 60 the birds were sacrificed and the volume of RA (robust nucleus of the archistriatum), area X and MAN (magnocellular nucleus of the anterior neostriatum) were analyzed for interhemispheric differences.

Most pronounced left/right differences after unilateral HVc lesions were seen in area X which was virtually absent or very small on the side of the lesion. RA volume was reduced by about 30% ipsilateral to the lesioned HVc, whereas MAN seemed to be masculine in morphology and symmetric and therefore not affected by the lesion. These data suggest that the E2-induced masculinization of area X, and to a lesser degree of RA, is dependent on the presence of HVc, whereas the masculinization of MAN does not seem to require an intact HVc.

Supported by a grant from the DFG (He1539/1-1) and NIH grant NS 19645.

113.11

ULTRASTRUCTURAL CORRELATES OF SONG DEVELOPMENT IN THE ZEBRA FINCH. R.P. Clower and T.J. DeVoogd. Dept. of Psychology, Cornell University, Ithaca, NY 14853.

The production of birdsong is controlled by a well defined system of brain nuclei, the core elements of which include HVc, RA, and nXII. In the male zebra finch, all three of these areas are clearly recognizable at 10 days of age, but the projection from HVc to RA does not appear to become functional until about day 30 (Konishi and Akutagawa, 1985). Kirn and DeVoogd (1985, 1986, and 1987) have shown that neurogenesis and cell death combine during development to produce the nucleus volumes and cell densities typical of adults.

While the sensitive period for song learning may last from 20 or 30 to as late as 85 (Price, 1979) days of age, the most dramatic behavioral changes, and probably most syllable aquisition, take place before day 60. It also appears to be during these first two months that the gross structure of the descending song system is established. We have found that substantial ultrastructural modification is also taking place during this period (Clower and DeVoogd, 1987). In RA of male zebra finches, synapse density increases across 5, 10, and 20 days, and by day 30 has reached the level seen in adults. In HVc, increases in synapse density seem to result in a state of overproliferation around day 30; the density in adults is about 31% lower.

To complement the above developmental data, we are now examining the emergence of synapses in female and isolate male zebra finches. If females do not sing in part because the anatomy of the system will not support song, this may be reflected in fine structure. The trend in RA toward higher synapse density with age seems to hold for females. At days 10, 20, 30 and 100+, values for synapses/100μ^2 are 4.1, 11.5, 16.5, and 19.8 respectively. In adult male zebra finches, the volume of RA is 4.8 times that in females (Nottebohm and Arnold, 1976). The density at 100+ days is somewhat higher than that found in males (13.7 synapses/100μ^2), probably due to what amounts to a compressed condition of the female nucleus relative to the male.

113.12

MORE EVIDENCE CONCERNING HYPERMASCULINIZING EFFECTS OF ANTIESTROGENS IN THE ZEBRA FINCH SONG SYSTEM. G. A. Mathews* & A. P. Arnold. Dept. of Psychology and BRI, UCLA, Los Angeles, CA 90024.

Tamoxifen, an antiestrogen, hypermasculinizes the song system of male zebra finches, *Poephila guttata* (Mathews et al., 1987). This result does not support the hypothesis that estrogen normally masculinizes the male's song system after hatching. Here we report similar hypermasculinizing effects with two other antiestrogens, and at two different ages. Zebra finch chicks of both sexes were subcutaneously injected daily with CI628 (25ug/3ul propylene glycol [PG]), LY117018 (50ug/3ul PG), or 3ul PG (controls) for the first 20 or 25 days post-hatch. The males in the 20-day groups were castrated at Day 20 and all animals in these groups were sacrificed at Day 60. The animals in the 25-day groups were sacrificed on Day 25.

Neuronal soma areas in MAN (magnocellular nucleus of the anterior neostriatum) were increased in males, but not females, at both ages by CI628 (p = .004) and by LY117018 (p < .001). At Day 60, but not at Day 25, areas of neuronal somas in HVc (caudal nucleus of the ventral hyperstriatum) were larger in treated males and females than in controls of each sex (p < .001). Neither antiestrogen affected neuronal soma areas in RA (robust nucleus of the archistriatum). Area X was the only song region whose volume was affected by the two antiestrogens. Females injected with both drugs possessed Area X, unlike controls. Area X in LY117018 males was smaller than in controls at Day 25 (p = .01) but larger than in controls at Day 60 (p = .004). Although the effects reported here are weaker and less consistent across song regions than those found with tamoxifen (Mathews et al., 1987), our results suggest that tamoxifen is not unique among antiestrogens in its hypermasculinizing effects. Moreover, like tamoxifen, the present antiestrogens failed to demasculinize young males. Supported by NIH Grant NS19645.

113.13

CASTRATION AND ANTI-STEROID TREATMENT IMPAIR VOCAL LEARNING IN MALE ZEBRA FINCHES. S.W. Bottjer & S.J. Hewer. Department of Biology, USC, Los Angeles, CA 90089-0371.

Both song behavior and its neural substrate are hormone-sensitive: castrated adult male zebra finches need replacement of gonadal steroids in order to restore normal song behavior, and sex steroids are necessary to establish neural song-control circuits during early development. This pattern of results suggests that hormones may be necessary for normal song development, but direct evidence that steroids are necessary for normal neural and behavioral development during song learning is lacking.

We addressed this question by attempting to eliminate gonadal steroids in juvenile male zebra finches between the time of initial song production and adulthood. Males were anesthetized and castrated at 20 days; they received Silastic implants of either an anti-estrogen (tamoxifen) and/or an anti-androgen (flutamide). Control birds were treated similarly but were sham-operated and received empty implants. At day 40, all birds were housed in individual cages and their song behavior was recorded until day 90.

Preliminary results indicate that the stereotypy of the overall song pattern as well as the production of individual syllables was disrupted in experimental birds. All birds were assigned a number between 1 and 5 indicating song quality (1 = very poor; 5 = very good). The $\bar{X} \pm$ SD for control (n = 7) and experimental (n = 6) birds, respectively, was 4.0 $\pm$ 1.4 (median = 5.0) and 1.7 $\pm$ 1.2 (median = 1.0). These results indicate that gonadal steroids are necessary during the time that male zebra finches are learning to produce the efferent commands that correspond to their normal song pattern.

113.14

CHRONIC TESTOSTERONE ADMINISTRATION IMPAIRS VOCAL LEARNING IN MALE ZEBRA FINCHES. S. Korsia & S.W. Bottjer. Department of Biology, USC, Los Angeles, CA 90089-0371.

Juvenile male zebra finches learn their song during a specific period of development. Once their vocal pattern becomes stereotyped, it is preserved unchanged throughout adult life. In adulthood, gonadal hormones are necessary for normal song production, but song learning occurs even in the absence of gonadal steroids.

Prompted by evidence that testosterone (T) modulates neural and behavioral plasticity, we investigated the effects of chronic administration of T on song learning and behavior in male zebra finches. Continued exposure to T might impair brain plasticity and consequently decrease learning ability.

We treated male zebra finches from the day of birth until adulthood with T. Subcutaneous implants were made so as to maintain a rate of release of roughly 10mgT/kg/day during the first 20 days of life. At day 20, the birds received Silastic implants packed with 10mm of crystalline T. At day 60, the birds were housed in individual cages and their song behavior was recorded until day 90, when stereotyped song has crystallized.

Preliminary results indicate that the number of different syllables produced during each song bout was decreased, resulting in a very limited repertoire. Furthermore most of the birds had stereotyped songs, with a tendency to repeat a single syllable in a pattern lacking the phrasing characteristic of normal song. Thus the results indicate that chronic administration of T disrupts the normal process of song learning and produces significant abnormalities in song structure relative to normal male songs.

113.15

NEURONAL TYPES IN CANARY HVc, A TELENCEPHALIC SONG CONTROL NUCLEUS: A QUANTITATIVE GOLGI STUDY. B. E. Nixdorf, S. Davis* and T. J. DeVoogd. Cornell University, Department of Psychology, Ithaca, N.Y.14853

The song control system of the canary brain is a fascinating system in which to study the effects of steroids on brain development and function, adult neurogenesis and neuronal plasticity, recovery of function, lateralization and sexual dimorphism - issues of general interest to neurobiology. The brain pathways for song control are well described (Nottebohm et al. 1976). Hyperstriatum ventralis, pars caudalis (HVc) receives direct or indirect input from Field L, a major telencephalic auditory station and projects indirectly to the syrinx, the avian vocal organ. Lesion and electrophysiological studies (Margoliash,1983; McCasland,1986) support a central role of HVc in integrating auditory and motor aspects of song. HVc in canaries is much larger in males than in females, a difference parallel to sex differences in singing behavior. The sex difference in HVc size seems closely related to the developmental and adult hormonal status of the animal. Each of these discoveries concerning HVc make it more clear that many exciting sorts of integration occur here and that there are many questions which presently cannot be answered.

To form a structural foundation for experimental manipulation and study of HVc, we have identified neuronal types in HVc in rapid Golgi-stained material, tracing them with the aid of a computer system which allows three dimensional reconstruction and analysis . Sholl analyses, branch morphology and dendritic spine density at various dendritic sites have been used for classification. We have analyzed a total of 103 neurons from adult male and female canaries. We find seven different cell classes in HVc, at least two of which appear to be sexually dimorphic. Dendritic fields range in size from 900 to more than 3800 µm and consist of from 30 to 80 branch segments. Spine density ranges from near zero on smooth stellate-like cells to 2.3 spines / µm on the class most densely packed with spines. Work is in progress to determine to which of these classes adult neurogenesis contributes.

113.16

ANDROGEN-INDUCED SEXUAL DIMORPHISM: PHENOTYPIC ALTERATION OF AN INTRASPINAL SUBSTANCE P (SP) PATHWAY. B.W. Newton and R.W. Hamill. Dept. of Neurology, Monroe Community Hospital / University of Rochester, Rochester, NY 14603

The sexually dimorphic male (M) cremaster nucleus (CN), in the rat L1,2 ventral gray spinal cord, receives a massive intraspinal SP innervation which diverges over CN motoneurons. These M SP patterns are nearly absent in females (F). To test whether the expression of the SP CN-pathway is androgen dependent, F rats were injected with testosterone propionate (TP; 1mg s c.) on postnatal days (P)0,2,4; and on P20,40,60 the SP patterns were examined in littermate M, F, and F-TP rats with the PAP technique. Anti-SP (IncStar lot # 8642009) was diluted 1:8000.

P20 M had a dense SP CN-pathway and moderate CN SP. These patterns were nearly absent in F. F-TP rats had a moderate SP CN-pathway but sparse CN SP. P40 M had a dense SP CN-pathway and dense CN SP. F had an adult SP pattern: sparse SP in the CN-pathway and CN. F-TP rats had a nearly M-like CN-pathway and moderate CN SP. **On P60 both M and F-TP had a M adult-like pattern:** a very dense SP CN-pathway and dense CN SP. F had no change from P40.

Thus, early postnatal TP causes the expression of the M intraspinal SP phenotype in adult F rats. This suggests that androgens either directly or indirectly influence F SP intraspinal neurons to produce SP at levels which are immunohistochemically similar to M. Supported by NS 22103 and Monroe Community Hosp. / U of R research funds.

IMMUNOHISTOCHEMICAL PATTERNS OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) IN RAT LUMBAR SEXUALLY DIMORPHIC NUCLEI. R.W. Hamill and B.W. Newton. Depts. of Neurology, and Neurobiology and Anatomy, Monroe Community Hospital / University of Rochester, Rochester, NY 14603

The male (M) rat lumbar spinal cord contains three known sexually dimorphic (s.d.) nuclei (spinal n. of the bulbocavernosus (SNB), dorsolateral n. (DLN) and cremaster n. (CN)) which contain a greater number of larger motoneurons than females (F). CN innervation is sexually dimorphic for 5HT, and substance P (M>F). Other peptides, such as CGRP, may also be s.d. Adult M and F rats (12) were perfused (Zamboni's) for the PAP technique and anti-CGRP (1:10,000) was applied. No colchicine was used.

In all cases M>F for SNB-, DLN- and CN-CGRP fibers. M CN CGRP fibers >> than all other M & F s.d. nuclei. Only occasional CGRP fibers were observed in M & F SNB and DLN, but CGRP fibers in all s.d. nuclei were > than surrounding ventral horn. However, CGRP fibers in entire VGH << than in laminae I-IV. Most VGH motoneurons contain CGRP except for the s.d. nuclei. M & F SNB and DLN contain scattered CGRP motoneurons whereas the M & F CN motoneurons do not apparently contain CGRP in non-colchicinized rats.

Thus s.d. nuclei are innervated by more CGRP fibers than the surrounding VGH but contain far fewer CGRP-containing motoneurons. CGRP innervation of s.d. nuclei may carry nociceptive information. Supported by NS 22103 and MCH/U of R research funds.

113.18

NERVE GROWTH FACTOR (NGF) PLAYS A PHYSIOLOGICAL ROLE IN FEMALE SEXUAL DEVELOPMENT. **H. Lara*, J.K. McDonald, S.R. Ojeda. Div Neuroscience, OR Reg Pri Res Ctr, Beaverton, OR 97006, and Dept Anat (JKM), Emory Univ, Atlanta, GA.**

Little is known regarding the role of growth factors in the development of neuroendocrine reproductive function. High titer polyclonal antibodies against NGF were produced in rabbits and injected into neonatal rats (12.5 μl/g BW, sc, postnatal day 1-3). While body growth and age at vaginal opening were normal, the age at first ovulation was significantly delayed, and the subsequent estrous cyclicity severely disrupted. Reproductive performance was diminished, as determined by the inability of 50% of the treated rats to sustain pregnancy. The ovaries from antiNGF-treated rats showed an absence of noradrenergic nerves and a marked reduction in neuropeptide Y and calcitonin-gene related peptide nerve fibers. The ovarian estradiol response to hCG was blunted. At a central level, median eminence LHRH nerve terminals from antiNGF-treated rats responded significantly less than controls to stimulation with prostaglandin E_2, a mediator of norepinephrine-induced LHRH release. The results indicate that: a) NGF, through its trophic effect on peripheral sympathetic neurons, plays a role in the acquisition of female reproductive capacity, and b) NGF may be involved in facilitating the development of the reproductive hypothalamus. (Grants HD24870 & RR00163 from the NIH, & The Rockefeller Fnd)

NEUROPEPTIDES AND BEHAVIOR I

114.1

POSSIBLE MU-1 OPIOID RECEPTOR INVOLVEMENT IN MATERNAL BEHAVIOR IN RATS. P.E. Mann, G.W. Pasternak, & R.S. Bridges. LHRRB, Harvard Medical School, Boston, MA 02115, Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Ctr., New York, NY 10021

Maternal behavior (MB) is under an inhibitory influence of opiates. Systemic and central administration of morphine (MOR) disrupts MB in steroid-primed, pup-induced virgin and lactating rats. Naloxonazine (NAZ), a selective and irreversible antagonist of mu-1 opioid binding sites, blocks certain pharmacological effects of opiates. The aim of the present study was to determine if MOR disruption of MB involves the mu-1 binding site. Virgin, Sprague-Dawley rats were mated and on day 3 postpartum jugular catheters were implanted in all rats. On day 5 the rats received one of the following treatments: MOR alone (10 mg/kg, n=10, s.c.); MOR (10 mg/kg) 24 h after NAZ pretreatment (10 mg/kg, n=10, i.v.); MOR (10 mg/kg) 1 min after naloxone pretreatment (NAL, 1 mg/kg, n=10, s.c.); or MOR (10 mg/kg) 24 h after NAL pretreatment (10 mg/kg, n=8, i.v.). MOR alone completely disrupted MB (0% responded) which was blocked by NAL administered 1 min before (100%). NAZ treatment partially blocked MOR disruption of MB (36% responded) which was significantly different from MOR alone. NAZ blocked MOR's effect on pup retrieval to an even greater degree (70% responded vs. 10% in MOR alone). NAL administered 24 h before MOR had no effect. These results suggest involvement of the mu-1 opioid receptor in the regulation of maternal behavior.

114.2

CORRELATION BETWEEN PARENTAL BEHAVIOR AND INFUNDIBULAR VIP-LIKE IMMUNOREACTIVITY IN THE DOVE. R. Cloues* and R. Silver (SPON: S. Stone), Psychology Department, Barnard College of Columbia University, NY, NY 10027.

It is well established that there is an association between prolactin and parental behavior in birds. Recent evidence suggests that the neuropeptide VIP releases prolactin in hens (MacNamee et al, GCE, 1986). We used immunohistochemical techniques to assess the possibility that VIP plays a role in naturally occuring changes in plasma prolactin during breeding in ring doves (Streptopelia roseogrisea). First, we determined the distribution of VIP-like immunoreactive cells throughout the brain. These cells are found in the septum, hyperstriatum, hypothalamus, and infundibular region. Next, we compared VIP profiles in breeding and non-breeding birds. There were differences between parental and non-parental birds in the ventral portion of the infundibular region. More specifically, there is an increase in VIP cell size and staining density in this region in breeding birds compared to simultaneously processed tissue from control animals. In both sexes, these changes in immunoreactivity are detectable at incubation day 5, anticipating the increase in plasma prolactin. Supported by NIMH grant 29380.

MATING ALTERS OXYTOCINERGIC TOPOGRAPHY AND CONTENT IN MALE MICE

G.F.Jirikowski, +J.D.Caldwell and H. Thierer*
Abt. Anatomie und Zellbiologie, University of Ulm, D-7900, FRG and +Biological Sciences Research Center, University of North Carolina, Chapel Hill, NC 27514.

The impact of mating on the distribution of hypothalamic oxytocin neurons and on oxytocin content was studied immunocytochemically and with radioimmunoassays of microdissected hypothalamic nuclei. 15 male unmated white mice were exposed to receptive females overnight. Mating was confirmed by the presence of sperm in the vaginal smear. The males were killed immediately thereafter. Another group of males was exposed to receptive females permanently for two months, unmated males served as controls. In singly mated animals oxytocin immunostained neurons appeared in the paraventricular- and supraoptic nuclei and were scattered in the ventral and dorsal preoptic region. In unmated and repeatedly mated males additional intensely immunostained oxytocin neurons were found in the medial and dorsal preoptic region, in the perifornical region, in the zona incerta and in the ansa lenticularis. In radioimmunoassays of the magnocellular nuclei, smaller amounts of oxytocin were measured in singly mated males as compared with controls or repeatedly mated males. The observed dynamics of the male oxytocinergic brain topography are perhaps due to steroid-dependent changes of the secretory activity of oxtocinergic systems. It is likely that oxytocin is involved in physiological and behavioral changes known to occur in males during sexual activity.

IN VIVO MEASUREMENT OF BIOGENIC AMINES FROM THE PARAVENTRICULAR NUCLEUS (PVN) USING PUSH-PULL PERFUSION: RELATION TO OXYTOXIN (OXY) INDUCED YAWNING. N.J. Laping and V.D. Ramirez. Dept. of Physiology, University of Illinois, Urbana, IL 61801.

Young adult male rats implanted with a push-pull cannula directed at the PVN were perfused with modified KRP buffer. Samples were collected every two minutes for one hour at a flow rate of 18μl/min while yawns were simultaneously recorded. After a ten minute basal collection period, the normal KRP was replaced with KRP containing 50ng/μl OXY for a ten minute duration. Samples were analyzed for dopamine (DA), DOPAC, and 5-HIAA using HPLC-EC. Detectable levels of DOPAC were recorded in all rats with basal levels of 5-100pg/min. Most animals also showed detectable levels of 5-HIAA with basal levels of 150-300pg/min. Samples from one animal also revealed detectable levels of DA with a release pattern mimicking that of DOPAC and basal values of 0-12pg/min. After the OXY treatment yawning was observed in 4 out of 5 rats. Levels of DOPAC during yawning behavior were compared with pre-OXY DOPAC values. This analysis revealed that yawning is associated with momentary decreases in DOPAC release from the PVN (-7.6 ± 4.0pg/min) vs. randomly selected DOPAC changes (10.5 ± 6.1pg/min), suggesting an inhibitory control of DA on yawning behavior.

114.5

ARCUATE NUCLEUS LESIONS MODIFY YAWNING BEHAVIOUR IN THE RAT. E. Doger* and B. Holmgren* (SPON: M.R. Budelli) Dept. de Ciencias Fisiológicas ICUAP, Univ. Aut. de Puebla.MEXICO

Yawning is a discrete behavioural item, that occurs spontaneously at variable frequencies, and is under a complex set of neurotransmitter influences: cholinergic excitatory, dopaminergic (DA) excitatory/inhibitory and other. Yawning can also be elicited by peptidergic hormones: ACTH, MSH, prolactin, oxytocin. Different experimental techniques have led to the proposition that many brain structures (septum, rombencephalon, striatonigral system, hippocampus, paraventricular hypothalamic nucleus, cerebral cortex) and the hypophysis are somehow involved in yawning. In the search for neuroanatomical sites of interactions between neurotransmitters and hormones in the control of yawning, we have made radiofrequency lesions of the arcuate hypothalamic nucleus (AHN) in male Sprague Dawley Rats. The AHN has an important number of DA and pro-opiomelanocortin neurons, and is known to exert an inhibitory control over the adenohypophysis. Bilateral lesions of AHN (n=17) produce a sixteen fold increase in average yawning frequency (normalized values), 24 h. after surgery, effect which declines progressively along 8 days. Unilateral lesions (n=11) induce a lower effect and sham lesioned rats show no change in yawning. Our results thus suggest that the AHN exerts a tonic inhibitory influence on yawning, and that AHN and the adenohypophysis might represent a DA-peptidergic link in the control of this behaviour.

ANTERIOR HYPOTHALAMIC VASOPRESSIN BLOCKADE INHIBITS INTRASPECIFIC AGGRESSION IN MALE HAMSTERS. M. Potegal and C. Ferris. N.Y. State Psychiatric Inst. and U. Mass. Medical Center, Worcester MA

Vasopressin-sensitive neurons in the anterior hypothalmus have previously been shown to affect flank marking, a behavior which occurs with high probability in hamster agonistic encounters. The contribution of these neurons to intraspecific aggression itself was evaluated in two experiments involving intrahypothalamic injections of the V_1-receptor antagonist $d(CH_2)_5Tyr(Me)AVP$. In the first experiment, in which two adult hamsters were paired in a neutral cage with both, one or neither animal having been microinjected with the antagonist, the drug significantly reduced aggression. The second experiment determined if the drug suppressed aggression directly or just affected the animals' aggression eliciting qualities. We found that the antagonist produced a significant, dose-related suppression of resident's attacks on a small intruder hamster. Because these intruders neither initiated aggression nor counter-attacked V_1 receptor blockade in the anterior hypothalamus appears to suppress aggression directly. Furthermore, the drug did not affect social contact nor sexual behavior toward an estrous female. Linkage between the vasopressin control of flank marking and aggression will be explored.

FLANK MARKING FOLLOWING LESION OF VASOPRESSINERGIC NUCLEI IN GOLDEN HAMSTERS. R.W. Irvin*, J.F. Axelson and C.F. Ferris. Dept Physiology, Univ Mass Medical Ctr. Worcester MA 01655

Flank marking in hamsters is controlled by vasopressin (VP)-sensitive neurons in the anterior hypothalamus (AH). The VP innervation to the AH involved in the control of flank marking is unknown. The present study examines flank marking prior to and following kainic acid lesions of the supraoptic nucleus (SON) (n=9), suprachiasmatic nucleus (SCN) (n=5), paraventricular nucleus (PVN) (n=5), bed nucleus of the stria terminalis (BNST) (n=6) and the nucleus circularis (NC) (n=10) of the AH. Hamsters were sacrificed and the lesion sites examined following ICC with anti-AVP using PAP with DAB. Lesioning VP nuclei outside the AH had no appreciable effect on flank marking despite the loss of VP immunoreactivity in the area of the lesion. The only lesion sites that consistently abolished flank marking were localized the area of the NC. However, since the NC is found in the same region of the hypothalamus that also controls flank marking it is not possible to lesion these cells without damaging the surrounding AH. While these results indicate that the VP neurons of the SON, PVN, SCN, and BNST do not appear to play an essential role in the control of flank marking the role of the NC is still unclear.

POSTERIOR PITUITARY HORMONES AND SEPARATION DISTRESS IN CHICKS. Jaak Panksepp, Department of Psychology, Bowling Green State University, Bowling Green, OH 43403.

Avian and mammalian posterior pituitary peptides Arg-vasotocin (AVT) and oxytocin (OXY) were found to be remarkably effective in reducing separation induced distress vocalizations (DVs) in chicks while neither the constituent fragments, tocinoic acid and Pro-Leu-Gly, nor Arg-Vasopressin (AVP) exert such an effect. The effects appeared to be behaviorally specific.

Domestic chicks between 2-14 days of age were injected into the 4th ventricle region with the above peptides just prior to separation. At doses above 10 picomoles of either AVT or OXY, highly reliable reductions in DVs were observed, the effect lasting about 2-3 hrs at 0.1 - 1.0 nmole doses. The animals exhibited no apparent sedation. Following these doses of AVT and OXY, three other discrete behaviors were markedly potentiated --1) lateral head shaking movements, 2) yawning, and 3) wing flapping. The wing flapping produced by AVT and OXY required social-facilitation for full expression, while the head shaking and yawning did not. Head shaking and yawing were potentiated by conjoint treatment with CRF (1 ug) while OXY-induced wing-flapping was reduced by CRF. Peripheral administration of these peptides yielded none of the above effects. The OXY and AVT effects did not show apparent tolerance during 7 successive test sessions. None of the above effects were observed by comparable doses of the ring (tocinoic acid) or linear segments (Pro-Leu-Gly) of OXY. AVP (1 ug) yielded modest increases in DVs with no other clear behavioral effects.

These results suggest that a normal brain function of OXY and AVT peptide systems is the reduction of separation distress, raising the possibility that social bonding mechanisms and related emotions may be mediated by such neurochemistries. An additional impression of the present investigator was that OXY and AVT treated animals appeared to be more less "fearful" or more "courageous" than controls.

a-MSH EFFECTS ON SEPARATION INDUCED DISTRESS VOCALIZATIONS IN CHICKS. B. Abbott* and J. Panksepp (Spon, F.G. DeEskinazi), Dept of Psychology, Bowling Green State University, Bowling Green, OH 43403

Past work has demonstrated that brain opioids very specifically reduce activity in separation distress vocalization (DV) circuits of the brain. Since a-MSH is co-localized in the same neurons as B-endorphin, it was of interest to determine whether that peptide would also modulate separation distress induced by isolating young animals from social stimuli. In 2-12 day old domestic chicks, centrally administered a-MSH (into the 4th ventricle region), but not peripheral a-MSH yielded powerful biphasic effects on DVs. Following an initial modest elevation of DVs (which lasted about 15 minutes, vocalizations were markedly reduced for an hour and a half. The elevation of vocalizations was observed at doses of .04, 0.2, 1.0 and 5.0 µg, but not at .008 µg, and was most clearly seen when base line levels of DVs were reduced by either testing animals in *pairs* or *ndividually* in mirrored test chambers. The two effects may be controlled by different mechanisms since low doses (.04 µg) were more effective in elevating DVs while high doses (1.0 µg) were more effective in reducing DVs. The effects of a-MSH (1 µg) did not exhibit tolerance over four repeated days of testing. Naloxone and morphine interactions studies indicated these effects were independent of *mu*-opioid receptor systems. Birds pre-treated with naloxone (1 mg/kg, i.p.) exhibited no change in the ability of 1 µg of a-MSH to reduce DVs. Likewise, the quieting effects of morphine (5 mg/kg i.p.) were not reduced by central a-MSH.

All doses of a-MSH which reduced DVs produced a strong squatting tendency resembling freezing responses normally seen during fear. Fear is known to reduce DVs, and a-MSH induced reductions in DVs could be explained by such a mechanism of action. Since fear increases measures of tonic-immobility (TI), we evaluated the effects of 1 µg of a-MSH on duration of TI in 3 week old birds. Duration of TI was doubled by this dose of a-MSH suggesting that central a-MSH participates in the generation of behavioral inhibition which normally accompanies fear. Whether a-MSH promotes just the behavior or the central affective state of fear needs to be evaluated in future research.

THE PROFILE OF NEUROBEHAVIORAL EFFECTS PRODUCED BY NEUROPEPTIDE Y. A. Drumheller[1], R. Rivest[1], J.N. Michaud*[1], S. St-Pierre*[2] and F.B. Jolicoeur[1]. [1]Dept. Psychiatry, Fac. of Med., Univ. of Sherbrooke, Québec J1H 5N4 and [2]INRS, Blvd. Hymus, Point Claire, Québec H9R1G6.

Neuropeptide Y (NPY) is a recently discovered member of the pancreatic polypeptide family and has been shown to be widely distributed in mammalian brain (Allen et al., Science 221:877, 1983). Studies concerned with delineating the possible neurobehavioral effects of this peptide have concentrated mainly on the effect of NPY on food and water intake in rodents. However, in view of the pervasive distribution of the peptide in the CNS we thought it worthwhile to design experiments aimed at constructing a more complete profile of the neurobehavioral effects of NPY following intracerebroventricular injections. More specifically, the effects of several doses (2.5-20µg) of the peptide injected into the lateral ventricle on spontaneous motor activity, muscular tone, body temperature, nociception and food intake, as well as its potential for producing catalepsy, were examined. Results indicate that starting at 5.0 µg, motor activity of animals was significantly decreased in a dose related fashion. At 10 µg, NPY induced significant catalepsy, and increased both muscular tone and food intake. Interestingly, body temperature was significantly increased by the smallest dose administered, but significantly decreased with 10 and 20 µg of NPY. In general, all neurobehavioral effects of NPY were already present at 15 min and persisted upto 60 min following administration. On the other hand, no dose tested significantly affected nociception in the animals as measured by the hot plate test. Together, our results indicate that the profile of NPY's neurobehavioral actions is more complex than previously demonstrated and suggests that the peptide might be implicated functionally in a variety of neurophysiological processes.

CHANGES IN THE CONCENTRATION OF BRAIN NEUROPEPTIDE Y (NPY)-LIKE IMMUNOREACTIVITY FOLLOWING OLFACTORY BULBECTOMY (OB) AND EFFECTS OF ANTIDEPRESSANTS IN RATS. Y.Kataoka* (1), M.Ushio* (2), S.Koizumi* (2), M.Niwa (1) and S.Ueki* (2) (Spon:M.Kabuto). (1) Dept. of Pharmacol.Nagasaki Univ.Sch.Med.Nagasaki 852, (2) Dept. of Pharmacol.Fac. Pharmaceu.Sci.Kyushu Univ.Fukuoka 812, JAPAN

OB-induced muricide (mouse-killing behavior) has been known to be a useful laboratory model for evaluating the property of antidepressants. Our previous study suggested that NPY might be involved in the regulation of muricide induced by OB in relation to that of noradrenaline (NA) in amygdala (AME) (Pharmacol.Biochem.Behav.,28,101,1987). The present study was, therefore, designed to investigate changes in NPY-like immunoreactivity (NPY-LI) and NA concentrations following OB and effects of chronic administration of desipramine (DMI) and mianserine (MIA). NPY-LI concentrations in hypothalamus (ventromedial:VMH, lateral:LH) and AME (basolateral:ABL, central:ACE) increased significantly by 25% and 50-70%, respectively, 28 days after OB. Chronic treatment (7 days) with DMI inhibited the elevation of NPY-LI in accordance with the suppression of muricide. The effect of chronic administration of MIA was similar to that of DMI, though the effect was not pronounced in potency.

Our findings provide further evidence for the involvement of NPY in the pathophysiology of depression and the neurochemical mechanism of action of antidepressants.

114.12

EFFECTS OF ALPHA-HELICAL CRF (9-41) ON CRF-AND FEAR-POTENTIATED ACOUSTIC STARTLE RESPONSE (ASR) IN RATS. K.T. Britton (1), N.R. Swerdlow (1) and G.F. Koob (2). (1) Dept. Psychiatry, UCSD Sch. of Med., San Diego, CA 92193; (2) Preclin. Neurosci., RISC, La Jolla, CA 92037.

The acoustic startle response (ASR) is a reflex contraction of the skeletal musculature following exposure to an intense acoustic stimulus. ASR amplitude is increased by conditioned fear, i.e. when the acoustic stimulus follows a cue previously associated with shock. We have reported that ASR amplitude is also increased by intraventricular (ICV) infusion of CRF, a neuropeptide implicated as a substrate in several fear- or stress-enhanced behaviors. We studied the relationship between CRF- and fear-potentiated ASR using alpha-helical CRF (9-41), a peptide known to antagonize the effects of CRF and fear on other behavioral and endocrine indices.

In the first experiment, pretreatment with CRF (9-41) (0-25 µg ICV) was found to reverse CRF-potentiation of ASR amplitude. CRF (9-41) alone did not significantly alter ASR baseline. In a second study, animals were trained in a conditioned-fear paradigm. CRF (9-41) significantly reversed the effects of conditioned fear on ASR amplitude. Doses of CRF (9-41) that reversed CRF- and fear-potentiated ASR were similar. In a third study, CRF (9-41) failed to antagonize the ASR-potentiating effects of strychnine (0.75 mg/kg, i.p.). These results suggest overlapping neural substrates for CRF- and fear-potentiated acoustic startle and suggest that endogenous CRF systems in the brain may be involved in behavioral responses associated with fear and stress.

114.13

THE IMPORTANCE OF CENTRAL AND PERIPHERAL NORADRENERGIC SYSTEMS IN THE ENHANCED CONDITIONED FEAR PRODUCED BY CORTICOTROPIN RELEASING FACTOR. B. J. Cole* and G. F. Koob. Scripps Clinic and Research Foundation. La Jolla. CA 92037.

Both central administration of corticotropin releasing factor (CRF) and activation of the norepinephrine (NE) containing nucleus locus coeruleus (LC) induce behaviors normally exhibited in threatening situations. Furthermore, CRF has been shown to activate NE neurones in the LC. The purpose of the present series of experiments was to investigate the role of NE in the enhanced fear (as measured in the conditioned emotional response paradigm) and the behavioral activation (as measured by locomotor activity in photocell cages) produced by CRF, using the beta-adrenoceptor antagonist propranolol. d,l- Propranolol itself was found not to affect performance of a conditioned emotional response (CER), but it did antagonize the enhanced conditioned fear produced by CRF. This antagonism was specific to l, propranolol, suggesting that it is receptor mediated. In contrast, propranolol was shown to potentiate the locomotor hyperactivity induced by CRF. These results suggest that activation of beta-adrenoceptors may be an important mechanism in the 'anxiogenic' effects of CRF. In addition, they suggest that the neurochemical mechanisms that underlie the 'anxiogenic' and the 'activating' behavioral effects of CRF are neuropharmacologically distinct. Since propranolol acts both in the central and peripheral nervous system, and CRF has also been shown to activate the autonomic nervous system, we are also investigating the relative importance of central and peripheral NE systems in mediating the behavioral effects of CRF using ST91. This drug is a non-lipophilic, selective alpha-2 agonist, that `does not cross the blood-brain barrier.

114.14

CORTICOTROPIN-RELEASING FACTOR PRODUCES ANXIOGENIC & BEHAVIORAL ACTIVATING EFFECTS FOLLOWING MICROINFUSION INTO THE LOCUS COERULEUS. P.D. Butler, J.M. Weiss, J.C. Stout*, C.D. Kilts, L.L. Cook*, and C.B. Nemeroff. Depts. Psychiat. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

Intracerebroventricular (ICV) injection of CRF produces anxiogenic effects and increases locomotor activity in rats. The norepinephrine-rich locus coeruleus (LC) may be of importance in producing these CRF effects; CRF terminals innervate the LC, CRF increases the firing rate of LC neurons, and CRF concentrations are increased in the LC following acute and chronic stress. To examine behavioral activation, struggling and floating were measured in Long-Evans hooded rats for 15 min using the modified Porsolt swim test. Forty-five min following ICV injection, CRF produced a dose-dependent decrease in floating, with the lowest effective dose being 500 ng. However, bilateral infusion of CRF directly into the LC produced significant decreases in floating at doses as low as 10 ng, consistent with the hypothesis that the LC may mediate CRF-induced increases in activity. To examine anxiogenic activity, rats were placed in an open field containing a small darkened compartment for 15 min. Forty-five min following infusion into the LC, CRF significantly increased the time rats spent in the compartment and decreased the amount of time spent exploring the outside of the compartment or venturing into the inner squares of the open field, all indices of anxiogenic behavior. Thus the LC also appears to play a role in the anxiogenic properties of CRF. Preliminary results indicate that bilateral infusion of CRF into the LC produces significant increases in the concentration of the NE metabolite DHPG in several forebrain projection areas of the LC (i.e. the posterior hypothalamus and the amygdala). These data, taken together, suggest that CRF may produce its locomotor activating and anxiogenic effects, in part, by increasing activity of LC NE neurons. (NIMH MH-42088, MH-40406 and MH-42637.)

NORADRENERGIC ACTIVATION OF CRF SECRETION MEDIATES STRESS-INDUCED CHANGES IN EXPLORATORY BEHAVIOR. Craig W. Berridge and Adrian J. Dunn, Department of Neuroscience, University of Florida, Gainesville, FL 32610

Exploratory behavior as measured by the time an animal spends investigating objects in a complex novel environment has been previously shown to be decreased by various stressors (Arnsten et al., 1985; Berridge & Dunn, 1986). Stress activates the release of both norepinephrine (NE) and corticotropin releasing factor (CRF) from neurons in the brain and both have been implicated in regulating behavioral responding. Thus, either or both NE and CRF may be responsible for the stress-induced decrease in exploratory behavior.

This effect of stress can be mimicked in mice by intracerebroventricular (ICV) CRF (5-100 ng) or by promoters of noradrenergic activity; a noradrenergic α-agonist, phenylephrine (50-100 ng injected ICV), and the α_2-antagonist, idazoxan (1.0 mg/kg). Further, the effect of restraint-stress can be antagonized by an α_1-antagonist (prazosin, 100-200µg/kg), an α_2-agonist (clonidine, 25 µ/kg), a noradrenergic neurotoxin (DSP-4) which destroys norepinephrine-containing neurons, and a CRF-antagonist (alpha-helical CRF_{9-41}, ICV 10-50 µg). These data implicate both CRF and NE in the stress-induced change in behavior observed in this paradigm

The behavioral response to ICV CRF is not affected by any of the above mentioned noradrenergic antagonists (DSP-4, prazosin, clonidine). However, the response to the noradrenergic α-agonist, phenylephrine (50-100 ng; ICV) can be reversed by alpha-helical CRF_{9-41} (20 µg). Therefore, these results suggest that behavioral responding during stress, involves an activation of noradrenergic systems which in turn stimulates the secretion of CRF.

CENTRALLY ADMINISTERED GROWTH HORMONE-RELEASING FACTOR AFFECTS FEEDING DIFFERENTIALLY ACROSS PHOTOPERIODS. D. Feifel and F.J. Vaccarino. Departments of Psychology and Psychiatry, University of Toronto, Canada.

We have previously reported that intracerebroventricular (ICV) administration of GRF in doses ranging from 0.4 to 40 picomoles produces a short-term facilitation of eating in the rat. Since all previous investigations were restricted to light photoperiods the present set of studies sought to investigate possible light/dark differences in GRF's feeding effect. Twenty rats were administered 0 (vehicle), 0.4, 4 and 40 picomole rhGRF ICV in the dark or light phase of a 12h:12h light:dark photoschedule. Feeding for the 90 minutes following injections in the light was dose-dependently facilitated similar to our previous results. Conversly, in the dark, a significant dose-dependent inhibition of eating was produced. Both facilitatory and inhibitory effects of GRF were limited to short-term feeding since no effect was seen on 24 hour consumption. Furthermore, since an inactive GRF analogue had no significant effect on eating and GRF itself did not significantly alter locomotor activity in either photoperiod, the differential effects of rhGRF on feeding seem not to be the result of non-specific neurochemical or behavioural influences. Together with other evidence from our lab, this study suggests that GRF may play some role in the endogenous regulation of circadian eating.

114.17

ACIDIC FIBROBLAST GROWTH FACTOR (aFGF) ACTING AS FEEDING SUPPRESSANT. Y. Oomura, K. Hanai*, N. Shimizu*, Y. Kai* and H. Kimura* Dept. of Physiol., Fac. of Med., Kyushu Univ., Fukuoka 812, Japan.

Regulation of feeding behavior and control of body weight involve neuronal and humoral factors. We investigated the effects of aFGF on food intake in the rat.

A phasic increase in aFGF activity was detected in the cerebrospinal fluid (CSF) after feeding. Intraperitoneal glucose injection also produced the increase with dose-dependent manner. CSF samples before and after feeding were applied on a heparin-sepharose column and washed with 1.0 M NaCl. aFGF was eluted in 1.0 M NaCl fraction. From the mitogenic activity change (using BALB/c 3T3 cells) recovered in this fraction before and after feeding, aFGF increased 10 fold after feeding. Intracerebroventricular injection of aFGF (8-20 pmol) suppressed food intake. Electrophoretically applied aFGF specifically suppressed the glucose-sensitive neurons activity in the lateral hypothalamic area (LHA). Neurons in the ventromedial hypothalamus (VMH) were unaffected by aFGF. Immunohistochemical study by aFGF antibody revealed aFGF containing neurons in the LHA, zona inserta, amygdala, hippocampus, globus pallidus, reticular thalamic nucleus, cortex etc. and ependimal cells, but not in the VMH. The glucose injection released aFGF from the neurons. In situ hybridization study indicated aFGF production in the neurons. The results suggest that aFGF participates in the central regulation of feeding.

114.18

DOPAMINE BLOCKADE RELEASES DE-ENCEPHALIZED JUMPING TRIGGERED BY POSTURAL INSTABILITY. T.K.Morrissey*, S.M. Pellis, V.C. Pellis and P. Teitelbaum, Dept. of Psychology, Univ. of Florida, Gainesville, FL 32611.

Rats made cataleptic by systemic haloperidol (0.5-10 mg/kg) jump explosively (up to 86 cm). This seems paradoxical, since the akinesia and inability to initiate movement in catalepsy are often emphasized. However, such catalepsy leaves intact a set of allied reflexes which defend stable static equilibrium (eg. by standing, clinging, bracing and righting). We show that such jumping is not paradoxical but is an allied reflex because it only occurs when postural instability causes the animal's hindlegs to slide forward out from under its body, e.g., by tilting the rat's head down on a board.

The jump under haloperidol is a de-encephalized form, intermediate between decerebrate and normal. Decerebrate cats leap whenever weight is shifted onto the hindlegs and the neck dorsiflexed, even if stable. Such decerebrate jumps are undirected. In contrast, intact rats, given haloperidol, only jump when a key releasing stimulus (instability) is added, but like decerebrate cats, they do not guide their jumps visually and thus leap into walls and over the table edge. In undrugged, intact rats, such jumping is fully adaptive, occurring only in response to postural instability, and only if it can be visually guided to land in a 'safe' location. By these modifications, the primitive jump becomes encaphalized.

114.19

EVALUATION OF THE CENTRAL NERVOUS SYSTEM (CNS) DEPRESSANT EFFECTS OF MURAMYL DIPEPTIDE. K.A. Serpa, W.H. Moos, and L.T. Meltzer. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105

Benzodiazepines (BDZ) are currently the drugs of choice for the treatment of insomnia. Unfortunately, clinically important adverse effects are associated with BDZ use (e.g., CNS depression and drug interactions). Thus, the development of new agents is warranted.

An endogenous muramyl peptide has been identified as the active component of urinary sleep factor S. The synthetic muramyl peptide, N-acetylmuramyl-L-alanyl-D-isoglutamine (muramyl dipeptide, MDP), induces sleep in rats, cats, rabbits, and monkeys. In the present studies, possible CNS depressant effects of MDP were evaluated.

In rabbits, a somnogenic dose of flurazepam induced ataxia (CNS depression) while an equisomnogenic dose of MDP did not induce ataxia.

In rats, triazolam produced a greater potentiation of ethanol-induced effects than did equisomnogenic doses of MDP. Both triazolam and MDP increased the percent of animals losing their righting reflex, the increase being greater after triazolam. Only triazolam increased the duration of the ethanol-induced loss of righting reflex.

Taken together, these data indicate that MDP produces less general CNS depression than do benzodiazepines.

Psychological induction of brain c-fos mRNA. P.F. Morgan, T. Nakajima[1] and M. Linnoila*. LCS, NIAAA and [1]BPB, NIMH, NIH, Bethesda, MD 20892, USA.

Transient induction of the proto-oncogene c-fos mRNA in mouse brain tissue has been reported following chemically- (Morgan, J.I. et al, Sci., 237:192,1987) and electrically- (Nakajima, T. et al, Neurosci. Lett., In press) evoked seizures. Expression of c-fos mRNA was studied in male Hartley guinea pigs 15 minutes after experimental procedures. Total RNA was extracted from whole brain and separated by agarose gel electrophoresis. The RNA was transferred to nitrocellulose membranes and hybridized with a nick-translated ^{32}p-c-fos DNA probe under high stringency conditions. Autoradiograms reveal hybridization to a single band of 2.2 kb. Male Hartley guinea pigs exhibit a delayed righting reflex, which can be of several minutes duration. We report that brain c-fos mRNA can be induced by a 1-minute inversion of such animals ($p<0.01$, compared to control, ANOVA/Scheffe). Brain c-fos is also induced by gently hand-immobilized such animals for a 1-minute period ($p<0.05$, compared to control, ANOVA/Scheffe). These results reveal that c-fos mRNA can be induced by non-invasive manipulations and may be a sensitive marker of psychological activity.

NEUROPEPTIDES AND BEHAVIOR II

115.1

CHOLECYSTOKININ: A MEMORY MODULATOR? E.E.Quinton and D.A.Quinton*. Dept. of Psychology, Univ. of Louisville, Louisville Ky. 40292.

The octapeptide fragment of cholecystokinin, 26-33(CCK-8), is widely distributed throughout the mesolimbic system. It has been claimed that the peptide functions as a memory modulator, but experimental results have been inconsistent when passive avoidance(PA) has been used as the learning paradigm. This study uses a PA procedure that has been extensively utilized to study memory. Groups of male C57BL/6j mice were injected subcu. with 200ug/kg CCK-8, saline, or 5mg/kg proglumid (PROG, a CCK-8 antagonist) immediately after training and 30 min before the test trial 72 hrs later, in a counter balanced design. The test performance of the three groups that received CCK-8 immediately after training was superior to all other groups except the PROG-PROG group, which was also superior to all remaining groups.These data suggest that CCK-8 administered immediately after training can enhance test performance on a PA task, but has no effect on test performance when administered shortly before the test trial. PROG needs to be further investigated.

115.2

EFFECT OF CENTRALLY ADMINISTERED CCK RESEMBLES THAT OF NEUROLEPTIC TREATMENT ON APOMORPHINE INDUCED YAWNING IN RATS. P. Curzon, E. Danaher*, A. Nadzan* and D. Britton. Neuroscience Research Division, Pharmaceutical Discovery, Dept. 47H, Abbott Laboratories, Abbott Park, IL 60064.

Apomorphine (APO) at very low doses (.032-1.78 mg/kg, s.c.) rapidly elicits a yawning response in rats with an inverted "U" shaped dose-response curve. The peak number of yawns occurs at between 0.056 and 0.078 mg/kg. ICV injection of 10 and 100 pmol of either CCK-8-S or BOC-CCK-4 prior to APO significantly reduced the number of yawns at either 0.056 or 0.078 mg/kg.

We have confirmed earlier reports (Protais et al., 1985; Argiolas and Melis, 1987) that the yawning response is antagonized by both typical and atypical neuroleptics. Haloperidol (.1 and .2 mg/kg), clozapine and sulpiride (each at 1.0 and 2.0 mg/kg) were tested against several doses of APO. All three drugs not only reduced the number of yawns but also shifted the dose of APO that produced the peak number of yawns to the right.

When CCK-8-S (10 or 100 pmol) is injected i.c.v. 15 min. prior to varying doses of APO, yawning is reduced by both doses of CCK-8-S and is significantly suppressed at 0.078 mg/kg of APO. These results suggest some common factors between CCK and neuroleptic pharmacology.

115.3

A "PERIPHERAL TYPE" CCK RECEPTOR ANTAGONIST (A-65186) BLOCKS BEHAVIORAL EFFECTS OF ICV AND IP ADMINISTERED CCK IN MICE. D.R. Britton, L. Yahiro*, M.J. Cullen*, J. Kerwin*, H. Kopecka* and A. Nadzan*, Neuroscience Research Div., Pharmaceutical Discovery, D-47H, Abbott Laboratories, Abbott Park, IL 60064.

Cholecystokinin octapeptide (CCK-8) administered centrally (icv) suppresses several types of behavioral activity in mice including exploratory locomotion. Systemic (ip) administration of CCK-8 also suppresses activity. At doses equimolar to those active for CCK-8, neither desulfated CCK (CCK-8-DS), nor the protected tetrapeptide fragment, BOC-CCK-4, is behaviorally active. Boc-CCK-4 failed to antagonize the effects of centrally administered CCK. A potent and selective antagonist to the peripheral type (Type A) CCK receptor, A-65186, when given systemically, blocked the effects of systemically administered CCK but failed to block the effects of icv administered CCK. Central administration of A-65186 blocked the effects of icv administered CCK. These results demonstrate that administration of exogenous CCK to mice can suppress exploratory locomotion by acting either centrally or peripherally and that in either case the behavioral effects are mediated via a "peripheral" type (Type A) CCK receptor.

115.4

LORDOSIS RESPONSE TO SITE-SPECIFIC CHOLECYSTOKININ (CCK-8) IN THE MALE. GJ Bloch*, WA Dornan, AM Babcock*, RA Gorski, and PE Micevych, Dep't of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, Ca. 90024.

In females, CCK-8 inhibits lordosis when injected into the ventromedial hypothalamus (VMH;Babcock et al, Physiol Behav:42,'88) and facilitates lordosis when injected into the medial preoptic area (MPO;Priest et al, Neurosci Abst:14,'88)). Intracerebroventricular CCK-8 has a dramatic facilitatory effect on lordosis in estrogen-primed males. We tested the lordosis response to site-specific injections of CCK-8 in males. Male rats were castrated as adults, then given injections of CCK-8 into the VMH or MPO 2 weeks later and their receptivity was assessed by determining a lordosis quotient (LQ). Animals with MPO cannulae were primed with 5 ug estradiol benzoate (EB) per dayX 3, while animals with VMH cannulae were given 5 ug EB/day X3 before each of 3 testing sessions, then 30 ug EB/day X3 before an additional 2 testing sessions. MPO injection of as little as 5 ng CCK-8 had a dramatic facilitatory effect (LQ=87.5±7.3 with CCK-8 vs 39.8±11.4 with vehicle, $p<0.01$). In contrast, VMH injection of 5 ng to 100 ng CCK-8 had no effect on the LQ when animals were either low- or high-receptive. These results demonstrate that: 1) CCK-8 injected into the MPO facilitates lordosis behavior in the estrogen-primed male, and 2) CCK-8 injected into the VMH inhibits lordosis in the female but not in the male. Supported by NS 21220 (PEM) and HD 01182 (RAG).

FACILITATION OF LORDOSIS BY INJECTION OF CCK-8 INTO THE MEDIAL PREOPTIC AREA IN THE FEMALE RAT. C.A. PRIEST*, W.A. DORNAN, G. BLOCH*, P.E. MICEVYCH, Department of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

Accumulating evidence supports a role for cholecystokinin (CCK) in the neural mediation of estrogen-induced sexual receptivity (lordosis) in the female rat. One neural substrate that has been reported to participate in the CCK mediation of lordosis is the ventromedial nucleus of the hypothalamus (VMH). Direct injections of CCK-8 into the VMH were found to inhibit lordosis in female rats. Recently, the VMH and the medial preoptic area (MPOA) have been shown to functionally interact in the activation of lordosis. Since the MPOA has extensive CCk terminal fields, we were interested in examining the effects on lordosis following CCK-8 injections into the MPOA. Adult Long-Evans ovariectomized female rats were implanted with unilateral guide cannulae aimed at the MPOA. One week following surgery, each female was injected with 5ug estradiol benzoate at 10 day intervals 53 hours before a mating test, for a total of 5 tests. Ten minutes prior to each test females were injected with artificial CSF or CCK (5, 50, 100 ng). The effects of these injections on lordosis were assessed by recording the number of lordotic responses following 10 mounts with pelvic thrusting by a sexually vigorous male. Injections of CCK-8 directly into the MPOA produced a facilitation of lordosis in ovariectomized estrogen treated females. In a previous study in our lab, peripherally injected CCK-8 facilitated lordosis when receptivity was low, and attenuated lordosis when receptivity was high. In contrast, in the VMH study injections of CCK-8 inhibited lordosis when receptivity was high and had virtually no effect on lordosis when receptivity was low. Taken together, these results strongly implicate CCK as a functional link in the reciprocal control of lordosis by the VMH and MPOA. (Supported by NS21220 PEM).

SUBSTANCE P IMMUNOREACTIVE NEURONS IN THE VENTROMEDIAL NUCLEUS PROJECT TO THE DORSAL MIDBRAIN CENTRAL GRAY. W.A. DORNAN, T.R. AKESSON, P.E. MICEVYCH, Department of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

Numerous studies have revealed the importance of the ventromedial nucleus (VMN) and the midbrain central gray (MCG) for the expression of sexual receptivity (lordosis) in the female rat. Cells within the VMN have been shown to project to the MCG and as a result, this pathway has been implicated in the regulation of lordosis. Recently, Dornan, Malsbury, and Penney (Neuroendocrinol., 45: 498, 1987) have demonstrated that substance P (SP) facilitated lordosis following injections into the dorsal MCG. SP-containing cells as well as SP receptors have been localized in the VMN and MCG respectively. Collectively, this suggested to us that perhaps SP neurons originating within the VMN terminate in the dorsal MCG and form part of the neural circuitry involved in the regulation of lordosis. Fluoro-gold was iontophoretically injected into the dorsal MCG of adult female Long-Evans rats. After a 14 days survival period all animals received ventricular injections of colchicine (100 ug) and were sacrificed 2 days following colchicine treatment. Only brains that had intense iontophoretic injection sites restricted to the dorsal MCG were subsequently processed for SP immunofluorescence (FITC). Alternate fluorescent illumination revealed cell bodies in the ventral lateral portion of the VMN for both FG and FITC (double-labelled). Double labelled cells were more abundant in the caudal aspect of the VMN. In addition, some doubled-labelled cells were also found in the central and dorsomedial subdivisions of the VMN. These results provide morphological evidence for a SP-specific projection from the VMN to the dorsal MCG, and strongly implicate this pathway as an important part of the neural circuitry modulating lordosis in the rat. Supported by NIH grants NS 21220 (PEM) and HD 22869 (TRA).

VAGOTOMY BLOCKS THE PERIPHERAL EFFECTS OF CCK-8 ON LORDOSIS BEHAVIOR IN THE RAT. AM Babcock*, JC Barton*, GJ Bloch*, PE Micevych (Spon:Adinolfi,AM). Dept of Psychology, University of S. Alabama, Mobile AL 36688 and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

We have previously reported that i.p. injection of CCK-8 alters lordosis behavior in estrogen-primed female rats (Physiol Behav:39,217,'87). Since the effects of i.p. CCK-8 on feeding and exploratory behaviors are blocked by vagotomy, we investigated the effects of CCK-8 on lordosis behavior in vagotomized rats. Adult female rats were ovariectomized and underwent vagotomy (VAG;n=12) or a sham (SHAM;n=12) procedure. One week following surgery, rats were injected with 10 ug estradiol benzoate and tested 53 hrs later. CCK-8 (3 ug/kg) or saline vehicle (SAL) was injected i.p. 10 minutes before behavioral testing. To evaluate increased levels of receptivity, rats were retested every 8 days for a total of 4 behavioral tests. Lordosis quotients (LQ) were evaluated using an independent t-test. Injection of CCK-8 significantly stimulated LQ in SHAM animals on behavioral tests 2 (CCK,60±15 vs SAL,26±9;$p<.05$) and 4 (CCK,70±12 vs SAL,25±11;$p<.05$). CCK-8 failed to alter the LQ of VAG animals for any of the 4 behavioral tests. These findings suggest that the stimulatory effects of i.p. CCK-8 on lordosis are, in part, mediated through afferent vagal fibers. Supported by USARC 3-61332 (AMB).

ANALGESIA INDUCED BY RESTRAINT STRESS IS ATTENUATED BY CCK AND ENCHANCED BY THE CCK ANTAGONISTS MK-329, L-365,031 AND CR 1409. **C.T. Dourish, M.L. Clark* and S.D. Iversen* Merck Sharp and Dohme Research Laboratories, Neuroscience Research Centre, Terlings Park, Harlow, Essex, CM20 2QR, U.K.**

The neuropeptide cholecystokinin (CCK) attentuates opiate-mediated analgesia induced by morphine injection or front paw shock (Faris et al, 1983). The selective CCK antagonist MK-329 enhances morphine analgesia and prevents morphine tolerance (Dourish et al, 1988). This study examined the effects of CCK and three CCK antagonists on analgesia induced by acute restraint stress. Analgesia was assessed using the radiant heat tail-flick method, as previously described (Dourish et al, 1988). Basal tail-flick latencies were determined 20 min prior to drug; test latencies 25 min post-restraint. Drug treatments were given prior to restraint as follows: CCK (10 min), naloxone (15 min), CCK antagonists (30 min). Data were expressed as % of maximum possible effect (% MPE). Restraint for a 15 min period produced analgesia, ranging from 25-40% MPE. The analgesia was dose-dependently reduced by naloxone (0.4-2.5 mg/kg sc) indicating that it was opioid mediated. Similarly, CCK (4-16 ug/kg ip) dose-dependently blocked the response. In contrast, the CCK antagonists MK-329 (0.05, 0.1 mg/kg sc), L-365,031 (0.5-2.0 mg/kg sc) and CR 1409 (0.3-1.0 mg/kg sc) significantly enhanced restraint-induced analgesia to 70-80% MPE. Thus, CCK antagonists enhance analgesia produced by endogenous or exogenous opioids, suggesting that they may be of value in the treatment of pain.

CHOLECYSTOKININ-TETRAPEPTIDE INDUCES PANIC ATTACKS IDENTICAL TO SPONTANEOUS PANIC ATTACKS IN PATIENTS SUFFERING FROM PANIC DISORDER. J. Bradwejn, G. Meterissian* and D.Koszycki*. St. Mary's Hosp., McGill Univ., Montreal, Quebec, Canada, H3T 1M5.

Cholecystokinin (CCK) is found in high concentrations in the limbic system of mammalian CNS. When applied on limbic neurons, CCK produces an excitation. Benzodiazepine receptor agonists selectively antagonize this excitation. Therefore, it has been suggested that CCK might play a role in anxiety and/or panic. We undertook this study to compare the effects of CCK-tetrapeptide (CCK-4, 30-33) with spontaneous panic attacks of patients suffering from panic disorder.

Eleven patients (6 males, 5 females; aged 20 to 51 years) were studied. Using a randomized, double-blind design, they received i.v. CCK-4 (50μg) and i.v. saline separately, on two different days.

CCK-4 induced a panic attack in all patients whereas saline had no effect. The attacks began 20 $\pm$ 3 seconds after the end of the injection and lasted 20.7 $\pm$ 7.3 minutes. The attacks were reported to be identical in symptoms to spontaneous panic attacks. The appearance of symptoms of CCK-4-induced attacks was identical to the one experienced during spontaneous panic attacks.

The reproduction of symptoms of spontaneous panic attacks by CCK-4 suggests that CCK might play a role in the neurobiology of panic disorder.

115.10

ANXIETY AND PANIC ATTACKS INDUCED BY THE TETRAPEPTIDE CHOLECYSTOKININ IN HEALTHY VOLUNTEERS. C. de Montigny. Dept. of Psychiatry, McGill University, Montreal, Canada.

From the observation that benzodiazepines antagonize cholecystokinin(CCK)-induced activation of CNS neurons in the rat, it was postulated that CCK might be involved in the pathogenesis of anxiety disorders. To put this hypothesis to the test, the tetrapeptide form of CCK (30-33) (CCK-4) was injected intravenously to 10 healthy volunteers (8 males; 2 females).

Seven of the ten subjects experienced a panic attack, lasting for 1 to 4 min, with doses of CCK-4 ranging from 20 to 100 µg. In the three others, doses of 80 to 100 µg induced a marked anxiety, but no panic. The CCK-4 injection produced pronounced gastrointestinal symptoms in all subjects.

Pretreatment of subjects, in whom CCK-4 had induced a panic attack, with lorazepam, but not with meprobamate or naloxone, prevented the panicogenic effect of CCK-4.

Intravenous injections of the sulphated octapeptide (26-33) (CCK-8S) induced intense gastrointestinal symptoms which precluded the administration of more than 40 µg. At this dose, CCK-8S did not induce any panic or anxiety.

It is concluded that CCK-4 can induce panic attacks or anxiety in healthy volunteers. Definite evidence remains to be provided that CCK-4 produces its panicogenic/anxiogenic effect through direct activation of CNS neurons of the limbic system.

115.11

CHOLECYSTOKININ POTENTIATES DOPAMINE-INDUCED HYPOLOCOMOTION IN THE VENTRAL TEGMENTAL AREA OF THE RAT. J.N. Crawley. NSB, NIMH, Bethesda, MD 20892.

Cholecystokinin (CCK) coexists with dopamine (DA) in ventral tegmental neurons projecting to the nucleus accumbens in the rat. To investigate the possible behavioral functions of CCK in the ventral tegmental area (VTA), CCK was microinjected alone or in combination with DA via indwelling cannulae at stereotaxic coordinates 5.8 mm caudal and $\pm$ 0.5 mm lateral to bregma, and 6.9 mm ventral to the surface of the skull. CCK (100 pg to 100 ng), had no effect alone on locomotion, but CCK (1 ng to 400 ng) significantly potentiated the hypolocomotion induced by DA (5 ug). Topographical analysis showed that CCK potentiated DA-induced hypolocomotion only in the medial and caudal VTA. Pharmacological analysis showed that unsulfated CCK-8 and CCK-4 also potentiated DA-induced hypolocomotion in the nanogram dose range, and that peripheral-type CCK receptor antagonists were less potent blockers of CCK potentiation of DA-induced hypolocomotion in the VTA, than of CCK potentiation of DA-induced hyperlocomotion in the nucleus accumbens (Crawley et al., JPET, 1986). These data suggest that CCK acts as a facilitatory modulator of DA in both the cell body and the postsynaptic regions of the mesolimbic pathway. The actions of CCK at the VTA site resemble the pharmacology of the central-type CCK receptor, while the actions of CCK at the nucleus accumbens site resemble the pharmacology of the peripheral-type CCK receptor.

MICROINJECTIONS OF CCK INTO THE NUCLEUS ACCUMBENS ATTENUTE THE LOCOMOTOR ACTIVATING EFFECTS OF SYSTEMIC HEROIN. F. J. Vaccarino, J. Mogil* and J. Rankin*. Departments of Psychology and Psychiatry, University of Toronto, Toronto, Ont. M5S 1A1.

Activation of opiate receptors in the nucleus accumbens (NA) is important for the locomotor activating properties of systemically administered heroin (Amalric and Koob, 1985, Vaccarino and Corrigal, 1988). Findings showing that cholecystokinin (CCK) terminals are present in the NA and that central CCK has neuromodulatory effects raise the possibility the NA CCK may influence the expression of heroin-induced locomotor activity. In order to examine this possibility, the present study investigated the effects of intra-NA CCK microinjections on locomotor activity induced by systemic heroin.

Rats with cannulae implants aimed bilaterally at the NA were tested for their locomotor response (over 120 minutes) to *systemic heroin (0.3 mg/kg, s.c.) followed by intra-NA* microinjections of sulfated CCK octapeptide in doses of 0.0 (saline vehicle), 0.5, 1.0, 2.0 and 4.0 µg. Each rat received all drug treatments in random order. Intra-NA CCK was administered in a volume of 0.25 µl per side over a 1 minute period using a microdrive pump. A minimum of 2 days separated drug tests.

The results demonstrated that CCK had opiate antogonist-like effects on heroin-induced locomotor activity. Intra-NA CCK dose-dependently attenuated the initial hypolocomotion and the subsequent hyperlocomotion produced by systemic heroin treatment. These results suggest that NA CCK plays a modulatory role in heroin-induced behavioural activation. Opiate antagonist-like effects of CCK have also been reported in morphine-induced analgesia studies, suggesting that CCK/opiate antagonism is present in other behavioural systems.

CCK was generously provided as a gift by the Squibb Institute for Medical Research. This work was supported by a grant from the Ontario Mental Health Foundation to FJV.

CYSTEAMINE-INDUCED DEPLETION OF CENTRAL SOMATOSTATIN AND PASSIVE AVOIDANCE CONDITIONING IN RATS.

G. R. Sessions, M. D. Matthews*, and G. F. Koob. Walter Reed Army Institute of Research, Washington, DC 20307, Drury College, Springfield, MO 65802 and Scripps Clinic and Research Foundation, La Jolla, CA 92037.

Intracerebroventricular (ICV) injections of somatostatin in laboratory rats have been shown to inhibit the extinction of active avoidance responding *(Vescie, et al., Acta Phys. Hung., 62:205, 1983)*, and to block ECS-induced amnesia *(Vescie, et al., Peptides, 4:293, 1983)*. Animals with depletions of somatostatin induced by ICV injections of cysteamine acquire an active avoidance task and inhibit punished avoidance responding in a normal manner *(Sessions, et al., Neurosci. Abs., 11:1113, 1985)*, but have been reported to be deficient in learning a one-trial passive avoidance task *(Bakhit & Swerdlow, Bn. Res., 365:159, 1986)*. Two experiments further investigated the capability of somatostatin-depleted animals to learn and retain a passive avoidance response. Groups of rats received ICV injections of cysteamine (250 or 350 µg in 2 µl saline) or saline for three (Exp. 1) or four (Exp. 2) consecutive days. Forty-eight hr following the last injection, they received one shock-punishment trial in a step-through passive avoidance task. Twenty-four hr later the animals were tested for retention of the passive avoidance response. In both experiments, results showed no differences in retention of the passive avoidance response between cysteamine-injected and saline-injected controls. These results lend no support for findings suggesting a passive avoidance deficit in animals with depletions of cerebral somatostatin, and, together with similar negative findings in a previous active avoidance study, suggest that somatostatin depleted animals do not suffer memory deficits detectable in avoidance paradigms.

STRUCTURE ACTIVITY STUDY OF NEUROTENSIN IN AN ANIMAL MODEL OF PARKINSON'S DISEASE. R. Rivest[1], S.St-Pierre*[2] and F.B. Jolicoeur[1]. [1]Dept. Psychiatry, Fac. of Med., Univ. of Sherbrooke, Quebec J1H 5N4 and [2]INRS, Blvd. Hymus, Pointe-Claire, Quebec H9R 1G6.

Intracerebroventricular (ICV) administration of neurotensin (NT) has been shown recently to attenuate specificParkinson-like symptoms induced by injection of 6-OHDA into the medial forebrain bundle (MFB) of rats (R. Rivest, F.B. Jolicoeur, Soc. Neurosci. Abst. (12) no. 41.22, 1986). In the present study, the effects of two NT fragments, NT_{8-13} and NT_{1-10}, and two NT analogues, [D-Tyr^{11}]-NT and [Ala^{11}]-NT, on muscular rigidity and tremors induced by 6-OHDA treatment were investigated. Male hooded rats received bilateral injections of 26 µg 6-OHDA in the MFB (A-0.8; L-2.0; V-8.0 in relation to bregma), and were implanted with an indwelling left ventricular cannula. The 6-OHDA treatment resulted in several neurobehavioral anomalies such as hypoactivity, catalepsy, recurrent bouts of hind leg tremors and muscular rigidity as measured by evaluation of tail rigidity and a prolonged grasping time. Peptides were administered ICV in doses ranging from 0.45 to 120 µg/10 µl and presence and intensity of the above symptoms were recorded over a 2 hr period following injections. Muscular rigidity and tremors were not altered by either NT_{1-10} or [Ala^{11}]-NT even at the highest dose, while 60 µg of NT_{8-13} decreased grasping time 15 min after injection. However, the NT analogue [D-Tyr^{11}]-NT proved to be markedly more potent in its anti-Parkinson-like effects. Compared to NT, which significantly decreased grasping time, tail rigidity and tremors at 30.0, 7.5 and 30.0 µg respectively, the analogue produced similar effects at 1.8, 0.9 and 0.9 µg respectively. Together these results indicate that our previous observations of anti-Parkinson's actions of NT are not solely due to unspecific effects of peptide administration, are largely dependent on the carboxy terminal of NT, and that the tyrosine residue in position 11 plays a critical role in these actions of NT.

EFFECTS OF HALOPERIDOL ON BOMBESIN-INDUCED HYPOTHERMIA AND APHAGIA IN FOOD DEPRIVED RATS. L. Perez,*K. Tyler,*A.M. Babcock,*(SPON: C.W. Brown). Dept. of Psychology, University of South Alabama, Mobile AL 36688.

Intranigral injections of bombesin (BBS) produce hypothermia and aphagia in food deprived rats. Since the substantia nigra (SN) contains dopaminergic elements which are implicated in feeding and thermoregulation, we evaluated the effects of haloperidol (HAL) on BBS-induced aphagia and hypothermia.

Food deprived (18 hrs) rats, previously implanted with cannulae aimed at the SN, received the following treatments in random order: HAL (.5 mg/kg; I.P.) + BBS (100 ng/.5 ul), HAL vehicle (.3% tartaric acid) + BBS, HAL + BBS vehicle (saline), HAL vehicle + BBS vehicle. HAL was given 60 minutes prior to BBS. Food intake was measured for 30 minutes following BBS or saline injection. Rectal temperature was measured before and after presentation of the test diet. Data were evaluated using ANOVA and Newman Keuls post hoc procedures ($p<.05$).

Intranigral injections of BBS significantly decreased food intake and core body temperature. Treatments of HAL alone significantly reduced food intake, but did not alter body temperature. Administrations of HAL attenuated BBS-induced hypothermia and aphagia.

These findings suggest that BBS-induced hypothermia, and perhaps aphagia, are in part mediated through an interaction with dopamine elements within the SN.

CONOTOXINS FROM A SNAIL-HUNTING CONE VENOM: BIOCHEMICAL CHARACTERIZATION AND CLONING. D.R. Hillyard*, S. Woodward*, C. Ramilo*, G.P. Corpuz*, B.M. Olivera and L.J. Cruz. Howard Hughes Medical Institute and Dept. of Biology, University of Utah, Salt Lake City, UT 84112, and Marine Sci. Inst., Univ. Philippines, Metro-Manila, Philippines.

We purified and biochemically characterized 3 major toxins from the venom of a mollusc-hunting snail, Conus textile, and are presently cloning the genes for these toxins. The 3 toxins, all 27 amino acids long, have quite different physiological effects on vertebrates and do not have related sequences. One of these toxins, the "King-Kong" peptide causes a convulsive-like state when injected into molluscs, and an abnormal "dominant" postural gait when injected into crustaceans. The other two peptides are Y-carboxyglutamate (Gla) containing, but not homologous to each other. One of these causes a mouse to phenocopy the "spastic" phenotype; the other peptide causes rapid running. The discovery of two Gla-containing major toxins in the venom of a snail-hunting cone suggests that neuroactive Gla-containing peptides will be widely found within Conus venoms.

cDNA clones have been obtained from Conus textile venom; the "king-Kong" peptide gene is presently being sequenced. A comparison of sequences of various toxin genes should reveal processing signals, at both the N terminus and C terminus, as well as sequences that are potentially important in proper peptide folding.

FMRFamide perfusion of the isolated Aplysia gill prevents habituation of siphon evoked gill withdraval. E. Colebrook, D. Cawthorpe, A. Higgins and K. Lukowiak. Dept. Med. Physiol. Faculty of Med. University of Calgary, Alberta, Canada.

The evoked gill withdrawal response (GWR) of the Aplysia gill which has been isolated from the abdominal ganglion has been described to exhibit forms of learning such as habituation and sensitization which may be modulated by peptides.

The results reported here are similar to those previously reported about the effects of FMRFamide upon the gill evoked GWR (Cawthorpe et al. 1988 Reg. Pep. in press). In these experiments the effects of FMRFamide perfusion upon the siphon evoked GWR was examined. FMRFamide perfusion of the gill via the afferent vein was found to increase the amplitude of the siphon evoked GWR with threshold effects around 3 nM. Habituation of the GWR to repeated siphon stimulation was prevented by perfusion of 10 nM FMRFamide through the gill.

These findings further support the role of FMRFamide as an endogenous modulator of gill adaptive behaviors.

DEVELOPMENTAL RESPONSIVENESS OF THE HEART AND FEEDING SYSTEM OF THE TERRESTRIAL SLUG, LIMAX MAXIMUS, TO SCP_B. I.G. Welsford and D.J. Prior. Dept. Biological Sciences, Northern Arizona University, Flagstaff, AZ. 86011-5640.

SCP_B had no effect on heart activity (rate or apparent force of heart contractions) or feeding activity in stage IV (7-10 days after laying) embryos of the terrestrial slug Limax maximus (0/5) but caused dose-dependent increases in heart activity in 100% (n=5) of stage V (12-15 days after laying) embryos with an approximate threshold concentration of 10^{-9} M. In contrast, SCP_B had no effect on feeding activity in stage V embryos (0/5). SCP_B caused dose-dependent increases in heart activity and initiated patterned feeding in 100% (n=5) of stage VI (22-25 days after laying) embryos with an approximate threshold concentration of 10^{-9} M. SCP_B had the same effects on 100% (n=4) of hatchling Limax 4 $\pm$ 2.3 hr. post-hatch in age and 80% (4/5) of hatchling Limax 70 $\pm$ 1.8 hr. post-hatch in age. For both groups, the approximate threshold SCP_B concentration was 10^{-9} M. Although SCP_B caused dose-dependent increases in heart activity in 100% (n=5) of Limax 1 mo. post-hatch in age, it initiated only the appetitive phase of feeding behavior in these animals(4/5). The threshold concentration of SCP_B for the increase in heart activity was 10^{-9} M while that for the effect on feeding was 10^{-7} M. These results suggest that peripheral targets in Limax are responsive to SCP_B earlier in development than central targets and central responsiveness to SCP_B is altered after 70 hr. post-hatching.

115.19

IMPAIRED BEHAVIORAL HABITUATION IN VASOPRESSIN DEFICIENT BRATTLEBORO RATS IS INDEPENDENT OF GENETIC BACKGROUND. **A. Cerbone and A.G. Sadile, Inst. Human Physiol. & Biomed. Phys., Univ. Naples, 1st Med.Sch., 80138, Naples, Italy.**

Aim of this study was to investigate the role of the genetic background and that of perinatal vasopressin (AVP) in determining the behavior of adult vasopressin deficient Brattleboro rats. To this end the genetic pool of Brattleboro rats, homozygous for diabetes insipidus (DI/DI: Inst. Anatomy, Univ. Oxford) was shuffled with that of normal, Long-Evans rats (+/+). The F2 hybrids, homozygous (DI/DI), heterozygous (DI/+) and normal (+/+), shared the genetic pool, differying for the vasopressin gene only. During perinatal development all rats were raised by normal mothers in presence of circulating plasma vasopressin. This group was compared with DI/DI rats born from DI/DI mothers, with no perinatal vasopressin. At the age of 80-90 days, all rats were tested in a Làt's maze for three 10min-exposure at 24 hr interval. Corner crossings and rearings were monitored per 30sec-blocks. DI/DI rats from the perinatal AVP group showed higher body and brain weight than those from the no vasopressin group. DI/DI rats were more active, the within exposure activity decline was similar across groups. The between exposures activity decrement (long-term habituation) was impaired in all DI/DI rats, including original Oxford-rats. The lack of response inhibition to novelty is a constant feature of DI/DI rats and does not result from a specific constellation of genes from high inbreeding.

MIF ACTS AS A CS FOR CONDITIONED MORPHINE TOLERANCE. C. R. McLaughlin, A. H. Lichtman, M. S. Fanselow* and C. P. Cramer. Dept. of Psychology, Dartmouth College, Hanover, NH 03755.

Pro-Leu-Gly-NH2 (melanotropin-release inhibiting factor, MIF) has been reported to inhibit the formation of morphine tolerance in rats (review in Bhargava, 1986). Because tolerance to morphine-induced antinociception can be an associative process that follows the laws of Pavlovian conditioning (Baker & Tiffany, 1985; Eikelboom & Stewart, 1982; Paletta & Wagner, 1986; Siegel, 1975), we tested the effect of MIF on the acquisition of tolerance and its efficacy as a cue predictive of morphine administration. Adult male rats were administered either MIF (4 mg/kg, ip) or water two hr prior to daily morphine administration (10 mg/kg, ip) for 10 days. MIF did not attenuate the acquisition of tolerance to morphine-induced antinociception, as measured by the latency to hindpaw lick in a hotplate test of analgesia. Half of the animals in each group were then reassigned to the other pretreatment group. Animals tested 72 hr later with a different pretreatment displayed longer pawlick latencies than those given the same pretreatment, indicating a loss of tolerance.

We suggest that MIF can interfere with the expression of tolerance by acting as a CS that reliably predicts the antinociceptive properties of morphine.

116.2

OPIOID MODULATION OF PAVLOVIAN LEARNING FOLLOWING LESIONS OF THE AMYGDALOID CENTRAL NUCLEUS. L.L. Hernández and P.C. Gantt. Dorn Veterans' Hospital and University of South Carolina, Columbia, SC 29201.

Albino rabbits prepared with bilateral lesions of the amygdaloid central nucleus (ACN), and sham-lesioned controls, were treated intravenously with either d-ala2-met-enkephalinamide (DALA; 10 μg/kg), naloxone-HCl (0.5 mg/kg) or saline vehicle (0.2 ml/kg), and were subjected to a variety of behavioral and physiological tests. Both DALA and naloxone treatments decreased locomotor activity but had opposite effects on Pavlovian conditioned bardycardiac responses to tones paired with paraorbital shocks. ACN lesions had no effects on locomotor activity or bradycardiac orienting reflexes to novel tones, but did reduce the magnitude of Pavlovian conditioned bradycardiac responses and altered responses to unsignalled shocks. Interactions between the effects of the opioid treatments and ACN lesions support earlier findings suggesting that certain effects of systemic opioid and antagonist treatments on Pavlovian conditioning and related behavior involve the ACN.

DYNORPHIN A: SELF-ADMINISTRATION IN CA3 HIPPOCAMPAL FIELD IN THE RAT. K.E. Stevens, G. Shiotsu*, J.D. Belluzzi and L. Stein. Dept. Pharmacol., Univ. Calif., Irvine, CA 92717

The presence of dynorphin terminals and kappa opioid receptors in the CA3 area of the rat hippocampus has been demonstrated by immunohistochemical and autoradiographic methods. Last year we reported *in vitro* operant conditioning of individual CA3 pyramidal cells in brain slices with locally applied dynorphin A (DYN) or U50,488H (U50) as reinforcement (Stein and Belluzzi, 1987). Here, we report evidence of DYN and U50 reinforcement at the behavioral level by demonstrating self-administration of these compounds in the hippocampal CA3 area in the intact animal. Rats were implanted with a unilateral guide cannula aimed at the CA3 pyramidal cell layer. Following recovery, they were connected to the EMIT self-administration system and allowed to self-administer DYN (0.01 - 33 pmol/inj.), U50 (0.1 - 33 pmol/inj.) or Ringer's vehicle by means of a nose-poke response which delivered 100 nl during a 5-sec infusion interval. Both kappa agonists were self-administered in a dose-dependant manner. Inverted-U dose-response curves were obtained for both agonists with peak response rates at 0.1 and 1 pmol/inj. for DYN and U50, respectively. Even the lowest dose of DYN used (0.01 pmol/inj.) supported significant self-administration behavior when compared to vehicle ($p < 0.05$); this dose is only about 3-fold greater than the reported endogenous concentration of DYN in the CA3 field. These behavioral results corroborate the *in vitro* single-cell operant conditioning data and suggest that dynorphin may be a natural "reinforcement neurotransmitter" in the CA3 area of the hippocampus.

DYNORPHIN A [1-17] PLACE PREFERENCE IN RATS: OPIOID-SPECIFIC AND DOPAMINERGIC. Edgar T. Iwamoto. Dept. of Pharmacol., Univ. of Kentucky, Lexington, KY 40536.

Sprague-Dawley male rats were administered 1.2 to 3.5 nmol of dynorphin A [1-17] (DYNA) or buffer into the lateral ventricle and then placed in one of two rooms of a place-conditioning apparatus for 20 min (Iwamoto, Alc Drug Res 6:327, 1986). The next day, the rats were not treated but simply placed in the other distinctive room for 20 min. On Day 3, rats were given free-access to explore the entire apparatus for 15 min, the number of sec spent in the treatment-paired (T) or the non-treatment-paired (NT) rooms was recorded, and a preference ratio (PR) was calculated as [T-NT]/[T+NT] for each rat. 2.3 nmol of DYNA in 1 or 2 ul of buffer induced a significant preference response as indicated by positive PRs greater than control: DYNA PR = 0.47 ± .07 vs buffer control PR = 0.18 ± .05 (N = 8 each). 3.5 nmol of DYNA also induced significant place preference; 1.2 nmol was without effect. 27.5 nmol, but not 5.5, of naloxone coadministered with 2.3 nmol of DYNA antagonized the reward response. Dynorphin A [2-17], a probable metabolite of DYNA that does not bind opiate receptors, did not condition place preferences at doses of 2.3 or 3.5 nmol. Twenty min pretreatment with 0.02 mg/kg SC of R(+)SCH23390 or 0.04 mg/kg of spiperone completely antagonized 2.3 nmol DYNA-induced reward indicating roles for D_1 and D_2 systems. The data indicate that DYNA may mediate or modulate neuronal substrates of CNS "reward". (KTRB and UKMCRF)

OPIATES MICROINJECTED INTO THE VENTRAL PALLIDUM/ SUBSTANTIA INNOMINATA (VP/SI) PRODUCE LOCOMOTOR RESPONSES THAT INVOLVE DOPAMINERGIC SYSTEMS. T.C. Napier, D. An*, M.C. Austin, and P.W. Kalivas. Dept. Pharmacol., Loyola Univ. of Chicago, Stritch Sch. Med., Maywood, Il 60153; Dept. VCAP, Washington State Univ., Pullman, WA 99164.

The VP/SI contains enkephalin peptides and projects to the mesencephalic locomotor region. Using rats implanted with guide cannulaes over the VP/SI, we reported at the 1987 Neuroscience meeting that opiate peptides microinjected into the VP/SI alter various motor functions in a naloxone-reversible fashion. One of these was an opiate-induced contralateral rotation. For the present studies, we determined if this circling involves brain dopamine (DA) systems. Cannulae-implanted rats were pretreated i.p. with 0.1 mg/kg SCH23390 or 0.5 mg/kg haloperidol (D1 and D2 DA receptor antagonists, respectively) 30 min before unilaterally-microinjecting the VP/SI with the ED_{50} for leu-enkephalin (3.3 nmoles) or DAGO (33 pmoles). SCH23390 blocked the contralateral rotations of both enkephalin- and DAGO-treated rats, while haloperidol was effective only against DAGO-induced circling.

These data suggest that motor functions of the VP/SI involve opiate and DA systems. Since DAGO, the *mu* receptor specific peptide, exhibited a smaller ED_{50}, and since only haloperidol blocked this response, it is likely that a DA-D2-receptor/opiate-*mu*-receptor interaction is an important VP/SI influence on motor behavior.

OPIOIDS MICROINJECTED INTO CENTRAL DOPAMINERGIC PATHWAYS: EFFECTS ON COPULATION IN MALE RATS. L. Band and E. Hull. SUNY at Buffalo, NY 14260.

Dopaminergic neurons are involved in morphine-induced reward and are thought to play a role in opiate enhancement of natural reward. The effects on sexual behavior of opiate receptor stimulation within A10 and A14 terminal areas were examined in the following experiments. Morphine (.01-6 nmol) and dynorphin (1-13; .01-3 pmol) were microinjected into the medial preoptic area (MPOA) and the nucleus accumbens (NA) of male rats. Morphine (10-100 pmol) and dynorphin (10-100 fmol) injected into the MPOA reduced both the latency to ejaculate and the number of intromissions triggering ejaculation; 6 nmol morphine produced a failure to resume copulating following the second ejaculation. Morphine (1-10 nmol) injected into the NA shortened the latency to the first intromission and lengthened the second postejaculatory interval. Morphine (1 nmol) injected into the NA increased the frequency of ejaculation in poor copulators. Naloxone (3 mg/kg IP) reversed morphine's effects on intromission latency and ejaculation frequency. Opioids and dopamine agonists injected into the MPOA and the NA produce change in the same copulatory factors; these findings are consistent with opiate modulation of a dopaminergic substrate.

116.7

REINFORCING PROPERTIES OF SUBSTANCE P, ITS FRAGMENTS AND MORPHINE DEMONSTRATED BY A NEW METHOD FOR PLACE CONDITIONING
M.S. Holzhäuer-Oitzl*, R. Hasenöhrl* and J.P. Huston (SPON: European Brain and Behavior Society). Inst. Physiological Psychology, Univ. Düsseldorf, D-4000 Düsseldorf, F.R.G.

Centrally applied substance P (SP) has reinforcing and memory promoting properties depending on the site of injection. Since peripherally injected SP facilitated the performance in various learning tasks in rats and mice, we hypothesized SP to have reinforcing properties as well.

A circular open field was used to assess the reinforcing effects of SP and its N- and C-terminal fragments. Morphine was used to validate the new method. Experimental sessions (15min) were run on 5 consecutive days. On Day 1 animals (male Wistar rats) were allowed to explore the apparatus. On Days 2,3 and 4 rats received an injection (i.p., 0.5ml/kg) of SP (5,50,250 µg/kg), SP1-7 (33,170,334 µg/kg), SP6-11 (5,27, 134 µg/kg), morphine (10mg/kg) and vehicle. After injection the rats were placed into the open field, which was divided by plexiglass barriers into 4 quadrants of equal size. On Day 5 rats explored the open field. Only rats treated with morphine, 50 µg SP and the eqimolar dose of SP6-11 (27 µg), but not SP1-7 (33 µg), significantly increased their time spent in the previously drug-paired quadrant, thus, reflecting a positive reinforcing effect. These results show that SP has positive reinforcing properties additional to its memory promoting effects, whereby the active components for reinforcement may lie within the C-terminal sequence of the SP-molecule.

116.8

STUDIES ON THE EFFECTS OF MICROINJECTIONS OF VARIOUS OPIATE PEPTIDES INTO THE MIDBRAIN RAPHE NUCLEI OR THE VENTRAL TEGMENTAL AREA.
M.A. Klitenick and D. Wirtshafter, Dept. Psychology, Univ. of IL at Chicago, Chicago, IL 60680.

Numerous studies have reported dramatic behavioral effects following various manipulations of the midbrain raphe nuclei. We have previously demonstrated that intra-MR microinjections of morphine elicit a dose-dependent increase in locomotor activity, comparable in magnitude to that produced by peripheral administration of amphetamine. In an attempt to further clarify the role of opiates within the MR, several selective opiate receptor agonists were injected into the MR and locomotor activity within a photocell cage was measured for a two hour period. We report here that intra-MR injections of DAGO (0, 13.67, 27.34, 54.68,109.4, 218.7 & 437.5ng) or DPDPE (0, 0.625, 2.5, 5, 10 & 20ug), selective agonists of the mu and delta opiate receptors, respectively, elicited dose-dependent increases in locomotor. Studies in which microinjections of DAGO, DPDPE or dynorphin A into the dorsal raphe nucleus (DR), rostral or caudal ventral tegmental area or the midline pontine tegmentum caudal to the MR, are currently in progress in order to better assess the most active site for opiate-induced hyperactivity. In other studies, preliminary results suggest that intra-MR injections of DAGO, DPDPE, dynorphin (1-8) or dynorphin (1-13) elicit pronounced dose-dependent increases in food and water intake and food spillage in non-deprived rats.

CYCLO-LEUCYL-GLYCYL ALTERS THE EFFECTS OF CHRONIC APOMORPHINE TREATMENT.
L.P. Gonzalez, O. Dimson*, J.F. Czachura*, and R.F. Ritzmann. Univ. Oklahoma Health Sciences Center, Oklahoma City, OK 73190-3000.

Our previous research has indicated that administration of the peptide cyclo-leucyl-glycyl (CLG) can reduce the development of dopamine receptor supersensitivity during chronic haloperidol administration. In the present study, we examined the effects of CLG in male Sprague-Dawley rats treated chronically with the dopamine agonist apomorphine (APO). Response measures included APO-induced motility as measured in an automated movement sensor, APO-induced hypothermia, and haloperidol-induced catalepsy. Following a test of initial drug sensitivity rats were divided into two groups, receiving daily injections of 1 cc/kg saline or 10 mg/kg APO HCl (i.p.) for 25 days. These were divided into 4 subgroups which received 0, 2, 8, or 16 mg/kg CLG (s.c.) at 3-day intervals during the 25-day chronic exposure period. Acute APO effects were again determined at the end of the chronic exposure period and for the next 2 months thereafter. Chronic APO-treated rats showed significantly more APO-induced motility, reduced hypothermia, and increased haloperidol-induced catalepsy, for at least 45 days after the termination of chronic treatment. CLG was found to have significant dose-related effects on the motility and catalepsy responses after chronic APO, but had no effect on APO-induced hypothermia. Supported in part by the State of Oklahoma Health Research Program, Contract 1676.

MORPHINE EFFECTS ON POSTPARTUM BEHAVIOR, TEMPERATURE AND ANALGESIA IN LACTATING MICE.
M.J. Haney*, K.A. Miczek, (SPON: J. Ellingboe) Dept. Psychology, Tufts Univ., Medford, MA 02155.

Endogenous opioid systems may play a role in the behavioral and physiological characteristics of lactating animals. In order to assess the contribution of opioid receptors to aggressive behavior, pup care, pain response and body temperature, we challenged mice with morphine at different phases of the lactation period. For comparison, morphine's effects on temperature and tailflick were also determined in virgin females.

Lactating mice were assigned to 1 of the 3 weeks of lactation and to 1 dose of morphine (0,1,3,6,10 mg/kg i.p.). After morphine administration, temperature and tailflick were assessed. Behavior toward 3 pups was observed for 5 min, followed by an aggression test with an intruder.

Morphine increased the latency to retrieve pups at doses that do not decrease motoric activity. Compared to virgins, lactating mice are less sensitive to the analgesic actions of morphine but similarly sensitive to its hypothermic properties. This differential sensitivity to morphine induced analgesia suggests that lactating animals undergo functionally relevant changes in opioid regulation of pain. Furthermore, morphine's specific inhibition of retrieval supports the hypothesis that decreased opioid peptide activity is important for the expression of certain postpartum behaviors.

116.11

ELECTROPHYSIOLOGICAL EFFECTS OF OPIATES ON NUCLEUS ACCUMBENS (NAS): DOPAMINE (DA) AND OTHER AFFERENT INFLUENCES.
R.L. Hakan and S.J. Henriksen. Preclin. Neurosci., RISC, La Jolla, CA 92037

The NAS is an important structure for opiate reward (Psychopharm.,86:37-42,1985). However, the precise role of ventral tegmental area (VTA)-NAS afferents in this process is unresolved. Single-unit recordings from the NAS of halothane anesthetized rats reveal that microinfusions of morphine into the VTA primarily inhibit spontaneously active NAS units. These inhibitory effects are reversed by alpha-flupenthixol (s.c), suggesting dopamine (DA) mediation. VTA opiate infusions also inhibit fimbria-driven, silent cells recorded in the NAS. This inhibition is reversed by naloxone (s.c.), but not by alpha-flupenthixol, implying a non-DA mechanism. Iontophoretic morphine applied within the NAS inhibits spontaneous activity but not fimbria-driven activity. However, VTA-induced inhibition of fimbria-driven activity is reversed by systemic opiates, indicating that opiates can also exert effects through other, as yet unidentified NAS afferent systems. Thus, systemic opiate effects on NAS neurophysiology must be complex, involving both local actions and indirect actions mediated by VTA DA-ergic, VTA non DA-ergic and other afferent systems.

116.12

PREDATOR-INDUCED ANALGESIA IN DEER MICE: POPULATION DIFFERENCES AND BENZODIZAEPINE AND OPIOID INVOLVEMENT.
M. Kavaliers, Div. Oral Biology, Univ. Western Ontario, London, Ontario, Canada N6A 5B7.

Although there is abundant evidence for predator recognition by prey, little is known about the neurochemical mechanisms associated with these aversive responses. In the present study determinations were made of the effects of exposure to a predator, the short-tail weasel, on the nociceptive responses of deer mice that had different histories of exposure to this predator. Peromyscus maniculatus artemisiae were from the mainland and P. m. angustus and P. m. triangularis were from small predator (weasel) free islands. In the mainland derived population, a short (30 sec), ecologically appropriate exposure to the scent of the weasel elicited a relatively brief analgesic response that was blocked by the benzodiazepine antagonist, Ro15-1788 and insensitive to the opiate antagonist naloxone. A 5 min exposure to the weasel elicited an analgesic response that was sensitive to both naloxone and Ro15-1788, while a 15 min exposure induced just the opioid mediated analgesia. In contrast, exposure of the island derived populations of deer mice to the weasel elicited only the naloxone-reversible opioid mediated analgesic responses. These findings indicate the existence of genetic variations (population differences) for benzodiazepine and opioid mediation of fright behaviors and aversive responses in the presence of a predator.

116.13

NALOXONE, CHOLECYSTOKININ, AND BOMBESIN INTERACT TO INHIBIT ETHANOL INTAKE. P.J. Kulkosky, H.D. Moore*, R.L. Cannon*, and N. Chiu.* Dept. of Psychology, Univ. of Southern Colorado, Pueblo, CO 81001

Naloxone (NAL), an opiate receptor blocker, and cholecystokinin (CCK) and bombesin (BBS), brain-gut neuropeptides, have each been shown to reduce alcohol consumption after peripheral injection (Myers & Critcher, 1982; Kulkosky, 1985). To characterize the interaction of these agents in the control of alcohol intake, NAL, CCK and BBS were injected i.p. in rats, in single doses and combinations of doses, prior to ethanol consumption induced by water deprivation. After an 8-day adaptation procedure, rats were randomly assigned to receive injections of 0.0, 0.1, 1, or 10 mg/kg NAL, followed by 0, 1, 2, or 4 µg/kg CCK or BBS, prior to 30 min access to 5% w/v ethanol. NAL, CCK and BBS inhibited ethanol intake when injected in single doses. CCK and BBS and NAL and BBS combined to inhibit ethanol intake in a dose-additive manner, except at 4.0 µg/kg BBS + 1 mg/kg NAL, where intake was inhibited supra-dose-additively. NAL and CCK typically inhibited intake infra-dose-additively. These data suggest that NAL, CCK, and BBS inhibit alcohol intake by multiple, interacting mechanisms of action. (Supported by NIH Grant No. RR-08197).

VASOPRESSIN FAILS TO MODULATE VOLUNTARY ETHANOL INTAKE IN RATS. A. Ross*, E. Perlanski* and L.A. Grupp. Dept. of Pharmacology, Univ. of Toronto. Toronto, Canada M5S 1A8.

Recent research from our laboratory has indicated that manipulations which increase activity in the Renin-Angiotensin System (RAS), attenuate voluntary consumption of ethanol (EtOH) in rats, suggesting that the RAS may participate in the regulation and termination of EtOH intake. Since Angiotensin II (AII) is known to stimulate the release of Vasopressin (VP), the possibility exists that AII attenuates EtOH intake indirectly through stimulation of VP release. In order to investigate this, rats were offered a choice between 6% (w/v) EtOH and water, for 1 hr each day, using a limited access procedure. When EtOH intake had stabilized, each group received AVP or DGAVP (a VP fragment with minimal pressor or anti-diuretic activity) at a dose of 2, 10, 20 or 200 µg/kg injected subcutaneously, immediately prior to EtOH access. Control animals received injections of vehicle only. While consumption of EtOH was not significantly altered by AVP or DGAVP at any of the doses tested, there appeared to be a transient decrease in water intake at the higher doses of both peptides. These findings indicate that VP does not mediate the ability of enhanced RAS activity to attenuate EtOH intake. Furthermore, it appears that VP does not play a critical role in the control of established EtOH drinking behavior. Supported by the Alcoholic Beverage Medical Research Foundation.

116.15

REDUCTION IN VOLUNTARY ETHANOL CONSUMPTION BY ACE INHIBITION IS NOT MEDIATED BY PERIPHERAL ANGIOTENSIN II RECEPTORS. T.B. Lingham*, E. Perlanski* and L.A. Grupp. (SPON: G.A. King). Dept. of Pharmacol., Univ. of Toronto, Toronto, Ont., Canada M5S 1A8.

Angiotensin converting enzyme (ACE) inhibitors, are potent antihypertensive drugs, that also reduce voluntary ethanol consumption in rats (Spinosa et al. 1988). To further characterize this phenomenon, four groups of male Wistar rats received intraperitoneal injections of the ACE inhibitor, Abutapril: CGS-16617 (5, 10 or 20 mg/kg) or saline, and were offered a choice between ethanol (6% w/v) and water using the limited access procedure. Whereas water consumption increased immediately, ethanol intake was reduced only during the second week of drug administration. This finding suggests that ethanol and water intake show different thresholds of responsiveness to the ACE inhibitor.

In the second phase of the experiment animals which received Abutapril (10 mg/kg) or saline, were also given subcutaneous [Sar1,Thr8]-Angiotensin II (500 µg/kg), an Angiotensin II receptor antagonist that does not cross the blood-brain barrier. The antagonist failed to reverse the effect of Abutapril on ethanol consumption, suggesting that if ACE inhibitors reduce voluntary ethanol intake by modulating the renin-angiotensin system, then it must be through the central and not the peripheral renin-angiotensin system. CALCIUM EFFECTS ON IMPULSE AFTERPOTENTIALS AND SUPERNORMALITY IN EARTHWORM MEDIAN GIANT FIBER. Katherine Lowe Perkins* and Stephen A. George. Neuroscience Prog., Amherst College, Amherst, MA 01002.

The second of two closely spaced impulses travels faster than the first impulse in earthworm giant fibers. This supernormality (SN) requires the presence of Ca^{++} in the bathing medium, and is increased in elevated $[Ca^{++}]$.

Intracellular recordings in median giant fibers revealed depolarizing afterpotentials (DAPs) lasting up to 1 second. In 60% of fibers, the afterpotential was purely depolarizing; in 40%, a hyperpolarization lasting approx. 50 msec was followed by a late DAP. DAPs were enhanced in high $[Ca^{++}]$, and an early DAP could be induced by elevated $[Ca^{++}]$ in fibers lacking one in normal $[Ca^{++}]$. The amount of SN varied with the amplitude of the DAP at all times after the 1st spike, and under conditions in which the DAP amplitude was altered by changing $[Ca^{++}]$.

Different mechanisms are responsible for the early and late phases of the DAP. (1) The amplitude of the early DAP varied monotonically with $[Ca^{++}]$ in the bathing solution up to 18 mM. However, the amplitude of the DAP measured at 500 msec peaked at approx. 7 mM $[Ca^{++}]$, and declined at higher $[Ca^{++}]$. (2) Co^{++} increased the early DAP, but reduced the amplitude of the late DAP.

The DAP and supernormality may be associated with the production of burst discharges in this fiber.

117.2

IONIC CONDUCTANCES IN CRUSTACEAN STOMATOGASTRIC NEURONS IN PRIMARY CULTURE. W.D. Krenz* and P. Fischer*. Zoology Institute, Univ. of Basel, CH-4051 Basel, Switzerland

Individual unidentified neurons from the stomatogastric ganglion of adult crayfish, Pacifastacus leniusculus, were isolated by suction after incubation of ganglia in collagenase/dispase. Cells were plated on poly-L-lysine-coated glass coverslips in supplemented L-15 medium. Under these conditions about 40 to 50% of the explanted neurons survive and grow processes.

After 4 days in culture resting membrane potentials are between -40 and -65mV. Under current clamp most explanted cells show strong outward rectification and only local responses are generated by depolarization. Few cells became fully excitable. Plateau-like potentials are generated by depolarizing current in some neurons.

Voltage clamp measurements reveal a fast transient and a slow delayed outward current as well as fast and slow inward currents. These results suggest that primary culture of stomatogastric neurons may enable the detailed analysis of the membrane conductances mediating e.g. conditional bursting in stomatogastric neurons. We are now attempting to isolate identified neurons from the stomatogastric ganglion.

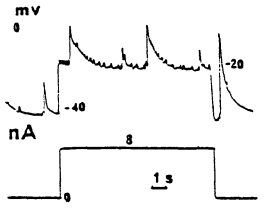
IDENTIFICATION OF VOLTAGE-DEPENDENT ION CHANNELS IN THE CARDIAC FOLLOWER CELL MEMBRANE OF LIMULUS. A.J. Meuse and D.G. Gibson, III. Department of Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA 01609.

Intracellular recording was used to determine the response of Limulus cardiac follower cells to injected current. Seventy percent of the follower cells impaled responded to depolarizing current by increasing the frequency and number of secondary (attenuated) spikes. These additional spikes enhance neuromuscular transmission. The spikes continue as long as depolarization of approximately 50% of membrane resting potential is maintained. The duration of each secondary spike is usually less than 25 msec; spikes appear to be produced by voltage-dependent fast sodium channels, as determined by ion substitution and TTX experiments.



117.4

LOCALIZATION OF CURRENTS IN STOMATOGASTRIC NEURONS. K. Graubard, and D.K. Hartline, Dept. of Zoology, Univ. of Washington, Seattle, WA 98195; and Békésy Lab., Univ. of Hawaii, Honolulu, HI 96822.

A two-electrode somatic voltage clamp was used on pyloric neurons left intact within the Panulirus stomatogastric ganglion, retaining their chemical and electrical synapses with other cells. Spikes in the distant axon are seen in the soma as 2-8 nA brief inward currents which are blocked by TTX. A slow inward current underlying bursts is also abolished by TTX. A TTX-insensitive inward current is revealed in the presence of TEA or TEA + 4AP and is probably caused by distant calcium spikes. A rapidly inactivating, TEA-insensitive, 4AP-sensitive, outward current resembles the "A" current of molluscan neurons. It is inactivated near rest (-50 mV). Hyperpolarization removes inactivation over a range of ca.-65 to -100 mV. The current activates rapidly above -45 mV and then inactivates over a period of 50-80 msec. A-current depresses the firing rate of sodium and calcium spikes in both voltage clamped and unclamped neurons and reduces the size of the sodium spike current. We infer that A-current is distributed on or near the soma and in a non-space clamped region near the spike generating zones. A calcium-dependent outward current, J-current, activates rapidly at clamp steps above -25mV and then decays with a compound time course. This current inactivates at depolarizing holding voltages. The calcium-dependent outward current has no clear effect on cell firing. Increasing depolarization results in an increase in both J-current and in firing rate, and reduces the amplitude of the sodium spike current. Maintaining a depolarization causes inactivation of J-current, spike frequency adaptation, and a further decrease in the amplitude of the sodium spike current. Blockage of J-current with Cd causes little change in spike firing pattern. One explanation of these observations is that J-current is localized to the soma and nearby regions.

WHOLE-CELL VOLTAGE-CLAMP RECORDINGS FROM MURINE RETINAL NEURONS IN CULTURE. M.W. Salter, I. Mody, M.C. Bartlett* & J.F. MacDonald. Playfair Neurosci. Unit, The Toronto Hosp. & Dept. of Physiol., Univ. of Toronto, Toronto, Ont.

Retinal cells were taken from embryonic mice (day 18) and grown in dissociated culture. Recordings were made using conventional whole-cell and single electrode switching voltage-clamp techniques. Electrodes contained (in mM) either 120 KCl and 35 KOH or 120 CsCl and 35 CsOH. In addition, the following were added (in mM): 10 HEPES, 11 EGTA, 4 $MgCl_2$, 2 K_2ATP and 2 $CaCl_2$. The extracellular medium was Hank's balanced salt solution containing HEPES (25 mM) and TTX (1 μM).

With electrodes containing KCl, outward voltage- and time-dependent currents sensitive to TEA were observed. In the presence of TEA (25 mM) and with CsCl electrodes, voltage-dependent inward currents carried by Ca^{2+} and blocked by Cd^{2+} (100 μM) could be recorded. Pressure application of kainic acid (200 μM) evoked currents which were inward at negative holding potentials, reversing between 0 and +5 mV.

The present results demonstrate that murine retinal cells in culture express voltage- and neurotransmitter-gated ionic currents. Hence, this culture preparation is suitable for electrophysiological investigation of mammalian retinal neurons.

MEMBRANE PROPERTIES OF EDINGER WESTPHAL NEURONS: A SYSTEM FOR COMPARING SOMATA WITH SYNAPTIC TERMINALS. J.T.Fujii. Dept. of Physiology, University of Colorado School of Medicine, Denver, CO 80262.

A subpopulation of Edinger Westphal (EW) neurons form large calyciform synaptic terminals that have been studied using intracellular recording techniques (Martin & Pilar, 1963, 1964; Dryer & Chiappinelli, 1985). To compare the membrane properties of these terminals with their parent cell bodies, a slice preparation of the chick midbrain was developed, containing the EW nucleus.

EW neurons exhibited two types of responses to prolonged pulses of depolarizing current (500 ms, 0.4-2.0 nA). Some cells fired repetitively, usually for as long as the pulse was applied. Firing frequency increased as the depolarizing current was increased, ranging from 6 to 100 Hz, and at higher levels often exhibited accommodation, *i.e.*, increase of interspike interval and decrease of action potential amplitude at the end of a train. In the second group, cells meeting the same criteria as the first group (similar or higher resting potentials, input resistances, and time constants) fired only a few action potentials regardless of the size of the depolarizing pulse.

Replacement of calcium with magnesium increased firing frequency of repetitively firing cells and reduced the amplitude of the after-hyperpolarizations (AHP) following trains of action potentials. This suggests that a calcium-activated potassium current is involved in limiting the firing frequency of the cells and is responsible for at least part of the AHP.

The repetitive firing observed in some EW cell bodies resembles that reported for calyciform terminals. Supported by NIH NS09660.

VOLTAGE DEPENDENT IONIC CURRENTS IN SINGLE CEREBELLAR CELLS GROWN IN THREE-DIMENSIONAL CULTURE. B. Fermini*, P.W. Coates, J. Netzeband*, J.C. Strahlendorf and H.K. Strahlendorf. Depts. Physiology, Cell Biology & Anatomy and Neurology, Texas Tech University Health Sciences Center, Lubbock,TX 79430.

Neurons isolated from cerebelli of late gestation rat fetuses quickly express distinct neuronal features yet grow as *single* cells in three-dimensional culture (Coates and Dunn, this volume), which may prove useful to elucidate intrinsic electrical properties of such neurons. We used this culture system to determine electrophysiological properties of isolated cerebellar neurons from 20 day old rat fetuses grown in culture for 24 to 48 hrs. Whole-cell voltage clamp experiments were performed at 25° C. Several sizable voltage dependent conductances were observed. Depolarizing steps from a holding potential (HP) of -90 mV elicited two outward currents showing different time course, amplitude and sensitivity to the potassium channel blockers tetraethylammonium chloride (TEA) and 4-aminopyridine (4-AP). Addition of 4-AP (5 mM) to the bathing medium abolished within 5 min a current showing properties similar to I_A, a transient outward current described in other neurons. TEA (20 mM) greatly reduced the amplitude of an outward current showing delayed rectification properties similar to I_K. Combined application of TEA and 4-AP unmasked two inward conductances activated by depolarization. These currents, separated by using different HP (-90 or -50 mV) were selectively inhibited by tetrodotoxin (30 μM) or cobalt chloride (5 mM) and were identified as I_{Na} and I_{Ca}, respectively. Results demonstrate that single cerebellar neurons devoid of cell-cell communication rapidly exhibit a number of ionic conductances previously observed in more mature interconnected cells and tissue slices. Supported by NS19296 (JCS & HKS) and NS20802 (PWC). BF holds a fellowship from the Canadian Heart Foundation.

SLOW INWARD AND SLOW OUTWARD CURRENTS INDUCED BY HYPERPOLARIZING PRE-PULSES IN CAT PARASYMPATHETIC NEURONS. E. Kumamoto* and P. Shinnick-Gallagher. (SPON: P.M. Callahan). Dept. of Pharmacology, Univ. of Texas Medical Br., Galveston, TX 77550

We have used the single electrode voltage clamp to examine membrane currents recorded as a result of hyperpolarizing pre-pulses in cat bladder parasympathetic neurons. Hyperpolarizing pre-pulses (10 ms - 1 s) to -90 to -130 mV from holding potentials of -30 to -60 mV elicited slowly decaying inward and/or outward currents. A short duration pulse (20-40 ms) induced only a slow inward current (SIC; 0.13 nA and 8 s); with a longer pre-pulse (1 s) a slow outward current was superimposed on the SIC (SOC; 0.18 nA and 32 s). SIC and SOC became larger at depolarized holding potentials, with large hyperpolarizing pre-pulses, and with long pulse durations, but their relative amplitudes were independent of each other. SIC and SOC were associated with an increased membrane conductance, the SOC had an extrapolated reversal potential around -89 mV at a holding potential of -60 mV. SIC not SOC was depressed in low Na (26 mM); SOC not SIC was reduced in high K (10-20 mM), depressed in low Ca (0.5 mM), and potentiated in high Ca (5 mM). TEA (10 mM) depressed the SOC, but not SIC. 4-AP (1 mM) blocked a transient outward current (I_A), but potentiated SOC. TTX (0.5 μM) and Cs (3 mM) did not affect either current, whereas Ba (1 mM) and Cd (0.5 mM) inhibited both currents. These results suggest that the SIC is a slow Na current and the SOC, a calcium-dependent K current. Supported by NS16228.

A TRANSIENT LOW-THRESHOLD Ca^{2+} CURRENT UNDERLIES AN AFTERDEPOLARIZATION IN DORSAL ROOT GANGLION NEURONS ACUTELY DISSOCIATED FROM ADULT RATS. G. White*, D.M. Lovinger*, F.F. Weight, Section on Electrophysiology, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852

In some central and peripheral neurons, action potentials are followed by an afterdepolarizing potential (ADP). Using whole-cell patch-clamp recording, the ADP and the currents underlying the ADP were studied in single dorsal root ganglion cells within 10 hours of being dissociated from whole ganglia by enzymatic and mechanical means. At membrane potentials of -60 mV a small ADP was present which increased in amplitude to between 50 and 65 mV upon hyperpolarization from -60 to -80 mV (n=8). Repetitive cell firing was observed within a narrow window of ADP amplitude. The ADP was only observed in cells which also exhibited a transient low-threshold Ca^{2+} current ($Ca_{(t)}$, n>30). $Ca_{(t)}$ was studied in part by voltage-clamping the cell to -80 mV and applying voltage jumps to -50 mV, a potential at which the active currents are composed almost entirely of $Ca_{(t)}$. The amplitudes of the ADP and $Ca_{(t)}$ were relatively unaffected by equimolar substitution of Ba^{2+} for Ca^{2+}; whereas the addition of 500 uM Cd^{2+} or replacement of external Ca^{2+} with Mg^{2+} resulted in a 90% decrease in the amplitude of the ADP and $Ca_{(t)}$ (n=6). The amplitude of the ADP was comparable between cells in which chloride gradients differed by 40 fold (n=5). We conclude that a transient low-threshold Ca^{2+} current underlies the ADP in adult rat DRG cells. Modulation of this ADP could serve to alter voltage sensitive activities of the cell (Lovinger and Weight, this meeting).

WHOLE CELL PATCH CLAMP RECORDINGS FROM ACUTELY ISOLATED NEURONES OF THE DORSAL RAPHE NUCLEUS OF THE ADULT RAT N.J. Penington* and J.S. Kelly. Dept. of Pharmacology, Univ. of Edinburgh Med. Sch., Edinburgh EH8 9JZ.

Whole cell recordings were made from individual neurones of the dorsal raphe nucleus of the rat, isolated by the method of Kay and Wong (1986), using a switching voltage clamp amplifier. The pipette contained in mM K^+ Gluconate 122, Hepes 10, $CaCl_2$ 1, $MgCl_2$ 2, EGTA-KOH 11, pH 7.3 with KOH. The mean membrane potential was -56 mV. The passage of depolarizing current pulses caused repetitive firing of fast TTX (0.5 µM) sensitive spikes 80-100 mV in amplitude. The spikes were followed by small A.H.P.'s. Some cells fired spontaneously at rest and each spike was preceded by a slow depolarizing potential. In TTX this prepotential resembled a low threshold Ca^{++} spike; a high threshold Ca^{++} spike could also be evoked. In voltage clamp steps from -60 mV to -20 mV caused an inward/outward current sequence in which the outward current increased with time and was followed by an outward tail current. A graded transient outward current resembling "I_A" was also recorded. Large inward non-inactivating Ca^{++} currents were also seen on steps from -60 mV to -20 and above. Under certain conditions GABA, 100 µM, caused an increase in conductance and an inward current at -60 mV which reversed close to -33 mV (E_{Cl}).

ELECTROPHYSIOLOGY OF THALAMIC-PROJECTING CHOLINERGIC BRAINSTEM NEURONS AND THEIR INHIBITION BY ACH. C.S. Leonard and R.Llinás, Dept. Physiol. & Biophys., NYU Med. Ctr. 550 First Ave. New York, NY 10016

Intracellular recordings were obtained from pedunculopontine (PPT) and laterodorsal tegmental (LDT) neurons in guinea pig brainstem slices. Three types of neurons were found. One type had "low threshold" Ca^{++} spikes (LTS). Another had an "A" K^+ conductance (A type) and the third type had both an A conductance and LTS (A+LTS type). Experiments were performed to resolve which types were thalamic-projecting and/or cholinergic. Rhodamine beads were injected into the dorsal-lateral thalamus 3-30 days prior to the experiments. Retrogradely labeled neurons were impaled, characterized electrophysiologically and stained with lucifer yellow. Nine doubly labeled neurons were all of the A or A+LTS type. Their mean diameter (20µm) and shape index (width/length = 0.7) agree well with those of PPT cholinergic neurons in rat (Rye et al., '87, JCN 259:483-528). The cholinergic nature of A and A+LTS neurons was confirmed for five neurons by combined lucifer yellow staining and NADPH-diaphorase histochemistry which selectively marks cholinergic neurons in PPT and LDT. In A and A+LTS neurons, Ach (3-30µM) produced dose dependent hyperpolarizations up to 20 mV with up to 60% reductions in input resistance in 10µM eserine. These effects were also evoked by carbachol and bethanechol and were blocked by atropine (0.5-10µM). In 2µM TTX or in Ca^{++} free/2mM Co^{++} medium, the effects were undiminished indicating a direct action of Ach on the impaled neurons. These actions of Ach likely arise from activation of a K^+ current since the Ach hyperpolarization is suppressed by hyperpolarization to E_K and it is not reversed by using 3M KCl electrodes. Preliminary evidence suggests this Ach inhibition is mediated by M_2 receptors since 1µM pirenzepine only partly blocks carbachol (30µM) hyperpolarizations while 10µM pirenzepine completely blocks them. We conclude that Ach inhibits thalamic-projecting cholinergic neurons of the PPT and LDT by activating a K^+ conductance via an M_2 muscarinic receptor. These results support the idea that M_2 receptors can play an autoregulatory role in Ach release by feedback inhibition. Support by NS07848 & NS13742.

OSCILLATORY MEMBRANE CURRENTS INDUCED IN RAT GONADOTROPES BY TREATMENT WITH GONADOTROPIN-RELEASING HORMONE. T.L. Croxton*, N. Ben-Jonathan, and W.McD. Armstrong*. Dept. of Physiology and Biophysics, Indiana Univ. Sch. of Med., Indianapolis, IN 46223

Cell-attached patch clamp studies were carried out with rat anterior pituitary gonadotropes identified in primary cultures by reverse hemolytic plaque assays. Under basal conditions, spontaneous current spikes were recorded. These could be eliminated by treatment with D600 and were apparently due to Ca^{2+} action potentials. Brief (15-30 sec) treatment with high K^+ produced a concurrent outward shift in current, consistent with membrane depolarization, and a delayed (3 min) period of inward current. Brief treatment with GnRH (2-100 nM) induced prominent oscillations in membrane current (10-30 per min) that persisted for several minutes. These consisted initially of clusters of action potentials but evolved over 5-10 min into a series of large amplitude inward current pulses. Similar treatments with TRH (100 nM) had no effect. In the presence of D600, GnRH stimulation did not induce inward currents but did produce oscillatory activation of small conductance K^+-channels. These results indicate that cellular mechanisms involved in GnRH responses have an intrinsic rhythmicity and that both K^+-channels and Ca^{2+}-channels are modulated by intracellular mediators. Our data suggest that GnRH stimulation leads to pulsatile increases in Ca^{2+} in gonadotropes. Supported by USPHS grants DK36575 and DK07554.

MUSCARINIC-DEPENDENT AFTERDISCHARGE IN RAT PREFRONTAL CORTEX. R. Andrade. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

To determine the mechanisms involved in the actions of acetylcholine in the prefrontal cortex, I have conducted intracellular recordings using in vitro brain slices from the prelimbic and dorsal anterior cingulate regions.

Layer V neurons typically exhibit membrane potentials in the range of -70 to -80 mV and respond to a brief depolarizing current pulse (300-600 ms) with a rapidly accommodating burst of spikes. Carbachol (1 µM-100 µM) elicits a dose-dependent depolarization which often fails to reach threshold even after prolonged bath administration (> 5 min). However, when the carbachol stimulation is paired with a brief depolarizing pulse, the resulting spike burst initiates a long-lasting afterdischarge which greatly outlasts (several seconds to minutes) the depolarizing pulse. This period of sustained spiking is made possible by the appearance of a long-lasting depolarizing afterpotential (DAP). This DAP can be elicited by low-threshold calcium spikes in the presence of TTX but is blocked by Ca^{2+} removal of Mn^{2+} administration suggesting that it is triggered by Ca^{2+} influx. Since the depolarization and the DAP are blocked by atropine, these actions appear to be mediated via muscarinic receptors. The ability of muscarinic receptors to induce the appearance of a long-lasting DAP confers unusual associative properties to the cholinergic input to this region. COMPARISON OF EXCITABLE MEMBRANE PROPERTIES IN IDENTIFIED NEURONS FROM MAMMALIAN VISUAL CORTEX. K. Giffin*, J.P. Doyle* and J.M. Nerbonne, Dept. of Pharmacology, Washington Univ. Med. Sch., St. Louis, MO. 63110.

In order to test the hypothesis that cortical cell "types" can be distinguished electrophysiologically, we are comparing excitable membrane properties in identified (projection and intrinsic) neurons derived from rat (Long Evans) primary visual cortex (area 17). Callosal-projecting cells are identified in vitro following in vivo retrograde labeling with rhodamine beads. Injections are made into the left hemisphere of area 17 at postnatal day 5, and ~2-15 days postinjection, cells from the contralateral area 17 are dissociated and placed in culture. Bead-labeled cells are identified prior to recordings under fluorescence illumination. The monoclonal antibody VC1.1 (generously provided by Dr. J.R. Naegele, Rockefeller) is being used to identify a population of intrinsic GABAergic neurons (Naegele, J.R. et al., J. Neurosci. 8:79-89); ~10-15% of dissociated rat area 17 cells are VC1.1-positive. For physiology, two methods are used to identify VC1.1-positive neurons: (1) prelabeling and visualization prior to recording, or (2) identification following recordings (from randomly selected cells) with Lucifer Yellow-filled electrodes. Using the whole-cell patch-clamp technique, the waveforms of voltage-activated currents and action potentials are being examined. Preliminary results suggest that, although the time- and voltage-dependent properties of the currents through voltage-gated Ca^{2+} channels are similar, there do appear to be differences in action potential waveforms in these two cell types. Ongoing experiments are aimed at investigating these observations further. Support: NIH (T32-HL07275).

CHARACTERIZATION OF MEMBRANE CURRENTS FOUND IN VIVO IN ELECTROPHYSIOLOGICALLY IDENTIFIED NEURONS IN CAT MOTOR CORTEX. A. Baranyi, M.B. Szente, and C.D. Woody, UCLA Med. Ctr., MRRC, BRI, Los Angeles, CA 90024.

Membrane conductances and currents of 486 neurons in the motor cortex of conscious cats were analyzed using bridge mode recordings and single electrode voltage clamp techniques. Pharmacologic separation and characterization of conductances were accomplished by intracellular pressure injection of drugs and cations. Five types of neurons were identified by their spike parameters, firing activity patterns, current-voltage relationships, and responses to ventrolateral thalamic and pyramidal tract (PT) stimulation: (i) fast PT, (ii) slow PT, (iii) bursting nonpyramidal tract (nPT), (iv) fast-spiking nPT, and (v) regular-spiking nPT neurons. Membrane currents were separated and characterized by their voltage-dependence, time course and pharmacologic sensitivity: (i) transient outward current (I_A), (ii) delayed rectifier current (I_K), (iii) Ca-activated fast (I_C) and slow ($I_{K(Ca)}$) potassium currents, (iv) persistent sodium current ($I_{Na(P)}$), (v) low threshold Ca current ($I_{Ca(T)}$), (vi) high threshold calcium current ($I_{Ca(L)}$), and (vii) inward anomalous rectifier current (I_R). The recorded combinations, magnitudes and parameters of activation and inactivation of these currents showed differences among cell types that contributed to their characteristic firing properties.

INTRACELLULAR INJECTION OF APAMIN REDUCES SLOW AFTERHYPERPOLARIZATIONS AND IPSPs IN NEOCORTICAL NEURONS OF CATS. M.B. Szente, A. Baranyi, and C.D. Woody, MRRC, BRI, Depts. of Psychiatry and Anatomy, UCLA Med. Ctr., Los Angeles, CA 90024.

Electrophysiologic effects of intracellularly injected apamin, a Ca^{2+}-dependent K^+ channel blocker, were investigated in neurons of the motor cortex of awake cats. Single electrode voltage clamp techniques were used to measure membrane and synaptically activated currents. Changes occurred within 2-4 min after pressure injection of apamin with partial recovery observed within 8-15 min. Apamin selectively abolished an outward current that mediated a slow afterhyperpolarization (AHP) following depolarizing current pulses and action potentials without influencing the duration of the action potentials or their fast AHPs. In addition apamin increased the firing activity evoked by depolarizing current pulses and produced a small increase in the rate of background firing. The resting potential and input resistance were essentially unchanged by apamin. Apamin also diminished a late, slowly decaying component of inhibitory postsynaptic potentials and currents elicited by stimulation of the ventrolateral thalamus or the pyramidal tract. The results suggest that the late, slowly decaying component of these inhibitory postsynaptic responses is generated by an apamin sensitive, Ca^{2+}-dependent K^+ conductance which is also responsible for the slow AHP.

VOLTAGE-DEPENDENT CALCIUM SIGNALLING IN SINGLE T LYMPHOCYTES. R.S. Lewis and M.D. Cahalan. Dept. of Physiology & Biophysics, University of California, Irvine, CA 92717.

A rise in intracellular free Ca^{2+} is believed to be an early triggering signal in the activation of T lymphocytes by mitogens. We have investigated the voltage dependence of this signal in single cells of the human T-cell leukemia line, Jurkat. Cells loaded with fura-2/AM were illuminated alternately at 350 nm and 385 nm, and their fluorescence measured with a photomultiplier attached to the microscope. The average response of a population of these cells to the lectin mitogen, phytohemagglutinin (PHA; 10 ug/ml), is a sigmoidal rise in $[Ca^{2+}]_i$ which peaks within several minutes at 22°C. Photomultiplier measurements show that the sigmoidal time course of this response results from an abrupt increase in $[Ca^{2+}]_i$ from ~100 nM to >500 nM in individual cells occurring with variable latencies after PHA addition, ranging from one to five minutes. After the initial rise, $[Ca^{2+}]_i$ in single cells oscillates with a period of minutes, suggesting positive and negative regulatory feedback. Membrane depolarization, induced by replacing Na^+ by K^+ in the external Ringer solution, inhibits the mitogen-stimulated Ca^{2+} rise, rapidly reducing $[Ca^{2+}]_i$ to values near the baseline level. This result contrasts markedly with the stimulatory effect of depolarization on $[Ca^{2+}]_i$ in most excitable cells. Depolarization may antagonize Ca^{2+} entry in T cells by directly inhibiting the entry mechanism or by reducing the electrical driving force on Ca^{2+} ions entering the cell. The effects of depolarization on $[Ca^{2+}]_i$ were studied further in Jurkat T cells voltage-clamped in the whole-cell mode, using patch pipettes containing K^+ aspartate and 100 uM fura-2 as the only Ca^{2+} buffer. Step depolarization to 0 mV does not detectably alter resting Ca^{2+} levels, consistent with previous evidence for a lack of voltage-dependent Ca^{2+} channels in T cells, and demonstrating that Ca^{2+} does not permeate to any significant degree through the T cell's voltage-dependent, depolarization-activated K^+ channels. SECOND MESSENGERS REGULATE CALCIUM INFLUX IN MAST CELLS. R. Penner*, G. Matthews+, and E. Neher*. *Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, FRG and +Dept. of Neurobiology, SUNY, Stony Brook, NY 11794-5230.

Mast cells are non-excitable cells that secrete histamine in response to a variety of external chemical agonists. Agonist stimulation increases $[Ca]_i$ due both to IP_3-mediated release from internal stores (Neher, *J. Physiol.*, **395**:193, 1988) and to influx of external Ca^{2+}. In experiments using simultaneous patch-clamp recordings and fura-2 measurements of $[Ca]_i$, we have identified two possible mechanisms of Ca-influx. First, IP_3 can induce Ca-influx with increases in total whole-cell current less than 1-2 pA and without discernible channel activity; if this influx is via IP_3-gated channels, they must be of small-conductance and highly calcium-specific. Second, agonist stimulation activates cation channels with a reversal potential of 0 mV and a single-channel conductance of about 50 pS in Ringer and 16 pS in isotonic Ba^{2+}. Activation of the 50 pS channel can produce a whole-cell current of 2-15 pA at -50 mV. This channel can also be activated by internal GTP-γ-S, and its activation by agonists can be blocked by GDP-β-S, indicating that it is second messenger-gated rather than direcly agonist-gated. High $[Ca]_i$ can also block activity of the 50 pS channel. Although this channel resembles the IP_3-gated channel reported in lymphocytes by Kuno & Gardner (*Nature*, **326**:301, 1986), it is not gated by either IP_3 or IP_4, since high levels of IP_3 and IP_4 in the pipette solution do not activate the channel or prevent its activation by agonist.

REPETITIVE FIRING PATTERNS IN CAT NEOCORTICAL NEURONS DEPEND ON PRECEDING SUBTHRESHOLD MEMBRANE POTENTIAL W.J. Spain*, P.C. Schwindt, W.E. Crill. Dept. of Physiology & Biophysics, Univ. of Washington, Seattle WA 98195.

Activation of sufficiently slow ionic currents with subthreshold voltage dependence can alter the firing pattern evoked by a subsequent stimulus and in this way provide a postsynaptic mechanism for coding the preceding level of membrane potential. We have identified such coding and its ionic mechanisms in neocortical neurons (in slices). These neurons normally exhibit a monotonic decline of firing rate (adaptation) to a final level during depolarization from resting potential evoked by an injected current pulse. Preceding a test current pulse with a subthreshold depolarizing prepulse (using voltage clamp) reduced the initial firing rate. Hyperpolarizing prepulses usually resulted in a biphasic response. The initial firing rate increased up to 100%. After this burst, firing rate declined below, and accelerated to, the control level over periods up to 0.8s. Other cells responded to hyperpolarizing prepulses only with a prolonged increase in firing rate lasting up to 0.6s or only with a prolonged depression of firing rate lasting 1-2s. The effects in each cell were graded with the level and duration of the conditioning prepulse, and they persisted in Ca^{2+}-free perfusate or with 400 μM Cd^{2+} added. We hypothesized that the effects were mediated by two previously identified currents: a slowly inactivating K^+ current (IA) that is partially inactivated at resting potential, and the anomalous rectifier (IAR) which is activated by hyperpolarization. Pharmacological studies with Cs^+ (a specific blocker of IAR) and 4-aminopyridine (a specific blocker of IA) suggested that the postinhibitory behavior is determined by the balance between deactivation of IAR and the activation of IA following hyperpolarization. Postinhibitory excitation occurs in cells where IAR dominates, whereas postinhibitory inhibition occurs when IA dominates. Supported by NIH grants NS16972 & NS01166.

NERVE IMPULSES MODIFY VOLTAGE-GATED CHANNELS IN FROG NEUROGLIA. H.G. Marrero*, M.L.Astion*, J.A. Coles*, R. Blanco* and R.K. Orkand. Institute of Neurobiology UPR-MSC Old San Juan PR 00901

Using the loose patch clamp technique, macroscopic voltage-dependent TTX-sensitive sodium currents as well as 4-AP and sodium sensitive potassium currents were recorded from the surface of the intact optic nerve of Rana pipiens. The currents likely arise from the surface astrocytes because they are still recorded when most of the axons have degenerated and in the presence of 10 times normal potassium, which blocks axon excitability. In the intact nerve the currents are facilitated after an action potential in the underlying axons. The facilitation following a train of nerve volleys (10 Hz, 1 sec) decays to one-half in about 0.3 sec. This is 4-5 times more rapid than the decay of glial depolarization. The timecourse of glial depolarization reflects changes in extracellular potassium following its release from active axons. The peak of the facilitation occurs 30 msec after a nerve volley while the axons themselves are partially refractory. After adding 4-AP, the timecourse of the facilitation is slowed. The modification of the channel behavior by nerve impulses may represent a new type of nerve-glia interaction.

INTRACELLULAR APPLICATION OF 4-AMINOPYRIDINE AND TETRAETHYLAMMONIUM DECREASES ACCOMODATION IN FROG MYELINATED AXON. M.O.Poulter and A.L. Padjen. Dept of Pharmacology and Therapeutics, McGill University, Montreal P.Q. Canada H3G 1Y6

The functional role of potassium conductances were studied by impaling myelinated axons of frogs with microelectrodes containing 4-aminopyridine (4-AP, 5-10mM; blocker of the fast potassium currents, G_{Kf1}, G_{Kf2}) and tetraethylammonium (TEA, 10-20mM; blocker of both the fast and slow potassium current, G_{Ks}). The after-hyperpolarizing potential (duration 2-5 ms following single action potential) disappeared and was replaced by an after-depolarizing potential lasting 50-100 ms within 5 minutes when either 4-AP and/or TEA were present in microelectrode. In response to intracellular current pulses (200 ms) accomodation of action potentials decreased more with TEA than with 4-AP. A computational model based on Hodgkin-Huxley equations, which included the three potassium and sodium currents, reproduced the results obtained with both blockers. These results imply that accommodation in amphibian myelinated axons is regulated by potassium channels and not function of sodium channel inactivation.

EFFECTS OF THE SUBSTITUTION OF LITHIUM FOR SODIUM ON THE RESPONSE OF MOLLUSCAN SMOOTH MUSCLE TO ZERO POTASSIUM. R.B.Hill. Department of Zoology, University of Rhode Island, Kingston, R.I. 02881.

Part of the evidence for a contribution to resting potential by an electrogenic sodium pump is provided by a control experiment, prior to Li treatment. A radular protractor muscle (RPM) of Busycon canaliculatum had a resting potential of 72 mV, just before being subjected to 3 minutes in zero potassium. The immediate response was a 3 mV hyperpolarization, giving way to a 3 mV depolarization, and followed by a 4 mV after- hyperpolarization on readmission of K. It was hypothesized that depolarization was due to the stopping of Na/K exchange, and that after- hyperpolarization was due to stimulation of Na/K exchange by excess internal Na. When Na was replaced with Li, the response to 3 minutes in zero K was 10 mV hyperpolarization, followed by 20 mV depolarization on readmission of K. When the RPM was returned to Na, the muscle behaved as a K-electrode, responding to 3 minutes in zero K with a simple hyperpolarization. The effect of pre-treatment with Li is thus like that of low Na. The Na-channels may be blocked.

118.7

EFFECTS OF RYANODINE AND RUTHENIUM RED ON NEUROMUSCULAR TRANSMISSION IN CRAYFISH. R.N. Friedman* Dept. of Physiol., Meharry Med. Col. and Dept. of Physics, Vanderbilt Univ. and S. Fleischer* (SPON: J.P.Wikswo) Dept. of Molec. Biol., Vanderbilt Univ., Nashville, TN 37235.

In preliminary studies, we observed effects of ryanodine (Ry) and ruthenium red (RR) on short-term facilitation at neuromuscular junctions (NMJs) of crayfish (Procambarus clarkii) 1st and 2nd walking limbs. Facilitation of excitatory junctional potentials (EJPs) was evoked by 30 Hz, 10s stimulation of the nerve to the dactyl opener muscle. Ry, which produces concentration-dependent activation and inactivation of calcium channels in sarcoplasmic reticulum (SR), enhances EJP amplitude (Δ as great as 100%) and duration over a wide range of concentrations (1-100μM). The effective concentration varied with individual preparations, possibly because of diffusion barriers. RR has been shown to depress EJPs at a frog NMJ via a presynaptic mechanism and to antagonize Ry effects on SR. RR reduced crayfish EJP amplitude in a concentration-dependent manner over a range of 1 to 50 μM. RR also antagonized Ry-induced EJP enhancement. Neither Ry nor RR at the concentrations examined affected the muscle membrane resting potential. Ry decreased muscle input resistance only at high (100μM) concentrations. These studies may help to determine if certain calcium-regulating mechanisms modulating neurotransmitter release at NMJs are similar to those affecting calcium release in muscle SR.

IONIC CONDUCTANCES IN TYPE I CELLS FROM THE CAROTID BODY. EFFECTS OF LOW O_2 TENSION. C. Gonzalez[1], J.R. López-López*[1], J. Ureña* and J. López Barneo* Depto. Fisiología. Facultad de Medicina. Universidad de Valladolid(1) and Universidad de Sevilla(2). SPAIN

Rabbit carotid bodies (c.b.) were enzymatically dispersed and cultured in Minimum Essential Medium supplemented with 1 mM glutamine on poly-lysine coated cover-slips. Two to twenty four hours later the cover-slips were transfered to a superfusion chamber. Type I chemoreceptor cells were patch-clamped using a whole-cell configuration.

By adequate combinations of internal and external solutions it was possible to define on pulse depolarization the presence of voltage-dependent Na^+, Ca^{++} and K^+ channels in these cells. Na^+ and Ca^{++} currents are unaffected by lowering the pO_2 in the supperfusion fluid. K^+ currents were reversibly reduced being the reduction related to the environmental pO_2; the effect of hypoxia was similar in the presence or absence of internal Ca^{++} and ATP. The findings suggest that this O_2-sensitive K^+ current may have a primary role in the transduction process in the c.b.

EFFECTS OF NH_3 AND CO_2 ON THE MAMMALIAN MUSCLE SPINDLES. Y. Fukami, Dept. Cell Biology & Physiology, Washington University School of Medicine, St. Louis, MO 63110.

The changes in impulse activity of the sensory endings of single isolated cat muscle spindles, as affected by NH_3 and CO_2 were analyzed. Muscle spindles in adult cat tail muscles were used. A single spindle isolated together with its innervating nerve was placed in an experimental chamber containing a normal Locke solution. To facilitate access of the bathing solution to the sensory endings the spindle capsule was nicked or partially resected. The pH of all solutions used was 7.4. Experiments were performed at room temperature of about 24°C.

Typically, NH_4Cl application resulted in an initial brief increase of impulse activity. This was followed by a reduction of the activity, usually to below the control level. Upon replacement of NH_4Cl solution with normal Locke, the activity further decreased, and only gradually returned toward the control level. Upon introduction of CO_2 solution impulse activities were immediately suppressed, which was followed by a gradual return to or by an increase even beyond the control level. Upon return to the normal solution the activity further increased and then gradually returned toward the control level.

In summary, we conclude that the effects of CO_2 and NH_3 on sensory impulse activity of the cat muscle spindle are most likely caused by changes in the pHi of the sensory ending.

IMPULSE ENTRAINMENT AT TRIGGER ZONES WITH NON-UNIFORM EXCITATION AND GEOMETRIC STRUCTURES. P.N. Steinmetz* and J.F. Fohlmeister. Neuroscience Program, University of Minnesota, Minneapolis, MN 55455.

The impulse encoding process has been simulated on a CRAY II supercomputer. Our intent is to characterize all possible impulse encoding phenomena that result from cable and channel-density non-uniformities alone, employing only the most fundamental impulse kinetics. The trigger zone was modelled as a short axonal segment continuous with a cylindrically symmetric excitable cable of indefinite length (but with possible variations in cable diameter). All channel gating kinetics were restricted to those of the Hodgkin-Huxley model; non-uniform excitability was achieved by changes in $\bar{g}_{Na}$ and/or $\bar{g}_K$ (i.e., channel-density) only. Whereas the space-clamped membrane becomes spontaneously firing when $\bar{g}_{Na} \geq 2\bar{g}_{Na}(HH)$ (depending on temperature), an embedded hyperexcitable trigger zone of 15 μm length (10 μm diam. axon) remains silent for $\bar{g}_{Na}(TZ) > 100\bar{g}_{Na}(HH)$. With a hyperexcitable trigger-zone ($\bar{g}_{Na}(TZ) \gtrsim 10\bar{g}_{Na}(HH)$) the neuron maintains repetitive firing under constant current stimulation with current injected into the "cable" hundreds of microns distant from the TZ; this is in contrast to phasic behavior (single impulse initiated at site of current injection) for a uniformly excitable cable with standard values of $\bar{g}_{Na}$ and $\bar{g}_K$. Once initiated, impulses propagate normally.

MODELLING ELECTRICAL EXCITABILITY IN THE CELL BODY AND AXON OF TYPE B BULLFROG SYMPATHETIC GANGLION CELLS. W.Yamada, C. Koch, P. R. Adams. Div. of Biology 216-76, California Institute of Technology, Pasadena, Ca. 91125, U.S.A. and Howard Hughes Medical Institute, SUNY at Stony Brook, NY 11794.

Using conventional microelectrode techniques, seven voltage- , calcium-, and time- dependant currents have been characterized in type B sympathetic ganglion cells. Previously, we presented an electrical model of these cells based on voltage-clamp data (Koch and Adams, 1985). The model incorporates all seven ionic currents (I_{Na}, I_{Ca}, I_A, I_{AHP}, I_C, I_K, I_M) as well as calcium diffusion, buffering and pumping, and describes the electrical behavior of these cells under various protocals (e.g. current clamp).

Several outstanding problems remain. In particular, under the assumption of a spherical soma, the experimentally measured value of whole cell capacity corresponds to an anomalously high value of specific membrane capacity (8 $\mu F/cm^2$; Adams, Brown & Constanti, 1982). Furthermore, patch clamp data (Jones, 1987) supports the notion of two distinct populations of sodium channels; one in the cell body proper with a high voltage threshold for action potential generation and an axonal sodium current with a much lower threshold. Accordingly, we added an "n compartment" nonmyelinated axon to our cell body which includes the I_{Na} and I_K currents characterized by Frankenhaeuser & Huxley's (1964) frog node of Ranvier data. Timing of axonal and somatic action potentials was studied by varying the midpoint activation and inactivation values of both sodium currents as well as the geometry of the axon.

NEURON SIMULATIONS WITH SABER. N.T.Carnevale, T.B.Woolf, and G.M.Shepherd. Neurol.Dept. and Dept. of Neurobiol. and Behavior, SUNY, Stony Brook, NY 11794, and Sect. Neuroanat., Yale Univ. Sch. of Med., New Haven, CT 06510

Modeling is essential for testing hypotheses of neuronal function that involve time- and voltage-dependent ionic conductances. Commercial simulation programs have been useful tools for this work (e.g. SPICE--Segev et al., Biol.Cybern. 53:27, 1985; Bunow et al., ibid. 41). However, SPICE needed analog computer circuits to emulate active currents. This increased model complexity, slowed simulations, and hindered its widespread use for neuronal modeling.

We report here our experience modeling biophysically realistic membrane properties with SABER (Analogy Inc.), a new general purpose simulator. Like SPICE, it handles linear electrotonus easily (Flach et al. Soc.Neurosci.Abs. 13:159, 1987). One major advantage of SABER is that it allows construction of models with arbitrary properties: the empirically determined equations that describe ionic conductances, currents, and concentration shifts can be translated directly into model elements ("templates") written in C-like code.

We have used these features of SABER to: write templates for ionic currents with various kinetic schemes including the classical descriptions of Hodgkin and Huxley; simulate action potential initiation and propagation; model the effects of dendritic active sites on synaptic transmission (Shepherd et al. Soc.Neurosci.Abs. 1988); simulate the effects of the ionic concentration changes that accompany neuronal activity on membrane currents.

118.13

THE SUPERNORMAL PERIOD IN NEURON MODELS. E. N. Yamoah* and N. Stockbridge* (SPON: R.E. Walley). Department of Surgery, University of Alberta, Edmonton, Canada T6G 2B7.

Supernormal excitability in nerves has been used to explain neural encoding, frequency dependent conduction at axonal branches and synaptic facilitation. However, the factors responsible for this phenomenon are unknown. We tested three neuron models for a supernormal period following a membrane action potential and investigated the basis for supernormality in the models that predicted it. A supernormal period was observed in the Hodgkin & Huxley (HH) model for the squid giant axon and the Connor, Walter & McKown (CWM) model of crustacean motor axons, while it was absent in the Frankenhaeuser & Huxley (FH) model of frog myelinated nerve fibres.

In the HH model, supernormal excitability results from undershoot of the potassium activation variable n during and following the after-hyperpolarization. Prevention of this undershoot in n removes supernormal excitability with no effect on the properties of the action potential except the after-depolarization. In the CWM model, inactivation of the A-current occurs during and following the after-hyperpolarization. We conclude that supernormal excitability, at least in the squid and crustacean axon models, is caused by the slow kinetics of potassium currents. The late reduction in potassium conductance persists after the membrane potential and inward current parameters have returned to their initial states and means that less depolarizing current is required to bring the membrane to threshold.

The absence of a supernormal period in the FH model shows one way this model is insufficient to account for all the observed properties of myelinated nerves.

SYMPOSIUM. AT LAST! POTASSIUM CHANNELS: EXPRESSION AND REGULATION. N.C. Spitzer, U.C. San Diego (Chairperson); P.R. Adams, S.U.N.Y. Stonybrook; R.W. Aldrich, Stanford; L.Y. Jan, U. C. San Francisco; B. Rudy, N.Y. University.

Knowledge of potassium currents and channels has taken a great leap forward in the past few years, as a result of the fruition of physiological, biophysical, genetic and molecular biological approaches. Studies of nicotinic acetylcholine receptors, $GABA_A$ and glycine receptors, and sodium and calcium channels blazed the trail. Potassium channels are ubiquitous, and an understanding of their function will have broad implications. Here, we focus on new information of at least five different kinds.

We will first examine physiological and biophysical evidence that demonstrates that qualitatively different potassium currents participate in similar cellular functions, and that each current in turn is the result of contributions of qualitatively different channels (**Adams, Aldrich, Spitzer**). It has been possible to understand the changes occurring during early stages of differentiation of the excitable membrane at the whole cell and single channel levels; mechanisms that regulate these changes will also be proposed (**Aldrich, Spitzer**). The roles of these currents have been quantitatively evaluated with computer models that have allowed formal and rapid tests of different schemes (**Adams, Spitzer**). Genetic studies have furthered the understanding of potassium channel function (**Aldrich**), and molecular analyses have now achieved the cloning of what will no doubt be several potassium channels (**Jan, Rudy**). Use of the *Xenopus* oocyte injection expression system has confirmed the success of the molecular approaches and has allowed further analysis of the structure-function relationships of these channels (**Jan, Rudy**).

122

WORKSHOP: NEW APPROACHES TO THE FUNCTIONAL DEVELOPMENT OF THE NEOCORTEX. D.O. Frost, Yale Med. Sch. (Chairperson), J. Sanes, Washington Univ. Med. Ctr., S. McConnell, Stanford Med. Sch., D. O'Leary, Washington Univ. Med. Ctr., M. Bear, Brown Univ.

Different neocortical areas are associated with distinct functional systems. In each area, functionally related sets of neurons and afferent axons are segregated into radially oriented modules; efferent neurons projecting to different targets are segregated at different depths within a module. This symposium presents new approaches to studying the development of these features at the molecular, cellular and systems levels.

J. Sanes will demonstrate how retroviruses can be used to study neuronal lineage and test the hypothesis that neurons that are vertically distributed within a neocortical module are clonally related. S. McConnell will show how grafting techniques can be used to demonstrate that the laminar position and efferent connections of some cortical neurons are determined before or at the time of their last mitosis in the ventricular zone. D. Frost will demonstrate that in animals with surgically induced retinal projections to the somatosensory thalamus, somatosensory cortical neurons have visual response properties very like those of normal visual cortical neurons; thus, the visual and somatosensory cortices may use similar neuronal circuits to perform similar transformations on their inputs. D. O'Leary will present data from transplant experiments showing that the modality of afferents to a sensory cortex may determine which among its multiple, immature descending projections to different sensory systems are maintained and which are eliminated. M. Bear will show how receptor blockers are used to demonstrate the action of NMDA receptor-controlled Ca^{2+} channels in mediating the influence of electrical activity on the stabilization and elimination of immature cortical connections.

123.1

PROTEIN KINASE C - A SECOND MESSENGER RESPONSIBLE FOR THE NEUROTROPHIC ACTIONS OF PHORBOL ESTER AND EXCESS K
A. R. Wakade, S.V. Bhave,* R.K. Malhotra* and T.D.Wakade*. Department of Pharmacology, SUNY Health Science Center, Brooklyn, N.Y. 11203

Sympathetic neurons (SN) of the chick embryo are supported in culture not only by nerve growth factor (NGF) but also by excess K and phorbol esters. Since phorbol esters exert their effects through activation of protein kinase C (PKC), it was of interest to know if neurotrophic action of phorbol 12,13-dibutyrate (PDB), excess K and NGF was mediated by PKC. 150,000 SN derived from peripheral ganglia of 10-day-old chick embryos were supported in culture by either NGF (40 ng/ml), PDB (30 nM), or K (35 mM) for 3 days. PKC activity was estimated in cytosolic and membranous fractions. The respective values (pmol/mg prot.) were: 0.14, 0.09 for NGF-, 0.14 and 0.7 for 35 mM K-, and 0.14 and 0.47 for PDB-supported SN. PDB caused a dose-dependent (3 to 100 nM) increase in survival of SN and an increase in PKC activity. K produced dose-dependent (7.5 to 75 mM) increase in survival and activation of PKC. 35 mM K and 30 nM PDB did not produce additive effects on survival and PKC activity. PKC activity of SN suported by PDB for 3 days returned to basal level 30 min after washout and was increased by addition of PDB or excess K but not NGF. We conclude that PKC plays the role of a second messenger in the neurotrophic action of PDB and excess K.

123.2

NEUROTROPHIC ACTION OF FORSKOLIN ON CHICK SYMPATHETIC NEURONS IS INDEPENDENT ON cAMP FORMATION.
T.D. Wakade,* R.K. Malhotra,* S.V. Bhave,* and A.R. Wakade, (SPON: F. Scalia) Department of Pharmacology, SUNY-Health Science Center, Brooklyn, N.Y. 11203.

Sympathetic neurons (SN) obtained from 10-day-old chick embryos were cultured in a serum-free medium. The surival of SN was determined 3 days after the addition of either nerve growth factor (NGF) or forskolin (FORK). About 40% of plated SN survived in the presence of 10 μM FORK. This value was comparable to that obtained with NGF (40 ng/ml). Morphological appearance of SN supported by FORK was different than that of NGF-supported SN. The neurotrophic action of FORK was evident for at least 6 days. cAMP content of SN supported by NGF and FORK for 3 days was not significantly different (9.1 ± 1.0 vs. 11.3 ± 2.6 pmols/mg prot.). SN supported by NGF for 3 days and then exposed to FORK for 15 min showed a marked increase in cAMP (144.6 ± 17.9 pmols/mg prot.). However, SN supported by FORK for 3 days failed to show an increase in cAMP upon re-exposure to fresh FORK. SN exposed to FORK for 2 hr (in which period there is more than 10-fold increase in cAMP) and then returned to forskolin-free medium did not survive in culture. We conclude that the neurotrophic action of FORK is probably unrelated to adenylase cyclase-cAMP system.

123.3

FIBROBLAST GROWTH FACTOR MIMICS SOME OF THE EFFECTS OF NEURONAL GROWTH FACTORS ON CHICK PARASYMPATHETIC NEURONS IN CELL CULTURE.
R. Nishi and F.P. Eckenstein, Dept. of Cell Biology & Anatomy, Oregon Health Sciences University, Portland, OR 97201

Neurons of the chick ciliary ganglion (CG) have been shown to proceed through a period of neuronal cell death that coincides with synapse formation in the periphery. It has been suggested that neuronal cell death during development is controlled by the availability of trophic molecules released by the target tissues which the neurons normally innervate. We have previously shown that ciliary ganglion neurons destined to die can be maintained in cell culture if the medium is supplemented with soluble molecules derived from extract of eyes (which contains all the target tissues of the CG). We have identified two biologically active molecules in eye extract based upon a long- term bioassay : one molecule promotes survival and growth, whereas the other induces choline acetyltransferase. We are currently purifying these trophic molecules. Recently, it was reported that fibroblast growth factor (FGF) promotes survival of CG neurons for 24 hrs in cell culture. Because FGF has been isolated from both retina and vitreous humor, we have tested whether FGF also acts as a trophic molecule for longer times in cell culture. We have shown that basic and acidic bovine FGF stimulate survival long- term growth of cultured CG neurons. The dose- response curves for both FGFs were similar and reached half- maximal values at a concentration of 200pg/ml. The response to bFGF was not affected by the presence of heparin, whereas the response to aFGF required heparin. Neither FGF promoted the specific induction of choline acetyltransferase activity. FGF is not responsible for the growth promoting activity that we are purifying because the partially purified molecule does not bind to heparin. The precise function of FGF during neural development has yet to be determined.

123.4

BASIC FIBROBLAST GROWTH FACTOR PROMOTES THE SURVIVAL AND DEVELOPMENT OF MESENCEPHALIC NEURONS IN VITRO.
G. Ferrari*, M.-C. Minozzi*, C. Soranzo*, G. Toffano and S.D. Skaper (SPON: M.G. Nunzi). Fidia Research Laboratories, Abano Terme, Italy.

Basic fibroblast growth factor (bFGF) has been reported to act as a neuronotrophic factor for CNS neurons. Neuronal survival and neurite extension induced by bFGF have been described in hippocampal, cortical, spinal cord and granule neurons in vitro. These effects, however, have never been tested on fetal mesencephalic-derived neurons, nor associated with specific CNS neuronal cell types (e.g., in terms of expression of neurotransmitter-related properties). To address these questions, serum-free fetal rat mesencephalic cells were utilized to study the effects of bFGF on neuronal survival with time in culture. Addition of bFGF increased the number of surviving cells with a neuronal morphology. Due to the heterogeneity of the neuronal cells it was important also to determine if the effects of bFGF were associated with specific neuronal cell types. The survival of dopaminergic and GABAergic neurons was assessed by measuring their specific ^{3}H-DOPA and ^{14}C-GABA uptakes, respectively. bFGF (in the ng/ml range) was capable of increasing, in a dose-dependent manner, both ^{3}H-DOPA and ^{14}C-GABA uptakes. This effect was completely abolished by antibodies against bFGF. These results strengthen the possibility that bFGF may play a key role in normal nervous system development or function.

123.5

A POSSIBLE AUTOCRINE ROLE OF BASIC FGF FOR MAINTENANCE AND TRANSMITTER STORAGE OF CHROMAFFIN CELLS.
K. Unsicker, R. Westermann*, C. Grothe*, D. Gehrke*, and P. Böhlen*. (SPON: European Neuroscience Association), Dept. of Anatomy and Cell Biology, Univ. of Marburg, F.R.G.

Adrenal chromaffin cells cultured from young postnatal rat require trophic factors for their survival and maintenance of transmitters. Nerve growth factor (NGF) and ciliary neurotrophic factor (CNTF) have been shown to serve these needs, but their presence in the adrenal medulla and putative physiological relevance have not been proven. We show that basic FGF may have such a role in as far as this protein is stored in and released from chromaffin cells and enhances survival and transmitter storage of cultured chromaffin cells. Several lines of evidence suggest that bFGF or an immunologically related molecule is present in the adrenal medulla: (i) a protein obtained in bFGF-enriched fractions from bovine adrenal medulla extracts co-migrates with purified bFGF and is recognized by anti-bFGF IgG in immunoblots, (ii) the same antibody blocks the neurotrophic activities of (a) rat adrenal medullary homogenates, (b) bovine chromaffin vesicle proteins, (c) a conditioned medium obtained from carbachol-stimulated isolated bovine chromaffin cells, (iii) chromaffin vesicle proteins stimulate proliferation of cultured bovine aorta endothelial cells. Purified bFGF supported survival and prevented catecholamine losses of chromaffin cells cultured from 8 day old rats,but,in contrast to NGF and CNTF, did not induce neurite outgrowth on polyornithine or laminin substrates during a 4-day culture period. These results suggest a potential role of bFGF as a trophic factor for chromaffin cells.

123.6

BASIC FGF IN MUSCLE AND ITS EFFECTS ON CULTURED MOTONEURONS AND SCHWANN CELLS.
Ken Vaca. Dept. of Neurology, Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030.

A polypeptide has been purified from autopsied adult human skeletal muscle using an increase of choline acetyltransferase activity in cultured chick ciliary ganglion cells as bioassay. It has a mass of 18 kDa and elutes from a heparin affinity column at 1.5 M NaCl. Its activity is precipitated by antibodies to basic FGF and mimicked by recombinant human basic FGF. Similar bioactivity is found in muscle-conditioned medium and can be extracted from extracellular matrix of lysed cultured embryonic chick muscle by heparinase treatment or high salt treatment and heparin affinity purification. Besides enhancing cholinergic differentiation, basic FGF increases survival of ciliary neurons and Schwann cells, neurite outgrowth, Schwann cell motility and interactions of neurons and Schwann cells to form small ganglion-like aggregates and nerve-like fascicles. Neurons cultured prior to or during the cell death period are more acutely sensitive to basic FGF's effect on survival than cultures of older neurons. It is proposed that, in the adult, heparan sulfate proteoglycan localizes basic FGF in the endplate region to modulate cholinergic expression and that denervation-induced release of degradative enzymes liberates basic FGF to induce sprouting and reinnervation acutely or the extensive fibroblast proliferation seen in chronic denervation.

123.7

CHARACTERIZATION OF A HIPPOCAMPAL MEMBRANE-ASSOCIATED CHOLINERGIC NEUROTROPHIC FACTOR. B.C. Wise and M.J. Mastrangelo, Jr.* FGIN, Georgetown Univ., Washington, D.C. 20007

We have identified a CNS cholinergic neurotrophic factor (NTF) associated with hippocampal membranes. The NTF which increases choline acetyltransferase (ChAT) activity in primary cultures of fetal rat septal neurons is developmentally regulated and is unevenly distributed in brain regions (highest in hippocampus, negligible in cerebellum). The membrane-associated NTF is solubilized by incubation with 1 M NaCl and is inactivated by trypsinization. The NTF does not change the number of septal neurons immunostained for ChAT, GAD, or NGF receptor nor does it alter GAD activity in cultured cells indicating a specificity of action toward the cholinergic neuron which is not due to a survival effect. Gel filtration of the high salt membrane extract indicates a MW of 500 kD for the NTF. The protein has been partially purified by ammonium sulfate fractionation followed by phenyl- and DEAE-Sepharose chromatographies. The protein has an isoelectric point of about 6 and is not a glycoprotein since it does not bind to wheat-germ agglutinin or Con A matrices. By various criteria, the NTF is not identical to other neurotrophic proteins such as NGF or laminin and its relationship to the neural cell adhesion molecule (NCAM), remains to be determined.

123.8

SENSITIVITY OF SUBSTANTIA NIGRA NEURONS TO EPIDERMAL GROWTH FACTOR. R. Loy, D. Heyer* and P. DiStefano. Department of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642 and Neuroscience Research division, Abbott Laboratories, Abbott Park, IL 60064

Neurons in the CNS are sensitive to several identified growth factors, and loss of trophic support has been suggested as contributing to cell loss associated with neurodegenerative disorders, such as Alzheimer's disease and Parkinsonism. High levels of epidermal growth factor (EGF) have been seen in the rat substantia nigra (SN), although sensitive cells have been previously identified only in cortex, cerebellum and hippocampus. Using a monoclonal antibody specific to the EGF receptor (EGFR), 151-IgG, we find EGF sensitive cells both in the pars compacta and pars reticulata of the substantia nigra. These are small sized, round or fusiform cells, and medium-sized multipolar cells, whose distribution shows very little overlap with dopamine-containing cells. In material double stained for tyrosine hydroxylase (TH), only a few of the smaller EGFR-positive cells are also immunoreactive for TH. Adjacent sections stained for glutamic acid decarboxylase (GAD), show a very similar distribution to EGFR, although double labeling will be necessary to confirm the colocalization of GAD and EGFR. The presence of EGFR suggests a possible role of this growth factor in SN cell survival and neurite growth. Supported by NIH grant #NS25169.

123.9

NERVE GROWTH FACTOR INDUCES GENE EXPRESSION FOR THE ALZHEIMER'S β-AMYLOID PROTEIN. W.C. Mobley, F.M. Longo,* R.L. Neve, S.B. Prusiner, and M.P. McKinley,* Dept. of Neurology, University of California, San Francisco, CA 94143 and Harvard Medical School, Boston, MA 02115

β-amyloid is the principal protein in both cerebrovascular and neuritic plaque amyloid in the brains of Alzheimer's disease (AD) and elderly Down's syndrome (DS) patients. It is a small molecule which is derived from a precursor (β-PP) encoded on human chromosome 21 (Nature 325:733; Science 235:877,880). β-PP gene expression in the brain is principally within neurons. We report that β-PP gene expression is regulated during development and that nerve growth factor (NGF) induces a marked increase in the level of β-PP mRNA in developing basal forebrain.

Slot blots of total RNA were probed with a cDNA encoding β-PP (FB68L-Science 235:880). β-PP mRNA was found in all brain regions sampled; significant increases occurred during the early postnatal period. In septum, β-PP mRNA was not detected until postnatal day (PD) 9. A marked increase followed; levels greater than in the adult were found at PD 12 and 16. The increase in β-PP mRNA in septum was coincident with increasing activity for choline acetyltransferase (ChAT) and suggested that these markers may be coordinately regulated. NGF (30 μg) administered intraventricularly had a marked influence on ChAT activity and on the level of β-PP mRNA in septum. Three injections during the first postnatal week increased β-PP mRNA levels by more than 10-fold relative to vehicle-treated animals. The β-PP mRNA induced by NGF migrated at 3.2 kb, identical to that found in vehicle-injected animals. The effect of NGF was regionally selective in that NGF induced no increase in β-PP mRNA in the thalamus or brainstem. These data suggest that NGF acts to increase gene expression for β-PP in basal forebrain cholinergic neurons; they raise the possibility that expression of the β-PP gene in these neurons may normally be regulated by NGF.

123.10

NEUROTRANSMITTER RECEPTOR EXPRESSION AND NEURONAL TROPHIC FACTOR SECRETION BY AN UNINNERVATED TISSUE: AVIAN AMNION. C.W. Bowers. Dept. Physiol., UCSF Med. Ctr., San Francisco, CA 94143.

The smooth muscle of avian amnion is unusual because it is normally never innervated. However, based on contractile responses, I have shown that this uninnervated and avascular tissue expresses at least 11 different types of receptors for neurotransmitter substances including acetylcholine, norepinephrine, histamine, 5-HT, VIP, urotensin II, neurotensin and somatostatin-28. Three neurotransmitters, histamine, 5-HT and norepinephrine, each act via two separate and antagonistic receptors. The amnion also responded to prostaglandin E_2. On the other hand, the tissue did not respond to substance P or bradykinin, two peptides known to affect smooth muscle contractility in other systems. Studies with organ cultured amnion indicated not all of the responses develop in a defined medium. Explants from chick ciliary, dorsal root and Remak's ganglia attached and extended neurites on amnion in culture. Furthermore, the normally uninnervated amnion secreted a factor that was required for ciliary neuron survival in vitro. In contrast, sympathetic neurons did not survive on amnion, even in the presence of NGF. The results indicate that this novel smooth muscle preparation will be useful for identifying epigenetic factors that control the expression of functional receptors.

123.11

SYNTHESIS OF NEUROTROPHIC FACTOR FOR SYMPATHETIC NEURONS IN XENOPUS OOCYTES BY TRANSLATION OF mRNA EXTRACTED FROM RAT WOUNDED CEREBRAL CORTEX. T.T. Quach, A.M. Duchemin, B.K. Schrier, R.J. Wyatt. Lab. Developmental Neurobiol., NICHHD, Bethesda, MD and Neuropsychiatry Branch, NIMH, Saint Elizabeths Hosp., Washington, DC.

Injury to the rat cerebral cortex induces the appearance in the area around the lesion of trophic factors which promote survival of dissociated neurons in culture (Nieto-Sampedro et al., Science 217:860, 1982). We studied the expression of at least one of these factors in frog oocytes using the survival of sympathetic neurons from 12 day old chick embryos to detect the activity. Level of detection of the assay was enhanced 10 fold, as compared with the standard microassay, by miniaturization using 100 cells in 10 μl of culture medium per well in Terasaki plates.

Tissues enriched in neurotrophic factors were obtained from the walls of a 7-day post-lesion wound cavity of the cortex of 150 gm rats. Poly(A+)RNA was prepared from these tissues and from similar cortex areas of control rats, size-fractionated on a sucrose gradient and injected into oocytes. While oocytes produced only low trophic activity from translation of mRNA fractions from control cortex, significant trophic activity was produced and secreted by oocytes injected with 1.5-2.0 Kb mRNA fractions from lesioned cortex.

123.12

EVIDENCE FOR DISTINCT FACTORS AFFECTING TRANSMITTER AND NEUROPEPTIDE PHENOTYPES. H. Nawa* and P. H. Patterson. (SPON: N. Davidson) Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

The over thirty neuropeptides that have been identified thus far are found in an enormous variety of combinations with classical transmitters. The specification of these transmitter phenotypes poses a difficult developmental problem. An instructional signal that specifies one transmitter phenotype (acetylcholine) has been purified to homogeneity from heart cell conditioned medium (CM) (Fukada, PNAS 82: 8795, 1985). We find that unfractionated heart cell CM also induces the expression of several neuropeptides and their mRNAs in rat sympathetic neurons: substance P (SP), somatostatin (SOM), vasoactive intestinal polypeptide (VIP) and dynorphin, but not neuropeptide Y. A different pattern of peptide induction was observed for CM from skin fibroblasts. The inducing activities for SP, SOM and VIP are separable from each other and from the cholinergic activity by ammonium sulfate precipitation and ion exchange chromatography. These observations raise the possibility that a large number of distinct factors may influence the choice of transmitter phenotype in developing neurons.

123.13

THE EXPRESSION OF NERVE GROWTH FACTOR PROTEIN IN THE DEVELOPING HIPPOCAMPUS IN REAGGREGATE CULTURE.

J. D. Roback*+, B. H. Wainer+, and T. H. Large# (SPON: P. C. Hoffmann).
+The University of Chicago, Chicago, IL 60637, and #The University of California School of Medicine, San Francisco, CA 94143.

In the rat central nervous system, nerve growth factor (NGF) has been found to exert trophic actions on the septal cholinergic neurons during both development and adulthood. Recently, NGF mRNA and protein have been found at high levels in the hippocampus, the primary target of septal efferents. In addition, septal neurons retrogradely transport NGF from the hippocampus. In light of the putative trophic effect of hippocampally-derived NGF on septal cholinergic neurons, we are investigating the regulation of NGF expression in the hippocampus during development.

We previously demonstrated that dissociated fetal murine septal and hippocampal neurons grown under reaggregating culture conditions recapitulate many aspects of development observed *in situ* (Hsiang,J.,et al,Neurosci.,21:333,1987). In the present studies, we reaggregated dissociated hippocampus from E_{15} mouse embryos and cultured the aggregates for up to 21 days. At E_{15}, the hippocampus has not yet received septal afferents, and so our hippocampal reaggregates have never interacted with septal neurons. We harvested the reaggregates at selected time points (days 7,10,14,19, and 21 in culture) and quantitated their NGF protein content using a sensitive two-site enzyme-linked immunoassay (ELISA) (Weskamp,G. and Otten,U., J. Neurochem., 48:1179,1987).

Hippocampal reaggregates demonstrate a 12-fold increase in NGF protein content between days 7 (3.6±2.0 pg NGF/mg prot.) and 21 (44.2±12.0 pg NGF/mg prot.) in culture. This increase is similar to that seen in the hippocampus *in situ* during the corresponding period, postnatal days 0 to 14 (Large,T.H.,et al,Science,234:3552, 1986). These results suggest that, in reaggregate culture, hippocampal neurons, in the absence of any interaction with septal afferents, are able to recapitulate the developmental profile of NGF protein expression observed in the hippocampus *in situ*.

CYTOSKELETON AND AXONAL TRANSPORT I

124.1

DISTRIBUTION OF MICROTUBULES IN CNS CELL BODIES PREPARED BY FREEZE-SUBSTITUTION. H. TATSUOKA and T.S. REESE. Lab. of Neurobiology, NINCDS, NIH, at MBL, Woods Hole, MA 02543.

In another abstract we report on the use of the chinchilla anteroventral cochlear nucleus as a preparation of CNS cell bodies amenable to direct freezing and freeze-substitution-here we report on the distribution of the myriad microtubules preserved in these cell bodies and analysed in stereo views of montaged serial reconstructions. Bundles of microtubules appear to originate near the concave face of the Golgi apparatus, between it and the nucleus, and run parallel to the nuclear envelope, in some instances toward the initial segment of the axon. Other microtubules originate close to nuclear pores. Vertically oriented microtubules cross the zone between the Golgi apparatus and rough endoplasmic reticulum but their concentration is lower than in the zone between the nucleus and Golgi apparatus. Microtubules run just beneath and parallel to the cell membrane in the outer cortical zone, between the endoplasmic reticulum and the cell membrane; some vertically oriented microtubules terminate very close to the plasma membrane. If microtubules in the cell body, like those in the axon, are pathways for organelle transport, then the characteristic distributions of microtubules in the cell body might represent transport pathways leading from one part of the cell body to another.

124.2

THE RETROGRADE TRANSLOCATOR IN SQUID AXOPLASM IS CYTOPLASMIC DYNEIN. B. J. Schnapp, Laboratory of Neurobiology, NINCDS, NIH, at the MBL, Woods Hole, MA. 02543.

We previously characterized two microtubule-based translocators in squid axoplasm that are candidates for the anterograde and retrograde vesicle motors responsible for rapid axonal transport (Vale et al, 1985, Cell, 43: 623). The anterograde translocator, kinesin, was purified while purification of the retrograde translocator proved elusive. I now report that HMW1 (Vale et al, 1985, Cell, 43:39), a high molecular weight (greater than 1000 kd) microtubule-associated protein in squid neural tissues is a microtubule translocator that promotes sliding of microtubules on glass at up to 2 um/sec and bead movement in the retrograde direction on centrosome-nucleated microtubules. This protein is indistinguishable from two-headed axonemal dynein and cytoplasmic dynein in bovine brain (MAP1C; Paschal et al, 1987; J. Cell Biol. 105:1273.) by sedimentation velocity (20s), electrophoretic mobility in SDS, and by its structure in molecular shadowed images. When axoplasmic supernatants exhibiting bidirectional bead movement are exposed to UV irradiation in the presence of vanadate, (specifically cleaves the dynein heavy chain; Eiford et al, 1986, J. Biol. Chem. 261:2337), retrograde bead movement is specifically blocked.

124.3

VESICLE TRANSPORT IN INTACT AND SEVERED GIANT AXONS OF CRAYFISH. T. A. Viancour. Biological Sciences, Univ. Maryland, Catonsville, MD 21228.

Vesicle fluxes and transport rates were studied using video microscopy techniques to view lateral and medial giant axons (LGAs and MGAs) which were either intact, or which were surviving an earlier transection. In the intact axons there were at least three transport-rate subclasses of vesicles moving by fast axonal transport. Rate distributions for anterograde moving vesicles were identical to those for retrograde moving vesicles. The fastest anterograde vesicles were optically distinguishable from retrograde vesicles. The results support the idea that elements of intact axoplasm impede vesicle translocations, possibly indicating a mechanism for targeting of vesicles.

Transection did not affect organelle fluxes in proximal segments of severed LGAs. Fluxes in distal segments of LGAs and MGAs declined more slowly than predicted from directly observed vesicle transport rates, taking 2-3 d to drop to 50% of normal. Fluxes fell to about 10% of normal by 7 days, and continued to drop toward zero in MGAs, but recovered in LGAs to about 50% of control levels. Both giant axons were physiologically normal for at least 28 days following transection.

3-D ULTRASTRUCTURE OF CYTOSKELETAL ELEMENTS IN BULLFROG OLFACTORY AXONS. P.R. Burton, M. Gurfinkiel*, and D.B. Treanor*, Department of Physiology and Cell Biology, The University of Kansas, Lawrence, KS 66045.

Images in serial micrographs of olfactory axons were examined, digitized, and subjected to computer-assisted 3-D reconstructions. Discontinuities in microtubules (MTs) and neurofilaments (NFs) are clearly shown. NFs are calculated to have an ave. length of 118 μm, are usually bundled, and the mean no. of profiles/axon is ~6.5 (range: 0-29); 8.5% of the axons lacked NFs in the regions examined. Axons show 2-3 MTs with an ave. length of 426 μm (Burton, Brain Res., 409:71). NFs and MTs tend to lie in their own domains in the axon, as does the smooth ER (SER) tubule. The typically single tubule is very long and is more often associated with NFs than MTs. Considering the calculated ave. lengths of NFs and MTs in olfactory axons, about 42 end-to-end NFs and 11 end-to-end MTs would be required to extend the length of a 5 mm long nerve. If NF and tubulin proteins are translocated from perikaryon to terminal as assembled polymers, it appears that they are moved into the axon within their own domains as trains of long segments with "free" ends. Extensive synaptic contacts occur between an axon terminal and many mitral cell dendrites with little evidence, to date, of axon branching. Typical asymmetric junctions show postsynaptic densities 250-400 nm wide, but a few junctions show an axon with a broader area of apparent synaptic activity partly surrounding a dendrite. Supported by NIH grant NS25518 and a grant from the KU Biomed. Comm.

ANALYSIS OF GENOMIC CLONES FOR THE 57KD NEURAL INTERMEDIATE FILAMENT PROTEIN (NIFP). L.M. Parysek* and C.A. Ley* (SPON: D.R. McCrimmon) Depts. Cell Biology & Anatomy and Neurology, Northwestern Univ., Chicago, IL 60611

Despite the exclusive neuronal distribution of the 57kD NIFP (Parysek and Goldman, J. Neurosci. 1988), cDNA's encoding this IF protein have indicated that it is more like Type III IF proteins than Type IV (neurofilament triplet) proteins (Leonard, et al, 1988, JCB, Parysek, et al., 1988, Neuron). We have isolated genomic clones representing the entire 57kD NIFP gene that have enabled us to obtain previously missing amino terminal coding sequence and begin an analysis of the promotor region of this gene. Sequence data indicates that from the ATG start codon, the region 453 bases upstream contains at least four GC boxes and two C-rich regions, one like that identified in the vimentin promotor. The sequence TATAA is located -82 bases upstream from the ATG start codon. There is no region of similarity to the 16mer GTAACGGGACCATG found in the genes of other Type III IF proteins, vimentin and desmin. Further analysis of this gene, particularly intron location, may provide clues to its neuron-specific expression.

A 66KDa protein is a putative subunit of mammalian neurofilament. F.-C. Chiu* (SPON: W.T. Norton). Dept. of Neuro. and Neurosci. Albert Einstein Coll. of Med., Bronx, NY 10461.

We have purified a 66KDa protein from the triton-insoluble, cytoskeletal fraction of rat spinal cord. Upon removal of urea, this protein (IF66) formed 10 nm filaments. IF66 was biochemically distinct from NF-L in pI (5.5 for IF66, 5.1 for NF-L) and in amino acid composition. Antiserum to IF66 was raised and, on western blots of spinal cord homogenates, it stained a major immunoreactive band at 66KDa and a minor band at 140 KDa. On vibratome sections, this antiserum stained intensely axons in spinal cord and in cerebellum. Neuronal perikarya and nuclei, astrocytes and oligodendrocytes were not stained. Adsorption with purified IF66, but not NF-L, NF-M or NF-H, completely removed the immunoreactivity on western blots and in tissue sections. Using purified IF66 as standards, we estimated that IF66 constituted about 0.5% of the total protein in the homogenate of adult rat spinal cord, whereas NF-L constituted about 1.5%. IF66 was found only in nervous tissues, primarily in CNS with only trace amounts in the sciatic nerve. IF66 was not detectable in cultured astrocytes and extraneural tissues such as liver and kidney.

124.7

CHARACTERIZATION OF PROTEIN KINASE ACTIVITIES IN A NEUROFILAMENT ENRICHED PREPARATION ISOLATED FROM BOVINE SPINAL CORD. HARISH C. PANT (SPON:K. KUSANO). LNC, NINCDS, NIH, BETHESDA, MD 20892

Protein kinase activities in a neurofilament enriched preparation from bovine spinal cord were examined using a variety of endogenous and exogenous substrates as well as specific activators and inhibitors. Incubations in the presence of [δ-^{32}P]-ATP and 10mM Mg^{2+} showed that all three neurofilament subunits (NF-L,M, and H) were phosphorylated under those conditions, but that the major labeled endogenous protein in this preparation was an 18KD protein. Neither activators or inhibitors of cAMP-dependent or Ca^{2+}/calmodulin dependent kinases altered this labeling pattern. However, staurosporine, a potent inhibitor of protein kinase C, selectively inhibited 32p incorporation into the 18KD protein, but not the neurofilament proteins (NF). Using various exogenous substrates (e.g., casein, H1 and H2A histones, and syntide-2) it was possible to demonstrate that this preparation did contain significant Ca^{2+}/calmodulin protein kinase II and PKC-like protein kinase activities which could be inhibited by mastoparan and staurosporine, respectively. High salt extraction of the NF preparation was used to separate the kinase activities. The kinase activity in the pellet, which contained virtually all the NF proteins, phosphorylated the 18KD protein and H1-histone but not the NF proteins or casein. The soluble fraction could phosphorylate all the NF proteins and casein, but not H-1 histone. These data indicate that the principal NF protein kinase activity in the bovine NF preparations appears to be due to casein-like protein kinase(s).

124.8

PHOSPHORYLATION OF SYNTHETIC PEPTIDES BY NEUROFILAMENT-ASSOCIATED PROTEIN KINASES. C.B. Caputo*, L.A. Sygowski*, & A.I. Salama. (SPON. J.B. Patel) Dept. of Pharmacology, ICI Pharmaceuticals Group, Wilmington, DE 19897.

Several protein kinases (PK) co-purify with neurofilaments (NF). We studied the peptide substrate & inhibitor specificities of these kinases. NFs with PKs were prepared from rat brain stem & spinal cord by an axonal flotation procedure & 77% of the PK activity was extracted with 0.8M KCl. PK phosphorylated 3 cAMP-dependent PK substrates, LRRASLG, LRRASLG-NH_2, & LRRASVA, with K_ms=2-5μM & V_{max}s=30μmol/min/mg. Neither cAMP nor cGMP enhanced these reactions. PK phosphorylated a Ca-calmodulin-dependent PK substrate, KKRPQRATSNVFS-NH_2, with calmodulin present (K_m= 17μM) & a segment of preproVIP, SSEGESPDFPEELEK (K_m=100μM), without cofactors. Peptide substrates for protein kinase C, casein kinase II, & tyrosine kinases were not phosphorylated by PK. A Walsh inhibitor peptide (aa 5-24) completely inhibited phosphorylation of cAMP-dependent PK substrates as 1μM (Ki=70nM). Trifluoperazine (Ki=30μM) & chlorpromazine (Ki=122μM) inhibited the calmodulin-dependent kinase. Caffeine inhibited phosphorylation of all peptides with a Ki=3.8mM for preproVIP & Ki=13.9mM for LRRASLG. At 1μg/ml heparin inhibited phosphorylation of preproVIP (by 89%) but not of LRRASLG. Thus, at least three types of PKs accompany NF proteins: one resembles the catalytic subunit of cAMP-dependent PK, the second is calmodulin-dependent, & the third is cofactor independent.

BEHAVIORAL PHARMACOLOGY

125.1

EEDQ-INDUCED INACTIVATION OF DOPAMINE D-1 OR D-2 RECEPTORS IN RATS DIFFERENTIALLY INHIBITS STEREOTYPIES INDUCED BY DA AGONISTS. J. Arnt and J. Hyttel. H. Lundbeck A/S, Ottiliavej 7-9, DK-2500 Copenhagen, Denmark.

Ex vivo D-1 or D-2 receptor binding in striatum was reduced by 65-78 per cent after treatment with EEDQ (N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline) (20-40 µmol/kg, s.c., 24 hours before) in combination with either the D-2 antagonist raclopride (2.5 µmol/kg, s.c.) or the D-1 antagonist SCH 23390 (0.90 µmol/kg, s.c.), respectively. Parallel to a 65 per cent reduction in D-1 receptor binding there was a 51 per cent decrease in the production of cAMP in striatal homogenates. In rats with D-2 receptor inactivation we observed an inhibition of the stereotyped behaviour induced by the D-2 agonist quinpirole when given alone or in combination with the D-1 agonist SK&F 38393. The effect of the mixed D-1/D-2 agonist apomorphine was also inhibited. In rats with D-1 receptor inactivation we found no changes in the behavioural effects of quinpirole when given alone or in combination with one of the D-1 agonists SK&F 81297, SK&F 38393 or SK&F 75670. Likewise the effect of apomorphine was unchanged. The D-1 agonists did not induce stereotypies when given alone, although oral dyskinesias were observed. These were more intense in rats with reduced D-2 receptor density. These results indicate that a near normal density of D-2 receptors is critical for expression of the stereotyped behaviour induced by DA agonists. In contrast, there is a large surplus of D-1 receptors to enable the response to a D-2 agonist. This is illustrated in particular by the persistant behavioural effects of the partial D-1 agonist SK&F 75670.

125.2

COMPUTERIZED STUDIES OF BEHAVIOR REVEAL ALTERATIONS IN RESPONSIVITY TO D-1 AND D-2 AGONISTS FOLLOWING CHRONIC NEUROLEPTICS. G. Ellison, R. See, and J. Kim*. Dept. Psychol., UCLA, Los Angeles, CA 90024.

Using novel computerized methods, we have studied progressive changes in the behavior of rats administered chronic neuroleptics for very prolonged periods. Oral movement (OM) dyskinesias are directly quantified by a computerized TV video system whereby OMs are directly measured via UV-sensitive spots on the upper and lower lips of the rats. Animals which have been given chronic neuroleptics very gradually develop increased OMs of very small amplitudes; these are detected by computer but not by human observer. FFT analyses indicate that these oral movements are of the exact same frequency range reported in humans with TD. Animals given chronic neuroleptics also show develop a heightened reactivity to the ability of D-1 agonists to induce OMs. Motor activity, feeding, drinking, and rearing are also recorded by computer. Animals given chronic neuroleptics again respond more to a D-1 than to a D-2 agonist challenge. Thus, alterations in D-1 receptor tone may be important in chronic neuroleptic-induced side-effects.

125.3

REINFORCING AND DISCRIMINATIVE STIMULUS EFFECTS OF GBR-12909 IN RHESUS MONKEYS. M.S. Kleven, E.W. Anthony, E.B. Nielson, and W.L. Woolverton. The Drug Abuse Research Center, The University of Chicago, Chicago, IL 60637.

GBR 12909 (1-[2-[Bis(4-fluorphenyl)methoxy]ethyl]-4-(3-phenyl-propyl)-piperazine dihydrochloride) is a highly selective dopamine reuptake blocker. Since blockade of DA reuptake is correlated with reinforcing and discriminative stimulus (DS) properties of cocaine (COC), it is possible that GBR 12909 would share these effects of COC. Three rhesus monkeys were prepared with intravenous catheters and, under baseline conditions, allowed to self-administer COC in daily experimental sessions (0.03 mg/kg/inj; FR 10; 2-hr/day). When COC self-administration was stable, 0.9% saline was substituted for COC for several consecutive sessions until responding declined to low levels (<10 inj/session). The monkeys were then returned to baseline conditions and, when behavior was again stable, GBR 12909 (0.01-0.3 mg/kg/inj) was substituted for COC in the same manner as saline. GBR 12909 was self-administered at rates that exceeded those maintained by saline in all 3 monkeys with peak rates of self-administration of 60-80 inj/session in 2 of the monkeys. A second group of rhesus monkeys was trained in a 2-lever, food-reinforced, drug discrimination paradigm to discriminate cocaine (0.2 mg/kg; i.m., 10 min pre-session) from saline. When the discrimination was acquired, the monkeys were injected before test sessions with various doses of the training drug or GBR 12909 (0.1-1.6 mg/kg; iv, 5 min pre-session). COC engendered a dose-related increase in the percent of responses that occurred on the COC-appropriate lever. GBR 12909 produced a comparable dose-related increase in cocaine-appropriate responding with the highest dose (1.6 mg/kg) completely substituting for the training dose of COC . Thus, GBR 12909 functioned as a positive reinforcer and had COC-like DS properties in rhesus monkeys. These results are consistent with the hypothesis that blockade of DA reuptake is associated with COC-like behavioral effects. (Supported by DA-00250)

125.4

BEHAVIORAL EFFECTS OF (+)3-PPP MEDIATED THROUGH A DOPAMINERGIC MECHANISM. W.D. Essman* and J.H. Woods (SPON: R. Davis). Depts. of Pharmacol. and Psychol., Univ. of Michigan, Ann Arbor, MI 48109.

Various doses of three dopaminergic (DA) antagonists (haloperidol, spiroperidol, and (+)butaclamol) and the sigma ligand BMY 14802 were given 15 minutes before cumulative doses of 3-(3-hydroxyphenyl)-N-propylpiperidine ((+)3-PPP) in an observation procedure using male Sprague-Dawley rats. Each DA antagonist produced a dose-dependent reduction in (+)3-PPP-engendered behaviors (locomotion, sniffing, sideways walking), but not (+)3-PPP-induced convulsions. BMY 14802 reduced (+)3-PPP-induced behaviors, but only at a dose that induced changes in behavior by itself. In a cross-tolerance study between (+)3-PPP and the sigma selective compound 1,3-di-ortho-tolyl-guanidine (DTG), dose-effect curves for (+)3-PPP were determined before and after five days of i.c.v. administration of 100ug of DTG. While backward walking, forelimb extension, and piano playing induced by DTG diminished across days, the before and after dose-response curves for (+)3-PPP-engendered locomotion and sniffing did not differ statistically (although sideways walking did show a slight reduction). These results corroborate past findings of the importance of a DA mechanism in the behavioral effects of (+)3-PPP in this observation paradigm. Supported in part by USPHS Grant DA-5437.

125.5

DISCRIMINATIVE STIMULUS (DS) PROPERTIES OF *S*-(+)-N-METHYL-1-(1,3-BENZODIOXOL-5-YL)-2-BUTANAMINE (*S*-MBDB). R. Oberlender* and D.E. Nichols. Dept. of Medicinal Chemistry and Pharmacognosy, Purdue Univ. Sch. of Pharmacy, W. Lafayette IN 47907.

The synthesis and preliminary pharmacological evaluation of N-methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine (MBDB), the alpha-ethyl homologue of MDMA, were recently described (Nichols, et al., J. Med. Chem., 29: 2009, 1986). In a subsequent study (R. Oberlender and D.E. Nichols, Psychopharmacology, in press), MBDB exhibited DS properties in rats similar to MDMA but not (+)-amphetamine.

We now report the results of experiments with rats trained to discriminate the more active *S*-(+)-isomer of MBDB (1.75 mg/kg) from saline in a two lever food reinforced (FR-50) paradigm. Complete substitution and similar stereoselectivity was observed with MDMA and the primary amine, MDA. No substitution was observed when the hallucinogens LSD, DOM and mescaline, or the stimulants (+)-amphetamine, methamphetamine and cocaine were tested. By contrast, both (+)-amphetamine and cocaine completely substituted in MDMA-trained rats. The results indicate that *S*-(+)-MBDB is pharmacologically less complex than MDMA, and in particular seems to lack dopaminergic properties. These studies support the hypothesis that MBDB may be the prototype of a distinct drug class, to be called entactogens.

125.6

INTERACTION BETWEEN YOHIMBINE (ALPHA-2 ANTAGONIST) AND CLONIDINE (ALPHA-2 AGONIST) IN THE GELLER-SEIFTER CONFLICT TEST AND SHUTTLE-BOX AVOIDANCE. J.L. Howard and G.T. Pollard. Wellcome Research Laboratories, 3030 Cornwallis Road, Research Triangle Park, NC 27709.

In man yohimbine is anxiogenic (e.g., Holmberg and Gershon, Psychopharmacologia, 2:93, 1961) and clonidine is anxiolytic (e.g., Hoehn-Saric et al., Arch. Gen. Psychiatry, 38:1278, 1981). These compounds have produced mixed results in animal models of anxiety. We reported (Howard and Pollard, FASEB Journal, 2:1384, 1988) that in rats both compounds increased responding in the conflict portion and decreased responding in the VI portion of a Geller-Seifter test; they also decreased avoidance responding in a two-way conditioned avoidance (CAR) test; effects were dose-related. Because of the similarity of the behavioral effects of the two compounds, we investigated their interaction in the Geller-Seifter and CAR tests by constructing dose-reponse curves for one compound in the presence of various doses of the other. Although the compounds produced similar behavioral effects, when given together their effects were not only not additive but were less than the effects of either alone. Isobolographic analysis confirmed infraadditivity (mutual antagonism) for the response rate increases in conflict and the response rate decreases in VI and avoidance.

125.7

TOLERANCE TO THE BEHAVIORAL EFFECTS OF THE CENTRALLY ACTIVE BETA ADRENERGIC AGONIST CLENBUTEROL. J.M. O'Donnell* (SPON: E.R. Flynn), Life Sciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545.

The centrally active beta adrenergic agonist clenbuterol reduced response rate and increased reinforcement rate of rats under a differential-reinforcement-of-low rate (DRL) 72-sec schedule, in a manner similar to that observed for anti-depressant drugs. However, in contrast to the effects of the tricyclic antidepressants imipramine and desipramine, tolerance developed to the effect of clenbuterol on DRL behavior. Prior to chronic treatment, clenbuterol reduced response rate and increased reinforcement rate with an ED_{50} value of about 0.1 mg/kg. The dose-response function for clenbuterol was redetermined after chronic treatment with clenbuterol for 1 week at 0.1 mg/kg/day followed by treatment for 4 weeks at 1 mg/kg/day. Following this chronic treatment regimen, clenbuterol, at doses up to 3 mg/kg, no longer affected DRL behavior. The density of beta adrenergic receptors was assessed in brain regions of rats administered clenbuterol chronically. It was found that chronic treatment with clenbuterol, using the regimen that resulted in behavioral tolerance, reduced the density of $beta_2$ adrenergic receptors. The differences between the behavioral effects of clenbuterol and desipramine following chronic treatment may be a result of their differing effects on the subtypes of the beta adrenergic receptor. (Supported by the Air Force Office of Scientific Research and USPHS Grant MH40694.)

125.8

BETA-ADRENOCEPTOR ANTAGONISTS AND CONFLICT BEHAVIOR IN THE RAT. D.J. Fontana*, T.C. McCloskey*, S.K. Jolly* and R.L. Commissaris* (SPON: T.E. Anderson). College of Pharmacy, Wayne State University, Detroit, MI 48202.

The beta-adrenergic antagonist propranolol is effective in treating phobic-type anxiety (i.e., stage fright). The present studies examined the effects of propranolol, diazepam, and phenobarbital, alone and in combination, on behavior in the Conditioned Suppression of Drinking (CSD) conflict paradigm, an "animal model" for the study of anxiety and/or anti-anxiety agents. In daily 10-minute sessions, water deprived rats were trained to drink from a tube which was occasionally electrified (0.5 or 0.125 mA), electrification being signalled by the presence of a tone. As expected, acute administration of diazepam (0.6-10 mg/kg) or phenobarbital (5-40 mg/kg) resulted in a marked and dose-dependent increase in punished responding at doses which did not alter background responding (water intake). In contrast, propranolol (0.5-8 mg/kg) did not affect CSD behavior. Moreover, pre-treatment with 2.0 mg/kg propranolol did not alter the anti-conflict effects of diazepam or phenobarbital. Finally, reduction of the shock intensity (i.e., decreased suppression) failed to alter the behavioral response to propranolol (1.5-5 mg/kg) or the interaction of 2.0 mg/kg propranolol with diazepam. These data suggest that the CSD paradigm may not be useful for the study of phobic-type anxiety or the agents used to treat it. (MH #42501-01) Protocol conforms with NIH Guide.

125.9

COMPARATIVE ACUTE AND CHRONIC EFFECTS OF PUTATIVE 5-HT2 AND 5-HT1A AGONISTS IN THE RAT: IS THERE MORE THAN ONE "SEROTONIN SYNDROME?" R. S. Pluchino* and M. R. Pranzatelli (SPON: R. Trifiletti). Department of Neurology, Columbia University, NY, NY 10032.

The phenylisopropylamine derivative DOI has been identified as a novel selective 5-HT2 receptor agonist, but the behavioral effects of DOI have not been reported. Acutely, in naive rats, both DOI and the 5-HT1A agonist 8-OH-DPAT induced behaviors of the "serotonin syndrome" but the two drugs could be differentiated. Only DOI evoked shaking behavior, body (skin) jerks, vertical head movements with sniffing, and hyperthermia. Only 8-OH-DPAT induced flat body posture, occasional hindlimb hyperextension, failure of habituation to acoustic startle, and reduction in rearing. Both drugs evoked forepaw tapping and lateral head weaving, but 8-OH-DPAT to a significantly greater extent. Both the 5-HT2 antagonist ritanserin (ID_{50}=0.39 mg/kg) and the 5-HT1A antagonist l-propranolol (ID_{50}=33 mg/kg) blocked the DOI syndrome, but DOI-induced body jerks were blocked only by ritanserin. The dose-response (0.5-40 mg/kg) for shaking behavior was biphasic (maximum at 3 mg/kg), but was monophasic for syndrome behaviors. The dose threshold and time course were similar, however. Chronic (21 d) treatment (3 or 9 mg/kg) with DOI prevented DOI-evoked shakes and other DOI-evoked behaviors but not behaviors evoked by 8-OH-DPAT. 8-OH-DPAT-induced behaviors, however, decreased signficantly after chronic 8-OH-DPAT treatment. These data suggest that putative selective 5-HT2 and 5-HT1A agonists both induce some behaviors of the serotonin syndrome but can be distinguished behaviorally. Supported by NIH grant 1-KO8-NS01158 and the Myoclonus Research Fund.

125.10

CONTRIBUTION OF MULTIPLE OPIOID RECEPTOR TYPES TO CONDITIONAL FEAR-INDUCED ANALGESIA. M.S. Fanselow*, D.J. Calcagnetti* and F.J. Helmstetter (SPON: H. C. Hughes). Psychology Dept., Dartmouth Coll., Hanover, NH 03755.

Pavlovian conditional fear stimuli elicit analgesia in rats. Since this analgesia is reversed by the opioid antagonists naloxone and naltrexone, it appears to be mediated by endogenous opioids. Using the formalin test as a measure of pain sensitivity, we examined the ability of three opioid antagonists to reverse conditional analgesia. Nor-Binaltorphimine (N-BNI), $Cys^2\ Tyr^3\ Orn^5\ Pen^7$-amide (CTP) and 16 methyl-Cyprenorphine (M80), are competitive opioid antagonists purported to be selective for k, μ and δ receptors, respectively. We found that CTP and M80 produced dose dependent reversals of conditional analgesia. However, N-BNI, even at doses that reversed the analgesia produced by the k agonist U50488H, had no impact on conditional analgesia.

NEUROENDOCRINE CONTROLS: PITUITARY II

126.1

ACUTE AND CHRONIC HYPERPROLACTINEMIA IN HUMANS: EFFECTS OF THE PRECURSOR AMINO ACIDS L-TYROSINE AND L-TRYPTOPHAN: H.Lehnert, J.Beyer*, U.Krause*, D.H.Hellhammer. Dept. of Endocrinology, II. Mediz. Universitätsklinik Mainz and Dept. of Clinical and Physiological Psychology, University of Trier, West-Germany.

Prolactin (PRL) secretion from the lactotroph cells of the anterior pituitary is under tonic inibitory control of the tubero-infundibular dopaminergic system. It has been shown that the dopmaine precursor amino acid l-tyrosine suppresses PRL secretion in chronically reserpinized rats, thus when DA neurons are activated. Tryptophan appears to stimulate PRL secretion at large doses.

We studied PRL secretion in healthy male volunteers (n= 12) and prolactinoma patients following intake of tyrosine and tryptophan (5 g orally) under basal and (in the volunteers) stimulatory conditions. Stimulation of PRL secretion was achieved by administration of metoclopramide (MCP, 10 mg i.v.) and TRH (200 μg i.v.).

Following administration of l-tyrosine we found an unexspected rise of basal PRL levels among the volunteers when compared with placebo (6,56+0,63 vs. 3,06+0,16 ng/ml; p 0,001). The drug-induced increase in PRL secretion was significantly attenuated. There was no effect of tryptophan. In prolactinoma patients, the administration of tyrosine appears to decrease PRL levels by about 15%, while tryptophan has no effect. Tyrosine administration may thus be effective in acute rather than chronic hyperprolactinemia.

126.2

MONOSODIUM GLUTAMATE LESIONS OF THE ARCUATE NUCLEUS INHIBIT PROLACTIN CELL ACTIVITY IN THE SYRIAN HAMSTER. D.E. Blask, C.A. Leadem* and D.B. Pelletier*. Dept. of Anatomy, Univ. Arizona Coll. Med., Tucson, AZ 85724.

Monosodium glutamate (MSG)-induced lesions of the arcuate nucleus destroy tuberoinfundibular dopamine neurons leading to a disinhibition of prolactin (PRL) secretion. In order to assess whether arcuate lesions in the hamster would have a similar effect on PRL synthesis, storage and secretion, we injected either MSG (8 mg/g BW) or saline into male and female hamsters on day 8 of the neonatal period. Fourteen and a half weeks later the pituitaries were removed for the analysis of PRL synthesis and storage via the incorporation of ^{3}H-leucine into PRL in vitro as well as by measuring the pituitary and media levels of PRL with a radioimmunoassay (RIA). Serum PRL levels were also determined by RIA as an index of in vivo PRL secretion. In both male and female hamsters, serum PRL levels were markedly decreased in response to MSG versus saline. MSG-induced arcuate lesions also caused a significant inhibition of PRL synthesis and storage in both sexes with the effect being more marked in female hamsters as compared with male animals. Therefore, unlike the rat, MSG-induced arcuate nucleus lesions in the hamster inhibit PRL cell activity suggesting that the neuroendocrine regulation of the PRL cell in these two species is markedly different, particularly with respect to the involvement of dopamine. Supported by PHS Grant 5R01 HD21212-02 from the NICHHD.

126.3

REGULATION OF THE TEMPORAL PROLACTIN SECRETORY RESPONSE TO INHIBITION OF DOPAMINE (DA). B.J. Arey* and M.E. Freeman* (SPON: P. Cancalon) Dept. Biol. Sci., Fla. State U., Tallahassee 32306.

We have recently reported that periodic pharmacologic depression of DA tone in ovariectomized (OVX) rats with the receptor blocker Domperidone (DOM) resulted in higher prolactin (PRL) secretory responses at 0300 h and 1700 h than at 1200 h. In this study we describe the role of serotonin (5-HT) or Vasoactive Intestinal Peptide (VIP) as possible stimulatory effectors of these heightened responses. Groups of OVX rats received either 2-days of pretreatment with p-chlorophenylalanine (PCPA, 250 mg/kg, s.c.) to block 5-HT synthesis or infusion of the VIP antagonist [D-4-Cl,Phe^6,Leu^{17}] VIP (VIP-A, 0.1 ug/kg/min) beginning 2 h before study. DOM (200 ug/kg,iv) injection at 1200 h in both PCPA-pretreated and control rats resulted in peak PRL values of approximately 120 ng/ml. Equivalent heightened patterns of PRL secretion were also evident at 0300 h in both control and PCPA-pretreated rats with peak levels of approximately 240 ng/ml. However, the heightened PRL secretory response to DOM at 1700 h was totally ablated by PCPA-pretreatment. There was no difference in the PRL secretory profiles of control or VIP-A infused rats during DOM challenge at 1200 or 1700 h. However, treatment of rats with VIP-A at 0300 h totally ablated the heightened PRL secretory response to DOM at this time. These data suggest that the temporal endogenous stimulatory rhythm on PRL secretion is differentially regulated. At 0300 h PRL is regulated by VIP, while the 1700 h component is driven by 5-HT. IN VIVO AND IN VITRO EVIDENCE FOR PROLACTIN FEEDBACK ACTIONS ON HYPOTHALAMIC OXYTOCIN, VASOACTIVE INTESTINAL PEPTIDE AND DOPAMINE SECRETION. D.K. Sarkar. Dept. of Reproductive Medicine, Univ. of Calif. at San Diego, La Jolla, CA 92093.

The feedback action of prolactin (PRL) on oxytocin (OT), vasoactive intestinal peptide (VIP) and catecholamine release was determined in ovariectomized rats and in fetal hypothalamic cells in primary culture. Ovariectomized rats, when transplanted with 4 anterior pituitaries (APs) to the kidney capsule for 2-3 weeks, had elevated plasma PRL levels (3.8-fold) and showed decreased in situ AP weights (.62-fold) and PRL concentrations (.63-fold). The levels of dopamine (DA) and OT in pituitary portal plasma of hyperprolactinemic rats were increased 1.7- and 1.9-fold, respectively. However, pituitary portal plasma levels of VIP of these rats were decreased .31-fold. The secretion of DA, dihydroxyphenylalanine (DOPA) and OT was increased whereas VIP secretion from cultured hypothalamic cells was reduced in a dose-dependent fashion following PRL treatment. These data suggest that PRL stimulates OT release and inhibits VIP release and that a subtle imbalance between the hypothalamic secretion of a PRL-inhibiting factor (DA) and PRL-releasing factors (VIP and OT) during elevated systemic levels of PRL is responsible for decreased lactotrophic function. (Supported by an NIH grant AG05454).

EFFECT OF HYPERPROLACTINEMIA (HYPERPRL) ON PRL AND LH SECRETION AS ASSESSED BY THE REVERSE HEMOLYTIC PLAQUE ASSAY. M.A. Sortino, I.R. Cohen and P.M. Wise. Dept. of Physiology, Univ. of Maryland, Baltimore, MD 21201.

HyperPRL, induced by exogenous administration of PRL, is associated with diminished secretion of endogenous PRL and LH. We undertook this study to better understand whether HyperPRL influences PRL and/or LH secretion via a direct action at the pituitary level. Rats were ovariectomized (day 0) and treated with PRL (4 mg/kg, sc., 3 times daily) from days 4-6. Pituitaries were collected 1 h after the final injection and prepared for the reverse hemolytic plaque assay. After 1 h incubation, PRL release from single lactotrophs was lower in HyperPRL rats (1295 ± 58 vs 794 ± 66 μm^2 for control and HyperPRL, respectively). Incubation with TRH (10^{-7} M) for 1 h stimulated a larger PRL release in control (158 ± 6.9%) compared to the HyperPRL animals (124 ± 14.4%). By 2 h basal and TRH-stimulated PRL secretion was the same in the 2 experimental groups. Under basal conditions the percent of PRL-secreting cells was similar in control and HyperPRL rats after 1 or 2 h of incubation. TRH stimulated an increase in the percent of PRL-secreting cells in controls at 1 and 2 h and in PRL-treated rats at 2 h only. In vivo treatment with PRL did not affect in vitro release of LH under basal or GnRH-stimulated conditions. Thus, HyperPRL influences PRL but not LH secretion at the pituitary level. HD-15955

DOPAMINE INDUCES OPENING OF VOLTAGE-OPERATED POTASSIUM CHANNELS IN RAT LACTOTROPHS. M. Memo, A. Valerio*, L. Castelletti*, C. Missale, A. Forgione·*, P.F. Spano. Inst. Pharmacol. Brescia Univ. Sch. of Med., Brescia. ·Ravizza Res Lab.s, Muggio', Italy.

The effects of dopamine (DA) on K fluxes in membrane of rat lactotrophs were studied by a radiochemical approach which consists of a manual rapid-quench method for measurement of 86Rb efflux. Rb efflux from Rb-preloaded lactotrophs into nominally Ca-free solution containing 5 mM K was linear from 1 to 60 s, with a calculated rate of 0.2 %/s. Raising the concentrations of K to depolarize the cells stimulated the Rb efflux (0.6 %/s) within 1 s. DA increased the efflux of Rb in a calcium-free medium containing 5mM K. This effect was statistically significant 15 s after exposure of the cells to 10 nM DA. Increasing K concentrations to gradually depolarize the cells enhanced the rate of increase of Rb efflux induced by DA, being evident in the initial 2-5 s of incubations. These effects were 1) pharmacologically characterized as D2-receptor mediated and 2) unaffected by treatment of the cells with forskolin. Our results indicate that DA promotes opening of K channels. This effect appear to be both calcium- and cyclic AMP-independent.

CYCLIC AMP-INDEPENDENT STIMULATION OF PRL RELEASE INDUCED BY VIP. M.Pizzi*,M.O. Carruba*, E. Simonazzi*, M. Benarese*, M. Memo,P.F. Spano Inst. Pharmacol., Brescia Univ., Sch. of Med., Brescia - Italy.

Vasoactive intestinal peptide (VIP) has been reported to stimulate prolactin (PRL) release from anterior pituitary cells by activation of adenylate cyclase activity. In the present study the calcium-dependence of VIP responce in rat anterior pituitary cells was evaluated. We observed that VIP dose- and time-dependently increased (10-1000 nM) PRL release from cells incubated both in a Ca-containing buffer (EC50 50 nM) and in Ca-free medium (EC50 500 nM). Concomitant measurement of cyclic AMP production in the cells indicated that the presence of Ca was necessary for VIP to elicit the activation of adenylate cyclase. Moreover we observed that the peptide (200 nM) strongly activated 45Ca influx in the cells at 5 sec of incubation. The present data indicate that VIP production of cyclic AMP in the cells is Ca-dependent. One of the earlier events produced by VIP is the entry of external Ca in the cell. In Ca-free condition high concentration VIP stimulates PRL release without producing changes in cyclic AMP levels. The involvement of a second messenger different from cyclic AMP or external Ca is proposed.

LACTATION INDUCED INHIBITION OF PLASMA OXYTOCIN AND CORTICOSTERONE, AND HYPOTHALAMIC CRF VASOPRESSIN AND ENKAPHALIN mRNA RESPONSES TO STRESS. S.L. Lightman and W.S. Young III Laboratory of Cell Biology, NIMH, Bethesda, MD 20892

In spite of efficient episodic release of oxytocin in response to nipple stimulation, lactating rats lose their oxytocin response to stress (Carter & Lightman, Neuroendocrinology 46: 543, 1987). We have now investigated whether lactation alters hypothalamic mRNA as well as hormonal responses to stress.

Control female rats or lactating rats 7 days post partum were injected i.p. with either 0.15M (controls) or 1.5M saline (1.8ml/kg body weight) and returned to their home cages. For the hormonal studies the rats were killed after 30 min and their trunk blood collected whilst for the mRNA studies the animals were killed at 4 hours and the brains rapidly removed into dry ice for subsequent quantitative in situ hybridisation histochemistry.

In the control rats i.p. hypertonic saline caused a 480pmol/l increase in oxytocin, a 54pmol/l increase in vasopressin and a 314ng/ml increase in corticosterone. In the lactating rats there was a considerable diminution in the responses of oxytocin (148pmol/l) and corticosterone (51ng/ml), but little change in that of vasopressin (41pmol/l). Stress also caused a marked accumulation of CRF vasopressin and enkephalin mRNAs in the control rats. In the lactating rats, however, this increase in CRF and vasopressin mRNAs was not seen and their enkephalin mRNA response was also markedly diminished.

IN VIVO CATECHOLAMINERGIC ACTIVITY (CA) IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVN) AFTER HEMORRHAGE IN CATS. K.V. Thrivikraman, D.A. Bereiter and D.S. Gann Depts. Surgery & Neurobiology, R.I. Hospital/Brown Univ. Providence, RI 02902

Although catecholaminergic inputs from hemodynamically-responsive areas in the brain stem affect PVN neural activity, the local CA response within the PVN to cardiovascular stimuli is not known. This study examined temporal changes in CA in the PVN after moderate hemorrhage (20% blood loss over 3 min), a physiological stimulus known to alter the activity of PVN neurons and to evoke pituitary hormone secretion. Cats were anesthetized with chloralose, paralyzed with gallamine triethiodide. An *in vivo* voltammetric technique (multistep chronoamperometry) was used to record oxidation current (OC) with carbon microelectrodes (Graphpoxy PX) and the OC at +250mV was used as an index of CA. The OC was sampled every min beginning at 4 min prior to onset of hemorrhage and during the hemorrhage paradigm. At each recording site the response during blood loss was compared by unpaired t-test. Of a total of 60 recording sites, 48 were identified histologically within the PVN. Hemorrhage caused a fall in the mean arterial pressure in all cats. The CA response to hemorrhage was dependent on the site of recording: an increase at 8 sites located in the caudal PVN and a decrease at 12 sites located anterolaterally to the above 8 sites. At the remaining 28 sites in the PVN, CA did not change during hemorrhage. Of the 12 sites outside PVN, CA decreased at 2 sites and did not change at 10 other sites. In the PVN, the response to blood loss was significant (> ± 2 SD) by 1 min at all sites. Reinfusion of the shed blood reversed the increases in CA at 6 of the 8 sites and reversed the decreases in CA at 7 of the 12 sites. The data indicate that sites at which CA increased after hemorrhage were confined to the caudal PVN, in an area shown previously to elicit pituitary hormone release. The data are consistent with the hypothesis that an increase in the release of catecholamines within the caudal PVN in response to hemorrhage is facilitatory for pituitary release of vasopressin and/or adrenocorticotropin. Supported by NIH grant DK-26831.

DEHYDRATION INDUCES FOS IMMUNOSTAINING IN HYPOTHALAMIC MAGNOCELLULAR NEURONS. S.M. Sagar and F.R. Sharp§, Depts. of Neurology and §Physiology, University of California, and VA Medical Center, San Francisco, CA 94121.

Fos, the protein encoded by the proto-oncogene c-fos, or a closely related antigen, is rapidly and transiently expressed in neurons in response to synaptic input, neurotransmitters and growth factors. In order to study the response of CNS neurons to a normal physiological stimulus, Fos immunostaining was performed in the brains of adult male rats after overnight water deprivation or three hours after i.p. injection of 1-4 ml 1.5M NaCl. Control rats received free access to water or 1 ml 0.15M NaCl, i.p., respectively. Affinity purified polyclonal antisera raised to synthetic Fos peptides were used.

Both stimuli selectively induce Fos immunostaining in nuclei of the magnocellular neurons of the hypothalamic-neurohypophysial system. The response to hypertonic saline is dose-related. Control animals have no detectable staining of the magnocellular neurons, and nuclear staining is blocked completely by adsorption of antisera with 100 ng/ml peptide antigen.

These observations add to the evidence that Fos, or a related protein, is expressed in neurons in response to normal stimuli and that Fos immunostaining offers a method of functional metabolic mapping at the cellular level of resolution.

GABA-CONTAINING AFFERENTS TO THE SUPRAOPTIC NUCLEUS FROM THE DIAGONAL BAND OF BROCA. L. D. Wilkin, L. Sherman* and E. Anton*. Dept. of Cell Biology & Anatomy, Chicago Medical School, Chicago, IL 60064.

Gamma-amino butyric acid (GABA) is a central nervous system inhibitory neurotransmitter that has been proposed to have a role in baroreflex inhibition of vasopressin secretion. The diagonal band of Broca (DBB) has been proposed as a potential inhibitory baroreflex relay center. However, specific cardiovascular-related inhibitory feedback pathways onto neurons controlling vasopressin secretion have not been demonstrated. In this study, GABA pathways between the septum/DBB region and the supraoptic nucleus (SON) of the hypothalamus were investigated using retrograde neural pathway tracing and glutamate decarboxylase (GAD) immunohistochemistry. Following discrete injections of the fluorescent dye fast blue into the SON, retrogradely labeled cells were found in the vertical limb of the DBB. Immunohistochemical analyses revealed GAD-immunoreactive neurons in the horizontal limb of the DBB and the ventral portion of the vertical limb. Some of the retrogradely labeled cells in the ventral portion of the vertical limb of the DBB were also immunopositive for GAD. These results provide anatomical evidence for potential inhibitory inputs from the ventral DBB to the SON which may play a role in baroreflex inhibition of vasopressin secretion.

NEUROTRANSMITTER ACTIONS ON NEUROHYPOPHYSIAL PITUICYTES. D.M. Burnard, B.A. MacVicar and Q.J. Pittman. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada. T2N 4N1

The neurohypophysis consists primarily of hypothalamic neurosecretory endings and glial cells known as pituicytes, which may regulate neurohypophysial hormone release. Pituicytes receive synaptoid contacts and have receptors for opiates and other neurotransmitters. In order to determine the actions of neurotransmitters on these cells, intracellular recordings were obtained from pituicytes (n=26) in the isolated pituitary maintained in vitro. Pituicytes were identified by an average resting membrane potential (RMP) of -38.2 ± 0.8 mV (5 mM K^+), an average membrane input resistance (R_{in}) of 9.0 ± 1.3 mΩ and an absence of action potentials in response to depolarizing current injection. Occasionally neurosecretory endings were impaled which exhibited spiking. Bath application of dynorphin (1-13)(1-10 μM) increased pituicyte R_{in} by 17.5 ± 4.1 mΩ and methionine-enkephalin (10μM) increased R_{in} by 9.7 ± 1.9 mΩ. No significant changes in RMP were observed. Isoproterenol (100 μM) decreased R_{in} of pituicytes, with no obvious changes in RMP. These findings may suggest a functional link between pituicytes and neurosecretory nerve fibres and a role for pituicytes in the regulation of neurosecretion.

INHIBITION BY ACETYLCHOLINE OF IDENTIFIED INTERNEURONS IN THE CAT LATERAL GENICULATE NUCLEUS, *IN VITRO*

H.-Ch. Pape* (SPON: P.R. Adams) and D.A. McCormick, Section Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

Gating of visual information through the dorsal lateral geniculate nucleus (LGNd) is controlled by ascending cholinergic brainstem neurons. In the present study we investigate ionic mechanisms of acetylcholine (ACh) action in the cat LGNd that may underlie cholinergic modulation of visual geniculate response properties. Intracellular recordings from cells in lamina A or A1 of the cat LGNd maintained *in vitro* revealed two distinct classes of neurons, which we term P- and I-neurons. P-cells displayed electrophysiological properties similar to those of thalamocortical relay cells (Crunelli et al., J.Physiol., 390: 243, 1987). I-neurons possessed on the average action potentials of a shorter duration (I: 0.34 +/-0.07 ms, mean +/ S.D., n=7; P: 0.50+/-0.20 ms, n=20), higher input resistances (I: 89+/-15 MΩ;P: 51+/-20 MΩ), more linear membrane potential to current relationships, and lacked the typical low threshold Ca^{++}spike of P-cells which underlies burst discharges. Local application of ACh to P-cells caused depolarizing responses (McCormick & Prince, J.Physiol.,392: 147, 1987), whereas I-neurons were inhibited by ACh due to a membrane hyperpolarization associated with an increased apparent input conductance. The muscarinic agonist acetyl-beta-methylcholine elicited a similar hyperpolarization of I-neurons, which reversed to a depolarization at an average membrane potential of -102+/-4.8 mV (n=3). Intracellular labeling with Lucifer Yellow revealed morphological features of P-cells typical for either type 1 or type 2 relay cells, whereas I-neurons displayed somatic and dendritic morphologies of type 3 GABAergic interneurons.

We conclude that the brainstem cholinergic system facilitates the relay of visual information through the LGNd during periods of increased alertness not only by depolarizing relay cells, but also by hyperpolarizing intrageniculate interneurons through a muscarinic receptor mediated increase in potassium conductance.

NEURONAL ACTIVITIES RELATED TO THE PONTO-GENICULO-OCCIPITAL (PGO) WAVES IN THE LATERAL GENICULATE (LG)-PERIGENICULATE (PG) COMPLEX. M. Steriade, D.Paré, D. Bouhassira*, M. Deschênes, and G. Oakson*. Lab. Neurophysiol., Sch. Med., Univ. Laval, Québec, Canada.

We have examined the discharges of LG and PG cells in relation to PGO waves in chronically-implanted, naturally sleeping cats. LG and PG neurons were identified by their responses to optic tract stimulation. PGO focal waves were recorded by the microelectrode used for action potential recording. One or two minutes before all other signs of REM sleep, PGO waves appear as single high-amplitude events over the background of a fully synchronized EEG. During REM sleep, they are grouped in wave clusters of much lower amplitudes.

Most PG neurons discharged short, high-frequency bursts followed by silenced firing in relation to single or clustered PGO waves. The PGO-related activity of LG neurons was different. (a) During the pre-REM stage, PGO waves correlated with a high-frequency discharge burst of LG cells, followed by a long (0.2-0.4 s) train of single spikes. In view of the low spontaneous firing rates of LG neurons during EEG synchronization, the PGO-related activity leads to a high signal-to-noise ratio during this transitional epoch. (b)During REM sleep, the spontaneous firing of LG neurons is tonic. The PGO-related activity lacks the initial burst (see a) and consists of a spike train that only slightly exceeds the high-rate of spontaneous discharges. These data explain the high amplitude of single PGO waves during the pre-REM period (likely due to synchronous bursts in a pool of LG neurons), indicate that PGO are not merely corollary discharges of eye movements as they appear well before the saccades of REM sleep, and suggest that the high signal-to-noise ratio in the visual thalamocortical system during the pre-REM stage may underly vivid imagery during this epoch. Supported by MRC Grants MT-3689 and MT-5781.

THRESHOLD REDUCTION IN CAT LGN NEURONS OF LAMINA A1 AT A LOCATION CORRESPONDING TO THE BLIND SPOT OF THE OTHER EYE. F.Schmielau*,M.F.Schmielau-Lugmayr* and U.Eysel* (SPON:ENA).Inst.for Med. Psychology, D-2400 Lübeck (Fed.Rep.of Germany).

In adult anaesthetized (Nembutal®)and paralyzed cats recordings were obtained from on- and off-center neurons of lamina A and A1 of the lateral geniculate nucleus (LGN) with receptive fields (RF) at various eccentricities in the visual field. Special interest was dedicated to neurons with RF eccentricities between 10 and 20° including the location of the blind spot (LBSP). For each neuron post stimulus time histograms were obtained to stationary stimulation of the RF center with small spots of light of various luminance values down to the threshold (Th). In lamina A neurons with RFs close to LBSP showed an increase of Th by more than 1 log unit within few degrees of visual angle. In contrast in neurons of lamina A1 a decrease of Th was observed when the RFs were localized at LBSP. This relative reduction of threshold in lamina A1 neurons at a location corresponding to the site of the blind spot is considered as a mechanism compensating for the lack of photoreceptors at the blind spot in binocular vision. A model including the perigeniculate nucleus is proposed.

127.4

SUBLAMINAR VERSUS COLUMNAR ORGANIZATION IN THE LATERAL GENICULATE NUCLEUS OF THE CAT. D.B. Bowling and J.I. Caverhill*. Department of Medical Physiology and the Lion's Sight Center, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

A question has recently arisen as to whether ON and OFF cells in the A layers of the cat LGN are arranged in vertical columns or in sublaminae. Whether the organization is columnar, sublaminar or both is important for understanding how the visual image is represented in the LGN and how signals from the nucleus are utilized in the synthesis of cortical receptive fields.

The hypothesis that ON and OFF cells form vertical columns was tested in two ways. First, data from 184 electrode tracks made parallel to the laminar borders (orthogonal to the hypothetical columns) were analyzed for ON/OFF periodicities. The results were compared with computer simulations based on different column sizes and mosaics. Second, a direct search for ON and OFF columns was made by making multiple, closely spaced vertically oriented electrode tracks.

Both tests were negative for columns but confirmed the sublaminar organization of ON and OFF cells in the layers.

Supported by MRC (Canada) and Alberta Heritage Foundation for Medical Research.

RESPONSES TO ABRUPT VELOCITY CHANGES IN CAT LGN DISCRIMINATE Y-CELLS FROM X-CELLS. B.W. Van Dijk[+*]; The biophysics laboratory; Rockefeller University; 10021 N.Y., N.Y. (spons.: ENA)

In this study the responses to two different sets of stimuli were compared. One set of stimuli consisted of random dot patterns which abruptly started and stopped moving. The random dot size and the velocity were chosen such that the stimulus would exactly repeat only after 32 cycles. In the other set of stimuli identical random dot patterns were counterphase modulated in one phase and steadily presented in another phase. The modulation rate was chosen to match that for the moving stimuli; again the stimulus would only repeat exactly after 32 cycles. Responses to both types of stimuli were averaged over 32 or 64 cycles. The two sets of stimuli result in nearly identical local luminance modulations; they differ in the global correlations of the local luminance modulations.

Data from 52 cat LGN cells recorded from 6 animals showed that all 18 X-cells did not respond differently to the two types of stimuli, while all 34 Y-cells responded much more vigorously to the moving stimuli.
Optimal responses from the Y-cells could be obtained at an equivalent local luminance modulation rate of approx. 8Hz for cells at all eccentricities (from 1.4^{o} to 43^{o}); although both the temporal and the spatial tuning of the responses were rather broadband and wider than those obtained using moving sine wave gratings.

The data can be described in terms of the Hochstein and Shapley model of the Y-cell receptive field, by assuming that the non-linear subunits have a gain which is smaller than unity and show saturation at low contrast levels.

127.6

BRANCHING OF X AND Y FUNCTIONAL PATHWAYS IN CAT LATERAL GENICULATE NUCLEUS. D. N. Mastronarde. Dept. of MCD Biology, University of Colorado, Boulder, CO 80309.

The cat LGN does not simply relay X and Y information from retina to cortex in two parallel streams. Drawing on direct recordings of retinal inputs to LGN cells in the A layers, I have previously described distinct classes of cells with excitatory X-input: single-input with lagged (X_L) and non-lagged (X_S) visual responses, multiple-input (X_M), mixed input (X/Y), and interneurons (X_I). Here I report analogous heterogeneity among Y-cells. By comparing the arrangement of Y-inputs to Y-cells with that of X-inputs to X_S- and X_M-cells, Y-cells can be divided into predominantly single input (PSI) cells and those that clearly have multiple input (MI). PSI and MI Y-cells have some consistent differences, such as in receptive-field center size, but do not seem to fall into distinct classes as X_S and X_M do. There is some evidence for separate classes of Y-interneurons (Y_I) and lagged Y-cells (Y_L). Each cell category mentioned here is estimated to provide at least as much coverage of the visual field as do retinal X- or Y-cells, indicating that each is competent to provide a complete representation of some aspect of visual information. Thus, from only two classes of retinal input, the LGN generates cells with fast responses at a series of spatial resolutions, cells at both low and high spatial resolution with delayed, relatively sustained responses, and X- and Y-interneurons for intrageniculate inhibition.

	higher ⟸ Spatial resolution ⟹ lower			
fast relay cells	X_S	X_M	X/Y	PSI Y ··· MI Y
lagged relay cells	X_L			Y_L
interneurons		X_I		Y_I

127.7

ORIENTATION SENSITIVITY IN THE CAT'S LATERAL GENICULATE NUCLEUS (LGNd). T. Shou* and A.G. Leventhal (SPON: J. Conlee) Dept. Anat., Univ. Utah Sch. Med., Salt Lake City, Utah 84132.

Most cat retinal ganglion cells and LGNd relay cells are weakly orientation sensitive. While some studies suggest that the biases of LGNd cells reflect those of their retinal inputs (Soodak et al., J. Neurophysiol. 58:267-275, 1987), others indicate that LGNd cells are more sensitive to orientation than are their retinal counterparts (Vidyasagar and Urbas, Exp. Brain Res. 46:157-169, 1982).

We studied the physiological orientation biases of over 400 cells in the cat's LGNd using the same visual stimuli (drifting sinusoidal gratings) used previously to study retinal orientation sensitivity (Levick and Thibos, J. Physiol. (Lond.) 329:243-261, 1982). The strength of the orientation biases and the distributions of the preferred orientations of LGNd cells subserving different parts of the visual field were compared with the physiological and anatomical orientation biases (Leventhal and Schall, J. Comp. Neur. 220:465-475, 1983) of ganglion cells in the appropriate parts of the retina.

We find (Soodak et al., 1987) that LGNd cells exhibit the same degree of orientation bias as do retinal ganglion cells. Also, the overall distribution of preferred orientations varies in different regions of the LGNd and reflects the overall distribution of preferred orientations of ganglion cells in topographically corresponding parts of retina. Unlike in the retina, however, LGNd cells having similar preferred orientations are clustered. It is known that cells having inputs from the two eyes, on, off, x, y, and w center ganglion cells are distributed nonrandomly in the LGNd. If cells having similar preferred orientations are also distributed nonrandomly then the initial sorting of all properties segregated in visual cortex may begin in the LGNd.

LATERAL GENICULATE NUCLEUS NEURONS IN AWAKE BEHAVING PRIMATES: I. RESPONSES TO B&W 2-D PATTERNS J. W. McClurkin, T. J. Gawne*, B. J. Richmond, L. M. Optican*, and D. L. Robinson. Lab of Neuropsychology, National Institute of Mental Health, and the Lab of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

We have shown that neurons in both inferior temporal and striate cortex convey stimulus-related information with temporal modulation. Is this temporal modulation also present in lateral geniculate nucleus (LGN) neurons?

We recorded the responses of 12 parvocellular X-like units from the lateral geniculate nucleus of two fixating rhesus monkeys. The stimulus set consisted of 224 orthogonal B&W Walsh patterns at 7 luminance combinations (0.4 - 62 cd/m2), and squares and annuli. The stimuli were based on either a 4x4 or an 8x8 rectangular grid. Every stimulus was presented to each cell a minimum of five times. The receptive fields were between 1 and 8 degrees eccentric to the fixation point. Whether the response was excitatory or inhibitory was governed by the luminance of the pixel stimulating the receptive field center. However, different stimuli elicited different temporal patterns in the response. For example, transient responses could have 1 or 2 peaks, and sustained responses could have rising or falling slopes. Two observations suggest that the variety of temporal patterns was not due solely to erroneous fixations or eye-movements. The responses to squares and annuli were similar to those typically found in anesthetized preparations. Also, a statistical analysis showed that the responses were stimulus dependent.

The responses of LGN neurons to complex visual patterns consist of temporal modulation as well as variations in strength. This temporal modulation depends on the pattern of luminance in the surround, as well as the luminance in the receptive field center.

127.9

LATERAL GENICULATE NUCLEUS NEURONS IN AWAKE BEHAVING PRIMATES: II. TEMPORAL MODULATION IS MORE IMPORTANT IN LGN NEURONS THAN GANGLION CELL FIBERS B. J. Richmond, J. W. McClurkin, T. J. Gawne*, and L. M. Optican*. Lab of Neuropsychology, National Institute of Mental Health, and the Lab of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

The preceding abstract showed that the stimulus pattern elicited temporally modulated responses from neurons in the LGN. We also recorded from 5 fiber-like units, which had low-amplitude spikes of very short duration (<0.25 msec), and were found directly above the LGN, where the optic tract spreads out over the nucleus. We hypothesize that these were ganglion cell fibers. How much information about the stimulus was conveyed by the temporal modulation?

The temporal modulation was quantified by decomposing the response waveforms into their principal components (PCs), which are waves of excitation and inhibition. For the LGN neurons the information transmitted by the three most powerful PCs (0.99 bits) was 1.9 times the information transmitted in the spike count (0.54 bits). For the ganglion cell fibers, the information transmitted by temporal modulation (0.99 bits) was 1.4 times that in the spike count (0.72 bits). This ratio was significantly smaller than that for the LGN ($P<0.02$).

We have previously determined that this ratio is 1.9 in striate cortex, and 2.25 in inferior temporal cortex. The changes in the ratio reflect a change in the amount of information in spike count, since the total amount of information in all areas was about 1 bit. We conclude that temporal modulation assumes a significant role in encoding stimulus-dependent visual information, beginning as early in the visual system as the LGN.

127.10

LATERAL GENICULATE NUCLEUS NEURONS IN AWAKE BEHAVING PRIMATES: III. SUCCESSFUL PREDICTIONS OF A MULTI-CHANNEL MODEL. T. J. Gawne*, J. W. McClurkin, L. M. Optican*, and B. J. Richmond (SPON: J. Carl). Lab of Neuropsychology, National Institute of Mental Health, and the Lab of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

We have shown that the temporally-modulated responses of striate cortical neurons can be represented by a model with parallel spatial-to-temporal filters. We tested the ability of a similar model to predict temporally modulated responses of LGN neurons to arbitrary patterns.

Using responses described in the preceding abstracts, a similar model was used to predict the first three principal components (PCs) of the temporal pattern of the response. These three PC's accounted for more than half of the total variability of the responses. In the model, each PC was regarded as the output of a separate spatial-to-temporal filter. Each channel consisted of a compressive input non-linearity cascaded into a linear spatial filter. Using parameters derived only from the Walsh patterns, the model successfully predicts the temporally modulated responses to "center-surround" annuli of different luminances. The first PC is driven by a spatial filter that had a dominant excitatory or inhibitory center pixel, with an anisotropic surround. The second PC is driven by a spatial filter that was dominated by a bipolar pair of pixels with an anisotropic surround. This model's third filter failed to predict the third PC.

The ability to predict the temporally modulated responses of LGN neurons to arbitrary, 2-D, B&W patterns suggests that they are encoding a richer description of visual stimuli than has previously been recognized. Because the proportion of information transmitted by temporal modulation is substantially greater in the LGN neurons than in ganglion cells, we hypothesize that one function of the LGN is to encode multiple stimulus features as temporal messages.

MODELING CHROMATIC CONTRAST DETECTORS AT THE OUTPUT OF THE PRIMATE LATERAL GENICULATE NUCLEUS. P. Gouras. Columbia Univ., Dept. Ophthalmology, 630 W. 168 St., NYC 10032

Color vision requires neurons to detect spectral contrast independently of the receptor quantal catch on either side of a boundary. We have examined each functionally distinct neuron in the cynomolgus lateral geniculate nucleus for its ability to do this (8 parvo and 2 magnocellular on- and off-center varieties) from a sample of 367 neurons. Only 3% of the cells, the short-wave subserving parvo on- and off-center cells, can do this but to a limited degree. In order to construct hypothetical detectors that can distinguish certain spectral (chromatic) contrast unequivocally from this output, the following strategy was used. The outputs of four varieties of on- and off-center parvo cells were linearly added or subtracted; off-centers were essential for detecting spectral contrast as a decrement of energy contrast. This implies that both on- and off-center cone opponent cells are essential for color vision. The receptive field size of the chromatic contrast detectors had to subserve a relatively large number of cones to reduce ambiguity arising from simple achromatic contrast. This implies that the grain of the chromatic detecting system must be larger than the achromatic one and could explain why orientation selectivity is more developed in the latter. The hypothetical chromatic contrast detectors are single opponent cells but antagonism between them could make them double opponent.

127.12

MORPHOLOGY OF RETINOGENCIULATE AXON ARBORS IN MONOCULARLY DEPRIVED PRIMATES. E.A. Lachica*, M.W. Crooks* and V.A. Casagrande. Depts. Psychol. & Cell Biol., Vanderbilt Univ., Nashville, TN 37232. (SPON: G. Condo)

In both primates and cats monocular pattern deprivation (MD) results in amblyopia in the deprived eye. In cats this behavioral change may be the result of the selective loss of retinogeniculate Y axons and physiological loss of Y-LGN cells in the A layers. The cause of these changes in the primate is less clear. In the prosimian primate galago, both X-like and Y-like LGN cells are smaller; W-like LGN cells appear to be unaffected. Physiologically, however, X-like, Y-like and W-like LGN cells are normal. To determine what affect MD has on retinogeniculate axon morphology, nearly 100 bulk HRP-filled axons from MD galagos were reconstructed and compared to normal adult arbors. Our main results show that retinal axons innervating X-like (parvocellular) and Y-like (magnocellular) LGN layers are smaller, abnormal in shape, have absolutely fewer boutons, but more boutons per unit area than normal and nondeprived counterparts. Axons innervating W-like (koniocellular) LGN layers appear unchanged. Hence, in primate, unlike cat, MD does not selectively eliminate or compromise retinal information conveyed by any one visual channel. Presumably, the comparable behavioral changes found in MD primates result from changes that occur central to the LGN. (Supported by EYO1778 to VAC & T32 EYO7007 to EAL)

NEUROETHOLOGY II

128.1

SITES OF MULTIPLE CONTROLS OF EXCITABILITY IN THE ESCAPE CIRCUIT OF THE COCKROACH PERIPLANETA AMERICANA. J. M. Camhi. Dept. of Zoology, Hebrew University Jerusalem, Israel

When a cockroach runs or flies, there is strong depression of the wind-evoked responses of its ventral giant interneurons (vGI's)--abdominal first order interneurons of the escape circuit. Are other controls of escape excitability also expressed at this early point in the circuit? Since dissected preparations show at best weak escape behavior, cuff electrodes were implanted on a thoracic (T1-2) connective, the body was closed, and one to two days later recordings were made during wind-evoked escape behaviors in tethered, but normally behaving, animals. In this T1-2 recording location, the small spikes of vGI axons are readily discriminated from the large spikes of postsynaptic, thoracic interneurons (TI's).

The strength of the escape behavior decreased owing to habituation, and to depression while the animal groomed its antennae or while it stood in a "quiescent" state. In all three of these depressed situations, the vGI responses to wind were unaltered; but the TI responses became strongly depressed. Thus, the vGI-TI connections appear responsible for these forms of behavioral depression.

In several other escape systems (e.g. crayfish), at some point following the main site of habituation, a single action potential in one giant neuron, easily excited by hook electrodes, evokes in a full the initial phase of escape. In the cockroach, it is already known that no one vGI by itself evokes escape. I stimulated through the T1-2 cuff in search of such an all-or-nothing excitation of escape behavior. Behavior exactly like the escape response to wind was evoked. However, the strength of the behavior was continuously graded over a wide range with the number, the frequency, and the voltage of the stimulus pulses. This suggests that, unlike most other escape systems tested, there is no one giant interneuron in which one spike--or even a burst of spikes--can evoke a full cockroach escape behavior.

128.2

EFFECTS OF LESIONING INDIVIDUAL GIANT INTERNEURONS ON THE DIRECTION OF THE ESCAPE TURNING RESPONSE IN THE ADULT COCKROACH, Periplaneta americana. C.M. Comer and G.T. Stubblefield. Dept. Biological Sciences & Committee on Neuroscience, Univ. of Illinois, Chicago, IL 60680

The wind-elicited escape response of the cockroach is believed to be mediated by giant interneurons (GIs). Gross lesion studies indicate that the direction of the turn which initiates escape (a turn away from the wind) may be based upon a comparison of wind-evoked neural activity in GIs on the two sides of the nerve cord. We have been testing this idea by lesioning specific GIs individually or in various combinations by intracellular injection of Pronase.

There are 7 bilaterally paired GIs, separated into distinct dorsal (dGI) and ventral (vGI) subgroups on each side of the nerve cord. We found that unilateral deletions of single vGIs from the cord can alter the direction of the turning response to wind. Comparable deletions of dGIs have not produced changes in turn direction.

Unilateral ablation of vGIs #1 or #3 (highly directionally selective cells) caused animals to turn toward winds from the ipsilateral side and the effect of ablating #3 was greater than that of ablating #1. Unilateral ablation of GI #2 (an omnidirectional cell) did not shift turn direction. Lesioning specific combinations of vGIs concomitantly greatly enhanced the shift in turning. These results suggest different roles for vGIs and dGIs in the escape response and they allow the formulation of models of the way activity in the GIs influences the direction of the motor response.

128.3

MULTIPLE FEEDBACK LOOPS AND DELAY LINES IN THE FLYING COCKROACH. F. Libersat and J. M. Camhi. Dept.of Zoology, Hebrew University, Jerusalem, Israel.

The wind sensitive giant interneurons (GI's) of the cockroach Periplaneta americana send their axons from the last abdominal ganglion (A6) to the thoracic locomotory ganglia. These cells comprise a dorsal group (dGI's) whose stimulation can evoke flight and a ventral group (vGI's) that mediate running escape behavior evoked by wind stimulation of the cerci (two posterior wind-sensitive appendages). We now show that during flight, the dGI's are activated rhythmically at the wingbeat frequency; by contrast, all the vGI's remain silent, in spite of strong flight winds and their wind sensitivity is decreased. The rhythmic activation of the dGI's involves several feedback loops. (1): A descending rhythmic activity of small diameter axons excites in A6 the dGI's whose spikes return to the thorax within one flight cycle. (2): This descending rhythm also produces, via motoneurons, a cercal vibration at the wingbeat frequency. This vibration, in turn, excites rhythmically cercal receptors known to excite the dGI's. The duration of this entire loop is two flight cycles. (3): the rhythmic wind gusts produced by the wings constitute a third feedback loop. The flight inhibition of the vGI's might prevent activation of escape movements of the legs by the flight winds. The dGI's, activated at the wingbeat frequency, could participate in flight maintenance.

COURTSHIP SUCCESS IN THE CRICKET *GRYLLUS BIMACULATUS*: DIFFERENTIAL CONTRIBUTION OF CARRIER FREQUENCY AND HARMONICS IN COURTSHIP SONG. L.A. Murray* and R. R. Hoy. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Male field crickets produce long-range calling songs to attract conspecific females to their territories, and short-range courtship songs to facilitate copulation. The courtship songs do not have the stereotyped, species-specific, pulse temporal patterns that characterize calling songs, but instead have a more complex harmonic structure. In the calling song of *G. bimaculatus*, the carrier frequency (4.5 kHz) is also the dominant frequency, but in the courtship song, the third harmonic (13.5 kHz) is the dominant frequency, although there is significant energy in the fundamental.

When male crickets are muted by wing surgery, their ability to successfully court females is diminished at least three-fold. However, when tape recordings of their pre-mute courtship songs are played back during active courtship, their copulatory success was restored by this "replacement therapy," to virtually normal levels. The behavioral effect of courtship song can be fractionated into its constituent harmonic elements. Specifically, we found that playback of artificial courtship songs composed of the third harmonic (13.5 kHz) component alone, was sufficient to restore the courtship success of muted males to normal levels. However, playback of artificial songs containing only the fundamental (4.5 kHz) component alone did not increase courtship success above the very low levels achieved by mute males. Thus, the third harmonic (dominant frequency) in courtship song appears to be both the necessary and sufficient frequency component to elicit copulation behavior in the female cricket.

An identified auditory neuron in the cricket, HF_1AN, is strongly excited by 13.5 kHz sound pulses, but much less so by 4.5 kHz sound. This same neuron has been implicated in avoidance steering during flight behavior. It is possible that this same neuron is sufficient for both copulation behavior and acoustic startle, switching its role depending upon the behavioral context of the animal.

ULTRASONIC NEURONS IN THE BRAIN OF CRICKETS. P.D. Brodfuehrer, M.L. May and R.R. Hoy. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Tethered flying crickets perform evasive steering movements in response to ultrasonic stimuli such that they fly away from the sound source. The neuronal circuitry controlling negative phonotaxis is partially understood. In particular, a sensory interneuron, Int-1, has been shown to be necessary and sufficient for eliciting this behavior. Int-1 is located in the prothoracic ganglion and sends its axon anteriorly into the brain where it terminates. Ultrasound, however, only elicits negative phonotaxis in flying crickets. On the other hand, Int-1's sensitivity to ultrasound is the same in flying and non-flying crickets. Thus it appears that the flight oscillator gates the ability of Int-1 to produce evasive steering movements associated with negative phonotaxis. We were interested in first, determining whether gating occurs in the brain and secondly, in identifying brain neurons which receive ultrasonic auditory input.

We found that first, descending auditory activity from the brain is graded with respect to ultrasonic stimulus intensity even in non-flying preparations, and secondly, the strength of this activity is increased during flight. Thus input from the flight oscillator and from Int-1 are gated at the level of brain neurons. We have also identified three classes of brain neurons which receive ultrasonic auditory input. These brain neurons include descending interneurons which are excited by ultrasound, and local circuit neurons within the brain which are either inhibited or excited by ultrasound. In general, these brain neurons are broadly tuned (5-30 kHz) and, the strength of their responses is graded with stimulus intensity. The role these neurons play in controlling negative phonotaxis is presently being investigated. Supported by NIH grant NS11630 to R.R.H.

128.6

A THREE-DIMENSIONAL MODEL OF THE ULTRASOUND-INDUCED NEGATIVE PHONOTACTIC RESPONSE IN THE AUSTRALIAN FIELD CRICKET (*TELEOGRYLLUS OCEANICUS*). M.L. May, B.R. Land*, P.D. Brodfuehrer and R.R. Hoy. Sect. of Neuorbiology and Behavior, Cornell University, Ithaca, NY 14853.

The ultrasound-induced negative phonotactic response in flying Australian field crickets is believed to be an escape behavior or, more specifically, a bat avoidance response. If crickets steer away from ultrasonic stimuli to avoid predation then the nature of the induced flight path is of primary importance in assessing the adaptive significance of the behavior. Moreover, an analysis of the flight path may produce cause and effect relationships between various body movements and the resultant steering effects.While several kinematic factors -- abdominal ruddering, forewing tilt, and increased wingbeat frequency -- and aerodynamic rotations -- pitch and roll -- have been examined in detail, there has been no attempt to deduce the three-dimensional flight path following an ultrasonic stimulus. Ideally, an analysis of the flight path should come from free-flight in the field or a wind tunnel but both options pose formidable experimental problems. As such, modeling offers a good first step in assessing the three-dimensional flight path. Further, crickets show stimulus intensity-dependent linearity of response magnitude in most kinematic and aerodynamic factors involved in negative phontaxis and this predisposes the system to modeling.

At present, our model incorporates the effects of ultrasound-induced pitch and roll rotations relative to a stimulus located in the horizontal plane of the cricket and 90° to the long axis of the body. From this model and empirically determined pitch and roll rotations, a 25 dB suprathreshold stimulus induces a 14 cm downward and 35 cm lateral deviation from the normal flight path. While this is a significant alteration in the flight path, it is only a conservative estimate of the total course deviation. A more accurate three-dimensional model will require the incorporation of additional effects due to yaw rotation and possible changes in flight speed.

128.7

SENSORY CUES CONTROLLING SONIC COURTSHIP IN *POLLIMYRUS ISIDORI* (MORMYRIDAE). J.D. Crawford* and C.D. Hopkins (SPON: O. Hamill). Neurobiology & Behavior, Cornell University, Ithaca, NY 14853

Pollimyrus isidori is an electric fish in which males court females with an acoustic song. Experiments showed that male singing was evoked by conspecific females but not by males. In play-backs, EODs were effective releasers of sonic courtship. Sexual dimorphism was pronounced in *Pollimyrus* EOD waveforms while the fish were breeding. However, when sequential presentations of male and female EODs were made, males did not show discrimination: male and female electric models were courted with equal vigor. Recognition of natural EOD sex-differences was examined further using a habituation-dishabituation paradigm. One EOD type (M or F), was presented at natural inter-EOD intervals, for 15 S. Bouts were repeated once each min until a male's vocal response fell below 80 % of his initial response. The other EOD type was then introduced and the male's response was compared with 4 reponses bracketing this EOD. Males showed no evidence of recognizing the introduction of a new waveform. Male responsiveness to a broader set of electric stimuli was explored by presenting EOD-like single period sinusoids ranging from 20 to 800 μS in duration (peak power from 50 KHz to 1.25 KHz). The vocal response showed a broad high-pass characteristic with a corner of about 7 KHz (143 μS). Other behaviors showed that males detected all presented stimuli.

In *Pollimyrus isidori*, the EOD plays a role in courtship communication but males do not extract sex information from waveform cues. This difference from *Brienomyrus brachyistius* (Hopkins & Bass, 1980, Science, 212) may be related to the importance of sound communication in *Pollimyrus*. Our field observations of breeding *Brienomyrus* have revealed no sonic component to courtship. Acoustic sex-recognition in *Pollimyrus* is under study. NIMH 5T3215793 (JDC) & MH37972 (CDH).

CONVERGENT EVOLUTION OF SONIC MOTOR SYSTEMS IN TELEOST FISHES: TEMPERATURE DEPENDENCE OF SYNCHRONOUS AND ASYNCHRONOUS SYSTEMS. A. H. Bass, M. Weiser*, and R. G. Baker. Section of Neurobiology & Behavior, Cornell University, Ithaca, N.Y. 14853; Department of Physiology & Biophysics, New York University Medical Center, N.Y., N.Y. 10016; and Marine Biological Laboratory, Woods Hole, Mass. 02543

Temperature was used as a physiological variable to compare the functional organization of the sonic motor system in four species of marine teleost fishes: *Porichthys notatus* and *Opsanus tau* (Order Batrachoidiformes); *Prionotus carolinus* and *Myoxocephalus scorpius* (Order Scorpaeniformes). In *P.n.* and *O.t.*, a midline sonic motor nucleus synchronously activates a bilateral set of muscles surrounding the swimbladder. In *P.c.* and *M.s.* the sonic motor nucleus occupies a ventrolateral position bilaterally. Sonic muscles fire asynchronously in *P.c.*, but in *M.s.* the sonic muscles are cranioclavicular and fire synchronously like in *P.n.* and *O.t.*. Sonic activity was evoked with either natural or brain stimulation. Discharge frequency was measured intra-cranially from sonic motor nerves over temperature ranges of 4-32°C. In *O.t.*, maintaining animals at temperatures of 18°, 16°, or 11° for periods of 2-4 months did not affect the discharge frequency over similar temperature ranges. At the same temperature, the fundamental frequency recorded from each sonic motor nerve was similar among all four species. Thus, the central pacemaker driving each system responds similarly to temperature change, even in *P.c.* where the discharge is asynchronous and effectively doubles the fundamental frequency at any temperature.

In conclusion, despite differences in central or peripheral anatomy, the functional organization of the sonic motor system is remarkably similar across different taxonomic levels. Supported by NSF, NIH and a Steinbach Fellowship from the MBL.

THE NUCLEUS PRAEEMINENTIALIS: PROPERTIES OF NEURONS PROVIDING DESCENDING INPUTS TO THE ELECTROSENSORY LATERAL LINE LOBE OF WEAKLY ELECTRIC FISH. J. Bastian and B.O.Bratton. Dept. of Zool., Univ. Oklahoma, Norman, OK 73019.

The nucleus praeeminentialis (NP) recives input from the electrosensory lateral line lobe (ELL) and provides a major descending input to this same structure. We studied the responses of NP neurons to stepwise increases in EOD amplitude, to sinusoidal EOD AMs of various frequencies, and to moving electrolocation targets. Some neurons responded to the rising phase of the AM (On cells), others responded to the falling phase (Off cells), and some responded to both (On-Off cells). These types produced very phasic responses and were non-spontaneous. Cells giving sustained responses were also non-spontaneous. Spontaneously active cells were inhibited by increased EOD amplitude. NP neuron responses to moving electrolocation targets show less decrement with increasing fish-target distance as compared to the ELL neurons, some show directional selective responses, and some show maximum responses at distances other than closest to the fish. NP cells were also marked with Lucifer yellow to allow morphological identification of physiological categories. Supported by NIH Grant NS12337, and OCAST #1669.

CONSPECIFIC EOD DETECTION IN A WEAKLY ELECTRIC FISH. L.J. Fleishman and H.H. Zakon. Dept. Zoology, Univ. Texas, Austin, TX 78712

Sternopygus produces a quasi-sinusoidal electric organ discharge (EOD) which differs in frequency between individuals and sexes (females roughly an octave higher). EODs are perceived by electroreceptors which have a V-shaped tuning curve, with a best frequency nearly equal to the EOD frequency. Males find mates by detecting female EODs, but this ability would appear to be limited by electroreceptor tuning.

We investigated the possibility that the addition of a fish's EOD to that of a conspecific results in nonlinear filtering, allowing greater detectability of two signals combined than could be predicted from the response to either alone.

We determined behavioral tuning curves using conditioning. We then eliminated the EOD by lesioning the pacemaker nucleus, and retested the fish. EOD elimination caused no change in relative threshold to different frequencies, indicating that there is no nonlinear interaction. Threshold at all frequencies was elevated by 20 dB, because the presence of the EOD placed the combined signal at an amplitude where the electroreceptors are most sensitive to small changes. Microelectrode recordings from electroreceptor units stimulated with the sum of two sine waves yielded comparable results.

Peripheral filtering is linear for added sinusoids, and must limit the ability of males to detect female EODs.

128.11

AN ELECTROSENSORY MAP IN THE SKATE TECTUM LIMITED TO THE VISUAL FIELD. D. Bodznick, M.C. Ronan and E.J. Schneider*. Dept. Biology, Wesleyan University, Middletown, CT 06457.

Visual and electrosensory maps in the tectum of the little skate, Raja erinacea, were studied using multiple and single unit recordings. Visual stimulus was a pulsed LED (560 nm, .5^0 diam.) approx. 30 cm from the eye; electric stimulus was a dipole field presented through an electrode pair 30 cm from the center of the fish or handheld electrodes scanned along the body surface. Visual responses were recorded from the superficial tectum with rostral (0^0) to caudal (180^0) azimuths mapped uniformly from rostral to caudal tectum. Visual elevation from directly overhead to the pectoral fin edge mapped medial to lateral, with an overrepresentation of the 20^0 span of field at the horizon. The electrosensory map in deep tectum has a similar uniform representation of azimuth from rostral to caudal levels. Elevation of electrosensory fields mapped medial to lateral with a similar large representation of horizontal fields near the fin edge. Roughly 80% of electroreceptors in little skates are located ventrally and have no corresponding visual field. Ventral receptors are mapped not in tectum but in the adjacent lateral mesencephalic nucleus (LMN). Electrosensory maps in tectum and LMN are aligned so that a continuous representation of electrosensory elevation extends from medial tectum to ventolateral LMN.

128.12

A KINEMATIC COMPARISON OF MAUTHNER AND NON-MAUTHNER C-STARTS IN GOLDFISH. R.C. Eaton, R. DiDomenico and J. Nissanov. Neuroscience Group, Campus Box 334, Univ. of Colorado, Boulder, CO 80309.

This study utilizes digitized kinematic data and lesions of individual Mauthner (M-) cells, large medial reticulospinal command neurons, to examine their role in goldfish C-starts elicited by displacement stimuli. Our results show a major difference in response lateralization in animals with only one M-cell compared to those with both cells intact, or both cells absent. Animals with one M-cell responded by turning to the side opposite the remaining M-cell in 94% of the trials, whereas those both M-cells intact responded with equal probability to both sides. In addition, M-responses were on the average 4 ms shorter in latency than those without the M-cell present. This difference may confer a behaviorally significant advantage to the M-cell in blocking other networks that can trigger C-starts. Nevertheless, with the exception of latency, the central program producing the escape behavior adapts automatically to the absence of both M-cells: animals with bilateral M-cell lesions continued to produce the full spectrum of response types and kinematic performance levels seen in intact animals. [Supported by NIH grant NS22621].

128.13

WHAT DIFFERENCE DOES IT MAKE HAVING A MAUTHNER AXON? S.M. Van Horne*, R. C. Eaton, J.R. Fetcho and J. Nissanov. Neuroscience Group, CB 334, Univ. of Colorado, Boulder, CO 80309, Dept. Physiol., SUNY at Buffalo, NY 14214, Neurobiology Unit, Scripps Inst. Oceanography, UCSD, La Jolla, CA 92093.

The lack of motor differences between C-starts with and without the Mauthner (M-) cell, questions the functional significance of M-axon size relative to other motor axons in the spinal cord. We analyzed spinal cords for the size distribution of axons to compare with the M-axon. At the mid-trunk level for two goldfish, 9.3 and 10.2 cm standard length, the M-axon diameters were 40 and 46 um. The next largest fibers were 25 um, a difference of 1.7 times, which should reflect the relative conduction velocities (CVs). If the M-axon conducts at 80 m/s, the next largest fibers would conduct at 47 m/s. Thus, the M-axon depolarizes along its length in 1.25 ms compared with 2.12 ms for the next largest fibers. This 0.88 ms difference would not be seen using present cinematic methods but it should cause a performance advantage of 0.43 to 1.3% of a body length more distance covered, depending on elapsed time during the C-start. The MLF occupies no more than 0.77 sq. mm and the M-axons occupy only about 0.4% of this. Thus, the M-axon CV gives only a small difference in performance, but this has little cost in terms of area occupied by the fibers. [Supported by NIH grant NS22621].

128.14

THE MOTOR PATTERN GENERATOR FOR SNAPPING IN TOADS. J.-P. Ewert and A. Weerasuriya*. (SPON: C. H. Hockman) Dept. of Neuroethology, University of Kassel, Kassel, Federal Republic of Germany.

The hypothesis that a neuronal network interposed between the output elements of the optic tectum, and hypoglossal and other cranial motoneurones subserves snapping in anurans is critically examined. Morphological and electrophysiological data have not revealed a direct monosynaptic connection between the optic tectum and hypoglossal motoneurones. On the contrary, the available evidence supports the presence of interneurones mediating impulse traffic from the tectum to cranial motoneurones. Since snapping is a ballistic stereotyped behaviour, it is argued that these interneurones are part of a motor pattern generator for snapping (MPG) in anurans. In order to localise these interneurones, HRP was iontophonetically deposited in the medial medullary reticular formation (MRF) of toads, resulting in retrograde cell labeling in the lateral tectum and anterograde terminal labeling in the hypoglossal nucleus. Bilateral tectal and toral inputs to MRF suggest that the MPG consists of two unilateral subunits having independent access to the relevant motoneurones. This is consistent with the observation that toads with unilateral tectal lesions are still capable of snapping. These results in conjunction with previous electrophysiological data from the medulla strongly support the concept of a MPG for snapping.

SEROTONIN RECEPTORS I

129.1

EFFECT OF ACUTE AND LONG-TERM ADMINISTRATION OF SM-3997 ON 5-HT NEURON FIRING ACTIVITY AND ON RESPONSIVENESS OF POST-SYNAPTIC NEURONS TO SEROTONIN AND NOREPINEPHRINE. R. Godbout, Y. Chaput and C. de Montigny. Dept. of Psychiatry, McGill University, Montréal, Canada H3A 1A1.

The anxiolytic SM-3997 is a selective 5-HT$_{1A}$ ligand, and its metabolite 1-PP is an antagonist of α_2-adrenoceptors (Chaput et al., this meeting).

Acute intravenous SM-3997 depressed dorsal raphe 5-HT neuron firing activity with an ED$_{50}$ of 9.1±1.1 µg/kg. In rats treated for 2, 7 or 14 days with SM-3997 (10 mg/kg, s.c.), there was a marked reduction of 5-HT neuron firing activity after 2 days, a partial recovery after 7 days and a complete one after 14 days of treatment. At this latter point in time, the effect of LSD on 5-HT neuron firing activity was markedly reduced, indicating a desensitization of somatodendritic 5-HT autoreceptors.

Microiontophoretic application of SM-3997 onto dorsal hippocampus pyramidal neurons blocked the effect of 5-HT, but not that of NE, indicating that SM-3997 is a partial agonist of postsynaptic 5-HT$_{1A}$ receptors. However, the responsiveness of these neurons to 5-HT, NE and SM-3997 was not modified by the 14-day treatment with SM-3997.

These data indicate that long-term treatment with SM-3997 desensitizes somatodendritic 5-HT autoreceptors, but not postsynaptic 5-HT$_{1A}$ receptors, and that, at the dose administered, neither postsynaptic 5-HT$_{1A}$ nor postsynaptic α_2-adrenoceptors are blocked by SM-3997 and 1-PP.

129.2

EFFECT OF 1-PP ON α2-ADRENOCEPTORS: ELECTROPHYSIOLOGICAL STUDIES IN THE RAT CENTRAL NERVOUS SYSTEM IN VIVO. Y. Chaput, O. Curet and C. de Montigny. Dept. of Psychiatry, McGill University, Montreal, Canada H3A 1A1.

1-PP (1-pyrimidinylpiperazine) is the common metabolite of the anxiolytic 5-HT$_{1A}$ agonists SM-3997, buspirone, gepirone and ipsapirone. The present in vivo studies were undertaken to determine the effect of 1-PP on pre- and postsynaptic α_2-adrenoceptors in male Sprague-Dawley rats.

1-PP applied by microiontophoresis (10 to 30 nA) or administered intravenously (4 to 8 mg/kg) blocked the effect of microiontophoretically-applied norepinephrine (NE) on CA$_3$ dorsal hippocampus pyramidal neurons, but not those of 5-HT and GABA. Since the effect of microiontophoretically-applied NE on these neurons has been shown to be mediated by postsynaptic α_2-adrenoceptors, these results provide evidence that 1-PP is an effective antagonist of postsynaptic α_2-adrenoceptors.

1-PP (4 mg/kg, i.v.) increased the effectiveness of the stimulation of the locus coeruleus in suppressing CA3 hippocampus pyramidal neuron firing activity. This data suggests that 1-PP blocks terminal α_2 autoreceptors.

1-PP reversed the suppressant effect of clonidine (20 µg/kg, i.v.) on the firing activity of NE neurons of the locus coeruleus (ED$_{50}$: 80 µg/kg, i.v.). This suggests that 1-PP blocks somatodendritic α_2-adrenergic autoreceptors.

In conclusion, these data demonstrate that 1-PP is an antagonist of both pre- and postsynaptic α_2-adrenoceptors.

129.3

MOUSE BRAIN SEROTONIN RECEPTOR-MEDIATED RESPONSES IN *XENOPUS* OOCYTES: IONIC MECHANISMS OF CALCIUM-ACTIVATED CHLORIDE CURRENTS. L. Yu, N. Davidson and H.A. Lester. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Serotonergic responses can be induced in *Xenopus* oocytes injected with mouse brain RNA, as a result of the expression of the mouse 5-HT_{1C} serotonin receptors. The response is in the form of a two-phase Ca^{++}-activated Cl^- current. The first phase is a fast transient inward current, followed by a sustained plateau in the second phase. The Cl^- current in mRNA-injected oocytes can be induced under three conditions: 1) addition of serotonin in low Ca^{++} (<1μM) solution; 2) addition of serotonin in normal Ca^{++} (1.8mM) solution; and 3) exposure to extracellular Ca^{++} at 1.8mM in the presence of serotonin. The latency of the Cl^- current varies depending on the activation condition. The addition of Ca^{++} in the presence of serotonin gives an immediate response. 5-HT induced response has a 10 to 15-second delay in the presence of normal extracellular Ca^{++}, while the delay time is doubled in the low Ca^{++} solution. These data suggest that the three types of Cl^- responses are the results of activation by Ca^{++} from different sources. The duration of the plateau phase depends on extracellular Ca^{++}.

129.4

^{125}I-Azido-PAPP, A SELECTIVE PHOTOAFFINITY LABELING PROBE FOR 5-HT_{1A} RECEPTORS. W. Yang*, C.H. Chen*, S. Chumpradit*, H.F. Kung*, and J. Shih. School of Pharmacy, Univ. of South. Calif., L.A., CA 90033, and Dept. of Radiology, Univ. of Penn., Phila., PA 19104

Previous work from this laboratory has shown that 1-[2-(4-aminophenyl)ethyl]-4-(3-trifluoromethylphenyl) piperazine (LY 165163, PAPP) is a selective ligand for 5-HT_{1A} receptor and ^{3}H-azido-PAPP is a specific photoaffinity labeling probe for 5-HT_{1A} receptor (for review, Shih et al. Psychopharm Bulletin 22:818-824, 1986; J. Neurochem. 49:1361-1366, 1987). Recently, we have synthesized Iodo-PAPP, Iodo-azido-PAPP and ^{125}I-azido-PAPP. In vitro binding studies show that both I-PAPP and I-azido-PAPP displaced about 60% of the total ^{3}H-5-HT bindings in bovine hippocampal membranes. At 2 nM ^{3}H-5-HT, the IC_{50} for I-azido-PAPP was 35 nM whereas IC_{50}'s for 5-HT, PAPP and azido-PAPP were 5.6, 8.1 and 5.0 nM, respectively. At 1 nM ^{3}H-DPAT, the IC_{50} for I-azido-PAPP was 40 nM, whereas the IC_{50} for 5-HT, PAPP and azido-PAPP were 6.0, 10.0 and 3.1 nM, respectively. Upon photoirradiation of ^{125}I-azido-PAPP with brain membranes, two proteins with molecular weight of 55K and 38K daltons were labeled. The photoincorporation of ^{125}I-azido-PAPP could be blocked by 5-HT_{1A} specific ligands 5-HT, DPAT, spiperone and LSD. These results suggest that ^{125}I-azido-PAPP is a selective photolabeling probe for 5-HT_{1A} receptors. (Supported by NIMH Grant No. MH 37020)

PHOTOAFFINITY LABELING OF RAT BRAIN 5-HT_{1B} RECEPTORS WITH [^{125}I]-IODOCYANOPINDOLOL DIAZIRINE. M.W. Hamblin, P.I. Adriaenssens*, G.L. Tan*, K. Ariani*, and R.D. Ciaranello. Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305.

[^{125}I]-iodocyanopindolol diazirine ([^{125}I]ICYPD) was originally developed as a beta adrenergic photoaffinity label (Bergermeister, et al, BBA 729:219, 1983). We now decribe its use as a photoaffinity label for rat brain 5-HT_{1B} receptors.

[^{125}I]-ICYPD (free concentration approximately 100-200pM) irreversibly photolabeled a number of rat hippocampus and substantia nigra membrane proteins. Specificity in labeling for two protein bands could be demonstrated. Isoproterenol (3-30uM) blocked photolabeling of a protein of Mr=64000, consistent with specific labeling of beta adrenergic receptors. Radiolabeling of a second protein of Mr=52000 could be blocked by inclusion of compounds with high 5-HT_{1B} affinity, such as RU 24969 (250nM), dihydroergotamine (50nM), or 5-HT (1000nM), but not by isoproterenol (3-30uM) or the 5-HT_{1A} specific compound DPAT (250nM). Inclusion of several protease inhibitors had no effect on the observed Mr. These studies were limited by considerable non-specific labeling related to the low abundance of 5-HT_{1B} receptors in these tissues. Nonetheless these studies provide the first estimate of molecular weight for the 5-HT_{1B} receptor and show that its size is typical for the G-protein linked receptor family of which it may be a member.

129.6

A PINDOLOL DERIVATIVE SELECTIVELY INTERACTS WITH 5-HT_{1A} RECEPTORS IN THE RAT HIPPOCAMPUS. L.M. Liau, J.W. Pitha*, and S.J. Peroutka. Dept. of Neurology, Stanford University Medical Center, Stanford, CA 94305.

A pindolol derivative with a high affinity for beta-adrenoceptors was synthesized (ISOBIM, N^1-(Bromoacetyl)-N^8-[3-(4-indolyloxy)-2-hydroxypropyl]-(Z)-1,8-diamino-p-methane). Radioligand binding studies indicated that the drug is extremely potent (<1.0 nM) at 5-HT_{1A} receptors labeled by ^{3}H-8-OH-DPAT. Moreover, the drug was also selective in that it was more than ten-fold more potent at beta-adrenergic receptors. ISOBIM (10^{-10} M to 10^{-3} M) alone had virtually no effect on baseline or forskolin-stimulated adenylate cyclase activity. By contrast, ISOBIM was able to significantly ($p<0.001$) reverse 8-OH-DPAT-induced inhibition of forskolin-stimulated activity. 8-OH-DPAT, a 5-HT_{1A} agonist, inhibited forskolin stimulation by 25-35%. In the presence of nanomolar ISOBIM, the amount of inhibition produced by 8-OH-DPAT was completely reversed and occassionally stimulation rates were brought above controls. Therefore, ISOBIM is a potent antagonist of 5-HT_{1A} receptors and may serve as a useful tool in the analysis of 5-HT_{1A} receptors and function.

PHARMACOLOGICAL CHARACTERIZATION OF THE SEROTONIN (5-HT) AUTORECEPTOR MODULATING THE ELECTRICALLY-EVOKED RELEASE OF [^{3}H]-5-HT FROM SLICES OF HUMAN FRONTAL CORTEX. A.M. Galzin*[1], P. Blier[1], J.P. Chodkiewicz*[2], M.F. Ppirier*[3], H. Lop*[3], F.X. Roux*[2], A. Bedondo*[2], A. Lista*[1], R. Ramdine*[1] and S.Z. Langer[1]. [1]Laboratoires d'Etudes et de Recherches Synthelabo (L.E.R.S.), 75013 Paris, France; Services de Neurochirurgie[2] et de Psychiatrie[3], Hôpital Sainte-Anne, 75014 Paris, France

In the rat brain, the presynaptic 5-HT autoreceptors located on 5-HT terminals belong to the 5-HT_{1B} subtype. Although there is controversy as to the existence of 5-HT_{1B} binding sites in the human brain, the presence of a terminal 5-HT autoreceptor of an uncharacterized pharmacological type has been documented (Schlicker, E. et al., Brain Res., 331:337, 1985). We studied the effects of 5-HT receptor agonists and antagonists on the electrically-evoked release of [^{3}H]-5-HT from preloaded human frontal cortex slices. Specimens of normal cerebral cortex (which had to be removed in order to gain access to deep-seated brain tumors) were obtained from seven neurosurgery patients. Two periods of electrical stimulation (3 Hz, 30 mA, 2 ms x 2 min) were applied 90 min (S_1) and 134 min (S_2) after the onset of superfusion. The fractional release evoked by the electrical stimulation (S_1) was 1.37±0.20% of the total radioactivity with a S_2/S_1 ratio of 1.40±0.12. The 5-$HT_{1A/1B}$ agonist 5-carboxamidotryptamine (5-CT) produced a potent inhibition (77% at 30 nM) of the release of [^{3}H]-5-HT which was blocked by 5-HT antagonists with the following efficacy: methiothepin>metergoline=methysergide >propranolol. The selective 5-HT_{1A} agonist 8-OH-DPAT at 100 nM did not modify the release of [^{3}H]-5-HT whereas the 5-HT_{1B} agonist RU 24969 produced a maximal inhibition of 65% at 100 nM. In contrast, a 100% inhibition of [^{3}H]-5-HT release was obtained in rat frontal cortex slices with 100 nM RU 24969. These results suggest that the release of 5-HT in the human frontal cortex is modulated by an inhibitory 5-HT autoreceptor which is different from the 5-HT_{1A} or $_{1B}$ subtypes. The relative potencies of 5-HT receptor antagonists to block the inhibition produced by 5-CT together with the difference in potency of RU 24969 between rat and human frontal cortex slices indicate that this receptor has a pharmacological profile that closely resembles that of the 5-HT_{1D} subtype described by Heurting, R.E. and Peroutka, S.J. (J. Neurosci., 7:894, 1987).

129.8

G-PROTEINS RECONSTITUTE BINDING TO NEM-INACTIVATED HIGH AFFINITY [^{3}H]5-HT BINDING SITES IN BRAIN. C. A. Stratford, G. L. Tan*, M.H. Hamblin, and R.D. Ciaranello. Laboratory of Developmental Neurochemistry, Dept. of Psychiatry, Stanford University Medical School, Stanford, CA 94305.

N-ethyl maleimide (NEM) inactivates high affinity [^{3}H]DPAT binding to 5-HT_{1A} and [^{3}H]5-HT binding to 5-HT_{1B}, and 5-HT_{1D} sites in rat and bovine brain. Antagonist binding to these sites is relatively insensitive to this treatment. Binding to 5-HT_{1C} and 5-HT_2 sites is not affected by NEM treatment (Soc. Neurosci. Abs.13(2): 1236). In the present study we show that binding to NEM-inactivated sites can be reconstituted by addition of purified G-proteins to the membrane preparations.

Binding to NEM inactivated membranes is reconstituted by addition of a mixture of G_i and G_o proteins purified from bovine brain in the presence of sodium cholate (.005%; final conc.), sonication and subsequent washing. Reactivation is maximal at a ratio of approximately 1000 G-protein molecules to 1 binding site. Binding of [^{3}H]DPAT to 5-HT_{1A} sites in rat brain and of [^{3}H]5-HT to 5-HT_{1D} sites in bovine brain is reactivated by addition of the G-proteins. The reactivated binding is sensitive to addition of 5'-guanylyl imidodiphosphate (GppNHp) to the binding assay. When membranes are treated with NEM, the apparent K_i for 5-HT displacement of [^{125}I]iodocyanopindolol binding to 5-HT_{1B} sites is increased from 2 nM to 57 nM and is no longer sensitive to GppNHp. Addition of G-proteins to the mixture decreases the apparent K_i (3-5nM) and restores GppNHp sensitivity of 5-HT displacement. These results suggest that 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D} sites are endogenously linked to G_i and/or G_o-like proteins.

129.9

5-HYDROXYTRYPTAMINE$_{1A}$ RECEPTORS ARE LINKED TO A G_i ADENYLATE CYCLASE COMPLEX IN RAT BRAIN. M.A. Harrington and S.J. Peroutka. Department of Neurology, Stanford University School of Medicine, Stanford, CA 94305.

5-Hydroxytryptamine$_{1A}$ (5-HT$_{1A}$) receptors can be radiolabeled with [^{3}H]-8-hydroxy-2-(di-n-propylamino)tetralin (^{3}H-8-OH-DPAT), are sensitive to inhibition by GTP and GDP, but not GMP, and have been shown to mediate the inhibition of adenylate cyclase following stimulation by forskolin. ADP-ribosylation of GTP-binding proteins by pertussis toxin was found to abolish both 5-HT- and 8-OH-DPAT-induced inhibition of forskolin-stimulated adenylate cyclase activity in rat hippocampal membranes, indicating that 5-HT$_{1A}$ receptors are linked to the G_i protein mediating the inhibition of adenylate cyclase.

To further characterize the interaction between 5-HT$_{1A}$ receptors and G proteins, rat cortical membranes were preincubated with nonhydrolyzable GTP analogues GTPgammaS and GDPbetaS, resulting in an increased K_D and lowered B_{max} of subsequent ^{3}H-8-OH-DPAT binding in a dose- and time-dependent manner. These findings indicate a decrease in receptor affinity and density of ^{3}H-8-OH-DPAT binding of up to 60%. 5-HT$_{1A}$ receptors have also been shown to be directly linked to a potassium channel. These data suggest that the receptors may be linked to two different effector systems.

129.10

LIMITATIONS TO USING THE INHIBITION OF FORSKOLIN-STIMULATED ADENYLATE CYCLASE TO SCREEN FOR COMPOUNDS ACTING THROUGH SEROTONIN$_{1A}$ RECEPTORS. L.J. Cornfield, P.J. Monroe, E.W. Taylor*, S.S. Nikam* and D.L. Nelson.. Dept. of Pharmacology & Toxicology, College of Pharmacy, University of Arizona, Tucson, Arizona 85721.

Numerous studies have shown that serotonin$_{1A}$ (5-HT$_{1A}$) receptors are negatively coupled to adenylate cyclase. Thus, this assay has potential as a screening tool for evaluating the functional activity of new putative 5-HT$_{1A}$ agonists and antagonists. The forskolin-stimulated adenylate cyclase assay was performed for this study using Sprague-Dawley rat hippocampal membranes. The potencies of known 5-HT$_{1A}$ agonists (such as buspirone, 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) and 5-HT itself) in this system were consistent with those at 5-HT$_{1A}$ sites defined by [^{3}H]8-OH-DPAT binding. Examination of some novel 5-HT$_{1A}$ ligands revealed several compounds (including spiroxatrine and three aralkylamines) that had potencies that did not correlate with 5-HT$_{1A}$ binding, despite exhibiting potential 5-HT$_{1A}$ agonistic activity in the cyclase system. Consequently, results from this functional assay must be interpreted with caution when screening compounds for 5-HT$_{1A}$ activity, due to the possible inhibition of adenylate cyclase via non-5-HT$_{1A}$-mediated mechanisms. (Supported by NIH Grants MH39530, NS16605 and NS01009).

129.11

BEHAVIORAL, DISCRIMINATIVE STIMULUS AND NEUROCHEMICAL ACTIONS OF DRUGS ACTING AT SEROTONIN (5-HT) RECEPTOR SUBTYPES: EFFECTS OF 5-HT$_{1A}$ AGONISTS AND 5-HT$_2$ ANTAGONISTS. J.E. Barrett, S. Gleeson* and M.A. Nader*. Dept. of Psychiatry, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

Effects of compounds believed to be agonists and\or antagonists at the 5-HT$_{1A}$ or 5-HT$_2$ receptor were studied in pigeons under procedures known to be indicative of anxiolytic activity. Key pecking was maintained under a schedule where each 30th response in the presence of a red or white keylight produced food; when the keylight was red, each 30th response also produced a mild (2-4 mA) electric shock. Keylight colors alternated every 3 min throughout a 30 min session. Ipsapirone (0.1-10 mg/kg), MJ-7378 (0.01-5.6 mg/kg), 2-mPP (0.3-10.0 mg/kg), and spiroxatrine (0.03-3.0 mg/kg), i.m. - compounds with high affinity for the 5-HT$_{1A}$ receptor - all increased punished responding at doses that did not affect or that decreased unpunished responding. The 5-HT$_2$ antagonists ritanserin (0.03-10 mg/kg) and ketanserin (0.1-10 mg/kg) also increased punished responding. In pigeons trained to discriminate spiroxatrine or buspirone from saline, all 5-HT$_{1A}$ compounds produced drug-appropriate responding, whereas the 5-HT$_2$ compounds produced responding on the key correlated with saline administration. Although these compounds produce their discriminative stimulus effects through different receptor subtypes, results with the punishment procedure indicate that all should be effective anxiolytic compounds.

129.12

5-METHOXY-LUZINDOLE (N-0745):A PARTIAL MELATONIN RECEPTOR AGONIST. M.L. Dubocovich, J.M. Fang* and L. Yousif*. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Luzindole (N-0774, 2-benzyl-N-acetyltryptamine, LUZ) is a competitive melatonin (MEL) receptor antagonist (Dubocovich, M.L., J. Pharmacol. Exp. Ther., in press, 1988). Here we report the pharmacological properties of 5-methoxy luzindole (5-M-LUZ) on MEL receptors. In the rabbit retina labeled in vitro with ^{3}H-dopamine (DA), 5-M-LUZ (0.1 nM-1 μM) inhibited (IC_{50} = 1.4 nM) the calcium-dependent release of DA, with a maximal inhibitory (35-40 %) effect at 100 nM. By contrast, the inhibitory effect of MEL (IC_{50} = 33 pM) was antagonized by 1, 10, 100 and 1,000 nM of 5-M-LUZ (IC_{50} = 0.95, 2.4, 15.2 and 118 nM, respectively). The equilibrium dissociation constant (K_B) of 5-M-LUZ calculated from the Schild plot was 0.12 nM (slope 0.93). In the C3H/HeN mouse 5-M-LUZ (30 mg/kg, i.p., 30 min) administered in vivo reversed the α-CH_3-p-tyrosine (α-MpT, i.p., 2 h)-induced depletion of norepinephrine (NE) (ng/ mg tissue) in the hypothalamus [Control: 2.85 $\pm$ 0.13 (6); α-MpT: 2.15 $\pm$ 0.1 (6); α-MpT plus 5-M-LUZ: 2.66 $\pm$ 0.12 (4), $p < 0.05$)]. 5-M-LUZ also blocked the reversion of the α-MpT induced depletion of NE by the agonist 6-Cl-MEL (30 mg/kg, i.p., 30 min) [α-MpT plus 6-Cl-MEL plus 5-M-LUZ: 2.24 $\pm$ 0.08 (8)]. In conclusion, 5-M-LUZ acts as a partial MEL receptor agonist, i.e., it shows pharmacological properties of a MEL receptor agonist and antagonist both in in vitro and in vivo models. Supported by MH 42922 and Nelson Research.

2-[125I]-IODOMELATONIN LABELS TWO DIFFERENT MELATONIN (MEL) BINDING SITES IN CHICKEN BRAIN MEMBRANES. (SPON: S.F. Holloway). G. Shankar* and M.L. Dubocovich. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago 60611.

We have characterized a 2-[^{125}I]-iodomelatonin (2-[^{125}I]-I-MEL) binding site in the chicken brain with pharmacological characteristics similar to the functional MEL receptor in the retina. The affinities (nM) of MEL analogs at this binding site were : 6-Cl-MEL (8) > 2-I-MEL (16) $\geq$ MEL (17) > 2-CH_3-6,7-diCl-MEL (50) > 6-OH-MEL (180) >> 5-HT (2,000). Here we report a second 2-[^{125}I]-I-MEL binding site with high affinity for compounds inactive at the functional MEL receptor. Chicken brain membranes were incubated with 2-[^{125}I]-I-MEL (100 pM) and various drugs at 0^{o}C. Monophasic dose response curves of 5-HT agents yielded the following pharmacological profile (affinity, nM): methysergide (70) $\geq$ spiperone (80) > RU-24969 (380) > spiroxatrine (480) > ketanserine (600) > ICS-205930 (1,050) > metergoline (3,600) > 5-carboxamidotryptamine (6,600) > 8-OH-DPAT (7,500) > methiothepine (7,800) >> gepirone (>100,000). Various α-and β- adrenergic compounds were inactive . This profile does not correspond to any 5-HT site. Further, the 5-HT analogs are inactive in chicken retinal membranes. It appears that 2-[^{125}I]-I-MEL labels two sites in the chicken brain: one site with affinity for compounds affecting MEL-induced inhibition of ^{3}H-dopamine release from chicken retina and a second site with affinity for compounds with no known functional response and which do not exist in the retina. Supported by MH 42922.

130.1

GABA FACILITATES AFFERENT NICOTINIC SYNAPSES IN THE INFERIOR MESENTERIC GANGLION. W. H. Stapelfeldt and J. H. Szurszewski. Dept. of Physiology and Biophysics, Mayo Medical School, Rochester, MN 55905.

Recent immunohistochemical studies demonstrated the presence of GABA immunoreactive material in afferent fibers of colonic origin projecting to the inferior mesenteric ganglion (IMG). To determine the functional role of this pathway the effects of GABA receptor/Cl-ionophore modulating drugs were studied in isolated guinea pig IMGs receiving ongoing afferent synaptic input from attached segments of distal colon using standard intracellular recording techniques. In the presence of bicuculline or picrotoxin (10-50 μM) depolarizing post-synaptic responses to exogenous GABA were reduced or abolished and ongoing nicotinic fast EPSPs were decreased in amplitude and frequency by 40%. Addition of diazepam (5 μM) facilitated the depolarizing response to exogenous GABA and caused a 40% increase in amplitude and frequency of ongoing asynchronous nicotinic fast EPSPs. Clamping of the postsynaptic depolarizing response revealed a presynaptic facilitatory action of GABA on afferent nicotinic terminals. Central preganglionic nicotinic synapses were not affected by GABA. These findings suggest that GABA is released in the IMG during ongoing colonic motor activity and functions as a presynaptic facilitatory modulator of nicotinic mechanosensory afferent synapses. (Supported by DK 17632.)

CENTRAL AND PERIPHERAL SYNAPTIC INPUTS TO THREE TYPES OF SYMPATHETIC NEURON IN THE GUINEA PIG CELIAC GANGLION. R.L. Meckler and F.M. McLachlan*, School of Physiol./Pharmacol., Univ. of New South Wales, Kensington, NSW 2033, AUSTRALIA.

Electrophysiological criteria were used to classify neurons into three types according to the ion channels in their membranes (Cassell & McLachlan, J. Physiol., 394:331-349, 1987). Two types of neurons discharge phasically during maintained depolarization; one of these has a long afterhyperpolarization (LAH). The third type discharges tonically. Excitatory synaptic potentials (e.s.ps) were evoked by stimulation of splanchnic (SPL) and celiac (CN) nerves. Phasic neurons receive <10 e.s.ps of splanchnic origin, one of which is usually suprathreshold; very rarely small e.s.ps are evoked from CN stimulation. LAH neurons generally receive fewer SPL and occasionally more CN inputs. In contrast, tonic neurons receive only a few e.s.ps from SPL, but up to 30 e.s.ps from CN stimulation. Thus activity of tonic neurons is dominated by synaptic inputs of peripheral origin, whereas phasic and LAH neurons receive predominant input from the central nervous system. The spatial distributions of neurons of different types within the ganglion correspond with the distribution of 3 types of neurochemically identified neurons that regulate different gastrointestinal functions: vasoconstriction, inhibition of motility and inhibition of secretion (Macrae, Furness & Costa, Cell Tiss. Res., 244:173-180, 1986).

130.3

CO-REGULATION OF NPY AND NE IN SUPERIOR CERVICAL GANGLION CULTURE. R.E. Mains and K.L. Marek. Dept. Neuroscience, Johns Hopkins Univ., Baltimore, MD. 21205.

The co-regulation of Neuropeptide Y (NPY) and Norepinephrine (NE) synthesis has been investigated in rat superior cervical ganglion (SCG) neuronal cultures. NPY synthesis was measured after incubation in medium containing [^{3}H]tyrosine followed by immunoprecipitation and SDS-PAGE. NE synthesis was determined from the same extract by RP-HPLC. NPY mRNA levels were quantitated in SCG cultures by Northern analysis.

In previous studies we have shown that the synthetic rates of NE and NPY were independently regulated in response to heart cell derived cholinergic inducing factor. In these experiments SCG cultures were maintained for 10 days in serum free medium containing specific adrenergic pharmacologic agents, dexamethasone, dBcAMP or phorbol myristate acetate (PMA). Synthesis and accumulation of NE decreased following treatment with reserpine (20-fold), clonidine (2-fold) and desipramine (3-fold), but NPY synthetic rate was unchanged. Dexamethasone and cAMP caused a coordinate increase and PMA a coordinate decrease in NE and NPY synthetic rate. Preliminary evidence indicates that NPY mRNA levels show corresponding changes. These data provide strong evidence for independent control of synthesis and release of NPY and NE in SCG neurons.

130.4

VAGAL CONTROL OF INSULIN SECRETION: FURTHER EVIDENCE FOR GASTRIC AND HEPATIC BRANCHES PLAYING THE MAJOR PHYSIOLOGICAL ROLE.

H.-R. Berthoud and T.L. Powley. Laboratory of Regulatory Psychobiology, Purdue U., W. Lafayette, IN, 47907.

Although vagal control of insulin secretion has classically been attributed to the celiac branches of the abdominal vagus, we have recently demonstrated that the gastric and hepatic branches mediate the bulk of electrical stimulation-induced (Soc. Neurosci. Abstr. 12, p 644) and cephalic phase (Soc. Neurosci. Abstr. 13, p. 332) insulin secretion. However, because the magnitude of the insulin response elicited by electrical stimulation is much larger than that produced by the cephalic phase of food intake or any other known neurogenic stimulus, it could be artifactual, due to the antidromic excitation of vagal afferents (Delbro et al. Acta Physiol. Scand. 118, 1983 and 122, 1984). It would thus not be affected by a ganglionic blocker. We performed, therefore, bilateral electrical cervical vagal stimulation in rats with only the gastric plus hepatic or only the hepatic abdominal branches intact, first in the absence and then in the presence of hexamethonium (HEX) (5-10mg/kg i.v. at -15min). HEX abolished the early (1 min) increase of peripheral insulin levels (control: +117±22% of basal; HEX: -4±8%) and suppressed the integrated 10 min response by more than 90%. Pancreatic glucagon secretion was similarly affected.

This suggests that vagal gastric and hepatic branch mediated stimulation of insulin and glucagon secretion is likely to be due to excitation of preganglionic motor fibers, and not antidromic excitation of afferents. (NIH Grant DK27627)

130.5

Light and Electron Microscopic Analysis of the Accessory Celiac Branch of the Vagus Nerve. J.C. Prechtl and T.L. Powley, Lab. of Regulatory Psychobiology, Purdue Univ., W. Lafayette, IN 47907

The accessory celiac branch (AC) is the least studied of the abdominal vagal branches in the rat. It separates from the ventral vagal trunk and courses on the left gastric artery towards the celiac plexus. Although the conclusion that the AC and the dorsal celiac branch form a symmetrical pair is supported by several observations (i.e. similar peripheral paths, preganglionics originating from homotypic columns in the dorsal motor nucleus, similar numbers of vagal efferents), the smaller size and less extensive branching of the AC suggests that it may not be a complete homotype of the dorsal celiac branch (Prechtl & Powley 1985, JCN; also 1987, Neurosci. Abst.). In order to characterize more thoroughly the AC, we prepared the abdominal vagal complexes from six rats for electron microscopy. From cross-sectional montages of the branches (X10,000), all axons were counted and their dimensions were determined (OASYS Image Analyzer). To evaluate the possibility of extrinsic fibers (non-vagal origin, see Prechtl & Powley, Anat. Embryol. 1987) in the AC, as well as to examine the intraneural organization of the branch point, 21 osmium-stained nerve whole mounts were prepared for light microscopy.

The AC branch contained 3103±404 unmyelinated fibers and only 5.5±2 myelinated fibers; two of the specimens contained no myelinated fibers at all. The mean diameter of the unmyelinated axons was 0.64±.01um, and that of the myelinated axons was 1.63±.1um. Finally, the whole mounts revealed that in at least 81% of the cases, the AC did contain extrinsic fascicles like those we have found in other vagal branches. (NIH grant DK27627)

130.6

DENDRITIC FIELDS AND MORPHOLOGY OF IDENTIFIED NEURONS IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS. E.A. Fox and T.L. Powley, Lab. of Regulatory Psychobiology, Purdue U., West Lafayette, IN 47907.

The dorsal motor nucleus of the vagus is composed of five primary, topographically separate, parallel, longitudinal columns of neurons; each is associated with a different subdiaphragmatic vagal branch (i.e. one of the two celiac, two gastric, or unpaired hepatic branches). Physiological and behavioral studies have shown that different columns and their respective branches mediate different (and in some cases multiple) functions. In the present ongoing study, the neurons of the different columns were compared in terms of their dendritic fields and morphology to characterize the substrate(s) for differential control of vagal responses. The preganglionics in individual columns were labeled by retrograde transport of fast blue (Brain Res. 341(1985) 269-282). Then the processes of cells randomly selected from these identified neurons (n=173) were stained by intracellular iontophoresis of lucifer yellow (Brain Res. 436(1987) 143-147). The coronal profiles of neurons in each of the celiac columns were more extensive than those in each of the gastric columns on several measures (no. primary dendrites, highest branching order, no. total dendritic segments and percentage of neurons with dendrites extending into the adjacent column). Celiac neuronal profiles were also more extensive than those of the hepatic column, which were similar to those of gastric neurons. The morphological characteristics of the different columns correlate with their different function specializations (Neurosci. Abstr. 12(1986) 644). Within all columns there were also rostrocaudal gradients in the above measures as well as in soma profile area, dendritic orientation, and percentage of neurons with extranuclear dendrites. Horizontal and sagittal views are being studied. (NIH grant DK 27627).

130.7

COLOCALIZATION OF CHOLINERGIC AND CATECHOLAMINERGIC (DOPAMINERGIC) RELATED PHENOTYPES IN NEURONES OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE ADULT WISTAR RAT. C. FEUERSTEIN, M. MANIER*, S. MOUSSAOUI*, P. MOUCHET*, N. MONS*, M. GEFFARD and J. THIBAULT* Lab. Physiology sect. Neurophysiology, INSERM U 318, Fac. Neurology, CHU of Grenoble, BP 217 X, 38043 Grenoble cedex, France.

Neuronal cell bodies containing Tyrosine Hydroxylase (TH) like immunoreactivity have been recently detected in the cervical spinal cord of Wistar rats (Dietl et al., Histochemistry, 1985, 82 : 385-389 ; Mouchet et al., Brain Res. Bull., 1986, 16 : 341-353), some of them being located dorsally to the central canal where they represent the caudal extension of the catecholaminergic cell group of the dorso medial medulla. Some of these cells contain also Choline Acetyl Transferase (Manier et al., Neurosci. Lett., 1987, 80 : 141-146) and they belong to the caudal portion of the dorsal motor nucleus of the vagus nerve (DMNV). To test whether the TH related immunoreactive material present in these cholinergic cells might have functional catecholaminergic properties, we have used immunohistochemical methods with specific antibodies raised against aromatic L-aminoacid decarboxylase, dopa, dopamine and norepinephrine. Our results evidence the presence of both dopa and dopamine related immunoreactivities, without detectable noradrenergic related ones. Both cholinergic and dopaminergic characteristics appear then colocalized in these DMNV cells, their selective target organs being yet unknown.

CATECHOLAMINE DISTRIBUTION IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE CAT: EVIDENCE FOR A ROLE OF NOREPINEPHRINE IN MODULATION OF GASTRIC MOTILITY. P.J. Hornby* D.H. Kuhn* W.P. Norman and R.A. Gillis* (SPON: S.N. Pradhan). Depts of Pharmacology and Anatomy, Georgetown University, Washington, DC.

Catecholamine (CA)-containing cell bodies in the dorsomedial medulla have been well documented; however, the precise organization of CA-containing terminals within nuclei of this region, and a functional role of this innervation remain to be elucidated. Use of antibodies to the CA-synthesizing enzymes and immunocytochemistry reveals striking differences in the distribution and density of fibers immunoreactive (-ir) to tyrosine hydroxylase (TH) and dopamine ß-hydroxylase (DBH). Specifically, a moderate density of TH-ir fibers and a very dense innervation of DBH-ir fibers and terminals is localized in the dorsal motor nucleus of the vagus (DMV). This DBH innervation is most dense in the region of the DMV (1-3mm rostral to the obex) where cell bodies are labelled with HRP-WGA after application of the tracer to the pyloric region of the stomach. Microinjection of norepinephrine (30-100ng) or clonidine (30-175ng) into the DMV results in a marked increase in gastric motility (preinjection minute motility index (MMI) is 0.70 ±0.37; post-injection MMI is 4.81±1.09), but no change in heart rate or blood pressure. The effect of microinjection of clonidine is abolished following i.v. yohimbine (1mg/kg). These data suggest that activation of noradrenergic neurons which synapse in the DMV leads to an increase in gastric motility via stimulation of α2-adrenoceptors. Supported by NIH grant AM 29975.

AREA POSTREMA: GASTRIC VAGAL INPUT FROM PROXIMAL STOMACH AND INTERACTIONS WITH NUCLEUS SOLITARIUS. W.D. Barber and C.S. Yuan*. Department of Anatomy, College of Medicine, University of Arizona, Tucson, Arizona, 85724.

This study was conducted on anesthetized cats to electrophysiologically evaluate the response of neurons in area postrema (AP) to electrical stimulation of 1) gastric vagal afferent fibers which serve the proximal stomach and 2) neuronal populations in nucleus solitarius (NTS) containing neurons which receive gastric vagal input. Small gastric branches of the ventral and dorsal vagal trunks were stimulated with single pulses, 0.3 msec duration, 300 uA at a frequency of 0.5 Hz. One hundred-sixty orthodromic unitary responses to gastric vagal stimulation were recorded bilaterally in AP. The majority of the units recorded in AP received input from gastric afferent fibers traveling in both the ventral and dorsal vagal trunks. The mean latency of the gastric vagally evoked response in AP was 272 ±56 msec. Orthodromic and antidromic unitary responses, evoked by electrical stimulation of NTS were recorded bilaterally in AP. These physiological data demonstrated 1) bilateral reciprocal connections between AP and localized areas of NTS which receive gastric vagal input and 2) unitary responses in AP to input from stimulation of vagal afferent fibers which serve the proximal stomach. These neuronal populations in NTS and AP, activated by gastric vagal afferents, may be functionally involved in the intake of food and/or nausea. (Supported by USPHS Grant DK 31804 and DK 35434).

130.10

ROLE OF THE RAT AREA POSTREMA IN SELECTIVE FACILITATION OF BAROREFLEXES BY VASOPRESSIN. J.D. Peuler*, G.L. Edwards, and A.K. Johnson (SPON: P.G. Schmid). CVC VAMC, Depts Int Med and Psych, U of IA, Iowa City, IA 52242.

Reflex inhibition of heart rate (HR) and renal sympathetic neural activity (RSNA) are facilitated in normal but not area postrema lesioned (APL) rabbits when arterial pressure (MAP) is increased by iv infusions of vasopressin (AVP) compared to phenylephrine (PE) (Circ Res 56:410-417, 1985). Reflex inhibition of HR but not lumbar SNA is facilitated in rats when MAP is increased by AVP vs PE (Vasopressin, Raven Press, NY, 1985, pp 11-18). To determine if effects of AVP on baroreflexes in rats are mediated through the area postrema, we monitored RSNA and HR in APL (n=8) and normal (sham-operated, n=8) rats under chloralose anesthesia during slow increases in MAP (<0.3 mmHg/sec; 3 min) induced iv by AVP (2-20 mU/kg/min) and by PE (1-10 µg/kg/min). Reflex inhibition of RSNA (-%Δ/ΔmmHg) was similar during AVP vs PE in normal (-3.8±0.6 vs -3.4±0.3) and APL rats (-4.4±0.6 vs -3.9±0.4). However, reflex inhibition of HR (-Δbpm/ΔmmHg) was facilitated when MAP was increased by AVP vs PE in normal rats (-2.9±0.5 vs -1.6±0.1, p<0.05) and this facilitation was absent in APL rats (-2.2±0.3 vs -2.2±0.4). Thus, unlike the rabbit, facilitation of baroreflexes by AVP in the rat is limited to HR but not RSNA. However, as in the rabbit, facilitation of reflex bradycardia by AVP is mediated through the area postrema.

130.11

ENHANCED EXCRETION OF SODIUM BY AREA POSTREMA-LESIONED RATS AFTER INTRAGASTRIC SALINE LOADS. G.L. Edwards, T.G. Beltz* and A.K. Johnson. Depts. of Psychology, Pharmacology and the Cardiovascular Center. Univ. of Iowa, Iowa City, IA 52242.

Previous studies indicate that rats with lesions of the area postrema and the adjacent nucleus of the solitary tract (AP-lesions) exhibit a marked increase in intake of concentrated saline solutions ad libitum (Brain Res. 211: 355, 1981). In this study we have examined the ability of rats with AP-lesions to excrete loads of concentrated saline solution. Rats received either sham lesions (n=14) or AP-Lesions (n=13) and were allowed to recover for at least 1 month. At this time AP-lesioned rats consumed significantly greater amounts of 3% saline solution ad libitum than sham operated rats (7.1 ± 1.4 ml/3h vs .4 ± .2 ml/3h). AP-lesioned and sham rats were gavaged with 10 ml 3% saline and urinary volume, sodium, potassium and osmolality were monitored for 6 h. AP-lesioned rats excreted significantly greater quantities of sodium during the first 2 h after the load than did sham operated rats (2.49 ± .22 meq vs 1.69 ± .12 meq). The enhanced excretion was accompanied by an increased urine volume in the AP-lesioned group during the first 2h after the load (9.2 ± .9 ml vs 6.5 ± .5 ml). These data suggest that AP-lesioned rats can excrete sodium loads more efficiently than control rats. Thus, it is possible that the enhanced sodium excretion by AP-lesioned rats contributes to the increased intake of concentrated sodium solutions. (Supported by NIH HL14388)

INTRACELLULAR ANALYSIS OF EXCITATORY NTS INPUTS TO THE NUCLEUS PARABRACHIALIS. A.R.Granata,S.Afshapour and S.T.Kitai. Dept. of Anat. and Neurobiol.,The Univ. of Tenn., Memphis. Memphis TN. 38163.

The nucleus parabrachialis (PBN) is interconnected with the mediocaudal nucleus tractus solitarius (NTS) . Ascending NTS projections to PBN may relay visceral and cardiovascular inputs to the forebrain. In addition, these autonomic signals can be integrated at the level of PBN. Therefore, it was of interest to study the synaptic actions of NTS inputs to the PBN using an intracellular recording technique. Rats were anesthetized with urethane plus ketamine. Excitatory postsynaptic potentials (EPSP) were evoked by ipsilateral NTS stimulation on 38 neurons. EPSP were considered monosynaptic because their latencies did not change with either variations in stimulus intensity or high frequency repetitive stimulation . A short EPSP onset latency ($\bar{X}$: 3.7 ms; S.D.: 0.4) and a long EPSP onset latency ($\bar{X}$: 6.1 ms; S.D.: 0.6) were observed. Six neurons, were antidromically(mean axonal conduction velocity : 4.6 m/sec, S.D.: 0.5) as well as orthodromically (EPSP) stimulated by NTS, indicating that PBN is reciprocally connected with the NTS. EPSPs were evoked by either central amygdaloid nucleus (Ac) or lateral hypothalamic area (HL) stimulation,in some neurons which were excited by NTS stimulation,denoting input convergence in a single neuron between the NTS and the HL or Ac The recorded neurons labeled with HRP were located in the ventrolateral and Kölliker-Fuse subdivisions of PBN. It is concluded, that PBN is monosynaptically excited by two different projections originated in the NTS. Some of these PBN cells in turn, project to the dorsal medulla. (Supported by AMER. HEART ASSOC. GRANT #861294 to A.R.G. and NIH GRANT NS20702 to S.T.K.).

CHARACTERIZATION OF PREPROENKEPHALIN DNA-BINDING PROTEINS
E.F. LaGamma, G. Weisenger, and N. Goldstein. Depts. of Peds. and Neurobiology, SUNY @ Stony Brook, NY 11794-8111

Recent work has shown that several receptor-linked, signal transduction, phosphoprotein mechanisms may act in concert to regulate the transcription of preproenkephalin mRNA in the rat adrenal medulla (La Gamma, Br. Res. 441:292, 1988). To identify relevant gene regulatory proteins, we are exploiting gel retardation assays to initially characterize this system. We have shown binding of medullary (cytosolic and nuclear proteins) to a 299 bp 32P labelled DNA probe representing a key portion of the 5' regulatory region of the preproenkephalin gene. All binding is reduced by increased K+ concentration (10mM). Elevated Na+ concentration (50 mM) appears to enhance binding of certain bands in the absence of K+. A K+ enhancement effect is also evident for some bands in low Na+. Moreover, retained bands are eliminated by proteinase K and are not competed away by nonspecific DNA (poly dA/dT or poly dI/dC). The 299 bp fragment contains a cAMP and phorbol ester conserved site and other regions having over 80% homology with SV40, GCN4, SP1, and AP1 protein binding and regulatory sequences. If binding to these sequences is confirmed by footprint analysis and transfection studies, the evolutionary significance of the apparent presence of shared gene regulatory mechanisms in these diverse systems would be intriguing. Supported by the National Science Foundaiton and Dysautonomia Foundation.

131.2

MODULATION OF HUMAN PRO-ENKEPHALIN GENE EXPRESSION: INTERACTIONS OF RECEPTOR SYSTEMS.
B. C. Beaubien* and J. Douglass* (SPON: E. Hanneman). Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, Oregon, 97201

The experiments reported in this communication provide evidence that induction of gene expression and stimulation of secretion are differentially regulated in neuroendocrine systems. In addition, the ability to inhibit induction of the cAMP-responsive element (CRE) in the human pro-enkephalin gene by G_i-associated receptors is shown to be dependent on cell type; not all receptors which inhibit cAMP synthesis reduce the increase in transcription observed in response to G_s-associated events.

The 5' sequence of the human pro-enkephalin gene has been studied with reference to cAMP responsivity and found to contain a region sensitive to cAMP induction. Attaching this nucleotide sequence upstream from a reporter gene, chloramphenicol acetyl transferase (CAT), allows cAMP-mediated events to be monitored. This system was used to investigate the association between stimulation of secretion and gene expression. Interestingly, in a comparison of two types of cells bearing a similar complement of receptors, the GH_4C_1 and AtT-20 lines, the sensitivity of cAMP-stimulated transcription to inhibition by somatostatin (SST) varied. AtT-20's exhibited the expected inhibition of CRF-stimulated transcription with SST, while GH_4C_1's showed enhanced transcription in cells exposed to medium containing vasoactive intestinal polypeptide (VIP) and SST, over those exposed to VIP alone.

This result is compared to other stimulatory modalities; in particular this divergence from the more simple secretion model is related to the role of Ca^{2+} in the control of cAMP catabolism.

ISOLATION AND STRUCTURAL CHARACTERIZATION OF THE BOVINE TYROSINE HYDROXYLASE GENE
S.R. D'MELLO*, L.M. TURZAI*, A.E. GIOIO*, and B.B. KAPLAN Molecular Neurobiology Program, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213

Investigations into the structure and regulation of expression of the genes involved in catecholamine biosynthesis has led to the isolation of the entire bovine tyrosine hydroxylase (TH) gene. A bovine TH cDNA probe was used to screen a Charon 28 genomic library. Screening of approximately one million recombinant phage resulted in the identification of one positively hybridizing clone. Preliminary results using restriction endonuclease mapping, Southern blot and sequence analysis reveal that the bovine gene contains 13 exons spanning approximately 8kb of genomic DNA. Determination of the transcription initiation site indicates that the TH gene has a 5' untranslated region of 27 bp. A TATA-box sequence is located between positions -29 and -24 from the transcription initiation site and a cyclic AMP regulatory element between -45 and -38. Genomic Southern blot analysis reveals only a small number of positively hybridizing bands with each restriction enzyme suggesting that TH is a single-copy gene in the cow. Comparison of the bovine gene with the TH genes from rat and human reveals striking structural and sequence similarities.

131.4

COMMON TRANS-ACTING FACTORS ARE INVOLVED IN REGULATION OF NEUROTRANSMITTER GENE EXPRESSION BY CYCLIC AMP.
S. E. Hyman, M. Comb* and H. M. Goodman*. Department of Molecular Biology, Massachusetts General Hospital., Boston, MA 02114

Gene expression can be regulated trans-synaptically through the actions of second messengers. Transcription of genes encoding proenkephalin (ENK), vasoactive intestinal polypeptide (VIP), somatostatin (SST), and tyrosine hydroxylase (TH) can be stimulated by cAMP acting through inducible enhancer-like DNA elements. With the discovery that neurons contain multiple transmitters it has become important to understand the mechanisms of coregulation of transmitter synthesis. We have compared the structure and function of cAMP-inducible elements within the ENK, VIP, SST, and TH genes, and have found that they all utilize at least one common trans-acting factor that is required for cAMP induction, as shown by competition for this factor in vivo (cotransfection competition) and in vitro (DNAse I footprint competition). This factor may be identical to CREB (Montminy, M. R. Nature 328:175, 1987). A second factor, AP2, (Mitchell, P. J. Cell 50:847, 1987) binds to the ENK and TH genes and is required for maximal stimulation of ENK transcription by cAMP. SST has a similar binding site. This analysis suggests a mechanism of transcriptional coregulation of cAMP-responsive, neuronally expressed genes, based on competition for binding of limiting trans-acting factors.

EXPRESSION AND CHROMOSOMAL LOCATION OF THE HUMAN LIVER MONOAMINE OXIDASE A AND B.
N.C. Lan*, C. Heinzmann*, I. Klisak*, E. Lai*, R. Sparks* and J. Shih (SPON: J. Rho). Sch. of Pharm., Univ. of South. Calif., L.A., CA 90033, Dep. of Med. UCLA, L.A., CA 90024, Div. of Biol., Calif. Instit. of Tech., Pasa., CA 91125.

Monoamine oxidase (MAO) is the central enzyme responsible for the degradation of neurotransmitters. Based on substrate and inhibitor specificities, two types of MAO, A and B, have been described. MAO A and MAO B from several tissues are shown to consist of two subunits with mol. wts. of 63,000 and 60,000 Kd, respectively.

Using oligonucleotide probes designed from the protein sequences, we have recently isolated two full length cDNA clones encoding human liver MAO A and MAO B. In this report, we have cloned these cDNA inserts into a mammalian expression vector containing the SV40 origin of replication and transfected them independently into COS cells. The enzymatic activities and inhibitor specificities of the expressed proteins obtained from these transfected cells are similar to that of the native proteins, suggesting that both enzymes consist of two identical subunits.

Using somatic cell hybrids, in situ hybridization, and field-inversion gel electrophoresis, we assigned the MAO A and B genes to be located on the x chromosome at xp11.23 and they appear to be closely linked. (Supported by Grant No. MH 39085 and MH 37020)

131.6

STRUCTURAL FEATURES OF HUMAN MONOAMINE OXIDASE A ELUCIDATED FROM PEPTIDE AND cDNA SEQUENCES.
Y-P. P. Hsu*, W.Weyler*, S. Chen, K.B. Sims*, W.B. Rinehart*, M. Utterback*, J.F. Powell* and X.O.Breakefield: E.K. Shriver Ctr., MA; VA Med. Ctr., CA; Beckman Res. Inst., CA; Clinical Res. Ctr., UK; Mass. General Hospital, MA; Harvard Med. Sch., MA

Monoamine oxidase (monoamine:O_2 oxidoreductase; EC 1.4.3.4; MAO) is a crucial enzyme in the metabolism of neurotransmitters such as dopamine, norepinephrine and serotonin. The primary structure for one form of the enzyme, MAO-A, has been determined through cloning and sequencing of a full length 2.0 kb cDNA from human liver. It codes for a 60 kd protein whose deduced sequence is highly homologous to tryptic peptides of MAO-A purified from human placenta. Two MAO-A messages from human placenta and one MAO-B message from human lymphocytes are recognized by this cDNA. Structural features which may be involved in binding of the FAD cofactor and targeting of the enzyme to outer mitochondrial membranes will be discussed.

131.7

STRUCTURE AND EXPRESSION OF A SEROTONIN 5-HT$_{1C}$ RECEPTOR GENE AND ITS cDNA B.J. Hoffman[1], M.H.T. Nguyen*[3], M.H.T. Le*[3], P.R. Hartig[1], H.A. Lester[2], N. Davidson*[2] and H. Lubbert*[3]. Dept. of Env. Health Sci., [1]Johns Hopkins University, Baltimore, MD 21205, [2]Divs. of Biology and Chemistry, Caltech, Pasadena, CA 91125 and [3]Preclinical Research, Sandoz AG, Ch-4002 Basel.

We have recently developed a strategy for the cloning of neurotransmitter and ion-channel genes using electrophysiological assays of mRNA-injected Xenopus oocytes (Lübbert et al. PNAS 84, 4332 (1987)). Using this strategy, we have isolated cDNA clones for the serotonin 5-HT$_{1C}$ receptor from a mouse choroid plexus papilloma. The receptor expressed in oocytes injected with hybrid-selected RNA is fully functional and displays appropriate pharmacology, indicating that a single 5-kb RNA encodes the 5-HT$_{1C}$ receptor. cDNA clones were used to identify mouse genomic clones. This serotonin receptor is homologous to muscarinic and adrenergic receptors, but has an additional hydrophobic region at the amino-terminus which may serve as a signal peptide. Like bovine rhodopsin, the gene of the serotonin receptor contains several introns in the protein coding region while those of adrenergic and muscarinic receptors are unspliced. In addition, we will present evidence for a loss of splicing specificity in choroid plexus tumors.

131.8

GENES INVOLVED IN MPTP NEUROTOXICITY. M.M.S. Lo, M.J. Kadan, S.G. Carlson*, R.C. Douglas*. NIDA, ARC, Baltimore, MD 21224.

Pheochromocytoma (PC12) cells were mutated by infection with a recombinant retrovirus, and selected with 500μM MPP$^+$ (an active metabolite of MPTP). Many different colonies surviving 2 weeks of treatment on MPP+ were isolated. Analysis of the proviral positions in 26 different mutants showed that 5 different loci in the PC12 genome suffered repeated viral mutation. A particular locus was found to contain integrated virus in four different MPP$^+$ selected mutants. This shows that only a few genes are involved in MPP$^+$ neurotoxicity. The provirus and flanking genomic DNA downstream to the virus were cloned from one mutant (M39). At least two distinct messages were detected in normal PC12 cells when the rescued genomic DNA was used as a probe. Three distinct areas in the rescued genomic DNA contained coding sequences. These coding sequences were used to isolate cDNA clones from a normal PC12 cDNA library. Two genes were identified and cloned in this manner. They were found to be unrelated. One gene was found to be induced by more than 20 fold in NGF treated PC12 cells compared to normal PC12 cells. The other gene was unstimulated. These two genes are specifically expressed in PC12 cells. The functional relevance to MPP+ neurotoxicity will be determined by expressing these cloned genes in MPP$^+$ resistant cells Support in part by a grant from Johns Hopkins C.A.A.T.

ISOLATION OF CDNAS ENCODING HUMAN ACETYLCHOLINESTERASE. C. A. Prody* and H. Soreq, Dept. of Biochemistry, Hebrew University, Jerusalem, Israel.

Acetylcholinesterase (AChE) and Butyrylcholinesterase (BuChE) differ in their substrate specificity and sensitivity to different inhibitors. To study the structure-function relationships between human cholinesterases, oligodeoxynucleotide probes were synthesized according to amino acid sequences in evolutionarily conserved and divergent peptides from electric fish AChE compared to human serum BuChE. The screening of a cDNA library from human brain basal ganglia with one of these probes resulted in the isolation of a clone encoding human AChE. This was then used to screen cDNA libraries from human fetal brain, liver and muscle, resulting in the isolation of several considerably longer clones. The peptide sequence deduced from the nucleotide sequence displayed an overall similarity of 51% to human BuChE, 56% to Torpedo AChE, and 31% to Drosophila AChE. In mRNA blots from fetal brain, muscle and liver, these cDNAs hybridized with two bands of 2.5 and 4.5 kb, probably corresponding to the two types of cDNAs that were isolated. Southern blot analysis demonstrated that AChE is encoded by distinct gene(s) from those encoding BuChE. These findings imply that variations in the primary sequence of cholinesterase genes and cDNAs may be implicated in differences in the substrate specificity and sensitivity to inhibitors of their resultant enzyme products.

131.10

IDENTIFICATION OF AN ENHANCER IN THE CHICKEN SKELETAL MUSCLE RECEPTOR ALPHA SUBUNIT GENE. **Y. Wang*#, H.-P. Xu*#, X.-M. Wang*#, M. Ballivet*&, and J. Schmidt#. #Dept. of Biochemistry, State University of New York at Stony Brook, Stony Brook NY 11794, and &Dept. of Biochemistry, Sciences II, University of Geneva, 1211 Geneva, Switzerland.**

The function of the upstream flanking region of the chick muscle acetylcholine receptor alpha subunit gene was investigated. A sequence extending from -1919 to +55 (with respect to the start site) and Bal31-generated deletions thereof were joined to the rabbit beta globin coding region, and the resulting constructs transfected into C2C12 mouse myogenic cells before and after differentiation, and into 3T3 fibroblasts. The reporter gene was transcribed only in C2 myotubes and only when the alpha-derived upstream region was at least 116 nucleotides long. The -116 to -41 segment, in combination with the SV40 early promoter, was functional regardless of orientation even when inserted 1.3 kb downstream of the cap site. Additional tests revealed that a 36-nucleotide fragment (-116 through -81), combined with either the alpha-subunit or the SV40 promoter, was sufficient for tissue- and stage-specific expression. This element retains the ability to stimulate correct transcription upon transposition and inversion, and thus fulfills the criteria of an enhancer. Considering the strength of this enhancer we propose that it is involved in the pronounced transcriptional activation of the alpha subunit gene during differentiation and, possibly, after denervation of mature muscle.

131.11

MOLECULAR MECHANISMS OF NGF GENE TRANSCRIPTION **M. Zheng and G. Heinrich. Lab. Molecular Endocrinology, Dept. Medicine, Howard Hughes Medical Institute, Mass. Gen. Hosp. and Harvard Med. School, Boston, MA 02114.**

NGF production is regulated at the level of transcription and mRNA stability. To study NGF gene transcription, the mouse NGF gene promoter region was analyzed by 5' deletions. In transient expression assays in L929 cells the segment from -36 to -76 was associated with increased, and the segment from -170 to -250 with decreased basal transcription, suggesting opposing regulatory elements are present. In gel retardation assays, a synthetic double-stranded oligonucleotide representing the segment -91 to -139 bound a nuclear factor with high affinity and specificity. Southwestern blots revealed bands at 30 kD and 31 kD that specifically bound the same oligonucleotide. For several other segments from +8 to -250 only low affinity binding patterns were found including in regions that contain the putative opposing regulatory elements. DNase-1 footprinting assays are being carried out in the 5' flanking region to map both high and low-affinity binding sites, and experiments are under way to measure the effects of protein binding on the secondary structure of specific segments of the 5' flanking region. These data indicate that basal NGF gene transcription involves multiple DNA/protein interactions and is functionally complex. Stimulation of NGF gene transcription by regulators such Il-1 as well as developmental and cell-specific regulation may be mediated through related mechanisms.

131.12

BIND AND CLONE: LIGAND-AUTORADIOGRAPHIC RECEPTOR EXPRESSION SCREENING. G.R. Uhl. Gene Nsci. Unit, ARC/NIDA & Depts. of Neurol.& Nsci. Johns Hopkins Med. Sch., P.O. Box 5180, Baltimore, MD 21224.

Study of neurotransmitter receptor genes can facilitate understanding of these important molecules and their regulation, yet classical purification and cloning approaches can be difficult. The high affinity, specificity, sensitivity and spatial localization afforded by receptor autoradiography are desirable properties for identifying receptor binding sites in eukaryotic expression libraries and could allow direct selection of cDNA or gene sequences encoding the receptor.

We have employed a polyester cloth replica-filter technique that: a) Samples cell membranes from eukaryotic cell colonies growing on culture dishes, b) Provides low nonspecific binding with ^{125}I-labeled ligands c) Retains membrane fragments and DNA through receptor autoradiographic incubations and d) Can be aligned with the master plates to recover DNA and/or cells from the regions of the culture plate where receptor expression appears.

We have used this system to screen: a) L-cells transfected with genomic DNA, and b) COS cells transiently expressing cDNA libraries in the eukaryotic expression vector pCDM8. Each of these approaches has yielded apparently-positive DNA-mediated expression of high-affinity ^{125}I-neurotensin binding sites in previously-nonexpressing cells.

132.1

MARKERS FOR THE EARLY SYMPATHOADRENAL LINEAGE. J. Carnahan* and P. H. Patterson (SPON: E. A. DeYoe). Biol. Div., 216-76, Calif. Inst. of Tech., Pasadena, CA 91125.

Adrenal chromaffin cells, sympathetic neurons and small intensely fluorescent (SIF) cells are all derived from the neural crest, but they each have distinctive phenotypes. In order to isolate and study the precursors for this lineage, it would be advantageous to have highly specific monoclonal antibodies (mAbs) directed against their surfaces. Since there is evidence that the precursors share properties with SIF and chromaffin cells, we used the immunosuppression method to obtain such mAbs. Mice were tolerized to neurons by injection of membranes from adult rat sympathetic ganglia and cyclophosphamide and then injected with membranes from neonatal adrenal medullae. Six mAbs were isolated that bind to postnatal chromaffin cells, but not to SIF cells or neurons. These mAbs bind to at least three independent, cell surface epitopes. Most importantly, all of the mAbs stain most, if not all, tyrosine hydroxylase-positive cells in early sympathetic ganglia. Staining is first apparent with the end of crest cell migration, disappears from ganglia by E15, but is maintained in adrenal chromaffin cells. Thus, these mAbs define a putative sympathoadrenal precursor that shares several traits with chromaffin cells.

132.2

SOME PERIPHERAL NEURONS AND PANCREATIC ISLET CELLS OF MAMMALS MAY ARISE FROM A COMMON SOURCE. G. Teitelman. Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Mammalian embryos contain cells that express several neuronal antigens but do not originate in the ectoderm. One of these cell types is pancreatic islet cells which stem from the endoderm. The question is raised as to whether endoderm and/or mesoderm, isolated prior to the arrival of migrating neural crest cells, can give rise to cells that express not only neuronal antigens but also a neuronal morphology. The timing of neural crest cell migration was determined using immunohistochemical techniques in a line of transgenic mice harboring a hybrid insulin gene (Hanahan, Nature 1985). In transgenic mouse embryos, neural crest cells express the insulin gene construct during migration. Migrating neural crest cells are first seen at E10. Therefore, at day 9 of development (E9; 4-10 somites) peripheral tissues lacked stained neural crest cells. To test the potentiality of the endoderm (and/or mesoderm), the neural tube was removed from mouse embryos at E9 (smaller than 10 somites) and the remaining tissues were examined after several days in culture. The embryonic explants contained endocrine cells that expressed pancreatic hormones, tyrosine hydroxylase (TH) and Neuronal Specific Enolase (NSE), two neuronal specific enzymes. The explants also contained cells that displayed a characteristic neuronal morphology and also stained with antisera against TH and NSE. These findings indicate that the endoderm and/or mesoderm contains cells able to express typical neuronal traits in culture and that these cells may differentiate into endocrine cells or neurons.

132.3

PROLIFERATION AND DIFFERENTIATION OF EMBRYONIC CHICK SYMPATHETIC NEURONS: EFFECTS OF CILIARY NEUROTROPHIC FACTOR (CNTF). H. Rohrer*, U. Ernsberger* and M. Sendtner* (SPON: Y.-A. Barde). Max-Planck Institute for Psychiatry, D-8033 Martinsried, FRG

Chick paravertebral sympathetic ganglia contain at early developmental stages (embryonic day 7) a cell population which divides in culture while expressing various neuronal properties. In the attempt to identify factors that control neuronal proliferation we found that CNTF specifically interferes with the proliferation of those cells expressing neuronal markers.

In addition, CNTF affects the differentiation of sympathetic ganglion cells by inducing the expression of VIP-immunoreactivity (VIP-IR) and by increasing the activity of choline acetyltransferase, which are markers for cholinergic sympathetic neurons. Whereas tyrosine hydroxylase immunoreactivity and VIP-IR was expressed by 85±5% and 0% of the cells respectively after 1 day in culture, after 4 days 50-60% of the cells expressed VIP-IR in the presence of CNTF. These results indicate that VIP-IR is induced in cells which initially express tyrosine hydroxylase immunoreactivity.

These findings suggest a role for CNTF as a factor affecting the proliferation and differentiation of developing sympathetic neurons.

COMMON PROGENITOR CELL FOR SENSORY AND AUTONOMIC NEURONS IN THE QUAIL NEURAL CREST. Maya Sieber-Blum. Dept. of Anatomy and Cellular Biology, Medical College of Wisconsin, Milwaukee, WI 53226.

In the vertebrate embryo the neural crest gives rise to all autonomic, all spinal sensory, and some cranial sensory neurons. Due to a lack of specific markers for sensory neuroblasts, little is known about the earliest stages of sensory and autonomic neuron development. In particular, it is not known if the neural crest contains cells that can generate both sensory and autonomic neurons, or if the two lineages segregate before the onset of neural crest migration. To answer this question, we first established that the stage-specific embryonic antigen 1 (SSEA-1) is a specific marker for embryonic sensory neurons in the quail. Three populations of sensory neuroblasts were observed in primary neural crest explants, 1) a small population consisting of late-migrating, early differentiating cells with a very limited proliferative potential, 2) a larger population of late-migrating, early-differentiating cells with a high proliferative potential, and 3) a large population of early-migrating, late-differentiating cells with a high proliferative potential. In vitro clonal analyses showed that the progeny of individual neural crest cells can indeed give rise to both autonomic (SSEA-1$^-$/dopamine-β-hydroxylase$^+$) and sensory (SSEA-1$^+$/dopamine-β-hydroxylase$^-$) neuroblasts. We observed two types of precursor cells. One type also gave rise to pigment cells in addition to autonomic and sensory neuroblasts, the other one did not generate melanocytes.

Our data are compatible with the view that the neural crest not only contains sensory neurons that segregate early in development, but also at least two types of progenitor cells common to the sensory and autonomic neuronal lineages. (Supported by USPHS grant HD21423)

CHANGES IN PROTEIN KINASE C ACTIVITIES ARE CORRELATED WITH CHANGES IN THE MORPHOGENETIC AND DIFFERENTIATIVE PROPERTIES OF NEURAL CREST DERIVED CELLS OF EARLY AVIAN EMBRYOS. G. Ciment, L. Hess* and T. Chamberlin*. Dept. Cell Biology & Anatomy and the Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

In previous work, we found that the phorbol ester drug 12-O-tetradecanoyl phorbol acetate (TPA) has major effects on the developmental properties of early neural crest-derived cells. First, TPA-treatment of cultured dorsal root ganglion (DRG) cells increases the extent of migration of these crest-derived cells upon subsequent grafting into host embryos. And second, TPA reverses the developmental restriction of melanogenesis that occurs early in peripheral nervous system development, causing Schwann cell precursors to undergo a metaplastic transformation into melanocytes.

In this study, we examine whether these effects of TPA may be mediated by changes in endogenous levels of protein kinase C (PKC) activities. We report that low levels of PKC activities correlate well both with changes in migratory behavior, as well as with the adventitious pigmentation of DRG cells. This correlation occurs, moreover, both during normal development, as well as with TPA treatment in culture. These results suggest that regulation of endogenous levels of PKC may play a role in controlling both the migration of neural crest cells, as well as their developmental fate.

IMMORTALIZATION OF CENTRAL DOPAMINERGIC CELLS BY THE FUSION OF ROSTRAL MESENCEPHALIC TEGMENTAL (RMT) CELLS WITH NEUROBLASTOMA (N18TG2) CELLS. H.K. Choi*, A. Heller, P.C. Hoffmann, P.J. Kontur, L.A. Won, D.N. Hammond, B.H. Wainer, and A.P. Fox. Dept. of Pharmacological and Physiological Sciences, The Univ. of Chicago, Chicago, IL 60637.

Clonal hybrid cell lines expressing high levels of dopamine (DA) have been developed from RMT of mice employing somatic cell fusion techniques. RMT cells from embryonic day 14 mice were fused with N18TG2 cells deficient in hypoxanthine phosphoribosyl transferase (HPRT). After the fusion, hybrid cells were selected in a medium containing hypoxanthine/aminopterine/thymidine which selects against HPRT-deficient N18TG2 cells. These hybrid cells retain chromosomes from both RMT and N18TG2 cells. Among the hybrid lines obtained, one expressed a high level of DA (100 ng/mg protein), another a high level of 3,4-dihydroxyphenylalanine (DOPA) (120 ng/mg protein), and a third no detectable level of catecholamines (<0.1 ng/mg protein). The DA and DOPA line also express norepinephrine (30 ng/mg protein). The dopamine line has characteristics typical of central dopamine cells including high endogenous catecholamine levels, catecholamine specific histofluorescence, neurite formation with immunoreactivity to the neurofilament proteins (NFP), large voltage-sensitive sodium currents (2000 pA/cell peak current), and an ability to aggregate in rotation-mediated cell culture. Supported by NIMH MH28942 and GM07151.

CELLULAR SUBSETS IN NEURAL CREST CELL DIFFERENTIATION
G.D. Maxwell and M.E. Forbes*. Department of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

Previous work using cell sorting and cell culture showed that neural crest cells sorted as HNK-1+ give rise to catecholamine-positive (CA+) cells, melanocytes, and unpigmented cells, whereas cells sorted as HNK-1- give rise to melanocytes and unpigmented cells, but few, if any, CA+ cells (Forbes et al. 1987 Soc. for Neurosci. Abstr. 13: 182).

We have extended these results by analyzing the developmental behavior of subpopulations of the HNK-1+ neural crest cells. The differentiation of the brightest third of the HNK-1+ cells was compared to the remaining HNK-1+ cells. Numerous CA+ cells arose from both populations, along with melanocytes and unpigmented cells. In contrast, when the development of the brightest third of the HNK-1+ cells was compared with that of the remaining HNK-1+ cells grown together with the HNK-1- cells, many CA+ cells developed from the brightest third of HNK-1+ cells, but few CA+ cells differentiated from the less bright HNK-1+ cells grown together with the HNK-1- cells. Melanocytes and unpigmented cells were seen in both populations. These results indicate that the capability to become CA+ is not restricted to the brightest HNK-1+ cells, but the presence of HNK-1- cells may alter the ability of some HNK-1+ progenitors to become CA+ cells.

REGULATION OF NEUROTRANSMITTER PHENOTYPE IN DEVELOPING PRIMARY SENSORY NEURONS. D.M. Katz. Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

Factors regulating neurotransmitter phenotype in primary sensory neurons, including the role of target tissues, are poorly understood. In the petrosal ganglion (PG) of adult rats, 80-90% of tyrosine hydroxylase (TH)-containing sensory neurons innervate a single target, the carotid body, indicating that catecholaminergic (CA) phenotypic expression and the pattern of peripheral innervation are highly correlated. To define regulation of CA phenotypic development in the PG, immunocytochemistry and Western blots were used to analyze TH expression in vivo and in culture. TH is first detectable at very low levels in carotid body afferents on embryonic day (E) 16.5 in vivo. TH levels rise sharply at birth resulting in a 4-5 fold increase in the number of immunoreactive cells by postnatal day 1. To examine the role of neuron-target interactions in TH expression at E16.5, PG were explanted to culture on E14.5 and grown in the absence of the carotid body. TH-positive neurons were detected after two days in culture, suggesting that target tissues are not required for enzyme expression in vivo . Preliminary data indicate that many developing ganglion cells are capable of expressing TH; therefore, the pattern of target innervation may restrict expression of the CA phenotype to appropriate subpopulations of sensory neurons. NEURAL-CREST ORIGIN OF HEART CONDUCTION TISSUE MYOCYTES IS SUGGESTED BY THE EXPRESSION OF NEUROFILAMENT PROTEINS.
M.Vitadello, S.Schiaffino*and L.Gorza*. C.N.R.-I.F.C.N., Milano and Inst. of General Pathology, Padova, ITALY.

Neurofilaments(NF) are the neuron specific class of intermediate filaments and anti-NF antibodies have been widely utilized as markers of neuronal cells. We present evidence for the presence of the low(NF-L) and middle(NF-M) molecular weight subunits of NF in the rabbit heart conduction system myocytes. 2 anti-NF-M and 1 anti-NF-L mAbs decorate a population of cardiac myocytes exclusively localized in the sino-atrial and atrio-ventricular nodes and His bundle. On immunoblots cardiac proteins recognized by anti-NF mAbs have the same electrophoretic mobility as NF-M and NF-L in the sciatic nerve. Reactivity due to contaminating cardiac nerves was excluded. We performed in addition an immunohistochemical study on hearts of rabbit embryos at various stages of development. It confirms the specificity of anti-NF antibodies for heart conduction system cells. Moreover it reveals that a number of NF-reactive cells in the embryonic hearts are in close contiguity with clusters of labelled cells localized in the 3rd and 4th branchial arches. All of these NF-reactive cells also display immunoreactivity for HNK-1 mAb, a marker of neural-crest derived cells.

REGULATION OF TYROSINE HYDROXYLASE mRNA IN CATECHOLAMINERGIC CELLS OF THE EMBRYONIC RAT: ANALYSIS BY IN SITU HYBRIDIZATION. G. M. Jonakait, M. Rosenthal* and J. I. Morrell, Dept. of Biol. Sci. and Inst. for Animal Behavior, Rutgers Univ., Newark, N.J. 07102

In situ hybridization was used to examine the appearance of mRNA specific for tyrosine hydroxylase (TH) in the peripheral nervous system of the rat embryo, including sympathetic ganglia (SG) and transiently catecholaminergic cells of the embryonic intestine. mRNA was first detected in SG at E11.5, the age corresponding to the initial immunohistochemical detection of TH protein. By contrast, mRNA for TH was difficult to detect in embryonic intestines at E11.5, but was found instead in cells clustered at the dorsal boundaries of the pharynx and foregut. Cells expressing TH mRNA were infrequently found in embryonic intestines of any age, even when TH protein was apparent. Treatment of pregnant rats with reserpine on E11.5 dramatically increased the number of gut cells at E12.5 with detectable TH mRNA. However, after E13.5 TH mRNA was undetectable even in reserpine-treated guts. These data are consistent with the hypothesis that the microenvironment of the embryonic intestine affects gene expression directly to alter phenotype. Moreover, while reserpine administration briefly increases TH mRNA levels, the effect is short-lived, and does not alter phenotypic conversion. Supported by grants NS23687 and HD22983. GMJ and JIM are Johnson & Johnson Discovery Research Fellows.

CHANGES IN ULTRASTRUCTURE AND INTERMEDIATE FILAMENT PROTEINS IN RPE AND RETINAL GLIA FROM HUMAN AND RABBIT EPIRETINAL MEMBRANES AND VITREOUS CULTURES. S. A. Vinores, H. A. Sen*, S. F. Hackett* and P. A. Campochiaro*. Dept. Ophthalmology, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Cellular epiretinal membranes are a significant cause of visual morbidity. The processes that lead to their development are not well understood. The participation of several cell types, including retinal pigment epithelium (RPE) and retinal glia, has been suggested based upon ultrastructural characteristics and light immunohistochemistry. We used electron immunocytochemistry to study cells in human epiretinal membranes obtained at surgery and compared them to RPE and retinal glia in animal and in vitro models of epiretinal membranes. Our data suggest that RPE cells which are normally keratin positive (K^+) may undergo transformation in epiretinal membranes to undifferentiated K^+ cells with large nuclei and sparse cytoplasm, polarized K^- cells with numerous microvilli, or K^-/fibroblast-like cells deep within the extracellular matrix. Some glial cells (GFA^+) appear to progress to cells which are morphologically indistinguishable from undifferentiated RPE cells. These data suggest that cells in epiretinal membranes may undergo alterations in both morphology and intermediate filament expression due in part to extracellular surroundings, and that neither alone is a reliable marker for cell identification.

132.12

MICROGLIAL AND MACROGLIAL MARKERS ARE SIMULTANEOUSLY EXPRESSED IN AN IMMORTALIZED CEREBELLAR MOUSE CELL CLONE.
B. Pessac and F. Alliot*. Centre de Biologie Cellulaire, C.N.R.S., 94205 Ivry-Sur-Seine Cedex, France.

The glia of the central nervous system (CNS) comprises the macroglia, i.e. astrocytes and oligodendrocytes, and the microglia, the origin of which remains unclear. We have recently shown that very rare single cells, dissociated from various brain regions of the adult and embryonic mice and cocultured on monolayers of an immortalized "velate protoplasmic like" cerebellar astroglial clone (Brain Res., 306:283, 1984), give rise to foci of around 200.000 cells each. The vast majority of these cells exhibit simultaneously a mixed macroglial and microglial phenotype (manuscript in preparation). These data led us to analyze the phenotype of a clonal cell line with an oligodendroglial like morphology that was spontaneously immortalized at the same time as the astroglial clones. All cells of this clone express simultanesouly microglial markers i.e. the Mac-1, F4/80 and Leu M3 epitopes, the Ia antigen and receptors for the acetylated form of the low density lipoprotein as well as macroglial markers, i.e., GFAP, GalC, MBP and PLP. Taken together these data show that the mouse CNS contains quiescent stem cells that can give rise in vitro to cells with a double microglial and macroglial phenotype.

RESPONSES OF NEONATAL AND ADULT GLIAL PROGENITORS TO NEURONAL CELL LINE-DERIVED MITOGENS. Samuel F. Hunter*, Matthias F. Seidel*, and Jane E. Bottenstein. Univ. of Texas Medical Branch, Dept. of Pharmacology-Toxicology, the Marine Biomedical Institute, and Dept. of Human Biological Chemistry & Genetics, Galveston, TX 77550.

We have reported earlier a trypsin-sensitive, mitogenic activity of conditioned medium (CM) derived from the B104 neuronal cell line (Bottenstein et al., J. Neurosci. Res. 20, in press) on A2B5$^+$ neonatal glial progenitors (GPs) in mixed glial cultures. We now find similar responses in both enriched neonatal GP and 30 day old-rat brain glial cultures. Enriched neonatal GPs were assessed by combined immunostaining and ^{3}H-thymidine autoradiography. After 1 day in tertiary culture, A2B5$^+$ cells had a maximal labelling index (LI) of 37% with 12 μg CM/ml, while control had 5%. At this time, control cultures contained <10% type 1 astrocytes and >75% A2B5$^+$. Continued survival of GPs required addition of 33% astrocyte CM, and after 3 days A2B5$^+$ cells showed a maximal LI of 68% with 16 μg B104 CM/ml, but only 7% with astrocyte CM alone. Enriched GPs respond similarly to those in mixed primary cultures containing 40% astrocytes, so the mitogenic action of CM factors is probably not mediated by the type 1 astrocyte. Mature rat brain glia were plated in 15% calf serum in DME and switched at 3 DIV to O3 medium with or without 8 μg B104 CM/ml. At 7 DIV, CM-treated A2B5$^+$ cells had LIs of 41% versus 14% control, and for galactocerebroside$^+$ (GalC$^+$) cells 3% versus 0.7%. At 10 DIV, A2B5$^+$ and GalC$^+$ cells were increased 8- and 1.7-fold, respectively. (NIH Grant NS20375)

SENSORY SYSTEMS: AUDITORY SYSTEMS I

PRODUCTION OF ENKEPHALINS BY OLIVOCOCHLEAR NEURONS DEMONSTRATED BY IN SITU mRNA HYBRIDIZATION. A.F. Ryan[1], D.M. Simmons[2,3], A.G. Watts[2], and L.W. Swanson[2,3]. [1]Depts. of Surgery/Otolaryngology and Neurosciences, UCSD School of Medicine and V.A. Medical Center, [2]Neural Systems Laboratory, Salk Institute, and [3]Howard Hughes Medical Institute, La Jolla, CA 92093.

Gerbils were injected in one cochlea with 2% fluorogold and in the other with 2% fast blue. After 24 hrs. their brainstems were prepared for in situ RNA hybridization. Alternate slides were treated with proteinase-K or Triton-X100 to increase hybridization in the fixed tissue. Sections were hybridized with a single stranded RNA complimentary to preproenkephalin mRNA, in which all uridine groups were labeled with ^{35}S. Sections were dipped in liquid emulsion for autoradiographic and fluorescent microscopic analysis.

Fluorogold and fast blue labeled cells were observed in the superior olivary complex and vestibular nuclei (consistent with the location of cochlear and vestibular efferents) of Triton-X-treated sections. Proteinase K digestion reduced fast blue labeling, and had less effect on fluorogold labeling.

Cells positively labeled for preproenkephalin were noted in the ventral nucleus of the trapezoid body, and between the medial superior olivary nucleus and the medial nucleus of the trapezoid body, locations consistent with the medial olivocochlear efferent system. Hybridization was not observed in the lateral superior olivary nucleus, the location of the lateral efferent system in this species. Some retrogradely labeled medial olivocochlear neurons did not display hybridization, indicating that the production of enkephalins is not a universal feature of medial cochlear efferents. Preproenkephalin hybridization colocalized with retrograde labeling in all vestibular efferents examined.

Supported by grant NS14945 from the NINCDS, and the Research Service of the VA. Preproenkephalin template DNA was provided by Dr. S.L. Sabol.

133.2

SYNAPSES FROM OLIVOCOCHLEAR COLLATERALS IN THE MOUSE COCHLEAR NUCLEUS. T.E. Benson[1] and M.C. Brown[2]. Departments of Anatomy and Cellular Biology[1], Cellular and Molecular Physiology[2], and Otolaryngology, Harvard Medical School, Boston, MA 02115; and Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA 02114.

The cochlea receives efferent innervation from cells of the superior olivary complex. Those cells of the medial olivocochlear (OC) group also project axon collaterals to granule-cell regions of the ventral cochlear nucleus (VCN). OC collaterals are thought to form both small boutons and mossy terminals. The latter together with granule and/or Golgi cell dendrites comprise neural glomeruli. In order to study synaptic relationships of OC collaterals in the VCN, we labeled OC axons by HRP injections into the spiral ganglion. Labeled collaterals were characterized by light microscopy (LM) and serial-section electron microscopy (EM).

By LM, OC terminal arbors exhibited extensive branching in and abutting granule-cell regions. Axosomatic contact was rare. Arbors had numerous angular *en passant* swellings and fewer terminal swellings. The morphology of labeled collaterals suggested that much of this specialized arbor was unmyelinated whereas parent axons were myelinated; this was confirmed for several collaterals and parent axons by EM.

The distal portion of the terminal arbor of one labeled collateral was analyzed by extensive EM. This arbor terminated in the posterior division of the VCN on the border of the granule-cell lamina Labeled terminals made asymmetric (thus possibly excitatory) synapses, some having postsynaptic dense bodies. Synapses were found with both tapering and varicose dendrites, suggesting that OC collaterals contact different cell types. Multiple OC synapses were found on a tapering dendrite which issued from a moderately sized (9x20 µm) neuron. The neuron had characteristics of multipolar cells. Although unlabeled mossy terminals were observed, these have not yet been observed coming from the labeled collateral. It is possible that mossy terminals are formed on more proximal portions of the arbor, such as at nodes of Ranvier. Our results indicate that OC collaterals are associated with granule-cell regions, but their postsynaptic targets may be diverse.

133.3

CENTRAL EFFECTS OF COCHLEAR HAIR CELL LOSS IN DEAFNESS MICE. D.B. Webster. Kresge Hearing Research Laboratory, Department of Otorhinolaryngology, LSU Medical Center, New Orleans, LA 70112.

In deafness mice, neither VIII nerve action potentials nor cochlear microphonics ever develop and hair cells start degenerating at 12 days of age. Using light microscopy, serial sections of the cochleas and brainstems were quantitatively studied in 11 groups of deafness mice ranging from 1 to 460 days of age. Through 12 days of age deafness mice have the same number of spiral ganglion neurons as in hearing CBA/J mice. After this there is a gradual loss of spiral ganglion neurons amounting to a 50% decrease by 460 days of age. The number of ventral cochlear nucleus neurons is normal through 9 days of age but from then through 460 days of age the number remains constant at 20% fewer than in CBA/J mice. Dorsal cochlear nucleus volume growth in deafness mice is indistinguishable from that in normal hearing CBA/J mice. However ventral cochlear nucleus volume stops increasing at 24 days of age and is more than 25% smaller than in CBA/J mice by 90 days of age. Neuronal soma areas in the ventral cochlear nucleus as well as in the superior olivary complex never attain the sizes found in CBA/J mice being on the average 20% smaller, These data are consistent with the hypothesis that central anatomical changes with peripheral deafness are caused by a lack of neural activity, spontaneous and/or evoked.

Supported by NIH grant NS-19238 and Kam's Fund.

133.4

EFFECTS OF AMINO ACID ANTAGONISTS ON AUDITORY NERVE SYNAPTIC POTENTIALS P. A. Starr * and W. F. Sewell Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Department of Otolaryngology, and the Program in Neuroscience, Harvard Medical School, Boston, MA 02114.

The identity of the neurotransmitter released by hair cells of the inner ear is unknown. However, it has been reported that transmission at the hair cell-afferent neuron synapse can be blocked by glutamate antagonists (Annoni *et al., J. Neuroscience* 4:2106, 1984). We have studied the effects of glutamate antagonists on sound-evoked synaptic potentials and on spontaneous miniature synaptic potentials (smsp's) in the goldfish auditory nerve. Because smsp's appear to correspond to the release of a single quantum of transmitter (Furukawa *et al., J. Physiol.* 276:211, 1978), we can infer whether the site of action of the drug is pre- or postsynaptic by comparing the effect of the drug on the amplitude of smsp's to the effect on the amplitude of sound-evoked synaptic potentials.

Synaptic potentials in the auditory (saccular) nerve of ketamine-anesthetized goldfish (10-16 cm long) were monitored with glass micropipettes. The hair cell-afferent nerve synapses were continuously superfused with a balanced salt solution, or with the same solution containing a drug to be tested. The sound stimuli (40 msec tone bursts) were delivered via an earphone into a closed cavity surrounding the fish's body posterior to the gills.

Both a broad-spectrum glutamate antagonist, gamma-DGG (gamma-d-glutamylglycine, 1.0 mM), and a specific NMDA (N-methyl-d-aspartate) receptor antagonist, APV (5-aminophosphonovaleric acid, 2.0 mM), completely and reversibly blocked sound-evoked synaptic potentials. However, the amplitudes of smsp's were only partially blocked at these concentrations. The antagonists had no noticeable effect on the microphonic potential, showing that they did not grossly alter current flow through hair cells. The fact that glutamate antagonists can partially block smsp's suggests that the transmitter receptor on auditory nerve terminals may be pharmacologically related to excitatory amino acid receptors in the CNS. However, the fact that glutamate antagonists can completely block sound-evoked potentials at a concentration that only partially blocks smsp's suggests that they also act presynaptically to reduce the number of quanta released for a given sound stimulus. Thus, the predominant actions of the glutamate antagonists were presynaptic.

133.5

AN ADDITIONAL DIMENSION IN THE TOPOGRAPHIC ORGANIZATION OF THE SPIRAL GANGLION PROJECTION TO THE VENTRAL COCHLEAR NUCLEUS. P. A. LEAKE* and R. L. SNYDER* (SPON: P. T. Ohara). Coleman and Epstein Labs, Dept. of Otolaryngology, Univ. of California, San Francisco, CA 94143-0526.

The morphological organization of inputs from restricted sectors of the cat cochlear spiral ganglion into the cochlear nucleus was studied by making discrete injections (0.05-0.5μL) of horseradish peroxidase (HRP) into the spiral ganglion within Rosenthal's canal. Injections produced Golgi-like labeling of a small cluster of ganglion cells.

Large injections labeled sectors of the spiral ganglion innervating ≥1mm (≈1 critical band distance) of the basilar membrane and resulted in discrete laminae of labeled axons and preterminal fields within each cochlear nucleus subdivision. The positions of these bands were consistent with the "isofrequency" laminae appropriate for the frequencies represented at the injection site. That is, bands of labeled fibers in the posteroventral (PVCN) and anteroventral (AVCN) cochlear nucleus were oriented in a roughly horizontal plane with high frequency laminae situated dorsally and lower frequencies progressively more ventral. These projection laminae extended across the entire lateral to medial dimension of the VCN. Labeled stripes in the dorsal cochlear nucleus (DCN) were oriented at an angle of approximately 60° relative to the laminae in the VCN. In DCN projecting fibers and terminals did not reach the dorsal margin of the nucleus but were excluded from the molecular cell layer.

In contrast to larger injections, very small HRP deposits labeled only a column or partial isofrequency lamina in the VCN. Specifically, injections restricted to the ventral (scala tympani) portion of the spiral ganglion labeled only the lateral portion of VCN isofrequency laminae, while dorsal injections (scala vestibuli aspect of the ganglion) projected to the medial aspect of the isofrequency planes. These data suggest a previously unrecognized topographic organization of the spiral ganglion, orthogonal to the frequency domain. That is, in addition to the spiral dimension (represented by the dorsal to ventral frequency map in the VCN) there is also an orderly and sequential topographic projection of inputs from the ventral to dorsal aspect of the spiral ganglion across the lateral to medial dimension of each lamina.

Supported by NIH Grant NS-16361 and the S. and I. Epstein Fund.

133.6

SEPARATE CODING OF HIGH AND LOW TEMPORAL ENVELOPE FREQUENCIES IN THE AUDITORY FOREBRAIN OF THE MYNAH BIRD. B. Hose and G. Langner. Inst. of Zool., Technical Univ., Schnittspahnstr. 3, 6100 Darmstadt, FRG.

Rhythms and pitch in natural communication sounds correspond to periodic amplitude fluctuations of signal envelopes with low or high envelope frequencies (EFs), respectively. Most auditory forebrain units in field L of mynah birds (Gracula religiosa) are tuned to a certain best envelope frequency (BEF). Field L is three-layered and tonotopically organized, with isofrequency planes cutting across the three layers L_1, L_2 and L_3. L_2 is the input layer. L_1 and L_3 are postsynaptic to L_2. BEFs are mapped within isofrequency planes. A BEF-map across all layers was found in terms of a synchronization criterion, the vectorlength R (Hose, B. et al., *Brain Res*, 422:367, 1987). R = n r is a mixed criterion and takes into account the neuronal discharge rate n as well as the probability r that the discharges are synchronized to the envelope of the stimulus. Further analysis of spike patterns and comparison of R, n and r as a function of EF revealed differences between the layers and between coding of high and low EFs: Besides the topological representation of predominant low BEFs in the postsynaptic layers and predominantly high BEFs in the input layer, a partly translation from a neuronal synchronization code to a rate code from pre- to postsynaptic layers provides evidence that **rhythm** information is **processed** at the forebrain level. In contrast, the percentage of units with temporal tuning mechanisms resembling those in the midbrain (Langner, G., *Exp Brain Res*, 52:333, 1983) suggests that **pitch** information which is already processed at the midbrain level is also **represented** in the input layer of the forebrain level. *Supp. by DFG.*

TONOTOPIC ORGANIZATION OF THE HUMAN AUDITORY CORTEX UTILIZING A MULTI-CHANNEL SQUID SYSTEM. T. Yamamoto*, W. Hosteller*, S.J. Williamson, and R. Llinás. Dept. of Physiology. & Biophysics, NYU School of Medicine, New York, NY 10016 and Dept. of Physics, New York University, 4 Washington Place. New York, NY 10003.

Progress in multi-channel SQUID (super-conductive quantum interference device) technology and a three-dimensional probe position indicator (PPI) has made it possible to record human brain magnetic fields at 14 sites simultaneously. By recording the surface magnetic fields generated by neuronal activity, the equivalent current dipole location may be estimated within a clinically reasonable time period. This non-invasive, real time (DC to 3KHz) technique has better spatial resolution than EEG or PET, and displays functional information from given brain regions which can be combined with CAT and MRI information. The present system consists of two probes each containing 8 dc SQUIDs and 3 rf SQUIDs, together with PPI and supporting electronics installed in a magnetically shielded room. Typical overall system noise is 20 to 30 fT/ $\sqrt{\text{Hz}}$. Analysis of the iso-magnetic field contour map allows the localization of neuronal activity and the characterization of its source strength. The average error in the dipole location for fields of physiological strength was 2 mm using a spherical head model containing a current dipole in a saline solution. Methods have also been developed for superimposing the characteristic tonotopic organization of the auditory cortex on an MRI. This will be illustrated for randomized auditory stimuli. The work was supported by NIH grant NS13742.

133.8

FISH SPATIAL HEARING REQUIRES BINAURAL ANALYSIS OF SOUND PRESSURE AND PARTICLE MOTION. N.A.M. Schellart and R.J.A. Buwalda (SPON: European Neuroscience Association). Laboratory of Medical Physics, Acad. Med. Center, Univ. of Amsterdam, Meibergdreef 15, 1105 AZ Amsterdam.

Without a cochlea, but with a swimbladder as a middle-ear analogon, fish hearing rivals that of higher vertebrates. The gas-filled bladder transforms sound pressure (p) into pulsations with body-fixed orientation that reach the nearby labyrinths, thus displacing the hair cells relative to the massive otoliths. The otolith organs are also stimulated directly by the particle motion vector (v) in line with the source because the fish oscillates with the water. The vectorsum of these "indirect" (p-induced) and "direct" (v) stimulations, which are not in phase, will result in elliptical displacement orbits (Schellart & de Munck, JASA 82:822, 1987). We surmise that these are centrally analyzed, with the sensory maculae mapped out on octaval nuclei, as in gravistatic detection. This provides fish with superior 3-D spatial hearing, without need for the binaural intensity and time difference cues used by man. According to this essentially monaural hypothesis, directional hearing should show strong azimuthal anisotropies.

In search of any such anisotropies we have studied trout in psychophysical heart rate conditioning paradigms, employing superpositioning of standing waves for total control of v direction and of phase and amplitude of v and p. Masked detection thresholds were determined as a function of source direction for two conditions: a 100 Hz probe signal with "normal" p/v phase and amplitude ratios, and a "pure v" signal together with a "pure p" noise masker. Omnidirectional v noise was always present. High or low thresholds were expected near 0° and 180°, since direct and indirect input are then (anti)paralel. However, these expected anisotropies did turn up only if the indirect input was mimicked by a longitudinal v vector of appropriate phase and strength. As in this case the sumvectors for both ears are identical, we conclude that in the normal case the surprising absence of any axis of directional sensitivity must be attributed to the processing of binaural differences introduced by bilaterally symmetrical components of the slightly diverging left and right indirect inputs.

133.9

EXPERIMENTAL VERIFICATION THAT INTERTYMPANIC COUPLING IS THE PREDOMINANT SOURCE OF DIRECTIONAL SOUND SENSITIVITY OF THE TREEFROG'S EAR. R.R. Capranica, Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853 and A. Michelsen*, Inst. of Biology, Odense Univ., DK-5230 Odense, Denmark

Behavioral studies have demonstrated that anurans(frogs and toads) can localize a low-frequency sound source with remarkable accuracy even though they lack an external ear (pinna or canal) and have small heads. The basis for this ability presumably resides in a pressure gradient mechanism whereby the anuran's eardrum receives sound at its external surface as well as at its internal surface. By means of laser vibrometry, we have measured the amplitude and phase of vibration of the eardrums of awake, unrestrained green treefrogs (Hyla cinerea) both before and after blocking the movement of the contrlateral eardrum in response to sounds of systematic incidence from 0 to 360°. The eardrum of an untreated adult green treefrog exhibits a change in vibrational amplitude of up to 10 dB or more with changes in azimuth, exhibiting a sharp decrease when the sound impinges directly from the contralateral side compared to the ipsilateral side. This directionality is dependent on frequency and is greatly reduced when the contralateral eardrum is coated with a heavy layer of grease. Coupling through the floor of the mouth, nares, or body via the lungs plays a much smaller role, as shown by selectively blocking each of these routes while measuring the vibrational amplitude and phase of the exposed eardrum

133.10

COMPARATIVE PHYSIOLOGY OF AUDITORY LOCALIZATION IN OWLS. S. F. Volman and M. Konishi. Biol. Div., 216-76, Calif. Inst. of Tech., Pasadena, CA 91125.

Bilateral ear asymmetry evolved in only some lines of owls. Barn owls use asymmetry for two-dimensional sound localization. Azimuth is computed from interaural time differences (ITD), and elevation from interaural intensity differences (IID) created by the vertical asymmetry. In a part of inferior colliculus (ICx), neurons tuned for ITD and IID are arranged into a map of auditory space.

We recorded from ICx in three other owl species: the great horned and burrowing owls with symmetrical ears, and the asymmetrical long-eared owl. In each species we found a map of azimuth entirely dependent on ITD. In the symmetrical owls, ICx neurons were insensitive to elevation; the long-eared owl had weak elevation tuning, probably based on IID. Curiously, in the symmetrical owls, the cells did require binaural stimuli, although they all preferred nearly equal interaural intensity, whereas the barn owl has a range of best IIDs. The frequency ranges of ICx units were: burrowing owl, 2-4 kHz; great horn, 2-5 kHz; long-eared, 2.5-7 kHz; and barn owl, 3-8.5 kHz.

These data suggest three generalizations: 1) All owls use ITD alone to code azimuth; 2) the use of IID cues in asymmetrical owls correlates with higher frequency hearing; and 3) the existence of binaurally exclusive IID tuning in symmetrical owls may have facilitated the evolution of asymmetry.

133.11

COMMISSURAL PROJECTIONS MEDIATE INHIBITION IN A LATERAL LEMNISCAL NUCLEUS OF THE BARN OWL. T.T. Takahashi and M. Konishi, Inst. of Neurosci., Univ. of Oregon, Eugene, OR 97403 and Div. of Biol., Caltech, Pasadena, CA 91125.

Nucleus ventralis lemnisci lateralis pars posterior (VLVp) is the first site in the owl's auditory system at which are found neurons sensitive to interaural level difference, the owl's cue for sound-source elevation. VLVp cells are excited and inhibited by stimulation of contralateral and ipsilateral ears respectively. The excitation arrives via a contralateral input from nucleus angularis, the cochlear nucleus specialized for coding sound level. Present tracer studies revealed commissural projections from one VLVp to the other which can account for the ipsilateral inhibition. Specifically, inhibitory cells in, say, the right VLVp are driven via the left nucleus angularis and project commissurally, thus enabling the left ear to inhibit the ipsilateral (left) VLVp. As a test of this hypothesis, we recorded from neurons in VLVp while locally anesthetizing VLVp of the opposite side (18 neurons, 3 owls). Injection of anesthetic (0.2 ul) rendered the binaural neurons insensitive to ipsilateral stimulation, making them monaural. Recovery took about 20 minutes if injection and recording sites had the same best frequencies. Otherwise recovery was quicker, suggesting that the projection is tonotopically organized. No convincing evidence of other inhibitory sources was observed.

133.12

ORGANIZATION OF INTERAURAL-INTENSITY-DIFFERENCE SENSITIVITY WITHIN FREQUENCY BAND STRIPS OF CAT PRIMARY AUDITORY CORTEX. D. R. F. Irvine, R. Rajan*, and L. M. Aitkin*. Depts. Psychology and Physiology, Monash University, Clayton, Vic. 3168, Australia.

The organization of neuronal sensitivity to interaural intensity differences (IIDs) in the primary auditory cortex (AI) was examined in anesthetized cats. IID-sensitivity functions were obtained for single neurons isolated along the dorso-ventral extent of frequency-band strips in the high-frequency region of AI. Four major classes of IID-sensitivity function were distinguished: those with a clearly defined peak response near zero IID; those with maximum response (either a peak or a plateau) at IIDs involving greater intensity at either the contralateral or ipsilateral ear; those that were relatively flat, indicating no sensitivity to IID. In the dorsal part of AI, it was frequently observed that all the neurons encountered within restricted segments of the frequency-band strip had the same form of IID sensitivity, i.e., there was a spatial segregation of different types of sensitivity. However, in all animals there were some regions, particularly in the ventral part of AI, in which there were rapid transitions in the form of IID sensitivity, even when successive neurons were separated by as little as 20-100 μm across the cortical surface. There appears to be an irregular mosaic of different forms of IID sensitivity across frequency-band strips in AI, and any given IID must therefore result in a complex pattern of activity across such a strip.

PAIN MODULATION: PHARMACOLOGY

134.1

POTENTIATION OF NONOPIOID SWIM ANALGESIA BY THYROTROPIN RELEASING HORMONE ADMINISTRATION INTO THE PERIAQUEDUCTAL GRAY IN RATS. J.A. Robertson, M.L. Cooper*and R.J. Bodnar. Dept. of Psychol. and Neuropsychol. Doctoral Sub-Program, Queens College, CUNY, Flushing, NY 11367.

Intracerebroventricular and intrathecal administration of thyrotropin releasing hormone (TRH) has been shown to modulate analgesic responses with the former injection route potentiating a nonopioid form of swim analgesia in rats. Since TRH is found in serotonergic cells implicated in pain inhibition in the midbrain periaqueductal gray (PAG), the present study evaluated the effects of intracerebral PAG injections of TRH (10 ug) upon nonopioid continuous cold-water swim (CCWS, 2°C, 3.5 min) analgesia on the tail-flick and jump tests in rats. Intracerebral administration of TRH into the PAG significantly potentiated CCWS analgesia on the tail-flick, but not the jump test, and concomitantly reduced CCWS hypothermia. When swim temperatures were increased to 21°C, intracerebral TRH produced similar specific potentiations. In contrast, intracerebral TRH failed to alter basal nociception in the PAG. These results indicate that the PAG is an important site of action for TRH modulation of a nonopioid, neurohormonal form of analgesia.

134.2

SELECTIVE GENDER AND GONADECTOMY EFFECTS UPON CENTRAL MORPHINE ANALGESIA. K.L. Kepler, B. Kest J.M. Kiefel, M.L. Cooper* and R.J. Bodnar. Dept. of Psychol. and Neuropsych. Doctoral Sub-Program Queens College, CUNY, Flushing, NY 11367.

Female rats display significantly less analgesia than age-matched males following either systemic morphine, opioid-mediated or nonopioid-mediated swim analgesia. Gonadectomy reduces these analgesic effects further in both genders. Since pharmacodynamic and pharmacokinetic effects cannot be definitively distinguished for systemic morphine analgesia effects as functions of gender or gonadectomy, the present study evaluated these variables upon morphine analgesia following intracerebroventricular injection. Weight-matched male and female rats received sham or gonadal surgery. One month later, morphine (0.1-40 ug) analgesia was assessed on the tail-flick and jump tests for up to 2 h following microinjection. Male rats displayed significant increases in morphine analgesia on both tests relative to females. Castration, but not ovariectomy also significantly reduced analgesic magnitude as compared to same-sex sham controls. These data strongly suggest both gender and gonadectomy affect morphine analgesia independent of pharmacokinetic effects.

134.3

REDUCTION IN OPIOID AND NONOPIOID FORMS OF SWIM ANALGESIA BY SEROTONIN TYPE 2 RECEPTOR ANTAGONISTS IN RATS. J.M. Kiefel, D. Paul and R.J. Bodnar. Dept. of Psychol., Queens Col., CUNY, Flushing, NY 11367 and Mem. Sloan-Kettering Cancer Ctr., NY, NY 10021.

Although the role of centrifugal serotonin pathways have been established for opiate analgesia, recent work has further implicated the S2 receptor in this response. The present study compared the serotonin receptor antagonist, metysergide with the S2 receptor antagonists, pirenpirone and ketanserin for their ability to alter opioid-mediated intermittent and nonopioid-mediated continuous cold-water swim (ICWS, CCWS, 2° C, 3.5 min) analgesia on the tail-flick and jump tests in male rats. Metysergide (0.1-5.0 mg/kg, IP), pirenpirone (0.04-0.2 mg/kg, IP) and ketanserin (1.0-5.0 mg/kg, IP) each produced dose-dependent decreases (50%) in CCWS analgesia on both tests. In contrast, ICWS analgesia was only marginally decreased by metysergide on the tail-flick, but not the jump test. These data implicate serotonergic, and particularly S2 type receptors in the mediation of nonopioid CCWS analgesia.

134.4

5-HT ANXIOLYTICS, BUSPIRONE AND IPSAPIRONE, POTENTLY BLOCK NON-OPIOID ANALGESIA IN DEFEATED MALE MICE. R.J. Rodgers* and J.K. Shepherd*, (SPON: European Neuroscience Association) Pharmacoethol. Lab., Sch. of Psychol., Bradford University BD7 1DP, England.

In male DBA/2 mice, the experience of social defeat is accompanied by an acute non-opioid form of analgesia. Although initial studies supported the involvement of benzodiazepine recognition sites in the mediation of defeat analgesia, more recent detailed analyses have suggested that this hypothesis is untenable (Rodgers, R.J.& Randall, J.I. Physiol. Behav. 41: 279, 1987). In the present study, the effects of two anxiolytic ligands for 5-HT_{1A} binding sites (buspirone HCl & ipsapirone HCl) have been assessed. Both compounds, administered i.p. 15 minutes prior to testing, were studied over a 2000-fold dose range (0.01-20 mg/kg). Results show that, although largely devoid of intrinsic effects on basal nociception, both drugs potently blocked the analgesic consequences of defeat experience:- minimum effective dose for buspirone=0.5mg/kg, for ipsapirone=0.05mg/kg. These findings provide evidence for the importance of 5-HT_{1A} binding sites in the mediation of a biologically-relevant form of environmental analgesia, and further suggest that this paradigm may be useful in screening for atypical anxiolytics.

We thank Bristol-Myers & Troponwerke for the gifts of drugs used. This work was supported by a YRHA research grant (LE97)

134.5

PARADOXICAL ANALGESIA PRODUCED BY THE OPIATE-ANTAGONIST NALOXONE IS MEDIATED BY INTERACTION AT A SITE WITH CHARACTERSITICS OF THE DELTA-OPIOID RECEPTOR. Y.O. Taiwo*, A.I. Basbaum, F. Perry* & J.D. Levine*, (SPON: S. D. Collins), Div. Neurobiol., UCSF, SF, CA 94143.

The paw-withdrawal and tail-flick tests were used, in 300 g male Sprague-Dawley rats, to measure effects of opioid analgesics on nociceptive thresholds. The analgesic effect of low-dose naloxone (LDN) was abolished in rats that had been pretreated 24 hrs earlier with a large intrathecal dose of naloxone. The latter procedure abolished the analgesic effects of the delta specific ligands DPDPE and DSLET but not that produced by mu ligands DAGO and morphiceptin and the kappa specific ligand U50,488. The analgesic action of LDN (on thermal and mechanical nociceptive threshold tests) also persisted in rats made tolerant to mu-opioid receptor specific ligands, but it was prevented by the delta-receptor specific antagonist, ICI-174,864. We conclude that the analgesic action of low dose naloxone is mediated via a stereospecific binding site with the characteristics of the delta-opioid receptor.

134.6

CENTRAL ALLOXAN REDUCES THE POTENCY OF MORPHINE ANALGESIA. E. Lubin and R.J. Bodnar. Dept. of Psychol. and Neuropsychol. Doctoral Sub-Program, Queens College, CUNY, Flushing, NY 11367.

While peripheral alloxan acts as a pancreatic beta-cell toxin, central administration of far lower doses of alloxan presumably alters central glucoreceptor mechanisms. It is through this latter effect that central alloxan has been thought to reduce opioid-mediated analgesia and hyperphagia induced by 2-deoxy-D-glucose (2DG). The present study extended the role(s) of central alloxan effects by evaluating its actions upon systemic morphine analgesia (1-20 mg/kg, SC) on the tail-flick and jump tests. Nociceptive and analgesic assessments occurred two weeks following intracerebroventricular administration of either vehicle or alloxan (200 ug). Alloxan significantly reduced the potency of analgesia induced by the 2.5 and 5 mg/kg doses of morphine on both nociceptive measures. However, central alloxan failed to shift the dose-response curve of morphine analgesia. In contrast to its central actions, intravenous administration of an identical dose of alloxan failed to affect systemic morphine analgesia. These results suggest that alloxan alters opioid mechanisms necessary for 2DG and morphine analgesia.

VITAMIN B-INDUCED SUPPRESSION OF SPINAL DORSAL HORN NOCICEPTIVE NEURONS IN THE CAT. Q.-G. Fu*, J. Sandkühler, E. Carstens, B. Stelzer*, M. Zimmermann (SPON: A.F. Haase).
II. Physiologisches Institut der Universität, D-6900 Heidelberg, FRG

Systemic administration of a vitamin-B-compound (Neurobion, E. Merck) produced analgesia in clinical therapy and animal models of pain. The mechanism underlying this analgesic action is not known. We have examined the effects of vitamin B on spinal transmission of nociceptive information.
Single neurons were extracellulary recorded in the spinal dorsal horn of pentobarbital-anaesthetized cats. Radiant heat (50 °C, 10 s) was applied to the glabrous foot pad as a noxious stimulus. Vitamin B compound ($B_1/B_6/B_{12}$, 100 mg/100 mg/1 mg in 3 ml) was injected intravenously (0.3 ml) or applied directly to the spinal cord dorsum at the recording segment by means of a small perspex pool. All neurons selected for this study were multireceptive, i.e. responded to noxious and non-noxious skin stimuli. In 6 of 9 neurons tested heat evoked responses were suppressed by spinal administration of vitamin B compound. The suppression began 3 to 15 min (5 ± 3.6 min, n = 6) after the start of spinal superfusion. The average maximal suppression was to 57.7 ± 11.8 % of control. Spontaneous activity of the neurons was not significantly changed. Intravenous injection also depressed heat evoked responses of the two dorsal horn neurons tested to 74.8 ± 5.2 % of control. This inhibition had a duration of 6 to 9 min.
Our data suggested that vitamin B can directly suppress the responses of spinal neurons to nociceptive stimulation. It is conceivable that this suppression is involved in the analgesia in clinical therapy.

DEPRESSION OF NOCICEPTIVE ACTIVITY EVOKED IN THE RAT THALAMUS BY VITAMIN B COMPLEX AND VITAMIN B_6. I. Jurna* and D. Bonke. Institut für Pharmakologie und Toxikologie der Universität des Saarlandes, D-6650 Homburg/Saar, F.R.G, and E. Merck, D 6100 Darmstadt, F.R.G.

It is frequently proposed that vitamins of the B group alleviate pain. In search of evidence of an analgesic property of these compounds, experiments were carried out on rats under urethane anaesthesia in which activity was elicited in single neurons of the dorsomedial part of the ventral nucleus (VDM) of the thalamus by electrical stimulation of nociceptive afferents in the ipsilateral sural nerve. This activity is highly sensitive to morphine (Carlsson et al., pain (1988) 313). Intraperitoneal injection of 5 ml/kg of a combination of vitamin B_1, B_6 and B_{12} (Neurobion®, containing thiaminchloridehydrochloride 33.4 mg/ml, pyridoxinhydrochloride 33.4 mg/ml and cyanocobalamin 0.34 mg/ml) depressed evoked nociceptive activity by 50 % (number of neurons; N = 9). At a lower dose (Neurobion® 3 ml/kg; N = 6), the depression amounted to 40 %. At both doses the effect manifested itself from 70 min onwards, was at its maximum from 90 to 120 min, and returned to the control level by the end of the experiments at 180 min. Intraperitoneal injection of pyridoxinhydrochloride (167 mg/kg; N = 8) caused depression to an extent and with a time course similar to that observed after 5 ml/kg with the combination of vitamins. Thiaminhydrochloride (167 mg/kg; N = 8) and cyanocobalamin (1.67 mg/kg; N = 10) caused a slight depression from 70 to 120 min. It is concluded that the combination of the vitamins B_1, B_6 and B_{12} may produce analgesia which is mainly due to the action of vitamin B_6.

134.9

ANTINOCICEPTIVE EFFECTS OF VITAMINS B_1, B_6, AND B_{12} IN RATS AND MICE. G. Bartoszyk and A. Wild* E. Merck Pharm. Res., POB4119, 61 Darmstadt/FRG

Combinations of the vitamins B_1, B_6, and B_{12} are clinically used alone or in combination with NSAIDs in some painful conditions (e.g. neuralgia or inflammation, resp.). Animal studies regarding the antinociceptive effects of vitamins have been reported only occasionally with contradictory results (e.g. Eschalier, A., et al., Psychopharmacology 81:228, 1983; Hanck, A., et al., Int. J. Vit. Nutr. Res. 27:189, 1985). Using male Wistar rats (280-360 g) we investigated the clinically used combination of B_1, B_6, and B_{12} in three experimental animal models: benzoquinone writhing test (WR, reduction in number of writhes), heat coil test, and hot plate test (both: increase in latency). Injection of aqueous solutions (content per 1 ml: 33.3 mg B_1, 33.3 mg B_6, 0.3 mg B_{12}) gave dose- and time-dependent response curves. In WR, injection of the single vitamins as well as their combinations, two by two, resulted in less pronounced effects indicating an at least additive effect of the single vitamins. Using female NMRI mice (20-37 g) in the WR, the antinociceptive effects of oral diclofenac and metamizol were enhanced by adding a vitamin combination which was inactive when given alone.

134.10

INHIBITORY ACTIVITY OF ANALOGS OF WIN 48098 IN ISOLATED TISSUE PREPARATIONS IN VITRO IS REFLECTIVE OF A MECHANISM OF ANTINOCICEPTION. Susan J. Ward, M. Miller, D. Luttinger, M.A. Eissenstat and M. Bell. (SPON: D.R. Haubrich). Departments of Pharmacology and Medicinal Chemistry, Sterling-Winthrop Res. Inst., Rensselaer, NY 12144.

In addition to inhibiting prostaglandin (PG) formation, the new analgesic Win 48098 inhibits neuronally-mediated contractions of mouse vas deferens (MVD) preparation apparently by a "novel" presynaptic mechanism (Ward et al., FASEB, 1987). Compounds were designed and synthesized that retain inhibitory activity in the MVD, but which do not inhibit PG formation. Representative examples of the results are summarized below:

	IC50 (μM) in vitro		Antinociceptive ED50 (mg/kg) Mouse		Rat
	MVD	PG	i.v.	p.o.	p.o.
48098	0.56	5.0	5.4	40	12
Analog 1	0.17	>30	9.7	1000	402
Analog 2	0.032	>30	3.8	106	—
Analog 3	0.015	>100	0.5	97	38
Analog 4	0.006	>30	0.12	23	7

Inhibitory potency of compounds in the MVD ranged over 3 orders of magnitude and was correlated with antinociceptive potency. Behavioral depression was observed in doses at and above the antinociceptive ED90 (iv and po) in mice, but was less apparent in the rat. The data suggest that the inhibitory activity of this series of compounds in the MVD may represent a new antinociceptive mechanism; however, this mechanism may also elicit behavioral depression.

134.11

WIN 48,098, A NOVEL AMINOALKYLINDOLE ANALGESIC: INHIBITION OF ADENYLATE CYCLASE IN RAT CEREBELLAR MEMBRANES. M. Pacheco, S.R. Childers and S.J. Ward. Depts. of Neuroscience and Pharmacology, Univ. of Florida Coll. Med., Gainesville, FL 32610 and Sterling-Winthrop Res. Inst., Rensselaer, NY 12144.

Win 48098 is an aminoalkylindole (AAI) analgesic with a dual mechanism of action: inhibition of cyclooxygenase (CO) and a "novel" mechanism with characteristics of a neurotransmitter receptor, reflected by inhibition of neurally mediated contractions in the mouse vas deferens (MVD) preparation. In the present study, Win 48098 and structurally related analogs devoid of CO activity were evaluated for effects on adenylate cyclase (AC) in brain. Crude membranes were prepared from various regions of rat brain, and AC activity was assayed in the presence and absence of 10 μM Win 48,098. AC was assayed with 100 mM NaCl and 50 μM GTP, in the presence and absence of 0.1-1.0 μM forskolin, using [3H]ATP as substrate in an HPLC procedure.

AAI's inhibited both basal and forskolin-stimulated AC activity by 20-35% in membranes from cerebellum. However, little or no inhibition was detected in other regions of rat brain, including striatum, brainstem, hypothalamus, thalamus, hippocampus, amygdala or cortex. The potencies of several AAI analogs to inhibit AC paralleled their potencies in the MVD:

Compound	IC_{50} vs. AC (μM)	IC_{50} in MVD (μM)
Win 48098	5	0.5
Analog 1	2	0.1
Analog 2	0.9	0.015
Analog 3	0.5	0.006

The effect of these analogs on AC was magnesium-dependent, with lower concentrations of magnesium (<5 mM) providing maximal inhibition levels. Inhibition of AC by these compounds was GTP-dependent, since removal of guanine nucleotides totally eliminated the inhibitory activity. Like other G-protein coupled receptor systems in brain, inhibitory activity was supported by GDP and GMP, but not by non-hydrolyzable GTP analogs like Gpp(NH)p and GTP-γ-S. These data suggest that these aminoalkylindole analgesics act through specific, G-protein-linked receptors in the CNS to inhibit AC.

134.12

THE ACTION OF ANESTHETICS AND DIPHENYLHYDANTOIN ON REPETITIVE RESPONSES OF CORNEAL A-DELTA MECHANORECEPTORS. Hilary W. Thompson,* Brett Dupuy,* and Roger W. Beuerman. LSU Eye Center, New Orleans, LA 70112.

A subpopulation of A-delta corneal mechanoreceptors in the rabbit responds with 1-3 action potentials to each cycle of a mechanical stimulus presented at low frequencies (1 Hz) for several hours. Recording were made from the long ciliary nerve. Mechanoreceptors were stimulated with 10-60 μm displacements of a 0.5 mm dia steel ball attached to a piezoelectric actuator. Drugs were injected into a constant flow of isotonic saline directed at the point of mechanical stimulation. Drug effect was defined as a decline in response probability below 90%. Drug concentrations that did not completely inhibit response produced shifts in response latency. Drug action, in terms of time to onset of effect (TOE) and duration (D), was defined for various topical anesthetics (benoxinate, proparacaine, and tetracaine): benoxinate: TOE = 6±1.5 (mean±SEM) sec, D = 580±376 sec at 10^{-2} M; proparacaine: TOE = 11±6.3 sec, D = 88±34 sec at 10^{-2}. Diphenylhydantoin, an anticonvulsant, acted at concentrations less than $5x10^{-4}$ M: TOE = 30±12 sec, D = 50±20 sec. The mechanism of action of diphenylhydantoin on the corneal innervation may be due to its effects on calcium channels. This technique permits assessment of pharmacological agents on peripheral free nerve endings, and represents a model for study of the ionic mechanisms of mechanoreceptive transduction in the cornea.

NEUROTOXICITY I

135.1

LACK OF TOLERANCE DEVELOPMENT TO SUBCHRONIC TOXICITY OF SOMAN AND TABUN. R. C. Gupta and W-D. Dettbarn. Dept. of Pharmacology, School of Medicine, Vanderbilt University, Nashville, Tennessee 37232

Male Sprague-Dawley rats were exposed daily to sublethal doses of soman (40 ug/Kg,sc) and tabun (50 ug/Kg,sc) for 4 weeks. With both the nerve agents 40 to 50% animals showed anticholinesterase toxicity signs after receiving four or five consecutive doses and died when given three to five more daily doses. Remaining 50 to 60% animals did not exhibit any signs of toxicity at any time up to 4 weeks of treatment. During an early episode of soman toxicity (day 5), when toxic signs were evident, a marked reduction ($P < 0.01$) in the activities of esterases, such as AChE, BuChE, and CarbE, was seen in the discrete brain regions and skeletal muscles of different characterstics. AChE activity in brain and skeletal muscles and CarbE activity in brain remained significantly ($P < 0.01$) depressed throughout the experiment; whereas BuChE activity in all the tissues (especially muscles), and CarbE activity in the liver (80%) and in the plasma (50%) indicated substantial recovery when examined after 4 weeks. Similar findings were also observed with tabun. The lack of tolerance development to the toxicity of soman or tabun following their subchronic exposure, unlike reported for DFP (Gupta, et al., Toxicol. Appl. Pharmacol. 84: 541, 1986) could be due to either non-recovering inactivation of AChE activity or insensitivity of in vivo protein synthesis.

135.2

MECHANISMS OF CHEMICAL INJURY IN RAT PERIPHERAL NERVE. M.W. Kalichman, O.A. Holovda*, H.C. Powell*, and R.R. Myers*. Depts. of Anesthesiology and Pathology, Univ. of California, San Diego, CA 92093.

Sprague-Dawley rats were used to study mechanisms of injury to saphenous or sciatic nerve following extraneural injection of various concentrations of local anesthetics including 2-chloroprocaine, procaine, etidocaine, and lidocaine, as well as neurolytics such as glycerol and phenol, in volumes of 0.2-1ml. Local anesthetics *are not normally used for their ability to produce neurolysis*; however, *in sufficient* concentration, all of the drugs tested demonstrated a concentration-dependent increase in long-lasting nerve injury, as indicated by the accumulation of endoneurial edema, cytoplasmic lipid droplets, and axonal degeneration and demyelination, at 48 hrs after administration. The following possible mechanisms of injury were considered: (1) *Physicochemical properties of the solutions tested.* Control studies using solutions characterized by a wide range of pH, tonicity, and lipid solubility, as well as various additives and vehicles, revealed no correlation with injury other than that predicted by neurolytic concentration. (2) *Ischemia.* Extraneural application of test solutions might compromise transperineurial vessels either by direct vasoconstriction or indirectly as a result of increased endoneurial fluid pressure associated with edema formation. In either case, injury should be restricted to the subperineurial region rather than centrally, where the axial circulation persists in spite of a loss of the transperineurial blood supply. Chemical neurolysis is not restricted to the subperineurial region; therefore, ischemia is not likely the principal mechanism of nerve injury. (3) *Specific chemical interactions between neurolytic agents and the affected cells.* Electron microscopic studies have demonstrated a highly selective neurotoxic property of local anesthetics: Schwann cells of unmyelinated fibers readily undergo lytic changes; whereas, myelinated fiber Schwann cells are much more likely to accumulate cytoplasmic lipid inclusions. These selective changes argue against a non-specific mechanism of injury such as might be expected with ischemia or general alterations of the endoneurial microenvironment. Additionally, in electrophysiological studies, diverse local anesthetics were found to inhibit nerve conduction acutely with the same relative potency demonstrated for the neurotoxic effect of endoneurial edema accumulation at 48hrs. These histopathologic and electrophysiologic data are consistent with the hypothesis that some chemical neurolytics produce injury to peripheral nerve by cell-specific effects at an appropriate receptor or ion channel.

135.3

MPTP LETHALITY IN MICE: EFFECT OF MAO-B INHIBITION AND AMINE UPTAKE INHIBITION. R. W. Fuller, S. K. Hemrick-Luecke* and K. W. Perry*. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is neurotoxic to nigrostriatal dopamine neurons, and its neurotoxicity is prevented by inhibition of monoamine oxidase type B (MAO-B) or by inhibition of the dopamine uptake carrier. We now report that the acute lethality of MPTP in Charles River CFW mice is also prevented by selective inhibition of MAO-B with deprenyl. Deprenyl (0.01-10 mg/kg i.p.) pretreatment prevented lethality and the observed behavioral effects at 1-3 hrs after high doses of MPTP (30-90 mg/kg s.c.). 1-Methyl-4-phenylpyridinium (MPP+) was more potent in causing lethality than was MPTP, and deprenyl did not affect its lethality. MPTP lethality was not antagonized by EXP 561, an uptake inhibitor that prevented the neurotoxic effects of a lower dose of MPTP on striatal dopamine and cortical norepinephrine neurons. The protective effect of deprenyl against MPTP-induced lethality paralleled the inhibition of MAO-B in brain but not in liver and persisted out to 14 days. Deprenyl pretreatment markedly reduced MPP+ concentrations in brain after MPTP injection, without altering MPTP concentrations in brain. Centrally formed metabolites of MPTP, probably MPP+, seem to account for the lethality of MPTP at higher doses as well as its neurotoxic effects toward nigrostriatal dopamine neurons at lower doses.

LONG-TERM COGNITIVE AND MOTOR DEFICITS IN MPTP-TREATED MONKEYS. J.R. Taylor, R.H. Roth, J.R. Sladek, Jr., D.E. Redmond, Jr. Yale Univ. Sch. of Med., New Haven, CT 06510, and Univ. of Rochester Sch. of Med., Rochester NY 14641.

To assess the stability of neural deficits produced by MPTP we studied performance on an object retrieval task. The task requires retrieval of a banana slice from a transparent box open on one side. The orientation of the open side, location of the box, and position of the banana in the box were manipulated in order to vary the cognitive and motor difficulty of the trials. African green monkeys (N=6) were treated with MPTP (2-3 mg/kg). A control group was sham-treated (N=5). The subjects examined were without any neurological or behavioral deficits but probably had dopamine depletions. When acquiring this task 8-12 months after MPTP treatment they had motor and cognitive deficits. During 3 months of testing, MPTP-treated subjects had motor problems and cognitive deficits, such as responding at the transparent side of the box. They were less successful at retrieving the reward on the first reach than controls. The impairments were stable throughout testing. On select trials when an identical, but opaque, box was used MPTP-treated subjects decreased reaches at the transparent side of the box, while motor problems were increased. The task is sensitive to cognitive and motoric deficits associated with this model of Parkinson's disease and confirms that these deficits are stable for many months. ASYMPTOMATIC AND SYMPTOMATIC MPTP-TREATED PRIMATES: REGIONAL HETEROGENEITY IN MESOSTRIATAL TOXICITY. J.D. Elsworth, A.Y. Deutch, D.E. Redmond, Jr., J.R. Sladek, Jr. and R.H. Roth. Depts. Pharmacol. & Psychiat., Yale Univ. Sch. Med., New Haven, CT 06510; Rochester Sch. Med., NY.

Primates treated with the same dose of MPTP exhibit different degrees of parkinsonism. Regional biochemical differences in the mesostriatal dopamine (DA) system were examined in asymptomatic (Asymp) and severely symptomatic (Symp) vervet monkeys 1-2 months after receiving MPTP. Large differences in DA depletions existed between Asymp and Symp groups in cell body areas. DA losses occurred at an earlier stage of MPTP toxicity in medial substantia nigra than in lateral retrorubral field, central substantia nigra and dorsal ventral tegmental area. Severe DA depletions were observed in striatum in both Asymp and Symp groups, suggesting that MPTP toxicity is initially exerted at the terminals. Unlike idiopathic, but similar to postencephalitic Parkinson's disease, DA losses in putamen were not greater than in caudate nucleus. Heterogeneity in MPTP susceptibility was apparent within striatum; regional DA losses in Asymp ranged from 75-99% and in Symp from 95-99%. The regional differences between Asymp and Symp groups in caudate nucleus and putamen suggest possible sites at which transplants may be most favorably placed for reversing parkinsonism and suggest that low but sustained DA production by grafts may be sufficient to ameliorate parkinsonian motor abnormalities. NINCDS PO1 NS24032.

135.6

LONG-TERM EFFECTS OF BRIEF EXPOSURE TO 1-METHYL-4-PHENYLPYRIDINE (MPP^+) IN ORGANOTYPIC CULTURES OF CANINE SUBSTANTIA NIGRA (SN). B. Christie-Pope* and W.O. Whetsell, Jr. (SPON: M.D. Johnson). Neuropathology, Vanderbilt Sch. of Med., Nashville, TN 37232.

Earlier investigations have shown that organotypic cultures of canine SN develop swelling of neuronal mitochondria followed by generalized disruption of all cellular components (neurons and glia) when continuously incubated in MPP^+ for up to 15 hours (Christie-Pope *et al.*, Neurosci. Abstr. 13:788, 1987). The present study examined ultrastructural changes in canine SN cultures and caudate (CA) cultures exposed to 0.1nM MPP^+ for 1.5 hours or 3 hours then washed and maintained on usual feeding medium for different periods of time. At 30 days after 1.5 hours exposure to MPP^+, SN cultures exhibited increased glial processes with evidence of neuronal degeneration. Prominent mitochondrial changes were observed in neurons including occurrence of large, swollen mitochondria in some nerve cells and increased numbers of normal-size mitochondria in other nerve cells; mitochondrial changes were not evident in glial cells. SN cultures exposed to MPP^+ for 3 hours then studied 30 days later showed similar ultrastructural changes. Neither sibling SN cultures maintained on usual feeding medium and studied at the same times as the MPP^+-exposed cultures nor other SN cultures maintained normally for up to 100 days showed such ultrastructural changes. CA cultures treated with MPP^+ for 1.5 or 3 hours and studied at 30 days or later showed no ultrastructural alterations compared to control CA cultures. These observations indicate that while prolonged exposure to MPP^+, even at very low concentrations, produces a non-specific toxicity in canine SN or CA cultures (*ibid.*), brief exposure to MPP^+ shows a remote and specific toxicity for SN neurons but not CA neurons in this *in vitro* model. [Supported by a grant from the United Parkinson's Foundation and a Pharmaceutical Manufacturers' Association Foundation Fellowship Award (BCP).]

ROLE OF GLYCINE IN THE NEUROTOXIC EFFECTS OF GLUTAMATE IN HIPPOCAMPAL CELL CULTURE. I. SHALABY AND M. PROCHNIAK*. Pfizer Central Research, Groton, CT 06340.

We examined the role of glycine in glutamate-induced neurodegeneration using 3 week old cultures of fetal rat hippocampal cells. Glutamate was added for 15 min to the cultures, washed, and cells were allowed to remain 24 hr after which time the cell media was analyzed for lactate dehydrogenase (LDH) activity as an index of cell toxicity. Glutamate induced a concentration-dependent increase in LDH at an ED50 of 200uM with a maximal elevation of 3 fold above controls. NMDA receptor blockers AP-7, PCP, and MK-801 antagonized the effects of glutamate, and were able to save neurons from ongoing degeneration. Glycine at concentrations up to 10uM did not potentiate the neurotoxic effects of glutamate. These results suggested that glutamate application might release sufficient endogenous glycine to potentiate its neurotoxic actions. To examine this possibility we incubated hippocampal cultures with [3H]glycine, thereafter repeatedly incubated cells in buffer from which 5 min fractions were taken to assess [3H]glycine release. 70mM potassium depolarization and 100uM glutamate induced a 2-fold and 1.0mM glutamate a 3-4 fold increase in [3H]glycine release compared to non-stimulated controls. In conclusion, glutamate induced a concentration-dependent release of glycine from hippocampal cell cultures. The glutamate-induced release of glycine may be sufficient to potentiate the neurodegenerative effects of glutamate, thereby rendering additional exogenous glycine application ineffective.

CSF PGE2 ELEVATION AFTER WATER CONTRAST MYELOGRAPHY. L. Maloney*, R. Evans*, D. Coombs*, L. Cromwell*, R. Colburn*. (SPON: S.J. Velez) Anesth. Research Lab., Dartmouth-Hitchcock Medical Center, Hanover, NH 03756.

Prostaglandin E2 (PGE2) is released with inflammation. We investigated whether myelography with water soluble iopamidol results in acute inflammation/arachnoiditis. METHODS: 59 patients undergoing lumbar myelography (disc disease/stenosis) gave informed consent (IRB approved). A 22 gauge spinal needle was placed fluoroscopically. Three ml of CSF were removed; 1.5-2ml was transferred to polypropylene tubes containing 15 mcg indomethacin to arrest arachadonic acid metabolism. The CSF was centrifuged and frozen at -70 C till analysis. Ten to 15 ml of iopamidol (E.R. Squibb, Princeton, NJ) was then injected. Eleven of the 59 came to surgery (herniated nucleus pulposis or nerve root entrapment). After dural exposure, CSF was withdrawn (25 gauge spinal needle). All blood contaminated samples were discarded. PGE2, cell count, and protein were evaluated in the CSF. RESULTS: Mean age all patients premyelogram vs surgical subgroup were comparable (49+15, 47+14 resp., p=NS). Protein and PGE2 were not different premyelogram in surgical and nonsurgical. Table 1 shows mean + S.E. CSF PGE2 and protein (surgical subgroup only). PGE2 and protein were significantly increased at surgery compared to premyelogram. There was no statistical relationship between cell count and PGE2. DISCUSSION: Injection of contrast dye likely generates inflammation marked by increased CSF PGE2 and protein. Origin of this PGE2 is unknown. PGE2 may influence healing/fibrosis and subsequent surgical recovery (under study).

Table 1	* Premyelogram	Surgical
PGE_2 (picogm/ml)	0.70 ± 0.34	7.88± 9.37
Protein (mg/dl)+	56.0 ± 26.9	74.5± 33.6

*P<0.02(premyel. v. surg. PGE_2), +P<0.01 (premyel. v. surg. protein)

Cummulative and Residual Effects of Low Level Lead Exposure on Development and Behavioral Activity in Three Generations of Mice. D.A. Rasile*, P.J. Donovick, and R.G. Burright*. Environmental Neuropsychology Lab, SUNY Binghamton, Binghamton, N.Y. 13901

In the past two decades, numerous experimental studies have established the teratogenic effects of low-level lead exposure on development and behavioral activity in laboratory animals. However, few attempts have been made to systematically study the cummulative and residual consequences of lead exposure across multiple generations. The present study addresses these issues and attempts to determine the cross-generational effects of lead toxicity on developmental measures such as body weight, age of eye opening and latency of home nest return--and on behavioral activity measures such as activity wheel, open field, and swimming, in Binghamton Heterogenous Stock mice.

A SENSITIVE HPLC METHOD FOR THE DETERMINATION OF β-N-METHYLAMINO-L-ALANINE (BMAA) IN CYCAD SEED AND ANIMAL TISSUES. G.E. Kisby, D.N. Roy *, and P.S. Spencer. Institute of Neurotoxicology, Albert Einstein Coll. Med., Bronx, NY 10461.

We have developed a method for detecting subpicomolar concentrations of β-N-methylamino-L-alanine (BMAA), a neurotoxin found in the seed of cycad plants (*Cycas* spp.) which has been linked to western Pacific amyotrophic lateral sclerosis and parkinsonism-dementia complex. BMAA and other amino acids were derivatized with 9-fluorenylmethyl chloroformate (FMOC) prior to HPLC separation and fluorescence detection (excitation λ 254 nm and emisson λ 315 nm). All amino acids, including BMAA, eluted from the column within 22 min. BMAA (t_r= 18.02 ±0.07 min) was detected in *Cycas circinalis* L. seed and in serum, cerebrospinal fluid and brain tissue from BMAA-treated monkeys and rats. The purity of synthetic FMOC-BMAA was established by a single peak after HPLC analysis (t_r=18.17 min) and by mass spectrometry (m/e 341.2). Physiological amino acids could also be detected since they were highly resolved from BMAA. Amino acids and BMAA were linear over the concentration range of 0.15 μM-7.5 μM with a relative standard deviation ranging from 2.1-6.7%. This method should prove useful in determining the biological fate and metabolism of BMAA in plant and animal tissues.

135.11

REGIONAL BRAIN QUINOLINATE INCREASES DURING AND AFTER HYPOGLYCEMIA. M.P. Heyes*, R.N. Auer, M. Papagapiou and S.P. Markey* (SPON: Q. Pittman) Lab. of Clinical Science, N.I.M.H., Bethesda, MD 20892 and Dept. of Pathology, University of Calgary, Alberta T2N 4N1, Canada.

Hypoglycemia (HG) is associated with neurodegeneration that is attenuated by NMDA receptor antagonists. HG increases brain L-tryptophan concentrations (Agardh: Diabetes, 28: 804, 1979) and could increase the synthesis of quinolinic acid (During: This Meeting), a neurotoxin, convulsant and NMDA receptor agonist. We investigated 1 h of HG and 1 h recovery (R) in rat on quinolinic acid (QUIN), L-TRP, 5-HT and 5-HIAA concentrations in cortex, striatum, thalamus and hippocampus; and striatal DA, DOPAC and HVA concentrations. In all regions, QUIN increased 2-3 fold during HG and 2-3 fold further during R; 5-HT decreased > 50% during H and R whereas 5-HIAA increased 2 fold during H and R. L-TRP increased > 50% during R only. Striatal DA decreased 74% during H only, DOPAC and HVA increased > 200% during H and R. We conclude that H induces increased synthesis of QUIN and release of brain 5-HT and striatal DA. QUIN may have etiologic importance in the neurodegeneration and convulsions of H.

135.12

COMPARATIVE NEUROTOXICITY OF FENFLURAMINE AND 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA). J.A. Wagner and S.J. Peroutka. Department of Neurology, Stanford University Medical Center, Stanford, CA 94305.

Fenfluramine is a phenethylamine used clinically as an oral anoretic and structurally related to MDMA. Biochemical and pathologic evidence suggest that MDMA produces a selective reduction of serotonin (5-HT) nerve terminals in rat and monkey. [^{3}H]Paroxetine was used as biochemical marker in order to assess the extent of 5-HT nerve terminal damage after administration of a single dose (0, 1, 3, 10, or 30 mg/kg s.c.) of fenfluramine. Rats were sacrificed two weeks later. B_{max} levels of [^{3}H]paroxetine were, respectively, 42.1 $\pm$ 3.4, 38.2 $\pm$ 3.4, 34.3 $\pm$ 2.5, 21.8 $\pm$ 2.2, and 9.9 $\pm$ 2.1 fmoles/mg wet weight. No change was seen in K_D. By contrast, only 30 mg/kg MDMA caused a significant reduction in [^{3}H]paroxetine binding. No [^{3}H]paroxetine binding alterations were observed rats sacrificed within 24 hours of fenfluramine or MDMA administration. These data suggest that fenfluramine and MDMA produce similar patterns of 5-HT neurotoxicity. The implications to the human users of these drugs will be discussed.

135.13

ASSESSMENT OF COMPLEX BEHAVIOR IN THE RHESUS MONKEY: EFFECTS OF CHRONIC MARIJUANA SMOKE EXPOSURE. W. Slikker, Jr.*, M.G. Paule, D.E. McMillan*, J.R. Bailey*, A.C. Scallet and S. F. Ali. Div. of Reprod. & Develop. Toxicol., NCTR, Jefferson, AR 72079 and Dept. of Pharmacol., UAMS, Little Rock, AR 72205.

A large scale study involving 30 periadolescent male rhesus monkeys was designed to assess the behavioral effects of exposure to marijuana smoke for 1 yr. All monkeys were trained (n=7-8/group) under 5 complex operant schedules, matched for performance levels and body weights, and exposed to either the smoke of 1 marijuana cigarette (mask) once a day, 7 days/wk, or 2 days/wk. Two control groups, one receiving smoke from an extracted cigarette devoid of cannabinoids (placebo) and 1 sham exposed (no smoke), were also exposed 7 days/wk. Behavioral assessments occurred 23 hr after exposures. Chronic marijuana smoke decreased task completion in conditioned-position response tasks and decreased rate and accuracy in incremental repeated acquisition tasks. Additionally, when compared to either placebo or sham groups, progressive-ratio response rates and breakpoints were significantly decreased in both the low and the high dose marijuana smoke groups. These data indicate that complex behaviors can be routinely assessed in a large number of monkeys and that long-term toxicity studies using inhaled compounds are feasible. The data also suggest that chronic marijuana exposure produces deficits in complex behavior. (Supported in part by NIDA-IAG #224-83-0005).

CARDIOVASCULAR REGULATION III

136.1

SOME PROPERTIES OF THE SYMPATHO-INHIBITION FROM THE CAUDAL VENTROLATERAL MEDULLA OBLONGATA (CVLM) IN THE CAT. K.Dembowsky*, J.Czachurski* and H.Seller*(SPON:D.W.Richter). I.Physiol.Inst., Universität Heidelberg, Heidelberg, F.R.G.

The CVLM contains a group of neurones which upon their activation by glutamate injections cause a complete inhibition of sympathetic activity. Recordings of the activity in several sympathetic nerves revealed that this inhibition is more pronounced in the renal than the cardiac nerve or white ramus T3. This inhibition was accompanied by a strong tonic excitation of phrenic nerve activity. Since this inhibition could still be evoked after a contralateral hemisection and a section of the ipsilateral ventral quadrant of the spinal cord, it is concluded that its spinal pathway is confined to the ipsilateral dorsolateral funiculus. This inhibition also persisted after blockade of alpha2-receptors with rauwolscine, making an involvement of noradrenaline as transmitter in this system unlikely. The question if this inhibition is due to disfacilitation or post-synaptic inhibition of sympathetic preganglionic neurones (SPN) was addressed with intracellular recordings of SPNs. Glutamate injections into CVLM resulted in a reduction of the on-going synaptic activity in SPNs and/or a membrane hyperpolarization. In 2 SPNs this was associated with no change in input resistance (R_N), whereas in 3 other SPNs a transient reduction of R_N was observed. Further evidence for post-synaptic inhibition of SPNs from CVLM was obtained in experiments in which IPSPs were evoked in SPNs in response to electrical stimulation of this area.

136.2

LATERAL TEGMENTAL FIELD SYMPATHOINHIBITORY (LTF-SI) NEURONS PROJECT TO MEDULLARY RAPHE NUCLEI. S.M. Barman and G.L. Gebber. Dept. Pharmacol., Mich. St. Univ., E. Lansing, MI 48824.

Both the LTF and raphe nuclei of the cat medulla contain neurons that are in SI pathways. Their activity is synchronized to sympathetic nerve discharge (SND), and their firing rate is increased during the inhibition of SND produced by baroreceptor reflex activation. LTF-SI neurons fire before raphe-SI neurons during the cardiac-related burst of SND. Whereas raphe-SI neurons innervate the intermediolateral nucleus, the axons of LTF-SI neurons do not project to the spinal cord. The current study was designed to test the hypothesis that LTF-SI neurons project to the raphe nuclei. We antidromically activated 18 LTF-SI neurons by microstimulation of the region of the medullary raphe (2-3 mm rostral to the obex) that contains raphespinal-SI neurons. The onset latency of antidromic activation was 19±3 ms when threshold current (133±24 μA) was used. This value was close to the mean difference (17 ms) between the spontaneous firing times of LTF-SI and R-SI neurons. LTF-SI neurons could not be antidromically activated by high intensity (1 mA) current applied either 2 mm lateral to the midline, contralateral to the recording site or in the raphe nuclei 1 mm caudal to the obex. The onset latency of antidromic activation of these neurons was shortened when threshold current was applied 1.5 mm lateral to the midline, ipsilateral to the recording site. Taken together, these data are consistent with the hypothesis that LTF-SI neurons innervate and excite raphespinal neurons which then inhibit SND. (Supported by NIH grant HL13187.)

IDENTIFICATION OF SEROTONERGIC AND SYMPATHETIC NEURONS IN MEDULLARY RAPHE NUCLEI. RB McCall and ME Clement. The Upjohn Company, Kalamazoo, MI 49001.

The purpose of this study was to identify midline medullary serotonin (5-HT) neurons and to determine if these neurons were distinct from raphe sympathoinhibitory and sympathoexcitatory neurons. Identification of medullary 5-HT neurons was based on electrophysiological and pharmacological similarities to dorsal raphe 5-HT neurons. Sympathoinhibitory and sympathoexcitatory neurons were characterized by an irregular discharge pattern which was temporally related to inferior cardiac sympathetic nerve discharge (SND) and to the cardiac cycle. Sympathoinhibitory neurons increased their discharge rate and the discharge of sympathoexcitatory neurons decreased during baroreceptor reflex activation. A third type of neuron fired in an extremely regular fashion. The discharges of regularly firing neurons were not temporally related to SND and were not affected during baroreceptor reflex activation. Regularly firing neurons had a spontaneous discharge rate of 1.1 spikes/s. Regularly firing neurons and sympathoinhibitory neurons could be antidromically activated by electrical stimulation of the intermediolateral cell column of the spinal cord. Axonal conduction velocities in the medullospinal pathway of regularly firing neurons was 1.3 m\s and 2.4 m\s for sympathoinhibitory neurons. Regularly firing neurons were completly inhibited by iontophoretic 5-HT or by i.v. or iontophoretic application of the 5-HT$_{1A}$ agonist 8-OH DPAT while much higher doses of 8-OH DPAT failed to affect the discharges of sympathoinhibitory and sympathoexcitatory neurons. Based on the striking similarities between regularly firing medullary neurons and dorsal raphe 5-HT neurons it is concluded that the regularly firing neurons are 5-HT containing neurons. Medullary 5-HT neurons are distinct from sympathoinhibitory and sympathoexcitatory neurons. Studies in our laboratory indicate that 5-HT neurons excite sympathetic preganglionic neurons.

136.4

RESPIRATORY MODULATION OF SYMPATHETIC PREGANGLIONIC NEURONS IN THE MID-THORACIC SPINAL CORD OF THE RAT. *S.F. Morrison, and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

The nucleus reticularis rostroventrolateralis (RVL) contains neurons that provide a major source of tonic sympathoexcitation as well as neurons that may be involved in the generation of the basal respiratory rhythm. The responses of sympathetic preganglionic neurons (SPNs) to stimulation of the RVL indicate that SPNs are driven by (1) a rapidly conducting RVL-spinal pathway, (2) RVL-spinal neurons with slowly conducting axons, or (3) both systems. In the present study we compared the respiratory modulation of SPNs with their responses to RVL stimulation to determine if the respiratory modulation of their discharge could be attributed to either the rapidly or the slowly conducting RVL-spinal pathway. SPNs were antidromically identified in the T6-T8 spinal segments of urethane-anesthetized,vagotomized, paralyzed, ventilated rats. The spontaneous activity of 80% of the SPNs was increased during the period of increased phrenic nerve discharge, while the activity of the remaining 20% was lower during the phrenic burst than during the phrenic silence. Of the SPNs in the former group, 36% were excited at a short latency (< 30 msec), 46% at a long latency (> 100 msec), and 18% had a bimodal response to RVL stimulation. Those with decreased firing in inspiration were exclusively responsive to the rapidly conducting pathway. The finding that respiratory modulation of SPNs was not correlated with the temporal characteristics of their responses to RVL stimulation suggests that respiratory modulation of SPNs derives either (1) from the respiratory modulation of the discharge of both classes (rapidly and slowly conducting) of RVL-spinal sympathoexcitatory neurons or (2) from the respiratory modulation of inputs to SPNs from a source other than the RVL. (Supported by NIH grants HL18974 and NS22721.)

PHENYLETHANOLAMINE N-METHYLTRANSFERASE-CONTAINING TERMINALS SYNAPSE DIRECTLY ON SYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT. *T.A. Milner, S.F. Morrison, C. Abate and D.J. Reis* Div. of Neurobiology and Molecular Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

The electron microscopic localization of a polyclonal antiserum directed against the adrenaline synthesizing enzyme, phenylethanolamine N-methyltransferase (PNMT) was examined in the intermediolateral cell column (IML) of the rat thoracic spinal cord utilizing the peroxidase-antiperoxidase labeling method. Terminals containing PNMT-immunoreactivity (I) constituted 76% (117 out of 154) of the labeled profiles. These terminals (0.5-1.4 µm in diameter) contained a few mitochondria and a large population of small clear and from 1-6 large dense-core vesicles. Of 117 terminals, 93 formed associations with unlabeled perikarya and dendrites. The synaptic junctions on perikarya were rare (n = 4) and exclusively symmetric; those on proximal (large) dendrites were more numerous (31% of 89) and were primarily symmetric membrane specializations. The vast majority (69% of 89) of the terminals with PNMT-I formed asymmetric synaptic junctions on distal (small) dendrites and dendritic spines. Moreover, many of the terminals with PNMT-I as well as their postsynaptic targets were closely invested with, or apposed to fibrous astrocytic processes.

In a subsequent set of experiments, immunoautoradiographic labeling for PNMT was combined with horseradish peroxidase (HRP) retrograde identification of sympathetic preganglionic neurons (SPNs). In these sections, terminals with PNMT-I directly synapsed on the HRP-containing (i.e., retrogradely labeled SPNs) perikarya and dendrites. The axosomatic synapses observed between PNMT-labeled terminals and SPN perikarya were exclusively symmetric; whereas the type and distribution of axodendritic association varied such that the majority were asymmetric on small dendrites and dendritic spines. The findings provide ultrastructural evidence that in the rat IML, adrenergic (i.e., PNMT-containing) terminals (a) may be either excitatory (asymmetric) or inhibitory (symmetric) depending on their site of termination and (b) can influence sympathetic nerve discharge through a direct effect on the SPN cell membrane. (Supported by NIH HL 18974.)

136.6

QUANTITATIVE-TOPOGRAPHIC ANALYSIS OF ADRENERGIC AND NON-ADRENERGIC SPINAL PROJECTIONS OF CARDIOVASCULAR AREA OF RVL. *S.L. Cravo*, D.A. Ruggiero, M.Anwar*, D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

The cardiovascular area (CAA) of RVL was defined in urethane-anesthetized rats by microinjections of the neuroexcitatory agent L-Glutamate (L-Glu, 1 nmol, 15 nL, pH 7.4). An area where the L-Glu provoked pressor responses larger than 10 mmHg (maximal response 30 mmHg) was defined along a longitudinal strip of 400 µm comprising the rostral third of the C1 adrenergic neurons group. Spinal projections from CAA were studied using the retrograde tracer WGA-HRP and immunocytochemistry for the presence of tyrosine hydroxylase (TH) and phenylethanolamine-N-methyltransferase (PNMT). After multiple injections of WGA-HRP in all segments of the spinal cord: a) 209±1 neurons (n=3) were retrogradely labeled with HRP in both CAA; b) 224±8 neurons were immunocytochemically stained for TH or PNMT; c) 137±14 (65±7% of the total number of cells labeled with HRP) neurons contained both retrograde and immuno-labels; d) the same number of neurons contained TH and PNMT; hence all are adrenergic. After injections restricted to thoracic spinal segments (n=3), 190±12 neurons were labeled with HRP, 259±6 with TH or PNMT, and 148±9 (78±1% of total number of HRP cells) contained both labels. Non-adrenergic cervical spinal projecting neurons were preferentially distributed dorsally to the adrenergic-spinal projecting cells but also intermixed with them. Adrenergic and non-adrenergic neurons projecting to the lumbar-sacral cord were localized medially to CAA. We conclude that in the rat the CAA of RVL is restricted, that in this area over 75% of thoracic projections are from adrenergic neurons, and that the reticulospinal projections from the entire RVL to the cord are topographically organized.

136.7

EFFECTS OF KYNURENATE (KYN) ON CAT SYMPATHETIC NERVE DISCHARGE (SND). G.L. Gebber, S.M. Barman and K.J. Varner. Dept. Pharmacol., Mich. State Univ., E. Lansing, MI 48824.

We investigated the role of excitatory amino acids in the genesis and control of SND in Dial-urethane anesthetized cats. Inferior cardiac SND was recorded before and after intracisternal (ic) or local medullary injection of the glutamate-receptor antagonist, KYN. Power density spectral analysis demonstrated that ic KYN (25-50 µmol) reduced SND (≥50%) and eliminated its cardiac-related rhythmic component. The former effect was reproduced by microinjection of KYN (50 nl of 250 mM solution) into the rostral ventrolateral medulla (RVLM) while the latter effect was observed when KYN was injected into the nucleus of the solitary tract. The primary component (>90% of total activity) in SND after ic KYN was a 2- to 6-Hz rhythm, not unlike that observed in baroreceptor-denervated cats. This rhythm is generated by brain stem circuits that provide driving input to RVLM sympathoexcitatory neurons innervating the spinal intermediolateral nucleus (Barman and Gebber, J. Neurophysiol. 57: 1410-1424, 1987). In baroreceptor-denervated cats, KYN (ic or RVLM microinjection) reduced SND without changing the relative proportion of neural activity in the 2- to 6-Hz band. Microinjection of KYN into the medullary lateral tegmental field (a potential source of the 2- to 6-Hz rhythm) failed to affect the power or frequency components in SND. These results indicate that the reduction of SND produced by KYN does not involve perturbation of 2- to 6-Hz rhythm generation. (Supported by NIH grant HL13187.)

136.8

EFFECTS OF KYNURENATE (KYN) ON RAT SYMPATHETIC NERVE DISCHARGE (SND). M. Zviman*, G.L. Gebber and S.M. Barman. (SPON: J.L. Bennett). Depts. of Pharmacol. and Physiol. Mich. State Univ., E. Lansing, MI 48824.

Sun et al. (Brain Res. 438: 23-40, 1988) have located neurons with pacemaker-like activity (beating frequency ≈20 Hz) in the rat rostral ventrolateral medulla (RVLM) after intracisternal (ic) injection of the glutamate-receptor antagonist, KYN. They proposed that these neurons are responsible for SND. The fact that RVLM pacemaker neurons discharge independently of each other after ic KYN blocks their synaptic inputs leads to the prediction that SND will be asynchronous. The results of the current study show that this is not the case. Splanchnic SND was recorded in urethane-anesthetized rats before and after ic KYN (5-25 µmol). As reported by Sun et al., KYN initially increased SND, eliminated its cardiac-related rhythmic component and prevented its inhibition upon baroreceptor-reflex activation. However, SND remained synchronized after ic KYN. Power density spectra of SND contained peaks between 2- and 8-Hz that accounted for >80% of total activity both before and after ic KYN. These results raise two possibilities. First, the limited-band white noise output of independently discharging RVLM pacemaker neurons is transformed in the spinal cord to a 2- to 8-Hz rhythm. Second, RVLM pacemaker neurons are not the primary factor involved in generating SND. These possibilities are currently under investigation. (Supported by NIH grant HL13187.)

136.9

BLOCKADE OF EXCITATORY AMINO ACID RECEPTORS IN RABBIT CAUDAL VENTROLATERAL MEDULLA DOES NOT ABOLISH THE BARORECEPTOR-VASOMOTOR REFLEX. W.W. Blessing, Centre for Neuroscience, Flinders University of South Australia, Bedford Park, SA

There is controversy as to whether or not inhibitory vasomotor neurons in the caudal ventrolateral medulla (CVLM) constitute the inhibitory link in the central baroreceptor-vasomotor pathway. Recent studies in favour of this hypothesis have suggested that blockade of excitatory amino acid (EAA) receptors in the rat CVLM interrupts the baroreceptor-vasomotor reflex (Gordon, F.J. Am. J. Physiol. 252: R628, 1987, Guyenet, P.G. et al, Brain Res. 407: 272, 1987). The present study investigates whether or not this is the case in the rabbit. N. Z. White rabbits (2.5-3 kg), previously prepared with vascular cuff occluders, were anesthetized with urethan (1.4 g/kg i.v.), paralysed and mechanically ventilated. Sympathetic nerve activity (rSNA) was recorded from the left renal nerve and arterial pressure (AP) was recorded from a catheter in the central ear artery. The reflex change in rSNA in response to electrical stimulation of the left aortic depressor nerve (ADN) and to increase or decrease in AP using occluders was recorded before and after bilateral CVLM injection (5 nmol in 100 nl) of either kynurenic acid (KA) or 2-amino-5-phosphonovaleric acid (APV). The rSNA response to ADN stimulation was abolished with EAA receptor blockade (see Table). However response to AP increase or decrease was preserved, consistent with Blessing and Willoughby (Am. J. Physiol. 253: H777, 1987).

		Percent change in rSNA		
		ADN	Increase AP	Decrease AP
KA	Pre-inj	-66±9 (6)	-76±6 (4)	+37±7 (4)
	Post-inj	-14±10**	-64±1	+61±8
APV	Pre-inj	-72±5 (6)	-69±6 (6)	+41±8 (6)
	Post-inj	+1±4 **	-46±6**	+43±1 7

136.10

BLOCKADE OF PARABRACHIAL PRESSOR RESPONSES BY SPINAL ADMINISTRATION OF AN N-METHYL-D-ASPARTIC ACID (NMDA) RECEPTOR ANTAGONIST. M.M. Kalis* and F.J. Gordon (SPON: B.L. Brown). Dept. Pharm., Emory Univ., Atlanta, GA 30322.

These studies investigated a potential role for spinal excitatory amino acid (EAA) receptors in the mediation of pressor responses evoked by electrical stimulation (50 uA, 0.5 msec pulses) of the lateral parabrachial complex. Rats were anesthetized with urethane, vagotomized, paralyzed and respirated. Stimulation of the parabrachial complex at 10, 20 and 40 Hz increased mean arterial pressure (MAP) by 15 ±4, 36 ±5 and 57 ±4 mmHg, respectively. Thirty min after intrathecal (i.t.) administration of the NMDA receptor antagonist D-2-amino-7-phosphono-heptanoic acid (D-AP7; 0.2 umol/10 ul) MAP had fallen from 97 ±4 to 62 ±2 mmHg and parabrachial pressor responses were reduced to -2 ±2, 1 ±2 and 6 ±2 mmHg. Neither i.v. D-AP7 nor i.t. infusion of vehicle had any effect on parabrachial pressor responses. I.t. infusion (10 ul) of NMDA (0.5 umol) or kainic acid (3 nmol) increased MAP by 43 ±7 and 38 ±6 mmHg respectively. D-AP7 eliminated the pressor action of NMDA without affecting that of kainic acid. These results indicate that the increase in MAP produced by electrical stimulation of the lateral parabrachial complex may be dependent upon synaptic activation of spinal NMDA receptors, and suggest that EAA neurotransmitters may play a role in mediating cardiovascular responses evoked by activation of descending sympathoexcitatory pathways. (NIH HL-36907)

136.11

BLOCKADE OF SPINAL PATHWAYS CAUSES NON-UNIFORM DECREASES IN PRE- AND POSTGANGLIONIC DISCHARGE. L.C.WEAVER AND L. QU* (SPON: B.Timney). The John P. Robarts Research Institute and Dept. of Physiol., Univ. of Western Ontario, London, Ontario, and Neurobiol. Dept., Northeastern Ohio Univ. Coll. of Med., Rootstown, Ohio.

Although discharge of many sympathetic nerves decreases substantially upon transection of the spinal cord in cats, firing of splenic and mesenteric nerves continues unabated (Brain Res. 338:123, 1985; J.Physiol. 396:155, 1988). Experiments were done in anesthetized cats to determine if ongoing sympathetic outflow to the splanchnic circulation depends less upon supraspinal excitatory drive than that directed to other vascular beds. Transection of the cervical spinal cord (CIX) significantly decreased firing of gastric, hepatic, adrenal and lumbar chain sympathetic nerves. Discharge of gastric and hepatic nerves decreased (-49% and -75%, respectively) as much as that of adrenal and lumbar chain nerves (-39% and -60%, respectively). Thus, sustained discharge after CIX is not necessarily characteristic of innervation of the splanchnic circulation. In contrast, discharge of preganglionic greater splanchnic nerves was not decreased after CIX, although the firing pattern changed from rhythmic to asynchronous. This suggests that preganglionic rhythmicity may be important for effective synaptic transmission to some but not all postganglionic neurons. Support: Can. Ht. Fdn. and NIH grant HL21436.

136.12

RENAL AND GREATER SPLANCHNIC NERVE RESPONSES TO BLOCKADE OF THE ROSTRAL VENTROLATERAL MEDULLA IN RATS. C.P. YARDLEY*, K. HAYES*, and L.C. WEAVER. The John P. Robarts Research Institute and Department of Physiology, University of Western Ontario, London, Ontario, Canada.

In cats, transection of the spinal cord decreases discharge of renal nerves, but does not decrease firing of preganglionic greater splanchnic nerves (Neurosci. Abst: 1988), suggesting that actions on postganglionic nerves do not necessarily reflect changes produced in preganglionic sympathetic nerves. Experiments were done to compare effects of blockade of excitatory drive from rostral ventrolateral medulla (RVLM) on renal and pre- and postganglionic splanchnic nerves in rats. Glycine (1M) was microinjected (150 nl) unilaterally into the RVLM of urethane anesthetized rats while recording renal (RNA) or greater splanchnic nerve activity (GSPNA) and blood pressure (BP). Eleven injections decreased RNA by 45% and BP by 36%. After seven other injections, mean GSPNA decreased by only 18% and BP fell by 30%. Moreover, the preganglionic component of SPNA (after hexamethonium) was reduced by only 13%, whereas RNA (sample from sites causing similar decreases in BP) was reduced by 33%. These results show that, in the rat, tonic discharge of RVLM neurons is more important for maintaining renal than pre-and postganglionic components of greater splanchnic nerve discharge. Supported by the Canadian Heart Foundation and NIH grant HL21436.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: VESTIBULAR SYSTEM II

137.1

VESTIBULAR AMPULLARY EPITHELIA IN A TURTLE, P.SCRIPTA: STRUCTURE AND INNERVATION. A.M. Brichta & E.H. Peterson. Department of Zoological & Biomedical Sciences & College of Osteopathic Medicine, Ohio University, Athens, Ohio 45701.

As part of a larger study aimed at understanding vestibular control of head movement in *P.scripta* we are characterizing the functional architecture of vestibular primary afferents. We have begun by assessing: 1) organization of the ampullary neuroepithelia using light and scanning electron microscopy (SEM) and 2) morphology and spatial distribution of vestibular peripheral processes using horseradish peroxidase (HRP).

SEM analysis of ampullary neuroepithelia revealed statistically significant regional differences in hair cell density, luminal surface profiles, and cilia complexes. Peripheral hair cell density is high (39±6 hair cells/1500um^2); mean profile areas are small (11.5 ± 3.7um^2) and tend to be elliptical. Stereocilia are generally smaller in diameter, length, and number than those found centrally. In contrast central hair cell density is low (26±1 hair cells/1500um^2), while outline areas are large (17.4 ± 5.3um^2) and more nearly circular. To relate hair cell morphologies to their innervation, we labelled peripheral endings of vestibular primary afferents using an *in vitro* HRP technique (Brichta and Peterson, '87, Soc. Neurosci. Abs.13:634). All afferents were traced back to their cell somas in the vestibular ganglia. There are three morphological types of vestibular primaries - calyceal, dimorphic, and bouton - that differ significantly in fiber diameter (Brichta and Peterson, '87). Reconstruction of individual primaries reveals that these types also differ in collecting territories, branching density and terminal number. Calyceal fibers terminate only in central regions of the epithelium and never branch before entering the crista. In contrast, bouton endings are found preferentially at the epithelial periphery, and dimorphic endings have a relatively homogeneous distribution. Both types sometimes branch before entering the crista; daughter branches may innervate widely separated regions of the epithelium, but always form the same terminal type. Terminal sprays of all three types are oriented normal to the long axis of the crista; the linear collecting distances of calyces are shorter (X=25.5±11 um) than those of dimorphic (X=54±20um) and bouton types (X=109±73um). Calyceal sprays had fewer terminal processes (X=4) than dimorphic or bouton types (>8). Taken together, these data suggest that there may be multiple information channels in *Pseudemys* vestibular nerve that differ in morphology, hair cell contacts, and spatial organization within the sensory epithelium.

HORIZONTAL CANAL AFFERENTS TERMINATE IN THE LATERAL VESTIBULAR NUCLEUS. G.A. Kevetter and A.A. Perachio. Dept. Otolaryng., U. TX. Med. Branch, Galveston, TX 77550.

The central distribution of afferents that innervate the horizontal semicircular canal was studied in order to continue the identification of areas that receive segregated and integrated input in response to head accelerations in both the vertical and horizontal planes. The lateral vestibular nucleus (LVN) was the focus of this study since it has been considered to receive primarily an otolith input. Horseradish peroxidase was ionophoretically applied to either the crista ampullaris of the lateral canal or intra-axonally into physiologically identified vestibular afferents in the gerbil. Labeled fibers and terminals were located in all four major vestibular nuclei and portions of the cerebellum. As the fibers entered the brainstem, they divided into an ascending and a descending branch. In the ventral LVN, medially directed collaterals were present. Swellings, resembling boutons en passant, were observed on these collaterals as they traversed the LVN and continued to the medial nucleus. Labeled terminals were abundant in the lateral portion of LVN. Afferents that were injected intracellularly had a distribution pattern similar to that seen after extracellular injections. Most injected afferents had an irregular spontaneous discharge rate. Additional features of the termination patterns in the LVN could be determined. Collaterals of the descending branch were thick and directed medially. Many small, thin branches emerged from these collaterals and ramified throughout the rostral caudal extent of LVN with many terminal boutons in the LVN. Many fewer fibers and terminals were located in the dorsal LVN. (Supported by NSF BNS 84/18559, NIH NS24391, and NASA NAG2-26).

137.3

VESTIBULAR PROJECTIONS TO MOTOR CORTEX IN MACACA NEMESTRINA. O.B. White and J.C. Brinkman*, Experimental Neurology, John Curtin School, A.N.U., Canberra, A.C.T. 2601, AUSTRALIA.

There are direct projections from the vestibular nuclei to nucleus VPLo in the monkey thalamus. Previous studies have identified vestibular responses only in areas 2 and 3a of the monkey cerebral cortex (Lang et al, Brain Res. 177:3, 1979), despite the fact that VPLo projects to area 4 (Friedman, D. and Jones, E., J. Neurophysiol. 45:59, 1981). In this study single unit recordings were made from the motor cortex of conscious monkeys during active performance of a stereotyped task, passive manipulation of the contralateral limbs and, during depolarization of the contralateral round window. Recording sites were confirmed histologically to be in area 4. Thirty-nine of 158 units tested responded to vestibular stimulation, 8 at latencies < 8 msecs. Unit responses were either phasic or sustained throughout the stimulus period. Twenty of 39 units also responded to passive manipulation of the contralateral limbs or axial musculature. An additional 9 units responded only to a combination of reaching out and labyrinthine depolarization. Thus, we have identified a vestibular field in that region of motor cortex which receives kinaesthetic afferent input from axial and proximal limb structures.

PASSIVE MEMBRANE PROPERTIES AND SPONTANEOUS SYNAPTIC ACTIVITY OF BULLFROG UTRICULAR AFFERENTS. R.A. Baird. Neurological Sciences Institute, Portland, OR 97209.

To study, in vitro, synaptic transmission and impulse initiation in the bullfrog utricular macula, microelectrodes were inserted into the apical surface of the sensory epithelium. Stable intracellular recordings were obtained from both supporting hair cells (SHCs) and unmyelinated afferent nerve terminals (ANTs). The two cells are readily distinguished by their responses to intracellular current. SHCs have large (-70 to -90 mV) resting potentials, low (10-30 MΩ) input resistances, and are electrically passive. ANTs, on the other hand, display smaller (-30 to -65 mV) resting potentials, larger (40-175 MΩ) input resistances, and respond with single spikes to small (0.1-1.0 nA) positive currents.

Most ANTs have spontaneous spiking and synaptic activity. The spike discharges of striolar ANTs are low (1-10 sp/s) and irregular. Extrastriolar ANTs have higher (10-20 sp/s), more regular, discharges with large postspike afterpolarizations. Spikes in all ANTs are notched at 20% of their amplitude and triggered off summated synaptic events. The smallest events, assumed to arise from single synaptic sites, are monophasic potentials of 0.2-0.6 mv with durations of 2-10 ms. Larger (1-2mV) events with no inflections on their rising or falling phase are seen, particularly in striolar ANTs, and may represent the synaptic input of hair cells multiply innervated by the afferent terminal. [Supported by NIH NS23584].

INPUTS FROM REGULARLY AND IRREGULARLY DISCHARGING VESTIBULAR NERVE AFFERENTS TO VESTIBULOSPINAL NEURONS OF THE SQUIRREL MONKEY. R. Boyle*, S.M. Highstein, and J.M. Goldberg (SPON: M. Meikle). Oregon Health Sciences Univ., Portland, OR 97201, Washington Univ., St. Louis, MO 63110, and Univ. of Chicago, Chicago, IL 60637.

In a previous study (J. Neurophysiol., 58:700, 1987) an electrophysiological paradigm, based on the differential excitability of irregular (I) and regular (R) afferents, was used to characterize the monosynaptic inputs from the ipsilateral vestibular nerve (V_i) to second-order vestibular nuclei neurons projecting to the oculomotor nucleus, flocculus, and spinal cord. Here we extend the analysis and record the monosynaptic EPSPs elicited by V_i stimulation of antidromically identified vestibulospinal neurons to different spinal segments in anesthetized squirrel monkeys (Saimiri Sciureus). Stimulating electrodes were placed on V_i, in the rostral MLF, and at spinal levels C_1, C_6, and T_{12}. Fifty-three neurons were identified as lateral vestibulospinal (LVST) neurons. The majority of cervical-projecting LVST neurons (22/25, 88%) receive a predominant mixed (M) to I afferent input. Of the 28 lumbar-projecting LVST neurons, 15 receive an I, 3 an M and 10 an R input; no correlation was observed between the neuron's afferent input and axonal conduction velocity. Nineteen neurons were identified as medial vestibulospinal (MVST) neurons. MVST neurons to the cervical plexus (n=4) receive an I afferent input, whereas those to the brachial plexus (n=4) receive an R input. Eleven MVST neurons projected both rostrally and caudally in the MLF; these bifurcating MVST neurons receive a predominant R to M afferent input (9/11, 82%). The results suggest that LVST and MVST neurons projecting to different segments of the spinal cord differ in their profile of V_i inputs.

BRAINSTEM AFFERENTS TO THE MONKEY'S VENTROLATERAL VESTIBULAR NUCLEUS,TVP NEURONS. T.P. Langer* and C.A. Scudder. (SPON: M.C. Chubb) Dept. Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195

Tonic-Vestibular-Pause (TVP) neurons, a group of neurons in the ventrolateral vestibular nucleus that discharge at a rate proportional to eye position and head velocity, and pause during saccades, participate in the vestibulo-ocular reflex. We injected HRP among recorded TVP neurons, labeling a small part of the ventrolateral vestibular nucleus. Labeled neurons were demonstrated with the TMB method.

Labeled neurons densely filled the ipsilateral ventrolateral vestibular nucleus, but did not extend into adjacent vestibular nuclei. Scattered neurons labeled in the medial and inferior vestibular nuclei, caudal to the injection, but many more cells labeled in the contralateral medial and inferior vestibular nuclei, particularly the rostral third of the medial nucleus. The supravestibular nuclei were lightly labeled, bilaterally. Neurons were labeled in the reticular formation that contains inhibitory burst neurons, about twice as often ipsilaterally. Many cells labeled in the ipsilateral lateral cuneate nucleus, the lateral reticular nucleus, bilaterally, and the contralateral dorsal accessory olive. (Supported by RO1 EY03212)

137.7

RESPONSES OF MEDIAL VESTIBULAR NUCLEI (MVN) NEURONS DURING HARMONIC LINEAR ACCELERATION IN DECEREBRATE RATS. G.A. Bush and A.A. Perachio, Dept. Otolaryngol., Univ. TX Med. Branch, Galveston TX 77550.

Spontaneously active MVN neurons were studied for their responses to both angular and linear acceleration. The responses were qualitatively characterized by rotating the animal's head around an earth vertical axis in the horizontal plane. Each cell's response to linear horizontal translational motion (0.6 Hz; peak acceleration of ±0.145g) along the sagittal (x) and interaural (y) head axes as well as vectors oriented ±45° to the midsagittal plane was tested. Type I (n=46) neurons had significantly ($p<0.01$) higher resting rates, mean ±SD 35.0±21.8 spikes/sec compared to 20.4±12.0 for type II cells (n=43). Both type I (69%) and type II (67%) neurons responded to dynamic linear acceleration. Seventy percent of the type I cells' responses were phase related to acceleration for each axis tested compared to 50% of the type II cells. Within this group, 83% of the type I and 75% of the type II cells showed greater sensitivity to y- than x-head axis translational motion. With respect to the vector producing the greatest response, 40% of the type I cells had a mean ±SD phase lead of 27.0° ±6.0, whereas the remaining type I cells had a mean ±SD phase lag of 20.9° ±10.4. With one exception, type II neurons exhibited a response phase lead, mean ±SD=13.3° ±3.2. Type I cells, which all responded throughout the stimulus period, showed a greater mean ±SD gain, 35.6±7.0 than non-rectifying type II neurons, 28.0±9.5 spikes/sec/g. Half of the type II cells analyzed exhibited some degree of rectification (silencing) during the stimulus. These type II neurons had lower average spontaneous firing rates, 18.0±10.5 spikes/sec, and a greater mean ±SD gain, 43.4±7.1 spikes/sec/g, when compared to either type I or non-rectifying type II cells. The average peak response ±SD had a phase lead of 49.4° ±31.8 re head acceleration. Approximately half of the rectifying type II cells responded in phase with head velocity, accounting for the large phase lead. (Supported by NASA grants NAG2-26, NTG 44-008-801; NIH grant NS24391)

137.8

EFFECTS OF SINUSOIDAL NECK ROTATION ON LOCUS COERULEUS-COMPLEX NEURONS. O.Pompeiano,C.D.Barnes,D.Manzoni*,G.Stampacchia* and P.d'Ascanio*. Dept. Physiol.& Biochem.,Pisa Univ.,56100 Pisa,Italy.

In precollicular decerebrate cats the activity of 99 locus coeruleus (LC)-complex neurons, 11 of which activated antidromically by stimulation of the spinal cord at T_{12}-L_1, was recorded during sinusoidal neck rotation. Among the noradrenergic LC-complex neurons (which had a slow and regular resting discharge and a typical response to a noxious stimulus characterized by a burst of activity followed by a silent period), 73 (73.7%) responded to neck rotation at 0.15 Hz, ±10°. In particular, 40 of 73 units (54.8%) were excited during side-down and depressed during side-up neck rotation, while 18 of 73 units (24.7%) showed the opposite pattern (average phase lead of +34.2° re to position). The observation that the predominant response pattern of LC-complex neurons to neck rotation was opposite to that of vestibulospinal (VS) neurons projecting to the same segments of the spinal cord should be related to the fact that while the VS neurons exert a direct excitatory influence on ipsilateral limb extensor motoneurons, the coeruleospinal (CS) neurons exert an inhibitory influence on the related Renshaw (R)-cells (Fung S.J. et al. Brain Res.402: 351-354,1987). It appears, therefore, that during side-up neck rotation ipsilateral limb extensor motoneurons are excited by an increased discharge of VS neurons, while the related R-cells are disinhibited by a reduced discharge of CS neurons. This would enhance the functional coupling of motoneurons with the corresponding R-cells, thus limiting the response gain of limb extensors to neck stimulation.

SPATIAL PROPERTIES OF SECOND ORDER VESTIBULOOCULAR RELAY NEURONS IN THE ALERT CAT. S. I. Perlmutter, K. Fukushima, B.W. Peterson, J.F. Baker, Northwestern Univ. Med. School, Chicago, IL 60611

Last year we reported that part of the spatial transformation in the VOR occurs as early as the second-order vestibuloocular relay neuron (2VON) in decerebrate cats. We have now analyzed the properties of 35 2VONs in the alert cat, identified by their monosynaptic response to electrical stimulation of labyrinth and antidromic response to stimulation of midbrain MLF. Responses were recorded to 0.5 Hz, 10° rotations in 3-10 vertical and horizontal planes. Neurons were classified according to the canal from which they received their strongest input. Of 20 2VONs that received their primary input from the posterior canal (PC: mean gain 2.2+1.0 spikes/s/deg/s), 16 responded maximally to rotation in a vertical plane within 10° of the PC plane while 4 received sufficient convergent input from the orthogonal vertical canal to shift their plane of maximum response >10° from the PC plane towards the roll plane and close to the plane of the oblique eye muscle. Of 15 neurons that received primarily anterior canal (AC) input (mean gain 3.2+0.9 spikes/s/deg/s), 13 were non-convergent, while 2 had maximum response planes which were >10° from the AC plane in the direction of the pitch plane. Thus **spatial transformation occurs at the 2VON level in alert cats.** 2VONs also received convergent horizontal canal (HC) input (mean gain for all neurons 0.4+0.3 spikes/s/deg/s). All 7 AC neurons whose maximum response plane was tilted >10° from the vertical by HC input exhibited Type II horizontal responses. Of 15 PC cells with tilts >10°, 11 exhibited Type I, 4 Type II responses.

None of 12PC and 6AC neurons examined showed a clear pause during saccades; 8/12 PC and 6/6 AC showed a significant correlation (sensitivity 0.5-2.4 spikes/s/deg) with vertical eye position (up for AC, down for PC). Responses were mostly tonic.

Pairing horizontal rotation with vertical optokinetic stimulus leads to development of vertical vestibuloocular responses to horizontal rotations in the dark (Brain Res. 371(1986)162). Two of 4 2VONs tested showed a large change in maximum response vector after such paired stimuli, producing more horizontal component. Thus **2VONs appear to participate in the adaptive change of the VOR.**

137.10

VESTIBULAR COMPENSATION: AN IN VIVO AND IN VITRO STUDY OF SECOND ORDER VESTIBULAR NEURONS. **C.de Waele*, M.Serafin*, M.Mühlethaler and P.P.Vidal. Lab. de physio. Neurosens.,CNRS, Paris, France and Dept de Physiol. CMU Geneve Switzerland**

Following the surgical removal of one labyrinth, guinea pigs exhibit a postural and oculomotor syndrome, due to a decrease of the resting discharge of second order vestibular neurons(dVII) in the deafferented side and an increase in the intact side. The recovery of a near balanced discharge between both sides is considered to be an essential mechanism for vestibular compensation. We have therefore recorded in situ the resting discharge of dVII before, immediately after and one week following surgery. In the acute stage neurons were found to be silent whereas already 4 days later they recovered a normal basal discharge. Preliminary studies have shown in brain slices and in the isolated whole brain in vitro the presence of at least three neuronal cell types in the vestibular nuclei. The exploration of their membrane properties after hemilabyrintectomy should provide an insight into the mechanisms of restauration of the resting discharge. (supported in part by grant no 3.288-0.85 from swiss NSF).

137.11

RECOVERY OF ACTIVITY OF TYPE II NEURONS IN THE MEDIAL VESTIBULAR NUCLEUS (MVN) FOLLOWING UNILATERAL LABYRINTHECTOMY IN THE DECEREBRATE GERBIL. S.D. Newlands* and A.A. Perachio. Depts. Otolaryng., Physiology & Biophysics, U. Texas Med. Branch, Galveston, TX 77550.

Recordings were made bilaterally from the MVN of gerbils in three types of preparations; labyrinth intact controls, acutely right labyrinthectomized (2 to 10 hours), and chronically right labyrinthectomized (4 to 6 weeks). Dynamic responses to horizontal rotation at 1.3 and .13 Hz (peak velocity 52°/sec) were recorded. An average cycle histogram was computed, curve fitted with the first and second harmonic, and the gain (in spikes/sec/deg/sec) and phase re velocity (in degrees) of the peak response were calculated. In normal gerbils, the gain and phase (±S.E.M.) of type II neurons at 1.3 Hz (n=22) were .61±.03 and -3.0±.9, and at .13 Hz (n=17) were .49±.03 and 23.6±2.9. Acute right labyrinthectomy resulted in a significant reduction in gain at both frequencies and a phase advance at .13 Hz bilaterally and an increased phase lag at 1.3 Hz on the left. The gain at 1.3 Hz was asymmetric and significantly higher on the right. In the right MVN at 1.3 Hz (n=35), gain = .30±.01 and phase = -1.6±.8; and at .13 Hz (n=27), gain = .19±.01 and phase = 48.1±0.4. On the left at 1.3 Hz (n=13), gain = .18±.01 and phase = -17.6±1.7; and at .13 Hz (n=9), gain = .13±.01 and phase = 58.7±2.4. Type II neurons were difficult to find in the left nucleus. In the compensated animals, the gain at 1.3 Hz improved significantly on the left, remained low relative to controls at .13 Hz bilaterally, and became equivalent bilaterally at both frequencies. The phase advanced at 1.3 Hz bilaterally. In the right nucleus at 1.3 Hz (n=22), gain = .37±.02 and phase = 14.8±.6; and at .13 Hz (n=19), gain = .19±.01 and phase = 43.5±.9. In the left MVN at 1.3 Hz (n=10), the gain = .35±.03 and phase = 9.1±1.5; and at .13 Hz (n=9), gain = .20±.01 and phase = 44.1±1.9. These data indicate that compensation of type II dynamic responses is incomplete and frequency dependent. (Supported by NASA grant NAG 2-26 and NIH grant NS24391)

NALOXONE INDUCES AN EXCITATORY EFFECT ON THE VESTIBULAR SYSTEM PRIMARY AFFERENTS. E. Soto, M. E. Pérez* and R. Vega.* Universidad Autónoma de Puebla, Depto de Ciencias Fisiologicas - ICUAP, Apartado Postal 406, Puebla, Pue. México.

It has been reported that in the cochlea and vestibular system there exist immunorreactivity to some neuropeptides, particularly enkephalines. With the aim to contribute to the understanding of peptides role in synaptic transmission on the peripherial vestibular organ, we studied the effect of naloxone on the activity of vestibular system primary afferents of the axolotl (Ambystoma mexicanum).

Multiunit recordings from afferent fibers were done by a suction electrode. Naloxone 10^{-4} and 10^{-3} M was applied by microperfusion in volumes of 20 µl. We found that naloxone 10^{-4} M induces an increase of about 40% of the basal resting discharge, its effect lasting about 2 min. Naloxone did not modify the response of afferent fibers to mechanical stimulation nor the effect induced by glutamate 10^{-3} M or kainate 10^{-4} M.

These results suggest that enkephalines participate in synaptic transmission in the inner ear of amphibians, exerting an inhibitory influence upon its synaptic target.

137.13

THE EFFECTS OF CHOLINERGIC AGONISTS ON THE PASSIVE MEMBRANE PROPERTIES OF RAT MEDIAL VESTIBULAR NEURONS IN VITRO. K.D. Phelan and J.P. Gallagher. Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

We have previously demonstrated that primary afferent transmission to the medial vestibular nucleus (MVN) is not mediated by acetylcholine (ACh), but rather an excitatory amino acid (Soc. Neurosci. Abstr. 11:104). The purpose of the present study was to determine the effects of cholinergic agonists on rat MVN neurons using intracellular recording methods in an in vitro transverse slice preparation.

Superfusion of ACh (10 µM) produced membrane depolarization (<10 mV), increased spontaneous firing, and decreased input resistance (<20%). Muscarine (10 µM), a selective muscarinic agonist, predominantly caused membrane depolarization (<10 mV) and increased spontaneous firing through an apparent decrease (<20%) of a K^+ conductance. In some instances, muscarine produced membrane hyperpolarization and decreased resistance. Pretreatment with atropine (1 µM) reversibly blocked the effects of muscarine. The selective nicotinic agonists, nicotine (20 µM) and dimethylphenylpiperazinium (DMPP) produced membrane depolarization (<10 mV), increased spontaneous firing, and decreased input resistance (<40%). Pretreatment with mecamylamine (10 µM) reversibly suppressed these effects. The effects of each cholinergic agonist persisted in the presence of tetrodotoxin or a low Ca^{2+}/high Mg^{2+} solution.

These findings indicate that MVN neurons possess muscarinic as well as nicotinic cholinergic receptors. Our results suggest cholinergic mechanisms may play a prominent role in the modulation of the activity of MVN neurons.

EFFECTS OF ACUTE HEMILABYRINTHECTOMY ON THE RESPONSES OF IPSILATERAL VESTIBULAR NUCLEAR NEURONS TO BIDIRECTIONAL OFF-VERTICAL AXIS ROTATIONS (OVAR). Y.S. Chan, Y.M. Cheung and J.C. Hwang. Dept. of Physiology, University of Hong Kong, Sassoon Road, Hong Kong.

This study aims to explore how coding of spatial and directional information about the animal's horizontal plane is processed in vestibular nuclear neurons on the lesioned side by subjecting the decerebrate hemilabyrinthectomized (HL) cats to constant-velocity OVAR in the clockwise (CW) and counterclockwise (CCW) directions. At 4-18 hr after HL, the responses of central vestibular units could be classified into 2 groups based on their responses to bidirectional 10° OVAR (1.75°/s). The first group of units exhibited response patterns similar to those obtained in cats with intact labyrinths (Chan et al., Brain Res., 406, 1987). These units responded to either CW or CCW OVAR with position-dependent discharge modulation (with comparable gains in either direction). About 2/3 of the units exhibited phase lead response, while the remaining 1/3 showed phase lag response. The mean response gain of these units, however, was only 1/3 of that observed in labyrinth intact animals. The other group of units showed discharge modulation only to 10° OVAR in either the CW or CCW direction but not to both. Some units of the latter group became responsive to bidirectional OVAR with increase in the amplitude of head tilt or the velocity of rotation, although the gain ratio of CW and CCW were not necessarily equal to 1.

For each bidirectionally responsive unit, the characterized directional axis which represents the direction given by the averaged position of the CW/CCW discharge maxima was determined. Such directional axis of each unit remained fairly stable at different head tilts (5-25°) or velocities of rotation (<15°/s), a phenomenon similar to that observed in intact preparations. In both the intact and HL preparations, the directional axes of the units were distributed fairly uniformly along the pitch and roll axes and the subtended angles. There was an apparent change in the relative percentage of type 1 to type 2 units, and that of type α to type β units in HL cats as compared to those of the intact cats. Such observed difference in the population of cells sampled could be due to the restricted sensory inputs from the contralateral intact otoliths. LINEAR VESTIBULO-OCULAR REFLEX (LVOR) OF SQUIRREL MONKEY: I. BASIC CHARACTERISTICS. D.L.Tomko and G.D.Paige. NASA Ames Research Center, Moffett Field, CA 94035.

Horizontal (H-LVOR), vertical (V-LVOR) and torsional (T-LVOR) eye movements were recorded with dual search coils in 6 squirrel monkeys during linear accelerations (0.5-5.0 Hz, 0.36g Pk) delivered by an air bearing linear sled. Linear stimuli were generated along the animals' naso-occipital (NO), inter-aural (IA) and rostro-caudal (RC) axes. For each stimulus axis, 4 of the following six animal positions were tested: upright, inverted, nose up or down, and left or right ear down. Gains (deg/s/g) and phases (eye velocity re head velocity) were calculated.

Two LVORs, H-LVOR during IA and V-LVOR during RC oscillation were compensatory, with eye velocity opposing head velocity (phase near 180 deg), aiding maintenance of gaze fixation. Gains for both reflexes rose from 15 to 30 deg/sec/g as frequency increased from 0.5 to 5.0 Hz. A noncompensatory T-LVOR during IA and V-LVOR during NO oscillation were also recorded whose gains were smaller (8-15 deg/sec/g) than the compensatory reflexes. For all axes of motion, no systematic modification in gain or phase was observed as a function of head orientation. Thus, the LVORs from 0.5 to 5.0 Hz behave as a set of specific vectorially-defined reflexes analogous to the angular VORs.

138.2

LINEAR VESTIBULO-OCULAR REFLEX (LVOR) OF SQUIRREL MONKEY II: VISUAL-VESTIBULAR INTERACTIONS. G.D. Paige and D.L. Tomko, NASA Ames Research Center, Moffett Field, CA 94035.

Horizontal (H-LVOR) and vertical (V-LVOR) eye movements were recorded (coil technique) in monkeys secured in a 3 axis positioning device riding on air bearings. Linear oscillations (0.5-5.0 Hz, 0.36g pk.) were generated along the naso-occipital (NO), inter-aural (IA) and rostro-caudal (RC) axes, in darkness and in light while monkeys looked at the container wall (visual suppression; LVSVOR).

The H-LVOR during IA and V-LVOR during RC oscillation were compensatory: eye velocity opposed head velocity. Compared to LVOR gain (o/s/g) in darkness , LVSVOR gain for both reflexes dropped to near 0 at 0.5 Hz. However, gain rose as frequency increased, to nearly double that in darkness at 5 Hz. Since visual influences on eye movements are nearly gone at 5 Hz, we surmised that a measure of target distance (TD), likely vergence-dependent, biased the LVSVOR for fixation on the container wall (TD=20 cm). Darkness presumably allowed distant "fixation" and smaller gains. When vergence was measured during oscillations (binocular coils), vergence angle and gain were closely linked. A simple geometric model explains the findings.

During NO motion above 0.5 Hz, responses depended on gaze re axis of motion (e.g. rightward during right gaze, upward during up gaze, etc.). This unique switching in the LVOR is consistent with a compensatory, TD- and gaze-dependent geometric model.

RELATIVE CONTRIBUTIONS OF COMPENSATORY HEAD AND EYE MOVEMENTS TO VISUAL STABILIZATION DURING CIRCULAR LOCOMOTION IN LIGHT. David Solomon and Bernard Cohen, Depts. of Neurology and Physiology, Mt. Sinai School of Medicine, City University of New York, 10029

We studied characteristics of gaze during running in light to determine the effects of properties of the visual surround. The dimensions of the running platform and experimental chamber were such that the monkey's axis of rotation (.3 m) was comparable to surround distances, necessitating a gain change to stabilize the visual surround. Eye velocity re head ($\dot{E}h$), head velocity re body ($\dot{H}b$), body velocity in space ($\dot{B}s$) and angular position relative to the surround were recorded as the animal circled in light. The curtain to the chamber was either open or closed, changing the surround distance in the direction of gaze during part of each revolution. An open curtain allowed for the possibility of an investigator appearing with a fruit reward. $\dot{E}h$ and $\dot{H}b$ were scaled and summed to yield gaze velocity re body ($\dot{G}b$). There was continuous compensatory nystagmus of the eyes and head during running. Ocular quick phases were larger and of shorter duration when the head was free than when it was fixed during passive rotation, probably due to the VOR acting toward the end of the movement.

Slow phase gain was calculated by dividing $\dot{G}b$ by $\dot{B}s$ and averaging according to angular postition. Gains were as low as .7, indicating some tolerance for retinal slip. When passing the presumed area of interest, gain varied from 1.0 to 1.3, depending on the animal's distance from the visual surround. $\dot{E}h$ gain was typically around .6 (range .3-.9) and $\dot{H}b$ gain around .3 (.2-.7). $\dot{H}b$ gain built to a maximum with a corresponding drop in relative $\dot{E}h$ contribution when $\dot{G}b$ gain was highest while running past the sector of interest. Thus, eye-head coordination strategies are used differentially when prolonged gaze stabilization of a particular field is desired. Supported by NS00294 & EY01867.

PITCH AND YAW VESTIBULO-OCULAR REFLEXES RESPOND DIFFERENTLY TO GRAVITY SENSE. S.A. Rude, K.D. Powell*, J.F. Baker. Dept. of Physiology, Northwestern Univ. Sch. of Med., Chicago, IL 60611.

Last year we presented a study of the horizontal vestibulo-ocular reflex (VOR) in the cat showing that during low frequency yaw rotations the horizontal VOR is significantly improved with the addition of a changing gravity stimulus. This improvement was observed when the animal was positioned on either its left or right side, despite reversed saccular otolith versus canal stimulus phases in the two positions. Does the vertical VOR show an analogous improvement in its low-frequency response during pitch rotations in prone and supine positions as compared to pitch on the side, where there is no changing gravity stimulus?

We made electro-oculographic recordings of the pitch vertical VOR during small amplitude oscillations from 0.01 Hz to 1.0 Hz in the prone, supine (rolled 180° from prone), left and right side (rolled ±90° from prone), and nose down (pitched 90° nose down) positions. Although the prone position vertical VOR was accurate at all frequencies, on side pitch produced phase advances below 0.1 Hz with corresponding gain decreases. On side vertical VOR was asymmetric, with stronger upward than downward slow phase. This confirms Tomko *et al.* (*Exp. Brain Res.*, 69:307, 1988) who used much larger amplitude rotations. The supine vertical VOR below 0.1 Hz showed average phase advances greater than on side VOR, and generally lower gains. However, supine VOR was difficult to interpret at 0.01 Hz and showed marked asymmetry of the upward vs. downward response. Barmack obtained similar results in rabbits (*J. Physiol.*, 314:547, 1981). Nose down orientations produced accurate VVOR phase responses though gain was somewhat lower than while prone.

Thus the vertical VOR was improved in the prone position, which involved a changing gravity stimulus. However, when the phase of the utricular stimulus was reversed with respect to the canal stimulus by placing the cat in the supine position the low frequency vertical VOR was less accurate than without a changing gravity stimulus. ADAPTATION IMPROVES THE LOW FREQUENCY PITCH VESTIBULO-OCULAR REFLEX (PVOR) IN SUPINE CATS. K.D. Powell*, S.A. Rude, J.M. Banovetz*, S.I. Perlmutter, B.W. Peterson, J.F. Baker. Interdepartmental Graduate Program in Neuroscience and Dept. Physiology, Northwestern Univ., Chicago, IL 60611. Support: EY05289, EY06485, EY07342.

In the preceding abstract we show that the pitch vestibulo-ocular reflex (PVOR) of cats in the prone position is accurate for whole body rotations at frequencies as low as 0.01Hz, but that the PVOR of cats in the supine position has advanced phase and lower gain below 0.1 Hz. This poor performance may be due to reversal of the utricular stimulus in the supine position. Is the deficiency of the supine PVOR a result of "hard wiring" of the PVOR neural network, or is it an adaptive response to greater experience in the prone versus supine position? If it is the latter, then an adaptation paradigm should produce improvement in the supine PVOR.

We attempted to adapt the supine VOR in 3 cats in 6 experiments. The PVOR was electrooculographically recorded during whole body pitch rotations in darkness at several frequencies in the prone, supine, and 90° rolled positions, before and after adaptation. During 2 hr adaptation, a supine cat was pitched at 0.05 Hz and viewed an optokinetic pattern which rotated at 0.05 Hz, but 180° out of phase with the head and thus in phase with desired VOR. In all 6 experiments low frequency PVOR gain in the supine position was significantly increased by adaptation. In 5 experiments low frequency PVOR phase in the supine position was significantly less advanced after adaptation. The PVOR of the cat in prone position was not made less accurate by the adaptation. We conclude that inaccuracy of the PVOR of the cat in the supine position is in part caused by inexperience. While supine PVOR improved, changes were smaller than we have observed in 0.05 Hz VOR direction adaptation experiments. The small effect could be due to habituation, asymmetry of up versus down eye movements, or less VOR plasticity in the supine position.

MACULO-OCULAR REFLEX OF THE RAT ELICITED BY LINEAR ACCELERATION AND OFF-VERTICAL AXIS ROTATION. B.J.M. Hess[1]* and N. Dieringer[2]*. Neurol. Clinic[1] Zürich (CH); Physiol. Institut[2], Munich (FRG).

The maculo-ocular reflex (MOR) was studied in brown rats during static tilt, sinusoidal linear acceleration on a sled and during constant-velocity rotation on a table tilted up to 30° re earth vertical (OVAR). Eye movements were recorded with a magnetic field search coil system which allowed to measure linearly horizontal, vertical and torsional components with a double search coil. Static tilt or sinusoidal linear horizontal accelerations (0.2-1.0 Hz, up to 30 cm) elicited predominantly vertical and torsional MOR responses with a gain up to 0.25, depending on the orientation of the head re direction of acceleration. OVAR elicited vertical and torsional eye movements with 2-3 times higher gains than corresponding MOR responses. An additional horizontal component, consisting of a bias velocity and a superimposed sinusoidal modulation showed a clear directional asymmetry for the two eyes: Responses of the eye ipsilateral to the direction of a table rotation had a smaller gain. The phase values of vertical and torsional OVAR responses reflected the animal's best orientation re acceleration for optimal MOR responses on the sled. (SPON: ENA)

EYE AND NECK MOTOR COUPLING IS DEPENDENT ON THE PRESENCE OF ORIENTING STIMULI. J. M. Banovetz*, K. Fukushima, S. A. Rude, J. F. Baker, and B. W. Peterson. Depts. of Physiol., Northwestern Univ., Chgo, IL and Hokkido Univ., Sapporo, Japan. Support: EY05289, EY06485, EY07342

Recent evidence suggests that neck reflex responses are the product of collateral excitation by oculomotor systems (Vidal, et. al.,1982). We propose that eye-neck coupling is dependent on visual or other sensory targets to which the animal trys to orient. Orienting responses may lead to neck EMG, torque, and position responses that are well correlated with eye movements. In the absence of such targets, the neck motor system is uncoupled and functions other than orienting can be effectively studied.

We have studied the extent of eye-neck coupling by measuring EOGs, Biventer, Complexus, Splenius, Occipitoscapularis, Rectus Major, and Obliquus EMGs, and torque production about the C1-C2 and C1-skull joints during whole body rotations in 3 dimensions. In the absence of target stimuli, the EMG's and torques are closely correlated with the vestibular stimulus, and are unrelated to saccadic eye movements. When the animal is rotated in the light, however, with consequent visual stimulation, the neck torques show a clear correlation with eye position. The important difference is the presence of target stimuli. Furthermore, when the vestibuloocular reflex (VOR) is adapted for two hours by rotating the animal in the dark with an optokinetic stimulus rotating synchronously in an orthogonal direction, the VOR develops an adaptive component in the optokinetic direction, but the neck torques demonstrate little or no adaptation. This evidence suggests that, although there may be overlap in the vestibular neuron populations that drive the ocular and neck reflexes, the neck motor output is not driven by or closely related to eye position, and the vestibular control loops are largely seperate. Coordinated eye and neck movements may be controlled by higher centers, such as the Superior Colliculus, perhaps activating a specific coupling pathway such as the tecto-reticulospinal pathway of Grantyn and Berthoz (1983, 1985).

GAZE-ADJUSTING SACCADIC COMPONENT OF GOAL-DIRECTED VESTIBULO-OCULAR FUNCTION. Bernard N. Segal & Joseph Bloom*. Dept. Otolaryngol., Sir MB Davis-Jewish General Hosp. & McGill Univ., Montréal, Qué., Canada H3T1E2

If a subject is briefly turned during short darkness intervals while trying to "look" at a point on the wall, the eyes tend to be kept on the unseen point by both slow-phase and rapid eye movements (Exp Brain Res 70: 26-32 (1988)). In a given turn, perhaps several rapid movements may occur, whose cumulative effect tends to correct inaccurate slow-phase movements. We now describe properties of individual rapid movements causing this effect.

Gaze (direction of regard in space) was reconstructed by adding computer-sampled head (re: space) and eye (re: head) position signals, the latter being re-calibrated during each turn. Parameters of rapid movements (initial and final gaze error (re: target); amplitude and peak velocity relationship (i.e., "main sequence"); etc.) were calculated.

Preliminary results indicated that the proportion of error-correcting rapid movements was greatest in subjects exhibiting the most slow-phase error. For example, a subject having ≈2/3 of rapid eye movements that reduced gaze error exhibited average slow-phase error, over all turns, that was ≈1/10 of head movement. Moreover, main sequence relationships computed with respect to space (i.e., gaze) were less variable than those computed with respect to the head (i.e., eye). These results suggested that excessive slow-phase error evoked rapid movements which responded to gaze error, and which combined linearly with slow-phase movements. Thus, such rapid movements appeared to be gaze-adjusting saccades which corrected variability of the slow-phase component of goal-directed vestibulo-ocular function.

EFFECT OF COMBINED LINEAR AND ANGULAR ACCELERATION ON THE VESTIBULO-OCULAR REFLEX (VOR). E.W. Sargent* and G.D. Paige (SPON: C. Scudder), Dept. of Otolaryngology, Washington Univ. School of Med., St. Louis, MO 63110.

The VOR during linear motion (LVOR) was studied indirectly from responses to angular rotation with the head placed eccentrically from the axis of rotation. Eye movements (dual search coil technique) were recorded from squirrel monkeys during angular oscillations generated with the subjects secured in a 3-D positioning device mounted on a radial rail fixed on a rate table. Head position was varied (0-40 cm), as was frequency (0.01-4.0 Hz) and velocity (25-200°/s pk). Low velocity, high frequency trials induced high tangential acceleration (T; .44g pk), whereas high velocities and low frequencies favored centripetal acceleration. With animals upright gain (pk eye/head velocities) of the horizontal VOR increased with T acceleration in the interaural (IA) axis when the monkey faced away from the rotation axis. When facing the axis, VOR gain dropped. The mean gain of the upright IA LVOR was around 70°/s/g. IA accelerations were also assessed with the monkey supine with the head eccentric (generating a torsional but not horizontal VOR). Mean gain of the supine IA LVOR was 30° /s/g. The difference may result from canal-otolith interactions generated by coplanar (vs. orthogonal) accelerations. Responses seen in other planes (e.g., vertical) during combined accelerations will also be discussed.

A WIDE RANGE OF OPTOKINETIC VELOCITIES ELICITS ADAPTATION OF VESTIBULO-OCULAR REFLEX (VOR) DIRECTION IN CATS. C.R. Mason*, S.A. Rude, J.F. Baker (Spon: W. Todd Rainey). Interdepartmental Graduate Program in Neuroscience and Dept. Physiology, Northwestern University Chicago, IL 60611.

Errors in the vestibulo-ocular reflex (VOR) produce retinal slip which, in turn, produces adaptation of the VOR and decreased retinal slip. Different experimental paradigms using lenses or optokinetic projectors produce varying velocities of retinal slip. We are studying the relative effectiveness of different optokinetic velocities in producing VOR direction adaptation.

Three cats were subjected to 0.25 Hz sinusoidal whole body pitch rotations while viewing a 0.25 Hz optokinetic stimulus oscillating horizontally in synchrony with the body rotation. Each cat was subjected to 2 hour training sessions at peak velocities of 6, 12, 24, 48, and 80°/s. Horizontal and vertical electro-oculographic recordings at a variety of pitch rotation frequencies (0.02, 0.05, 0.1, 0.25, 0.5, 1.0, and 2.5 Hz) were made in the dark before and after the training session. Saccades were removed from the records and adaptation was measured as the vectorial difference between pre- and post- adaptation gain of horizontal VOR during pitch.

Maximal VOR direction adaptation occurred at an optokinetic stimulus peak velocity of 24°/s, with decreased adaptation at extremes of velocity.

Two of the 3 animals received aspiration lesions of cerebellar nodulus and uvula, which may be involved in optokinetic following and VOR adaptation. VOR direction adaptation gain was significantly lower after the lesions; however, both animals still exhibited clear VOR adaptation.

We conclude that a wide range of peak velocities of optokinetic stimuli can be paired with head rotation to produce VOR adaptation, and that nodulo-uvular lesions reduce but do not abolish VOR direction adaptation.

AGE AND LESION DEPENDENCE OF SIZE OF DEITERS GABA IMMUNOPOSITIVE TERMINAL STRUCTURES IN WEAVER MUTANT MICE. J. Bäurle*, U. Grüsser-Cornehls* and B. G. Grover*. (SPON: European Neuroscience Association). Dept. of Physiology, Freie Univ. Berlin, Arnimallee 22, 1000 Berlin 33 (FRG.

The postnatal degeneration of cerebellar granule cells in Weaver mutant mice leads to a reorganization of neuronal circuitry and plastic changes in subjacent cerebellar structures (Grüsser-Cornehls U. and Grover B. G. Neurosci., 13:1224,1987). The goal of the present investigation was to determine whether aging or cerebellar lesions result in size changes of terminals abutting vestibular nuclear cells, from which at least some portion must represent Purkinje cell terminals. Control and Weaver mutant mice ranging in age from 7 days to 9 months and adult cerbellectomized mice were examined.

Camera lucida drawings of terminal structures were made using plan-apo-oil-phase-contrast optics (Zeiss) from material immunoreacted for GABA. The cross-sectional terminal area was evaluated with a Kontron Mini-Mop after Xerox enlargement.

In control mice terminal sizes were smallest in 7-day-old mice (range: 0.2 to 1.6 um^2), increased slowly thereafter up to 5 to 7 months (range: 0.2 to 2-3 um^2), then decreased again. The same was found for mutant mice with the significant difference that terminal sizes encompassed a larger range (7 days: 0.2 to 2.2 um^2, 5 to 7 months: 0.2 to 6 um^2). In cerebellectomized mutant mice terminal sizes were smaller than in unoperated and even smaller than those in age-matched unoperated normals. The increased number of large terminal structures seems to be specific to weaver mutants and is probably one of the functional and plastic changes in cascade caused by the degeneration of granule cells. (Supp. by a DFG grant, Gr 276/19-5)

HISTOCHEMICAL CORRELATES OF VESTIBULAR COMPENSATION FOLLOWING HEMILABYRINTHECTOMY IN RATS, R.W. Sikes, Dept of Physical Therapy, Northeastern Univ, Boston, MA 02115.

Unilateral damage to the vestibular labyrinth produces profound disturbances of posture and eye movement that are rapidly compensated in most species. In rats, posture returns to nearly normal within hours, and abnormal nystagmus dissipates within days. This study examined changes in relative levels of cytochrome oxidase (CO) in the rat during vestibular compensation.

The membranous labyrinth was surgically removed on the left side in anesthetized Long-Evans rats (200-400g). After a period of 10 hours to one week, the rats were deeply anesthetized and perfused with fixative. Frozen sections were processed histochemically to reveal the levels of CO in the brainstem and spinal cord. The optical density of the reaction product in nuclei ipsi- and contralateral to the lesion was determined and expressed as percent difference.

Differences in CO levels between sides were observed in several nuclei. Density in the ventral horn of the contralateral lower cervical spinal cord was about 16% greater than the ipsilateral side, and densely stained motor neurons were more frequently seen contralaterally. Both the rostral medial and superior vestibular nuclei had greater CO levels contralaterally in the acute animals. The CO levels in the lateral cuneate nucleus were greater ipsilaterally.

L-BACLOFEN AND THE VOR BEFORE AND AFTER NODULO-UVULECTOMY; GABA RECEPTOR HYPERSENSITIVITY IN THE VESTIBULAR NUCLEI? D. Helwig* and B.Cohen.(SPON: H. Cohen). Depts. of Neurology and Physiology. Mt. Sinai School of Medicine CUNY, New York, N.Y. 10029

We have previously shown that a racemic mixture of baclofen, when injected intramuscularly in doses of 1-5 mg/kg, acts centrally to produce a dose dependent shortening of the dominant time constant (Tc) of the VOR and of OKAN (Cohen et al. 1987). The reduction is at steady state for 1-3 hours after injection and disappears within 12-18 hours. The Tc, measured in the steady state, varied linearly with dose in 8 animals, falling 11%/mg/kg; r = 0.92). Baclofen also causes a reduction in the gain of OKN and the nystagmus produced by off-vertical axis rotation (OVAR) . These responses are all functions of the velocity storage mechanism in the vestibular system (Raphan et al. 1977, 1979), suggesting that inhibitory control of velocity storage is established by GABA, acting on GABAb receptors. In the present study we compared effects of d- and l-baclofen on the VOR and OKAN time constant with the racemic mixture in rhesus monkeys before and after nodulo-uvulectomy. L-baclofen was about twice as effective as the racemic mixture in shortening the VOR and OKAN Tc's, shifting the dose-response curve to the left. D-baclofen was ineffective in changing the Tc's at dosages up to 5 mg/kg. After nodulo-uvulectomy both the racemic mixture and the l- form were more effective in producing a decrease in the Tc than before operation and the dose response curve was shifted to the left. The data indicate that l-baclofen is the active enantiomer that produces inhibition of velocity storage. Postoperative findings are consistent with the hypothesis that a loss of the output of nodular and uvular Purkinje cells to the vestibular nuclei produces GABAb receptor hypersensitivity. SIMULATIONS OF LIZARD HEAD MOVEMENTS DUE TO VISUAL AND VESTIBULAR STIMULATION. H.B.Wang* and J.H.Anderson. Depts. of Otolaryngology and Physiology, Univ. of Minn., Minneapolis, MN 55455.

Experimental recordings in the lizard have shown that the head movements due to body rotation in the dark and due to the rotation of the visual surround (optokinetic stimulation, OKS) are dependent on the amplitude of the stimulus. The gain of the response first increases and then decreases as the stimulus amplitude increases. This may be due to a threshold and a saturation which is dependent on the neck angle. When body rotation is combined with the OKS in a synergistic manner, there is a linear summation of the expected responses to each stimulus. However, in the conflict situation (no movement of the body relative to the visual surround) there is not a linear interaction.

In order to characterize these non-linearities further and to define the relative roles which different reflexes play under closed-loop conditions, a model has been developed. Simulations indicate that the effective elasticity of the head/neck system is dependent on the neck angle. Adaptation which is characteristic of the vestibular and proprioceptive inputs is required to give appropriate head velocity profiles. A decrease in the gain of the vestibular input may be present during sensory conflict, but in the synergistic case it can cause oscillations. (Supported by NS-12125 and NS-16567.)

THE EFFECTS OF GRAVITOINERTIAL FORCE LEVEL ON SUPPRESSION OF VESTIBULAR NYSTAGMUS BY HEAD TILTS. P. DiZio and J.R. Lackner, Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

The time constant of post-rotary nystagmus decay (T) is shorter in free fall (0G) than in normal (1G) or increased (1.8G) gravitoinertial force (gif) levels, and is further shortened by 40° pitch head movements in 1G and 1.8G but not 0G.* Here, we studied 90° post-rotary head tilts. In 0G, 1G and 1.8G four blindfolded subjects were rotated at 60°/s with their heads 45° ventriflexed; they were then stopped suddenly and instructed either to keep their head still or to tilt it back 90°. As previously, we recorded the horizontal electrooculogram and used a log-linear fit to compute T (below, in seconds).

Post-rotary head position	0G	1G	1.8G
No tilt, 45° ventriflexed	10.1	16.8	15.5
90° tilt back from 45° ventriflexed	10.0	8.6	8.7
40° tilt back from 20° ventriflexed*	10.4	11.2	11.4

The data confirm that without head movements T is shorter in 0G than in 1G and 1.8G. In 1G and 1.8G, post-rotary head tilts shorten T by an amount proportional to head tilt amplitude. Head tilts in 1G and 1.8G shorten T significantly below the 0G, no head tilt value, yet in 0G head tilts do not further shorten T. This means sensory-motor signals related to head tilt relative to gif, not tilt relative to the trunk or head movements per se, trigger shortening of post-rotary nystagmus.

POSTURAL SYNDROM FOLLOWING GLOBAL AND SELECTIVE LESION OF THE VESTIBULAR APPARATUS IN GUINEA PIG. VIDAL P.P., de WAELE C., GRAF W. (SPON: J.J. Dreyfuss)

The present study was undertaken in order to determine to what extent biomechanical constraints might influence the postural syndrom observed after hemilabyrinthectomy. In the first part of this work, X-ray photographies from above and profile were performed in hemilabyratinthecomized guinea pigs and the different parameters of the postural syndrom analyzed. We found that the head rotation in the horizontal plane, towards the side of the lesion, was mainly due to a rotation of the C1 C2 joint whereas the ipsilateral tilt of the head in the frontal plane was caused by a rotation of the thoracic vertebrae which provocked an en bloc bascule of the cervical column. In the second part, selective lesions of the different branches of the vestibular nerve were realized in order to study the resulting postural syndroms. The section of the horizontal ampullar nerve modify the head neck geometry exclusively in the hozontal plane whereas the destruction of the utricle caused a large head tilt only in the frontal plane. The results lead us to suggest that skeletal geometry influences not only postural control but also its pathology. Furthermore, it appears that to the functionnal segmentation of the cervical column corresponds a functionnal partition of the vestibular afferences.

MOTION SICKNESS IN SUNCUS MURINUS: A NEW EXPERIMENTAL ANIMAL. N.Matsuki*, S.Ueno*, T.Kaji* and H.Saito*(SPON: M.Kimura). Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., Univ. of Tokyo, Tokyo 113, Japan.

Our previous report have shown that Suncus murinus (house musk shrew), a species of Insectivora, vomits in response to various emetic agents and several antiemetic drugs prevented it (S.Ueno et al., Life Sci.41,513,1987). In the present study, we found that the Suncus murinus vomited when they received reciprocal motion stimulus. Healthy adult Suncus murinus of either sex weighing 40 to 70g were used for the experiments. The animal was placed in a transparent cage on a shaker and received mild reciprocal shaking on a horizontal axis (amplitude: 10-40mm; frequency: 0.5-3Hz) for 5min. The motion stimulus induced the vomiting which was dependent on both amplitude and frequency. When the motion stimulus was repeated, the animals acquired adaptation to the motion sickness. The motion sickness was prevented by the pretreatment of antihistamines. Scopolamine was less effective. Dopaminergic(D_1) antagonists strongly inhibited the motion-induced emesis, and autoradiographic study showed the existence of D_1-receptor in the area postrema, suggesting the involvement dopaminergic nervous system. These results indicate that Suncus murinus is a good animal model not only for the research on motion sickness and adaptation but also for the development of anti-motion sickness drugs.

138.18

POSTURAL DISTURBANCES IN PAROXYSMAL POSITIONAL VERTIGO. A.Katsarkas and R.Kearney. Dept. of Otolaryngology and Biomedical Engineering Unit, McGill University, Montreal, Quebec, H3A 1A1, Canada.

Postural sway was measured in fourteen patients suffering from paroxysmal positional vertigo in which the nystagmus elicited during attacks was the short rotatory-oblique type (Katsarkas, A: Ann. Otol. Rhinol. Laryngol.; 96: 305-308, 1987). Patients stood on a force plate for 20 s while the antero-posterior and medial-lateral projections of the center of force were recorded and standard deviations computed. Recordings were made before and after placing the patient's head in the provocative position. Vertigo was elicited and the nystagmus was observed in 10/14 patients; neither vertigo nor nystagmus was induced in the other four, during these recordings.

A paired t test of the sway data ($p<0.01$) showed the medial-lateral sway unchanged in all patients. The antero-posterior sway increased following the provocative maneuver in patients who experienced vertigo and developed nystagmus, while it did not change in those who did not.

It is concluded that paroxysmal positional vertigo, with nystagmus of the rotatory-oblique type of short duration, increases the antero-posterior sway immediately after the vertigo attack, while the medial-lateral sway remains unchanged. These observations have medico-legal implications.

MODELLING THE THREE DIMENSIONAL STRUCTURE OF THE VELOCITY STORAGE INTEGRATOR. D. Sturm and T. Raphan. Dept. of CIS, Brooklyn College of CUNY, Brooklyn, N.Y. 11210

Velocity storage is present in vertical and roll components of compensatory eye movements if the head is oriented appropriately with regard to gravity (Raphan & Cohen, 1983; Matsuo & Cohen, 1984; Raphan & Cohen, 1987). To explain this, it has been postulated that gravity orients the principal axes of the three dimensional representation of velocity storage towards the space vertical (Raphan & Cohen, 1987; Sturm and Raphan, 1988). Velocity storage which is expressed by OKAN (Raphan et al, 1979), has been represented as a dynamical system, $\dot{x} = Hx$, where x is a three dimensional vector representing the state of the system and H is the matrix containing the parameters that govern its dynamic behavior. The parameters of H were calculated such that the eignevectors associated with the body vertical in the upright position tended to align with gravity. The model simulates the absence of vertical and roll OKAN in the upright position and the increases in vertical and roll velocity storage as a function of head position. It also predicts and simulates the cross-coupling from the horizontal to vertical and roll planes when subjects are on their sides or supine, respectively (Raphan & Cohen, 1988). The model indicates that velocity storage has a three dimensional structure and that the eigenvalues and eigenvectors of its system matrix are closely linked to the gravitational field.

VISUAL-VESTIBULAR INTERACTION IN PSYCHOSIS: EFFECTS OF BACKGROUND ILLUMINATION R.T. Pivik, P.M. Cooper*. Univ. of Ottawa & Ottawa General Hosp., Ottawa, Canada

The failure of fixation suppression, impaired smooth pursuit tracking under light conditions and significant improvement during dark conditions in psychotic patients (Pivik, et al, Prog. Neuro-Psychopharm. Biol. Psychiat., 11:259, 1987) suggest dysfunction of cerebellar and brainstem structures in these patients. The present study examined the effects of variations in background illumination on the slow phase velocity (SPV) during fixation suppression in psychiatric patients. Psychotic patients [23 actively-ill (A) 23 remitted (R)] and 23 normal controls (C) were studied. Caloric nystagmus was recorded electrooculographically with assessment of visual fixation and arousal. Relative to controls, patient groups showed decreased fixation suppression during both light and dark conditions ($p < .02$). Group light-dark suppression ratios were: C--1.6; R--1.2; and A—.97, i.e., C data were similar to those reported for normal subjects, and, like cerebellar patients (Hood and Waniewski, J. Neurol. Sci., 63:27, 1984) group A data were virtually unaffected by background illumination. R group performance was intermediate. These similarities between cerebellar and psychotic patients provide further evidence suggestive of vestibulo-cerebellar dysfunction in psychotic patients.

SPINAL CORD AND BRAINSTEM: IMMUNOCYTOCHEMISTRY

139.1

IMMUNOCYTOCHEMICAL LOCALIZATION OF GABA IN NEURONS PROJECTING TO THE DRG. C.A. Livingston and A.J. Berger. Physiol. & Biophys., Univ. of Wash. Sch. Med., Seattle, WA 98195.

Monosynaptic inhibition of dorsal respiratory group (DRG) inspiratory neurons by Botzinger Complex (BOT) expiratory neurons located near the retrofacial nucleus (RFN) may be mediated by γ-aminobutyric acid (GABA). Using a double-labeling technique, we localized GABA-like immunoreactivity (GABA-LI) in neurons projecting to the DRG. In anesthetized cats, we located the DRG by recording inspiratory related activity in the ventrolateral nucleus of the solitary tract using glass microelectrodes containing 10-25% horseradish peroxidase (HRP). HRP was iontophoresed unilaterally into the DRG. The anesthetized cats were maintained for ∿24 h, then perfused with physiological saline followed by 1% paraformaldehyde/2% glutaraldehyde in 0.1 M phosphate buffer (pH=7.4). Serial transverse sections of the medulla were processed to visualize the retrograde tracer, HRP, and GABA-LI. Reticular neurons retrogradely labeled from the DRG (punctate black staining) were scattered bilaterally in the lateral tegmental field and lateral reticular nucleus, but were most densely distributed in the rostral ventrolateral medulla. 20-30% of all cells retrogradely labeled from the DRG were also positive for GABA-LI (punctate black staining/homogeneous brown background). The exclusive distribution of these double-labeled cells in the rostral medulla near the RFN suggests that they are BOT neurons. Presumptive GABA-ergic terminals were noted in the DRG. These observations indicate that GABA is a transmitter utilized by BOT expiratory neurons. (NS 14857 & HHS NS 07097)

139.2

COLOCALIZATION OF 5-HT FIBERS AND MOTONEURON POOLS IN THE CHICK SPINAL CORD DETERMINED WITH CHOLERATOXIN HRP AND IMMUNOHISTOCHEMISTRY. S. Homma*, K. Kohno* and N. Okado. Dept. Anat., Inst. Basic Med. Sci., Univ. Tsukuba, Ibaraki 305, Japan.

50-100 µl of 0.1 % HRP conjugated with choleratoxin subunit B (List lab) was injected in the muscle, and chicks were perfused with Zamboni's fixative. The alternative sections of the spinal cord were processed with TMB and with an antibody against 5-HT. In the lumbar spinal cord (segments XXIV-XXXI), the distribution pattern of 5-HT immunoreactive fibers in the lateral motor column (LMC) varied for different MNPs. In segments XXV and XXVI, a high density of 5-HT fibers was located in the dorsolateral and dorsomedial parts of the LMC, which corresponds to the MNPs of the iliotibial and ischioflexorius muscles, respectively. In segment XXVII, there were two regions with high density of 5-HT fibers in the MNPs of the iliofibular and dorsal shank muscles (lateral), and of the accessory muscles (mediolateral). In the caudal part of the lumbo-sacral spinal cord (segments XXIX - XXXI), a high density of immunoreactive fibers was found in the dorsolateral LMC, as in the MNP of the caudiliotibial muscle. The present study has demonstrated that the pattern of distribution of 5-HT fibers varies considerably between different MNPs suggesting that MNPs may be differentially affected by ongoing changes of 5-HT synaptic transmission.

139.3

IDENTIFICATION OF CATECHOLAMINE FIBERS AND SYNAPSES IN LAMINA IX OF THE RAT LUMBAR SPINAL CORD. E.W. Johnson* and H.O. Nornes. Dept. of Anatomy and Neurobiology, Colorado State University, Fort Collins, CO. (Supported by NIH #NS21309-02)

A double labeling technique was used to identify catecholamine (CA) fibers and terminals simultaneously with retrogradely labeled motor neurons in the lumbar cord. Both techniques used a peroxidase label and a DAB reaction product for identification. Motor neurons were retrogradely labeled by injecting the gastrocnemius muscle with WGA-HRP. The immunocytochemical procedure employed primary antibodies directed against tyrosine hydroxylase (TH) - the rate limiting enzyme in CA synthesis.

At the light microscopic level, the TH-immunoreactive fibers were distinguished from the labeled motor neurons and could be found surrounding them. For ultrastructural analyses, labeled motor neurons and surrounding fibers were isolated for electron microscopy.

Distinctive differences between the two labels were confirmed at the ultrastructural level. The HRP in the motor neurons was in electron dense vesicles distributed within the cytoplasm of somata and proximal dendrites. TH-immunoreactive fibers were filled with an amorphous electron dense reaction product which also surrounded the mitochondria.

CA fibers were observed to form synapses on processes within lamina IX of the rat lumbar spinal cord. Contacts between CA fibers and retrogradely labeled motor neurons have also been observed.

This double labeling protocol is a reliable method for identifying catecholamine fibers simultaneously with motor neurons at the LM and EM levels. The presence of CA synaptic terminals in lamina IX of the lumbar spinal cord is consistent with the implicated role of this system in modulation of reflexes and locomotion.

139.4

CATECHOLAMINE NEURONS IN THE BRAINSTEM OF THE BABOON. I. Nadelhaft, R. Segal*, S.K. Wolfson, E.E. Cook* and P.J. Jannetta. VA Med. Ctr., Univ. of Pittsburgh, Depts. of Neurosurgery and Pharmacology, and Montefiore Hosp., Pittsburgh, PA.

As a part of our study of neurons in the ventrolateral medulla (VLM) and their role in the control of blood pressure we have determined the locations of catecholaminergic neurons in the baboon medulla. Antisera to dopamine beta hydroxylase and phenylethanolamine-N-methyltransferase were used to identify noradrenergic (NA) and adrenergic (A) neurons respectively. In a typical animal (8.7 kg) NA neurons were found from 1 to 10 mm rostral to obex and had a broad peak at about 4 mm whereas A neurons were located between 2.5 and 8 mm from obex with a peak at about 6 mm. There were about 10,000 NA neurons and about 8,000 A neurons (uncorrected). These were equally divided between sides. The cells had a fusiform shape (45 x 15 microns) and exhibited apical processes. A neurons were restricted to the VLM whereas NA neurons were found in the VLM and also in a narrow band extending dorsally to the floor of the fourth ventricle. In conclusion, the distribution and morphology of these neurons in the primate is similar to that found in the lower animals.

139.5

CATECHOLAMINE INNERVATION OF DEVELOPING DENDRITE BUNDLES IN THE LUMBOSACRAL SPINAL CORD OF THE RAT. **P.E. Kunkler* and W.J. Anderson. Indiana University School of Medicine, Terre Haute Center for Medical Education, Terre Haute, IN**

In previous investigations from our laboratory, the morphological description of dendrite bundles (DB) in the lumbar spinal cord of the rat have been described. The motoneurons (MN) related to these DB's have been identified as innervating the levator and bulbocavernosus muscles. Since these MN groups are dimorphic in nature, our interest was in determining the noradrenergic innervation. Catecholamine (CA) histofluorescence in 30 day old rats showed the CA fibers enter the DB perpendicular to the horizontally-oriented dendrites and then turns rostrally or caudally to course adjacent to the dendrites or form pericellular rings around DB related MN's. At day 1 and 5, CA fibers could be seen in concentrated amongst the MN's. At day 7 this increased slightly, and by day 10 reached it's maximum intensity. At day 15, the intensity decreases until day 20 where it is similar to 30 and 45 day old rats. This pattern correlates exactly with the longitudinal dendrite growth in these MN's.

139.6

ORIGIN OF CATECHOLAMINERGIC PROJECTIONS TO THE SPINAL CORD IN THE DEVELOPING OPOSSUM. R.R. Pindzola, R.H. Ho and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University College of Medicine, Columbus, Ohio, 43210.

Tyrosine hydroxylase-like immunoreactive (TH-IR) axons are present in the marginal zone of the spinal cord in newborn opossums and they innervate the gray matter over an extended period of time. The brainstem origin of such axons, presumably catecholaminergic, to the lumbar spinal cord was studied in developing opossums using a combination of the retrograde transport of fluorescent dyes and immunofluorescence. By at least postnatal day 20, TH-IR neurons that project to the lumbar cord could be identified within all the nuclei which contain them in adult animals (Pindzola et al. Neurosci. Abst., 12(2), 1547, 1986). Retrogradely labeled neurons containing TH-IR were also found in areas not containing them in adult animals. For example, they were present in the dorsal part of the locus coeruleus, a region which does not project to the spinal cord in adult animals, but does so in young opossums. It is possible that these neurons provide transient catecholaminergic projections to the spinal cord. (Funded by NS25095).

SPINAL CORD AND BRAINSTEM: ANATOMY

140.1

THE FINE STRUCTURE OF RUBROSPINAL PROJECTIONS IN THE NONHUMAN PRIMATE DEMONSTRATED BY ANTEROGRADE AXONAL TRANSPORT OF WGA-HRP. D.D. Ralston, A.M. Milroy* and G. Holstege. The Department of Anatomy, University of California, San Francisco, California 94143.

The spinal cord of the primate receives descending motor projections for processing motor output to axial and distal musculature from a variety of sources: corticospinal, vestibulospinal, reticulospinal and rubrospinal. This latter system in the primate, a phylogenetically older extrapyramidal system, has long been considered subordinate to the corticospinal tract, utilizing the interneuronal population of the intermediate spinal grey matter to affect, polysynaptically, the motoneurons lying in the lateral motoneuron pools of the ventral horn that subserve distal musculature of the upper and lower extremities. This study demonstrates the nature of the ultrastructural projections from the red nucleus to the spinal intermediate and ventral grey matter.

Macaca fascicularis were used to determine the nature of these projections. The daily care, housing, anaesthesia and pre- and postoperative care were provided according to N.I.H. and U.C.S.F. Animal Care Committee guidelines. Injections of 5% WGA-HRP were placed into the red nucleus allowing survival times of 2-3 days at which time the animals were perfused intracardially with aldehyde solutions. The tissue was reacted for TMB-EM (Olucha, '85) and prepared for electron microscopy following a slow osmication method (Henry, '85) and then viewed with a JOEL 100 CX electron microscope.

The results indicate that the red nucleus projects primarily to intermediate grey matter but also to the motoneuronal pools. Labeled round vesicle terminals making asymmetric contacts predominate, synapsing upon small, medium and large dendrites and occasional cell somata of both regions. Pleomorphic and flat vesicle terminals have also been observed to contain label. Some vesicles within the terminals are coated and occasionally subsynaptic densities demonstrate Taxi bodies. The large neurons in the ventral horn receiving labeled synapses have not been identified as α- or γ-motoneurons.

We conclude from this study that the rubrospinal tract projects primarily to the intermediate grey matter to affect the motoneurons subserving distal musculature via a polysynaptic pathway. However, there is a direct monosynaptic rubrospinal projection to motoneurons in the ventral horn inferring greater influence of the red nucleus on motor output then previously thought. This study provides additional evidence for the mechanism of processing descending rubral projections. (Supported by NS-23347 from N.I.H.)

140.2

ANATOMICAL EVIDENCE FOR DIRECT RUBROSPINAL PROJECTIONS TO MOTONEURONS IN THE MONKEY. A LIGHT MICROSCOPICAL WGA-HRP STUDY. B. F. M. Blok*, G. Holstege and D. Daly Ralston (SPON: W. R. MEHLER) Dept. Anatomy University California San Francisco CA 94143

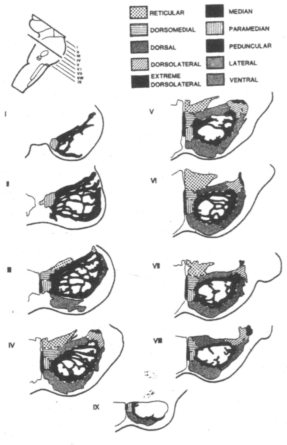
Recently, direct rubrospinal projections to motoneurons have been demonstrated in the cat (Holstege 1987; McCurdy et al. 1987). This raised the question whether this was also the case in monkey. Therefore, in 3 cases relatively large unilateral WGA-HRP injections were made in the mesencephalic and rostral pontine tegmentum of the rhesus monkey. In 2 cases the injection-sites involved the red nucleus. After 4 days survival, the animals were deeply anaesthetized and perfused with an aldehyde solution. Serial vibratome sections were made of the brainstem and spinal cord. They were processed using TMB as a chromogen.

In all 3 cases the ipsilateral interstitiospinal tract was labeled, distributing fibers to the medial part of the intermediate zone, throughout the length of the spinal cord. In the two cases, in which the magnocellular red nucleus was injected, labeled fibers were also present in the contralateral rubrospinal fiber bundle, terminating in Rexed's laminae V, VI and VII, but not in lamina VIII. In one case these projections were found throughout the length of the spinal cord, but in the other case, in which the injection was smaller and more medial, labeled fibers were sparse at lumbosacral levels. In both cases labeled fibers were also distributed to the motoneuronal cell groups, innervating muscles of hand and peripheral parts of the arm and in the case with the large injection they were also found in the motoneuronal cell groups innervating the muscles of the feet and peripheral parts of the leg. No projections were found to motoneurons innervating more proximal muscles of the body. These results indicate that in the monkey, the rubrospinal tract terminates in the same parts of the spinal gray as the contralateral corticospinal pathway. Supported by NASA Grant 2-484903-26308

140.3

CYTOARCHITECTURE OF BASIS PONTIS IN RHESUS MONKEY. J.D.Schmahmann & D.N.Pandya. Boston University & Bedford VA Hospital.

Early workers defined distinct nuclei within the mammalian basis pontis, however these findings have been only loosely utilized in recent studies. Using cresyl violet, thionin, and acetylcholinesterase stained transverse sections, the pontine nuclei of ten rhesus monkeys were studied in terms of the size, shape, degree of Nissl staining, packing density, and orientation of their neurons. The boundaries and characteristics of the nuclei were thereby established.



140.4

COURSE OF SPINOCEREBELLAR AXONS IN THE VENTRAL AND LATERAL FUNICULI OF THE CAT SPINAL CORD. G. Grant and Q. Xu*. Dept. of Anatomy, Karolinska Institutet, S 104 01 Stockholm, Sweden.

The aim of this study was to produce selective labeling of spinocerebellar fibers in the spinal white matter by retrograde axonal transport and to locate such retrogradely labeled spinocerebellar fibers originating from different spinal levels. Following unilateral transections of the ventral and lateral funiculi at different spinal levels or lesions of the restiform body, HRP or WGA-HRP was injected bilaterally into the cerebellum. This resulted in different labeling patterns related to the level and extent of the lesion. Based on this finding, the fiber course of the spinocerebellar fibers in the spinal white matter could be established. It was found that the fibers of the dorsal and ventral spinocerebellar tracts (DSCT and VSCT) ascending in the dorsolateral and ventrolateral fasciculi undergo a shift during their rostral course. Interestingly, the dorsalmost part of the VSCT, originating from the sacrococcygeal region, shifts into the dorsolateral fasciculus to join the DSCT. Both the DSCT and the VSCT are topically arranged. In addition to the course of the fibers of the DSCT and the VSCT, the course in the white matter for spinocerebellar fibers originating from the cervical enlargement and from the central cervical nucleus could also be established.

140.5

MOTONEURONS INNERVATING THE RAT AXIAL MUSCLE LONGISSIMUS CERVICIS ARE NOT CONFINED TO THE MEDIAL MOTOR COLUMN OF THE CERVICAL SPINAL CORD.
M. Kramer and T. W. Deacon. Biological Anthropology, Harvard University, Cambridge, MA 02138.

It is generally accepted that the neurons of the medial motor column provide the sole innervation of axial musculature, while the neurons of the lateral motor column innervate the remainder of body musculature. As a continuation of our previous work which characterized the motoneuronal organization of axial muscles in the rat and macaque, the present study focuses on the organization of motoneurons innervating the cervical epaxial muscle, the longissimus cervicis, of the rat. In this study 1-3 microliters of WGA-HRP were injected into the longissimus cervicis of the rat (N=4). Care was taken to prevent spread of the tracer to the overlying shoulder and neck muscles. In addition, adjacent epaxial muscles were cut and reacted to verify the injection site.

The motoneurons in the cervical spinal cord of the rat can be cytoarchitectonically divided into 3 nuclei: a medial motor column nucleus, M, and two lateral motor column nuclei, VL and DL. Following injections into the longissimus cervicis labelled motoneurons are observed in the medial motor column nucleus, M. In addition, labelled motoneurons are observed in the VL nucleus of the lateral motor column. These data demonstrate that the longissimus cervicis of the rat is innervated by motoneurons located in both the medial and the lateral motor columns. This finding suggests that the traditional view that the motoneurons innervating axial musculature are confined solely to the medial motor column does not adequately describe the innnervation of the epaxial muscle, the longissimus cervicis, of the rat.

140.6

CORTICOSPINAL AXONS FROM HAMSTER SENSORY AND MOTOR CORTEX PROJECT DIFFERENTIALLY TO DORSAL AND VENTRAL HORN SPINAL CORD NEURONS.
R.Z. Kuang* and K. Kalil. (SPON: W. Welker). Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

The rodent sensorimotor cortex has been divided by physiological mapping studies into a broad sensory area in which the body surface is topographically mapped and a narrower motor area from which movements of different regions of the body can be elicited. Regions of sensorimotor overlap have also been reported. However, no detailed anatomical studies have been carried out in rodents to determine whether, as in primates, efferent corticospinal projections arising from layer 5 also reflect these functional distinctions.

Iontophoretic injections of the plant lectin *phaseolus vulgaris* Leucoagglutinin (PHA-L) were used to label small regions of either the sensory or motor cortex in adult hamsters. Survival times of 2 weeks were used to ensure complete filling of corticospinal axon arbors and their terminal boutons. The overall pattern of projections showed that, as in primates, the sensory cortex innervates only the dorsal horn with the heaviest labeling in the medial region of laminae 3, 4 and 5, whereas the motor cortex projects almost exclusively to laminae 5-9 of the ventral horn, with the densest innervation in lamina 7. Moreover, although individual fibers ramify widely, they project exclusively to either the dorsal or the ventral horn. Single axon arbors were reconstructed through serial sections to demonstrate that, as in primates, single corticospinal fibers may project directly to motor neurons occupying several motoneuronal cell groups in lamina 9. These results suggest that projections of the rodent corticospinal pathway reflect their dual sensory and motor cortical origin and may thus have a dual function in modulating afferent sensory inputs to the dorsal horn as well as exerting a direct effect on motoneurons and their associated interneurons in the ventral horn. (Supported by NIH Grant NS-14428).

140.7

A NEW CERVICAL MEDULLARY MOTOR NEURON DENDRITE BUNDLE: FUNCTIONAL IMPLICATIONS OF BRAINSTEM SPINAL CORD INTERACTION
J.B. Taylor and W.J. Anderson. Indiana University School of Medicine, Terre Haute Center for Medical Education, Terre Haute, Indiana.

Previous investigations in our laboratory have morphologically described compact dendrite bundles in the lumbar and cervical spinal cord of the rat. The cervical dendrite bundle group is composed of three motoneuron dendrite columns including the medial dendrite bundle (MDB), the central dendrite bundle (CDB) and the lateral dendrite bundle (LDB), C2-C6. This study describes a new dendritic bundling found in the medulla at the level of the obex which is continuous with the previously characterized cervical bundles. The columns of motoneurons are composed of a MDB and a LDB which converge at C1 to become central and then diverge into the MDB and the LDB once again. There appears to be a direct interaction with the hypoglossal nucleus and possibly the raphe obscurus in the medulla. This motoneuron continuity of dendritic interactions between the medulla and cervical region raises many interesting concepts of spinal cord function.

140.8

DO NUCLEUS AMBIGUUS (NA) CELLS WHICH PROJECT TO THE CEREBELLUM ALSO PROJECT THROUGH THE VAGUS? A FLUORESCENT TRACER STUDY.
J. Lovell and S.L. Stuesse. Neurobiology Department, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

Scattered reports have indicated that various cranial nerve nuclei, including NA, project to the cerebellum. Most previous studies utilized the less sensitive retrograde tracer horseradish peroxidase (HRP). We verified the presence of cerebellar afferents in NA and determined if these cells also sent axons through the vagus by the use of a double labeling technique involving the fluorescent tracers True Blue (TB) and Fluorogold (FG). Rats received approximately 35nl TB in the cervical vagus sheath and 2-3 injections of the same amount of FG at various sites in the cerebellum. 2 days post-injection, 40um serial transverse brainstem sections were obtained and observed. FG labeling was found throughout the length of NA, with the most cells (usu. 10-12/section) occuring near the obex, 4-5 cells caudal to the obex and 2-3 rostral to it. Cells closest to the obex also contained the most FG. A topography of cell types existed such that FG cells were always on the interior of NA surrounded by TB cells. Thus NA projects throughout its length to the cerebellum, with the most projections arising near the obex. NA cells which project to cerebellum are sepa te from those projecting through the vagus.

140.9

NUCLEAR ORIGINS OF PROJECTIONS FROM THE BRAINSTEM RETICULAR FORMATION TO THE CEREBELLUM IN THE RAT.
D.B. Newman and C.Y. Ginsberg*, Department of Anatomy, USUHS, Bethesda, MD 20814-4799

Projections from the brainstem reticular formation (RF) to the cerebellum were examined in hooded rats using retrograde transport of 1% HRP-WGA or 10% HRP. Tissue was processed using TMB histochemistry. Retrogradely-labeled neurons were most numerous in classic precerebellar RF nuclei such as the medullary lateral reticular and paramedian reticular nuclei, as well as the pontine reticulotegmental nucleus. However, many isodendritic, diffuse RF nuclei contained significant numbers of labeled neurons, including medullary RF nuclei such as reticularis dorsalis, ventralis pars alpha, and magnocellularis, pontine nuclei such as pontis caudalis alpha and pontis oralis medialis; and the pedunculopontine nucleus at isthmic levels.

Vermal injections tended to produce more retrogradely labeled RF neurons than hemispheric injections, and injections involving the deep nuclei produced more RF labeling than those confined to the cerebellar cortex.

Within individual RF nuclei, the morphology of labeled neurons was identical to that reported previously by this laboratory subsequent to spinal or cortical HRP injections.

140.10

CAT MOTONEURONS INNERVATING THE URETHRAL AND ANAL SPHINCTERS HAVE DIFFERENT DENDRITIC ARBORS.
Q. Li* M. G. Leedy, M.S. Beattie, and J.C. Bresnahan. Depts. of Anatomy and Surgery, Ohio State Univ., Columbus, OH. 43210.

Cholera toxin conjugated to HRP was injected into the anal (AS) or urethral (US) striated sphincters of anesthetized female cats to compare locations and dendritic arborization patterns of motoneurons within Onuf's nucleus. TMB processing showed that AS motoneurons are localized dorsomedially in Onuf's nucleus (caudal S1 and rostral S2 segments), while US motoneurons are located ventrolaterally. Dendritic arbors are distinctly different: **AS** dendrites extend dorsally to the **dorsal and interband regions** of the sacral parasympathetic nucleus (SPN); they also extend ventro- and dorsolaterally into the **lateral funiculus. US** dendrites project laterally, then ventrally into mainly the **lateral band** of the SPN; other dendritic arbors invaded the **ventral funiculus.** Both AS and US dendrites project to lamina X. Thus, dendritic arbors of AS and US motoneurons are associated with regions of the SPN subserving defecation and micturition, respectively, and may receive different patterns of descending input. Supported by NS-10165.

140.11

FINE STRUCTURE AND SYNAPTOLOGY OF ESOPHAGEAL MOTONEURONS IN THE RAT. M. R. Moyles* and D. A. Hopkins. Department of Anatomy, Dalhousie University, Halifax, NS, B3H 4H7.

The nucleus ambiguus (AMB) has three major subdivisions which project to the upper alimentary tract in the rat (Bieger and Hopkins, '87). The esophagomotor component, located in the compact formation of the AMB (AMBcom), receives afferent projections from several levels of the neuraxis but very little is known regarding its ultrastructure and synaptology. Therefore, an electron microscopic study of the AMBcom was undertaken.

Transverse or sagittal sections of the medulla oblongata containing the AMBcom of unoperated rats and rats which received lesions of the vagus nerve or injections of WGA-HRP into the esophageal wall or nucleus of the tractus solitarius (NTS) were processed for electron microscopy.

Esophageal motoneurons in the AMBcom were densely packed and had longitudinally oriented dendrites. Somata were characterized by a round nucleus, centrally located nucleolus and abundant short segments of rough endoplasmic reticulum which were not organized into typical Nissl bodies. Perikarya and dendrites were frequently closely apposed without intervening glial processes. The neuropil contained many small-diameter axons adjacent to the perikarya and dendrites of esophageal motoneurons. Axosomatic synapses were very infrequent but axodendritic synapses were numerous and most axon terminals contained round clear vesicles with a few dense-cored vesicles and formed asymmetric junctions with one or more dendrites. After injections of WGA-HRP in the NTS, labeled axon terminals in the AMBcom were characterized by round vesicles and asymmetric synaptic junctions.

In conclusion, the AMBcom contains atypical motoneurons and appears to receive excitatory inputs from the central subnucleus of the NTS.

Supported by MRC of Canada.

MOTOR NEURONS FOR ACCESSORY RESPIRATORY MUSCLES: COMPARISON WITH PHRENIC AND NON-RESPIRATORY NEURONS. C. G. Charlton, B. Crowell* and R. Benson*. Neuroscience Unit, Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

Motor neurons (MN) for the pectoralis (PE), trapezius (TR), external oblique (EO) and rectus abdominis (RA) were retrogradely labeled to determine if there are distinctions that are related to their role in supportive skeletal and in respiratory functions. These MN were compared with the triceps (T) and phrenic MN.

The accessory respiratory muscles (AMR) MN were mainly confined to the ipsilateral ventrolateral tip of the ventral grey of C6-7. Within this locale the majority of MN for the PE were medial to ventromedial, those for the TR were lateral and those for the EO ventrolateral. The T MN were dorsal to the AMR MN. No MN were observed for the RA in C2 to T2. A second MN column were labeled for the TR in the medioventral ventral grey of C4-6.

The MN for the AMR were oval, of medium size and surrounded by labeled fascicles that may represent mono-synaptic spinal afferent terminals. Like the P MN the AMR MN superimposed a high density of substance P receptors. The T MN were large, elongated with distinct labeled processes and an absence of labeled fascicles. The MN within each column occurred in clumps. The columns are seperated, probably, for achieving discriminatory influences.

THE MORPHOLOGY OF JAW-MUSCLE SPINDLE AFFERENTS. D. Dessem* and A. Taylor. Sherrington School of Physiology, St. Thomas's Hospital Medical School, London, England, SE1 7EH.

Intra-axonal penetrations of jaw-elevator muscle spindle afferents in rats were characterized by their increased firing to jaw-opening (muscle stretch), gentle probing of the jaw muscles, failure to be activated by stimulation of the inferior alveolar and maxillary nerves and for some penetrations, activation from the masseter nerve. Horseradish peroxidase was injected for 35-245nA min. into stable penetrations with membrane potentials more negative than -40mV and the tissue was processed histochemically to allow visualization of the axons. All stained axons were located in the motor root of the trigeminal nerve and could be followed dorsomedially before bifurcating into an ascending branch in the tract of the mesencephalic nucleus and a descending branch in the tract of Probst. The largest concentration of axon collaterals and synaptic boutons was in the region of the trigeminal motor nucleus with synaptic boutons most numerous dorsal to the motor nucleus. It is not clear however, how many of these contacts are onto cells in this region and how many are onto distal dendrites of motorneurons. Boutons within the motor nucleus were always restricted to a small portion of the nucleus with some closely associated with stained motorneurons presumably representing somatic contacts. Axon collaterals and boutons were also found in the parvicellular reticular formation caudal to the trigeminal motor nucleus, the reticular formation at the level of the facial nucleus, and overlying somata of caudal mesencephalic trigeminal cells.

TOPOGRAPHICAL ARRANGEMENT AND DENDRITIC ARCHITECTURE OF HYPOGLOSSAL MOTONEURONS IN THE RAT. X. Bao, S.M. Altschuler* and R.R. Miselis. Depts. of Animal Biology and Pediatrics and Inst. of Neurol. Sci., Univ. of Pennsylvania, Philadelphia, PA 19104.

Cholera toxin-horseradish peroxidase conjugate prepared in our laboratory was injected in small quanities into the geniohyoid, genioglossus, styloglossus and hyoglossus muscles to determine the topographic arrangement and dendritic arborizations of the motoneurons of the hypoglossal nucleus (HN) . Motoneurons innervating the geniohyoid and genioglossus muscles were located just outside and ventrolateral to HN caudally and in the ventral HN rostrally. The styloglossus and hyoglossus motoneurons were in the lateral (caudally) and dorsal portion of the HN (rostrally). A few dendrites extended to the nucleus of solitary tract, medial vestibulat nucleus and raphe obscurus. Many dendrites were in the reticular formation and others formed a plexus under the fourth ventricle and around the central canal. Another delicate dendritic plexus formed a light encapsulation of the dorsal HN motoneurons. The upper boundary of the latter was sharpley defined along the ventral border of the dorsal motor nucleus. Therefore, there is a wide ranging target for central afferents to the HN and an interesting interlocking of dendrites and cell bodies of the two motoneuronal groups of the HN. Supported by GM27739 and the MacArthur Foundation.

THE INFERIOR OLIVARY COMPLEX (IOC) OF THE MANATEE, TRICHECHUS MANATUS: UNEQUIVOCAL EVIDENCE FOR SUBNUCLEUS C AND NUCLEUS BETA AS SEPARATE ENTITIES. M-C. Holst, J.I. Johnson, R. L. Reep, W.I. Welker. Anat., Mich. State U., E. Lansing, MI 48824; Neurosci., U. Fla., Gainesville, FL 32610; Neurophysiol., U. Wis., Madison WI 53706.

The caudorostral elaboration of the medial olive (MO) and associated minor nuclei is particularly evident in the large, well differentiated manatee IOC. Frontal, horizontal and sagittal, Nissl and myelin stained serial sections reveal the caudal pole (subnucleus b) connects medially to subnucleus c, and laterally to a ventral subnucleus a, resulting in a "c-shape". More rostrally, the lateral part of this "c" (subnucleus b) disappears. Concomitant dorsoventral enlargement of subnuclei a and c, and appearance of nucleus beta results in an "s-shape".

The manatee MO emphasizes a general phenomenon of the mammalian MO: the restriction of subnucleus b to caudalmost levels. We see it, for example, in marsupial possums and placental raccoons. Mid IOC levels include subnucleus c (rather than b) and a separate nucleus beta. Supported by NSF Grant BSR 8503687.

THE GRACILE NUCLEUS IN SPONTANEOUSLY DIABETIC BB-RATS. S.S.W. Tay, W.C. Wong and A.A.J. Kamal.* Anatomy Dept., Natl. Univ. of S'pore, Kent Ridge, Singapore 0511.

Systematic and progressive changes occur in the gracile tract of spontaneously diabetic BB-rats (Sima & Yagihashi, Diabetes Res. Clin. Pract., 1 : 289, 1986). The present study examines the gracile nucleus in the same species.

Prediabetic BB-rats (Health and Welfare Canada, Ottawa, Ontario) were carefully monitored. After detection of diabetes, insulin was administered daily. Diabetic rats were anesthetized and killed by perfusion with a mixed aldehyde solution at 3 and 7 days, 1, 3 and 6 months. Age-matched Wistar rats served as controls. Tissues containing the gracile nucleus were processed for electron microscopy. At 3-7 days post-diabetes, axons, axon terminals and dendrites showed electron dense and electron lucent degeneration. Degenerating axons were characterized by swollen mitochondria, vacuolation, accumulation of glycogen granules, tubulovesicular elements, neurofilaments and dense lamellar bodies. Degenerating axon terminals made synaptic contacts with cell somata, axons and dendrites. Degenerating dendrites were postsynaptic to normal and degenerating axon terminals. At 1-3 months, electron dense and electron lucent degenerating axons, axon terminals and dendrites were present. Several neuronal cell bodies showed dissolution of their cytoplasm and nucleus. Unidentifiable debris were engulfed by macrophages. At 6 months, degenerating elements were similar to those at earlier intervals. Terminal degenerating axons appeared amorphous and vacuolated. Early degenerating axon terminals and dendrites were still prevalent. It is concluded that neuronal degeneration occurs in the gracile nucleus of diabetic BB-rats.

RETROGRADE, TRANSNEURONAL TRANSPORT OF PSEUDORABIES VIRUS IN RAT HYPOGLOSSAL AND VAGAL MOTONEURONS: LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. L. Rinaman, M.E. Whealy*, J.S. Schwaber, A. Robbins*, J.P. Card, and L. Enquist*, Inst. of Neurological Sciences, Univ. of Pennsylvania, Philadelphia, Pa., and E.I. DuPont Co., Wilmington, Del. 19898.

In a recent light microscopic immunohistochemical investigation, Ugolini and coworkers (Brain Res., 422: 242, '87) demonstrated retrograde transneuronal transfer of herpes simplex 1 virus following injection of the virus into either the tongue or hypoglossal nerve. In the present study we have utilized light and electron microscopy to define the central neuronal distribution of pseudorabies virus following injection into either the tongue or stomach. Light microscopic immunohistochemistry revealed discrete labeling of motor neurons consistent with the known innervation of the respective organs; ie. virus-containing neurons in the hypoglossal nucleus were only observed ipsilateral to the injection, while injection of the ventral stomach musculature selectively labeled motoneurons in the left vagal nucleus. The number of labeled neurons and the intensity of labeling increased with longer survival times and both injection paradigms resulted in trans-neuronal labeling of second order neurons. Electron microscopic analysis of the motor nuclei revealed virus particles in motor neuron perikarya and dendrites as well as within afferents synapsing upon these profiles. In addition, the ultrastructural analysis demonstrated that glial profiles rarely contained virus, even when located immediately adjacent to severely afflicted neurons.

CLINICAL CNS NEUROPHYSIOLOGY I

141.1

REDUCED NA (VISUAL ERP) INDEXES MISALLOCATION OF ATTENTION IN SCHIZOPHRENIC CHILDREN. R.J. Strandburg, J.T. Marsh, W.S. Brown*, R.F. Asarnow* and D. Guthrie*. Dept. of Psychiatry, UCLA, LA, CA. 90024.

ERPs were recorded from 17 normal and 13 schizophrenic children during performance a reaction time task (RT) and a visual discrimination, the Span of Apprehension Task (Span), which is sensitive to vulnerability factors in schizophrenia. Identical stimuli (12 letter arrays) were presented in both conditions. Subjects responded to the visual arrays in the RT condition and differentially to the presence of either a T or F in the Span condition.

EEG was recorded at 19 scalp sites, and ERPs included activity 1 second before to 1 second after the Span arrays. Difference potentials (Span - RT) were computed to isolate endogenous activity (NA) associated with the Span discrimination. Topographic fields were computed at the peak of N1 and NA.

Schizophrenics were found to produce significantly less NA activity than normals. This endogenous negativity differed in its topography and time course from the exogenous components (P1, N1 and P2). NA is associated with attentional effort during pattern recognition (Ritter et al. 1983). Our results support the hypothesis that schizophrenics are impaired in their ability to allocate adequate attentional resources for Span processing. This deficit is apparent quite early in discriminative processing.

141.2

EYE MOVEMENTS IN SCHIZOPHRENIA: CLINICAL AND NEUROBIOLOGICAL CORRELATES. G.Thaker, R.Buchanan*, B.Kirkpatrick*, C.Tamminga; Maryland Psychiatric Research Center, P.O. 21247, Baltimore, MD 21228.

Although abnormality of smooth pursuit eye movement (SPEM) has been extensively described in schizophrenic patients, its underlying mechanism and clinical correlates remain unclear. To further explore these issues we carried out eye movement examination in saccade, anti-saccade, fixation, and smooth pursuit paradigms in schizophrenic patients. The presentation of each paradigm was randomized. 54 schizophrenic patients (DSM III) and 19 normal controls have participated in this ongoing study. Distractibility score obtained from anti-saccade paradigm, qualitative SPEM score, number of saccades during fixation tasks, and latency for volitional saccades differentiated the patients from the normal controls. However, saccadic distractibility did not correlate with SPEM score but was significantly associated with tardive dyskinesia (TD; r=0.59). In contrast, SPEM score and latency for volitional saccades did not correlate with TD; the latter significantly differentiated schizophrenic patients with deficit state (mean volitional saccade latency, 356 $\pm$ 66 msecs) from non-deficit patients (299 $\pm$ 60, $p<0.01$). Significance of using such oculomotor paradigms to study heterogenous illness like schizophrenia and its neuroanatomic implications will be discussed.

141.3

MIDLATENCY AUDITORY EVOKED RESPONSES IN SCHIZOPHRENICS R. Erwin, M. Mawhinney-Hee*, and R.E. Gur*, Dept. of Psychiatry, Univ. of Penn., Philadelphia, PA 19104.

Studies using a paired stimulus protocol have found that the long-latency auditory evoked component P50 has an abnormal recovery cycle in schizophrenics (Freedman et al., Biol. Psych., 18:537, 1983). Recent studies (Erwin and Buchwald, EEG suppl., 40:461, 1987) examing the effects of stimulus rate on the midlatency response (MLR) component P1 (50-65 ms latency) found P1 recovery cycles in normals similar to P50 recovery cycles in normals. Evidence from both the human and cat model suggests that the P1 is generated by a component of the ascending reticular activating system. The present study attempted to replicate the findings in schizophrenics using a rate protocol and MLR recording procedures.

MLRs were recorded from a group of 11 schizophrenics and 24 normal adults in response to clicks (.1ms, 50 db HL) presented at 3 rates: .9/sec, 5.1/sec and 9.9/sec. Evoked potentials were recorded from the vertex (Cz) and referenced to linked mandibles.

Analyses indicated that schizophrenic P1 amplitudes did not decrease as much as normal P1 amplitudes at faster rates of stimulation (rate x group ($F(2,68)=3.67$, $p<.05$)). These findings suggest that the P50 and P1 component reflect similar brain mechanisms and that abnormal recovery cycles found in schizophrenics may reflect dysfunction in the ascending reticular activating system.

141.4

EEG AND MEG (MAGNETOENCEPHALOGRAPHY) MAPPING OF THE AUDITORY 40HZ RESPONSE: A STUDY OF DEPRESSION. U.Ribary, H.Weinberg*, B.Johnson*, R.J.Ancill* and S.Holliday*. Brain Behavior Lab., Simon Fraser Univ., Vancouver, B.C., V5A 1S6, Canada.

Two relatively new technologies, the mapping and the analysis of digital distributions of electric (EEG) and magnetic (MEG) fields, were combined, in order to study midlatency responses and source estimates after a 40Hz auditory stimulation in controls and depressed patients (30-50, 65-75 years). The steady-state evoked response in humans is known to be maximal in amplitude around 40Hz and involves cortical and subcortical brain areas. EEG data in controls indicate a phase shift from anterior to posterior part of the brain, with a main response in frontal brain (around Cz). Lower amplitudes are found at 31 and 46Hz. The pattern of phase vectors and amplitudes over the head are influenced by changes in frequency after monaural or binaural ear stimulation. In patients (major depression), phase vectors and amplitudes show a different pattern over the skull at 40Hz, at 31 and 46Hz, and in some patients an interaction with ear stimulation and an increasing effect of age. MEG data estimate 2 dipoles in brain, which are more in phase in controls than in patients. It is suggested that more than one generator must be responsible for the 40Hz response, which are changed during depression.

These data indicate a new possibility to study pathological changes and drug effects in human brain.

141.5

ORIGIN OF THE MAGNETIC EVOKED FIELD PRODUCED BY APPLIED ELECTRIC FIELD IN THE ISOLATED TURTLE CEREBELLUM. Y.C. Okada, L. Lopez* and C. Nicholson. Dept. of Physiology and Biophysics, New York Univ. Med. Ctr, New York, N.Y., 10016.

We applied a spatially uniform electric field (50-500 μs in duration) across the surface of the cerebellum suspended vertically in a bath of Ringer solution to stimulate Purkinje cells and others whose dendrites or axons are aligned predominantly along the field direction (Chan, C. and Nicholson, C., J. Physiol., 371:89, 1986). The component of the magnetic evoked field (MEF) normal to bath surface was monitored at 20 mm from the cerebellum with a superconducting detector (Okada, Y.C. et al., Brain Res., 412:151, 1987). The field potential (FP) was simultaneously monitored with a glass micropipette. The MEF was predominantly biphasic with the underlying current for the first component directed from the ventricular to the dorsal side and that for the second in the opposite sense. Its waveform was similar to the FP measured near the Purkinje cell layer. Both components of the MEF as well as FP were abolished either by replacing Ca^{2+} with Mn^{2+}or by bath application of tetrodotoxin (0.3-1.0 μm).

These results indicate that both the MEF and FP were produced by synaptically mediated Na-currents and not by the direct activation of Na-channels or Ca-channels in Purkinje cells (Chan et al., J. Physiol., in press) in these experiments.

The laminar profile of the FP shows that the MEF was most likely produced by synaptic inputs from the climbing fibers activated by the applied electric field.

A RAT BRAIN GLIOMA MODEL FOR STUDYING CONTRAST ENHANCED M.R.I. D.M. Kaufman*, V.M. Runge*, S. Jacobson. Dept. of Radiology, & Dept. of Anat. & Cellular Biology, Tufts New England Med. Ctr., Boston, MA. 02111.

The introduction of contrast agents for magnetic resonance imaging (MRI) has prompted the need for developing a reliable model to quantify and compare the enhancement characteristics of these agents.

We have developed a reproducable rat gliosarcoma model which is grown in culture and was stereotactically implanted into 67 Fisher rats. These animals were scanned with MRI (Siemens 1T Magnetom) fitted with a custom designed small animal coil, 10-14 days post-implantation, both before and 10 min. after, I.V. injection (.25mmol/kg) of contrast agent. 22 animals were injected with Gd-DTPA, 19 animals were injected with Gd-DOTA, and 23 animals were injected with Gd-DO3A. T2 (TR/TE=2300/90) and T1 (TR/TE=500/25) weighted scans allowed visualization of tumor pathology and tumor enhancement, respectively. Thin 3mm slices are used to improve resolution and allow visualization of tumor on multiple slices. Pathologic correlation of excised tumor was performed and actual tumor locations were compared to the scanned images confirming the presence of the tumor.

All three contrast agents provided improved visualization of the tumor, on post-contrast T1 weighted scans, when compared to pre-contrast images. In many cases tumor could only be identified retrospectively on the pre-injection T1 weighted scans. Tumor enhancement by DTPA and DO3A are comparable (62±29% vs 59±41% respectively) while enhancement by DOTA is inferior (32±6%).

This model has proven itself as a viable means for assessing the clinical efficacy of MRI contrast agents and prompted reason for its continued use.

141.7

A MULTI-MODAL, MULTI-PLANE COMPUTER IMAGING SYSTEM FOR STEREOTACTIC NEUROSURGERY. J.X. Zhang, C. Wilson, M. Levesque*, R.M. Harper, and J. Engel. Brain Res Inst and Depts of Neurology, Neurosurgery, and Anatomy, UCLA, Los Angeles, CA 90024.

Electrode placement for localization of subcortical seizure foci in patients with complex partial epilepsy requires knowledge of 1) dysfunctioning brain tissue, as revealed by positron emission tomography (PET), 2) brain and skull structures, as revealed by computerized tomography (CT), 3) brain structures, as indicated by magnetic resonance imaging (MRI), and 4) visualization of the vascular supply, as indicated by digital subtraction angiography (DSA). Since images supplied by these displays differ on absolute size and translation and may suffer from distortion, we developed an imaging system, based on a modified Leksell stereotactic frame and a MicroVAX/GPX computer, that allows for simultaneous display from the four imaging devices in multiple windows, adjusted for common coordinates with reference to fiducial markers. Moreover, with any single imaging modality, different views (e.g., saggital, coronal, and horizontal, or, in the case of DSA, lateral or AP) can be simultaneously displayed with appropriate coordination of cursors in each view. The system has been applied to nine patients undergoing surgery for electrode placement in temporal lobe structures simultaneously with conventional ventriculography procedures.

141.8

RESPIRATORY EFFECTS OF SINGLE PULSE STIMULATION OF HUMAN AMYGDALA AND HIPPOCAMPUS. R. C. Frysinger, R. M. Harper, C. Wilson and J. Engel. Depts. of Anatomy, Neurology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763.

In the cat, amygdala neurons discharge phasically with the respiratory cycle, and tonic discharge rates correlate with spontaneous changes in respiratory rate. Single pulse stimuli to the central amygdala of cats produce a transient enhancement of inspiratory activation. A subset of hippocampal neurons discharge in phase with the respiratory cycle in both cats and humans. The amygdala and hippocampus have thus been implicated in control of respiration; this study was designed to assess the effect on respiration of single pulse stimulation of these two structures in the human.

We record respiratory air flow during pulse stimulation of amygdala, presubiculum, and pes hippocampi of epileptic patients three to four days following chronic depth electrode implantation. Respiratory period, inspiratory and expiratory times, inspiratory slope, duty cycle, and inspiratory, expiratory and total areas are calculated on a breath-by-breath basis off-line, and the data are partitioned into four groups on the basis of the respiratory phase quadrant of the stimulation. Analysis of variance is used to detect changes from prestimulation values.

The most pronounced effect is observed with presubicular stimulation. Pulses to this area during inspiration result in prolongation of the respiratory cycle, while pulses during expiration reduce the period of the stimulated breath. This effect may result from an inspiratory activation, resulting in prolongation of, or early switching to, inspiration. Supported by NS 02808-27.

141.9

SPINAL SENSORY AND MOTOR TRACT ACTIVATION FOLLOWING EPIDURAL ELECTRICAL STIMULATION IN THE CAT. G.Niznik*, F.Shichijo*, B.Pomeranz, F.Gentili*, E.Transfeldt* and T.Ohshima*. Dept. of Zoology, University of Toronto, Toronto, Ont. M5A 1A1.

The use of epidural stimulation as a method of monitoring spinal cord function during surgery is gaining popularity. The aim of this study was to clarify the spinal sensory and motor components of various centrally and peripherally recorded potentials. 37 adult mongrel cats were anesthetized with Ketamine and ventilated. Anesthesia was maintained with Ethrane and nitrous oxide. Bipolar stimulating electrodes were placed in the left and right dorsolateral epidural space at T7. Recording sites included the spinal cord epidurally at L3, the right L7 dorsal and ventral nerve roots, the left and right sciatic nerves and the right gastrocnemius muscle. Optimal stimulating parameters were determined by varying the stimulus intensity and frequency. Selective spinal cord lesions were made at T13. The results of these suggest that: 1) the dorsal root and sciatic potentials reflect activity in the dorsal columns; 2) the ventral root potential reflects activity in the ventral spinal motor tracts; and 3) potentials recorded from the spinal cord reflect activity in both spinal sensory and motor tracts.

141.10

EFFECT OF UPPER EXTREMITY FORCED USE ON ENHANCED FUNCTION IN CHRONIC STROKE AND TRAUMATIC BRAIN INJURED PATIENTS. S.L. Wolf, D.E. LeCraw*, L.A.Barton* and B.J. Rees*. Dept. of Rehabilitation Medicine, Emory Univ. Sch. of Medicine, Atlanta, GA 30322.

To test the clinical counterpart of the learned disuse theory, 25 chronic hemiplegic stroke and head injured patients with minimal to moderate upper extremity extensor muscle function were required to wrap their uninvolved upper extremity within a hand-enclosed sling for 2 weeks. During forced use and for 1 year thereafter, changes in force or time-based measures among 21 functional tasks were compared to values at the sixth baseline session when preintervention relearning had plateaued. Significant ($p<.05$, Friedman's repeated measures followed by Tukey multiple comparison tests) changes were seen in 19 of the 21 tasks with most persisting at 1 year followup. There were no significant differences when subjects were compared by diagnosis (brain injury versus stroke) or by predominantly involved extremity (left versus right). Results suggest that a learned disuse phenomenon may occur among select chronic neurologic patients.

Future work should be directed toward determining whether modified forms of forced use can overcome functional deficits among individuals with more profound motoric dysfunction.

141.11

THERAPY REDUCES GAPS IN EMG ACTIVITY OF CHRONIC CVA PATIENTS. S.S. Fitts, M.C. Hammond*, and G.H. Kraft*. Rehabilitation Medicine, University of Washington, Seattle, WA 98195.

A common view that recovery is complete within the first 6-12 months post-stroke may result in termination of therapy before maximum recovery is achieved. We have reported that gaps (>100 msec) in the EMG interference pattern correspond to a clinical impression of impersistent recruitment and "ratchety" movement. Thus, we predicted that gaps should be reduced after therapy which improved function in the same patients.

The 8 male and 5 female patients included 7 left- and 6 right-CVA's. All were right-handed and at least one year post-stroke (X=26.6 mo). Ten patients had therapy combining electrical stimulation with voluntary control; 3 had conventional therapy.

Patients were signaled by buzzers to maintain maximal wrist flexion or extension against an isometric restraint apparatus for 3, 6, or 9 sec. 24 trials were presented in a balanced random order. Intramuscluar EMG activity was recorded from flexor carpi radialis (FCR) and extensor carpi radialis longus (ECR).

More gaps were recorded from ECR than FCR (X's = 4.9 & 2.4, $p<.05$), which is consistent with functional deficits. More gaps were recorded before therapy than immediately or 3 mo. after therapy (X's = 4.5 vs 3.1 & 3.2, $p<.05$), which is consistent with functional gains. Improvements were not significantly greater in one muscle than the other, nor with one therapy than another.

Biometer International & Medtronic, Inc. provided therapy equipment. NIDRR grant #G008435053 supported this research.

141.12

THE EFFECT OF HYPERTENSION ON CAROTID ARTERY BLOOD FLOW CHANGES DURING A CARDIOVASCULAR STRESSOR. B. Therrien, B.L. Metzger*, B. Cimprich*, and S. Kuhnke*

Marked shifts in cerebrovascular blood flow velocity and pressure in response to straining are life-threatening in individuals with cerebrovascular disease (CVD). We examined the confounding influence of hypertension and obesity on carotid artery blood flow velocity (CABFV) during Valsalva strain. Subjects strained by blowing into a pressure gauge meter to 40 mmHg for 10 sec. CABFV was measured by noninvasive techniques during all phases of the Valsalva. Normative CABFV changes during Valsalva were established in 145 healthy, normal wt controls (30-55 yrs). This sample consisted of both hypertensive adults of average wt and fatness and obese hypertensive adults aged 30-55 yrs (n=20). During strain CABFV fell an average of 54 ± 24% from baseline. In hypertensive adults, the fall in CABFV during strain was significantly greater (>75%; $p<.0001$). In contrast to the <300% total CABFV change across the Valsalva observed in controls, the average % change observed in hypertensives from onset of strain to overshoot was >650%. Overall CABFV changes were less extreme during strain (67% vs 87%) and across the Valsalva (514% vs 990%) in obese hypertensives compared to hypertensives of average wt and fatness. These data suggest that ability to compensate for sudden change in peripheral blood flow velocity and/or cardiac output is severely compromised in the adult with hypertension.

141.13

SEX DIFFERENCES IN CEREBRAL INJURY CAUSED BY ACUTE SEVERE HYPONATREMIA. J. KUCHARCZYK, C.L. FRASER*, P. SARNAKI*, D. NORMAN* AND A.I. ARIEFF*. Dept. of Medicine and Neuroradiology, Univ. California, Sch. of Medicine, San Francisco, CA 94143.

During the past 18 months, over 100 cases of death or permanent brain damage have been reported in patients with severe symptomatic hypernatremia. Over 90% of these cases have involved young cyclic women. To determine if the cation extrusion mechanisms which normally defend against intracerebral edema are less effective in females than males, we studied Na^+-K^+ transport in synaptosomes prepared from the brains of severely hyponatremic (serum Na^+ 102-114 mM for 1 day) and normal female and male rats. A 250% greater increase in veratridine-sensitive Na^+ uptake was found in female brain synaptosomes. This sex difference was abolished by ouabain, suggesting that Na^+, K^+-ATPase pump function may be responsible for hyponatremia-induced cerebral edema. Since recent studies indicate that Na^+ K^+-ATPase pump in specific regions of the brain is sensitive to gonadal steroids and endogenous neuropeptides, we examined the influence of vasopressin administration on cerebral phosphorus metablism in normal young adult female and male rats using ^{31}P magnetic resonance spectroscopy. Females injected s.c. with 20 I.U. of arginine vasopressin (AVP) showed a rapid deterioration in cerebral oxidative phosphorylation and a significant intracellular acidosis within 30 min of injection of AVP. In contrast, there was only a slight depletion of high energy phosphates in male brains. The high circulating levels of AVP found in severe hyponatremia may therefore contribute to the genesis of cerebral edema in females.

141.14

NEUROPHYSIOLOGICAL STUDY OF THE SHORT-TERM EFFECTS OF INTRATHECAL BACLOFEN IN SPASTICITY. M. L. Latash*, R. D. Penn, D. M. Corcos, and G. L. Gottlieb. Rush-Presbyterian St. Luke's Med Center, Chicago, IL, 60625.

Six patients, with long-standing spasticity resistant to oral baclofen, received a bolus injection of lumbar intrathecal baclofen. Responses to passive joint movements, H-reflexes, ankle clonus, and Babinski's response were considerably suppressed 30-45 min after the injection and practically disappeared after 1.5 - 2 hours. Ankle clonus was seen only in patients with H-reflexes, and it disappeared when the reflex responses to stimuli of n.tibialis were absent. A decrease in clonus amplitude was accompanied by a decrease in clonus frequency. These observations support an auto-oscillation hypothesis of clonus.

Before baclofen, attempts at voluntary activation in patients with residual motor control were accompanied by uncontrolled bursts of activity in antagonist and distant muscles. Baclofen injection led to considerable improvement in selective voluntary activation of leg muscles by eliminating responses in antagonist and distant muscles. There was only a slight effect on agonist activity. These results suggest that the execution of voluntary motor commands suffered from functionally abnormal spinal circuitry rather than from changes in the descending motor commands. Intrathecal baclofen demonstrates selectivity in its action upon different spinal pathways and appears to be an effective way to treat severe spasticity. It allows voluntary motor function on a background of suppressed muscle tone and spasms.

This work was partially supported by NIH grants NS 15630, R29 NS 23593, and AM 33189.

141.15

DIFFERENTIATION OF MULTIPLE SCLEROSIS, CEREBROVASCULAR DISEASE AND NORMAL AGING WITH MAGNETIC RESONANCE IMAGING. A.L. Hunt*, W.W. Orrison*, R. Rhyne*, and G.R. Rosenberg* (SPON: L.A. Hershey). Univ. Of New Mexico Sch. of Med., Albuquerque, NM 87131.

It is difficult to differentiate multiple sclerosis (MS) from cerebrovascular disease (CVD) based on white matter lesions (WMLs) seen on magnetic resonance imaging (MRI). We studied the anatomic distribution of WMLs on MRI (1.5 Tesla) in 12 definite MS patients, 52 patients with CVD risk factors and 19 aging controls with WMLs, but no CVD risk factors. The anatomic distribution of WMLs was assigned by group consensus without knowledge of age or clinical history. Frontal, parietal and occipital lobes were the most common sites for WMLs, regardless of diagnosis. Cerebellar WMLs were somewhat more common in MS (32%) than in patients at risk for CVD (15%) or in aging controls (5%). Temporal lobe WMLs were somewhat more frequent in MS (66%) than in patients at risk for CVD (40%) or in aging controls (11%). The combination of both cerebellar and temporal lobe WMLs was significantly ($p<0.01$) more common in those with MS (33%) than in those at risk for CVD (5%) or in aging controls (0%). The presence of WMLs in cerebellum and/or temporal lobes on MRI should lead one to suspect the diagnosis of MS, rather than CVD or normal aging.

142.1

SPATIAL CODING OF MOVEMENT DIRECTION IN FRONTAL CORTICAL AREAS. R. Caminiti, P.B. Johnson, R.A. Pastore and A. Urbano. Inst. of Physiology, Univ. of Rome, 00185 Rome, Italy.

M. nemestrina monkeys were trained to make arm movements of same direction within different parts of space using different patterns of muscle activity. We studied extracellularly 169 cells of areas 4 and 6 while monkeys performed the task. Directionally tuned cells (92%) were selected and their preferred directions (PDs) computed. The spherical space where the animal performed was divided into sectors, the PDs of cells lying in each given sector expressed as 3-D vectors and their mean vector computed. These mean vectors were then compared (Watson-Williams test, $p < 0.01$) with those obtained from the PDs of the same cells studied when monkeys made movements of similar directions in other parts of extrapersonal space. In all cases these mean vectors mantained invariant their 3-D orientation, suggesting that frontal areas code direction of arm movement as a variable independent from the underlying patterns of muscle activity since these patterns differed when movements of same direction were performed in different parts of space.

142.2

NEURONAL MECHANISMS OF PREPARATION FOR MOVEMENT DIRECTION **A. RIEHLE*, J. REQUIN.** CNRS-LNF 1, Unit of Cognitive Neurosciences, 31 ch.J.Aiguier, 13402 Marseille 09, France.

Movement preparation is defined as a process which promotes selection and assembly of motor program elements. We have studied the underlying neuronal mechanisms, which result in a reduction of reaction time when movement parameters are known in advance as compared to when these parameters are not known. Monkeys were trained to perform flexion and extension wrist movements of small and large extent. The preparatory signal supplied the animals with information about either direction and extent (complete information), direction or extent (partial information), or gave no information. Single-cell recordings in the primary motor and premotor cortex during the performance of the task showed that 66% (207/313) of the neurons exhibited directionally selective activity patterns, either related to the preparation (n=71) or to the execution (n=139) of the intended movement. Two types of preparation-related neurons have been found. The activity changes of one type reflect a process which may facilitate the triggering of the programming operation after the occurrence of the response signal, while the second type may be involved in a process responsible for programming in advance movement direction during the preparatory period. A possible model of the functional interaction between both types of directionally selective, preparation-related neurons is discussed.

142.3

INFORMATION TRANSMITTED BY THE DIRECTION OF 2-D ISOMETRIC FORCE EXERTED BY THE UNRESTRAINED ARM. J.T. Massey, G. Hovey* and A.P. Georgopoulos. Bard Labs. of Neurophysiology, Dept. of Neuroscience, The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

We have measured the direction of 2-D isometric forces produced by human subjects in response to visual stimuli using a novel experimental apparatus. The visual instruction was presented to the subject by means of vivid dynamic stereograms of planes (disks) whose angle of tilt about a horizontal axis in the plane of the CRT screen varied from 15° (near vertical) to 80° (near horizontal). Targets were shown in the plane of the disk, and x-y forces were recorded. These force values were fed back onto the target plane as a cursor. Target positions varied from 4 to 60, and were distributed equidistantly on a circle of 30 mm radius. Subjects were asked to exert a force in the direction of the target when it appeared; no capture of the target was required, only crossing of a force threshold. Data from 24 naive subjects indicated that the information transmitted increased with input information and tended to reach a plateau at approximately 4.1 bits; this held for the range of plane tilts used. This is remarkably similar to the result obtained for 2-D arm movements (Georgopoulos and Massey,Exp. Brain Res. 69:315,1988).

142.4

MOTOR CORTICAL CELL ACTIVITY DURING A CONDITIONAL MOTOR TASK WITH A DIRECTIONAL TRANSFORMATION. A.P. Georgopoulos, M. Petrides, J.T. Lurito*, A.B. Schwartz, J.T. Massey and N. Porter*. Bard Labs of Neurophysiology, Dept. of Neuroscience, The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

The activity of 225 cells in the arm area of the monkey motor cortex was recorded during performance of a conditional motor task which incorporated a directional transformation. In the "direct" task the animal moved a handle towards a dim light on a plane; in the "transformation" task it moved the handle 90° counterclockwise (CCW) from a bright light. The dim/bright condition and 8 stimulus locations were randomly mixed. In many cases the changes in cell activity differed from those observed when the light appeared in the same location or when the movement was made in the same direction. The neuronal population vector (Exp. Brain Res. Supl. 7:327, 1983) was computed every 20 ms during the reaction time. In the "direct" task it pointed in the direction of the movement (which was the same with the direction of the stimulus). In the "CCW transformation" task the population vector pointed initially towards the stimulus direction and then shifted gradually CCW to the direction of the upcoming movement. These findings indicate that the motor cortex is involved in the transformation of a stimulus direction into a different movement direction.

142.5

CROSSCORRELATIONS BETWEEN MOTOR CORTICAL CELLS SIMULTANEOUSLY RECORDED DURING REACHING TASKS IN THE MONKEY. J.T. Lurito*, A.B. Schwartz, M. Petrides, R.E. Kettner and A.P. Georgopoulos (SPON: V.B. Mountcastle). Bard Labs of Neurophysiology, Dept. of Neuroscience, The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

We used a multielectrode recording technique (see Soc. Neurosci. Abstr. 13:629, 1987) to record simultaneously (0.1 ms resolution) the activity of up to 8 cells in the arm area of the motor cortex of two monkeys performing reaching tasks (driven activity) or sitting quietly (spontaneous activity). Cross-correlations (CC) were computed at 1 ms and .1 ms resolution for 1240 simultaneously recorded cell pairs (driven activity; 1176 from different electrodes 0.6-4.2 mm apart and 64 from the same electrode tip). Clear and narrow CC's (up to 3 ms peak width) were observed between 77 pairs; they occurred much more frequently between pairs recorded from the same electrode (41%) than from different electrodes (4.3%). Altogether, 49/77 (64%) pairs showed a peak at zero indicating common input, 25% showed a peak near zero, and 11% showed inhibition. Directional tuning properties of cells were analyzed. Cells with different preferred directions were activated simultaneously, a finding consistent with the hypothesis of a distributed population coding of movement direction. (Supported by USPHS Grants P01 NS20868 and NS17413.)

142.6

SUPPLEMENTARY MOTOR AREA (SMA): CODING OF BOTH PREPARATORY AND MOVEMENT-RELATED NEURAL ACTIVITY IN SPATIAL RATHER THAN JOINT COORDINATES. M.D. Crutcher and G.E. Alexander. Dept. Neurol., Johns Hopkins Univ., Baltimore, MD 21205.

Single cell recordings in monkeys making limb movements to track visual targets have shown that the SMA and other precentral motor fields contain not only movement-related neurons, but also neurons that discharge during the preparation for limb movements. When directionally selective, both preparatory activity and movement-related activity are generally assumed to reflect the direction of the limb movement and not that of the target shift, even though these two variables have not been dissociated. To determine whether preparatory activity and movement-related activity are actually related to the direction of limb movement (in joint coordinates), or reflect instead the direction in which the target moves (in spatial coordinates), we trained rhesus monkeys to perform a visually guided, delayed step-tracking task that dissociated these variables. In some blocks of trials, the monkey was required to flex or extend his elbow so that the forearm moved in the same direction as the target shift, while in others he was required to move in the opposite direction. Single-cell recordings in the SMA revealed that cells with directional preparatory activity were usually related to the direction of the upcoming target shift, rather than the direction of the upcoming limb movement (20 of 23 neurons). Directional movement-related activity was also coded in terms of target location rather than the direction of limb movement for a significant proportion of cells (17/82). These results are similar to our recent findings in primary motor cortex, indicating that in both of these areas much of the preparatory activity, and a small portion of the movement-related activity, is coded in spatial rather than joint coordinates. This suggests that both areas may be involved in the highest levels of the sensory-motor transformations required for the planning and execution of visually guided limb movements.

142.7

MOTOR CORTICAL DISCHARGE DURING SINUSOIDAL ARM TRAJECTORIES. Andrew B. Schwartz. Division of Neurobiology, Barrow Neurological Inst., 350 W. Thomas Road, Phoenix, AZ 85013.

The relation between movement direction and the discharge rate of arm-related single cells recorded in the motor cortex was examined after a rhesus monkey performed two different arm-movement tasks.

During the 'direction' task, the animal was required to hold its finger in a center target on a touch-sensitive graphics monitor. This target would then disappear and one of 8 radially oriented targets appear. The monkey was trained to move its finger rapidly across the screen to the radial target for a reward. As shown previously, cells were found to have directionally sensitive discharge rates, as shown by a regression to a cosine (r^2 >.7).

In the 'sinusoid' task, three sinusoids of different amplitudes were traced horizontally, from left to right and in the opposite direction. These data were analyzed by calculating the direction of movement every 20 msec throughout the task. These directions were used to generate a predicted rate of discharge, using the relation determined in the 'direction' task. Each of the directionally sensitive cells had actual discharge rates which were modulated over the sinusoidal movement. Preliminary results show that the predicted rate of discharge calculated from the instantaneous direction of movement covaries with the actual rate. The actual discharge pattern leads the movement-derived prediction by approximately 150 msec. This interval remains constant for each of the drawn sinusoids and is independent of the spatial location of the hand on the screen. This finding as well as the consistently good fit of the prediction throughout the sine wave suggest that the directional properties of motor cortical discharge are valid for reaching movements with continually changing direction as well as for straight movements taking place in a single direction.

142.8

POPULATION CODING OF DIRECTED ARM MOVEMENTS IN SPACE BY MOTOR CORTICAL NEURONS: MATHEMATICALLY SUFFICIENT CONDITIONS FOR ACCURATE MOVEMENT. R.E. Kettner, Dept of Psychology, Indiana Univ, Prog Neural Science, Bloomington, IN 47405.

In previous work Georgopoulos, Schwartz and Kettner (Science 1986) have shown that accurate predictions of movement direction require analyses based upon large populations of broadly tuned neurons. Are there conditions which allow perfect prediction? Mathematical analyses will be presented which show that exact predictions result from populations of neurons with (1) uniformly distributed preferred directions, (2) uniformly distributed average firing magnitudes, and (3) individual neuron firing rates which are radially symmetric about their preferred direction. This population code is mathematically robust: severe violations in preferred-direction uniformity can be compensated by correction factors which are easily implemented using known brain circuits. Simulations and mathematical proofs will be presented to illustrate these points.

142.9

PRINCIPLE COMPONENT ANALYSIS OF THE RESPONSES OF PRE-MOTOR CORTICAL NEURONS TO MOVEMENT IN TWO DIMENSIONS. T.M. Amos*, C.M. Vermeersch*, S.-K. Park and T.J. Ebner (SPON: W.R. Roberts). Depts. Neurosurgery and Physiology, Neuroscience Grad. Prog., Univ. of MN, Mpls., MN 55455.

Two monkeys were trained to perform a task requiring movement in the horizontal plane, moving from a central start box to one of 6 equally spaced targets (60°) arranged around the central target. Distances to the targets varied with each set of six. The targets were displayed on a video screen and the monkey moved a cursor between targets using a manipulandum. During the task single unit responses from the premotor cortex were recorded. The responses of a single cell to a series of targets were then used to obtain a covariance matrix from which the principle components (eigenvectors) were obtained. Many cells showed similar first components, suggesting there are groups of cells with the same basic response pattern. Results indicate that over 80% of the variance in responses could be accounted for by the first component. Only the first few coefficients (used to reconstruct the original data from the eigenvectors) contribute to response amplitude modification for different targets. For some cells these coefficients varied with movement parameters (direction and amplitude). These findings suggest each cell has a basic response pattern which only needs to be scaled for movements in the plane. Supported by NSF/BNS-8707572.

142.10

EVALUATION OF MOTOR PARAMETERS IN THE PREMOVEMENT DISCHARGE OF PREMOTOR CORTICAL NEURONS DURING TWO-DIMENSIONAL MOVEMENTS. S.-K. Park, J.H. Kim and T.J. Ebner. Depts. Neurosurgery and Physiology, Neuroscience Grad. Prog., Univ. of MN, Mpls., MN 55455.

Our previous work has shown that the discharge properties of many neurons in the primate premotor cortex covary with different movement parameters (target distance and position). In this chronic unit study emphasis was placed on determining whether these parameters are represented in the premovement discharge of these neurons, by comparing their responses in two tasks. Two Rhesus monkeys were trained to move to various targets in the horizontal plane. In one task (delayed movement task) the animal was required to withhold the movement while the target was displayed until an additional instruction to move was given. In the second task (reaction time task) the animal was allowed to move as soon as the target was presented. In the delayed movement task the premovement component of the discharge peaked soon after target presentation and was maintained while movement was withheld. Premovement activity exhibited the same movement field as the discharge during the reaction time task. Both the position and distance were reflected in the discharge prior to the movement. These observations suggest that the discharge components of these neurons before and during movement contain comparable representations of movement parameters. Supported by NSF/BNS-8707572.

DOES AREA 5 ACTIVITY PREDICT MOVEMENT DIRECTION DURING AN INSTRUCTED-DELAY PERIOD? Donald J. Crammond* and John F. Kalaska, Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, H3C 3J7.

Arm-related area 5 cells were studied in an instructed-delay task requiring movements of the arm in 8 different directions away from a central start position. Monkeys were presented a visual signal (CUE) at the target end-point of an impending movement but had to withold the movement for a delay period of 1.2-2.8 sec, at which time the CUE signal changed colour (GO). To date, 41 cells have been recorded in one monkey. Nineteen cells showed changes in activity during the instructed-delay period, the intensity of which varied in a significant continuously-graded, unimodal fashion with the direction of the impending movement, centred on a preferred direction (PD). The PD of CUE activity typically was similar to that associated with movement toward the targets, but often different from that while holding over the target end-points. All cells with direction-specific activity during the instructed-delay period were also active during movement. Activity during the CUE period was less intense than during movement. We have not observed any area 5 cells active exclusively during the instructed-delay period. Supported by MRC Group Grant in neurological sciences.

TRAJECTORY-DEPENDENT SYNAPTIC INTERACTIONS IN PRIMATE MOTOR CORTEX DURING REACHING. H.C. Kwan, Y.C. Wong* and J.T. Murphy. Dept. Physiology, Univ. Toronto, Toronto, Ont. Can. M5S 1A8.

Even though the motor cortex has relatively direct access to the motor apparatus, its role in movement control is not clear. This study examines the possibility of patterning of synaptic interaction among motor cortical neurons as a mechanism for limb trajectory specification and control. Single unit recordings were performed in monkey motor cortex (M. arctoides) with two independently maneuverable electrodes. The task involved reaching out for one of six buttons which was lighted, depressing it to extinguish the light, and returning the arm to the resting position. A maximum of four separate units, two from each electrode, could be recorded. Limb trajectories for the target buttons were monitored by an optoelectronic device (Selspot). Cross-correlation analysis of spike trains revealed that close to 80% of correlated pairs of neurons exhibited variations in correlation strength as a function of limb trajectory. Further, analysis of spike trains from triplets provided evidence for trajectory-dependent synaptic interactions between members of the triplet, and trajectory-dependent common input shared by the same triplet. These findings are consistent with our hypothesis that specific patterns of synaptic interactions among motor cortical neurons play a role in the generation and control of limb trajectories. Supported by the MRC of Canada.

143.1

[^{35}S]TBPS BINDING SITES ARE DECREASED IN THE COLLICULI OF MICE WITH HIGH SENSITIVITY TO ETHANOL. J. Peris & N.R. Zahniser. Dept. Pharmacology, Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

One of the major actions of ethanol in the brain is to enhance GABAergic function. In support of this, long sleep (LS) and short sleep (SS) mice, genetically selected for different ethanol-induced sleeptimes, differ in GABA-dependent Cl^- flux and in muscimol inhibition of [^{35}S]TBPS binding in cerebellum. TBPS binds to the convulsant site allosterically linked to the $GABA_A$ receptor. Homogenate binding assays show no difference in the number of cerebellar TBPS sites however, it is possible that the density of these sites may differ in other more discrete brain areas which can be studied using quantitative autoradiography (QAR). We measured the density and affinity of the [^{35}S]TBPS binding site in LS and SS mice using QAR analysis of saturation isotherms. The number of [^{35}S]TBPS sites was highest in the colliculli (4.7±0.5 pmol/mg protein), cerebellum (4.7±0.5 pmol/mg), hippocampus (4.0±0.8 pmol/mg) and cortex (2.7±0.3 pmol/mg). Binding in striatum and brain stem was very low. The Bmax was lower in collicular areas of LS mice than in SS mice (1.8±0.3 vs. 4.7±0.5 pmol/mg) including both superior and inferior colliculus. There were no differences between lines in Bmax in any other area and in Kd in any area (120±12 nM). These data point to the colliculi as a potentially interesting area for ethanol research especially since GABAergic transmission in inferior colliculus may be reduced in rats during ethanol withdrawal (Frye et al., J. Pharmacol. Exp. Ther. 227:663-670, 1983). Supported by AA 03527.

143.2

CHARACTERIZATION OF N-(4,4-DI(3-METHYL-2-THIENYL)BUT-3-EN-1-YL)NIPECOTIC ACID (NO-328) HIGH AFFINITY BINDING TO THE BRAIN GABA UPTAKE CARRIER. P.D. Suzdak, U. Sonnewald, L. Knutsen, K.E. Anderson and C.L. Braestrup. Dept. of Pharmacology, NOVO Industri A/S,DK-2880 Bagsvaerd,Denmark. N-(4,4-di(3-mentyl-2-thienyl)but-3-en-1-yl) nipecotic acid (NO-328) is a potent anticonvulsant in mice and rats.We have shown that NO-328 is a potent inhibitor of ^{3}H-GABA uptake into a rat forebrain synaptosomal preparation (IC_{50}=67nM).Inhibition of ^{3}H-GABA by NO-328 is of apparent mixed type when NO-328 is preincubated prior to ^{3}H-GABA, inhibition is apparently competitive without preincubation. NO-328 is not a substrate for the GABA uptake carrier.^{3}H-NO-328 shows saturable and reversible binding to rat brain membranes in the presence of NaCl.Specific binding of ^{3}H-NO 328 is inhibited by known inhibitors of ^{3}H-GABA uptake, the amino acid GABA uptake inhibitors, however, are less potent than expected which indicates that the binding site is not identical to but overlapping with the GABA recognition site of the uptake carrier.The affinity constant for binding af ^{3}H-NO 328 is 18nM, Bmax=669 pmol/g original rat forbrain tissue.The regional distribution of NaCl dependent ^{3}H-NO 328 binding follows that of symaptosomal ^{3}H-GABA uptake.The development of photoaffinity ligands for the GABA uptake site and ion dependency will be discussed.It is concluded that NO-328 is a potent and selective inhibitor of GABA uptake and that ^{3}H-NO 328 is a useful radioligand for labelling the GABA uptake carrier in brain membranes.

143.3

CLONING OF THE ALPHA SUBUNIT OF THE HUMAN GABA-A RECEPTOR K.M. Garrett*, R.S. Duman, N. Saito*, B.Beer, A.J. Blume, M.P. Vitek and J.F. Tallman. Department of CNS Research, Lederle Laboratories, Pearl River, NY., and Ribicoff Research Facilities, Yale University School of Medicine, New Haven, CT.

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter in the brain, and the GABA-A receptor is the site of action of several classes of CNS depressants. In an effort to more completely understand the mechanism of these drug actions, we have cloned the alpha subunit of the human GABA-A receptor. Based on the amino acid sequence of the bovine GABA-A alpha subunit (Schofield et al., Nature **328**: 221), we designed several oligonucleotide probes which were optimized for human codon usage. The probes were pooled and used to screen a λgt11 library derived from the cerebellum of a 7 year old child (ATCC). One positive clone was obtained, Gα-1, which hybridized strongly to 7 of the 8 probes. The sequence of the human clone shares a high degree of similarity with the DNA sequence of the bovine a subunit. Hybridization of Gα-1 to Northern blots of RNAs from various regions of adult human brain shows a 4.3 Kb RNA which appears to be most abundant in the cerebellum. Hybridization of Gα-1 to Northern blots of rat brain RNAs shows a 4.3/4.5 Kb doublet which is present in the cortex, hippocampus, and cerebellum. We are continuing to investigate the regional distribution of the alpha subunits and the potential heterogeneity of both the alpha and beta subunits.

143.4

RO15-4513: ANTAGONISTIC SPECIFICITY OF ETHANOL INTERACTIONS WITH THE GABA BENZODIAZEPINE RECEPTOR. D.M. Turner* and R.W. Olsen (SPON: R.N. Pechnick). Dept. of Pharmacology, Mental Retardation Research Center and Brain Research Institute, Univ. of California, Los Angeles, CA 90024.

Ro 15-4513 labels two sites in cerebellum: a diazepam-sensitive (DZ-S) site and a diazepam-insensitive (DZ-IS) site (Turner and Olsen, Abstr. Soc. Neurosci. 13, 962 (1987)). We have found the DZ-IS site to possess a unique pharmacology for BZ (DZ-S) receptor ligands. At 2 nM [^{3}H]Ro 15-4513, the compounds CGS 8216 and Ro 15-1788 have IC_{50}s of <100 nM; DMCM and ZK95962 <250 nM; and ZK93426 <1 μM. Other compounds that partially inhibit at 10 μM are ZK91296 ZK93423, βCCE and βCCM (>75%) clonazepam (40%) and CL218872 FG7142, Ro 5-4864 and flurazepam (<15%). The findings that both agonists and inverse agonists inhibit the binding of Ro 15-4513 and that FG7142 does not inhibit the binding indicate that the DZ-IS site is not responsible for the inhibition by Ro 15-4513 of the action of ethanol.

In studies of chloride efflux in rat hippocampal slices, Ro 15-4513 (5 μM) did not inhibit muscimol-induced chloride flux nor the enhancement of this flux by pentobarbital or the steroid alphaxalone. A slight enhancement of muscimol-induced chloride flux by 25 mM ethanol was altered by Ro 15-4513. The finding that Ro 15-4513 does not inhibit muscimol, pentobarbital or alphaxalone enhancement of chloride flux at a concentration which has previously been found to inhibit ethanol enhancement indicates the specificity of Ro 15-4513 for the ethanol effect. NIH Grant HD 06576.

143.5

DIVALENT CATIONS MODULATE $GABA_A$ RECEPTOR AFFINITY AND DESENSITIZATION. D. Mierlak* and D.H. Farb (SPON: L. Friedman). Dept. of Anatomy and Cell Biology, SUNY Health Science Ctr., Brooklyn, NY 11203.

GABA-evoked Cl^- conductance is modulated by various compounds including benzodiazepines, β-carbolines, barbiturates and convulsants. We have shown that GABA receptor desensitization is also a locus for modulation by benzodiazepines (Mierlak and Farb, 1988). Here we investigate the effect of divalent cations on GABA responses and GABA receptor densensitization using intracellular current clamp recordings from chick spinal cord cell cultures. The conductance increase induced by pressure ejection of 10 uM GABA is inhibited reversibly in the presence of Cd^{2+}, Ni^{2+} or Co^{2+}. Cd^{2+}(EC50= 15 uM) is a more potent inhibitor of GABA responses than Ni^{2+}(EC50= 300 uM). Both Cd^{2+} and Ni^{2+} produce a maximal inhibition of 80-85%.

In the presence of 50 uM Cd^{2+}, the GABA dose-response curve is shifted to the right in a parallel fashion with little effect on the maximal GABA response. The efficacy of Cd^{2+} inhibition of the GABA response is inversely related to Ca^{2+} concentration. The results suggest an allosteric decrease in affinity of GABA receptors mediated by a Ca^{2+}-sensitive site. In addition to inhibiting GABA responses, the presence of Ni^{2+} or Cd^{2+} results in an increase in the rate and extent of GABA receptor desensitization as compared to equivalent GABA responses in the absence of Ni^{2+} or Cd^{2+}. Taken together, these results suggest a modulatory role for divalent cations on control of GABA receptor affinity and desensitization.

143.6

HUMAN GLIAL TUMORS HAVE HIGH AFFINITY FOR ISOQUINOLINE DERIVATIVES BUT NOT BENZODIAZEPINES. J.M.M. Olson,* L. Junck,* A.B. Young, J.B. Penney, P.E. McKeever,* and W.R. Mancini* (SPON: J.T. Greenamyre) Depts. of Pharmacology, Neurology and Pathology and the Neuroscience Program, University of Michigan, Ann Arbor, MI 48104.

PK 11195, Ro5-4864 and flunitrazepam binding were compared in human glioma tissue to determine whether the drug specificity of human tissue was different from that of rat. Postmortem human brains with glioma were assayed for 1 nM [^{3}H]PK 11195, 1 nM [^{3}H]Ro5-4864 or 5 nM [^{3}H]flunitrazepam binding autoradiographically. Specific [^{3}H]PK 11195 binding was significantly higher in tumor than in normal brain whereas [^{3}H]flunitrazepam binding in the presence of 1 μM clonazepam (to block "central benzodiazepine receptors") and [^{3}H]Ro5-4864 binding were low and nonspecific in both tumor and normal brain. In human glioma biopsies the same results were observed. Binding was also assayed in monolayers of rat or human glioma lines grown in culture. [^{3}H]PK 11195 binding was high in both human and rat cultured cells. Specific [^{3}H]Ro5-4864 and [^{3}H]flunitrazepam binding were observed in rat glioma, but not in three human glioma lines. Thus, human glioma cells bind the isoquinoline PK 11195 but have low affinity for Ro5-4864 or flunitrazepam. [^{11}C]PK 11195 may be a more appropriate ligand for PET scanning human gliomas.

Supported by USPHS grant NS 15655.

143.7

HOMOLOGOUS AND HETEROLOGOUS REGULATION OF THE GABA/ BENZODIAZEPINE RECEPTOR COMPLEX.

D.J. Roca*, J. Rozenberg*, D.H. Farb. Department of Anatomy & Cell Biology SUNY Health Science Center, Brooklyn N.Y. 11203

We have previously found that chronic flurazepam treatment of 7d primary cultures of chick brain cells significantly decreases GABA potentiation of ^{3}H-flunitrazepam (FNZ) binding. This effect is blocked by Ro15-1788. Moreover, chronic exposure to methylxanthines (MX) such as theophylline and caffeine reduces GABA potentiation of ^{3}H-FNZ binding. Chloroadenosine, an adenosine receptor agonist, blocks this effect of theophylline. To determine if the effects of chronic MX or benzodiazepine treatment were the result of increased GABA activity, cultures were treated approximately every 12h with 50 or 200 µM GABA for a total of 48h. While GABA potentiation of ^{3}H-FNZ binding was unaltered, ^{3}H-FNZ binding sites were reduced from 0.28 ± .05 pmol/mg in control cells to 0.2 ± .04 pmol/mg in cells treated with 50 µM GABA ($p < 0.05$) and 0.18 ± .03 pmol/mg in cells treated with 200 µM GABA ($p < 0.05$). There was no change in affinity. When cells were co-treated with 100 µM bicuculline and 100 µM GABA down-regulation was inhibited ($n = 2$). Chronic treatment with 10 µM muscimol also resulted in a down-regulation ($n = 4$). Thus, it appears that the GABA receptor complex can be regulated in a variety of ways. GABA receptor agonists act directly to cause down-regulation. In contrast, BZD positive modulators cause a decrease in GABA potentiation. MXs reduce GABA potentiation through a site that resembles an adenosine receptor.

143.8

GABA-A/BENZODIAZEPINE RECEPTORS IN THE RAT AND HAMSTER CIRCADIAN SYSTEM.

K.M. Michels, L. Smale, L.P. Morin and R.Y. Moore, Depts. of Neurology and Psychiatry, SUNY Stony Brook, NY 11794

The benzodiazepine, triazolam, produces phase shifts of circadian rhythms (Turek and Losee-Olson, 1986) which are abolished by destruction of the intergeniculate leaflet (IGL; Smale et al, 1988), the source of a secondary visual pathway innervating the principal pacemaker of the circadian system, the suprachiasmatic nucleus (SCN). The dorsal raphe (DR) is a source of serotonin innervation to both the IGL and the SCN. In the present study we investigated the localization of GABA-A/benzodiazepine (GABA-A/BZ) receptors in the circadian system using immunocytochemistry with a specific monoclonal antibody to the receptor (Vitorica et al, 1987) and localization of binding of [^{3}H]diazepam (DZP) and [^{3}H]flunitrazepam (FLU) by autoradiography.

There is no GABA-A/BZ receptor immunoreactivity in either the IGL or SCN but the DR shows a fine granular pattern of immunoreactivity. Semiquantitative analysis of autoradiograms for DZP and FLU binding reveals levels close to background in the IGL with the DR and SCN having levels of binding approximately 2.5 times greater than background. This pattern of immunoreactivity suggests that the DR is the most likely site of BZ effects on the circadian system but does not exclude the possibility that the IGL or SCN might mediate the effects.

Supported by NIH grants NS-16304 and NS-22168.

MOLECULAR WEIGHT ESTIMATION OF THE PERIPHERAL BENZODIAZEPINE RECEPTOR SOLUBILIZED FROM RAT LIVER.

A.L. Parola*[1], A.R. Buckley*[2], C.W. Putnam*[3,4,5], D.W. Montgomery*[5], D.H. Russell*[2], and H.E. Laird II[1]. Depts. of Pharm/Tox[1], Pharm.[3], and Surgery[4], Coll. of Pharmacy and Medicine, Univ. of Arizona, Tucson, AZ 85721 and VA Medical Center[5], Tucson, AZ 85723 and Dept. of Pharm/Therapeutics[2], Univ. of South Florida, Tampa, FL 33612.

Peripheral benzodiazepine receptors (PBZR) have been demonstrated in rat liver. The PBZR ligand, ^{3}H-Ro 5-4864, was used to pharmacologically characterize this site in the liver and revealed a single homogeneous receptor population ($n_H = 1$). Scatchard analysis of a saturation isotherm at 4°C gave a dissociation constant of 0.95 nM with a B_{max} = 5.2 pmol/mg protein. Analysis of digitonin solubilized receptors revealed a single homogeneous population of ^{3}H-Ro 5-4864 binding sites (n_H = 1) with k_d=2.6nM and B_{max} = 1.8 pmol/mg protein. Approximately 35% of the membrane receptor sites were solubilized and had the same rank order of potency for PBZR ligands as the membrane PBZR.

A PBZR photoaffinity ligand, ^{3}H-PK 14105, has been used to isolate the receptor protein from liver. A 5 nM solution of ^{3}H-PK 14105 was incubated with a crude liver membrane preparation in the presence and absence of 1 uM PK 11195 and irradiated. Approximately 25% of ^{3}H-PK 14105 was irreversibly bound after irradiation. The photoaffinity labeled PBZR was solubilized and run on SDS-PAGE. Autoradiography of the gel revealed a single radioactive band with an apparent molecular weight of 15 kd. This is in agreement with other estimations of the molecular weight for the PBZR from rat kidney.

143.10

DEMONSTRATION OF A DISTINCT CLASS OF HIGH-AFFINITY RECEPTORS FOR [^{3}H]ß-CARBOLINES IN MAN AND RAT.

H. Rommelspacher, S. Strauss*and T. May*. Dept. Neuropsychopharmacology, Free University, D-1000 Berlin 19, F.R.Germany

[^{3}H]Norharman ([^{3}H]ß-carboline) binds with high affinity (K_D 1.55 nmol/l, B_{max} 148 fmol/mg protein) to plasma membranes of rat brain (Pawlik and Rommelspacher, Eur. J. Pharmacol. 147: 163, 1988). High affinity binding sites were demonstrated for [^{3}H]harman (1-methyl-ß-carboline) in rat brain, spinal cord as well as human lymphocytes. Some evidence has been presented that both ß-carbolines act as endogenous modulators in the brain. They occur endogenously in man and rat and stimulate adenylate cyclase - suggesting activation of a second messenger mechanism (Rommelspacher et al., Arch. Pharmacol. 337: 116, 1988). The ß-carbolines have been found to elicit convulsive and conflict-augmenting effects at remarkably low doses. Quantitative autoradiography in rat brain slices revealed a distribution pattern which differs from that of other previously described receptors or binding sites (e.g. benzodiazepine, tryptamine, 5-hydroxytryptamine (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}, 5-HT_2)) which suggests that a unique class of [^{3}H]ß-carboline binding sites exists in the rat brain. The present findings may explain the biological effects of these ß-carbolines which differ from other ß-carbolines which bind with high affinity to the benzodiazepine binding sites. The latter substances show k_i-values higher than 2200 nmol/l for [^{3}H]norharman binding.

REPEATED ADMINISTRATION OF BENZODIAZEPINE RECEPTOR LIGANDS IN THE BABOON.

CA Sannerud, JM Cook and RR Griffiths*
The Johns Hopkins Univ Medical School, Baltimore, MD 21205 and the University of Wisconsin, Milwaukee, WI 53201

Five groups of baboons received repeated administration of saline, 5.6 mg/kg midazolam (MDZ), 5.0 mg/kg flumazenil (Ro15-1788, Ro), 3.2 mg/kg 3-carboethoxy-ß-carboline hydrochloride (ßCCE) or 10 mg/kg ßCCE for 5 days. Behavioral signs of sedation and excitation were scored for one hour after intramuscular injections. Repeated MDZ resulted in tolerance to its initial sedative and ataxic effects; the significant increases in signs of abnormal postures, falls and ataxia on day 1 were attenuated by day 5. Repeated ßCCE resulted in a progressive sensitization to its convulsant properties; signs of abnormal postures and incidences of myoclonic jerks/seizure significantly increased over the 5 day exposure in the 10 mg/kg ßCCE group. Repeated Ro or saline produced no changes in behavior. In a second study, 3 groups of baboons received repeated daily injections of MDZ (5.6, 11.2 or 20 mg/kg) for 6 days. All 3 groups became tolerant to the sedative and ataxic effects of MDZ. Acute injections of 5.0 mg/kg Ro on day 5 produced a dose-dependent withdrawal syndrome, (i.e. twitch/jerk, limb tremor and abnormal postures). Ro produced an equivocal attenuation in the degree of tolerance to MDZ on day 6 with large between-animal differences in signs of ataxia and abnormal postures. Thus, tolerance to MDZ in baboons may have been partially reset by antagonist administration.

PRENATAL DIAZEPAM (DZ) EXPOSURE: NEUROCHEMICAL AND BEHAVIORAL EFFECTS IN RAT OFFSPRING.

S.F. Ali, P. Sullivan*, G.D. Newport*, R.R. Holson and W. Slikker, Jr.*
Division of Reproductive and Developmental Toxicology, NCTR, Jefferson, AR 72079.

Recently it has been suggested that benzodiazepine (BZ) exposure in utero increases stress reactivity in offspring. We hypothesized that such alterations may be mediated by changes in brain GABA or BZ receptors. Pregnant rat dams were injected with DZ or vehicle (VEH) s.c. at 5 mg/kg on gestational days (GD) 15, 16, 19, 20 and 21 and 7.5 mg/kg on GD 17 and 18. At postnatal day (PND) 70, DZ and VEH treated male offspring were exposed to 1 of 3 experimental conditions: shock, handling or no handling. At PND 90, all males were exposed to a behavioral test battery sensitive to fear. Subjects were sacrificed on PND 104 and brains were dissected for neurochemical analysis. Prenatal treatment effects on behavior were slight and not suggestive of enhanced stress reactivity. BZ receptor binding was unaltered by prenatal DZ in hippocampus, hypothalamus and thalamus. NE levels were unaltered in hypothalamus. However, GABA receptor binding in thalamus increased across levels of conditioned fear, and this increase interacted significantly with the prenatal BZ treatments. These data do not support the contention that prenatal BZ exposure directly enhances fearfulness. They do suggest the possibility of more subtle alterations in response to fear-eliciting pretreatments.

STEROIDS MODULATE THE $GABA_A$ RECEPTOR LINKED Cl^- IONOPHORE THROUGH DISTINCT SITES OF ACTION. K.W. Gee, R.E. Brinton and D. Joy*. Sch. of Pharm., USC, L.A, CA 90033

Progesterone (P) and some of its metabolites can modulate the $GABA_A$/benzodiazepine receptor (GBR) linked Cl^- ionophore (Majewska et al., Science, 232:1004, 1986; Gee et al., Eur J. Pharmacol., 136:419, 1987). The barbiturate-like actions of the most potent P metabolites prompted the hypothesis that these steroids share a common site and mechanism of action with the hypnotic barbiturates. Pregnenolone sulfate (PS) was reported to act as a GABA "antagonist" at the same site as the chloride ionophore ligand, t-butylbicyclophosphorothionate (TBPS, Majewska & Schwartz, Brain Res., 404:355, 1987). In this study, the effect of P metabolites on the binding of ^{35}S-TBPS to the GBR-linked Cl^- ionophore in rat brain suggests that they act at sites independent of any known regulatory sites on the complex. Analysis of interactions between the steroids as modulators of ^{35}S-TBPS binding indicate multiple sites of action. The interactions between the hypnotic steroids and barbiturates in similar studies show characteristics inconsistent with a competitive-type interaction. PS will allosterically modulate the dissociation of ^{35}S-TBPS in a manner that suggests PS and TBPS do not act at a common site. Whether these steroid effects are "receptor" mediated or the result of membrane-lipid perturbations remain to be determined. (Supported by a NIH Grant NS 24645)

STRESS HORMONES, ETHANOL, AND GABA INTERACTIONS IN LS AND SS MICE. B. J. Martin* and J. M. Wehner. (SPON: M.Upchurch). Inst. for Beh. Gen., Univ. of Colo., Dept. of Psych., Boulder, CO 80309.

Recent investigations have demonstrated that steroid hormones and their metabolites enhance GABAergic activity. In addition it has been proposed that ethanol's effects may be mediated via interactions with the GABA/BZ receptor. To determine the relationship between ethanol, stress hormones and their effects on the GABA/BZ receptor, GABA-enhanced ^3H-flunitrazepam (FNZ) binding was measured in long-sleep (LS) and short-sleep (SS) mice after adrenalectomy (ADX) and in vivo treatments. A time course evaluated 24 hr-14 days post-ADX demonstrated an increase in enhancement in cortex, cerebellum and hippocampus in both LS and SS mice. The greatest degree of enhanced binding appeared by one week post-surgery in cortex and cerebellum and by two weeks in hippocampus. Intraperitoneal injections of 2.5 g/kg ethanol 30 min before sacrifice significantly increased enhancement in SS but not LS cortical tissue. In cerebellum, ethanol treatment increased enhancement in both lines with the greater response demonstrated by LS mice. A similar pattern of FNZ-binding was observed after stress induced by a 20 min confinement to an open arm of the elevated plus-maze.

IMMUNOCYTOCHEMICAL LOCALIZATION OF THE ENDOGENOUS BENZODIAZEPINE LIGAND OCTADECANEUROPEPTIDE (ODN) IN THE RAT BRAIN. M.C. Tonon*[1], L. Désy*[2], H. Vaudry*[1] and G. Pelletier[2] (SPON: A. Dupont). [1]Lab. Endocrinologie, Univ. Rouen, France and [2]MRC Group Mol. Endocrinol., C.H.U.L., Quebec, Canada.

In order to study the distribution of the endogenous benzodiazepine ligand octadecaneuropeptide (ODN) in rat brain, we have developed antibodies against this peptide. By immunocytochemistry, ODN-immunoreactive material was detected in cells which have the appearance of glial cells. They were found in high concentrations in the cerebral cortex and the hypothalamus, especially in the supraoptic, periventricular and arcuate nucleus. No positive axons or terminals could be observed. Immunostained cells were also observed in the cerebellar cortex. They seem to correspond to basket cells. Immunoabsorption with synthetic ODN completely prevented immunostaining. Using a radioimmunoassay for ODN, we have observed that synthetic ODN and serial dilutions of cerebral cortex extracts gave parallel displacement curves. These studies clearly demonstrate that ODN immunoreactive material is present in large amounts in areas such as the cerebral and cerebellar cortex which are known to contain high concentrations of benzodiazepine receptors. Immunostaining appears to be mostly associated with glial cells. Whether or not these cells are involved in the biosynthesis of ODN or ODN-related peptide(s) remains to be established.

CEREBRAL GABA CHANGES IN PYRITHIAMINE-TREATED RATS: IMPLICATIONS FOR THE PATHOGENESIS OF WERNICKE'S ENCEPHALOPATHY. M. Héroux* and R.F. Butterworth, Lab. of Neurochem., André-Viallet Clin. Res. Ctr., Hôpital St-Luc, Montreal, Que., Canada H2X 3J4.

Treatment of rats with pyrithiamine (PT) results in severe neurological dysfunction. GABA content of brain tissue from PT-treated rats was reduced in thalamus (by 45%, $p<0.01$), cerebellum (by 18%, $p<0.05$) and pons (by 30%, $p<0.05$). Activities of the thiamine-dependent enzyme α-ketoglutarate dehydrogenase (αKGDH) were reduced in parallel with the GABA changes and alanine concentrations were found to be concomitantly increased. Activities of glutamic acid decarboxylase remained within normal limits as did affinities and densities of high affinity ^3H-muscimol binding sites. Thiamine administration to symptomatic animals resulted in reversal of neurological abnormalities and in normalization of GABA and alanine levels and of αKGDH activities in cerebellum and pons. These results suggest that the reversible symptoms of PT treatment result from impaired GABA synthesis in pontine and cerebellar structures. Similar mechanisms may play a role in the pathogenesis of the reversible symptoms of Wernicke's Encephalopathy in man. [Supported by MRC (Canada)]

DIAZEPAM BINDING INHIBITOR IN HEPATIC ENCEPHALOPATHY. J. Rothstein, G. McKhann, P. Guarneri, M. Barbaccia, A. Guidotti, E. Costa. Dept. Neuro., Johns Hopkins Univ., Baltimore, MD 21205 and FIDIA Georgetown Inst., Wash. D.C. 20007.

Recent theories on the neurochemical etiology for hepatic encephalopathy (HE) suggest activation of GABA systems. GABA receptor sites are modulated by benzodiazepines (BZ) and BZ receptor antagonists have ameliorated HE in several small clinical trials. The neuropeptide diazepam binding inhibitor (DBI) is an endogenous modulator of GABA systems at the BZ receptor. We measured CSF and serum DBI, ammonia and amino acid concentrations in patients with HE. Several amino acids were significantly elevated in the CSF of patients with HE including glutamine, tyrosine and phenylalanine ($p<0.05$). Cerebrospinal fluid DBI levels were elevated 4-5 fold in patients with HE ($p<0.001$), but were normal in those patients with liver disease not associated with mental status changes. Levels of DBI correlated with the clinical staging of HE ($p<0.05$) and with CSF glutamine concentrations ($p<0.05$). Normalization of mental status was shown to result in normalization of CSF DBI levels. These data and others suggest an important role for endogenous BZ in the pathogenesis of HE.

AUTOANTIBODIES DIRECTED AGAINST GABA-ERGIC SYNAPSES IN FOUR MORE PATIENTS AFFECTED BY STIFF-MAN SYNDROME. F. Folli *+, M. Solimena*0+, V. Toso +, and P. De Camilli*0. *Dept. of Medical Pharmac.-CNR Center of Cytopharmac and +Clinica Medica VII, S.Raffaele Hosp., Univ. of Milano, Italy; Div. of Neurol., Castelfranco Veneto Hosp., Italy; 0Dept. of Cell Biology, Yale University, USA.

We have recently reported the occurrence of autoantibodies directed against GABA-ergic synapses in both serum and cerebrospinal fluid (CSF) of a patient affected by stiff-man syndrome (SMS), epilepsy and type 1 diabetes mellitus. Glutammic acid decarboxylase (GAD) was identified as the major target of those autoantibodies. (M. Solimena, F. Folli, S. Denis-Donini, G.C. Comi, G. Pozza, P. De Camilli and A. Vicari. New Engl. J. Med. 1988, 318: 1012-21). We have now found that the sera of four other patients affected by SMS contain antibodies which produce staining patterns identical to those produced by the autoantibodies of the previous patient and by GAD antibodies when tested by light microscopy immunocytochemistry on rat tissue sections. An identical staining pattern was also produced by the CSF of one of the patient (the only CSF so far available to us). "Western blot" experiments are in progress to identify the protein antigens recognized by the autoantibodies. These findings strongly support the hypothesis that autoimmunity, and possibly autoimmunity directed against components of GABA-ergic synapses, might be involved in the pathogenesis of stiff-man syndrome. (Supported in part by grants from the Italian CNR and from MDA to P.D.C. We are indebted to Dr. F. Howard [Mayo Clinic] and to Drs. A. Harding and C.D. Marsden [Natl. Hosp. for Nervous Diseases, London] for referring their patients to us).

EFFECTS OF TAURINE DERIVATIVES ON GABA AND BENZODIAZEPINE BINDING IN INTACT NEURONS AND IN EPILEPTIC PATIENTS. O.Malminen* and K.Nieminen. Lab. of Clinical Pharmacology, Huhtamäki Pharmaceuticals, POB 325, Helsinki, SF-00101 Finland.

Exogenous taurine has been tested to be an effective anticonvulsant when applied topically in most animal models of epilepsy. The underlying mechanism may be the modulation of GABA neurotransmission in the brain. However, its penetration through the blood brain barrier is poor due to its polarity and lipophobic nature. We have studied the properties of some lipophilic taurine derivatives with radioligand binding techniques and also summarize data from clinical trials where epileptic patients were treated with taltrimide (MY 117, 2-phthalimidoethanesulphon-N-isopropylamide), the pharmacologically most promising derivative in preliminary animal studies.

The effects of six lipophilic taurine derivatives on GABA and BZD receptor binding to intact granule cells of neonatal rat were studied with primary cell culture. The amide and isopropylamide derivatives of phenylsuccinyl-imidotaurine, MY 135 and MY 136 enhanced muscimol binding, whereas taurine reduced muscimol binding. Five of the compounds studied, as well as taurine itself, reduced flunitrazepam binding stimulated by GABA, being thus able to interfere with the coupling between GABA and BZD receptors. The effect was not significant with taltrimide.

In previous, open clinical trials taltrimide was ineffective to suppress convulsive seizures when it was given to severe epileptic patients. It was also ineffective to reduce photoconvulsive response in EEG. In controlled, randomized, cross-over trial orally administered taltrimide was compared with sodium valproate and placebo in 17 epileptic patients on carbamazepine monotherapy : in primary generalized epilepsy taltrimide reduced the number of attacks by 49 % and valproate by 38 %. Also the subjective evaluations made by patients and physician suggest that taltrimide is at least as effective as valproate in primary generalized epilepsy. In focal epilepsy taltrimide was not more effective than placebo.

143.20

GABA OVERFLOW IN RAT GLOBUS PALLIDUS FOLLOWING NEUROLEPTIC AND APOMORPHINE ADMINISTRATION MEASURED BY IN VIVO MICRODIALYSIS. K.L. DREW, W.T. O'CONNOR*, J. KEHR* AND U. UNGERSTEDT*. Dept. of Pharmacology, Karolinska Institute, Stockholm, Sweden.

The dopamine agonist apomorphine (1.0 mg/kg,sc) decreased, while the DA antagonists haloperidol (0.5mg/kg,sc) and clozapine (20.0mg/kg,sc) increased GABA overflow in the rat globus pallidus. These data are consistent with electrophysiological studies indicating that DA receptor stimulation enhances the activity of pallidal neurons (presumably by decreasing the release of GABA in the globus pallidus).

Male, Sprague-Dawley rats were anesthetized with halothane and dialysis probes (Carnegie Medicin) were implanted into the right globus pallidus. Probes were perfused with ringer solution at a flow rate of 2.0 ul/min. Samples were collected at either 30 min or 10 min intervals. Ten ul of perfusate from each fraction was then analyzed for GABA by a novel OPA/t-butylthiol, precolumn derivitization, reverse phase HPLC procedure with electrochemical detection. Additional experiments are in progress to study GABA overflow in the substania nigra and the effects of more selective D-1 and D-2 agonists and antagonists on GABA overflow in the globus pallidus and substantia nigra.

AMINO ACIDS: GABA AND BENZODIAZEPINES III

144.1

EVALUATION OF THE ANTICONVULSANT EFFECTS OF DIAZEPAM AND MK-801 IN SOMAN POISONING. T.-M. Shih, T. Koviak*, and D. Rennix. Biochem. Pharm. Br., U. S. Army Med. Res. Inst. Chem. Def., Aberdeen Proving Ground, MD 21010.

The acute toxic effects of the organophosphorus cholinesterase inhibitor soman are tremors, convulsions and death. The purpose of this study was to establish a rat model to evaluate potential anticonvulsants in soman poisoning. To increase survival, the oxime HI-6 (125 mg/kg, ip) was given to male rats either 30 min prior to or immediately after various subcutaneous doses of soman. In both treatment modes, soman at a dose of 1.6 LD50 produced 100% occurrence of convulsions. Pretreatment with HI-6 showed the least variability in the onset of convulsions and mortality, and was chosen as the mode for studying the anticonvulsant effects of diazepam and MK-801. Various doses of both compounds were given with or without the concomitant administration of the atropine sulfate (16 mg/kg, im) 30 min prior to soman (1.6 LD50, sc) challenge. Without atropine, diazepam (1.25 to 10.0 mg/kg, im) did not prevent soman-induced convulsions nor did MK-801 at or below 2.5 mg/kg, but above this dose MK-801 markedly potentiated soman-induced toxicity and death. In the presence of atropine, the anticonvulsant ED50s for diazepam and MK-801 were 134.2 and 36.8 µg/kg, im, respectively. The findings indicate that in soman poisoning diazepam and MK-801 are effective anticonvulsants only in the presence of atropine sulfate.

144.2

EFFECTS OF CENTRALLY ADMINISTERED Ro 15-1788 ON BETA-CARBOLINE-3-CARBOXYLIC ACID ETHYL ESTER INDUCED ALTERATIONS IN LOCOMOTOR ACTIVITY AND ANXIETY IN RATS. L.J. Wichlinski and R.A. Jensen. Biopsychology Lab., Dept. of Psychology, Southern Illinois University, Carbondale, IL 62901.

This experiment was aimed at replicating our previous finding of enhancement of locomotor activity following a 10.0 ug dose of B-CCE administered i.c.v. to rats. A second goal was to block this expected enhancement with the benzodiazepine receptor antagonist Ro 15-1788, also given i.c.v. Such antagonism would confirm that central benzodiazepine receptors mediate this effect.

Ro 15-1788, 0.25 ug or 1.25 ug, or vehicle was given i.c.v. five minutes before either vehicle or 10.0 ug B-CCE (n = 5-8). Locomotor activity was then electronically monitored for 30 minutes. B-CCE enhanced locomotor activity once again, here during the 15-20 min time block after infusion. Neither dose of Ro 15-1788 significantly attenuated this effect. However, the two B-CCE groups pretreated with Ro 15-1788 did not differ significantly from vehicle-treated animals. Following activity testing, the rats were placed in an elevated plus maze, a behavioral measure that detects anxiogenic activity. B-CCE failed to produce anxiogenic effects, although the B-CCE-treated rats were highly sensitive to touch. Five of the B-CCE-treated rats, regardless of pretreatment condition, showed almost complete suppression of activity during the first 5 minutes following drug administration, an effect not seen in any non-B-CCE-treated rats.

144.3

REGULATION OF GLUTAMIC ACID DECARBOXYLASE IN THE CEREBRAL CORTEX, D.L. Benson, P.J. Isackson, A.J. Tobin and E.G. Jones Department of Anatomy and Neurobiology, University of California, Irvine, 92717 and Department of Biology, University of California, Los Angeles.

Antisense RNA probes prepared against cat and human cDNAs for glutamic acid decarboxylase (GAD) were used to localize the sites of synthesis of GAD in the cat and rat cerebral cortex, hippocampus, brainstem, striatum, thalamus and hypothalamus and in different regions of monkey cortex. Consistent with various immunocytochemical studies, 25-30% of the neurons with these regions contained GAD mRNA. Northern blot analysis of RNA prepared from different regions of rat, cat, and monkey brains demonstrated the presence of two apparent GAD transcripts which could be resolved on formaldehyde agarose gels. Both transcripts were present in all brain regions examined.

GAD immunoreactivity has been previously shown to decrease in ocular dominance columns of the visual cortex of monocularly deprived macaque monkeys. RNA prepared from visual cortex of these monkeys does not show a major change in levels of GAD mRNA relative to normal visual cortex from nondeprived monkeys Potential regulation of GAD at the mRNA level in monocularly deprived monkeys is currently being more rigorously examined with in situ hybridization.

144.4

EFFECT OF DIAZEPAM (DZ) ON ELECTROACUPUNCTURE (EA) -INDUCED CHANGES IN BRAIN REGIONAL GABA. S.Chakrabarti* and M.K.Poddar. Dept. of Biochemistry, University of Calcutta, 35, B.C. Road, Calcutta 700 019, India.

EA(10Hz, 1 volt; 15 min) or DZ (5 or 20 mg/kg, i.p.) -induced increase of GABA level in pons-medulla (PM) and thalamus (T) but not in other regions of adult male albino rats was potentiated in T and reduced in PM when animals were exposed to both EA and DZ. Cotreatment with EA and DZ significantly reduced GAD activity in only PM although EA or DZ alone was ineffective. EA-induced rise in hypothalamic (H) and fall in spinal (S) GAD activity did not change with DZ. DZ alone increased GAD activity in only S. EA or DZ-induced rise in GABA-T activity in T, H and S was potentiated in H and S but reduced in T during their cotreatment. Cotreatment of EA and DZ normalized the EA-induced rise of PM and cortical (C) GABA-T activity. DZ alone reduced GABA-T activity in only C. EA-induced rise in glutamate (Glu) level in C and PM was increased with both EA and DZ. DZ alone reduced Glu level in only C. DZ-induced increase of GABA turnover (TO) in all the regions was greatly enhanced when DZ and EA were cotreated. EA alone stimulated GABA TO of S, without affecting other regions. These results suggest that EA or DZ-induced characteristic and region specific change in GABA system is either potentiated or abolished when the subject is co-exposed with EA and DZ.

LATENCIES CORRESPOND FOR GABA DEPLETION AND VACUOUS CHEWING BEHAVIOR ELICITED BY INTRANIGRAL ISONIAZID. S.E. Bachus. Dept. Pharmacol., Georgetown Univ., Wash. D.C., 20007.

We have previously reported[1] that intranigral isoniazid (INH) elicits vacuous chewing movements in rats after a latency of 20 min. I have measured nigral GABA levels at 10, 20, 30 and 40 min after microinfusion of 1.02 µmol INH/ 1 µl/6 min through guide cannulae in free-moving rats, with the enzymatic-fluorometric assay of Okada et al.[2]

At 10 min after INH, GABA, at 93.5% of control values, was not yet significantly reduced. GABA levels were significantly reduced ($p<.0005$) by 20 min, at 70.1% of control values, and remained low at 30 min (61.0% control) and 40 min (61.2% control). Thus, the latency for significant depletion of nigral GABA by INH appears to match that for elicitation of vacuous chewing movements.

We also noted[1] that rats receiving intranigral INH under ether anesthesia responded with vacuous chewing behavior only after a longer latency. In another group of rats, I compared nigral GABA levels 20 min after intranigral INH infused either through guide cannulae, or under ether anesthesia. GABA levels after INH were markedly higher in ether-treated rats (83.2% control; $p<.01$) than in rats with guide cannulae, whose GABA levels resembled those reported above (71.4% control). Ether had no effect on basal GABA levels. We are continuing to investigate whether ether interferes with the mechanism of action of INH, or affects GABA turnover rate.

QUANTAL RELEASE OF AMINO ACID TRANSMITTERS IN THE MEDIAL NUCLEUS TRACTUS SOLITARIUS (M-NTS) ANALYZED USING ISOLATED ADULT NEURONS. J.A. Drewe and D.L. Kunze. Baylor College of Medicine, Houston, TX, 77030.

The baroreceptor afferents synapse in the M-NTS, primarily on 10-15 µm diameter bipolar neurons. Neurons of this morphology were enzymatically dissociated from adult guinea pig M-NTS. We previously reported that spontaneous transient excitatory amino acid (EAA)-mediated synaptic currents (EPSC) and GABA-mediated synaptic currents (IPSC) could be recorded in this preparation. EAA activate non-specific cation conductances ($pNa=pK=pCs$), while GABA activates a Cl conductance ($pCl>>pMeSO_3$). Whole cell patch clamp recordings were made using a normal bath solution. $Cs\text{-}MeSO_3$ was used internally (E_{Cl}=-91 mV). The amplitudes of the spontaneous currents appeared to fluctuate in a quantal fashion. To limit the range of amplitudes, we studied the spontaneous GABA-mediated currents in nominally 0 Ca^{2+}. This decreased the amplitudes encountered to less than 15 pA. At 0 mV the miniature IPSC (mIPSC) were separated into 1 pA bins and the majority occurred at 3-5 pA (90mV from E_{Cl}). An 80 pS conductance change was found for the miniature EPSC. The frequency of the mIPSC was increased by exposure to a 0 K^+ extracellular solution which blocks the Na pump and produces presynaptic depolarization. This is a first report of quantal EPSC and IPSC in an adult mammalian CNS preparation where events of this magnitude are resolvable. Supported by DHHS 36840.

THE EFFECT OF SACRIFICE BY DECAPITATION OR MICROWAVE IRRADIATION ON RAT BRAIN AMINO ACIDS. J.M. Miller*, T.N. Ferraro, R.S. Jope, O.C. Snead and T.A. Hare. Depts. Pharmacology and Neurology, Thomas Jefferson Univ., Phila., PA 19107 and Univ. of Alabama, Birmingham, AL 35294.

Decapitation has been the principal method of animal sacrifice for neurochemical studies. Modern focused beam microwave irradiation (FBMI) instruments allow sacrifice of small animals with concomitant inactivation of brain enzymes, thereby eliminating enzyme-mediated post-mortem metabolic changes.

Over 30 amino acids and related compounds were measured in the substantia nigra, striatum, hippocampus and cortex of male Sprague-Dawley rats sacrificed by decapitation (n=5) or by FBMI (n=5). After homogenization in perchloric acid, supernatants were analyzed using a fully validated triple column ion-exchange amino acid analyzer with postcolumn o-phthalaldehyde derivatization and fluorometric detection.

Ala, GABA, Ethanolamine and NH_3 concentrations were significantly lower in all four brain regions of the FBMI group. Val, Leu, Tyr and Phe levels were also significantly lower in the substantia nigra, hippocampus and striatum of the FBMI group. The FBMI group showed significantly reduced Asp levels in the substantia nigra and hippocampus as well as Gly levels in the striatum, hippocampus and cortex. The only amino acid levels significantly higher in the FBMI group were GSH levels in the striatum and substantia nigra and Glu in the substantia nigra.

These results document the substantial impact of method of sacrifice on the baseline concentrations of brain amino acids.

144.8

STUDIES OF THE FORMATION OF γ-HYDROXYBUTYRIC ACID (GHB) FROM GABA AND 1,4-BUTANEDIOL (BD) IN BRAIN. O.C. Snead, R. Furner*, & C.C. Liu*, Department of Pediatrics & Neuropsychiatry Research Program, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama 35233.

GHB is a naturally occurring compound in brain which has the ability to produce absence-like seizures in animals. Although GABA is thought to be the main parent compound for GHB, there is some evidence that 1,4-BD is also a putative precursor for this substance. The relative formation of GHB from GABA and 1,4-BD was explored by following the formation of ^{13}C-GHB in rat brain after intracerebroventricular (icv) administration of either ^{13}C-GABA or ^{13}C-1,4-BD.

^{13}C-GHB was readily formed in brain after the icv administration of the stable isotope of either GABA or 1,4-BD. The turnover times of GABA- and 1,4-BD-derived GHB were 2.04 and 1.40 nM/G/h respectively. The conversion of ^{13}C-GABA to ^{13}C-GHB was completely blocked by GABA-T inhibitors. The 1,4-BD->GHB pathway was not sensitive to inhibition by either pyrazole or ethanol indicating involvement of some enzyme other than alcohol dehydrogenase in this conversion. These data confirm the GABA->GHB pathway in brain, demonstrate conclusively that the brain is capable of converting 1,4-BD to GHB, and support the hypothesis that a 1,4-BD->GHB pathway is operative in brain (Barker et al, Biochem Pharm 34:1852, 1985).

DOPAMINE MODULATES GABA RELEASE IN THE PARS RETICULATA OF THE RAT SUBSTANTIA NIGRA. B. Florán*, A. Arias*, A. Sierra*, D. Martínez-Fong* and J. Aceves* (SPON: J. Hernández). Dept. of Physiology. Centro de Investigación del IPN. México, D.F. México.

Although there are D-1 DA receptors on striatonigral GABA terminals innervating nigra reticulata cells, the role of these receptors is not clear. Here we present evidence showing that these receptors are involved in the modulation of GABA release by DA coming from DA dendrites. The experiments were done in slices of nigra reticulata of normal rats in comparison with rats with degeneration of the DA cells induced by 6-OHDA. The slices were loaded with tritiated GABA in the presence of β-alanine (1 µM). The superfusion solution contained nipecotic acid (10 µM). Release was evoked by a continuous high (15 mM) K depolarization. In normal rats, both the GABA-B agonist, Baclofen (100 µM), and the D-1 antagonist, SCH 23390 (1 µM), inhibited the GABA release, but the D-2 antagonist, Sulpiride (10 µM), stimulated the release. In the DA-denervated slice, the effect of these drugs was lost, but DA (100 µM) markedly enhanced the release; this enhancement was blocked by SCH 23390 but not by Sulpiride. The results suggest a reciprocal DA-GABA interaction in nigra reticulata: DA, stimulates GABA release, and, GABA inhibits DA release.

Ca^{2+}-DEPENDENT and Ca^{2+}-INDEPENDENT [^{3}H]GABA RELEASE FROM HIPPOCAMPAL NEURONS AT DIFFERENT TIMES IN CULTURE Katherine M. Harris and Richard J. Miller Department of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637

γ-aminobutyric acid (GABA) release from neurons has been shown to have both Ca^{2+}-dependent and -independent components. GABA may be released by the reversal of the electrogenic Na^+/GABA cotransport process. Hippocampi dissected from fetal (E 18) rats were dissociated, grown in primary culture and used experimentally after 8, 15 or 22 days in vitro. Cultures of hippocampal neurons accumulated and stored [^{3}H]GABA. [^{3}H]GABA was released when the cells were depolarized with either 50mM K^+ or 30µM veratridine. Veratridine stimulated release was 4-fold higher than 50mM K^+ stimulated release at 8, 15, and 22 days in vitro. The amount of [^{3}H]GABA released, increased with time in culture. Release evoked by either 50mM K^+ or 30µM veratridine was more Ca^{2+} sensitive at 15 days in vitro than at 8 days in vitro. The amount of [^{3}H]GABA released by 100µM N-methyl-D-aspartate (NMDA) or 100µM kainate did not change with time in culture. Release evoked by 50mM K^+, 30µM veratridine, 100µM NMDA, or 100µM kainate could be inhibited by GABA transport inhibitors, nipecotic acid, SKF 100330-A, SKF 89976-A or SKF 100561. The SKF inhibitors were more effective than nipecotic acid at blocking release. The increased Ca^{2+} sensitivity of [^{3}H]GABA release with time in culture may reflect an increase in synaptogenesis in vitro.

EVIDENCE THAT VAGINOCERVICAL STIMULATION RELEASES AMINO ACIDS INTO SUPERFUSATES OF THE SPINAL CORD. D.B. MASTERS, C. BEYER, ^F. JORDAN*, J.L. STEINMAN AND B. R. KOMISARUK. INST. OF ANIMAL BEHAVIOR AND ^DEPT. OF CHEMISTRY, RUTGERS UNIVERSITY, NEWARK, N.J. 07102 USA.

We hypothesized that inhibitory amino acids are released endogenously in the spinal cord in response to vaginocervical mechanostimulation (VS) and thereby produce analgesia. This hypothesis was tested by HPLC analysis of the amino acid content of superfusates of the spinal cord before, during and after VS (400g force) in the urethane-anesthetized rat. Artificial cerebrospinal fluid was continuously superfused over the spinal cord through the intrathecal space surrounding the sacral-lower thoracic region. Automated pre-column derivatization with ortho-phthalaldehyde (OPA) was performed to achieve less than 1.0 picomole fluorescence detection.

VS significantly increased (n=8; $p \leq 0.01$; ANOVA) the levels of the following inhibitory amino acids from baseline levels (mean % increase ± S.E.M.): glycine (48.8±10.9), taurine (40.9± 9.3), alanine (23.8±5.6), and serine (40.2±10.6). VS also significantly increased the levels of the following excitatory amino acids: aspartate (265.7±161.4) and glutamate (109.9 ±33.7). Levels of other amino acids were also increased significantly by VS: glutamine (44.2±13.1), threonine (37.4±10.3), and arginine (36.5±9.4). Superfusion with KCl (34.0 mM) significantly increased aspartate (77.4±26.8), glutamate (39.4±15.0), GABA (199.2±65.8), glycine (80.9±17.0), taurine (30.1±13.0), alanine (16.1±8.0), and arginine (15.4±7.2).

Thus, inhibitory and excitatory amino acids are released into the spinal cord by VS and may mediate its effects. The observed effect of KCl provides supportive evidence that the amino acid release is a consequence of intraspinal neuronal activity. Preliminary results with microdialysis of the sacral dorsal horn support the above findings.

THE IMIDAZOBENZODIAZEPINE RO 15-4513 LOWERS THRESHOLD FOR KINDLED SEIZURES IN THE BASOLATERAL AMYGDALA OF THE RAT. M.A. Bixler and M.J. Lewis. Dept. of Psychology, Howard University, Washington,D.C. 20059.

RO 15-4513 is reported to block the anticonflict and behavioral intoxicating effects of ethanol (Suzdak, P.D. et al., Science, 234: 1243, 1986). Based on evidence that it may also induce convulsive behavior (Miczek, K.A. and Gold, L.H., Psychopharm., 81: 183, 1983) and EEG activity indicative of seizure (Britton, K.T. et al., Science, 239: 648, 1988), the present study investigated the effect of RO 15-4513 (6.0 mg/kg, i.p.) on threshold for seizures in fully kindled rats. Bipolar electrodes were implanted in the basolateral amygdala (-2.2AP, +4.7L, -8.5V). Following recovery, daily stimulation (200 microamperes, base-to-peak) was administered until stage 5 seizure was observed. Threshold determinations were then conducted on an A-B-A design. RO 15-4513 treatment was found to significantly lower seizure threshold relative to the level observed following the initial vehicle pretreatment.

Supported in part by NIAAA grants AA06263 and RR08016.

EFFECTS OF GABA ANTAGONISTS ON THE ELECTRIC ACTIVITY OF HYPOTHALAMIC ARCUATE (ARC) AND VENTROMEDIAL (VMN) NUCLEI NEURONS IN VITRO. S. Ogawa, L.-M. Kow and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

To examine the possibility that neurons in the ARC and VMN are tonically inhibited by intrinsic GABAergic neurons, extracellular single-unit activity of ARC and VMN neurons was recorded from hypothalamic tissue slices prepared from female rats. In one type of experiment, slices were perfused with a GABA antagonist, picrotoxin (PTX; 0.25mM), or vehicle. In the ARC, the percentage of spontaneously firing neurons (57% of 152 for PTX vs 55% of 130 for vehicle) and their firing rates ($\bar{x}$±SEM spikes/sec, 1.24±0.14 vs 1.62±0.21) were not affected by PTX. In the VMN, the percentage of spontaneously firing neurons was actually lower (Chi-square test, $p<0.02$) with PTX (55% of 86) than with vehicle perfusion (69% of 84), although their firing rates were not different (1.91±0.18 vs 2.19±0.23). In another type of experiment, bath applications of bicucullin methiodide (BMI; 0.125mM) and PTX (0.125mM) were found to affect the firing rate of some ARC and VMN neurons, indicating interruption of tonic GABA action. The effect of BMI was often different from that of PTX. Thus, intrinsic tonic GABA inhibitions appear to exist in the ARC and VMN, but GABA may act through more than one mechanism.

144.14

PREDICTABILITY, CHRONICITY, AND TYPE OF STRESS: DIFFERENTIAL EFFECTS ON PICROTOXIN-INDUCED SEIZURES AND OPEN FIELD BEHAVIOR IN THE RAT. T.D. Wolinsky*, E.E. Coons*, and D.J. Nutt*. (SPON: D. Quartermain) NYU, Dept. of Psychology, NY, NY 10003 and NIAA, Bethesda, MD 20892

Using an animal model of depression (Katz, et al, Neurosci Biobev Rev, 1981) we previously reported that chronic varied, unpredictable stress (3 weeks) reduces the convulsant potency of the GABA antagonist picrotoxin (7.5 mg/kg, i.p.). Acute swim stress had an effect in the same direction but of a lesser magnitude. Relative to no-stress controls, we now compare the effects on seizures of chronic varied, chronic restaint and acute restraint stress. Behavioral depression was assessed by open field behavior 1 hour after the last treatment. Picrotoxin was administered the following day.

Chronic varied stress provided greater protection from picrotoxin-induced seizures than did other treatments. Both chronic stress groups showed the same degree of behavioral depression in the open field. Unlike acute swim animals, the acute restraint group exhibited more severe seizures relative to the other groups and the greatest attentuation of activity in th open feild. The severity of seizures in chronic restraint animals was less than acute restraint, but greater than chronic varied and no-stress groups.

These results demonstrate that different schedules of stress presentation influence the magnitude and direction of changes in seizure susceptibility in the rat, and by inference, changes in GABA activity. This suggests a role for the GABA/benzodiazapine system in adaptation to stress and in stress-induced depression.

EFFECTS OF THE β-CARBOLINE, NORELEAGNINE, ON ACTIVITY AND STARTLE HABITUATION IN PREWEANLING RATS. P.S. McGuire*, J. Tizzano, J.A. Johnson*, B.S. Martin* and J. Buelke-Sam. (SPON: J. Numberger) Dept. Pharmacol. and Toxicol., Ind. Univ. Med. Cen., Indianapolis, IN 46223, and Toxicol. Div., Lilly Res. Labs., Greenfield, IN 46140.

This study was designed to evaluate the actions of noreleagnine (NOR), a water soluble β-carboline, on developmental locomotor activity and startle habituation of preweanling rats. Six litters of SD rats and 15 litters of CD rats were tested; 1 pup/sex/litter was assigned to each dose group (0, 2, 4 or 8 mg/kg/day NOR ip). Dosing occurred on days 13-20 and testing was initiated 30 min later. The SD pups were tested in SDI home cage activity monitors for 30 min on days 13-20. The CD pups were tested in SDI Figure-8 mazes for 30 min on days 14, 16, 18 and 20, and again on day 21 with no drug pretreatment. On days 13, 15, 17 and 19, the CD pups were tested in SDI startle chambers. Each 50-trial session was made up of alternating 5-trial blocks of auditory (120 dB) and tactile (20 psi air puff) stimuli presented at 8-sec intervals. A dose-related increase was found in home cage activity in SD pups of both sexes on days 13-17 with significant increases on day 15 in males and day 13 and 15 in females. Figure-8 maze activity showed a dose-related decrease on days 16-20 in CD pups of both sexes. Activity levels on day 21 were comparable in all groups. Startle amplitude was increased by NOR treatment in a manner dependent on dose, sex, age and eliciting stimulus. Greater enhancement was seen: 1) in tactile than in auditory startle, 2) in females than in males, 3) at days 15 and 17, 4) at 4 mg/kg in males and 8 mg/kg in females. These results suggest that NOR affects early activity and reactivity in a manner consistent with its purported benzodiazepine/GABA inverse agonist properties.

ELECTROCONVULSIVE SHOCK (ECS) SELECTIVELY ALTERS THE PROFILE OF GABA LEVELS IN RAT BRAIN. T.N. Ferraro, G.T. Golden and T.A. Hare, Thomas Jefferson Univ., Phila. PA 19107 and VAMC, Coatesville, PA 19320.

ECS is a clinically effective antidepressant therapy with an unknown mechanism of action. Recent reports suggesting GABAergic involvement in the pathogenesis of depression have led us to study the effects of ECS on brain GABA levels. Male Wistar-Furth rats were subjected to ECS via earclip electrodes (EE) (n=6) or corneal electrodes (CE) (n=6) given once/day (120 V, 0.5 sec) for 10 days. A group of naive rats served as control. Current was measured and seizures were scored during each ECS trial. Rats were sacrificed by decapitation 24 hr after the last ECS, brains rapidly dissected according to a timed protocol and 8 discrete regions frozen on dry ice. GABA was measured in per-chloric acid extracts using an ion-exchange/fluorometric method. Results showed that rats receiving ECS via CE were subjected to significantly more current compared to rats treated with EE while exhibiting behavioral seizures of a similar duration. Compared to control, GABA levels were increased in all brain regions examined from rats treated with EE, except hippocampus; rats treated with CE exhibited significant GABA increases in hippocampus, frontal cortex, hypothalamus and olfactory bulbs. These results suggest that the mode of ECS delivery can selectively alter regional brain GABA levels. This effect may be a function of current intensity or localization.

SEIZURE THRESHOLDS IN DIAZEPAM-SENSITIVE AND -RESISTANT MICE. E.J. Gallaher* and S.E. Gionet* (SPON: JC Crabbe). VA Medical Center and Depts. of Pharmacology and Medical Psychology, Oregon Health Sci. Univ. Portland, OR 97201.

To facilitate the study of benzodiazepine (BZ) mechanisms, we developed diazepam (DZ)-sensitive (DS) and DZ-resistant (DR) mouse lines by selective breeding based on duration of rotarod impairment (Gallaher et al., Psychopharmacol., 93:25, 1987). Here we ask if the anti-convulsant BZ effect also segregated into the two lines.

We injected vehicle or DZ (po in corn oil; 0.3 to 300 mg/kg) into male DS, DR, and DC (control) mice. At 30 min we infused pentylenetetrazol (5 mg/ml, 1 ml/min) into tail veins to produce a myoclonic jerk. We saw no differences between lines in baseline seizure threshold (mg/kg PTZ±SEM, 8/group) or in dose-dependent protection by DZ. Higher DZ doses did not protect further.

Dose\Line	DS	DC	DR
Vehicle	56± 7	58± 7	60±11
1 mg/kg	59± 8	63± 6	74±20
10	112±19	93±10	85±11
100	137±11	141± 7	125±11

These data suggest that the anti-convulsant effect did not segregate during selection, indicating an underlying mechanism different from that which causes sedation.

EFFECTS OF DIAZEPAM AND ETHANOL ON RATS IN A RADIAL MAZE. C.H.M. Beck and E.A. Loh. Dept. of Psychology, University of Alberta, Edmonton, AB, Canada T6G 2E9.

Ethanol reduces the variability of behavior of rats in the acquisition and extinction of learned responses (Devenport, L.D., Behav. Neurosci., 98, 979, 1984). To determine the degree to which the reduced variability could be due to sedation, we compared sedation and behavioral variability in a study of the effects of diazepam and ethanol on extinction of food reinforced performance in an eight-arm radial maze. Eight groups (n = 6) of male Sprague Dawley rats were given one of diazepam (0.0, 1.5, 3.0, or 6.0 mg/kg, ip, -30 min) or of 10% ethanol (0.0, 1.0, 1.5, or 2.0 g/kg, ip, -15 min) for 18 sessions of acquisition and 5 sessions of extinction. Both diazepam and ethanol reduced the variability of behavior in extinction as indicated by more reentries into arms, higher probability of repeating a specific angle of turn between arm choices, and more frequent retracing of the same route. Sedation effects of the drugs were noted in slower running speeds, reduced frequency of rearing, and increased time spent immobile instead of sniffing the environment. Covariance and correlational analyses revealed that animals which showed reduced behavioral variability were more sedated.

BEHAVIORAL EFFECTS OF THE INTRACRANIAL ADMINISTRATION OF BICUCULLINE. P. Roy*, N.E. Goeders, S.I. Dworkin and J.E. Smith. Dept. of Psychiatry, LSU School of Medicine, Shreveport, LA 71130.

The amino acid neurotransmitter GABA is an inhibitory neurotransmitter in the central nervous system involved in the reinforcing effects of abused drugs. The contingent administration of morphine has been shown to increase GABA turnover in several brain regions and to decrease turnover in the nucleus accumbens (Smith et al., Pharmacol. Biochem. Behav., 16, 509-519, 1982). This study investigated the reinforcing effects of the GABA antagonist bicuculline. Rats were implanted with a chronic unilateral injection cannula into either the ventral tegmental area (VTA) or the preoptic region of the diagonal band (PO). The rats were connected to an electrolytic microinjection transducer system and placed in standard operant conditioning chambers. The subjects were given the opportunity to self-administer 100 pmole of bicuculline delivered in a 100 nL volume over 7.5 sec directly into the VTA or PO. Sessions were 3 hours in duration and were scheduled every third day. The subjects appeared to quickly acquire the lever press response that resulted in contingent intracranial injections of bicuculline. However, it was subsequently determined that the intracranial injections of the drug were producing nonspecific increases in general motor activity that included responding on the lever.

PEPTIDES: RECEPTORS II

145.1

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF RAT LIVER VASOPRESSIN V_1 RECEPTORS EXPRESSED IN XENOPUS LAEVIS OOCYTES. G.S.F. Ruigt, J. Brands, S. Geveling, J. Meyerink, R. van Rooijen and L. van Wezenbeek (SPON: F.Jenck). CNS Pharmacol., Organon, Oss, The Netherlands.

As a preliminary stage to the cloning and identification of the rat brain vasopressin receptor we report here the successful expression of rat liver V_1 receptors in Xenopus oocytes. Rat liver mRNA was isolated from 25 grams of tissue and was fractionated by preparative PAAG electrophoresis. Stage IV-VI oocytes were either injected with about 25 ng mRNA solution (0.5 mg/ml) or an equal volume of distilled water. After incubation intracellular voltage changes in response to superfusion of 10^{-9}M Arg-vasopressin were recorded in intact oocytes. Responses were only observed in cells injected with the 20S mRNA fraction and consisted of a delayed (1-4 min), longlasting (3-15 min) depolarising oscillation of the membrane potential. These oscillations gradually faded out in frequency, but less in amplitude, towards the end of the response. The vasopressin responses showed pronounced desensitization after repeated administration of vasopressin which could not be prevented by prolonged intermittent washout or by pretreatment of the oocytes with conA. DDAVP was ineffective in concentrations up to 100 μM, while vasotocin was as active as vasopressin. This indicates that the receptor is of the V_1 type, which was confirmed by complete block of the response by low doses (0.1 μM) of a selective V_1-antagonist.

145.2

MEASUREMENT OF VASOPRESSIN RECEPTORS IN THE SEPTUM OF MALE AND FEMALE RATS. M. D. Brot, M. A. Miller*, and D. M. Dorsa, GRECC, VA Medical Center, and Depts of Med, Pharm, and Psychology, Univ of WA, Seattle, WA 98108

Sexually dimorphic patterns of vasopressin (AVP) innervation have been reported in the rat brain, with the greatest differences occurring in the limbic system. Both the number of AVP neurons and the density of staining of fiber pathways is greater in male than in female rats. This pattern of innervation suggests that AVP receptor number and/or affinity might also display sex-related differences, as AVP receptor number has been shown to be influenced by the level of endogenous ligand in other models such as the Brattleboro rat.

In order to determine the existence of gender-specific AVP receptor characteristics, receptor binding assays were performed using membranes prepared from the septum of intact male and female adult Long-Evans rats. When receptors were labeled with the specific V_1-receptor antagonist ^{125}I-d(CH_2)$_5$-tyr(Me)AVP, Scatchard analysis revealed no difference in either the affinity [(K_d,nM) male: 0.48±.09, female: 0.53±.08], or number of binding sites [(B_{max}, fmol) male: 7.6±1.07, Female: 11.6±2.3].

These data suggest that septal AVP receptor density is equivalent in the sexes, even though AVP innervation is clearly dimorphic. Future studies will address the specificity of this observation to the ligand used, and the role of steroids in modulation of receptor density.

145.3

VASOPRESSIN RECEPTORS IN THE HUMAN BRAIN: LOCALIZATION BY QUANTITATIVE RECEPTOR AUTORADIOGRAPHY. R.E. Brinton, B.S. McEwen and A. Biegon▲ Rockefeller University, 1230 York Ave., NY, NY 10021 and ▲Weizmann Institute of Science Rehovot, Israel.

Vasopressin (AVP) has been found to influence memory function in human subjects (Weingartner et al., Science, 211:601, 1981). Based on the behavioral effects of AVP, we explored the existence of AVP receptors in human brain using light microscopic autoradiography to determine their localization. Binding parameters for labeling AVP receptors were those previously described in Brinton et al., (PNAS, 81:7248, 1984) and in Biegon et al., (Neurosci. Lett, 44: 229, 1984). Recognition sites for ^{3}H-AVP were detected in both hippocampus and cortex. In the hippocampus, AVP recognition sites were detected in each of the pyramidal cell layers (16.4 ± 0.8; 14) and in the dentate gyrus (21 ± 0.9; 14). Binding sites were also detected in the occipitotemporal cortex, (18.7 ± 0.7; 13). Values represent mean ± SEM; n, fmoles ^{3}H-AVP specifically bound/mg protein. Localization of AVP recognition sites in sagittal and coronal sections from post-mortem human brain will also be presented.

These studies were supported by the Rockefeller-Weizmann Foundation.

145.4

CHARACTERIZATION OF ARGININE-VASOPRESSIN BINDING (3H-AVP) SITES IN THE CINGULATE GYRUS OF THE RAT PUP. P. Szot, M. Swank*, K. Myers* and D. M. Dorsa. GRECC, VAMC and Depts. of Med. and Pharm, Univ. of WA, Seattle, WA 98108.

CNS vasopressin receptors have been shown autoradiographically to undergo dramatic changes during development. The caudate nucleus, dorsal hippocampus and cingulate gyrus (CG) display intense labeling by 3H-AVP in early postnatal stages, with little labeling in the adult.

3H-AVP equilibrium binding was performed on crude membranes prepared from CG of Long-Evans rat pups (7-10 days) and adults (90 days). Analysis of saturation isotherms yielded Bmax values of 13.0±1.3 and 21.5±3.0 fmol/mg protein, and Kd values of 0.89±0.1 and 4.5±0.9nM for pup and adult, respectively. Both the Bmax and Kd of the 3H-AVP site was significantly increased in the adult CG compared to the pup. Competition experiments using various AVP analogs were performed on crude membranes prepared from pup CG and adult septum, an area in the CNS where V1 receptors are located. The pharmacological profile of AVP analogs in the pup CG differed from that observed in the adult septum, especially when displacement potency of receptor antagonists was examined. The differences between pup CG and adult septal receptor specificity and affinity suggest that the pup CG 3H-AVP site is a subtype of the V1 receptor. (Sponsored by VA and NS 20311.)

145.5

COMPARISON OF EFFECTS PRODUCED BY CHOLECYSTOKININ (CCK) AND A CCK ANTAGONIST ON CELLS IN THE RAT NUCLEUS ACCUMBENS (NAc) AND FRONTAL CORTEX (FC). R.J. Kasser, X.T. Hu, and R.Y. Wang. Depart. of Psychiat. and Behav. Sciences, SUNY at Stony Brook, Stony Brook, NY 11794.

Based on receptor binding studies, CCK receptors have been classified into two subtypes: Type A (sulfate-dependent, like-pancreas) and Type B (sulfate-independent, like-brain). In the present study, the techniques of extracellular single cell recording and iontophoresis were used to examine and compare the effect of CCK-8S, CCK-8US and CCK-antagonizing effect of LORG (a selective Type A CCK receptor antagonist) on neurons in the NAc and FC. CCK-8S excited medial NAc neurons. Furthermore, it potently facilitated excitation induced by glutamate. Neither CCK-8US nor CCK-4 mimicked the action of CCK-8S. Moreover, in the NAc, LORG potently and selectively blocked the action of CCK-8S. In contrast to results from the NAc, CCK-8US mimicked the action of CCK-8S; it excited 10 of 16 FC cells tested. In addition, LORG blocked CCK-8S induced effects only in 1 out of 11 FC cells tested. Unexpectedly, LORG facilitated both CCK-8S and CCK-8US induced effects and independently activated 3 of 6 FC cells tested. These results suggest that the CCK receptors in the NAc and FC most closely resemble Type A and Type B, respectively. (Support by USPHS Grants MH-41440, MH-41696, MH-00378 to R.Y.W. and MH-43893 to R.J.K.)

145.6

HETEROGENEITY OF PERIPHERAL TYPE CCK-8 RECEPTORS. S.McCreedy*, S.Augello-Vaisey*, R.Simmons*, J.Comstock*, J.Rosamond*, & J.Blosser. Pharmaceutical Div., Pennwalt Corp., Rochester, NY 14623.

CCK-8 receptors have been pharmacologically distinguished as central or peripheral types. Recently, it was reported that analogs of CCK-8 in which DAla or DTrp was substituted for Gly at position 4 had greatly diminished potency and efficacy to contract gallbladder (GB) but retained activity comparable to CCK-8 to stimulate pancreatic exocrine function in vivo in dogs (Biomed.Res.6:111,1985). To explore these potential differences in CCK-8 receptors, we prepared a series of CCK-8 analogs with DAla substituted for Gly and compared their potencies in vitro to contract guinea pig GB with their potencies to compete with the binding of ^{3}H-L364,718, a CCK-8 antagonist, to rat pancreatic membrane receptors (PMR). In contrast with reported findings in GB in vivo, DAla containing analogs possessed full agonist activity in vitro. The potencies of (DAla^{4})CCK-8, Succ-(DAla^{3})CCK-7, and Desamino-(Tyr^{1},DAla^{3})CCK-7 to contract GB was 1/5 to 1/15 that of their respective Gly containing analogs. CCK-8 and Gly containing analogs had an IC50 of 15-25 nM with an apparent Hill coef. (n) of 0.5 for PMR. In contrast, the binding affinity of DAla containing analogs were 100-200 fold less (n=0.65). These findings may reflect differences in the pharmacological specificity of pancreatic and GB receptors, or alternatively, differences in selectivity of high and low receptor affinity states.

145.7

IDENTIFICATION OF CCK-8 ANALOGUES WITH HIGH AFFINITY AND SELECTIVITY FOR THE BRAIN CCK RECEPTOR. R.J. Knapp*, S.N. Fang*, G.K. Lui*, V.J. Hruby*, and H.I. Yamamura (SPON: J. Lai). Depts. of Pharmacology and Chemistry, Univ. of Arizona, Tucson, AZ 85724.

A series of sulfated and unsulfated cholecystokinin (CCK 26-33) analogues have been synthesized and their affinities measured at the CCK receptors in guinea pig pancreas and cortex. We present data here for the analogues: methyl-Nle^{31} CCK 29-33 (8701), methyl-Nle^{28,31}CCK26-33 (8702), and methyl-Nle^{28},Nle^{31}bis sulfate CCK 26-33 (8712). Guinea pig pancreatic membranes were prepared using the procedure described by Steigerwalt and Williams, Endocrinology, 109: 1746(1981), while guinea pig cortical membranes were prepared using the procedure of Saito et al., J. Neurochem., 37:483(1981). Binding studies with both tissues were carried out using the same assay buffer and conditions as described by Steigerwalt and Williams (op. cit.) except that Bolton-Hunter labeled CCK 26-33 was used as the tracer at a concentration of about 50pM. The results obtained by nonlinear regression analysis are as follows:

Analogue Number	Pancreas IC-50 (nM + SEM)	Cortex IC-50 (nM + SEM)	Ratio P/C
8701	8,004 ± 858	3.34 ± 0.32	2396
8702	958 ± 103	0.23 ± 0.01	4146
8712	29,073 ± 5,073	3.19 ± 0.17	9099

DISTRIBUTION OF CHOLECYSTOKININ (CCK) BINDING SITES IN SYRIAN HAMSTER BRAIN. M.O. Miceli and M. Steiner. McMaster University and St. Joseph's Hospital Research Institute, Hamilton, Ontario, Canada L8N 4A6.

Previously reported species differences in the pharmacological characteristics and CNS distribution of CCK receptors prompted us to map and characterize brain CCK binding sites in the Syrian hamster, a species with a CNS distribution of CCK immunoreactivity that differs from that of other rodents. Autoradiograms of brain sections incubated in 34 pM ^{125}I-Bolton Hunter CCK-8 were generated on LKB Ultrofilm. Binding specificity was assessed in adjacent sections incubated in the presence of 1 µM unlabeled CCK-8 or desulfated (DS) CCK-8. High binding densities were distributed in the cerebral cortex, olfactory bulbs and nuclei, area postrema and the interpeduncular, inferior olivary, cochlear, and solitary nuclei. Moderate binding densities were present in the striatum, amygdala, hippocampus, hypothalamus, zona incerta, habenula, thalamic parafascicular and paraventricular nuclei, central gray, and medial vestibular nucleus. Specific binding was not detected in the cerebellum. Binding sites with a low affinity for DS CCK-8 were noted in the solitary complex and in regions of the hypothalamus (supraoptic, paraventricular, dorsomedeial and accessory magnocellular nuclei) where such specificity has not been demonstrated in other species. Our observations provide further evidence of species differences in CCK receptor distribution and specificity. (Supported by St. Joseph's Hospital Foundation)

PERIPHERAL-TYPE CHOLECYSTOKININ (CCK) RECEPTORS IN CHP212 NEUROBLASTOMA CELLS: ASSOCIATION WITH INOSITOL PHOSPHOLIPID HYDROLYSIS. Ronald W. Barrett*, Michael E. Steffey* and Caroline A. W. Wolfram* (SPON: C. Briggs). Neuroscience Research Division, Pharmaceutical Discovery, Dept 47W, Abbott Laboratories, Abbott Park, IL 60064

[^{125}I]BH-CCK8 and [^{3}H](-)L364718 membrane binding assays were used to identify and characterize CCK receptors in a human neuroblastoma cell line (CHP212). Based on ligand binding properties, CCK receptors in these cells are similar to those found in pancreas and differ from the predominant subtype of CCK receptor found in brain. Binding of [^{125}I]BH-CCK8 was reduced by guanyl nucleotides. A substantial difference in the Bmax for the radiolabeled agonist ([^{125}I]BH-CCK) and antagonist ([^{3}H](-)L364718) was noted. These observations are consistent with CCK receptors existing in G-protein coupled and uncoupled states. Similar to its action in pancreatic acinar cells, CCK8(S) stimulated the formation of [^{3}H]inositol phosphates in CHP212 cells (EC50=6 nM; Max. response= 4.5 x basal). This stimulation of PI hydrolysis was not diminished by treatment with pertussis toxin. The intrinsic activity of CCK analogs in stimulating PI hydrolysis was substantially less than their intrinsic activity in pancreatic acinar cells. The CHP212 neuroblastoma cell may serve as a useful model for peripheral-type CCK receptors found in the CNS.

ONTOGENY OF CHOLECYSTOKININ RECEPTORS IN THE RAT BRAIN. D. Pelaprat*, I. Dusart* and M. Peschanski (SPON: B. Scatton). U.161 INSERM, 2 rue d'Alésia, 75013 PARIS (FRANCE).

The ontogeny of cholecystokinin (CCK) binding sites in the rat forebrain and midbrain was studied by in vitro receptor autoradiography, using (125I) Bolton-Hunter CCK_8. In the majority of structures, the densities of sites were low in the prenatal period and over the first week after birth, increased until the third week, and decreased over the fourth week to reach adult levels. However, both the rate of increase and the extent of the decrease varied in large proportions among structures. For instance, labeling became detectable at day 10 in neocortex, at day 7 in paleocortex, and at birth in endopyriform nucleus. On the other hand, the decrease over the fourth week was negligible in cingulate cortex, small (32%) in the thalamic reticular nucleus, and reached 70% to 100% in various layers of hippocampus. These different timetables may depend mostly on the differential growth of cells expressing the CCK receptor gene within the developing brain. Finally, the absence of CCK binding sites in most of the regions during the prenatal and the early postnatal periods precludes a major role of this peptide in the embryonic development of the rat brain.

145.11

HELODERMIN AND (D-CL-PHE^{6}-LEU^{17})VIP ACT ON VASOACTIVE INTESTINAL PEPTIDE RECEPTORS IN CEREBRAL BLOOD VESSELS. D.N.Krause[1], I.Jansen[2*], and L. Edvinsson[2*]. [1]Dept. Pharmacol., Univ. of Calif., Irvine, CA 92717 and [2]Dept. Exp. Res., Univ. of Lund, Malmö Gen. Hosp., S-214 01 Malmö, Sweden.

Cerebrovascular receptors for vasoactive intestinal peptide (VIP) were characterized using several newly-described VIP-related peptides. Helodermin, a peptide isolated from the venom of the lizard Heloderma Suspectum which shows a high degree of sequence homology with VIP, was found to potently displace ^{125}I-VIP from high affinity receptor binding sites in pig cerebral arteries. It was more potent than its analogues, helospectrin I and helospectrin II, and peptide histidine isoleucine (PHI) and the proposed VIP antagonist (D-Cl-Phe^{6}-Leu^{17})VIP. A similar order of potency was found when the above peptides were tested on specific ^{125}I-VIP binding to intracerebral microvessels. The potencies for VIP receptor binding correlated with the ability of the helospectrin analogues and PHI to induce dilation of precontracted ring segments of pig cerebral arteries. The putative VIP antagonist was found to act as an agonist at cerebrovascular VIP receptors and did not antagonize the VIP response, in contrast to what has been found in non-vascular tissues.

CROSS-LINKING OF LABELED VIP TO RECEPTORS IN NERVOUS AND IMMUNE TISSUES. A.I. Kook*, J.B. O'Neill, C.B. Pert* and J.M. Hill. Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, Bethesda, MD 20892.

VIP has a broad range of biological functions due to the presence of its receptors in a wide variety of tissues throughout the body.

Recent evidence suggests that VIP binds to multiple receptor subtypes, and that the AIDS virus may bind to at least one of these. AIDS is a neuroimmune disorder in which HIV infects cells by binding first to a 60 kD surface protein (T4) found in cells of the CNS and immune system.

In this study ^{125}I-VIP was bound to membranes prepared from the brain, thymus, and T lymphocytes. Binding was competed with VIP, GTP, secretin, and peptide T; an amino acid sequence from HIV envelope protein which is homologous to a portion of VIP.

Brain tissue, especially cortical and hippocampal membranes have a major ~60 kD band and also a band at 47-48 kD. In preliminary studies, T lymphocytes also show a 60 kD band. Thymocytes have a major band at 47-48 kD. VIP, secretin, GTP, and peptide T displace the 47-48 kD band to varying degrees. The 60 kD band is partially displaced with VIP, displaced to a greater extend by peptide T, but not at all by secretin.

These results suggest that T4, the 60 kD surface protein to which HIV binds, is actually the 60 kD VIP receptor found in brain and T lymphocytes. HIV is presumably able to occupy the VIP receptor because the peptide T region of the envelope protein is homologous with a portion of VIP.

The functional aspects of these receptors are not as yet understood, but these results suggest VIP may have more than one mechanism of cell activation.

INTERACTIONS BETWEEN MONOAMINES AND VASOACTIVE INTESTINAL PEPTIDE RECEPTORS ON ASTROGLIA IN PRIMARY CULTURE. L.Rönnbäck[1,2] and E.Hansson[1]. [1]Institute of Neurobiology and [2]Department of Neurology, University of Göteborg, Göteborg, Sweden.

Many of the proposed functions of astrocytes in developing and mature brain are dependent on the ability of the cells to recognize and respond to specific neuronal signals. Evidence from a large number of laboratories indicate that astroglia cultured from immature brain exhibit a wide variety of membrane receptors with eg. cyclic AMP or inositol-trisphosphates as second messengers. Interactions between different receptors or second messenger systems have recently been observed. In this poster we demonstrate the presence of a VIP (vasoactive intestinal peptide) receptor with cyclic AMP as second messenger on cultured astrocytes. We also present data supporting an interaction between the second messenger systems for VIP and α and β adrenoceptors. The functional implications are at present unknown, but it might be that the peptide can modulate the response of the second messenger of catecholamines on astroglial cells through intramembrane mechanisms.

Two questions should be addressed. Even if the cultures used are well characterized both to their cellular content (no neurons or mature oligodendrocytes present) and to their degree of differentiation, they represent an immature system cultivated in the absence of neuronal contacts for 2 weeks. Thus, it might be questioned whether or not mature astrocytes in brain exhibit receptors and receptor interactions similar to those expressed by cultured astroglia. Second, what cellular events, beyond activation of second messengers, are influenced by receptor stimulation? Studies along these lines are in focus of our considerations.

145.14

ELECTRON MICROSCOPIC LOCALIZATION OF MU OPIOID RECEPTORS IN THE RAT LOCUS COERULEUS BY IN VITRO RADIOAUTOGRAPHY. E.Moysé*, K.Leonard*, A.Beaudet (SPON:O.Calvillo)Dpt.Neuroanatomy,Mtl. Neurol.Inst.,McGill Univ.,3801 University, Montréal,Canada.

Mu opioid binding sites were visualized by light and electron microscopic radioautography in slices of rat pontine tegmentum incubated in vitro with the met-enkephalin analog 125I-FK 33-824, in the absence(total binding)or in the presence(non specific binding)of 1μM non radioactive naloxone. In light microscopic radioautographs from slices incubated with 125I-FK alone,the labeling was intense throughout the locus coeruleus(LC),where it appeared evenly distributed over nerve cell bodies and neuropil.The addition of non radioactive naloxone to the incubation medium reduced the grain density by 72% in both compartments.At the electron microscopic level,almost 50% of the grains arising from specifically labeled 125I-FK binding sites were detected inside neuronal perikarya and dendrites,with a selective enrichment of the endoplasmic reticulum and Golgi apparatus. Most of the remaining grains were associated with neuronal interfacesinvolving the plasma membrane of intrinsic perikarya and dendrites.Among these,axosomatic and axodendritic appositions showed the highest concentration of label over random.Only a few of the labeled interfaces,however,exhibited synaptic specialization in the plane of section.These results provide a morphological support for direct non-jonctional action of opioid peptides on the perikaryon and dendrites of LC neurons. SUPPORTED BY MRC.

145.15

FUNCTIONAL COUPLING OF OPIOID RECEPTORS IN HUMAN NEUROBLASTOMA CELLS. Syed M.I. Kazmi, Cia Barlas* and Ram K. Mishra. Neuropharmacology Lab., Depts. of Psychiatry and Neurosciences, McMaster Univ., Hamilton, Canada, L8N 3Z5.

The profile of opioid receptor occupancy and functional response under pertussis toxin (PT) catalyzed ADP ribosylation of guanine nucleotide inhibitory protein (Ni) and phorbol ester (4β phorbol, 12β myristate, 13α acetate, PMA) induced stimulation of protein kinase C was studied in human neuroblastoma, SH-SY5Y cells. PMA (10^{-7} -10^{-6}M) treatment (1-2 hours) to SH-SY5Y cells caused a selective decrease (30-50%) in opioid agonist binding by reducing the agonist high affinity state of the receptor. Pertussis toxin also caused time- and dose-dependent decrease in opioid agonist binding. The effect of sodium ions on agonist binding was potentiated in PT-treated cells. Opioid agonist, DADLE, caused a significant increase in low K_m GTPase activity and a reduction (40-50%) in forskolin-stimulated cyclic AMP levels; the effects could be completely reversed by naloxone while δ-selective antagonist, ICI-17184, was effective only at concentrations higher than 10^{-7}M. Pertussis toxin completely abolished the effects of DADLE on low K_m GTPase and cyclic AMP levels, whereas PMA shifted the agonist response curves to the right. PT-catalyzed ADP ribosylation of 41K protein (α_i of N_i) appeared to decrease in PMA treated cells. These results would facilitate in elucidating the mechanisms of the regulation of opioid receptor G-protein coupling in human neuroblastoma cells.

145.16

ELECTRON MICROSCOPIC LOCALIZATION OF DELTA OPIOID RECEPTORS IN RAT BRAIN. F. Pasquini*, A. Beaudet, P. Bochet*, J. Rossier and B.P. Roques* (SPON: M. Frankfurt). Neuroanatomy Lab, Montreal Neurol. Inst., 3801 University St., Montreal, Canada, H3A 2B4; CNRS, 91190 Gif sur Yvette, France; Univ. René Descartes, 4, ave. de l'Observatoire, 75270 Paris, France.

The distribution of delta opioid receptors, selectively labeled in vitro with the photoaffinity probe ^{125}I-azido-DTLET was analyzed by electron microscopic radioautography (EM RAG) in sections of rat neostriatum. Glutaraldehyde-prefixed vibratome-cut striatal slices were incubated with 0.7 nM ^{125}I-azido-DTLET, irradiated with a single U.V. flash, postfixed in aldehydes and OsO_4, dehydrated in ethanols, embedded in Epon and thin-sectioned for EM RAG processing. Between 25 and 30% of the bound radioactivity, 75% of which corresponded to specific binding, was retained in tissue after histological processing. Fifty percent probability circle analysis of EM radioautographs revealed that a significant proportion of the specifically bound ^{125}I-azido-DTLET molecules was intraneuronal. Specifically, 16% of the labeled binding sites were found in dendrites, 12% in perikarya and 4% in axon terminals. The remaining binding sites were associated with axo/dendritic (20%), dendro/dendritic (7.0%) and axo/axonic (4%) interfaces. Only a small proportion (≈ 1.0%), however, was found at the level of synaptic specializations. These results suggest that endogenous as well as exogenous delta ligands primarily act non-junctionally on the plasma membrane of dendrites in the neostriatum. Supported by MRC.

145.17

CHANGES IN OPIOID (OP), NEUROTENSIN (NT) RECEPTOR DENSITY AND NEUTRAL ENDOPEPTIDASE (NEP) IN PARKINSON AND HUNTINGTON BRAINS. W.H. Rostène, A. Dubois*, J.M. Zajac, F. Agid*, P. Kitabgi and B.P. Roques. INSERM U.55, 266, 289 Paris, LERS Bagneux and CNRS Nice, France.

Several data suggest a functional relation between OP, NT systems and the dopaminergic (DA) nigrostriatal neurons (NS). In order to determine the effects of the degeneration of the NS on OP and NT receptors, sections of human basal ganglia and mesencephalon obtained from postmortem control, Parkinson (PK) and Huntington (HU) brains were incubated with ligands specific for mu (3HDAGO), delta (3HDETLET), kappa (3HEKC) receptors as well as for NEP (3HHACBO-Gly) and NT receptors (125I-NT). Films were then processed for computerized quantitative autoradiography. In the substantia nigra from controls, high densities of Kappa, NEP and NT binding sites were observed. In PK, no change in OP receptors was detected whereas NT binding site densities decreased by 50%. In HU, a decrease in both NEP and NT binding sites was observed. In the basal ganglia high densities in mu, delta, NEP and NT binding sites were found. In PK, OP receptor density was not different from controls whereas a 50% reduction in NT binding sites was observed in the caudate nucleus and putamen. In HU brains, a decrease in all OP binding sites and NEP was noticed with no change in NT receptors. These data suggest a different localization of OP and NT binding sites on the human NS and that NT receptor density represents a good index of the integrity of this DA pathway. (Sup. by Fondation de France and Réseau INSERM).

145.18

CELLULAR LOCALIZATION OF MU OPIOID RECEPTORS IN THE LOCUS COERULEUS OF THE RAT. D. Marcel, P.D. McNeely and A. Beaudet (SPON: B.E. Jones). Neuroanatomy Laboratory, Montreal Neurological Institute, 3801 University Street, Montreal, Quebec, H3A 2B4, Canada.

The cellular localization of radioautographic labeled mu opioid binding sites was investigated in rat locus coeruleus (LC) using a combined immunohistochemical/neurotoxin lesioning approach. In light microscopic radioautographs from sections incubated with the met-enkephalin analog ^{125}I-FK 33-824 (^{125}I-FK), high ^{125}I-FK binding densities were detected throughout the LC. Processing of serial adjacent sections for tyrosine hydroxylase (TH) immunohistochemistry revealed that within the LC, the distribution of ^{125}I-FK-labeled binding sites was in perfect register with that of constituent noradrenalin cells. Moreover, intracerebroventricular injection of the catecholamine neurotoxin, 6-hydroxydopamine, virtually suppressed ^{125}I-FK labeling in the region while concomitantly reducing both the intensity of TH-immunostaining and the number of TH-immunopositive cells. In contrast, intracerebroventricular injection of the serotonin neurotoxin, 5,6-dihydroxytryptamine, did not affect ^{125}I-FK binding in LC, despite a massive decrease in endogenous 5-HT, as recorded locally by HPLC. The present results suggest that within the LC, mu opioid binding sites are mainly associated with the perikarya and dendrites of NA neurons and not with afferent 5-HT axons. These receptors are likely to subserve opioid/noradrenalin interactions documented in LC.

145.19

CROSSLINKING OF κ RECEPTORS IN THE GUINEA PIG CEREBELLUM WITH ^{125}I-DPRO^{10}DYNORPHIN (1-11). Y-H. Yao*, J. Guerain*, J-C. Meunier*, J.M. Hiller*, T.L. Gioannini*, J. Cros*, and E.J. Simon. (SPON: O. Keren). Depts. of Psychiatry and Pharmacology, NYU Medical Center, New York, NY 10016 and Laboratoire de Pharmacologie et Toxicologie Fondamentales, CNRS, 31077 Toulouse, CEDEX, France.

DPro^{10}dynorphin (1-11) (DProDyn) was radioiodinated and used as a crosslinking probe to determine the size and number of κ binding proteins present in the guinea pig cerebellum, a tissue with a preponderance (>80%) of κ receptors. Dissociation constant and binding capacity for the binding of the iodinated peptide were found to be 0.31±0.02nM and 141±15 fmol/mg protein, respectively, in good agreement with previous results in guinea pig brain. Competition studies indicated displacement of ^{125}I-DProDyn by unlabeled DProDyn, bremazocine and U50,488, with IC_{50}'s of 0.18, 0.25, and 20nM, respectively. DPDPE did not compete and DAGO was effective only at very high concentrations (IC_{50} of 2.8 μM). When guinea pig cerebellar membranes were bound with labeled ligand, washed and crosslinked with BSCOES, SDS-PAGE followed by autoradiography revealed two major bands of apparent mol. wts. of 55 and 35kDa. Only the 55kDa band was completely eliminated when binding was carried out in the presence of U50,488, DProDyn or naloxone. The 35kDa band was decreased in intensity by these competing ligands but not eliminated. The 55kDa band was unaffected by DPDPE and only slightly reduced by high concentrations of DAGO. We therefore conclude that the major κ binding protein in guinea pig cerebellum has an apparent mol.wt. on SDS-PAGE under reducing conditions (100mM DTT) of 55kDa. (Supported by grant DA-00017 to EJS from the National Institute on Drug Abuse).

145.20

LOCALIZATION OF OPIATE RECEPTOR SUBTYPES IN THE FOREBRAIN OF THE MARMOSET. L.S. Brady, E. Johnson McClure* and M. Herkenham. Unit on Functional Neuroanatomy, Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892.

The common marmoset, *Callithrix jacchus jacchus*, is a small new world primate. In fresh-frozen sections from adult males, μ and δ receptors were labeled with [3H]D-ala2, N-me-phe4, gly5-ol-enkephalin or [3H]D-ala2, D-leu5-enkephalin, respectively. κ Receptors were labeled with [3H]bremazocine (BRM) or [3H]U-69,593 (U-69). Dense μ binding was found in the supraoptic and paraventricular nuclei, median eminence and medial thalamus, moderate binding in the ventrobasal hypothalamus, bed nucleus of the stria terminalis and basal amygdala and low binding in the striatum, hippocampus and cortex. Dense δ binding was seen in the striatum, dentate gyrus molecular layer and homogeneously throughout the amygdala and cortex. Dense κ binding (BRM) was present in the supraoptic and paraventricular nuclei, median eminence, medial thalamus, cortical layer VI and claustrum, moderate binding in the striatum, globus pallidus and basal amygdala and low binding in the hippocampus. In contrast, κ receptors labeled by U-69 were dense only in the median eminence, cortical layer VI, globus pallidus and claustrum. The localization of dense μ and κ (BRM) binding in the hypothalamus is consistent with effects of opiate antagonists on neuroendocrine function. δ Binding is localized in large areas of cortex and striatum, suggesting a ubiquitous role in higher functions. U-69 labels a subset of structures showing dense BRM binding; most of these structures are μ receptor poor. Thus, each opiate receptor subtype shows distinct distributions in the marmoset forebrain, similar to patterns seen in rhesus and squirrel monkey brains.

146.1

LOCALIZATION OF ATRIAL AND BRAIN NATRIURETIC PEPTIDES IN THE RAT BRAIN. H.R. Holmes, K.M. Hurley, and C.B. Saper. Depts. of Pharm. & Physiol. Sci. and Neurology, Univ. of Chicago, Chicago, IL 60637

Brain natriuretic peptide (BNP) is a recently discovered peptide hormone isolated from porcine brain that has biological activities similar to atrial natriuretic peptide (ANP). We have used immunohistochemistry to examine the localization of BNP-like immunoreactivity (BNPir) in the rat brain. BNPir innervation tends to avoid areas, such as the anteroventral periventricular nucleus, that contain large numbers of ANPir cell bodies. In contrast, BNPir fibers innervate certain structures, such as the subfornical organ and area postrema, that participate in control of water balance and blood pressure, but do not have much ANPir innervation. Other areas of the brain that contain ANP binding sites, but little ANPir innervation, such as the olfactory bulb and cerebellar cortex, receive substantial BNPir input. BNPir cell bodies are found in several areas that contain no ANPir neuronal perikarya, such as the cerebral cortex and both the parasympathetic and sympathetic preganglionic cell groups, in the medulla and spinal cord. Many sensory afferent fibers, in the vagus nerve as well as trigeminal and spinal sensory roots, are also BNPir. None of these structures are ANPir. BNPir is more widely distributed in the brain than ANPir. However, the two peptides appear to belong to a family of neuromodulators that is involved in the regulation of blood pressure and fluid volume at a central nervous system level.

HRH is a Chicago Heart Assoc. Senior Research Fellow.

146.2

COMPARATIVE ONTOGENY OF CALCITONIN GENE-RELATED PEPTIDE AND SUBSTANCE P IN THE RAT SPINAL CORD. D. Gledic*, H. Gilbertson* and S. Jeftinija (SPON: R. Bowman). Dept. Vet. Anatomy, Iowa State University, Ames, IA 50011.

Substance P (SP) and calcitonin gene-related peptide (CGRP) immunoreactivities (IR) have been shown to be present in the dorsal root ganglion (DRG), dorsal horn (DH) and ventral horn (VH) of the adult rat spinal cord. In addition, SP and CGRP are co-localized in some DRG neurons and primary afferents. Although the ontogeny of SP-IR in the rat spinal cord has been studied (Senba, et al., 1982, J. Comp. Neurol. 208:54-66), very little is known about the development of CGRP-IR in the spinal cord. To provide additional information about the development of CGRP system and the interaction between SP and CGRP, the first appearance and distribution of SP and CGRP-IR at all levels of the rat spinal cord from gestational day 14 (E14) to postnatal day 25 (P25) have been systematically investigated. SP-IR was first found in cells of the ventral part of the dorsal horn at E16. At the same age CGRP-IR was seen for the first time in cells in the motoneuron region, and was present in those cells from that time on. The first appearance of SP and CGRP-IR in DRG neurons was at day E17. SP-IR fibers in the DH first appeared at E15, and CGRP-IR fibers appeared at E17. CGRP-IR was present in motoneurons at all ages examined. No CGRP-IR was seen in DH interneurons. SP positive interneurons in the dorsal horn disappeared at birth. Supported by DHHS/NIH Grant 2 SO7RR07034 and USDA PL95-113, section 1433.

146.3

COEXISTENCE OF PEPTIDES IN PRIMARY AFFERENT NEURONS IN CAT SPINAL CORD. M.G.Garry, L.D.Aimone†, T.L.Yaksh† and V.S.Seybold §. Dept. of Cell Biol. and Neuroanat., § Grad. Program in Neurosci., Univ. of MN, Minneapolis, MN 55455; † Dept of Neurologic Res., Mayo Fnd., Rochester, MN 55905.

It is generally assumed that a substance which is observed in the perikaryon of a neuron will also be localized to the axons of that neuron. In the present study, the peptide immunoreactivity (IR) of the central axonal processes of primary afferent neurons was investigated in the L6 spinal segment of unilaterally ganglionectomized (L4-L7) cats (n=3). Simultaneous visualization of two antigens by immunofluorescence was used to detect peptides. The difference in immunoreactivity between the ganglionectomized and the intact dorsal horns of the spinal cord was attributed to the contribution of primary afferent neurons. Substance P (SP) and calcitonin gene-related peptide (CGRP) coexisted in varicosities within laminae I and II of the dorsal horn on the control side. The proportions of coexistence of SP and CGRP in primary afferent axons were calculated to be similar to those which we observed in colchicine treated L6 dorsal root ganglia (DRG) of cat. Somatostatin (SOM)-IR varicosities were observed primarily within lamina II of the dorsal horn and coexisted minimally with CGRP. The minimal coexistence of SOM and CGRP calculated for primary afferent axons contrasts with our observations in the DRG. Bombesin (BOM)-IR varicosities were observed in moderate density in laminae I and II on the control side and were calculated to arise largely from primary afferent axons. In contrast to the lack of BOM-IR observed in the DRG, these data indicate that BOM-IR may be contained in primary afferent axons. Furthermore, BOM-IR coexisted with SOM-IR in varicosities within lamina II. In summary, these data suggest: a) the coexistence of some peptides in varicosities of primary afferent neurons within the dorsal horn of cat do not parallel the patterns of coexistence observed in the DRG; and b) BOM-IR is present in varicosities of primary afferent neurons but occurs in a form or concentration undetectable by immunohistochemistry in the L6 DRG of the cat. This work is supported by USPHS grants NS 17702 and T32 DA 07234.

THE VIP IMMUNOREACTIVITY IN THE NORMAL AND ISOLATED RAT LUMBOSACRAL SPINAL CORD. K. Chung and W.T. Lee*. Dept. of Anat. and Neurosci. and the Marine Biomed. Inst., Univ. of Tex. Med. Br., Galveston, TX 77550.

Previous studies on vasoactive intestinal polypeptide (VIP) in the mammalian spinal cord indicate that VIP is located in neurons; either in dorsal root ganglion cells or in neurons within the spinal cord. There is, however, a brief mention of an occasional extremely dense VIP immunoreactivity within the ependymal cell layer. The present study extended the VIP distribution in normal and isolated rat lumbosacral spinal cord by an immunohistochemical method. The most prominent VIP immunoreactivity in normal rat spinal cord was found in ependymal and subependymal cells and their processes. The basal processes of ependymal and subependymal cells project to pia mater or capillaries in the spinal gray matter. Sparse VIP fibers and terminals were localized in the marginal zone and lamina II of dorsal horn and the central gray matter. The VIP immunoreactivity in isolated spinal cord was increased dramatically in lamina II. In addition, many VIP-immunoreactive neurons were found in all areas of spinal gray matter. VIP neurons can be divided into three groups based on the morphology of their somata: small bipolar; medium bipolar; and medium multipolar neurons. This study is supported by grants from the National Institues of Health NS11255, the Muscular Dystrophy Association, the Marie Hall Endowment and Bristol-Meyers.

SUBSTANCE P- AND CGRP-IMMUNOREACTIVE NERVE FIBRES IN LYMPH NODES RELATED TO THE LOWER RESPIRATORY TRACT OF THE GUINEA PIG. Ch. Heym*, W. Kummer* and R. Kurkowski*. Dept. of Anatomy, University of Heidelberg, D-6900 Heidelberg, FRG.

The presence of substance P-receptors on T-lymphocytes (Payon, DG. et al., J. Clin. Invest.,74:1532,1984) and the biochemical characterization of authentic substance P in lymphatic tissue (Gepetti, P. et al., Reg. Pept.,18:321, 1987) prompted us to investigate the distribution of substance P and its common cotransmitter CGRP in lymph nodes of the guinea pig lower respiratory tract.

Double labelling experiments revealed colocalization of substance P and CGRP in virtually all intranodal nerve fibres. Immunoreactive (IR) fibres were present in varicose nerve fibres in the capsule, in the medulla and in the paracortical zone. Medullary fibres predominated in the hilus and preferentially were located in close contact with blood vessels. No substance P- or CGRP-IR nerve fibres were visible in follicles. Ultrastructurally, varicosities of unmyelinated substance P-IR fibres in addition to small clear vesicles contained few large dense core vesicles.

In view of the characteristic peptide combination a sensory origin of the observed substance P-/CGRP-IR fibres is suggested. This assumption is in line with the loss of extractable substance P-IR from rat thymus following capsaicin administration (Gepetti, P. et al., Reg. Pept., 18:321,1987). (SPON: R.H. Whitworth, Jr.)

INTERACTIONS BETWEEN CHEMICALLY IDENTIFIED NERVE FIBERS AND NEURONS IN FEMALE RAT PARACERVICAL GANGLIA. R.E.Papka and H.H.Traurig, Dept. Anat.& Neurobiol., Univ. KY., Lexington, KY 40536

Some neurons of the paracervical ganglia(PG) project to reproductive organs, sensory fibers traverse the PG and send collaterals to principal neurons, and there are other terminals, probably efferent, in the PG. The present study examines the circuitry of the PG to determine if there is specific chemical coding between identified nerve terminals and principal neurons. We used [a] adjacent cryostat sections; one immunostained for a nerve fiber marker and one immunostained for a cell body marker and [b] the immunostaining(for a cell body marker), elution, reimmunostaining(for a terminal marker) method of Tramu et al. on single cryostat sections. Overlap of staining was compared. Cell body markers were acetylcholinesterase(ACHE), tyrosine hydroxylase(TH), neuropeptide Y(NPY) and vasoactive intestinal peptide(VIP). Nerve terminal markers were substance P(SP), neurokinin A (NKA), calcitonin gene-related peptide(CGRP), cholecystokinin(CCK-8), enkephalin(ENK) and atrial natriuretic factor(ANF). To date, it appears that most cell bodies receive input from nearly all types of terminals, but in different proportions. (Supported by NIH Grant NS-22526).

SEGMENTAL ORIGINS AND POSSIBLE VASCULAR DESTINATION OF PEPTIDE CONTAINING SENSORY FIBERS IN BULLFROG SYMPATHETIC GANGLIA. J. P. Horn and W.D. Stofer Dept. of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Paravertebral sympathetic ganglia 9 & 10 of the bullfrog contain sensory fibers that are immunoreactive for substance P(Sub P) and calcitonin gene-related peptide(CGRP) [*Soc. Neurosci.Abstr.*, 13:297, 1987]. We now report experiments to establish quantitatively the segmental origins of these sensory neurons and to test the hypothesis that some of these fibers innervate blood vessels.

In 3 frogs, the sympathetic chain was cut at the level of ganglion 9 and exposed to 1% fast blue. After survival times of 12 to 28 days, the dorsal root ganglia were removed and serially sectioned. Retrograde transport of the dye labeled an average of 313±168(s.d.) sensory neurons in DRGs 4-8. Counts were corrected for split cells. The distribution of labeled cell profiles, expressed as a percent of total labeled profiles in each animal, was: DRG4: 5±1%, DRG5: 9±1%, DRG6: 19±3%, DRG7: 29±12%, DRG8: 38±15%.

To estimate the percentage of sensory neurons which project to sympathetic ganglia 9 & 10 and contain immunoreactivity for Sub P and CGRP, 2 other frogs were similarly labeled with fast blue and 119 sections from DRGs 4-8 were double labeled with a rabbit anti-CGRP serum and a rat anti-Sub P antibody. Cells containing fast blue were then scored for immunofluorescence. Of 735 dye-labeled cell profiles, 80% contained both Sub P and CGRP-like immunoreactivities, 7% contained only Sub P-IR, 4% contained only CGRP-IR and 9% contained no immunoreactivity. This pattern of staining was seen at all segmental levels.

One target that is functionally innervated by C neurons in sympathetic ganglia 9 & 10 is the descending aorta[*Neurosci.*, 22:S336, 1987]. Axons from these ganglia enter the aorta directly by way of small postganglionic rami communicantes. We therefore examined double labeled sections of rami and aorta to look for sensory fibers. Indeed both structures contained many axons that were positive for Sub P and CGRP-IR. Supported by NIH grant NS21065.

A RARE CLASS OF BULLFROG SYMPATHETIC NEURONS THAT ARE ENCRUSTED WITH SUBSTANCE P CONTAINING SYNAPTIC BOUTONS. W.D. Stofer and J. P. Horn Dept. of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Paravertebral sympathetic ganglia of the bullfrog contain a rich plexus of fibers that are immunoreactive for substance P(Sub P). Previous studies demonstrate that these fibers are of sensory origin and that most of them also contain calcitonin gene related peptide-like immunoreactivity(CGRP-IR). When examined at the light level, these fibers have not been found to make obvious synaptic contacts with postganglionic sympathetic neurons.

We now report a rare class of sympathetic neurons in paravertebral ganglia 2, 9 and 10 that are contacted by substance P containing synaptic boutons. The postganglionic neurons contacted by such fibers tend to have relatively large cell bodies and are heavily invested with immunoreactive boutons on the soma and axon hillock. In order to estimate the number of such cells and to identify them, ganglia 9 and 10 were serially sectioned at 10 μM and every other section was double labeled with antibodies to Sub P and neuropeptide Y(NPY). In 2 animals, we found a total of 68 neurons covered with Sub P containing boutons. None of these neurons contained NPY-IR. Given that NPY-IR is a marker for C cells and that B cells tend to be larger than C cells, it appears most likely that the contacted cells are a subset of sympathetic B neurons. When the adjacent serial sections were double labeled for Sub P and CGRP-IR, we found that all Sub P containing boutons on ganglion cell bodies were also positive for CGRP-IR. In another abstract at this meeting, we report that 80% of the sensory neurons projecting to ganglia 9 & 10 contain both Sub P and CGRP-IR. Since neurons containing both of these peptides are not present in the intermediolateral cell column of the spinal cord, we conclude that the ganglionic fibers containing Sub P and CGRP-IR are of sensory origin and that such fibers make morphologically recognizable synaptic contact with approximately 1% of the sympathetic B neurons in ganglia 9 and 10.

This work was supported by NIH grant NS21065.

ELECTRON MICROSCOPIC EXAMINATION OF VASOACTIVE INTESTINAL POLYPEPTIDE IN THE BABOON LUMBOSACRAL SPINAL CORD. A. Brady*, W.C. de Groat and I. Nadelhaft. VA Medical Center and Depts. of Neurol. Surgery, Pharmacol. and Behav. Neurosci., University of Pittsburgh, Pittsburgh, PA 15261.

Light microscopic studies of the distribution of vasoactive intestinal polypeptide (VIP) in the sacral spinal cord of rhesus monkeys and of humans demonstrated thick linear deposits of reaction product (2-16 microns diameter) that were interpreted as axonal bundles. These bundles were concentrated in Lissauer's tract (LT) but were also seen in parts of the gray matter. Similar studies in cats and rats revealed reaction product only in what appeared to be single axons. We studied the characteristics of VIP axonal bundles in LT of the baboon sacral spinal cord using immunohistochemical techniques at the electron microscopic level. VIP reaction was found in unmyelinated fibers in Lissauer's tract but was never detected in myelinated fibers. The VIP fibers were located within bundles together with fibers which were unlabelled. The reaction product was contained in synaptic vesicles measuring approximately 1200 angstroms in diameter and in much smaller "particles" whose boundaries were not well defined. Round profiles of about the same size were devoid of reaction product. It is concluded that VIP axonal bundles in LT of primate spinal cord are heterogeneous structures containing VIP and non-VIP axons.

SOMATOSTATIN (SS) AND NEUROPEPTIDE Y (NPY) CONTENT OF SUPERIOR CERVICAL GANGLION NEURONS PROJECTING TO THE SUBMANDIBULAR GLAND AND IRIS. L.L. Wright and J. Luebke. Dept. Anatomy, BUSM, Boston, MA 02118

The present study was done to determine whether postganglionic neurons of the rat superior cervical ganglion (SCG) that project to the submandibular gland (SMG) or iris differentially contain SS-like immunoreactivity (ir) and NPYir. Six adult male Sprague Dawley rats were anesthetized and injected bilaterally with the retrograde tracer fluorogold into the anterior chamber of the eye or the SMG. One week following injection, SCGs were removed and frozen sections of the SCGs were processed for immunocytochemical localization of SSir and NPYir using the Vector ABC-glucose oxidase technique. Control sections incubated in the absence of primary or secondary antiserum showed no immunoreactivity. Sections were examined and photographed with fluorescence microscopy to demonstrate the fluorogold, then brightfield exposures of the same fields were taken to demonstrate the presence of single and double labelled neurons. The figures below represent the percentage of fluorogold labelled neurons that displayed immunoreactivity.

IRIS:SS	IRIS:NPY	SMG:SS	SMG:NPY

PEPTIDERGIC INNERVATION OF THE MAMMARY GLAND. M. Eriksson, T. Hökfelt and K. Uvnäs-Moberg. Depts. of Pharmacology and Histology, Karolinska Institutet, S-104 01 Stockholm, Sweden.

The blood flow in mammary tissue and the tone of smooth muscle around the milk ducts are factors of importance for milk secretion and milk ejection. How the vascular and non-vascular smooth muscle in this region is regulated is not fully known. In the present study the distribution of regulatory peptides is demonstrated in the mammary gland with help of immunohistochemical techniques. Calcitonin gene-related peptide (CGRP) and substance P immunoreactivity were localized within and beneath epidermis, around blood vessels and in the smooth muscle of the milk ducts. These two peptides have been associated with sensory information from the periphery as well as with dilatation of vessels and contraction of smooth muscle. Vasoactive intestinal peptide (VIP) immunoreactivity was found in fibers around vessels and in smooth muscle. VIP is related to relaxation of vascular and non-vascular smooth muscle. Neuropeptide Y (NPY) is a peptide associated to sympathetic nerve fibers and is known for its contraction of vascular and non-vascular smooth muscle. NPY was localized around the vessels and in the smooth muscle of the mammary tissue.

Conclusion. Oxytocin and prolactin are known to stimulate milk secretion and milk production. Demonstration of regulatory peptides in the mammary gland indicates that local mechanisms may contribute to the control of milk secretion.

LOCALIZATION OF VASOACTIVE INTESTINAL PEPTIDE (VIP)- AND PEPTIDE HISTIDINE ISOLEUCINE AMIDE (PHI)-LIKE IMMUNOREACTIVITIES (IR) IN PREGANGLIONIC NEURONS THAT PROJECT TO THE RAT SUPERIOR CERVICAL GANGLION (SCG). C. Baldwin, C. A. Sasek and R. E. Zigmond, Dept. of Biol. Chem. & Mol. Pharm., Harvard Med. Sch., Boston, MA 02115

The rat SCG has been shown to contain both VIP- and PHI-IR cells and fibers. These peptide-IR were shown to accumulate on the spinal cord side of a ligature of the preganglionic cervical sympathetic trunk (CST) of the SCG. Sections of spinal cord segments T1 -T3, immunostained for VIP and PHI, showed some IR cells in the intermediolateral (IML) nucleus (Soc. Neurosci. Abst. 13:1337, '87).

The present study shows 1) the localization and distribution of VIP- and PHI-IR cells and fibers in spinal cord segments T1 - T3 of colchicine-treated rats, 2) the distribution of preganglionic cells retrogradely labeled with fluorogold (FG) from the CST and 3) the colocalization of VIP- and PHI-IR cells with FG-labeled cells.

Both VIP- and PHI-IR cells were found (in descending order of frequency) in the lateral spinal nucleus of the dorsal lateral funiculus, lamina 7 (L7), nucleus proprius, substantia gelatinosa, IML, and the central autonomic region. The IML region contained about 70% of the neurons that had been retrogradely labeled with FG. One in four IML regions examined (20 μm sections) contained, on the average, one VIP- or PHI-IR cell. Of these peptide-IR cells, at least 10 % were also labeled with FG. VIP- and PHI-IR fibers were found throughout the regions examined but were most dense in the IML and L7 regions. In the IML, peptide-IR fibers were often seen apposed to FG labeled cells. PHI-IR fibers always appeared at a greater density than VIP-IR fibers, though their distributions were similar.

These studies support the hypothesis that VIP- and PHI-like peptides are localized in preganglionic neurons that project to the rat SCG and, thus, may function as neurotransmitters in that ganglion. (NS12651 and MH00162)

CALCITONIN GENE-RELATED PEPTIDE-LIKE IMMUNOREACTIVE (CGRP-LI) NERVES IN THE CORNEAS OF NEWBORN AND ADULT RATS. C. F. Marfurt, M. Jones* and D. F. Turner. Northwest Ctr. for Med. Educ., Indiana Univ. Sch. Med., Gary, IN (CFM & MJ), and Dept. Oral Biol., Univ. Mich. Sch. Dent., Ann Arbor, MI (DFT).

The density and distribution of CGRP-LI nerves were examined in corneas of newborn (1-12 days old) and young adult (2 months old) rats. Corneas were immersion-fixed and processed as whole mounts (neonates) or serially sectioned in a cryostat (adults) and then processed for CGRP immunoreactivity according to the avidin-biotin procedure. On day 1, a dense plexus of CGRP-LI nerve fibers was already present within the cornea and formed a complicated network of anastomosing branches that appeared to distribute relatively uniformly throughout both peripheral and central regions of the cornea. Modest numbers of labeled fibers were present also within the limbus, where they were found associated with blood vessels or free within the stroma. Intraepithelial nerves were not convincingly demonstrated at this stage of development; additional studies of sectioned material are underway to confirm this observation. By day 5, the preterminal and terminal regions of the CGRP-LI nerve fibers in the paracentral regions of the corneal stroma increased in branching complexity, and by day 12 terminal axons in the central half of the cornea were organized in parallel arrays of short, radially directed fibers (precursors of subepithelial leashes) beneath the epithelium. In the adult corneas, parallel leashes of multiple, beaded axons were abundant in the superficial stroma and basal epithelium of the central cornea and were present in lesser numbers in the peripheral cornea. Intraepithelial branches arose from the leashes and coursed obliquely or vertically into the more superficial cell layers. In conclusion, the results of this study have shown that a very high percentage of rat corneal nerves contain CGRP-LI at all postnatal stages of development. We hypothesize that these fibers, in addition to playing roles in corneal sensation, may also subserve important efferent functions related to corneal trophism, metabolism, and, perhaps, wound healing.

146.14

AN IMMUNOHISTOCHEMICAL AND BIOCHEMICAL ANALYSIS OF SEROTONIN (5HT) AND SUBSTANCE P (SP) COLOCALIZATION IN NUCLEUS TRACTUS SOLITARIUS (NTS)-AFFERENT PROJECTIONS IN RAT. K.B. Thor, K. Hill*, C. Harrod*, C. Helke. Uniformed Services Univ., Bethesda, MD 20814.

5HT- and SP-immunofluorescent (IF) terminals have been identified in the NTS. The current study determines the colocalization of 5HT and SP in these terminals and in NTS-afferent neurons. Dual-color IF studies, using FITC- and RITC-labelled secondary antisera, showed that a small proportion of the IF terminals in medial portions of the NTS at all rostrocaudal levels contain both transmitters; the majority of the terminals were singly-IF. The density of doubly-IF terminals in the medial NTS were similar to that seen in the ventral horn (VH) of the spinal cord. However, because of the higher density of terminals in the NTS that were IF for only 5HT or SP, the proportion of doubly- to singly-IF terminals was less in the NTS than in the VH. Micropunch dissection and radioimmunoassay showed that i.c.v. administration of 5,7 dihydroxytryptamine, which destroyed serotonergic terminals (88% decrease in 5HT levels), caused nonsignificant decreases in SP content at caudal and intermediate levels of the NTS but a 45% decrease ($p<0.05$) at rostral levels. Retrograde labelling of NTS-afferent neurons with rhodamine beads (RBs), combined with dual-color IF (using FITC- and AMCA- [amino-4-methyl coumarin acetate-] labelled secondary antisera) in colchicine-treated rats (n=4), showed that the following numbers of NTS-afferent neurons were: 1) not IF; 2) only 5HT-IF; 3) only SP-IF; or 4) 5HT- and SP-IF. The percentage of each type of cell in each area is in parenthesis.

AREA	1	2	3	4
N. Raphe Pallidus	71(47%)	11(7%)	13(9%)	56(37%)
N. Raphe Obscurus	95(62%)	20(13%)	7(5%)	31(20%)
Paraolivary N.	93(61%)	10(7%)	8(5%)	41(27%)
N. Raphe Magnus	339(74%)	50(11%)	9(2%)	63(14%)

These studies indicate that NTS-afferent neurons in the raphe nuclei that are IF for 5HT usually, but not always, are also SP-IF, and vice-versa. However, most SP in the NTS arises from non-5HT neurons.

146.15

Mediation of changes in VAS mRNA to hypophysis (HY), medullary vagal complex (MVC) and thoracic spinal cord (SC). S.Pretel and D.Piekut. University of Rochester, School of Medicine and Dentistry. The Neuroendocrine Unit.

Neurons of the hypothalamus are involved in mediating autonomic responses of HY, MVC and SC. Periventricular hypothalamic (PVH) neurons containing vasopressin (VAS) respond readily to changes in osmolality produced by substitution of drinkung water with 2% NaCl/water. It is hypothesized that information about these changes might be transmitted to autonomic centers outside the hypothalamus. This was examined by combining in situ hybridization (ISH) of a synthetic oligonucleotide probe to VAS* (Young et al.1986) with retrograde tracer labeling.

Salt loaded (7-18days) and control rats received .5-1µl injections of either fluorogold or rhodamine latex microspheres into the HY, MVC or SC (T1-3). After 3-8days survival time, the anaesthetized animals were perfused with 0.1M phosphate buffer (PO4), 4% paraformaldehyde and 20% sucrose in PO4. Brain, HY and SC were removed, briefly postfixed in 4% paraformaldehyde/ sucrose PO4, cryoprotected in 30% sucrose/PO4 and frozen in liquid nitrogen. The VAS probe, labeled with ^{35}S - deoxy ATPand terminal deoxynucleotidyl transferase, was applied to 10µ cryostat sections. After 5 days exposure with NTB2 solution, the slides were developed for autoradiography, fixed, counterstained with neutral red and coverslipped.

The tracer injections resulted in typical neuronal labeling of the PVH and supraoptic nuclei. Increased duration of NaCl intake resulted in increased amounts of VASprobe labeling, expressed by density of labeling in individual neurons and a slight increase in number of labeled neurons in the medial parvocellular (mp) area. Neurons containing VASprobe and projecting to HY, MVC or SC were seen consistantly in control and experimental animals. They were present in magnocellular and mp nuclei. In experimental animals, some projection neurons showed increased levels of VAS probe. These data suggest that changes in VAS mRNA due to changes in osmolality might be transmitted not only to the HY, but also to MVC and SC.

TRANSIENT APPEARANCE OF SOMATOSTATIN AND ITS COEXISTENCE WITH CGRP IN NEONATAL RAT HYPOGLOSSAL NUCLEUS. K.B. Seroogy, D.E. Millhorn and T. Hökfelt*. Dept. of Physiology, Univ. of N. Carolina, Chapel Hill, NC, 27599 and Karolinska Institute, Stockholm, Sweden.

The developmental appearance of SOM and CGRP immunoreactivities (I) in the neonatal rat hypoglossal nucleus (12N) was examined by using a double-labeling colocalization technique. At postnatal day (P) 0, high numbers of SOM-I perikarya were observed mainly in caudal aspects of 12N. CGRP-I somata were situated throughout the rostrocaudal extent of this sturcture except at extreme caudal levels. When present in the same sections, both peptide immunoreactivities exhibited a high degree of colocalization. At P7, few to moderate numbers of SOM-I cells were found as well as a corresponding reduction in the incidence of SOM/CGRP-I coexistence. By P14, only rare SOM-I perikarya were observed and by P29, SOM-I somata were no longer detected. CGRP-I neurons, on the other hand, were present throughout development. These data demonstrate that SOM is transiently expressed in cell bodies of the hypoglossal nucleus in the neonatal rat, and, when present, often coexists with CGRP. We are currently using in situ hybridization techniques to determine whether the developmental disappearance of the perikaryal SOM-I is due to changes at the level of transcription or translation. (HL 33831, SMRC 04X-2887, NATO Fellowship).

146.17

LOCALIZATION OF CALCITONIN GENE-RELATED PEPTIDE IN THE CARDIAC GANGLION OF THE FROG. Q. Chen and H.B. Peng (SPON:E.J. Elliott). Dept. of Cell Biology & Anatomy, Univ. of North Carolina, Chapel Hill, NC 27599.

Calcitonin gene-related peptide (CGRP) has been localized in the motoneuron terminals at the neuromuscular junction in skeletal muscle. Since the parasympathetic postganglionic neurons in the cardiac ganglion receive nicotinic inputs from the vagus nerve, it is of interest to know whether this peptide is also present in the nerve terminals. The interatrial septa were dissected from the frog (Rana pipiens). After fixation and permeabilization, they were double-labeled with a polyclonal antibody against human CGRP and a monoclonal antibody (SV48) against the 65kD protein on synaptic vesicles. By double immunofluorescence technique, the distribution of CGRP immunoreactivity was examined in relationship to the presynaptic boutons (identified by SV48 staining) on the postganglionic neurons. We found that all of the boutons were positive in CGRP immunoreactivity. In addition to the boutons, the CGRP antibody also stained a set of nerve fibers within the vagosympathetic trunks. The staining was abolished by preabsorbing the antibody with 2.6nM synthetic human CGRP. In contrast to the nicotinic boutons on the neurons, the muscarinic varicosities on atrial muscle fibers, identified by SV48 staining, were negative in CGRP immunoreactivity.

146.18

ULTRASTRUCTURAL EVIDENCE FOR COEXISTENCE OF CALCITONIN GENE-RELATED PEPTIDE (CGRP), TACHYKININ AND SOMATOSTATIN IMMUNOREACTIVITY IN PRIMARY SENSORY NEURONES AND IN FIBRES OF THE DORSAL HORN OF RAT. A. Merighi[1,2*], S.J. Gibson[1*], G. Fumagalli[2*], K. Valentino[3*] and J.M. Polak[1], (SPON: J. Wharton). [1]Dept. Histochemistry, Royal Postgraduate Medical School, London W12 ONN, U.K., [2]Dept. Veterinary Morphophysiology, Turin, Italy, [3]Dept. Psychiatry and Behavioural Sciences, Stanford University, CA, USA.

Rat dorsal root ganglia and dorsal horn were immunostained using immunogold techniques on Lowicryl K4M embedded material or ultrathin frozen sections. In the dorsal root ganglia peptide-immunoreactivities were consistently found in large (60-100nm diameter) electron dense vesicles in cell bodies and intraganglionic regions of axons. A number of vesicles were double-labelled. In particular colocalisation of CGRP + tachykinins, CGRP + somatostatin and tachykinins + somatostatin immunoreactivities was observed. In the dorsal horn peptide immunoreactivities were also localised to the large, dense-core secretory vesicles in fibre varicosities and terminals. Most large vesicles were double-labelled with different combinations of peptide antisera used in this study. Although primary afferent fibres do not represent the sole origin of peptide immunoreactivity in the dorsal horn, at least a proportion of the fibres are derived from primary sensory neurones. The data suggest that a number of peptides are co-stored in the same secretory vesicles in cell bodies of primary sensory neurones and transported to the central terminals. This provides possible support for co-release of peptides from terminals in the spinal cord.

146.19

CALCITONIN GENE-RELATED PEPTIDE (CGRP)- AND SUBSTANCE P-IMMUNOREACTIVE SENSORY NEURONES AND CGRP-IMMUNONOREACTIVE MOTONEURONES CONTRIBUTE TO THE AFFERENT AND EFFERENT INNERVATION OF CREMASTER MUSCLE AND SCROTAL SKIN

Kar S.,* Gibson S.J.,* Polak J.M., Dept. Histochemistry, Royal Postgraduate Medical School, London W12 ONN, U.K.

The genitofemoral nerve projects to the cremaster muscle and scrotal skin. These tissues play a part in thermoregulation of the testis. Origins of peptide-containing nerves in the cremaster muscle and scrotal skin of the rat were investigated using retrograde tracers (True blue or Fluoro-gold) in combination with immunocytochemistry. Dorsal root ganglion cells and motoneurones of spinal segmental levels L1/L2 were ipsilaterally labelled after unilateral genitofemoral nerve injection. In the ganglia, labelled cells were immunoreactive for CGRP (8%) and substance P (5%). Somatostatin-immunoreactive cells, although present, were not retrogradely labelled. In the spinal cord a number of labelled motoneurones were CGRP positive. Genitofemoral nerve section induced a loss of CGRP and substance P positive fibres in the muscle and skin. Neonatal capsaicin treatment resulted in a similar loss of immunoreactivity but in cremaster muscle some CGRP positive fibres remained, confirming a dual, sensory and motor origin for CGRP. Vasodilation in scrotal skin, mediated by release of CGRP and substance P from sensory nerves and contraction of cremaster muscle by CGRP from motor nerves, is consistent with known actions of these peptides. Thus, it is likely that both peptides contribute to temperature regulation of the testis and hence spermatogenesis.

146.20

THE ORIGIN OF CGRP TO THE DORSAL HORN IN THE RAT LUMBAR SPINAL CORD. W.T. Lee*, K. Chung and S.M. Carlton (SPON: R.B. Leonard). Department of Anatomy and Neurosciences and the Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

Immunohistochemical studies indicate that calcitonin gene-related peptide (CGRP) is found in a large subpopulation of small to medium sized dorsal root ganglion cells. Consequently, the possibility of using CGRP as a primary marker was suggested. In the present study, the origin of calcitonin gene-related peptide (CGRP) to the dorsal horn in the rat lumbar spinal cord is investigated. CGRP immunostained fibers and terminals are mapped following unilateral and bilateral dorsal rhizotomies and isolated spinal cord preparations. Unilateral multiple dorsal rhizotomies result in a drastic decrease in CGRP stained terminals on the operated side. Following bilateral dorsal rhizotomies and isolated cord preparations, very few CGRP stained profiles can be seen in the dorsal horn. The numbers of CGRP immunostained varicosities observed in the latter two preparations were not significantly different, suggesting that few if any axons descending from the brain contribute to the CGRP terminal population in the spinal cord dorsal horn. Supported by a grant from the National Institutes of Health, NS11255, the Muscular Dystrophy Association, the Marie Hall Endowment and Bristol-Meyers.

EVIDENCE FOR A Cl^- CONDUCTANCE IN CHICK RETINAL PIGMENT EPITHELIUM THAT MAY CONTRIBUTE TO RESPONSES ORIGINATING AT THE BASAL MEMBRANE. Ron P. Gallemore* and Roy H. Steinberg, Depts. of Physiology and Ophthalmology, UCSF, San Francisco, CA 94143.

While little is known about the transport properties of the retinal pigment epithelium (RPE) basal membrane, mechanisms for anion movement across the basal membrane appear to be present (Hughes *et al.*, 1984). To alter anion movement, we added the anion transport blocker DIDS to the choroidal bath of a chick retina-RPE-choroid preparation. Previously, we found that DIDS hyperpolarized the basal membrane and increased its resistance (Gallemore and Steinberg, 1987). In the present study, we found that a^i_{Cl} is above equilibrium across both RPE membranes and that DIDS increased a^i_{Cl}. These results are all consistent with blockade of a basal membrane Cl^- conductance. We also studied the effects of DIDS, and similar agents, on responses that originate as depolarizations of the RPE basal membrane: the light peak of the electroretinogram, the response to azide and the response to a retinal hyperosmotic load. The anion transport and Cl^- channel blockers DIDS, SITS, phenylanthanylic acid and thiocyanate each suppressed the light peak. DIDS, the most potent agent, abolished the basal membrane light-peak depolarization. Choroidal azide depolarized the basal membrane and decreased its resistance, as in cat (Linsenmeier and Steinberg, 1987). The basal membrane depolarization, recorded extracellulary as an increase in trans-tissue potential (TTP), was blocked by DIDS. Azide also increased the c-wave and suppressed the light peak. A retinal hyperosmotic load increased the TTP, increased the c-wave and decreased the tissue resistance (Shirao and Steinberg, 1987). DIDS suppressed each of these effects. We conclude that the light peak, the response to azide and the response to a retinal hyperosmotic load may each originate as an increase in a basal membrane anion conductance that may be permeable to Cl^-.

147.2

INTRAOCULAR SYNTHESIS OF SERUM RETINOL BINDING PROTEIN AND TRANSTHYRETIN. **R.L.Martone*, T.Cavallaro*, A. Dwork*, D.S.Goodman*, E.A.Schon* and J.Herbert* (SPON: R. Liem) Depts. of Neurology, Pathology, Psychiatry and Medicine, Columbia Univ., and Dept. of Neurotoxicology and Neuropathology, NY State Psych. Inst., New York, NY 10032.**

As the chromophoric group of the visual pigments, retinol plays an essential role in vision. Several retinoid-binding proteins have been described within the eye and are believed to play a role in the intraocular transport and storage of retinoids.

Retinol-binding protein is the major serum transport protein for retinol. Holo-RBP circulates in the serum in a 1:1 molar complex with transthyretin (TTR, prealbumin). We have detected, by Northern analysis, transcripts for both RBP and TTR in total rat eye RNA. Western blotting confirmed the presence of immunoreactive RBP and TTR in whole eye homogenates. In situ hybridization studies established the retinal pigment epithelium (RPE) as the unique site of synthesis of both TTR and RBP mRNA. However, immunohistochemical studies revealed a widespread but specific distribution of these proteins throughout the eye.

These findings suggest that RBP and TTR are synthesized and secreted locally by the RPE, and participate in the intraocular transport of retinol.

147.3

RETINYL ESTER HYDROLASE ACTIVITY IN THE BOVINE RETINA AND PIGMENT EPITHELIUM. A.T.C. Tsin and D. Malsbury. Division of Life Sciences, The University of Texas at San Antonio, San Antonio, TX 78285.

Retinyl ester hydrolase (REH) activity was studied in tissue homogenates prepared from the bovine neuroretina and retinal pigment epithelium (RPE). Tritiated palmitic acid was used to prepare the substrate (all-trans retinyl palmitate) and the REH assay was carried out according to the method of Blaner et al. (J. biol. Chem., 262: 53, 1987). Within a three hour incubation period, the REH activity increased in proportion to incubation time in both retinal and RPE homogenates. REH activity also increased linearly with protein in the reaction mixture (up to 1.5 mg of retinal or RPE homogenate proteins). The pH optimum for retinal REH was 7-8 whereas in the RPE, the optimum REH activity was observed at pH 5. By varying the substrate concentration and then measuring the formation of the reaction product, we estimated that the apparent K_m of retinal REH to be 20 uM whereas it was only 3.7 uM for REH in the RPE. However, the V_{max} for REH in the retina (101 pmol/mg/hr) was similar to that in the RPE (96 pmol/mg/hr). These results suggest that bovine neuroretina and RPE may possess different REH enzyme(s) to hydrolyze retinyl esters. Supported by grants from the NIH, DOD and the San Antonio Area Foundation.

FORSKOLIN STIMULATES MELATONIN RELEASE FROM Y-79 HUMAN RETINOBLASTOMA CELLS. M.E.Pierce*, J. Harrington*, D.Barker*; and J.S.Takahashi (SPON:B.Pratt). Dept. Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208.

The view is emerging that the circadian synthesis of melatonin plays a key role in the regulation of certain aspects of photoreceptor metabolism including photoreceptor membrane turnover, retinomotor movements, and modulation of neurotransmitter release. Recently, Kyritsis et al. (1987) demonstrated that antibodies to hydroxyindole-O-methyl transferase (HIOMT), the final enzyme in the melatonin synthetic pathway, label Y-79 human retinoblastoma cells. Y-79 cells also express significant HIOMT activity, suggesting that this cell line may provide a model system in which to study the regulation of melatonin biosynthesis. We have used a highly sensitive radioimmunoassay to measure melatonin release from these cells. We report that although basal release from cells grown in static culture is low, the adenylate cyclase activator, forskolin (10 uM), stimulates significant melatonin release. The phosphodiesterase inhibitor, IBMX, also increases melatonin release. Similar results are also observed in cultures which have been treated with sodium butyrate, a treatment which causes Y-79 cells to differentiate. These results suggest that in human Y-79 retinoblastoma cells retinal melatonin biosynthesis and release may require a cAMP-dependent mechanism, as has been described previously for lower vertebrates.

A MODEL FOR STUDIES OF RETINAL PIGMENT EPITHELIUM PROLIFERATION IN ADULT MAMMALS. R. Butler and M.J. Hollenberg*. Anatomy Dept., McMaster Univ., Hamilton, Ont. L8N 3Z5 and Anatomy Dept., Univ. Toronto, Toronto, Ont. M5S 1A8.

In lower albino vertebrates, the RPE not only proliferates extensively following retinectomy, but also transdifferentiates into new neural retina. To study RPE proliferation in mammals, we used a congenic strain of rats in which siblings are either albino or pigmented. Between 2 hours and 40 days following retinectomy, eyes were fixed, embedded and 1 μm thick plastic sections prepared for light microscopy. Controls show that our retinectomy technique completely removes the neural retina but leaves the RPE layer intact in both albino and pigmented animals. Some isolated islands of proliferation are found in pigmented animals, but rarely exceed 4 cell layers thick. Extensive proliferation can be found in albino animals over the entire RPE surface (i.e. both central and peripheral). There are areas, however, where the RPE does not proliferate. The greatest extent of proliferation is in areas where layering is in excess of 30 cells thick. In these regions, there is a tendency towards stratification. It is not yet known whether this represents a differentiation of proliferating RPE cells or whether it is due to connective tissue.

REGULATION OF RETINAL MELATONIN IN *XENOPUS* G.M. CAHILL and J.C. BESHARSE. Dept. of Anatomy and Cell Biology, Emory University School of Medicine, Atlanta, GA 30322.

In the retina, the activity of serotonin N-acetyltransferase (sNAT), the penultimate enzyme in the synthesis of melatonin, is regulated by a circadian clock and by light, resulting in high synthetic activity at night. In *Xenopus* retina however, the regulation of melatonin content and release apparently involves other mechanisms as well. Cultured eyecups have the capacity for rapid deacetylation of melatonin, producing 5-methoxytryptamine, which is then deaminated by monoamine oxidase. The deacetylation of melatonin is inhibited by eserine, which inhibits aryl acylamidase activity. When eyecups are cultured in the presence of eserine, release of endogenously synthesized melatonin into the medium is increased 7-fold at night but is unchanged during the day. Carbachol has no effect on retinal melatonin release.

We have recently found evidence that melatonin synthesis in *Xenopus* retina is limited by the availability of serotonin. Pargyline, which blocks serotonin breakdown, acts synergistically with eserine to increase melatonin release. Addition of 100 µM 5-hydroxytryptophan to culture medium results in increased production of melatonin and melatonin metabolites by eyecups. Our results indicate that melatonin levels in the retina can be regulated by precursor availability and by local degradation, as well as by circadian variation in sNAT activity.

147.7

THE EFFECTS OF VITAMIN A SUPPLEMENTATION ON RETINOL BINDING PROTEIN AND DARK ADAPTATION H. Zwick*, B. Burri*†, E.S. Beatrice* (SPON: C.T. Bennett) Letterman Army Institute of Research and Western Human Nutrition Research Center†, San Francisco, CA 94129-6800

The effect of vitamin A supplementation on a subject with abnormally high dark adaptation threshold, but normal serum vitamin A and total retinol binding protein (RBP) was investigated. Vitamin A supplementation significantly increased the subject's serum vitamin A, total and free RBP concentrations, while decreasing the subject's parafoveal and paramacula dark-adapted threshold by more than a 1000 fold. Contrast sensitivity functions during repletion showed an abrupt but delayed increase in sensitivity for very fine spatial frequencies while showing an immediate and more gradual increase for coarser spatial frequencies. The abnormally low concentration of transthyretin-bound RBP found in this subject may explain why vitamin A supplementation was required and that this retinol transport protein may differentiate foveal receptor systems. These findings suggest that many subjects appearing to have normal vitamin A status but having poor dark adaptation might actually be vitamin A deficient.

EXPERIMENTAL MODEL OF RETINAL LIGHT DAMAGE: EFFECT OF ANTIOXIDANT, STEROID, AND CHELATION TREATMENT. R.D. Glickman†, R.M. Cartledge§*, and W.R. Elliott III†*. †KRUG International, San Antonio, TX; and §USAF School of Aerospace Medicine, Brooks AFB, TX.

Light damage to the retina may be caused by activation of nonlinear, thermal, or photochemical processes. Because biochemical intermediates are involved in photochemical, and possibly to some extent, thermal light damage, we investigated the feasibility of reducing light damage in an isolated retina eyecup preparation following damaging light exposures from a laser source. The transretinal electroretinogram (ERG) was obtained from an eyecup preparation derived from the white New Zealand rabbit. The amplitude of the ERG was recorded before and after a laser exposure at the lesion threshold, with and without pretreatment with one of the following agents: ascorbic acid, D-alpha-tocopherol, 3-aminotyrosine (3-AT), dexamethasone, and EGTA. Only 3-AT provided statistically significant protection against permanent, laser-induced loss of ERG amplitude. The rate of ERG-amplitude recovery after the laser exposure, however, was the same as in untreated retinas. These results indicate 1) a significant portion of retinal light damage is due to oxidative reactions, and 2) antioxidant therapy may have clinical applications in preventing or treating ocular light damage. VISUAL EFFECTS OF TRANSIENT AND PROLONGED SMALL SPOT LASER EXPOSURES. Robbins D.O., Zwick, H.*, Nawim, M.S.*, and Long, R.C.* Division of Biorheology, Letterman Army Institute of Research, San Francisco, CA 94129 and Department of Psychology, Ohio Wesleyan University, Delaware, OH 43015

The creation of an isolated punctate foveal lesion by a single, 15 nsec, laser (532 nm) pulse produces little if any transient or permanent changes in visual acuity, although such an exposure may hinder the ability to consistently maintain a stable acuity thereafter. Multiple exposures however, may ultimately summate to produce a significant permanent shift in baseline visual sensitivity. Exposure of the fovea or parafovea to extended periods (15 minutes) of less intense coherent light (514.5 nm) of similar dimension produces transient suppression of both visual acuity and contrast sensitivity. The magnitude of this suppression is comparable to that observed with relatively large diameter, 100 msec, retinal exposures (350 microns) when the energy levels were above threshold for damage. These data suggest that the suppressive mechanism may be relatively independent of visible damage processes although the consequences for visual acuity and contrast sensitivity may be quite similar.

TAURINE DEFICIENCY LEADS TO LOSS OF OPTIC NERVE FIBRES IN THE RAT N. Lake, N. Malik* and G. Battista*. Depts. of Physiology and Ophthalmology, McGill University, Montreal, Canada.

It has been known for several years that taurine deficiency in cats, rats, monkeys and man is associated with retinal dysfunction and cell degeneration. Pathologies of the photoreceptors have been emphasized, but the optic nerve has not been examined. We produce taurine depletion in rats by *in vivo* treatment with guanidinoethyl sulfonate (GES), an antagonist of taurine uptake. Adult female Sprague Dawley rats were examined after 40 days of treatment which reduces retinal taurine to about 50% of control. Cross-sections of the optic nerve were taken about 1.5-2.0 mm behind its exit from the eye. Axon counts and total nerve area (using a digitizing tablet) were taken from photomontages of semi-thin sections; fibre densities (counts / area) were also obtained from electron micrographs from each nerve. The fibre density and the total number of axons were significantly reduced in taurine-depleted animals compared to controls. Correlated changes in fibre diameter and/or myelination are currently being examined; analysis of more than 2000 axons per group indicates that the dispersion of fibre diameters about the mean is much higher for depleted than for control animals. Ganglion cell degeneration may be a direct effect, or transynaptic (secondary) to effects on taurine-sensitive elements at more distal retinal sites.

CYTOCHROME OXIDASE STAINING OF THE DYSTROPHIC RAT RETINA. J.R. Cotter. Dept. Anatomical Sciences, State University of New York at Buffalo, Buffalo, N.Y. 14214.

Royal College of Surgeon rats (RCS-p+) and their congenic controls (RCS-rdy+ p+) were studied using cytochrome oxidase histochemistry. This technique has been used as a marker of neuronal activity (Wong-Riley,M., Brain Res.,171,1979) and so it was thought that the application of this technique to the dystrophic rat retina might demonstrate changes in the morphology of the retina and reveal changes in the functional state of cells in the various layers. The dystrophic animals studied were approximately 2 months of age. Except for the ora serrata, the pattern of cytochrome oxidase staining in all other regions differed markedly from that observed in normal animals. Local differences in the rate of degeneration produced different patterns of staining which may correlate with the initial development of small holes or voids in the layer of inner segments. In the dystrophic rat, inner segments were shortened. As in the normal animal, inner and outer plexiform layers stained as did horizontal cells, displaced ganglion cells and ganglion cells. In more advanced stages of degeneration, inner segments were completely lost and staining of the inner plexiform layer reduced. Such results indicate that oxidative metabolism is sustained in inner and outer portions of the retina even after substantial damage to photoreceptors.

IMMUNOCYTOCHEMICAL INVESTIGATION OF GFAP AND (Na,K)-ATPase IN THE RETINA OF CONTROL AND RCS DYSTROPHIC (rdy/rdy) RATS DURING DEVELOPMENT. H.J. Sheedlo and J.E. Turner (SPON: W.K. O'Steen). Dept. of Anatomy, Bowman Gray School of Medicine, Wake Forest Univ., Winston-Salem, NC 27103.

Glial fibrillary acidic protein (GFAP) and (Na,K)-ATPase were localized immunocytochemically using paraffin section and wholemount methodology in the retina of young-adult Sprague-Dawley rats and Royal College of Surgeons (RCS) dystrophic (rdy/rdy) rats and age-matched RCS controls. This study was undertaken to assess the effects of photoreceptor cell degeneration in the retina of RCS rdy/rdy rats on the distribution of GFAP and (Na,K)-ATPase. As shown in retinal paraffin sections of Sprague-Dawley rats, GFAP-immunostained astrocytes and processes were detected in proximity to the optic nerve fiber layer (ONFL), while (Na,K)-ATPase immunostaining was distributed on rod inner segments, in the inner and outer plexiform layers and on axons in the ONFL. Less dense (Na,K)-ATPase staining was detected in the inner and outer nuclear layers. As revealed in wholemount preparations viewed from the vitreal surface, GFAP-immunostained astrocytes and processes were interspersed between blood vessels, with astrocyte endfeet contacting these vessels, while (Na,K)-ATPase immunostaining was observed at the periphery of radially-oriented nerve fiber tracts and, immediately beneath, surrounding ganglion cell bodies. Astrocytes and processes immunostained for GFAP were also observed in the retina of 11 day-old RCS dystrophic rats and (Na,K)-ATPase immunostaining in the retina of these mutant rats did not differ significantly from age-matched control rats. Results of GFAP and (Na,K)-ATPase immunostaining in the retina of RCS dystrophic rats at more advanced stages of development will be presented. Supported by NIH grant EY-04337.

ESTABLISHMENT AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF NEURORETINAL CELL LINES OBTAINED BY RETROVIRUS-MEDIATED ONCOGENE TRANSFER. D.P. Lenzi, K. Radke,*(1) E.L. Gleason and M. Wilson (SPON: A.T. Ishida). Depts. of Zoology and Avian Sciences (1), University of California, Davis CA 95616.

The study of the retina is made difficult by the many cell types present and the complexity of their connections. Acute isolation of adult retinal neurons and primary culture of embryonic retinal neurons are two widely used methods for obtaining retinal cells for electrophysiological enquiry. We describe here an alternative: the production of retina-derived cell lines.

Dissociated embryonic day 7 Quail neuroretinal cells were incubated with the avian retrovirus MH2 PA200 (RAV-1 pseudotype) that carries the *mil* oncogene. These cells have grown through 48 population doublings, while uninfected cells stopped growing after 4 doublings.

Electron microscopy shows these cells to release virus, and immunoprecipitation of the *gag-mil* fusion protein shows these cells to express the oncogene.

We have begun the characterization of these cells using the patch-clamp technique in the whole-cell configuration. We have measured current responses to voltage steps and to the application of putative retinal transmitters. Of 27 clones generated by limiting dilution, 4 have been studied. Some but not all cells tested within these clones (1) responded to 1mM glycine with an increased conductance, and (2) show large inward currents at short times after the application of depolarizing steps. Also, most cells recorded from showed inward rectification.

147.14

THE α AND β SUBUNITS OF BOVINE RETINAL CYCLIC GMP PHOSPHODIESTERASE ARE DISTINCT BUT RELATED POLYPEPTIDES. J. J. Erdos*, H. Tamir*, A.B. Fawzi* and J. K. Northup* (SPON: M.E. Bowers). Depts. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510

Purified bovine retinal cyclic GMP phosphodiesterase (PDE) was used to raise polyclonal antisera. Four of four immunized rabbits developed titers of 1:10,000 or greater by immune-spot test. All four sera recognized both the α and β subunits of PDE and recognized only these subunits in Western transblots of crude retinal extracts. Antisera 3 and 4 recognized the native conformation of PDE more strongly than denatured PDE.

The α and β subunits were resolved and isolated by SDS PAGE using 11% separating gels for Cleveland mapping. Using 2 μg of α or β subunits, digestion with trypsin (1 μg) and chymotrypsin (1 μg) yeilded proteolytic fragments with a high degree of homology. Papain (3 μg) yeilded distinct terminal digestion products. *Staphylococcus aureus* V8 protease over a range of 5 -1000 ng yeilded a set of nearly identical intermediate digestion products and distinct terminal fragments.

Reactive epitopes of the α and β subunits were determined by Western transblot analysis of *Staph. aureus* V8 protease digests. Antisera 1, 2, and 4 revealed distinct epitopes unique to the α and β subunits. The data suggests that the α and β subunits of cyclic GMP phosphodiesterase are related but distinct proteins. The differences in terminal fragments and epitopes between the subunits make it unlikely that the subunits arise from simple post-translational protein modification and suggests that the subunits may be distinct gene products.

147.15

CHARACTERIZATION OF A ZINC METALLOTHIONEIN IN BOVINE RETINA, M. Ebadi and T. Takahashi*. (Spon: A.M. Earle) Dept. of Pharmacol., Univ. Neb. Coll. of Med., 42nd St. and Dewey Ave., Omaha, NE 68105

Mammalian retinas, which contain photoreceptor systems and initiate electrical impulses on illumination, possess the highest concentrations of zinc in any known living tissues. For example, nocturnal animals with keen vision, such as foxes, have been reported to exhibit a zinc level of 138,000 ppm or 13.8% by weight in the iridescent layer tapetum lucidum of the choroid. Furthermore, zinc deficiency has been implicated in impaired night vision and zinc excess has been detected in inherited retinal dystrophy. The conversion of retinol to retinaldehyde, which in turn is necessary for the formation of rhodopsin (visual pigment), is a zinc-dependent process and is impaired in zinc deficiency state.

In order to study the metabolism of zinc in the retina further, we have measured its subcellular distribution in the bovine retina and found it to be nonuniform, exhibiting the following concentrations (;g zinc/mg protein): rod outer segment (0.230), pre-pellet (0.090), pellet 1 (0.119), pellet 2 (0.091), and post-pellet 2 (0.038). In addition, the bovine retina contains a low molecular weight metallothionein-like protein which exhibits an elution volume (Ve/Vo) of 1.9 on gel permeation chromatography, and produces only one isoform, which on reverse phase HPLC exhibits a retention time of 16.22 min and is similar to that produced by zinc-induced hepatic metallothionein II. The precise compartmentation of the retinal metallothionein-like protein is being investigated at this time. (Supported in part by a grant from USPHS ES-03949.)

VALIUM UNMASKS STIMULATION-INDUCED FEEDING.
T. Bushnik-Harris and C. Bielajew. School of Psychology, University of Ottawa, Ottawa, Ontario, Canada, K1N 6N5.

Electrical stimulation of many of the same medial forebrain bundle sites induces self-stimulation and feeding. However, some animals with positive self-stimulation placements fail to demonstrate feeding when stimulated but do appear highly aroused and interested in food, while others may eat but will require relatively high stimulation thresholds. In two rats with self-stimulation electrodes in the medial forebrain bundle, feeding was reliably observed only in one animal. The frequencies required to support half-maximum performance for a wide range of currents (80 - 1000 μA) were determined for self-stimulation and stimulation-induced feeding. These frequency-intensity trade-offs were collected following the administration of valium, a benzodiazepine, or the vehicle. Valium elicited feeding in one subject and significantly reduced the thresholds for feeding in the other, without having any effect on self-stimulation thresholds in both. During the three weeks of testing, in which valium was administered on alternate days, lowered thresholds for eating in one animal and the observation of eating in the second animal were drug-dependent. These results suggest that valium unmasks feeding that may be inhibited by emotional factors without influencing the thresholds for rewarding brain stimulation.

148.2

HYPOTHALAMIC STIMULATION THAT EVOKES FEEDING DOES NOT RELIABLY AMPLIFY THE HEDONIC EVALUATION OF TASTES. K.C. Berridge, and E.S. Valenstein. The University of Michigan, Department of Psychology, Ann Arbor, MI 48109.

Taste-reactivity measures of natural responses were used to examine the effects of feeding-eliciting brain stimulation upon motor activation, taste perception, and palatability evaluation. After implantation with LH stimulating electrodes and chronic oral cannulae, rats were screened for hypothalamic stimulus-bound feeding.

Positive feeders were videotaped, and their natural responses subsequently analyzed in slow-motion detail, in three conditions: in an empty chamber for motor reactions; in a chamber with food pellets and water available to verify stimulus-bound feeding; and in a chamber where taste solutions of different palatability (sucrose, HCL, or quinine) were continually infused for 1 min into their mouths. LH stimulation was delivered in alternating 15 sec-ON and 15 sec-OFF bins.

Hypothalamic stimulation elicited moderate oromotor activity and locomotion when delivered alone, and stimulation-bound feeding when food was available. Stimulation did not potentiate the positive palatability reactions to food or infusions of preferred sucrose. We conclude that LH stimulation induced feeding through a psychological system that is separable from food hedonics.

148.3

A STIMULUS-RESPONSE ANALYSIS OF INGESTIVE TASTE REACTIVITY. P. Breslin* and H. Grill (SPON: D. Jameson). Dept. of Psych., Univ. of Penn., Phila., PA 19104

Examination of oral motor responses in the 60 sec following a 0.25 ml pulse of intraoral sucrose stimulation reveals that oral responding increases linearly as a function of increasing concentration. It was also found that responding decreases post stimulus. The exponential decay constants for responding over time also shows significant differences as an inverse function of concentration; weaker solutions decaying more quickly than stronger ones. Stronger solutions stimulate greater central excitation resulting in the slower decay of post stimulus elicited behavior.

The modulatory effect of a metabolic manipulation on this stimulus-reponse system was also investigated. When rats were examined for enhancements of their post stimulus oral motor response in the food deprived state, responses were enhanced at 48-h deprivation but not at 24-h. This difference is taken to mean that the potentiation of taste elicited oromotor behavior is greater under conditions of more extreme deprivation, is consistent with deprivation data from the blowfly (Dethier et al., J. Comp. Phys. Psych., 60: 303-313, 1965).

148.4

ANORECTIC EFFECTS OF AMMONIA INFUSION. T. Foley-Nelson, L. Cao*, J.L. Nelson, J.E. Fischer* and W.T. Chance. Dept. of Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, OH 45267.

Our research concerning the mechanisms of cancer anorexia suggests that ammonia released from tumor tissue may be an important cause of this phenomenon. To better evaluate this hypothesis we infused various concentrations of equal parts ammonium acetate and bicarbonate (pH = 7.9) into the external jugular vein of freely-moving Fischer 344 rats. Catheters were implanted into 12 anesthetized rats, while an additional 5 rats served as operated controls. After 3 days of continuous infusion of saline at 2 ml/hr, 6 of the cannulated rats were begun on ammonium infusion (0.1 M). The concentration was increased each of the next 3 days by 0.1 M to a final concentration of 0.4 M, after which the rats were sacrificed. In another experiment 12 rats were infused with either saline or 0.2 M ammonium salts for 5 days and sacrificed. Intake of rat chow was decreased significantly by concentrations of ammonium greater than 0.1 M (25 to 90% decrease). Significant increases were observed in brain glutamine (422 & 158%), methionine (150 & 120%), tyrosine (178 & 109%), phenylalanine (466 & 134%) and tryptophan (197 & 109%) as well as in striatal DOPAC (34 & 22%), HVA (47 & 47%) and 5-HIAA (168 & 56%) following the respective infusion of 0.4 M or 0.2 M ammonium salts. These results demonstrate that hyperammonemia can cause anorexia and induce neurochemical alterations that are similar to those observed in anorectic tumor-bearing rats.

148.5

CANCER ANOREXIA AND HYPERAMMONEMIA. W.T. Chance, T. Foley-Nelson, L. Cao*, J.L. Nelson and J.E. Fischer*. Dept. of Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, OH 45267.

Although the etiology of cancer anorexia remains unspecified, recent experiments suggest that it may be mediated by a factor secreted by the tumor into the venous circulation. Based upon experiments investigating tumor metabolism, we hypothesized that this factor was ammonia. Therefore, we assayed plasma ammonia concentrations enzymatically prior to and after the development of anorexia in rats bearing methylcholanthrene (MCA)-induced sarcomas (sc). Amino acid concentrations were determined in plasma and brain using an automated analyzer. Analyses of amine neurotransmitters and metabolites were also conducted on the corpus striatum. Although plasma ammonia concentration was elevated prior to the onset of anorexia (134±11 vs 68±8 nmol/ml), it was even more concentrated after anorexia developed (240±15 nmol/ml). It correlated negatively with food intake ($r = -0.70$, $p < 0.01$) and positively with tumor size ($r = 0.70$, $p < 0.01$). In the brain the percent increase of glutamine (29&52), methionine (88&188), tyrosine (67&192), phenylalanine (86&192), and tryptophan (45&67) was significant ($p < 0.01$) in both groups of TB rats, with the anorectic rats exhibiting a greater ($p < 0.01$) increase in each of these compounds. Striatal levels of dopamine, DOPAC and HVA were increased only in the anorectic TB rats, suggesting that the anorexia may be associated with increased dopamine metabolism and amino acid derangements that are secondary to cerebral detoxification of ammonia. [Supported by NICR grant 86B34 to WTC]

NEONATAL GASTROSTOMY FEEDING MUST OCCUR EARLY TO INDUCE ACCELERATED WEIGHT GAIN IN RAT PUPS. J. Diaz, P. Garvie and D. Fordham . Department of Psychology, University of Washington, Seattle, WA 98195.

Gastrostomy reared rat pups overfed formula milk via chronic intragastric fistulas not only become obese pups but in addition defend these obese weights as adults (J. Nutr. 112, 1339, 1982; J. Nutr. 117, 1259, 1987). The present studies were undertaken to determine if there are short critical periods for this induction of obesity.

On postnatal Day 9 or Day 7, Long-Evans hooded rats were assigned to one of three groups for each day: 1) animals that were reared in litters of ten under normal conditions (MR); 2) animals gastrostomy fed enough milk formula to match the weight gains of their MR siblings (WM); and 3) animals gastrostomy fed as much volume as the WM group but a formula diet with 20% W/V added fat (OB). Animals were gastrostomy fed for four days beginning either on Day 7 or Day 9. After these four days the animals were returned to their mothers and weaned at Day 21. All the animals were sacrificed on Day 48 and organ weights were recorded. The results indicate that both the Day 9 and Day 7 OB animals did not show accelerated weight gains; nor did Day 9 nor Day 7 WM animals show increased adiposity.

These data suggest that four days of gastrostomy feeding is not sufficient and/or must begin very early in life to induce obesity in rat pups.

148.7

REPEATED VMH-AREA STIMULATION LEADS TO REDUCED WEIGHT GAIN IN THE RAT. Peter A. Pawson. Division of Biol. Sci., National Research Council Canada, Ottawa, Canada.

We have determined hypothalamic sites (the posterior AH and the anterior VMH) where acute stimulation leads to marked increases in energy expenditure as measured by whole animal oxygen consumption (Soc.Neurosci.Abstr. 13:1163). In the course of these studies I noted that rats that underwent repeated testing had a decreased rate of weight gain. One element of the VMH-lesion induced obesity syndrome is believed to be an associated decrease in energy expenditure, leading to obesity even in rats that are restricted to a normal rate of food intake. This suggests that regular VMH-area stimulation would lead to increased energy expenditure and reduced weight gain in normophagic rats. To test this hypothesis 5 rats were stimulated every third day over a 15-day period. Each stimulation session was composed of 20 trains over a 6 hr period; each 50 Hz train (400 ms on/600 ms off) of 300 microamperes cathodal current lasted 60s. While both control and stimulated rats had identical food intake over the period, the stimulated rats had a reduced net weight gain (33.2 ±18g.) versus unstimulated controls (62.8 ±8g.). The data indicate that increased neuronal activity in the VMH region leads to decreased weight gain and perhaps to differences in overall body composition.

148.8

PERMANENT ALTERATION IN LICKING PATTERN OF RATS DUE TO NEONATAL LEAD EXPOSURE. P.M. Martin and R.B. Mailman. Biological Sciences Research Center, Departments of Psychiatry and Pharmacology, Chapel Hill, NC 27599-7250.

Administration of lead acetate p.o. (200mg/kg/day for 8 consecutive days) to Long-Evans rat pups younger than 21 days of age results in a permanent increase in lithium-induced polydipsia during adulthood, although 24 hr water consumption of these animals do not differ from controls in the absence of lithium (Mailman, R.B., Psychopharmacol., 80:143-149, 1983). In the present experiment, a detailed analysis of drinking behavior was made to test the hypothesis that lead alters drinking without changing overall intake. Animals were given either lead or sodium acetate (n=7) on days 2-9 of age and at approximately 60 days of age were placed in test chambers during two separate 24 hour sessions. Tongue contacts to the sipper tube of a water bottle mounted outside the chamber were recorded via a PC microcomputer, and bout analysis was used to characterize the temporal organization of drinking. Mixed design analyses of variance showed that lead treated animals exhibited more licks per burst ($F=5.122$; $df=1,12$; $p<0.05$) and shorter interburst intervals ($F=5.15$; $df=1,12$; $p<0.05$) than did controls, although they did not differ in total number of drinking bouts, number of lick bursts per bout, or interlick interval. Animals then were sacrificed, and concentrations of dopamine, norepinepherine, serotonin, and their metabolites in various microdissected brain regions were measured by HPLC. Results suggest that brief neonatal lead exposure results in perseverative drinking, possibly through perturbation of dopaminergic motor areas. (Supported, in part, by Grant ES01104).

148.9

EFFECT OF FOOD TEXTURE ON ORAL-MOTOR BEHAVIOR. E.G. Gisel. School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, H3G 1Y5.

Oral-motor behaviors change rapidly in human infants from 6 months to 2 years of age. During this weaning period children make the transition from the ingestion of liquids through sucking to the ingestion of solids through chewing. Although little is known about the influence of food texture on oral-motor development, children are generally offered a diet of increasingly resistive textures during this phase. Therefore, the purpose of our study was to examine the effect of three different textures of food (solid, viscous, puree) on chewing duration, as well as to describe tongue movements during chewing and swallowing. Fifty-two children from 6 months to 2 years were studied using video analysis. The influence of taste was controlled by using sweet flavors.

Preliminary data indicate that chewing time decreases for a comparable volume of food as the texture becomes softer. Chewing time also decreases for all textures resulting in greater chewing efficiency acrosss age. Within the same age groups, puree elicits more immature tongue patterns than the other textures. Therefore, different food textures elicit unique oral-motor patterns. It was shown earlier that the severity of a feeding problem in children with neurologic deficits (cerebral palsy) can be identified through the use of different textures of food. Supported by NHRDP #6605-2430.

ADJUSTMENT OF INTAKE PATTERNS IN FOOD DEPRIVED RATS TO VARYING TRIAL LENGTH IN A DISCRETE TRIALS PARADIGM *M.L. Volkov*, A.K. Bayer*, and S.M. Feldman.* Department of Psychology, New York University, NY, NY 10003.

A discrete trials paradigm was employed to study the intake curve and time course of the first meal following a 24 hr. fast in rats. We divided the meal into constrained bouts (trials) which permitted the sampling of intake and its components. Previously we have shown through the use of this paradigm that intake rate declines over the course of a session as a function of decreasing bite size, with constant bite frequency (Volkov, et al., *Soc. Neurosci. Abstr.*, **13**:334, 1987). In the present study we investigated the effect of trial length (defined by food availability) on the deceleration of the intake curve. Deprived subjects were adapted to trial-structured meals of wet mash (Purina rat chow and water, 3:2, w/w) over a 7 day training period. Experimental sessions consisted of feeding trials of either 15, 30, 45 or 60 sec. duration, with a constant interval of 2 min. separating trial initiation. Food intake was measured following each trial and sessions were recorded on videotape for subsequent analysis of latency, duration and bite frequency.

Results showed that the slope of the trial intake curve was a negatively accelerated linear function of trial duration. The time course of the meal also depended upon trial length, with the shortest meals consumed under the 60 sec. condition. Interestingly, cumulative intake was the same under all conditions. In addition, intake rate was an inverse function of trial duration, which indicates an alteration in either bite size or bite frequency.

FURTHER CHARACTERIZATION OF EFFECTS OF EXOGENOUS INSULIN IN THE SPINY MOUSE - MEAL FREQUENCY AND STOMACH EMPTYING. D. A. Czech and R. Prince*. Department of Psychology. Marquette University, Milwaukee, WI 53233.

Expt 1: Spiny mice were injected s.c. with 2 doses of insulin (10 & 30 U/kg) and saline vehicle in a within-S design. Frequency of entry and time spent in a food hopper were monitored with photodetector electronics and a microcomputer for 6 hr. Amount eaten was also recorded. A feeding bout (meal) was defined as at least 1 min of nearly continuous time in the feeder followed by a post-meal interval of 15 min. ANOVA and t-tests showed that meal frequency was significantly higher for both insulin conditions relative to control condition ($p< 0.05$). Meal duration was not significantly altered by insulin.

Expt 2: Mice were injected s.c. with insulin (30 U/kg) or saline following overnight food deprivation, given access to powdered chow, and visual monitoring was begun. Mice were sacrificed 0, 25, 50 & 75 min after eating a meal (meal end defined as 3 min without eating). Under ether anesthesia, the stomach was removed and its contents rinsed into a preweighed tube. It was centrifuged, the supernatant drawn off and remaining material dried to a constant weight. Dry weights were converted to percent of dry weight of 0-delay controls. A 2-factor ANOVA design showed both main effects and the interaction to be significant. Evaluation of the interaction revealed that weight of stomach contents was significantly lower in insulin treated mice than in saline controls at all non-0 delays ($p <.05$, 1-tail).

148.12

CHEMICAL COMPARISON OF TWO SATIETINS (SAT) WITH ALPHA1-ACID GLYCOPROTEIN (AAGP). V.E. Mendel) and M. Palieschekey*. Depts. of An. Physiol. and An. Sci., Univ. of Calif., Davis, CA 95616.

Isolation of human SAT (hSAT) by ultrafiltration of plasma (PM-10 microfilter) and precipitation with trichloroacetic acid (TCA) followed by passing the supernatant through a sizing chromatography column (Sephadex G-15) plus an affinity chromatography column (Concanavalin-A) and, finally a weak anion exchange HPLC column (Synchropak AX300), using a linear gradient of 0-60%B in 25 min. (A:0.02M Tris Acetate, pH8; B: A+1M NaAcetate, pH8), resulted in three peaks. The major peak (PKC) corresponds to the 45 Kd protein standard. This peak was eluted from the column at 0.46M salt and represents 57% of the protein (PKA = 31%, PKB = 12%). The HPLC profile of comparably prepared rat SAT (rSAT) is like hSAT except that PKA is the major peak.

A literature search revealed that PKC at 45 Kd corresponds to a major plasma protein (44Kd), namely, alpha1-acid glycoprotein (AAGP). Thus, we have compared SAT to AAGP. Pure AAGP and SAT when precipitated with (TCA) have nearly identical HPLC elution patterns but both hSAT and rSAT also have a 68 Kd band corresponding to albumin on SDA-Page gel. Biological activity of satietin, therefore, may be only an artifact of preparation.

148.13

REPEATED EXPOSURE TO ACTIVITY-INDUCED SELF-STARVATION: EFFECTS ON FOOD INTAKE, RUNNING, AND SURVIVAL. Y. Beaulieu* and R. Eikelboom, Psychology Dept., Queen's Univ., Kingston, Ontario, Canada, K7L 3N6.

Rats placed on daily 23 hr food deprivation with concurrent activity wheel access (the Activity-Induced Self-Starvation (AISS) procedure), display a reduced food intake relative to home-cage controls on the same deprivation schedule (Routtenberg, JCPP, 66: 234-238, 1968). This decrease is accompanied by marked daily increases in running and, unless interrupted, the severe weight reduction that ensues leads to death. However, in the present experiment, animals were returned to ad libitum feeding in the home-cage after 23% weight loss (days until removal was defined as survival time). We hypothesized that repeated exposures to AISS with intervening recovery periods would result in increasing survival times (i.e., slower weight loss). Over 3 exposures, animals increased their food consumption and running, resulting in longer survival times (8, 11.8, and 14.6 days respectively). Experience with an activity wheel prior to AISS increased survival time (10.6 days) as running did not show the expected increase. Deprivation experience, with recovery, before AISS resulted in marked increases in survival time (18.6 days) as food consumption was elevated while running was low. These results, in contrast to Routtenberg, suggest a major role for novelty in AISS and imply that, given enough experience, animals may adapt to this procedure.

148.14

HERITABILITY OF FISCHER-344 NACL AVERSIONS. S.I.Sollars*, E.E. Midkiff* & I.L.Bernstein, Depts of Psychology, University of Washington, Seattle, WA 98195 and Pacific University, Forest Grove, OR 97116.

Fischer-344 (F-344) rats fail to prefer NaCl solutions to water at any concentration, and avoid NaCl solutions preferred by other strains, including the Buffalo (BF) rat. These findings implicate a genetic mechanism in the F-344's salt aversion and the present study examined patterns of heritability of this behavior. Two inbred strains, F-344 and BF, were crossed and offspring from 8 litters examined. In half the breeding pairs, F-344 was the maternal genotype. NaCl preference of male offspring was examined in 24-hr, two bottle preference tests with water and NaCl solutions. Twelve pairs of F1 animals were randomly mated to produce an F2 population and the males received similar preference testing. For the purposes of analysis preference data of the BF strain were used to establish 99% confidence intervals around the mean NaCl preference at each concentration. This lower limit of NaCl preference provided a basis for excluding F1 and F2 animals from the norm of BF salt preference or classifying them as similar to the F-344. One of 33 animals in the F1 generation had preference scores below this cutoff. No differences in NaCl preference scores were evident between F1 animals based on maternal genotype. Thus, F1 males show NaCl preference which is similar to BF rats. Also, the gestational and suckling environment provided by F-344 dams appears not to be sufficient to produce NaCl aversion. In the F2 generation, 16 of 56 animals (29%) displayed NaCl preference scores which fell below the criterion levels on all NaCl concentrations and therefore their preference was more like F-344 rats. These results are consistent with a simple genetic model where a single, recessive gene carries the trait of NaCl aversion in F-344 rats although additional studies would be needed to confirm this.

148.15

THE EFFECT OF IN VIVO TREATMENT WITH GABA MIMETICS ON THE LEVEL OF GABA BINDING IN HYPOTHALAMUS. P.C. Madtes Jr. and V.S. Wahby. Dept.Biol. Point Loma Nazarene Col., San Diego, CA 92106 and VA Medical Center, N. Chicago, IL 60064.

Opposing GABAergic mechanisms may be acting in appetite regulation, one to suppress appetite in the lateral hypothalamus (LH) and the other to inhibit satiety in the ventromedial hypothalamus (VMH). Since eating behavior influences obesity and the GABA systems may, at least in part, control eating behavior, we studied the effect on in vivo treatment by GABA mimetics on the level of GABA binding in the brain. Young (5 wk and 10 wk) CD rats (Charles River) were lightly anesthetized with ether and treated by intraperitoneal injection 48 hr and 24 hr prior to sacrifice with one of the following: saline; THIP (GABA agonist) (7.5 mg/kg); picrotoxin (GABA antagonist)(1 mg/kg); or nipecotic acid (GABA uptake blocker)(20 mg/kg). The animals were sacrificed and 4 brain areas (cerebral hemispheres, cerebellum, LH, and VMH) were rapidly removed and stored frozen until assayed for both high- and low-affinity ^{3}H-muscimol binding. All 3 drugs lowered high-affinity binding in VMH in 5 wk and 10 wk rats and low-affinity binding in 10 wk rats. These data suggest that treatment with GABA mimetics may be useful in studying eating behavior.

148.16

Blood glucose and insulin responses to glucose infusions in the free-feeding rabbit. P.J. Geiselman, L. O'Farrell, D.S. Gray*, A. Acevedo-Cruz*, and L.J. Jakobsen*. Dept. Psychol. and Neurosci. Prgm., UCLA; Div. Diabetes, USC Sch. Med., Los Angeles, CA 90024.

Rabbits were given duodenal infusions of 0.3M glucose or 0.15M NaCl at a fast rate (3ml/min) or a slow rate (1ml/min).

Fast intraduodenal glucose infusion resulted in a sharp increase in blood insulin levels followed by a precipitous decline in blood glucose levels when food was not presented. However, when food was present, rabbits increased their food intake and, thus, did not show the precipitous decline in blood glucose levels.

After slow intraduodenal glucose infusion, blood insulin levels showed only a moderate increase, which failed to decrease glycemic levels. When food was present in this condition, rabbits suppressed food intake.

Thus, insulin levels that are sufficient to produce a precipitous decline in blood glucose levels are associated with hunger. However, moderately increased insulin levels that are insufficient to produce a significant reduction in glycemic levels appear to mediate satiety.

MOLECULAR INTERACTIONS OF HEPARAN SULPHATE PROTEOGLYCANS ASSOCIATED WITH SENSORY NEURONS IN VITRO. K.E. Dow and R.J. Riopelle. Queen's University, Depts. of Pediatrics and Medicine, Kingston, Canada K7L 3N6.

Proteoglycans on the cell surface and in the extracellular matrix have been implicated in cell adhesion and in the regulation of neurite outgrowth.

Dissociated sensory neurons in vitro displayed Alcian blue positive labelling on cell bodies and processes in the presence of 0.3 and 0.7 M $MgCl_2$ but not at 1.0 M $MgCl_2$, suggesting the presence of chondroitin sulphate (CS) and heparan sulphate (HS). In conditions where there was no apparent contribution of released proteoglycans (PGs) to neurite outgrowth , outgrowth was inhibited if the sensory neurons were coincubated with HS glycosaminoglycan (GAG) and if the cells were treated prior to seeding with heparitinase. Pretreatment of cells with HSGAG or with the monoclonal antibody HNK-1 (Leu 7) which recognizes a carbohydrate domain on cell adhesion glycoproteins, also resulted in inhibition of neurite outgrowth on laminin. Inhibition by HNK-1 (Leu 7) and HSGAG was not additive and the inhibitory effect produced by coincubation with HSGAG was eliminated by pretreatment with heparitinase or with HNK-1 (Leu 7) and/or HSGAG. These data suggest that HSPGs associated with sensory neurons bind by non-covalent interactions to distinct GAG binding domains on laminin and on the oligosaccharides of cell adhesion glycoproteins and promote neurite outgrowth by bridging between the cell adhesion glycoproteins and laminin.

149.2

THE IDENTIFICATION OF PHOSPHORYLATED PROTEINS ASSOCIATED WITH EPIDERMAL GROWTH FACTOR (EGF)-INDUCED NEURITE OUTGROWTH IN CULTURES OF CNS NEURONS. J.R. Moskal and R. S. Morrison. Albert Einstein College of Medicine, Bronx, NY 10467.

The stimulation of cyclic AMP-dependent protein kinase and the down regulation of protein kinase C appear to be key events in EGF-induced neurite extension. Thus, we have begun to examine protein phosphorylation patterns using 2D-SDS PAGE in primary cultures of rat cortical neurons treated with dibutyrl-cyclic AMP (dBcAMP: 1 mM), phorbol-12-myristate-13-acetate (PMA: 320 nM), and EGF (10 ng/ml). Autoradiograms were analysed using PDQUEST (Protein Data Bases, Huntington Station, NY). EGF treatment induced the phosphorylation of 7 proteins not found in control cultures. EGF treatment also led to the disappearance of 13 phosphorylated proteins found in the control cultures. In the dBcAMP-treated cultures 16 proteins with significantly altered phosphorylation patterns compared to controls were identified. Two of these proteins (Mr=80.1, pI=5.37 and Mr=17, pI=6.66) also were found in EGF-treated cultures and showed a similar pattern (increase) of phosphorylation. In PMA-treated cultures one protein (Mr=41.1, pI=5.36) was found that was present in EGF-treated cultures and showed an opposite (decrease) phosphorylation pattern. These results (1) demonstrate that EGF is capable of inducing a large number of protein phosphorylation changes, many of which are different than those induced by either dBcAMP or PMA and (2) suggest that the specific phospho- proteins with Mr=80.1, 41.1, and 17 are involved in regulating neurite extension.

149.3

SUPPRESSION OF PROTEIN KINASE C ACTIVITY POTENTIATES THE NEUROTROPHIC ACTION OF EPIDERMAL AND BASIC FIBROBLAST GROWTH FACTORS. R.S. Morrison, J.L. Gross*[1] and J.R. Moskal. Albert Einstein College of Medicine, Bronx, NY 10467, [1]Dupont Co., Wilmington, DE 19898.

The addition of either epidermal growth factor (EGF) or basic fibroblast growth factor (bFGF) to primary cultures of CNS neurons enhances cell survival and induces neurite outgrowth and arborization. The purpose of this study was to examine the role of protein kinase C in a signal transduction pathway utilized by EGF and bFGF. Previous work has suggested that some growth factors initiate their action by stimulating PKC. The role of PKC in neurite outgrowth was studied in primary cultures of cerebral cortical neurons established from the brains of neonatal rats. The activation of PKC by phorbol dibutyrate (PDBu), in EGF-treated neurons significantly **depressed** total neuronal survival as well as neurons bearing long processes. The addition of 4-beta-phorbol, a very weak tumor promoter, did not inhibit survival or process outgrowth. However, when neurons were first **pretreated** with PDBu to down regulate PKC, the action of the growth factors was dramatically potentiated. The potentiation was dependent on the duration of PDBu pretreatment, reaching an optimum after 24 hr. Moreover, the addition of a PKC **inhibitor (H7)** promoted neurite outgrowth when added alone or in combination with EGF or bFGF. Therefore, we conclude that the neurite extension induced by binding EGF and bFGF to cortical neurons does not require stimulation of PKC for signal transduction. In fact, down regulation of PKC may be a consequence of growth factor binding to cortical neurons.

SURVIVAL ACTIVITY OF HYDRA HEAD ACTIVATOR PEPTIDE FOR PERIPHERAL NEURONS IN CULTURE. A.M. Duchemin, T.T. Quach, B.K. Schrier, R.J. Wyatt. Laboratory of Developmental Neurobiology, NICHD, Bethesda, MD and Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, DC.

The head activator (HAP) is a signal for nerve cell differentiation in hydra (S. Hoffmeister and C. Schaller, Dev. Biol. 122:7, 1987). This undecapeptide, with completely conserved amino acid sequence, is also present in significant amounts in intestine and hypothalamus of adult and developing mammals.

We tested the activity of HAP on the survival of 12 day old chick embryo sympathetic and dorsal root ganglion neurons in culture. HAP was found to support neuron survival when applied at concentrations ranging from 0.1 to 10 pM in both cell assays. In hydra, HAP is also active at picomolar concentrations. The level of neuron survival with HAP was similar to that obtained with NGF (1 nM). Bradykinin, which has some amino acid sequence homology with HAP, was inactive as a trophic factor in these assays. HAP may have neuron maintenance or trophic function across the animal kingdom.

149.5

SOLUBLE FACTORS FROM RAT OLFACTORY BULB AND HIPPOCAMPUS SUPPORT THE SURVIVAL AND DIFFERENTIATION OF CULTURED RAT BASAL FOREBRAIN NEURONS. M. Martinic*, G. Garden*, M. P. Lambert and W. L. Klein. Department of Neurobiology and Physiology, Northwestern University, Evanston, Il. 60208.

Rat basal forebrain cells have been used to test trophic factor activities of various preparations. Soluble proteins from rat olfactory bulb and hippocampus support long-term survival (longer than 9 days) and process outgrowth in these cultures. These proteins also induce aggregation of the cells and fasciculation of neurites. Immunocytochemical labeling for NSE and GFAP shows that these cultures are primarily neuronal. Extracts from other neural areas, such as cerebellum, are able to support survival for up to 7 days, but do not induce aggregation or fasciculation. The addition of heart extract does not support survival for even 24 hours. Fetal calf serum and adult rat serum both promote long-term survival, but do not induce aggregation. Serum also induces proliferation of flat cells, not seen with neural extracts. Cells grown with extracts from the olfactory bulb and hippocampus, both targets of basal forebrain cholinergic neurons, show the highest proportions of acetylcholinesterase-positive staining.

149.6

BASIC FIBROBLAST GROWTH FACTOR STIMULATES THE SYNTHESIS OF THREE NEW PROTEINS IN THE GOLDFISH RETINA. M.A. Deaton*, C.A. Barba*, C.R. Flores*, A.M. Dahlberg*, G.P. Jones*, and M.C. Powanda* (SPON: D.J. Ramsay). Division of Ocular Hazards, Letterman Army Institute of Research, Presidio of San Francisco, CA 94129.

Basic fibroblast growth factor (bFGF) promotes the survival of neurons *in vitro* and *in vivo*. Since specific newly synthesized proteins appear to be essential for neuron survival after axotomy, bFGF might promote neuron survival by inducing the synthesis of new proteins. Thus we injected *C. auratus* eyes intravitreously with 10, 100, or 1000 ng bFGF and evaluated subsequent changes in retinal protein synthesis using 2-D PAGE/fluorography of [35S]met-labeled proteins. Incubation with bFGF was for 4 or 24 hr. bFGF-treated retinae (all doses/times) synthesized 3 new proteins (i.e., not found in controls) which comprised a substantial percentage of the total resolved protein. Each has a MW less than 20 KD, and an acidic pI. Furthermore, these 3 proteins are distinct from known retinal stress/heat shock proteins. Thus bFGF can induce the synthesis of new proteins in a neural tissue.

149.7

FIBROBLAST GROWTH FACTOR (FGF) LEVELS IN THE DEVELOPING BRAIN. C.G. Caday, A. Mirzabegian*, J. Prosser*, M. Klagsbrun*, and S.P. Finklestein. Mailman Research Center, McLean Hospital, Belmont, MA, 02178.

Fibroblast growth factors (FGF) are polypeptides with potent effects on the growth and differentiation of CNS neurons, glia, and endothelial cells. Both acidic and basic forms are found in the mammalian CNS. These factors are unique by virtue of their strong binding to heparin.

We used a 3T3/BalbC cell mitogenic assay to examine the levels of FGF in the developing and mature rat brain. FGF levels were relatively low in the embryonic brain (5-10 units/mg protein) and showed a rapid rise to reach adult levels (90-100 units/mg protein) during the first month of life. Most (> 90%) of this activity bound strongly to heparin-affinity columns, confirming its identity as FGF. These results on total FGF levels parallel those reported previously for the basic form alone (Logan, A., et al., Neuroscience, 15:1239-1246, 1985).

The marked increase in FGF levels during the first month of life may play a central role in the glial and endothelial proliferation, and neuronal differentiation that is occurring during this time. Sustained high levels of FGF may play an important role in the maintenance of these cell types in the mature brain.

149.8

BASIC FIBROBLAST GROWTH FACTOR (WITH HEPARIN) INCREASES THE SURVIVAL OF RAT DENTATE GRANULE CELLS IN CULTURE. D.L. Needels and C.W. Cotman. Preclinical CNS Biology, Bristol-Myers Co., Wallingford, CT 06492 and Dept. Psychobiology, Univ. California, Irvine, CA 92717.

Basic fibroblast growth factor (bFGF) is a potent heparin-binding growth factor reported to have trophic effects on a variety of cultured CNS neurons; including those from hippocampus, cortex and spinal cord. We report here that bFGF (in the presence of heparin) also supports dentate granule neurons grown in low density cultures.

Dentate gyrus was dissected from the hippocampus of 4-5 day old rats and cultured at 17,000 cells/cm2 under serum-free conditions. Neurons steadily died over the first 5 days in culture, as determined by phase contrast microscopy. The addition of 5 ng/ml of commercial bFGF delayed, but did not prevent, this neuronal death.

Cultures grown in the presence of 2-50 ug/ml heparin had a very different appearance. Very few flat cells were present (1% of cells at 3 days), suggesting that heparin may be useful in reducing the number of glial cells in these cultures. Neurons were phase bright with few neurites. Although the addition of heparin initially increased the number of live neurons, all neurons had died by 5-7 days. The combination of bFGF plus heparin resulted in the survival of up to half of the seeded cells at 5 days, and they were much larger with neurites.

CHARACTERIZATION OF NEUROLEUKIN ACTIVITY IN NEUROBLASTOMA CELL LINES.

Y Mizrachi, ME Gurney, DD Ho*. Cedars-Sinai Medical Center/UCLA School of Medicine, Los Angeles, CA 90048.

Neuroblastoma cell lines were studied for their responsiveness to neuroleukin (NLK), a mediator of the nervous and the immune systems. NLK was expressed by transfection of COS cells, and control supernatant fluids were from COS cells transfected with expression vector DNA alone. Human neuroblastoma cell lines (LA-N-1, LA-N-2, SK-N-MC) and a rat cranial neuroblastoma cell line (B35) responded to NLK by a 30-50% reduction in ^{3}H thymidine incorporation. No such response was noted for SK-N-SH, IMR-132 and B50 neuroblastoma cell lines. In addition, the responsive cells (LA-N-1, LA-N-2) showed enhanced neurite extension when grown on laminin in the presence of NLK but laminin alone was without effect. NLK shares partial sequence homology with gp120, the envelope glycoprotein of HIV-1. The reduction in ^{3}H thymidine incorporation induced by NLK was antagonized (50-75%) by HIV-1 lysates and purified gp120. These HIV-1 protein preparations had no direct effect on neuroblastoma cells in the absence of neuroleukin. Recently, NLK was shown to be identical to phosphoglucoisomerase and to have enzymatic activity. Studies concerning that point are currently in progress.

149.10

CHARACTERIZATION OF THE NEURONAL BASIC FIBROBLAST GROWTH FACTOR(bFGF) RECEPTOR.

P.A.Walicke, J.J. Feige* and A. Baird*. Dept. of Neuroscience, UCSD, and Laboratories for Neuroendocrinology, Salk Institute, La Jolla, CA 92093

Previous studies have shown that bFGF is neurotrophic, increasing neuronal survival and process growth in vitro. Serum-free cultures of fetal rat hippocampal neurons were used to characterize the neuronal bFGF receptor. Two components of [^{125}I] bFGF binding at 4°C were distinguished: one removed by 2M NaCl represented binding to glycosoaminoglycans, while the second stable to 2M NaCl represented a receptor. Scatchard analysis showed the presence of about 26,500 receptors/neuron with a Kd of 0.1 nM. Crosslinking with disuccinimidyl suberate (DSS) produced a major labeled band of 150 kD and a minor band of 100 kD. Labeled proteins of similar size were detected in cultures of neurons from several brain regions, and in membranes prepared from fetal brain. Specificity was demonstrated by blockade with cold bFGF but not a variety of other proteins. The contribution of carbohydrates to receptor structure was investigated with degradative enzymes. N-glycanase decreased receptor size by 10-15 kD, but neuraminidase, endoglycosidase H and heparinase were inactive. Wheat germ agglutinin (WGA) blocked bFGF binding and activity in the bioassay. To determine the domain of bFGF interacting with the receptor, a series of 13 synthetic peptide fragments of bFGF were tested. Two peptides from the carboxyl terminal region inhibited binding in the radioreceptor and crosslinking assays and neuronal survival in the bioassay.

149.11

S100β AND NEURITE EXTENSION FACTOR ACTIVITY: SYNTHESIS, EXPRESSION, AND SITE-DIRECTED MUTAGENESIS OF AN S100 GENE.

L.J. Van Eldik*, J.L. Staecker*, S.W. Barger* and F. Winningham-Major* (SPON: R. Selinfreund). Depts. of Pharmacology and Cell Biology, and Howard Hughes Medical Institute, Vanderbilt University, Nashville, TN 37232.

The S100 family is a group of structurally similar proteins that includes calcium binding proteins, cell proliferation and differentiation markers, and the cystic fibrosis antigen. As an initial step in addressing what structural features of the S100 family are related to their specific functions and localizations, a gene coding for one of the S100 proteins, S100β, was synthesized and expressed in E. coli. The gene was designed to allow rapid, efficient changes at single or multiple amino acids by using cassette-based mutagenesis. The recombinant S100β (termed VUSB-1) is structurally and functionally similar to bovine brain S100β, including the ability to stimulate neurite outgrowth from cerebral cortex neurons. Because the neurite extension factor (NEF) activity of S100β appears to require a disulfide form of the protein, initial experiments to analyze the structural requirements for NEF activity involved mutagenesis of the cysteine residues of VUSB-1. Currently, we are characterizing the NEF activity of the mutant S100 proteins, and testing the hypothesis that S100β may be a neurotrophic factor in the central nervous system.

THE MAJOR NEURITE OUTGROWTH PROMOTING ACTIVITY IN MOUSE HEART CELL CONDITIONED MEDIUM (NEURONECTIN) IS A 600 kDa SIALYLGLYCOPROTEIN.

M.D.Coughlin, J.Stanisz*, D.E.Jang*. Dept. Neurosci. McMaster Univ., Hamilton, Ont. CAN L8N3Z5

Neuronectin is the major substrate-binding neurite extension factor isolated from mouse heart cell conditioned medium and has M_r 350 kDa as determined by radiation inactivation analysis (Coughlin et al., J. Neurosci. 6:1553). We have now purified this factor and determined that it is a sialylglycoprotein. Activity isolated on a DEAE column (Coughlin et al.,Dev.Biol.82:56) was purified by Sephacryl S-300 column chromatography and preparative gel electrophoresis with a final yield of 10% of initial activity and 100-fold purification. Analysis by SDS PAGE revealed a single major band of stained material at ~600 kDa. The glycoprotein contains approximately 5% sialic acid. Treatment with chondroitinase ABC, heparitinase, and neuraminidase caused no loss of activity. Western blot and dot blot analysis of neuronectin with antibodies to neuronectin, laminin and heparan sulfate proteoglycan (HSPG) core protein (gift of Dr. John Hassell) suggests that there is less than 1% cross reactivity of neuronectin with anti-laminin or anti-HSPG. Differences between radiation inactivation and SDS PAGE estimations of molecular size will be discussed.

LAMININ-LIKE IMMUNOREACTIVITY IN ADULT RAT BRAIN NEURONS.

M. Manthorpe, T. Hagg, E. Engvall*, S. Varon. Dept. Biology, Univ. of California, San Diego, La Jolla, CA 92093. *La Jolla Cancer Research Foundation, La Jolla, CA 92037

Laminin (LN), a glycoprotein component of the extracellular matrix, is abundant in basement membranes of several tissues, including those of the nervous system where it is produced by Schwann and astroglial cells and occurs largely in an extracellular location. We report here the widespread presence of LN-like immunoreactivity associated with neuronal cell bodies of the adult and neonatal rat CNS. Animals were perfused with 4% paraformaldehyde, brain sections were cut on a freezing microtome and immunostained using an ABC method and nickel chloride and mild osmication to intensify the DAB reaction product. Affinity-purified polyclonal and monoclonal antibodies raised against rat and human LN caused the expected staining of the basement membranes but also a distinctive cellular staining that was not found with pre-immune sera, control antibodies or with anti-LN antisera pre-absorbed or pre-incubated with rat LN. The size and morphology of the stained cells indicated them to be neurons and the pattern of reactivity suggested an intracellularly located antigen that sometimes extended into the processes. Some regions of the brain including the cortex, striatum, thalamus and hippocampus showed heavy neuronal immunoreactivity whereas other regions including the basal forebrain, hypothalamus, cerebellum and spinal cord revealed very weak or no reactivity. The LN-like immunoreactivity in these neurons could be due to the recognition by the anti-LN antibodies of i) LN epitopes or ii) non-LN molecules containing epitopes found in LN. Supported by NSF grant BNS 17034 and NIH grant NS 25011.

LAMININ EXPRESSION IN THE DEVELOPMENTAL RAT BRAIN: AN IMMUNOCYTOCHEMICAL AND IN-SITU-HYBRIDIZATION STUDY.

C. T. Hu*, F. C. Zhou, Y. W. Hwang* and C.H.Lee* (SPON: J. F. Hyde) Dept. of Anatomy and Pathology, Indiana Univ. Indianapolis, IN 46223

Laminin has known to promote neurite outgrowth in the *culture* (review: Davis et al., TINS, 8:528, 1985). We recently provided evidence that laminin facilitates and guides fiber growth of grafted neurons in the *brain* (Zhou & Azmitia, J. Chem. Neuroanat, in press). In this study the morphology of the laminin in the brain were investigated at various developmental stage.

Brains from Sprague-Dawley rats of 16 days embryo (E16), postnatal day 1 (P1), P7, and P29 were used for immunocytochemical staining of laminin with antibodies to EHS laminin (E.Y and Biogenex Lab). Antibodies preabsorbed with EHS laminin was used as control. Four forms of immunostained laminin, small punctates, large punctates, sheath form and peri-somatic form, were observed in the E16, P1, and P7 brains. Only sheath form was detected in P29 brain. Small punctates distributed in patches in all regions of brain, whereas large punctates only exist in the hippocampus of E16, P1, and P7. Peri-somatic form of laminin was also detected in E16, P1, a nd P7. Sheath form of laminin was found on outer limiting membrane, ependyma , choroid plexus, and on blood vessels. Staining in control remains negative.

Paraffin section of E16, P7, and P29 brains were examined for laminin mRNA by in situ hybridization. A 50-base long oligonucleotide complementary to B2 region of laminin gene was labelled with alpha-^{35}S (or ^{32}P)-dATP at 3' end and used to detect laminin mRNA. Both neurons and glia of E16 and P7 brain have positive signal. Dense granules (positive signal) were observed in outer limiting membrane, ependymal cells, and endothelial cells of vessels of all the stages. The amount of dense granules were greatly reduced in P29 brain, and the granules only exist in where sheath form laminin was found. These results indicate that laminin is expressed in the developmental stage but is turned off upon maturation.

PERIPHERAL NERVE SECTIONS CONTAINED IN HOLLOW FIBERS FUNCTION AS A DELIVERY SYSTEM OF NEUROTROPHIC MOLECULES. J. E. Springer, T.J. Collier, and M.F.D. Notter, Dept. of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, New York 14642.

Schwann cells, a major support cell for peripheral nerves, are known to produce neurotrophic and neurite-promoting substances such as nerve growth factor (NGF) in vitro and in vivo. Following sciatic nerve transection in rats, mRNA encoding for NGF in Schwann cells distal to the cut increases dramatically, as does NGF synthesis. We tested whether sciatic nerve sections contained in hollow porous fibers would provide a source of NGF for NGF-sensitive cells in culture. Rat sciatic nerve sections were injected into hollow fibers (Amicon Corp) containing uniform pores with an maximum molecular weight exclusion of either 100 or 500kDa. These peripheral nerve-containing fibers were then placed into cultures of undifferentiated rat pheochromocytoma cells (PC12). Within 24 hours, PC12 cells began to differentiate and send out neurites indicating the presence of NGF or a similar substance. These nerve containing fibers continued to exhibit this NGF-like effect for up to 21 days following placement in culture medium. A similar effect was observed using only nerve fiber-derived conditioned medium.

Magnocellular cholinergic neurons in the basal forebrain are known to transport and utilize NGF derived from their target areas. When these targets are removed, these cholinergic neurons are thought to shrink and/or die, an event similar to that observed in individuals suffering from Alzheimer's disease. Exogenous NGF treatment will reverse axotomy-induced degeneration of basal forebrain cholinergic neurons in rodents. From the present results, it is suggested that transplantation of these peripheral nerve fibers may provide an alternative source of trophic support for damaged cholinergic neurons. Studies utilizing cultures of basal forebrain neurons, as well as transplantation of peripheral nerve fibers into the CNS of rats are currently under investigation. Supported by grants from the American Federation for Aging Research and PHS DA05274 (JES), and ADRDA FSA85015 (TJC).

SUSTAINED REGENERATION OF AXOTOMIZED CHOLINERGIC NEURONS USING CO-GRAFTS OF NGF-RICH TISSUE AND FETAL RAT BASAL FOREBRAIN. Dorothy Heyer (*), Timothy J. Collier, Rebekah Loy, and Joe E. Springer. (Spon: G. Thomas) Dept. of Neurobiology and Anatomy, Univ of Rochester Med Ctr., Rochester, N.Y., 14642.

Magnocellular cholinergic neurons in the basal forebrain appear to utilize nerve growth factor (NGF) for trophic support. Specifically, damage to the dorsal septo-hippocampal pathway results in a loss of cholinergic neurons in the medial septum (MS). We have recently demonstrated that transplants of NGF-rich tissue will increase the survival of these axotomized cholinergic neurons. We now report that fetal rat basal forebrain co-grafted with NGF-rich tissue provides a substrate for regenerating host cholinergic neurons. Adult female Long Evans rats received unilateral fimbria-fornix transections followed by intraventricular grafts of either male mouse submaxillary gland (a rich source of NGF), day E15 rat basal forebrain, or both. At 4 or 8 weeks following transplantation, animals were perfused and 30μm brain sections prepared for NGF receptor (NGFR) or choline actyltransferase (ChAT) immunocytochemistry.

As reported previously, grafts of male mouse submaxillary gland (but not fetal basal forebrain) increased the number of NGFR- and ChAT-positive neurons in the host MS. When animals received both grafts, numerous regenerating cholinergic neurons from the host MS were found to innervate the fetal basal forebrain graft. These NGFR- and cholinergic-positive fibers were maintained for at least 2 months following transplantation (the longest time period analyzed). It is suggested that, given the appropriate environment, i) regenerating fibers from "rescued" cholinergic neurons can be sustained within an intraventricular basal forebrain graft for up to 2 months, and ii) functional reinnervation of the target area by regenerating host neurons may be possible. Supported grants from the American Federation for Aging Research (JES) and ADRDA FSA85015 (TJC). JES is an NRSA postdoctoral fellow.

REGULATION OF NEUROTRANSMITTER EXPRESSION IN CULTURED SYMPATHETIC NEURONS BY A MEMBRANE ASSOCIATED FACTOR. V. Wong & J.A. Kessler, Depts. Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Contact of sympathetic neurons with other cell membranes regulates neurotransmitter expression. Treatment of cultured sympathetic neurons with membranes isolated from sympathetic ganglia or from spinal cord stimulates levels of choline acetyltransferase (CAT) and induces expression of the peptide neurotransmitter substance P (SP). A 29kDa membrane associated neurotransmitter stimulating (MANS) factor which reproduces the effects of neuronal contact with membranes has been solubilized and partially purified from adult rat spinal cord membranes (Wong & Kessler, PNAS 84:8726, 1987). The onset of action of MANS was rapid; treatment of freshly plated cells with MANS resulted in a 26-fold increase in CAT activity within 48 hours. Older cultures responded less rapidly and less intensely. Treatment with MANS induced levels of preprotachykinin mRNA (PPT-mRNA), which were undetectable in control cultures, indicating that pretranslational mechanisms mediate effects of the factor. Treatment with rat fibroblast conditioned medium (RFCM) in addition to saturating levels of MANS resulted in further increases in CAT activity, suggesting that soluble factors in RFCM and MANS act through different mechanisms. Spinal cord cholinergic neurons were also responsive to the factor (see Lombard-Golly, Wong, & Kessler; this volume). To help further characterize the MANS molecule, monoclonal antibodies to the partially purified factor were generated. Six clones have been identified which produced antibodies that partially blocked the cholinergic-promoting actions of the factor. Further efforts will be directed towards determining whether these antibodies are specific for the MANS factor. In toto, our observations suggest that MANS mediates the stimulatory effects of cell-cell contact on cholinergic and peptidergic expression by sympathetic neurons.

149.18

REGULATION OF CHOLINERGIC SPINAL CORD NEURONS IN CULTURE BY A MEMBRANE FACTOR WHICH MEDIATES EFFECTS OF CELL-CELL CONTACT. D. Lombard-Golly*, V. Wong and J. A. Kessler, Depts of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neuronal contact with other cell membranes plays an important role in regulating neuronal growth and development. We have been examining the role of cell-cell contact in the development of cholinergic spinal cord neurons. Levels of the cholinergic biosynthetic enzyme, choline acetyltransferase (CAT), were stimulated by increasing cell density in cultures of embryonic rat spinal cord. Our laboratory has recently solubilized and partially purified a 29 KDa molecule (MANS) from adult rat spinal cord membranes which reproduces the stimulatory effects of cell-cell contact (Wong and Kessler,P.N.A.S. 84: 8726, 1987). Treatment of low density cultures with MANS on day 3 in vitro increased CAT activity to levels comparable to those in higher density cultures. MANS treatment of 3 day old cultures had progressively less effect with increasing cell density. Freshly plated cells were more responsive to the factor than the older cultures. MANS appeared to stimulate cholinergic differentiation rather than survival of cholinergic neurons although effects on survival could not be excluded. Effects of the factor were examined in ventral and mediodorsal spinal cord cultured separately. In both types of culture, the treatment of freshly plated cells increased CAT activity after 1.5 days in culture. However, effects on the mediodorsal cultures were transient and levels of CAT activity in treated and control cultures did not differ significantly after 14 days in vitro. By contrast, effects of treatment of freshly plated ventral cultures persisted with time in culture; after 3 weeks CAT activity in treated cultures (15.64 nmol./mg prot./hr) was about 2.5 times the level in controls (6.69 nmol./mg prot./hr). Thus ventral (motor neuron enriched) cholinergic spinal neurons are more responsive to the factor than mediodorsal (autonomic neuron enriched) populations. Our observations suggest that development of cholinergic spinal cord neurons may be regulated by cell-cell contact and that the MANS factor may mediate the stimulatory effects of cell-cell contact on cholinergic expression.

MEMBRANE ASSOCIATED SURVIVAL FACTOR FOR CULTURED CILIARY GANGLION NEURONS. J.B. Tuttle and D.J. Creedon, Dept of Physiol. and Neurosci., Univ. of Virginia Sch. of Med., Charlottesvl., VA, 22908.

Survival of avian ciliary ganglion neurons in culture depends upon an exogenous supply of trophic factor(s). Skeletal muscle, one of the normal ganglionic synaptic targets, is a well-documented provider of survival-promoting activity, yet the molecular basis of this activity has not been thoroughly investigated. To test the source of skeletal muscle support, dissociated neurons were plated into microwells containing either: medium conditioned by myotubes; membrane remnants of osmotically lysed myotubes; or, membrane remnants and conditioned medium. Neuronal counts after one, two, five, and seven days revealed that partial neuronal survival is supported by both muscle conditioned medium and the membrane remnants of cultured myotubes. Together, these two sources furnish trophic activity equivalent to live myotubes. The results suggest that both soluble and membrane-associated trophic factor(s) are involved in neuronal survival in vitro, and they draw attention to membrane contact phenomena as important events in neuronal trophic signaling. Because the membrane-associated activity can be recovered from a high-speed supernatant, comparison of this with known purified soluble factors will reveal if this form is a novel trophic factor or a novel mode of trophic exchange. EXPRESSION OF NGF BY PERMANENT CELL LINES DERIVED FROM POSTNATAL HIPPOCAMPUS. H.J. Lee, D.N. Hammond, T.H. Large§, and B.H. Wainer. Comm. on Neurobiology, The University of Chicago, Chicago, IL 60637 and §Department of Physiology and Howard Hughes Medical Institute, Univ. of California, San Fransisco, CA 94143.

In the central nervous system, nerve growth factor (NGF) is produced by hippocampal cells and has neurotrophic effects on septal neurons, the primary source of cholinergic innervation to the hippocampal region. To examine NGF expression by hippocampal cells in an isolated system, postnatal day 21 mouse hippocampal cells have been immortalized through somatic cell hybridization to murine N18TG2 neuroblastoma cells as previously reported (Lee, H.J. et al., *Soc. for Neurosci. Abst.* 13: 701, 1987). Postnatal day 21 was chosen to maximize the probability of deriving an NGF-producing cell line since rat NGF protein and mRNA levels reach a developmental peak at this time.

We now report that several hippocampal cell line subclones synthesize significant quantities of NGF. A sensitive 2-site ELISA for NGF, modified after Weskamp and Otten (*J. Neurochem.*, 48: 1179, 1987), demonstrates that cell extracts of these lines contain over 7,000 fg NGF/mg total protein when cells are grown to 90% confluency in 10% fetal calf serum in DMEM. This level of NGF content is comparable to reported values of ~1,300 fg NGF/mg wet weight for adult rat hippocampal tissue. Using a rat probe for NGF receptor mRNA, Northern blot analysis of the parent lines displays low levels of binding.

These NGF-producing hippocampal lines display a variety of morphologies: some extend mutiple processes while others are round and relatively undifferentiated in appearance. Their hybrid nature has been documented by isoenzyme and karyotype analysis. These hybrid hippocampal cell lines may provide a useful tool to elucidate the mechanisms underlying hippocampal NGF expression and may provide a source of novel, hippocampally derived trophic factors that affect septal neurons. Supported by NIH grants 5-T32HD070009, NS 01244, and NS 25787; grants from the Alzheimer Disease and Related Disorders Association, the American Philosophical Society, and the French Foundation; and the Illinois Department of Public Health.

MEDIUM CONDITIONED BY A HIPPOCAMPAL CELL LINE INCREASES CHOLINE ACETYLTRANSFERASE ACTIVITY OF SEPTAL CELLS IN SERUM-FREE CULTURE. D.N. Hammond, H.J. Lee, B.H. Wainer, and A. Heller. University of Chicago, Chicago, IL 60637.

Target-derived cell lines may serve as useful sources of trophic factors which influence normal projecting neurons. A series of cell lines has been derived from murine hippocampus using polyethylene glycol-mediated fusion with neuroblastoma cells. Using a serum-free culture system, medium conditioned by these hippocampal cell lines has been examined for effects on the choline acetyltransferase (ChAT) activity of cells of the septal region, the major source of cholinergic innervation of the hippocampus.

Embryonic mouse septal cells are dissected and dissociated. The cells are suspended in modified N2 medium (after Bottenstein and Sato), and plated on poly-lysine-coated microtiter plates. At the conclusion of time in culture, ChAT activity is assayed directly in culture wells using a modification of the method of Fonnum. Under these conditions, ChAT activity increases over time in culture, with a peak at 7 - 10 days. The effect of NGF (100 ng/ml) on primary septal cells has also been studied using this bioassay system. ChAT activity increases by 2- to 3-fold when NGF is added to the medium. When serum-free medium conditioned by one of our hippocampal cell lines (HN10) is added, there is a 2- to 3-fold increase in ChAT activity compared to controls. These studies indicate that medium conditioned by a hippocampal cell line contains factor(s) which increase the ChAT activity of murine septal cells in serum-free culture. (Supported by grants NS01244, NS25787, and HD070009; grants from the American Philosophical Society, French Foundation, Alzheimer's Disease and Related Disorders Association; and the Illinois Department of Public Health.)

DOES NERVE GROWTH FACTOR (NGF) ENHANCE SURVIVAL OF DEVELOPING CENTRAL CHOLINERGIC NEURONS? B.H. Wainer[a], S.D. Price[a*], S.G. Nelson[a*], and W.C. Mobley[b]. The University of Chicago[a], Chicago, Illinois; 60637, and The University of California, San Francisco, 94143.[b]

Previous work in this laboratory has demonstrated increased numbers of septal cholinergic cells in the presence of target (hippocampal), but not non-target (cerebellar) cells in reaggregate co-cultures (Hsiang et al. Neuroscience.21: 333-343, '87). Further electron microscopic (EM) experiments revealed that the hippocampal target cells enhanced cholinergic cell survival; ie. in the presence of non-target cerebellar cells, large numbers of degenerating acetylcholinesterase (AChE)-positive cells were observed (Wainer et al. Soc. for Neurosci. Abs. 12: 586, '86). In other studies, addition of NGF to septal reaggregate cultures resulted in increased numbers of AChE-positive cells (Wainer et al. Neurosci. Lett. 26: S17, '86).

The present experiments were designed to determine if NGF actually increases the survival of cholinergic neurons. Septal reaggregates, prepared from E15 mouse embryos, were cultured for either 15 or 21 days and either in the presence or absence of 10ng/ml NGF. The reaggregates were then processed for AChE histochemistry and EM. AChE-positive neurons were identified by electron dense reaction product associated with the nuclear membrane and endoplasmic reticulum. The mean number of healthy cells in samples of 15-day untreated aggregates was 31 as compared to 43 for NGF-treated cultures. In the 21-day untreated cultures the mean number of healthy cells was 33 as compared to 78 in the NGF-treated cultures. At both time points the numbers of AChE-positive cells undergoing degeneration were not significantly different with respect to the presence or absence of NGF in the respective cultures. This data suggests that NGF treatment increases the numbers of AChE-positive cells observed, by enhancing expression of AChE. No evidence for an actual cell survival effect was obtained. Supported by NS 25787, the Alzheimer Disease and Related Disorders Assoc., and the Brain Res. Fndtn. of the Univ. of Chicago.

NEURONAL DEATH I

150.1

LONG-TERM NUCLEUS BASALIS LESIONS INDUCE NEURONAL LOSS OR ATROPHY IN NEOCORTEX, AMYGDALA, AND ENTORHINAL CORTEX. G.W. Arendash, J. Mazziotta*, V. Dillela*, S. Saba*, P. Mouton*, V. Panzarino*, and R. Randhawa*. Dept. of Biology, University of South Florida, Tampa, FL 33620

We have previously reported a marked neuronal loss within the fronto-parietal cortex long-term (14 months) after nucleus basalis magnocellularis (nBM) lesioning in the rat (Science 238:952, 1987). In order to quantify the time-course of this neocortical cell loss, as well as to quantify neuronal changes in other brain areas we know to be affected by nBM lesions, adult rats were infused unilaterally or bilaterally with ibotenic acid into the nBM and sacrificed 3 to 22 months later. Significant neuronal losses in fronto-parietal cortex were first evident at 5 months after lesioning and became progressively more severe (often 30% or higher) at time points thereafter. Through 14 months after unilateral lesions, no decrease in neuronal density was observed in the basolateral nucleus of the amygdala (BLA) or in layers 2 and 3 of the entorhinal cortex. However, a significant 36% decrease in mean neuronal area occurred within the BLA by this time point. Also, significant neuronal atrophy within entorhinal cortex layer 2 was present by 5 months following unilateral lesions; this entorhinal atrophy was more severe at later post-lesion time points. The progressive, protracted nature of these degenerative changes suggest a mechanism involving anterograde transneuronal degeneration, most probably initiated by a lesion-induced loss of nBM cholinergic neurons.

150.2

DISAPEARANCE OF TRANSMITTER-ASSOCIATED ENZYME STAINING DOES NOT CORRELATE WITH DEATH OF AXOTOMIZED CHOLINERGIC NEURONS B.E. Lams*, O. Isacson, M.V. Sofroniew. Department of Anatomy, University of Cambridge, England

To assess the validity of using loss of transmitter-associated enzyme staining to document the death of injured cholinergic neurons, we have compared the disappearance of staining for choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) with the death or survival of cholinergic neurons following axotomy, as documented by other means. Neurons in the vagal and hypoglossal nuclei were examined because they can unambiguously be identified using Nissl stains or retrogradely transported dyes which remain intracellularly in live cells for many weeks following transport. At 7 d or 28 d post axotomy, staining for ChAT or AChE had disappeared from >95% or >70% of vagal neurons respectively and from >50% or <15% of hypoglossal neurons respectively. In contrast, no significant losses of either vagal or hypoglossal neurons were found at 7 d or 28 d post axotomy using Nissl stains or detection of True Blue which had been transported retrogradely prior to axotomy. Longer survival times and similar studies with basal forebrain cholinergic neurons are currently under investigation. These findings show that intracellular levels of the transmitter-associated enzymes ChAT and AChE can be regulated independently of neuronal survival following axotomy, and that absence of ChAT or AChE staining is not an absolute indicator of the death of cholinergic neurons.

150.3

Numerical reduction and proliferation during development of frog trochlear motoneurons

R. Sonntag* and B. Fritzsch, Fac. Biol., Univ. Bielefeld, 4800 Bielefeld, FRG.

During vertebrate development, the proliferation of motoneurons usually ceases before a period of cell death is believed to achieve a proportional, quantitative relation between pre- and postsynaptic elements (Oppenheim, R.W., TINS 8:487, 1985). Previous studies of the trochlear motoneurons of Xenopus laevis revealed a significant decrease in number between st 42 and st 46 (Sonntag, R. & Fritzsch, B., Neurosci. Lett. 77:143, 1987); the number of muscle fibers of the sole target muscle remains constant throughout these stages. Subsequently, the number of motoneurons, nerve fibers, muscle fibers and neuromuscular endplates increases throughout larval life. ^{3}H-Thymidine injections at the onset of the phase of numerical reduction result in 25% ^{3}H-Thymidine labelled trochlear motoneurons, as identified by retrograde HRP-filling. Single motoneurons show double labelling even after ^{3}H-Thymidine injection at st 49, i.e. long after the initial numerical reduction. These data show that a continuous motoneuron proliferation is overlaid by an early phase of numerical reduction in the frog trochlear system. - This work was supported by DFG, SFB 223.

150.4

VASOACTIVE INTESTINAL PEPTIDE VIA cAMP RESCUES MAMMALIAN RETINAL GANGLION CELLS FROM TETRODOTOXIN-INDUCED DEATH. Peter K. Kaiser* and Stuart A. Lipton (SPON: A. Ganser). Dept. of Neurol., Children's Hosp. & Harvard Med. Sch., Boston, MA.

Tetrodotoxin (TTX, 1 μM) causes death in 50% of rat retinal ganglion cells (RGCs) *in vitro* during a critical period of development [Lipton, *PNAS* 1986;83:9774]. Since natural cell death *in vivo* occurs in neurons of similar type and age, and in the same proportion as that produced by TTX in culture, it is tempting to speculate that electrical activity is involved in the mechanism of natural cell death. Conditioned medium prevents TTX-induced death [Lipton, *ibid*]. Thus, a critical element for survival may represent a trophic factor related to the level of electrical activity. Here, we show in retinal cultures from 1 week-old rat pups that forskolin (100 μM) or 8-bromo:cAMP can protect against the lethal effect of TTX. cAMP is normally present in the cultures, and TTX decreases cAMP. Vasoactive intestinal peptide (VIP, 10 nM-1μM), found in some amacrine cells that synapse on RGCs, prevents *(i)* cAMP from falling, and *(ii)* the death of RGCs in the presence of TTX. The action of VIP appears specific since the related peptides PHI-27, secretin, and VIP_{10-28} are ineffective. Taken together with work on spinal cord cultures [Brenneman et al., *PNAS* 1986;83:1159], our results suggest that VIP, mediated through cAMP, has a specific trophic effect on central neurons.

150.5

THE EFFECT OF A SMALLER TARGET MUSCLE ON MOTOR NEURON DEATH DURING DEVELOPMENT. G.S. Sohal, L.R. Campbell*, S.D. Stoney, Jr. and T. Arumugam*. Med. Col. of Georgia, Augusta, GA 30912.

About half of the motor neurons produced by many neural centers die during normal development. We tested the hypothesis that target size determines the number of surviving neurons by forcing the larger trochlear nucleus (TN) of a duck to innervate the smaller superior oblique muscle (SOM) of a quail and determining the number of surviving neurons. Chimeras were produced by substituting the embryonic forebrain of a 50 hr old duck with that of a 40 hr old quail. The quail origin of the SOM was confirmed by Feulgen staining which identified the characteristic nucleoli of the quail. The smaller size of the target was confirmed by determination of myofiber number and motor endplate counts. Innervation of the target by appropriate neurons was confirmed by injection of HRP into the SOM and identification of reaction product in the cell soma of all trochlear neurons. Electrophysiologic studies demonstrated functional afferent and neuromuscular connections. The hypothesis was tested by counting the number of surviving trochlear neurons on day 20. The number of motor neurons was found not to be significantly different from those of duck and to significantly exceed those in quail suggesting that in the TN the number of surviving neurons is not determined by target size. Supported by NIH grants HD17800 and 18280.

150.6

THE PROTECTION OF SEPTAL AREA CELLS AFTER SECTION OF THE FORNIX BY NIMODIPINE

Y. Shen, A. H. Mandel and R. L. Isaacson Center for Neurobehavioral Sciences, Dept. of Psychology State University of New York at Binghamton, New York 13901

Damage to the fimbria-fornix induces the death of cells in the medial septal complex. The death of such cells is not, however, a necessary consequence of the lesion since the direct application of nerve growth factor (NGF) to the septal area preserves many cells in this area. A calcium "overloading" of mitochondrial membranes may be involved in the pathophysiology of the cell death. In the brain nimodipine is an antagonist of "L" calcium channels and it has been shown to protect both cardiac cell and neurons from ischemia. In this study, we examined the effect of nimodipine on septal area cells after transection of fimbria-fornix. Complete unilateral fimbria-fornix transections were made in adult male rats. Immediately afterwards, the animals were injected with nimodipine (20 µg/rat) i.p. in a PEG 400 vehicle. Control animals received only the vehicle. The injections were given daily for next 7 days. At different times after surgery, the brains of the rats, especially the medial septal area were examined using histochemical staining for of acetycholinesterase (AChE) or Cresyl Violet.

One day following the transection no decrease in the number of cells was observed in the medial septal area. A substantial loss of both AChE-stained cells and Nissl-stained cells was noted at 14 days. The loss of AChE stained cells was 52% in the medial septal area of animals receiving the vehicle, but there was little change (-4%) in the drug- treated rats. In the Nissl stained sections of lesioned controls, the septal cells were decreased 21%, while in the drug treated animals, the loss was only 2%. At 7 days, the effect of nimodipine on the preservation of septal cells was not as great as at 14 days.

150.7

DIPYRIDAMOLE AND BRAIN DIALYSATE ADENOSINE CONCENTRATION DURING CEREBRAL ISCHEMIA IN NEONATAL PIGLETS.

T. S. Park*, R.Rubio* and R.M.Berne*, (SPON:J.A.Jane).
Dept. of Neurosurgery & Physiology, Univ of Virginia Sch. of Med., Charlottesville, VA 22908

We have demonstrated in neonatal piglets that hypoxia and seizures elevate brain interstitial fluid adenosine (ISF ADO). While dipyridamole (DP) inhibits transport of adenosine across the myocardial cells and elevates myocardial ISF ADO, its effects on *in vivo* brain ISF ADO under control and ischemia in the neonate are unknown. In this study, we sampled ISF ADO of ketamine-anesthetized piglets (<5 days of age) using the brain dialysis technique. Dialysis probes were placed in the bilateral frontal cortex; artificial CSF with or without DP (10^{-4}M) was infused through the probes on each side. 5-min cerebral ischemia was induced by clamping the subclavian and brachiocephalic arteries via a thoracotomy. Dialysate samples were collected every 5 min.

Results	Dialysate s DP	Dialysate c DP
control	0.20±0.03	0.45±0.10†
ischemia	0.96±0.23*	1.79±0.89*
p ischemia1	3.05±0.72*	3.58±0.67*
p ischemia2	0.65±0.14	2.04±0.56*†
p ischemia3	0.22±0.04	0.76±0.25*

Values are means±SE of dialysate ADO (µM). *=p<0.01 vs control; †=p <0.05 s DP vs c DP

These data indicate that piglet ISF ADO rises during and immediately after cerebral ischemia; DP increases resting ISF ADO and the period of elevated ISF ADO following ischemia via its *in vivo* inhibition of transport of adenosine. Supported by NS009240 & NS21045.

150.8

AN OVERVIEW OF THE PATTERN, MORPHOLOGY, AND POSSIBLE MECHANISMS OF CELL DEATH IN THE NEURAL TUBE OF 11-DAY CONTROL RAT EMBRYOS AND COMPARABLE EMBRYOS EXPOSED TO DEFICIENCIES OF ZINC, FOLIC ACID, VITAMIN E, AND TO NICOTINE AND ALCOHOL. R.S. Tuisl, I. Dreosti, I. Record, M. Joschko, A. Harding and J. Bremert. Dept. of Anatomy, University of Adelaide, and CSIRO, Adelaide, Box 498 G.P.O. S.A. 5001.

In the past decade, as part of a multidisciplinary study, we have examined the effect of maternal exposure to agents on the developing neural tube in a large number of 11-day control and experimental rat embryos. Three major observations are summarised. Firstly, in the control embryos, the incidence of cell death in the recently closed portion of the neural tube ranged from 0.26 to 0.42%. The details of cell death were indistinguishable from those in experimental animals. Secondly, the incidence of cell death was significantly higher than in the controls when a single agent was used. Thirdly, when zinc deficiency was combined with another agent the incidence of cell death increased markedly. For example, when zinc and vitamin E deficiencies were superimposed, TEM showed extensive cell death in both mesenchymal and neural tube tissues. SEM revealed collapse of surface features of embryos and open neural tubes. In yet another experiment there was a three-fold increase in the incident of cell death and malformation when zinc deficiency was combined with folic acid deficiency, than when either of the two agents was applied alone. There was evidence that cell death occurred throughout the neural tube and extended from those cells lying near the lumen to those on the mesenchymal border of the tube. In the second example the mechanism of cell death is probably synergistic rather than additive.

150.9

MORPHOLOGICAL AND IONIC CHANGES IN IRREVERSIBLE CEREBRAL ISCHEMIA: EFFECTS OF GANGLIOSIDE PRE- AND POST-TREATMENT. A. Gorio, A.M. DI GIULIO, V. DE CRESCITO*, W. YOUNG. Inst. Pharmacol. Sci., Univ. of Milano, Via Balzaretti 9, Milano, Italy, and Dept. Neurosurg., New York Univ. Med. Center, New YorK, N Y

Permanent middle cerebral artery occlusion (MCAo) caused morphological and ionic changes which were monitored up to 7 days post-lesioning. Ganglioside daily treatment 30 mg/kg was performed either beginning 1 or 3 days prior or immediately after MCAo up to sacrifice. The results show gradual Na loading and K loss with maximum between 6-24 hours. Ca gradually accumulates reaching maximum level at 7 days. Ganglioside treatment failed to protect from early ionic changes, but remarkably blocked the late Ca loading occurring between 1 and 7 days. The morphology of the interzone between ischemic dying tissue showed an intense axonal outgrowth.

150.10

AFFERENT CONTROL OF NEURONAL SURVIVAL IN THE DEVELOPING BRAIN. R. Linden and A.S. Renteria*, Inst. de Biofisica UFRJ, Rio de Janeiro, Brazil

Developmental neuron death is classically attributed to limited target space, but it has been shown that developing afferents may control neuron death. We tested the hypothesis that the afferents may determine the number of target neurons. The model was the direct projection from the rat superior colliculus (SC) to the middle division of the ipsilateral parabigeminal nucleus (Pbm). Partial deletions of the SC were obtained in newborn rats by aspiration or contralateral enucleation. The deafferented Pbm was quantitatively analyzed after the period of natural cell death. The number of neurons surviving in Pbm was linearly related to the number of neurons remaining in the SC. Lesions limited to the caudal third of SC produced no cell loss in Pbm, consistent with the lack of a tectal projection therefrom. Equivalent cell loss distributed across SC after eye removal, however, reduced the number of neurons in Pbm by predictable amounts. Thus, the number of neurons may be determined by their afferents. The results support our hypothesis of a major role of afferents in the control of quantitative matching in the developing brain. (CNPq, FINEP, CEPG-UFRJ)

LENGTHY ADMINISTRATION OF LOW-PROTEIN DIET TO ADULT RATS INDUCES CELL LOSS IN THE HIPPOCAMPAL FORMATION BUT NOT IN THE MEDIAL PREFRONTAL CORTEX. M.M.Paula-Barbosa, J.P.Andrade*,F.P.Azevedo*, M.D.Madeira* and M.C.Alves*, Dept. of Anatomy, Oporto Medical School, Portugal.

Reduction in the number of neurons have been described in adult rats submitted to perinatal protein deprivation. Conversely, it was accepted that the mature CNS was resistant to this condition. Yet, we have demonstrated that 2--month old rats fed with a low-protein diet (8% casein-ICN) for 6, 12 and 18 months showed marked cerebellar granule cell loss. Thus, we decided to extend these investigations to the hippocampal formation (HF) and to the prelimbic (PL) area of the prefrontal medial cortex and compare the results with those obtained in aged-matched controls (27% casein).

Groups of 6 rats treated as above refered were used. The numerical densities of the HF granule cells and CA3 pyramidal cells (6,12 and 18 months) and the pyramidal cells of layer III of the PL area (6 and 18 months) were determined using the unbiased disector method applied to epon embedded serial semithin sections. In the HF we found a significant decrease of both cell types after 6 months of treatment, whereas in the PL area no significant cell reduction was detected. We concluded that low-protein diet-induced neuronal loss is a marked and widespread phenomenon, although displaying regional selectivity.

CYCLOHEXIMIDE INHIBITS ECDYSTEROID-REGULATED NEURONAL DEATH IN THE MOTH MANDUCA SEXTA. S.E. Fahrbach and J.W. Truman.Dept. of Entomology, Univ. of Illinois, Urbana, IL 61801 and Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

Half of the neurons in the unfused abdominal ganglia of the moth Manduca sexta die during the first 3 days of adult life. This death is a response to the decline in blood ecdysteroids that occurs at the end of metamorphosis. We have asked whether the response to the withdrawal of the hormone requires new protein synthesis by studying the effects of treatment with cycloheximide.

The stage of degeneration of the D-IV neurons was used as an indicator of neuronal death. Moths were given single injections of cycloheximide (200 ug) or saline vehicle at 2 hr intervals from the time of adult emergence until after the onset of degeneration. Treatment with cycloheximide before the steroid hormone commitment point (10 hr before the onset of degeneration) or after the neurons had begun to die had no effect on the process of degeneration. However, treatment with cycloheximide after the steroid hormone commitment point and before the start of degeneration significantly delayed the onset of death. This treatment was effective in delaying death even when given as late as 1-2 hr before the D-IV neurons initiate degeneration. An identical pattern of results was seen when the effect of cycloheximide on the degeneration of other identified motoneurons (MN-2, MN-12) was studied.

MK-801 PREVENTS HYPOXIC-ISCHEMIC HIPPOCAMPAL NEURODEGENERATION IN NEONATAL RATS. L.M. Ford, M.H. Fogelson,* A.B. Norman and P.R. Sanberg. Lab. of Behavioral Neuroscience, Dept. of Psychiatry, College of Medicine and Dept. of Ped. Neurology, Children's Hospital, University of Cincinnati, Cincinnati, Ohio 45267.

Treatment with the glutamate N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 (Merck, Sharp, Dohme) reduces hypoxic-ischemic (HI) neurodegeneration. We evaluated the ability of MK-801 to prevent hypoxic-ischemic hippocampal neurodegeneration in neonatal rats, thus resulting in improved neurologic/behavioral outcomes. Seven day old rats with and without MK-801 pretreatment were subjected to unilateral carotid ligation followed by hypoxia. At age 30 days, spontaneous alternation behavior (SAB) to evaluate hippocampal learning and memory functions were measured; mean alternation scores were: normal controls (N=14) 77%, HI/MK-801 (N=29) 74%, HI/saline (N=28) 64%. The HI/saline group demonstrated significant impairment in SAB vs. controls and HI/MK-801 groups ($p<0.01$). Histological studies revealed pyrimidal neuronal cell loss in the hippocampal CA1 region in HI/saline group, while MK-801 treatment prevented cell loss ($p<0.01$). While hippocampal lesioned rats showed defective learning and memory, MK-801 treatment was neuroprotective. Pharmacologic blockade of the NMDA receptor prevents neonatal asphyxial brain damage.

REDUCTION OF NATURALLY OCCURRING NEURONAL DEATH IN VIVO BY THE INHIBITION OF PROTEIN AND RNA SYNTHESIS. R.W. Oppenheim and D.M. Prevette.* Anatomy Dept., Wake Forest Univ., Winston-Salem, NC 27103.

Recent in vitro studies of chick sympathetic ganglion cells and in vivo studies in invertebrates suggest that occurrence of embryonic cell death requires gene expression and active protein and RNA synthesis. These observations indicate that cell death is a particular type of differentiation or cell fate and thus may be regulated by the same general mechanisms involved in the fate of all developing cells. To determine whether active protein or RNA synthesis may be necessary for the occurrence of neuronal death in vivo, we treated chick embryos with inhibitors of protein and RNA synthesis and examined their effects on the degeneration of motoneurons (MN) and DRG cells. Embryos were treated with puromycin, actinomycin-D and cycloheximide by administration onto the chorioallantoic membrane once every 2-3 hours over a 9-12 hour period on embryonic day 8. At the end of the treatment, embryos were killed, staged and processed histologically. Pyknotic motoneurons were counted throughout the lumbar region and dying DRG cells were counted in the third lumbar (L3) DRG. Based on their morphological stage as well as on other criteria (e.g., neuronal size) embryos developed normally following treatment with the above agents. At the appropriate dose, all of the agents significantly decreased the number of pyknotic cells. For example, cycloheximide (1 µg) reduced the total number of dying MN from 337 ± 24 to 53 ± 8 ($p<0.001$) and the number of dying L3 DRG cells from 463 ± 91 to 63 ± 26 ($p<0.01$). In the future it should be possible to use the techniques of molecular biology to identify the specific genes and gene products responsible for the determination of the cell death fate in developing neurons. Supported by NS 20402.

ROLE OF VOLTAGE-ACTIVATED CALCIUM CHANNELS IN THE PROMOTION OF NEURONAL SURVIVAL BY POTASSIUM. F. Collins. Synergen. 1885 33rd St., Boulder, CO 80301.

Elevated concentrations of potassium in the culture medium, sufficient to depolarize cells, have been reported to promote the survival of embryonic nerve cells in vitro. One consequence of potassium-induced depolarization would be the opening of voltage-activated calcium channels. To determine whether the activation of such channels is involved in the survival-promoting effect of elevated potassium, we have used dihydropyridine antagonists and agonists of voltage-activated L-type calcium channels.

We have observed that the survival-promoting effect of potassium on chick embryo ciliary ganglionic nerve cells is blocked by the calcium channel antagonists nitrendipine and PN200-110. The calcium channel agonist BAY K 8644, in contrast, strongly potentiates the survival-promoting effect of elevated potassium. These results indicate that activation by elevated potassium of dihydropyridine-sensitive, presumed L-type voltage-activated calcium channels is necessary and sufficient to promote neuronal survival.

151.1

Effects of Neuroleptic and Reinforcement Manipulations on Initiation Latencies in a Food-Rewarded Task. E. O'S. Hammond and A. Ettenberg. Department of Psychology, University of California, Santa Barbara, CA 93106.

Controversy exists concerning the observation of neuroleptic-induced deficits in response initiation. For some, such deficits represent a motoric incapacitation which might account for some of the behavioral data otherwise thought to support a drug-induced "anhedonia" position. Others have suggested that the major neuroleptic deficit is in the animals' ability to maintain responding and that any increases in response initiation are too small to be of behavioral significance. In the present study, the latencies to contact a food cup were measured following repeated presentations of a tone that predicted reward availability. Reinforcement reductions and haloperidol pretreatments (0.15 & 0.3 mg/kg) produced comparable results in which initiation deficits tended to increase within a session. In contrast, a nembutal-treated "motor" control group produced response latencies that were initially high but decreased over the course of the test session. These results suggest that while neuroleptics do produce deficits in response initiation, the pattern of these deficits is most comparable to that which results from a reduction in actual reward magnitude.

151.2

PARADOXICAL EFFECTS OF HALOPERIDOL ADMINISTERED DURING THE EXTINCTION PHASE OF AN OPERANT RUNWAY TASK. J.C. Horvitz and A. Ettenberg. Dept. of Psychology, University of California, Santa Barbara, CA 93106.

Neuroleptic drugs typically produce deficits in rates of operant responding. In investigations of such deficits, a paradoxical effect of haloperidol (HAL) was revealed. Male albino rats were trained to traverse a straight-arm runway for food reward during eight single daily acquisition trials. Rats then received daily non-rewarded (extinction) trials over the next four days. On the fourth extinction trial, animals traversed the runway under the influence of either 0, 0.15 or 0.30 mg/kg of HAL, i.p. Surprisingly, the group receiving the high dose of HAL (0.30 mg/kg) showed dramatic and reliable increases in running speed relative to animals receiving either the vehicle (.002 M lactic acid) or the lower dose of the drug. Having twice replicated this phenomenon, additional experiments were conducted to test incentive motivational, attentional, and motoric hypotheses which might account for this neuroleptic effect.

151.3

Effects of haloperidol on conditioned place preferences produced by electrical stimulation of medial prefrontal cortex. C.L. Duvauchelle* and A. Ettenberg. Dept. of Psychology, University of California, Santa Barbara, CA 93106

Although rats will work to obtain electrical stimulation of the prefrontal cortex, the precise neurochemical substrates mediating the rewarding effects of such stimulation remain unclear. In the present study, a Conditioned Place Preference procedure (see Duvauchelle & Ettenberg, Soc Neurosci Abstr, 1987; 13:1323) was used to investigate the effects of dopamine antagonist application on rewarding prefrontal stimulation.

Rats exhibited strong preferences for the side of a two-compartment test apparatus in which they experienced sessions of experimenter-administered 0.5 sec trains of PFC sine-wave 60Hz stimulation. Pretreatment with the dopamine antagonist drug, haloperidol (0.15 & 0.3 mg/kg IP) resulted in a dose-dependent reduction in the magnitude of observed place preferences. Preference tests were conducted 24 hours after drug-conditioning trials and, hence, were not subject to motoric or other nonspecific actions of the neuroleptic treatments. These results are consistent with the view that dopamine neurotransmission is required for the demonstration of brain stimulation reward in the medial prefrontal cortex.

151.4

DOPAMINE AUTORECEPTOR AGONIST PROPERTIES OF A NOVEL SERIES OF [3-(4-PHENYL-1-PIPERAZINYL)PROPOXY]AROMATIC COMPOUNDS. **L.D. Wise*, H.A. DeWald*, J.J. Jaen*, B.W. Caprathe*, T.A. Pugsley and T.G. Heffner (SPON: F.M. Hershenson). Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, MI 48105.**

We have reported that 7-[3-(4-phenyl-1-piperazinyl)-propoxy]-2H-1-benzopyran-2-one (PD 116,795) is an orally active dopamine (DA) autoreceptor agonist (Soc. Neurosci. Abst. 13, #128.9, 1988). The unique properties of this agent led us to examine related phenylpiperazines for DA agonist activity. Compounds in which the benzopyranone of PD 116,795 was replaced with indole or benzofuran did not have DA agonist activity as assessed by DA receptor binding and inhibition of GBL-stimulated brain DA synthesis in rats. Replacement with a phenol afforded weak DA agonist activity in biochemical tests and resulted in loss of locomotor inhibition (LMI) in rats after oral administration. Replacement of the benzopyranone with aromatic systems such as aniline, chromone, or chromanone provided agents with biochemical and behavioral profiles comparable to that of PD 116,795. More potent behavioral activity (LMI ED_{50}s of 1-3 mg/kg PO) was seen with benzomorpholinone, carbostyril or quinoline analogs. These results indicate that orally active DA autoreceptor agonists can be obtained by replacement of the benzopyranone of PD 116,795 with related aromatics.

151.5

SPONTANEOUS ACTIVITY OF MIDBRAIN DA NEURONS AFTER ACUTE AND CHRONIC ADMINISTRATION OF THE SELECTIVE D-1 ANTAGONIST, SCH 23390. Jeffrey M. Goldstein and Linda C. Litwin*, Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

We previously reported that SCH 23390 (SCH) potently reversed d-amphetamine suppresion of substantia nigra (A9) and ventral tegmental (A10) DA cell firing. Since activity in this test is correlated with clinical antipsychotic (AP) properties, SCH may be a potential AP. To further explore this possibility, the effects of SCH on the population response of A9 and A10 DA cells were investigated. One hour pretreatment with SCH (0.0125, 0.025, 0.05 mg/kg sc) caused a dose-related increase in the number of spontaneously firing DA cells in both the A9 and A10 areas. There was no evidence of differential effect at any acute dose. Chronic (28 day) treatment with SCH (0.05 mg/kg sc) caused a selective decrease in the number of A10 DA cells which was found to be reversed by a subsequent injection of apomorphine, inferring that the decrease was due to depolarization inactivation. On A9 DA cells, chronic treatment with SCH caused a slight but nonsignificant increase in the number of actively firing cells. The ability of SCH to cause depolarization inactivation of A10 DA cells after chronic administration confirms and extends our previous findings that this agent may have potential AP properties. Moreover, the lack of effect of chronic SCH on A9 DA cells suggests the possibility that this agent may not induce neurological side effects.

151.6

U-65556A: A PROPOSED NOVEL ANTIPSYCHOTIC. N.F.Nichols, P.J.K.D.Schreur, and J. Szmuszkovicz*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

U-65556A (2,3-dihydro-N,N-dimethyl-1H-phenalen-2-amine monohydrochloride) appears to have both dopamine autoreceptor agonist and postsynaptic antagonist activities. It was tested in Sprague-Dawley rats for its effects on open-field locomotor activity in several protocols (Omnitech Digiscan monitors) and on turning behavior (visual scoring).

In the exploratory activity test, U-65556A showed mixed activity. At 3 mg/kg it had a profile similar to that of autoreceptor agonists (decreased total distance, increased number of movements, modestly increased rest time), and at 30 mg/kg it was similar to postsynaptic antagonists (decreased total distance and greatly increased rest time).

In two other tests, U-65556A showed only postsynaptic dopamine antagonist activity. In rats habituated to the test apparatus, 30 mg/kg significantly antagonized both apomorphine-and amphetamine-induced hyperactivity. It also antagonized amphetamine-induced turning in rats with unilateral substantia nigra (SN) lesions.

U-65556A had no postsynaptic dopamine agonist activity. In habituated rats, it did not stimulate locomotor activity. When given to rats with unilateral SN lesions, it caused no turning activity.

In conclusion, U-65556A shows both autoreceptor agonist activity and postsynaptic antagonist activity. It is active subcutaneously, intraperitoneally, and orally. The oral and intraperitoneal potencies are approximately equal.

151.7

U-65556A, A NEW ATYPICAL ANTIPSYCHOTIC. M.F.Piercey, J.Szmuszkovicz*, W.E.Hoffmann, J.T.Lum, and W.H.Darlington*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

U-65556A (1H-phanalen-2-amine,2,3-dihydro-N,N-dimethyl, monochloride) and its desmethyl derivative, U-64273A (1H-phenalen-2-amine,2,3-dihydro-N-methyl, monochloride) were evaluated for effects on firing rates of dopaminergic neurons in the substantia nigra pars compacta (SNPC) and on 5-HT neurons in the dorsal raphe (DR) of chloral hydrate-anesthetized rats using standard criteria (Bunney et al., JPET 185:560, 1973; Aghajanian et al., JPET 137:178, 1977). In SNPC, U-65556A and U-64273A reversed amphetamine-induced depressions of firing rates with ED50's of 150 and 2600 ug/kg, respectively. ED50's for haloperidol and clozapine were 7 and 1600 ug/kg, respectively. Haloperidol, but not clozapine, U-65556A or U-64273A increased firing rates of SNPC cells. Compared to amphetamine antagonism potencies, haloperidol and U-64273A were equipotent in reversing depression of SNPC firing by autoreceptor doses of apomorphine (100 ug/kg). Clozapine and U-65556A were weaker in reversing apomorphine (amph antag/apo antag potency ratios of 3.9 and 8.0, respectively), suggesting predelictive effects at postsynaptic sites. The related dihydrophenalene, U-68553B, was a dopamine agonist which depressed SNPC cells. In DR, U-65556A, U-64273A, and U-68553B all depressed firing rates with ED50's of 275, 1450, and 46 ug/kg, respectively. It is concluded that 1) both dopamine agonists and antagonists exist in the dihydrophenalene series, and 2) U-65556A is a novel antipsychotic with clozapine-like properties.

151.8

DISTINCTION OF THE NOVEL ANTIPSYCHOTIC CI-943 FROM DOPAMINE ANTAGONISTS AND DOPAMINE DEPLETING AGENTS. **T.G. Heffner, J.N. Wiley*, A.E. Williams* & T.A. Pugsley. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.**

CI-943 (8-ethyl-7,8-dihydro-1,3,5-trimethyl-1H-imidazo[1,2-c]pyrazolo[3,4-e]pyrimidine) is a novel antipsychotic candidate that is not a brain dopamine antagonist. We reported previously that CI-943 inhibits spontaneous locomotion, apomorphine-induced cage climbing, self- stimulation and conditioned avoidance responding in rodents and primates (Soc. Neuroscience Abst. 13:459-460). Unlike dopamine antagonists, CI-943 augments locomotor stimulation caused by amphetamine in mice and rats. But, CI-943 neither induced stereotyped behavior nor augmented amphetamine-induced stereotypy in rats, and it did not potentiate apomorphine-induced climbing in mice. Unlike reserpine, high doses of CI-943 neither depleted brain dopamine nor potentiated the locomotor stimulant effect of apomorphine in rats. In addition, doses of CI-943 higher than those necessary to reduce locomotor activity reversed reserpine-induced sedation in rats. These results indicate that the preclinical profile of CI-943 differs from that of dopamine antagonists and dopamine depleting drugs. The ability to augment effects of amphetamine and to reverse effects of reserpine suggest that CI-943 may provide efficacy for negative schizophrenic symptoms.

151.9

EFFECTS OF HALOPERIDOL ON STRESS-INDUCED CHANGES IN MESOCORTICAL DOPAMINE NEURONS. David J. Mokler and Tammy Hay*. Dept. Pharmacology, Univ. New England, Biddeford, ME 04005.

The effects of subchronic administration of haloperidol (HAL) on changes in medial prefrontal cortex dopamine neurons following acute or chronic stress were examined. Male Fischer-344 rats were exposed to an acoustic stressor (115 dB) for 2 sec/min for 2 hours for one day or eight days over a period of sixteen days. During the last ten days half of the animals received 0.5 mg/kg HAL s.c. Following the last day of chronic stress or the acute stress session animals were sacrificed. Medial prefrontal cortex was dissected out and analyzed by HPLC with electrochemical detection. Norepinephrine or 5-hydroxytryptamine were unaffected by stress or HAL or the combination. Levels of DA were increased by chronic stress, while dopamine turnover as estimated by the ratio of either of the dopamine metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) or homovanillic acid (HVA) to dopamine was increased by acute stress and decreased by chronic stress. HAL increased the levels of HVA in control animals and the levels of HVA and DOPAC in acute and chronic stress. This resulted in a further increase in dopamine turnover following acute stress, but a reversal of the decrease in turnover following chronic stress. These data suggest that HAL may reverse the stress-induced changes in mesocortical dopamine metabolism following chronic stress. This may relate to the anti-psychotic efficacy of haloperidol.

151.10

EFFECT OF ATYPICAL AND TYPICAL ANTIPSYCHOTIC DRUGS ON D-1 and D-2 DOPAMINE (DA) RECEPTORS AND SEROTONIN $(5\text{-HT})_2$ RECEPTORS. **S. Matsubara and H.Y. Meltzer Case Western Reserve University School of Medicine Cleveland, Ohio 44106**

The biochemical features which distinguish atypical antipsychotic drugs (AAD) from typical AD (TAD) are unclear. We determined the affinities for D-1 and D-2 sites in striatal membranes using ^{3}H-SCH-23390 and ^{3}H-spiperone, respectively and for the 5-HT_2 binding site in frontal cortex using ^{3}H-ketanserin of 6 AAD (clozapine, fluperlapine, RMI-81582, setoperone, melperone and amperozide) and 7 TAD (haloperidol, chlorpromazine, loxapine, thiothixene, cis-flupentixol, thioridazine and mesoridazine) by log-probit analysis. Among the noteworthy findings were the following: 1) a discriminant function based on D-1, D-2, and 5-HT_2 values distinguished the AAD and the TAD; 2) the D-2 affinity contributed more than the D-1 and 5-HT_2 affinities to this discrimination and also to a stepwise discriminant analysis; 3) D-1 and D-2 affinities of the AAD were significantly lower than the TAD but there was no difference in 5-HT_2 affinities; 4) there was no overlap in 5-HT_2/D-2 ratio, the same was true for 5-HT_1/D-2 ratio with the exception of RMI- 81582. These results agree with Altar et al. (Brain Res Bull 16, 517, 1986) that a low 5-HT_2/D-2 ratio is characteristic of AAD but also highlight the low D-2 and D-1 affinities and a low D-1/5-HT_2 ratio.

151.11

ALPHA-ACID GLYCOPROTEIN IN PSYCHIATRIC INPATIENTS. A. Patel*, R. C. Young, R. Klein*, J. Kream* (SPON: C. A. Shamoian) New York Hospital-Cornell Medical Center, Westchester Division, White Plains, New York 10605.

Alpha-1-acid glycoprotein (AAG) is a major binding protein for psychotropic drugs. However, there is little available data concerning AAG in psychiatric patients. We have begun studies of serum AAG in patients admitted to an acute care psychiatric hospital (N = 55). Their ages ranged from 16 to 94 yrs. The median age was 56 yrs. The sex ratio was 19:36 (M:F). Their predominant diagnoses were affective disorders and schizophrenia. None had evidence of inflammatory disease. Serum AAG was determined by rate nephelometry. Mean serum AAG was 67.8 mg/dl and ranged from 19.9 to 144.0 mg/dl. In female patients, AAG was significantly positively correlated with age ($r = .43$, $p < .01$), but in male patients it was not ($r = -.23$, NS). There was a nonsignificant trend for higher AAG in female patients. AAG was not correlated with body weight. These preliminary data in psychiatric patients are in part consistent with relationships reported in normal subjects.

151.12

α_2-ADRENERGIC ANTAGONISTS AND LIPOPHILIC α_1-ADRERGIC AGONISTS BLOCK THE CLOZAPINE-INDUCED HYPOTHERMIA IN MICE. V.G. Haddox*, and M.K. Menon. Psychopharmacol. Res. Lab. V.A. Med Ctr., Sepulveda, CA 91343, and Dept. Psychiat. UCLA Sch. Med., Los Angeles, CA 90024.

Clozapine produced dose-related hypothermia in male Swiss-Webster (Charles River) mice. This response was promptly blocked by pretreatment (i.p., 10 min before) with the lipophilic α_1-adrenergic agonists St 587 (3 mg/kg) cirazoline (0.3 mg/kg) or SKF 89748 (1 mg/kg). The relative potencies of these three drugs roughly paralleled their α_1-agonistic potencies as determined by other procedures. Sgd 101/75, a lipophobic α_1-agonist did not antagonize clozapine hypothermia. This response to clozapine (6 mg/kg, i.p.) was also completely blocked by pretreatment (10 min. before, i.p.) with the α_2-adrenergic antagonists yohimbine (1 mg/kp), idazoxan (1 mg/kg), CH 38083 (5 mg/kg) and SKF 86646 (5 mg/kg). However, their antagonistic effects were more pronounced at 90 min after clozapine than at 30 min. It indicated that their effectivenesses were dependent upon the accumulation of NE in the brain areas resulting from α_2-adrenergic blockade. The suitability of clozapine-induced hypothermia as a model for the evaluation of α_1-agonists and α_2-adrenergic antagonists is being investigated. Supported by the Veterans Administration.

151.13

LITHIUM AND MAGNESIUM PREVENT HALOPERIDOL-INDUCED ABNORMAL LICKING PATTERNS. S.J. Lytle and K. M. Kantak. Lab. of Behav. Neurosci., Dept. of Psychol., Boston Univ., Boston, MA. 02215.

Alterations in the control of the oropharyngeal musculature were indirectly observed in mice after chronic neuroleptic administration by recording their licking patterns. Aberrant licking patterns follow a time course parallel to the human condition tardive dyskinesia. The present investigation compares the effectiveness of magnesium (Mg^{2+}) and lithium (Li^{2+}) in preventing this abnormal licking pattern. All groups increase the number of licks over 3 months, with potentiated effects measured with Li^{2+}/hal and Mg^{2}/hal treatments. The number of bouts was increased by haloperidol. The licking pattern as specified by the licks per bout indicates that haloperidol alters the licking pattern after 2 months of treatment which persists into the 3rd month of treatment. Li^{2+}/hal and Mg^{2+}/hal prevent this altered licking pattern, with Li^{2+}/hal and Mg^{2+}/hal producing equally potentiated effects after 2 months. After 3 months, Mg^{2+}/hal continues to prevent an altered licking pattern. Li^{2+}/Hal greatly increased the licks per bout at this time indicating that Mg^{2+}/hal may be more beneficial than Li^{2+}/hal in the long term prevention of TD.

151.14

THE USE OF CONDITIONED AVOIDANCE BEHAVIOUR IN PREDICTING ANTIPSYCHOTIC ACTIVITY. J.A.M. van der Heyden, M.T.M.Tulp* and B.Olivier. Dept of Pharmacology, Duphar B.V., P.O.Box 2, 1380 AA Weesp, The Netherlands.

Several behavioural animal models can be used to predict the antipsychotic activity such as attenuation of apomorphine-induced behaviour and/or inhibition of conditioned avoidance behaviour. The activity of neuroleptics in these models is most likely due to their blockade of DA receptors.

Drugs affecting the 5-HT system have similar effects and can thus be classified as putative antipsychotic drugs. We have studied the effect of several types of drugs affecting the 5-HT system on one-way conditioned avoidance behaviour in rats.

The 5-HT_{1a} specific compounds 8-OH-DPAT and ipsapirone were inactive in our procedure. Buspirone did show an inhibitory effect, which can be atributed to its strong DA receptor blockade. The 5-HT_{1b} agonists TFMPP and RU24969 both inhibited CAR without affecting the ER. The 5-HT precursor 5-HTP and 5-HT releaser fenfluramine did inhibit CAR in contrast to the 5-HT uptake inhibitor fluvoxamine. The 5-HT_2 antagonist ketanserine was inactive, as were the mixed 5-HT_2 / 5-HT_{1c} antagonists ritanserin and mianserin. The 5-HT_3 antagonists GR38032F and MDL72222 showed a no and non-specific effect, respectively. On basis of these data, it can be concluded that drugs stimulating 5-HT receptors inhibit conditioned avoidance behaviour comparable to the neuroleptics.

A recently developed 5-HT agonist, Befiperide also inhibits conditioned avoidance behaviour and strongly inhibits apomorphine-induced stereotypy without blocking the DA receptor. Clinical studies on its antipsychotic efficacy will have to confirm the 5-HT hypothesis on basis of which this drug was developed.

151.15

EVALUATION OF Wy47,384, A GAMMA-CARBOLINE ANTIPSYCHOTIC CANDIDATE, IN A PRIMATE MODEL OF PSYCHOSIS. R.F. Schlemmer, Jr. & J.M. Davis. U. of Illinois at Chicago & Ill. State Psychiatric Inst., Chicago, IL 60612.

Wy47,384, 8-fluoro-2,3,4,5-tetrahydro-2-[3-(3-pyridinyl)-propyl]-1H-pyrido[4,3-b]indole HCl, has been identified as an antipsychotic candidate in rodent screens. This study was designed as a preliminary evaluation of the behavioral effects of Wy47,384 (Wy) in nonhuman primates. Wy was tested alone & in combination with apomorphine (APO) which was used to induce a model psychosis. Four females from a social colony of 5 Stumptail macaques received 4 doses of Wy, 1-8 mg/kg, for 2 days in a cross-over design. Wy was given n.g. at 0700 & 1700 on day 1 & at 0700 on day 2. APO, 1 mg/kg, was given i.m. at 1015. Two 60 min observation sessions were conducted daily at 0900 & 1030. Wy produced a dose-dependent antagonism of APO-induced stereotypy, increased checking, & increased submissive gestures, behaviors which model positive symptoms of psychosis; but Wy failed to reverse social withdrawal, a negative symptom. Wy alone caused an increase in resting. Movement disorders were only noted at the highest dose for less than 20% of the time. This study demonstrates that Wy antagonizes a primate model of psychosis consistent with known antipsychotics. Although the results suggest that Wy may produce sedation & extrapyramidal side effects, these were only pronounced at doses higher than those indicative of antipsychotic activity. (Supported by Wyeth Laboratories).

EFFECTS OF ACUTE AND CHRONIC ADMINISTRATION ON CLOZAPINE LEVELS IN BLOOD PLASMA AND BRAIN TISSUE. H.F. Villanueva, J.H. Porter, N. Narasimhachari, J.K. Stewart*, B. Landa* and J.L. Wiley. Depts. of Psychology, Psychiatry and Biology, Virginia Commonwealth Univ., Richmond, VA 23284.

With a chronic dosing regimen, tolerance to the rate suppressing effects of clozapine (CLZ) on operant responding develops within 6 to 10 days (Kaempf & Porter, JPET, 243: 437-445, 1987). In order to determine possible mechanisms of this tolerance the present study measured clozapine levels in blood plasma and in frontal cortex and corpus striatum following a single acute 10 mg/kg dose of clozapine (n = 6) or following 10 days of chronic dosing with 10 mg/kg clozapine (n = 5).

HPLC assays revealed that there were no significant differences in mean CLZ levels following the acute dose or the 10 days of chronic dosing in the blood plasma or in brain tissue. However, there were significantly higher levels of CLZ in the frontal cortex as compared to the corpus striatum. These results suggest that the tolerance to CLZ's effects seen in operant studies is due to a pharmacodynamic mechanism rather than a metabolic mechanism.

	Plasma (ng/ml)	Cortex (ng/g)	Striatum (ng/g)
Acute	271.5	13.41	8.25
Chronic	281.2	14.93	9.81

EFFECTS OF RACEMIC AND ENANTIOMERIC BMY 14802, A POTENTIAL ANTIPSYCHOTIC DRUG, ON NORADRENERGIC LOCUS COERULEUS NEURONAL ACTIVITY. C.P. VanderMaelen and J.P. Braselton.* Bristol-Myers Co., Preclinical CNS Research, 5 Research Parkway, Wallingford, CT 06492.

BMY 14802 is a potential antipsychotic drug which does not bind to dopamine D2 receptors, binds to sigma sites, is active in animal models of antipsychotic efficacy, and shows some similarities to haloperidol in electrophysiological studies of A9 dopamine cells (Matthews et al., JPET, 1986, 239, 124-131; Taylor et al., Soc. Neurosci. Abst., 1985, 11, 114; Taylor & Dekleva, Drug Dev. Res., 1987, 11, 65-70). Haloperidol increases locus coeruleus (LC) neuronal firing (Dinan & Aston-Jones, Brain Res., 1984, 307, 359-362). In this study BMY 14802 and its (+) and (-) enantiomers were administered i.v. to chloral hydrate anesthetized rats, and effects on noradrenergic LC neuronal firing were observed using standard extracellular single-unit recording techniques. Both enantiomers, as well as the racemic mixture of BMY 14802 produced increases in LC neuronal firing. The dose required to increase the firing rate of an LC neuron by 25% (ED_{25}) was estimated to be 0.31 mg/kg, i.v. for (-)-BMY 14802, and 0.55 mg/kg, i.v. for (+)-BMY 14802, while the ED_{25} for racemic BMY 14802 was calculated to be 0.36 mg/kg, i.v. These results are congruent with other data suggesting that BMY 14802 may be an effective antipsychotic drug with reduced propensity for extrapyramidal side effects.

151.18

THE POTENTIAL ANTIPSYCHOTIC BMY 14802 INHIBITS SIGMA BINDING BUT NOT PCP BINDING. Duncan P. Taylor, Jennifer Dekleva,* and Susan H. Behling.* CNS Biology, Bristol-Myers Company, P.O. Box 5100, Wallingford, CT 06492-7660.

BMY 14802 has been identified as a potential antipsychotic agent in behavioral testing (**Soc Neurosci Abstr 11**: 114, 1985). In addition to its low affinity for D-1 and D-2 dopamine receptors *in vitro*, BMY 14802 did not induce catalepsy in rats. We have shown that this agent has affinity for the haloperidol-sensitive site labeled with high affinity by (+)-[^{3}H]NAN and by (+)-[^{3}H]3-PPP (**op.cit. 13**:457, 1987). However, BMY 14802 has low affinity for the site labeled by [^{3}H]TCP. These findings have been confirmed and extended employing [^{3}H]DTG to selectively label sigma sites and [^{3}H]MK-801 to label NMDA-associated PCP sites.These data suggest that if BMY 14802 proves clinically efficacious, its novel mechanism of action will provide a safer alternative to currently available agents for the treatment of schizophrenia.

Agent	[^{3}H]DTG	(+)-[^{3}H]3-PPP	[^{3}H]TCP	[^{3}H]MK-801
Haloperidol	2	1.4	>1,000	18,000
(+)BMY 14802	32	28	>10,000	>100,000
(+)3-PPP	91	24	>10,000	>100,000
(-)BMY 14802	140	310	>10,000	>100,000
PCP	1200	640	34	57

Data are mean K_I (nM) for at least 3 determinations.

152.1

SEROTONERGIC DRUG ACTION AND THE TREATMENT OF OCD. W.K. Goodman, L.H. Price, G.M. Anderson*†, P.L. Delgado, J.M. Palumbo*, G.R. Heninger and D.S. Charney. Depts. of Psychiatry and Lab Medicine†, Yale University School of Medicine, New Haven, CT 06508

The serotonin (5-HT) hypothesis of obsessive compulsive disorder (OCD) has been strengthened by recent studies showing that the potent and selective 5-HT reuptake inhibitor fluvoxamine (FVX) is superior to placebo in treating OCD. To examine the relevance of FVX's effects on 5-HT function to its antiobsessional action in OCD: 1-the efficacy of FVX was compared to the relatively selective norepinephrine (NE) reuptake blocker desipramine (DMI), and 2- CSF levels of metabolites of 5-HT, NE, and dopamine (5-HIAA, MHPG, and HVA, respectively) were measured before (drug-free) and after 6-10 wks of FVX treatment. METHODS:1-DRUG TRIAL. After 1 wk of placebo, OCD outpatients (data available on N=29) were randomized to 8 wks of double-blind FVX or DMI. Raters assessed OCD with the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) and by global improvement ("responder" = "much" or "very much improved"). 2-CSF STUDY. Lumbar CSF was obtained in 12 OCD patients (incl. 5 patients from a different FVX trial) between. 10AM and 12PM. HVA and 5-HIAA were assayed by HPLC with electrochemical (HVA, 5-HIAA) and flourometric (5-HIAA) detection. MHPG was assayed by gas chromatography-mass spectrometry RESULTS: 1-DRUG TRIAL. (Interim analysis of N=29) Only 2/14 (14%) patients treated with DMI were responders; whereas, 8/15 (53%) patients treated with FVX were responders ($p<.05$, Fisher's Exact). 2-CSF STUDY. Pre- v. post-FVX CSF levels, respectively: 5-HIAA =17.1±7 v.10.9±6 ng/ml, $p<.001$ (paired t-tests); MHPG= 6.9±1.4 v. 6.3±1.5ng/ml, $p<.05$; HVA=28.±9 v. 34.4±14ng/ml, NS. All patients showed a decrease in CSF 5-HIAA with FVX (mean reduction = 36%). There were no significant correlations between changes in OCD severity (measured by the Y-BOCS (mean improvement =37%)) and metabolite levels (either at baseline or in change from baseline). CONCLUSION: The preliminary finding that FVX is superior to DMI in treating OCD suggests that the 5-HT reuptake properties of a medication are relevant to its antiobsessional efficacy. The robust decrease in CSF 5-HIAA is evidence that chronic FVX has major effects on 5-HT function in the brain. The approx. 50% response rate to FVX and the lack of clinical correlates with CSF 5-HIAA suggest the need for other approachs to assessing the pertinent neurochemical effects of FVX in OCD.

152.2

INCREASED PLASMA CONCENTRATIONS OF α_1-ACID GLYCOPROTEIN, AN ENDOGENOUS MODULATOR OF THE PLATELET [3H]-IMIPRAMINE BINDING/5HT TRANSPORT COMPLEX, IN PATIENTS WITH MAJOR DEPRESSION. C.B. Nemeroff, K.R.R. Krishnan*, D.L. Knight*, D. Benjamin* and L.R. Meyerson. Depts. Psychiat. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710 and Med. Res. Div., Amer. Cyanamid Co., Mahwah, NJ 07430.

Many depressed patients exhibit a reduction in the density (Bmax) of platelet [3H]-imipramine binding sites (Raisman et al., Psychopharmacol 75, 368-371, 1981). This platelet [3H]-imipramine binding site is similar to, if not identical with, the [3H]-imipramine binding site identified on presynaptic 5HT nerve terminals and is allosterically coupled to, but distinct from, the serotonin transporter. Recently an α_1-acid glycoprotein has been isolated from human plasma which fulfills criteria for an endogenous modulator of the platelet [3H]-imipramine binding site - 5HT transport complex (Abraham et al., Biochim Biophys Acta 923, 8-21, 1987). In the present study, the plasma concentration of this α_1-acid glycoprotein was measured by radial diffusion assay in 21 drug-free patients that fulfilled criteria for major depression and 18 controls. Plasma concentrations (μg/ml) of the α_1-acid glycoprotein were significantly ($p < 0.02$) elevated in the depressed patients (mean ± SEM = 858 ± 60) when compared to the normal controls (mean ± SEM = 687 ± 35). Ten of the 21 depressed patients had plasma concentrations higher than the highest normal control. These results provide the first evidence of alterations of an endogenous modulator of [3H]-imipramine binding/5HT transport in depression (Supported by NIMH MH-40159 and MH-42088).

152.3

ACUTE AND CHRONIC EFFECTS OF MONOAMINE UPTAKE BLOCKADE ON PARADOXICAL SLEEP IN THE CAT. R.J. Ross, W.A. Ball*, P.J. Gresch* and A.R. Morrison. VA Med. Center and Depts. of Psychiatry and Animal Biology, Univ. of Penna. Schools of Med. and Vet. Med., Phila., PA 19104

The monoamines norepinephrine (NE) and serotonin (5-HT) may inhibit paradoxical sleep (PS) generation. The relatively specific NE uptake blocker desipramine (DMI) suppresses PS acutely in the cat (Hishikawa, Y., et al., Electroenceph. Clin. Neuro., 19:518, 1965). 5-HT uptake inhibition likely has a similar effect acutely (Sommerfelt, L., et al., J. Neural Transm., 68:127, 1987). Less is known about the chronic effects of monoamine uptake blockers, yet clinical experience suggests their antidepressant actions take 2-3 weeks to appear. We investigated changes in PS in the cat after single and repeated doses of DMI or the selective 5-HT uptake blocker sertraline. Six cats were implanted with standard EEG, EOG, EMG, and lateral geniculate electrodes. Sleep was recorded first under placebo then after acute (day 1) and chronic (19 days) p.o. administration of drug (0.75 mg/kg acute dose; 2.0mg/kg chronic daily dose). Three cats received only DMI, two received only sertraline, and one received both drugs (27 day "washout" period). Six-hour records were scored according to standard criteria (Ursin, R., Sterman, M.B., Brain Info. Serv./U.C.L.A., 1981). PS percentage (PS time/total sleep time) fell after acute DMI (25.0 vs. 4.0%, $p<.05$), rose again after chronic DMI (4.0 vs. 14.0%, $p<.05$), but failed to reach placebo level ($p<.05$). Likewise, there was a tendency for PS percentage to drop after acute sertraline (23.0 vs. 6.0%) and then return towards baseline after chronic sertraline (6.0 vs. 17.0%) ($p<.07$). Thus, chronic administration of both NE and 5-HT uptake blocking drugs leads to some recovery in PS despite the marked initial decline also noted by other investigators. Receptor mechanisms that may underlie these behavioral changes remain to be determined. (Supp. by VA Med Res Svc)

152.4

CAN TIME SERIES ANALYSIS OF SEROTONIN TURNOVER TEST THE THEORY THAT CONSCIOUSNESS IS A FIELD? N. Pugh*, K.G. Walton and K.L. Cavanaugh* (SPON: V. Argiro). Dept. of Chem. and Dept. of Mngmnt. and Public Affairs, Maharishi International University, Fairfield, IA 52556.

Over 30 studies in the last 15 years support the theory that consciousness in its pure form is a field. These studies, mostly sociological in nature, were inspired by Maharishi Mahesh Yogi's claim in 1960 that 1% of a population practicing the Transcendental Meditation (TM) technique would improve the quality of life for the entire population. The basis of the claim is the central theme of the ancient Vedic tradition which he represents, namely, that the unified field of natural law is nothing other than the "least excited state" of individual consciousness, "pure consciousness", a field directly accessible to the human nervous system. Many of the above studies purport to show that group practice of the TM and related TM-Sidhi techniques has a more powerful beneficial effect than individual practice. The question we addressed is whether an increase in the number involved in the group practice of these techniques at MIU might increase the rate of 5-HIAA excretion by individuals. In diet-controlled studies involving 5 and 3 subjects, nightly 5-HIAA excretion rates over periods of 91 and 50 days, respectively, were compared to the daily numbers in the group. The data were analyzed by the linear transfer function method of time series analysis modified by the use of the Akaike information criterion, a method of minimizing subjective bias in model selection. The result of the first study was highly significant at lag 0, $t\,(68) = 2.82$, $p < .0063$. (This effect at lag 0 indicates a contemporaneous, same-day increase of 5-HIAA excretion and number in the group.) The second study was highly significant at lag 0, $t\,(34) = 2.91$, $p < .0063$ and at lag 8, $t\,(34) = 4.72$, $p < .0001$. In both cases the total effect (overall steady-state gain) was positive. The results strongly suggest that increasing the size of the group increases the turnover of serotonin not only in the group members (Expt. 1) but also in individuals completely outside the group (Expt. 2).

152.5

DIFFERENTIAL EFFECTS OF 5-HT1B AGONISTS ON FEMALE AND MALE SEXUAL BEHAVIOR IN THE RAT. S.D. Mendelson and B.B. Gorzalka Dept. Psychology, Univ. British Columbia, Vancouver, B.C. V6T 1Y7 Canada

Varying doses of the 5-HT1B agonists 1-(3-trifluoromethylphenyl)piperazine (TFMPP) and m-chlorophenylpiperazine (MCPP), and the 5-HT1A/5-HT1B agonist RU24969 were evaluated for effects on sexual behavior in ovariectomized female and intact male rats. In female rats treated with estrogen, TFMPP (0.2-1 mg/kg), MCPP (1 mg/kg) and RU24969 (0.2 mg/kg) facilitated lordosis behavior. In female rats treated with estrogen and progesterone, TFMPP (0.04-1mg/kg) and MCPP (0.04-1 mg/kg) were ineffective, that is, lordosis behavior remained at high baseline levels, whereas RU24969 (1 mg/kg) inhibited lordosis. In male rats low doses of the agonists (0.04-0.2 mg/kg) were ineffective. However, at the highest dose MCPP (1 mg/kg) reduced the number of male rats that displayed ejaculation, and TFMPP (1 mg/kg) and RU24969 (1 mg/kg) profoundly reduced the number of males that displayed mounting, intromission and ejaculation behaviors. It was concluded that activity at 5-HT1B receptors produces differential effects on female and male sexual behavior. Activity at 5-HT1B receptors facilitates sexual behavior in female rats but inhibits sexual behavior in male rats.

152.6

EFFECTS OF L-TRYPTOPHAN ON SLEEP IN THE RAT. M.J. Bakalian* and J.D. Fernstrom. Departments of Psychiatry and Behavioral Neuroscience, University of Pittsburgh School of Medicine, Pittsburgh PA 15213.

L-tryptophan (TRP) administration has been reported to reduce sleep latency and enhance other sleep parameters in rats and man. These effects are reputed to follow from a TRP-induced stimulation of serotonin (5HT) synthesis and release in brain. Recently, several studies have shown that 5HT presynaptic reuptake blockers (e.g., fluoxetine, zimelidine) have little effect on sleep onset or total sleep time, but delay rapid-eye movement (REM) sleep onset, and reduce total REM-sleep time. 5HT reuptake blockers and TRP should produce similar effects on sleep, since both enhance 5HT synaptic transmission. We have therefore reexamined the effects of TRP on sleep in rats. Animals were prepared for EEG recording as described previously (Pastel and Fernstrom, Brain Res 436: 92, 1987). After recovery, they received saline or TRP (125 mg/kg ip) at light onset, and EEG recordings were made for 6 hr. Fluoxetine (2.5 mg/kg ip) was also tested as a positive control. Sleep onset and total sleep time were unaffected by TRP, but REM latency was increased, and REM sleep time was reduced for 3 hr. A similar, but more robust effect was seen with fluoxetine, as observed previously (above reference). In no case did TRP produce sleep-promoting effects. These results indicate that TRP does not behave as a hypnotic agent in rats. Rather, it produces effects similar to those of a 5HT reuptake blocker; viz., to suppress selectively REM sleep.

152.7

SEROTONERGIC INFLUENCES IN THE AMYGDALA AFFECT BEHAVIORAL INHIBITION IN RATS. M.M Curtis*, P.M. Saxton (Wixom) and J. Siegel. Institute of Neuroscience and School of Life and Health Sciences, Univ. Delaware, Newark, DE 19716

Behavioral inhibitory mechanisms are being investigated using a differential reinforcement of low rate of response (DRL) operant task. Rats were trained on a DRL schedule which involves an active behavioral inhibitory process. Cannulae were directed to the basolateral amygdala bilaterally for the administration of a 0.25 µl suspension of serotonin (5-HT) (40 µg); fluoxetine, a 5-HT agonist (16 µg) or *p*-chlorophenylalanine (PCPA), a 5-HT antagonist (40 µg). Control conditions involved injections of saline vehicle. An error on the DRL schedule occurred when an animal failed to withhold a bar press for 15 sec. Reinforcement was received when the animal bar-pressed at least 15 sec after a previous reward. Both 5-HT and fluoxetine reduced errors 35% and PCPA increased errors 41%. This suggests that raphé projections to the amygdala and the release of serotonin play a role in an animal's ability to actively withhold the impulse to respond. Additional neurotransmitter systems are being investigated prior to histological verification of cannulae placement.

152.8

SEROTONERGIC MODULATION OF SEXUAL BEHAVIOUR IN MALE RATS. B.Olivier, J.Mos* and P.Bevan. Dept. of Pharmacology, Duphar B.V., P.O.Box 2, 1380 AA Weesp, Holland.

Recent evidence indicates a differential contribution of the brain serotonergic system to the modulation of sexual behaviour in male rats; 5-HT_{1A} receptors and 5-HT_{1B} receptors exert opposite effects upon activation by specific serotonergic agonists. Treatment with 5-HT_{1A}-agonists like 8-OH-DPAT, buspirone, ipsapirone and Cle-PAT may stimulate sexual behaviour, dependent on the behavioural status and sexual experience of the animals. In sexually experienced males, we were unable to stimulate sexual behaviour with 8-OH-DPAT, whereas in sexually sluggish or naive rats, 8-OH-DPAT strongly stimulates sexual behaviour, measured by a decrease in the number of mounts and intromissions preceding ejaculation, a decreased ejaculation latency and an enhanced number of animals reaching ejaculation. Buspirone, ipsapirone and Cle-PAT showed a similar, although less strong effect in naive rats. After ejaculation, male rats produce 22 kHz ultrasonics, the postejaculatory song (PES). 8-OH-DPAT influenced PES dramatically. In most rats no PES occurred and many males displayed a pre-ejaculatory sound in the frequency range of 30-40 kHz.

Drugs (agonists) with high affinity for the 5-HT_{1B}-receptor like TFMPP and RU 24969 (both also having high affinity for 5-HT_{1A}) inhibit male sexual behaviour. These drugs enhance the latency to reach ejaculation and increase the number of mounts and intromissions to reach ejaculation. Apparently, the 5-HT_{1B} effects overrule the possible stimulatory 5-HT_{1A} effects of both drugs. Interaction studies with 5-HT_{1A} and 5-HT_{1B} ligands (including antagonists) should unravel whether both receptors play a dualistic role in the modulation of male sexual behaviour on a receptor or a functional level.

152.9

SELECTIVE 5-HT RECEPTOR AGONISTS HAVE AN INHIBITORY CONTROL ON AGGRESSION. K. A. CULHANE and K. M. KANTAK. Lab of Behav. Neurosci., Dept. Psychol., Boston Univ., Boston, MA 02215.

Decreases in serotonin (5-HT) have facilitory influences on most forms of aggression. Thus, an inhibitory control by 5-HT on aggression is suggested. In order to elucidate the differential roles of 5-HT receptor subtypes in mediating aggression, the effects of 5-HT_{1a}, 5-HT_{1b}, and 5-HT_2 agonists on resident-intruder offensive aggression were measured. The 5-HT_{1a} agonist PAPP and the 5-HT_{1b} agonist mCPP significantly reduced aggressive attacks; the 5-HT_2 agonist DOB also reduced aggression. Further analysis revealed a dose response function for the effect of each agonist on lowering aggression. It is unclear whether the 5-HT_{1a} and 5-HT_{1b} agonists are reducing aggression via their actions at inhibitory presynaptic 5-HT receptors or at postsynaptic sites. The results for DOB suggest that 5-HT_2 stimulation is inhibitory for aggression, and further, suggest that the inhibitory effects of mianserin, a non-selective 5-HT_2 antagonist, on aggression may be more related to its effects on α_2 receptors.

152.10

MEDIAN RAPHE RADIOFREQUENCY LESIONS, BUT NOT DORSAL RAPHE LESIONS OR PARA-CHLORO-AMPHETAMINE, INCREASE ACOUSTIC STARTLE RESPONSES IN RATS. J.H. Kehne*, V.L. Taylor, C.K. Black, P.J. Robinson*, and C.J. Schmidt, Merrell Dow Research Institute, 2110 E. Galbraith Rd., Cincinnati, OH 45215.

It has been suggested that various substituted amphetamines, including para-chloroamphetamine (PCA), have selective neurotoxic effects on serotonergic neurons originating in the dorsal raphe (DR) while having little effect on the median raphe (MR) serotonergic pathway (Soc. Neurosci. Abst., 13: 907, 1987). One goal of the present study was to investigate a possible functional correlate of serotonergic destruction. Combined lesions of the DR and MR nuclei have previously been shown to increase acoustic startle responses (Physiol.Beh.,12:425, 1974). To separate the relative contributions of these two nuclei, rats were administered multistage radiofrequency lesions of the MR or DR, tested behaviorally a week later, and sacrificed for subsequent brainstem histological reconstruction and forebrain neurochemical analysis. Relative to the appropriate controls, MR lesions produced elevated acoustic startle responses, whereas DR lesions or PCA treatment (20 mg/kg; 1 wk before) were without effect. These data (1) suggest that the MR tonically inhibits acoustic startle responses; and (2) are consistent with the notion that PCA neurotoxicity does not alter MR function.

152.11

FURTHER EVIDENCE THAT SEROTONIN PRODUCES NEOCORTICAL LOW VOLTAGE FAST ACTIVITY, HIPPOCAMPAL RHYTHMICAL SLOW ACTIVITY AND CONTRIBUTES TO INTELLIGENT BEHAVIOR. C.H. Vanderwolf, G.B. Baker, L.-W.S. Leung and B. Robertson*. Dept. of Psychology, Univ. of Western Ontario, London, Ont., Canada, N6A 5C2 (CHV & BR); Dept. of Psychiatry, Univ. of Alberta, Edmonton, Alta., Canada (GBB); Dept. of Clin. Neurological Sci., Univ. of Western Ontario, London, Ont., Canada (L-WSL).

Anesthetized rats, pretreated with desmethylimipramine, received injections of 5,7-dihydroxytryptamine (0.5-1.0 µl, 25 µg/µl) or vehicle at 4 sites in the midbrain (in cell groups B7, B8 and B9). After recovery, polygraphic recording plus power spectral analysis revealed severe attenuation or total loss of atropine-resistant neocortical low voltage fast activity and atropine-resistant hippocampal rhythmical slow activity. Polygraphic patterns characteristic of normal quiet sleep and active sleep and a circadian rhythm of motor activity were present but there were severe abnormalities in a variety of behavioral tests (open field, swim-to-platform, grooming, social behavior, shock avoidance). Post-mortem histological and HPLC analysis revealed a selective 90-95% depletion of neocortical and hippocampal serotonin in the experimental rats.

Supported by grants from NSERC, MRC and the Alberta Heritage Fund for Medical Research.

ESTROUS CYCLE CHANGES IN 5-HT_{1A} BINDING SITES AND THE 5-HT SYNDROME. D.Croissant*, R. Richards*, L. Addison*, and L. Uphouse. (SPON: John Hines), Texas Woman's University, Denton Texas, 76204.

The role of serotonin during female reproduction is well recognized but poorly understood. Recent studies suggest that some of the contradictory findings may stem from the presence of multiple serotonin receptors which have quite different effects on female reproduction. In the following studies, emphasis was placed on the 5-HT_{1A} binding site, which recently has been suggested to play an inhibitory role in female sexual receptivity. Female proestrous rats were tested for sexual behavior with a sexually experienced male. After a minimum of 10 mounts, the female was injected with 0 to 0.25 mg/kg of the 5-HT_{1A} agonist, 8-OH-DPAT. A dose dependent reduction of sexual behavior occurred. When present, inhibition usually occurred 5 to15 minutes following injection. Previous studies have shown that 5-HT_1 binding sites and 5-HT levels increase on the night of proestrus. It was suggested that an upregulation of 5-HT_1 sites might result from a relative reduction in the synaptic availability of serotonin. To determine if this upregulation occurred for 5-HT_{1A} sites, binding sites were examined with ^{3}H-8-OH-DPAT plus or minus unlabelled serotonin. The binding showed a complex profile indicative of a possible change in K_d for binding In a test of functional variations in 5-HT_{1A} sites, diestrous, proestrous and estrous females were injected with varying concentrations of 8-OH-DPAT and were monitored for the "serotonin syndrome". Sensitivity to 8-OH-DPAT was lower on proestrus than on other stages of the estrous cycle. Collectively, these observations suggest that for those stages of the estrous cycle where sexual behavior is facilitated, the female's sensitivity to activation of the inhibitory 5-HT_{1A} site is low. Alternatively, sensitivity to 5-HT_{1A} agonists is high on the stages of the cycle when sexual behavior is inhibited.

152.13

EFFECTS OF LY237733, A SELECTIVE 5-HT_2 RECEPTOR ANTAGONIST, ON COPULATORY BEHAVIOR OF MALE RATS. M. M. Foreman, R. L. Love* and J. L. Hall*. Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285.

Previously we have reported that DOI, a selective 5-HT_2 receptor agonist, suppressed sexual behavior and LY53857, a selective 5-HT_2 antagonist, amplified sexual behavior in male rats (Foreman et al., Neurosci. Soc. Abstr. 116.8, 1987). LY237733, a selective 5-HT_2 receptor antagonist activity with a greater potency and duration of action than LY53857, was evaluated for effects on male rat sexual behavior. Male, Sprague-Dawley rats were selected for stable sexual performance. The performance divisions included rats that did not mate, rats that were unable to ejaculate and rats that had full sexual capacity. These rats were given 0.001-100 µg/kg LY237733 s.c. 30 min prior to testing. Over half of the non-maters and non-ejaculators showed mating behavior and ejaculatory responses, respectively, with 0.1 µg/kg LY237733. This dose was also the minimum effective dose to induce significant reductions in ejaculatory latency and significant increases in copulatory rate and copulatory efficiency in the "normal" rats. LY237733 is 1000X more potent than LY53857 in activating and amplifying male rat sexual behavior. These studies add further supportive evidence to the proposal that 5-HT_2 receptors have an inhibitory role in modulating sexual behavior in the male rat.

152.14

BEHAVIORAL EFFECTS OF D,L-5-HYDROXYTRYPTOPHAN (5-HTP) ADMINISTRATION TO RATS WORKING ON AVOIDANCE AND APPROACH SCHEDULES. J.N. Hingtgen, M.L. Brust*, D.A. Grossman* and M.H. Aprison. Inst. Psychiat. Res. and Program in Medical Neurobiol., Depts. of Psychiatry and Biochem., Indiana U. Sch. Med., Indianapolis, IN 46223.

The hypersensitive postsynaptic serotonin receptor theory of depression (Aprison et al., In: Neuropharm. and Behavior, Plenum, 1978; Aprison and Hingtgen, In: Serotonin, Plenum, 1981) was developed from an animal model in which 5-HTP induced suppression of food-reinforced operant behavior was correlated with CNS serotonergic mechanisms. Previous studies from our group have not observed changes in avoidance responding after 5-HTP, in spite of the elevated 5-HT levels in key forebrain areas. Since the avoidance rats had not been also trained on approach schedules, in the present study rats were trained on both a milk-reinforced VI schedule and a Sidman avoidance schedule (RS 20; SS 10). Injections as high as 75 mg/kg of 5-HTP did not produce disruptions in avoidance rats, but did produce the typical period of depression in the same rats working on VI approach schedules. Other rats, trained on a milk-reinforced VI alternating-lever schedule, showed significant reductions in accuracy, as well as response rates, following 5-HTP. These data are discussed in terms of the 5-HTP model of depression. (Supported in part by Indiana Dept. Mental Health.)

STRAIN SPECIFIC REDUCTION IN QUIPAZINE RESPONSIVENESS FOLLOWING ISOLATION IN MICE. **K. Ornstein and A. Malnoë* (SPON:ENA). Nestlé Research Centre, Nestec Ltd., Vers-chez-les-Blanc, CH-1000 Lausanne 26, Switzerland.**

Head twitch response induced by the serotonin (5-HT) agonist quipazine and its modification by isolation or exposure to a L-tryptophan (TRP) supplemented diet was compared in DBA/2 and C57BL/6 mice. In C57 mice, central 5-HT turnover, as judged by the 5-HIAA/5-HT ratio is faster than in DBA mice. Concomitant to the higher 5-HT turnover rates, C57 mice showed a weaker head twitch response following s.c. administration of a 2.5 mg/kg dose of quipazine [38±2 (n=6) vs 62±4 (n=6)]. Individual housing for a 6 week period decreased quipazine-induced head twitch response in both mouse strains, with a more pronounced decrease in DBA mice [C57:-26 %; DBA:-47 %]. Following exposure to a diet supplemented with 4 % TRP to a final concentration of 4.3 %, group housed DBA mice showed reduced head twitches following application of quipazine (-40 % as compared to control mice fed a diet containing 0.3 % TRP), while no reduction in the response to quipazine occurred in C57 mice. Furthermore, the reduction in quipazine induced head twitches observed following TRP supplementation no longer occurred in isolated DBA mice. These results suggest that the reduction in quipazine response observed following isolation or TRP exposure rely on a common neural substrate.

EFFECTS OF ACUTE SEROTONERGIC MODULATION ON BEHAVIOR IN CHAIR-RESTRAINED RHESUS MONKEYS. J.H. Krystal, C. Heninger, A. Smith*, G.R. Heninger. Abraham Ribicoff Research Facilities, Connecticut Mental Health Center, Yale Univ. Sch. of Med., New Haven, CT 06508.

Serotonergic (5-HT) systems have been implicated in anxiety, depression, schizophrenia, sleep, and appetite regulation, but the absence of selective 5-HT receptor ligands for human use has limited the study of serotonergic influences on behavior. In this study, a spectrum of 5-HT ligands are employed to evaluate 5-HT influences on behavior in the chair-restrained non-human primate.

Method: 2 sets of 4 chair-restrained male monkeys received intravenous infusions of serotonergic agonists +/- antagonists including : 5-HT_{1A} agonists: buspirone, gepirone, ipsaperone, 8-OHDPAT, or MCPP; 5-HT_2 agonist: mescaline; 5-HT_{1A} antagonist, metergoline; and 5-HT_2 antagonists: ritanserin or ketanserin. Dopaminergic antagonists SCH-23390 (D_1) and haloperidol (D_2) were employed as comparison drugs. Behavior was recorded on videotapes which were rated by a blind observer. Plasma sampled via venous catheters was analyzed for endocrine indices and are reported in a companion abstract (G.R. Heninger, et al. this volume).

Results: The behavioral effects of 5-HT_{1A} and 5-HT_2 agonists could be distinguished in the monkeys. 5-HT_{1A} agonists produced sedation, decreased goal-directed behavior (chair grasps and picks), and decreased chewing; effects which were insensitive to reversal by 5-HT_2 antagonists. 5-HT_2 agonists increased chewing slightly and had mild sedative effects, both of which were antagonized by 5-HT_2 antagonists. Non-selective 5-HT agonists or partial agonists could be distinguished by their behavioral effects and partial antagonism by selective agents. The behavioral profilesof the 5-HT drugs generally paralleled the prolactin responses which they provoked. However, buspirone dose-dependently elicited catelepsy and marked increases in plasma prolactin consistent with its anti-dopaminergic actions.

INHIBITION OF DOM-INDUCED ALTERATIONS IN LOCOMOTOR BEHAVIOR BY THE 5-HT2 ANTAGONIST KETANSERIN. L.L. Wing and M.A. Geyer. Dept. of Psychiatry, UCSD, La Jolla, CA 92093.

Previous studies of rat locomotor and investigatory behaviors identified a behavioral profile characteristic of 5-HT2 agonists such as the hallucinogens LSD or DOM. Specifically, when rats are tested in a novel environment, 5-HT2 agonists decrease the initial levels of crossovers and holepokes and reduce the time spent in the center of the test chamber.

In the present study, male Sprague-Dawley rats were injected with 0.16-2.5 mg/kg of the 5-HT2 antagonist ketanserin 30 min prior to a 60 min test. No siginificant behavioral effects were found. Other animals were then tested after s.c. injections (at 30 min and 10 min) of either saline/saline, saline/DOM (0.5 mg/kg), ketanserin (1.0 mg/kg)/saline, or ketanserin/DOM. While having no effect by itself, the ketanserin pretreatment blocked the DOM-induced decreases in crossovers, holepokes, and time spent in the center. Similar results were also obtained with the selective 5-HT2 antagonist ritanserin. These findings indicate that these behavioral effects of DOM are mediated by agonist actions at 5-HT2 receptors.

152.18

EFFECTS OF PHENCYCLIDINE ON PATTERNS OF LOCOMOTION AND INVESTIGATORY RESPONDING. V.L. Masten* and M.A. Geyer (SPON: P. Tueting). Dept. of Psychiatry, UCSD Sch. of Med., La Jolla, CA 92093.

A Behavior Pattern Monitor (BPM) was used to assess the effects of phencyclidine (PCP) on investigatory responding and on the perseverative quality of hyperactivity produced by various doses of PCP in rats. The BPM provided both quantitative measures of crossovers, rearing, and holepokes, and qualitative measures of spatial patterns of locomotion. Male Sprague Dawley rats weighing 250-300 g were obtained from Charles River Lab. Each animal was tested for 60 min at 10 min after an s.c. injection of saline, 0.25, 0.5, 2.5, or 5.0 mg/kg PCP. PCP produced a dose-dependent increase in locomotion; however, the perseverative quality of the locomotor patterns markedly changed as a function of dose (ie, low dose randomization and high dose perseveration), as reflected by a decrease or increase in the coefficient of variation (CV) of area transitions, respectively. During the initial 30 min in the BPM, the CV of region transitions was increased in a dose dependent manner. Rearing was reduced by the 2 highest doses. Holepoking was also altered in an inverted U-shaped manner, with the highest dose reducing this measure of investigatory responding. Additionally, low doses of PCP produced a preferential enhancement of perseverative (repeated) holepokes. These results are discussed in relation to the effects of other psychoactive drugs in this paradigm.

SITE SPECIFICITY IN MAHPOA HEAT GAIN PATHWAYS OF KETAMINE ANESTHETIZED RATS. C.W. Simpson* and G.E. Resch* (SPON: Fred Samson) Sch. Basic Life Sci., Univ. Missouri, Kansas City, MO 64108. Medial anterior hypothalamic preoptic area (MAHPOA) sites have been identified with heat gain control in our previous work. Female Sprague Dawley rats were prepared as before. Acetylcholine (ACh), Nicotine (Nic.), Serotonin (5-HT), and Prostaglandin (PGE2) were injected in lul volumes to elicit a criterion response of 0.5°C. increase in colonic temperature in 30 min. Sites were screened with PGE2 or other agonists in 0.2 mm increments below the guide tube until a criterion response was observed. An example will illustrate some of the diverse subtypes of heat gain sites demonstrated in these mapping experiments. The first injection of PGE2 elicited a rise in Tc of 0.6°C. in 30 min. at a site 0.2 mm below the guide tube. Injections of PGE2 at the same dose at 0.4 and 0.6 mm below the guide tube however, failed to elicit criterion responses. An injection of PGE2, 0.8 mm below the guide tube elicited a 0.6°C rise in colonic temperature. In addition to the anatomical diversity, we found unique neurochemical diversity within the anatomically defined microsites for heat gain. Different sites responded to 4,3,2 or 1 agonist. The combination of anatomical and neurochemical data and the strong criterion evidence of effective sites suggests a disperse population of differentially neurochemically coded microsites. These sites are functionally important in the heat gain pathway in Ketamine anesthetized rats. Supported by AFOSR 87-0297.

152.20

A KETAMINE ANESTHETIZED ANIMAL MODEL TO STUDY HEAT GAIN REGULATION. G.E. Resch* and C.W. Simpson* (SPON: Don R. Justesen). Sch. Basic Life Sci. and Sch. Med., Univ. Missouri, Kansas City, MO 64108. Medial anterior hypothalamic/preoptic area (MAHPOA) heat gain control sites previously reported in awake animals show response to microinjection of 100 ng to 50 ug of various agonists. In this report data from Ketamine (50 mg/kg, IP) anesthetized female Sprague Dawley rats (200 - 250 gm) demonstrated a rise in colonic temperature (Tc) elicited by 1 ag to 100 ng of the agonists prostaglandin E2 (PGE2), acetylcholine (ACh), nicotine (Nic), or serotonin (5-HT). Doses of each agonist were test until a minimum effective dose was found. Rises in Tc were recorded after PGE2 at 1 ag, ACh at 1 fg, Nic at 1 pg, and 5-HT at 1 fg. Over a wide dose range the Tc response did not show dose dependency but rather an "off-on" character. Starting Tc values, which varied from 38 to 34 C due to ketamine, showed no effect on the magnitude of elicited rise in Tc ($F = 1.65$; $P>0.202$). The just effective dose of antagonists were found for SC 19220, atropine, hexamethonium, and methylergonovine maleate. Specific blockade of Tc response was demonstrated against their respective agonists. Duration of blockade (up to 150 min) did not reverse while the rat remained anesthetized, unlike in the awake rat. The data indicate that ketamine anesthetized rats show heat gain responses to microinjection of four specific agonists into the same MAHPOA heat gain site at doses lower than previously reported. Implications for ketamine separation of heat loss and heat gain controls will be discussed. The ketamine anesthetized rat model may open new possibilities for the study of central organization of heat gain controls. (Supported by AFOSR-87-0297).

NEUROPHARMACOLOGY OF THE PHOTORECEPTIVE PATHWAY IN CORALS. R. S. Jakubczak*, C.H.Keith , and J. W. Porter*. Dept. Zoology, University of Georgia, Athens, GA 30602.

In addition to the familiar contractile response of coral polyps on tactile stimulation, they show a slow contractile response in response to light. The nature of this photoreceptive pathway - neuronal or nonneuronal in nature, and the mediators involved - is completely unknown.

We have employed a schedule of impulse blockers and neurotransmitter agonists and antagonists to characterize this pathway in the scleractinian coral Meandrina meandrites. Low levels of tetrodotoxin inhibit photocontraction without affecting contraction in response to touch, suggesting that the photoresponse is neuronally mediated, and is distinct from the tactile contractile pathway. General cholinergic agonists, nicotine, and muscarinic antagonists cause contraction in a light-independent fashion. Muscarinic agonists and GABA inhibit light-triggered contraction. Thus, the photocontractile response appears to involve two pathways: a nictoinic cholinergic pathway that stimulates contraction, and a muscarinic cholinergic/GABAergic pathway that inhibits contraction.

This work represents the first evidence for a neural component in coral photosensation, and the first characterization of synapse nature in the Scleractinia.

DESCRIPTIVE CATALOG OF DIMMING CELLS IN HEMIGRAPSUS NUDUS. E.Pak*. D.D. Rafuse* (SPON: B.J. Vasquez). Dept. of Physiol Loma Linda Univ., Loma Linda, CA 92350.

Cells that respond specifically to a decrease in light intensity (dimming cells) form a distinct population of visual neurons in the intertidal crab Hemigrapsus nudus. Pin electrode recordings from the optic nerve tract established cells responsive to decremental changes in relative light levels (40-0.08 lux). Dimming cell responses are well documented in other species. Study of observed activity in this dimming cell population (n=30) identified several subgroups. A description of these subgroups identified whole eye receptive fields; responses to jittery movement; abrupt light On/Off; tactile mechanoreceptive sensitivity; and pacemaker activity. Some dimming cells also showed increased sensitivity to a specific lux level of light intensity. Depending on the extent of this enhanced range, they were described as Brief Range (BR) or Extended Range (ER) responses. From these observations, dimming cells in H.nudus may be considered multimodal. Dimming cells may detect movement by changes in total light via changes in overall illuminance. Yamaguchi and Ohtsuka's model of reciprocal inhibition in dimming and sustaining fibers (J.Fac.Sci.Hokk.Univ.Ser.VI Zool. 19:15-30, 1973) may help explain the dimming cell characteristics of H.nudus.

SEX-SPECIFIC CONNECTIVITY IN THE FIRST OPTIC NEUROPILE OF THE MALE HOUSEFLY. A. Fröhlich, J.L. Chiasson and C.F. Winchcombe. Mt. St. Vincent Univ., Halifax, NS, Canada, B3H 2J6.

The frontal-dorsal region of the compound eye of the male housefly, Musca domestica has been related to sex-specific behaviour such as the chasing of female flies. Here a male-specific class of photoreceptor R7 ends and synapses in the first optic neuropile (as do R1-R6) instead of terminating (together with R8) in the second optic neuropile like its female counterpart. The connectivity of this male-specific R7 has been shown to be different (Hardie, 1983) from that of R1-R6 in the female. We have largely confirmed and extended Hardie's results. An R7 terminal was reconstructed. The number of R7 synapses was determined to be about 600. 186 R7 synapses of 2 terminals were analyzed: 92% had 2 (dyads), 8% had 3 (triads) postsynaptic elements. One of these was always monopolar cell L3, the other always the same central monopolar (L1 or L2). 35 R1-R6 synapses of 3 terminals were analyzed at the level of the R7 terminal. In contrast to their female counterparts with four postsynaptic elements, most synapses were dyads, one element being L3, the other being either L1 or L2. In a few cases glial elements were postsynaptic, but amacrine cells were never found to be postsynaptic as they are in the female.

Thus the major differences between male and female connectivity emerging so far from our studies are the enormously increased visual input to L3 and a possibly decreased input to either L1 or L2 and to amacrine cells.

FAST OSCILLATORY RESPONSES IN PERIPHERAL VISUAL NEURONES OF DIPTERA. D. Moore and S.R. Shaw, Life Sciences Ctr., Dalhousie University, Halifax, N.S., Canada B3H 4J1.

The responses of the postsynaptic lamina (L) monopolar cells in the dipteran visual system are much more transient than those of the photoreceptors (R cells) which drive them directly. R cells are also directly presynaptic to amacrine (Am) neurones. The transience could be due in part to direct L→R or Am→R feedback, the two local reciprocal synaptic circuits present in advanced flies. Negative feedback circuits oscillate unless critically damped, and we find pronounced light-on (ON) oscillations in some L cell responses. Electrical measurements suggest that the active oscillatory site is the presynaptic R terminal, in agreement with recent optical evidence (van Hateren, J. Comp. Physiol. 161: 849, 1987).

We have also investigated a primitive dipteran family (Stratiomyidae) in which a direct, local Am→R feedback loop is absent, finding much more pronounced and often prolonged oscillatory responses both at ON and OFF, at a significantly lower tuning frequency. The first few cycles of OFF oscillation often trigger action potentials, not usually seen in the L responses of more advanced groups unless the neurones are hyperpolarized extrinsically (Guy and Srinivasan, J. Comp. Physiol. 162: 317, 1988). The OFF oscillation has a lower characteristic frequency than that at ON, suggesting an origin in a different underlying mechanism. [Supported by NSERC, Canada].

BOTH INSECTS AND SPIDERS PROCESS WIDE-FIELD MOTION AND SMALL-FIELD FORM IN SEPARATE PATHWAYS. Wulfila Gronenberg* and Nicholas J. Strausfeld [SPON: J.B. Angevine]. ARL Div. Neurobiology., Univ. of Arizona, Tucson, AZ 85721.

In insects, parallel relays from the compound eye diverge to two subsystems, one supplying wide-field motion sensitive neurons, the other supplying assemblies of small-field neurons associated with form and color vision. The first system is conserved amongst a variety of insect orders, involving a modest population of small-field retinotopic neurons that segregate out to a specialized neuropil (the lobula plate or its homologue) containing wide-field directional-motion-sensitive neurons. The second system is associated with complex stratified neuropil (the medulla and lobula), containing discrete aggregates of retinotopic units, many expressing great morphological complexity. In spiders, which have single-lens eyes, specific eyes (anterior lateral, posterior lateral, posterior median) are employed for wide-field motion perception, whereas the dichromatic tiered retina of the anterior median eyes are devoted to small-field form detection [e.g., salticids; Land, M.F. J. Exp. Biol. 51, 443-493 (1969)]. The lateral and posterior median eyes supply a panoramic array of small-field retinotopic inputs to the dendrites of giant wide-field neurons of the so-called "mushroom body." In contrast, the anterior median eyes, specialized for form and color perception, are associated with the highly complex stratified and columnar neuropil of the "central body." The separation of visual pathways into distinct form and motion neuropils in arthropods suggests analogies at the level of cellular organization with the segregation of form- and motion-processing pathways in the mammalian visual system. **Supported by NIH Grant No. R01 EYO7151-01**

THE LAMINA CARTRIDGE IN THE OPTIC LOBE OF DROSOPHILA. I.A. Meinertzhagen and S.D. O'Neil*, Life Sciences Centre, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The anatomy and electrophysiology of the optic lobe in adult Drosophila has been little studied, despite a clear need to analyse the departures from wild type found in many visual mutants. We have examined the synaptic connections and their quantitative characteristics in the wild-type lamina cartridge of D. melanogaster, from a series of 600 consecutive transverse EM sections. Synapses are most readily itemised by comparison with those in the housefly, Musca, whose cells are larger (by 67% in receptor terminals) and allow examination of the effects of scaling cell size. By contrast, synaptic size differs little between the two.

The cells in the Drosophila cartridge have corresponding positions to and are presumed homologues of those in Musca, but their positional organisation is less orderly. Their interconnections differ from those in Musca as follows: L3 contributes at R1-6 afferent tetrads in the proximal lamina; L2 forms feedback synapses upon R1-6 but with L4, not T1, the second element of a postsynaptic dyad; L3 receives α input along with β at dyads; L5 receives rare inputs from C2; T1 receives α input at modified gnarls but there are no reciprocal T1 inputs upon α; α processes form a second feedback upon R1-6. Our observations on the wild type provide the first basis for the analysis in Drosophila of connectivity mutants that we hope will reveal the nature of the genetic control of selectivity during synaptogenesis.

153.7

LIGHT-ADAPTATION OF VISUAL OBJECT SIZE SELECTIVITY IN IDENTIFIED INTERNEURONS OF DRAGONFLY. R.B.Pinter,R.M.Olberg,E.Warrant*,Univ.Wash.,Seattle;Union College,Schenectady;Australian Nat'l Univ.,Canberra.

In dragonfly ventral nerve cord eight large descending visual interneurons,identified by dye injection,have highly selective response to small visual objects moved in their visual field.The change in object size selectivity as a function of mean background luminance was measured intracellularly.The preferred object size consistently decreased with increase of mean luminance,from 10 deg.visual angle at low levels (.11cd/ft^2)to 1 deg.at outdoor midday sunlit levels (680cd/ft^2).Latency of response and incremental sensitivity also decreased with increase of mean luminance.The time course of shift of size preference on luminance decrease was less than 30 sec.,sometimes longer.We have measured photoreceptor receptive field width as function of similar mean luminance decrease(and increase)and found changes in width are insufficient to account for adaptation of size preference, which must therefore arise from changes in neural circuitry, such as efficacy of lateral inhibition. A deterministic nonlinear differential equation set describing nonlinear lateral inhibition is shown to be a sufficient model for size preference dependence on mean luminance. Supported in part by NSF grant BNS-8510188.

Olberg,R.M.(1986) Identified target-selective visual interneurons descending from the dragonfly brain.J.Comp.Physiol. A 159:827-840.

ULTRASTRUCTURE OF RETINAL DEGENERATION IN THE COMPOUND EYE AND OCELLI OF Drosophila. W. S. Stark and R. Sapp*. Div. Biol. Sci., Univ. of Missouri, Columbia, MO 65211.

Since Harris & Stark introduced rdgA & rdgB (J.Gen. Physiol.69,261-291,1977), Drosophila is a model of retinal degeneration. EM observations of receptors and their synapses underly this review of degeneration in white eyed flies from degeneration & excitation mutants vs aging in cyclic room light. rdgB has light induced degeneration of R1-6 but not R7/8 in the compound eye and not in ocelli. Higher order neurons are spared. rdgB's demise is blocked by ora (outer rhabdomeres absent, an allele of R1-6's opsin gene) and norpA (no receptor potential) but not trp (transient receptor potential or Acph- (Acid phosphatase null). The Acph- result was confirmed by microspectrophotometry (MSP). $rdgA^{BS12}$ has widespread degeneration of compound eye receptor somata. Some terminals and synapses survive; some ocellar receptors lose rhabdomeres and degenerate. $rdgA^{PC47}$ has a more gradual demise, preferentially in R1-6. Acph- does not slow rdgA's demise, confirmed by MSP. trp has degeneration in the compound eye but not in ocelli. ora remains intact. norpA has diminution of rhabdomeres, but only the scattered cell death of white eyed otherwise nonmutant flies reared for 3 weeks in cyclic room light (Stark et al., J. Neurogenet. in press). norpA loses rhabdomeres in the ocelli, but cells, feed forward and feed back synapses remain.

153.9

PHOTORECEPTOR SCREENING PIGMENT IN *LIMULUS* LATERAL EYE: DISTRIBUTION, MOVEMENT, AND CONTROL MECHANISMS. C.K. Kier* and S.C. Chamberlain (SPON: A. Ecker). Dept. of Bioengineering and Institute for Sensory Research, Syracuse University, Syracuse, New York 13244.

The radial and longitudinal distribution of retinular pigment in the lateral eye of *Limulus* was quantified with specialized point counting stereology under a variety of experimental conditions. Pigment position was characterized by the center and width of the radial distribution.

Under diurnal lighting, intact animals show movement of pigment granules from the periphery of the retinular cell at night towards the junction of the arhabdomeral and rhabdomeral segments of the retinular cell in the day. In total darkness, intact animals exhibit the same circadian rhythm. Animals with cut optic nerves (and thereby no circadian efferent input), show little pigment movement in diurnal lighting. In none of these cases did pigment granules move into the R-segment.

When dark-adapted animals are suddenly exposed to increments of light, pigment enters the R-segment. This phenomenon is not specifically associated with membrane shedding, but occurs whenever, and as often, as such exposures occur.

We investigated the effects of length of light increment (15 to 240 min) during the day (1600) and at night (0300). In both cases, pigment enters the R-segment, but the response at night is sluggish. Four hours of light exposure at night, however, moves the pigment to a daytime position.

Circadian efferent input, not diurnal lighting, appears to be the major determinant of screening pigment position. A second, faster mechanism is overlaid to provide protection during sudden light increments and appears to be optimized for daytime performance. Supported by NIH grants.

A LATERAL LINE ANALOGUE IN CEPHALOPODS. B.U. Budelmann* and H. Bleckmann* (SPON: J.I. Kitay). Marine Biomedical Inst., Univ. Texas Med. Branch, Galveston, TX 77550 and Div. Biol., Univ. Bielefeld, D-4800 Bielefeld, FRG.

For more than 75 years it has been a subject of discussion whether cephalopods, like aquatic amphibians and fish, are able to sense local water movements and thus have a system similar to the lateral line.

Naef (Fauna Flora Golfo Napoli, 35:1, 1928) was the first who mentioned 4-5 pairs of regularly arranged lines of epidermal cells that run in an anterior-posterior direction on their head and arms of embryonic cephalopods. Later, Sundermann (Cell Tissue Res., 232:669, 1983) described these cells as being ciliated, probably sensory, cells. We have now been able to demonstrate that these lines of cells serve to detect small water movements and thus are a further example of convergent evolution between a sophisticated cephalopod and vertebrate sensory system.

In the cuttlefish Sepia and the squid Lolliguncula, local water displacements, generated by a vibrating sphere, cause receptor potentials that are local to the lines and have many features known from the lateral line microphonic potentials. The minimal threshold of the lines on the head is 0.2 µm peak-to-peak water displacement. Besides physiological data, details on the gross-morphology of the lines and the ultrastructure of the hair cells will be presented.

153.11

HAIR CELL MORPHOLOGY IN THE STATOCYST OF THE SQUID *ALLOTEUTHIS SUBULATA*. R. Williamson*. (SPON: G.E. Meredith). The Marine Laboratory, Citadel Hill, Plymouth PL1 2PB, England.

The sensory epithelium of the octopus vestibular system is unusual in that it contains both primary and secondary hair cells (B.U. Budelmann et al., Phil.Trans.R.Soc.Lond.B.315:305, 1987). To ascertain whether both types of hair cells also occur in decapod cephalopods and to visualise the morphologies of the cells, hair cells in the squid statocyst were intracellularly injected with the dye Lucifer Yellow.

It was found that the hair cells on the dorsal side of the statocyst crista are primary hair cells with axons passing into the statocyst nerve. However, fills of ventrally located hair cells showed that many had short processes extending from their bases and some had long processes extending along, and parallel to, the length of the crista section. It was not possible to trace these processes into the crista nerve, either because they do not enter the nerve or because dye filling is incomplete.

As a test of whether these cells have an axon in the crista nerve, the nerve was backfilled with HRP from the brain cavity. This procedure clearly stained the primary hair cells on the dorsal side of the crista, the afferent neurons beneath the crista, and the afferent neurons on the ventral side of the crista section. However the hair cells on the ventral side of the crista were not stained.

Thus the squid does appear to have both primary and secondary hair cells in the statocyst crista but the latter, in contrast to descriptions of vertebrate hair cells, can have long processes extending along the crista section.

SENSORY ORGANS OF THE THORACIC LEGS OF THE MOTH MANDUCA SEXTA. L. Griffin-Austin*, K.S. Kent, and R.B. Levine (SPON: T. Tobin). ARL Div. Neurobiol., Univ. Ariz., Tucson, AZ 85721

We have used cobalt filling, anti-HRP, and SEM to characterize sensory organs of the larval and adult thoracic legs and to examine the transition between stages. Externally, larval legs contain singly innervated mechanosensory hairs and few recessed dome-shaped sensilla (probably campaniform sensilla). Internally, they contain sensory organs (probably stretch receptors) consisting of clusters of small cells with dendrites extending into strands that attach at more distal sites within the leg. During prepupal stages, sensory neurons innervating external sensilla retract from the sensilla as the underlying epidermis retracts from the larval cuticle. For several days the sensory neurons remain associated with their sensilla via greatly elongated dendrites. As late as 2 days following pupation, some larval sensory neurons are still present within the new pupal leg suggesting that they may persist to serve as guides for the new adult sensory axons. All segments of the adult leg (except the claw) contain singly innervated flat hairs beneath the scales. Singly innervated dome-shaped sensilla located on the femur, tibia, and tarsus are probably campaniform sensilla. The coxa and trochanter contain hair-plates consisting of clusters of singly innervated sensilla. The tibia and tarsus contain multiply-innervated stout hairs which curve outward, extending beyond the scales. These sensilla contain marked surface indentations and dendrites extending within the lumen (suggesting an olfactory function). Singly innervated spines cover the tarsus, and several characteristic sensilla are present at the distal tip of the tarsus, including multiply innervated blunt hairs. The blunt hairs have small terminal indentations suggestive of a gustatory function. Internally, chordotonal organs are obvious within the femur and tibia. (NIH #NS28422 and NSF #8607066).

153.13

SEGMENTAL HOMOLOGY OF AUDITORY AND LEG SENSORY SYSTEMS IN LOCUSTS. H. Reichert and T. Meier*. Department of Zoology, University of Geneva, CH-1211 Geneva, Switzerland.

The locust ear is a peripheral sensory structure located on the first abdominal segment of the animal. It is composed of numerous auditory sensory neurons and an associated tympanal membrane. We use cellular, developmental and immunological methods to show that this sense organ derives in the embryo from a transiently expressed first abdominal proleg (pleuropod) that is lost after hatching. The sensory cells of the auditory system are organized and develop in this proleg in the same manner as do the chordotonal organs, groups of proprioceptive neurons, found in each of the true thoracic legs. Axonal pathfinding processes and axonal projections of the auditory sensilla into the central nervous system are segmentally equivalent to those made by the leg proprioceptors. However, the auditory sensory cells are established closer to the body wall and can thus survive proleg loss. The fact that the peripheral auditory system of locusts is segmentally homologous to leg proprioceptors suggests that parts of the central nervous organization of the auditory system, such as the G-neuron network, may also be an evolutionary elaboration of the circuitry associated with the sensorimotor control of an arthropod leg.

ENCODING PROPERTIES OF MECHANORECEPTIVE NEURONS ON THE FLY WING. M.H. Dickinson*(SPON:C.M. Lent). Dept. of Zoology, U of WA, Seattle, WA 98195.

Insect wings are flexible structures, subject to both active and passive bending during flight. Wings are equipped with a set of campaniform sensilla that act as strain gauges to monitor these deformations. White noise analysis has been used to examine the linear and non-linear characteristics of encoding in these mechanoreceptive neurons.

The encoding characteristics of these sensilla are accurately modeled as a linear filter followed by a zero memory rectifier. The linear filter is composed of the series of coupling processes that link wing strain to the transduction current. The sharp rectification is most-likely the result of the encoding process when the transduction potential is transformed into a train of action potentials.

The sharp rectification in these neurons might act to reduce timing errors in control circuits used during flight. When stimulated with pure sinusoidal inputs at wingbeat frequency, these neurons are strongly phase locked. The linear component of the encoding establishes the rough phase delay, while the rectification sharpens the response to a more precise delay value.

PHYSIOLOGICAL RESPONSES OF MECHANOSENSORY AFFERENT NEURONS INNERVATING THE LOBSTER SWIMMERET. K.A. Killian and C.H. Page. Dept. Biol. Sci., Rutgers Univ., Piscataway, N.J. 08855.

Lobsters have four pairs of abdominal swimmerets. These biramous appendages consist of two paddle-like rami attached to a stalk-like coxa. Mechanical stimulation of the swimmerets modulates both postural and swimmeret motor activity produced within the abdominal nerve cord (Cattaert,D. and Clarac, F., J.Comp.Physiol.160:55,1987; Kotak,V.C. and Page, C.H., J.Comp.Physiol.158:225,1986; 161:695,1987). To better understand these reflex responses, the properties of several mechanosensitive swimmeret afferents have been physiologically and morphologically investigated. These afferents include large and small feathered hair sensilla fringing the rami and subcuticular hypodermal mechanoreceptors. Two populations of large feathered hairs have been found on the swimmeret rami: 1) proximal feathered hairs, localized to the basal 2/3 of each ramus, and innervated by a single bipolar mechanosensory neuron responding phasically, with a single spike, to hair deflection and 2) distal feathered hairs located on the distal 1/3 of the rami. These hairs are not innervated by a mechanosensory neuron but are mechanically coupled to nearby hypodermal mechanoreceptors. Afferents innervating small feathered hairs respond to nearfield water vibrations and tactile stimulation.

DIVERSE MODULATORY EFFECTS OF PROCTOLIN, FRMRAMIDE, OCTOPAMINE AND 5-HT ON CRAYFISH MECHANORECEPTORS. V.M. Pasztor and D.L. Macmillan Biology Dept., McGill Univ., Canada and Zoology Dept., Univ. of Melbourne, Australia.

Specific elements of signals in primary afferents of a crustacean mechanoreceptor, monitoring ventilatory movements in *Homarus*, can be reversibly modified by neuromodulators (Pasztor and Bush, Neurosci. Abst. *13*, 1987). Responses from two of the three oval organ afferents are enhanced by proctolin and reduced by octopamine and 5-HT, whereas those from the other unit are unaffected. The present study compares three mechanoreceptors with very different response characteristics in the crayfish, *Cherax destructor*, to determine whether a relationship exists between receptor type and sensitivity to modulators.

Three mechanoreceptors were studied: 1. The abdominal muscle receptor organ (MRO) which has two spiking neurons, one with a phasic and one with a tonic response (Wiersma *et al.*, 1953). 2. The swimmeret non-spiking stretch receptor (NSSR) which has two similar units lacking impulse generation and using analog signals (Heitler, 1982). 3. The oval organ of the scaphognathite which has 3 units conducting both analog and digital signals, whose fibers range identifiably from the sparsely-spiking to the full-spiking condition (Bush & Pasztor, 1982).

The three mechanoreceptors and their individual sensory afferents have diverse responses to the modulators proctolin, FRMF-amide, Octopamine and 5-HT.

CRUSTACEAN PROPRIOCEPTION: SINGLE CELL ANALYSIS OF CHORDOTONAL ORGANS. Robin L. Cooper and H. Bernard Hartman. Dept. of Physiology, Health Sciences Center and Dept. of Biological Sciences, Texas Tech University, Lubbock, TX 79430, and Oregon Institute of Marine Biology, Charleston, OR 97420, U.S.A.

Joint receptors of Crustacea consist of elastic strands into which are inserted the dendrites of paired bipolar sensory cells. Recordings made from axons teased from nerves indicate that these cells signal movement, direction of movement and static position. Analysis of individual cells from the PD organ revealed an orderly arrangement of these neurons along the elastic strands according to function. We sought to determine if the chordotonal organs at the other joints are similarly arrayed. Extracellular recordings made from cell bodies and axons of the CP1 and MC1 as well as the CP2 and MC2 organs revealed cell position and size determines cell function. In each case, the most distal cells (10-20μm) are tonic and signal static positions. Proximal cells are phasic, responding to dynamic position and direction of displacement of the joint. Large proximal cells (30-40μm) fire upon strand relaxation while smaller proximal cells (20-30μm), most commonly seen in MC1 and CP1, respond to stretch of the strand. Cells sensitive to stretch of the elastic strands are more numerous than has been previously reported, but are still outnumbered by their counterparts. Supported by NSF grant BNS-8700506 to H.B.H.

TENSION RECEPTORS ON THE OPENER, PRODUCTOR, AND REDUCTOR TENDONS OF THE DUNGENESS CRAB CANCER MAGISTER. H. Bernard Hartman and Robin L. Cooper (Spon: R. Nathan). Dept. of Biol. Sci., Texas Tech Univ. and Dept. of Physiol., Health Sciences Center, Lubbock, TX 79430, and Oregon Inst. of Marine Biology, Charleston, OR 97420.

Tension receptors in arthropods were first described by Macmillan and Dando (Mar. Behav. Physiol. 1: 185, 1972) on the tendons of the powerful extensor and flexor muscles of the meropodite of walking legs. Hartman (J. Comp. Physiol. A 157: 355, 1985) examined the closer muscle and with rigorous physiological criteria proved that neurons there also respond specifically to muscle tension. To determine if tension receptors are to be found on the other tendons of the limbs, we examined the opener, productor, and reductor muscles of chelipeds and walking legs. The opener muscle exerts little force. Located along the lower margin at the distal end of the tendon are four sensory cells with the anatomical and physiological properties described for tension receptors. Upon emerging from the muscle, axons from these neurons immediately join the opener motor nerve. Receptors of typical anatomical profile and meeting the physiological criteria for tension reception are found on the productor and reductor tendons. Axons from these receptors form a nerve which exits near the CP1 organ and merges with its nerve; those from the reductor join the CP2 organ joint receptor nerve. Supported by NSF grant BNS-8700506 to H.B.H.

INVERTEBRATE SENSORY SYSTEMS II

154.1

PERSISTENCE OF THE EFFECTS OF BRIEF PERTURBATIONS IN NEURONAL OSCILLATORS. M. Holmgren*+, O. Diez-Martínez*+ç and R. Budelli*+ (SPON: E.J. Muñoz-Martínez). + Depto. de Ciencias Fisiológicas, Instituto de Ciencias, Universidad Autónoma de Puebla; ç Departamento de Fisiología, Facultad de Medicina, UNAM.

Abdominal slowly adapting stretch receptors (SASR) of crayfish were submitted to single pulse-like lengthenings (i.e. tugs). Neuronal discharges of SASR were recorded extracellularly. A large number of tugs were applied irregularly to the receptor muscle, at long intervals, and independently of SASR spikes. The perturbed interval was shortened with respect to the expected or natural interval (N); the shortening was a function of the phase. Weak stimuli affected the perturbed interval but the following ones were identical to N. Intermediate stimuli lengthened the first post-perturbed interspike interval (PPII), rarely affecting subsequent ones. Strong stimuli significantly prolonged the first PPII and sometimes the second and third. Thus, effects upon PPII depend on the stimulus parameters. We developed a computer program based on the model of Perkel et al. (Science, 145: 61, 1964) that, by varying the time constant of the threshold, reproduced our results and those of Buño and Fuentes (Brain Res., 303: 101, 1984) who reported phase compensation employing thoracic SASR. Discrepancies between results in abdominal and thoracic receptors can be explained on the basis of a greater sensitivity to velocity of the abdominal receptors.

154.2

TIMING OF ACTION POTENTIALS IN GIANT INTERNEURONS OF THE COCKROACH. J. Westin and R.E. Ritzmann. Department of Biology, Case Western Reserve University, Cleveland, OH 44106

The giant interneurons (GI's) of the cockroach are involved in triggering escape from wind. They are excited by sensory neurons, which, in turn, are excited by deflection of wind sensitive hairs on the cerci. The GI's are arranged in two groups in each connective of the nerve cord, with the larger ventral GI's having a shorter latency than the smaller dorsal GI's (Westin, et al, 1977).

It has been shown that the ventral GI's excite several populations of thoracic interneurons (TI's). PSP's produced by two GI's at the same time can summate dramatically (Ritzmann et al, 1988). We have now undertaken an investigation of the relative timing of action potentials (AP's) in the different GI's. We would like to determine the relative temporal properties of the various individual GI's and whether AP's of GI's within the ventral group with similar directional properties (eg. GI2 left and GI2 right), and which excite the same TI's, are timed to arrive in the thorax at the same time. If this is the case, we will explore the mechanism used for insuring synchronous arrival of action potentials.

To accomplish these goals we have recorded intracellularly from pairs of GIs in preparations set up in an apparatus that delivers reproducible wind stimuli from various different directions. Preliminary results show that, as expected, there is no relationship between the timing of action potentials in a ventral and a dorsal GI, even when their responses overlap. However, a reproducible relationship between the timing of individual ventral GIs does exist. For some pairs of ventral GI's, at least the first two to three AP's are synchronized.

Supported by NIH grant NS 17411.

MORPHOLOGICAL ANALYSIS OF CONNECTIVITY BETWEEN GIANT INTERNEURONS AND THORACIC INTERNEURONS. J.L. Casagrand and R.E. Ritzmann, Dept. of Biology, Case Western Reserve Univ., Cleveland, OH 44106.

The nervous systems of insects are functionally organized. Sensory neurons which receive input from particular regions project to predictable locations in the central nervous system. The giant interneuron system of the cockroach, Periplaneta americana, consists of two populations of identified giant interneurons, dorsal (dGIs) and ventral (vGIs), which mediate wind-evoked escape behavior. The GIs make a unique pattern of connections onto a population of identified thoracic interneurons (TIs). All of the TIs characterized as receiving vGI input have ventrally located midline (VM) branches in the general area of vGI axons. Some of the TIs have bilateral VM branches, while others have unilateral VM branches. The physiological data suggest that these VM branches are the site of connection with vGIs. We are examining overlap directly at the light microscopic level by filling GIs and TIs with different fluorescent dyes (Texas Red and Lucifer Yellow) in the same preparation and seeing whether the cells overlap, and if so, on which branch overlap occurs.

Preliminary experiments in which GI axons in one connective were lesioned early in development also support the idea that the VM branches receive GI input. In three cells which normally have symmetric VM branches, loss of all GI input on one side resulted in a reduction in the VM branch on the deprived side as compared to the nondeprived side. More lateral branches, which are believed to receive proprioceptive input from the legs, were not affected, nor were any branches from cells which do not receive GI input. Thus, selective effects were observed on those branches believed to receive GI input.

INPUT-OUTPUT RELATIONSHIPS OF SENSORY AFFERENT NEURONS IN THE CRICKET CERCAL SENSORY SYSTEM. M.A. Landolfa*, G.A. Jacobs and J.P. Miller. Grad. Group in Neurobiology, U.C. Berkeley, Berkeley, CA 94720.

The cercal sensory system of the cricket extracts and encodes relevant sensory information from the animal's air current environment. The inputs to this system consist of about 2000 afferent neurons, each of which innervates a single mechanosensory hair on the cerci. The input-output relationships of single sensory neurons were characterized by recording from an afferent axon while presenting appropriate stimuli to the sensory hairs. 1)Afferents are directionally sensitive. Graphs of afferent response amplitude versus wind stimulus direction are approximately sinusoidal, with distinct preferred and anti-preferred directions. 2)Afferents are velocity sensitive. Each afferent encodes wind velocity over a range of about 1.5 log units. 3)Different afferents have different velocity thresholds. The overlap of these different sensitivity curves insures that the system as a whole can encode wind velocities that span several log units. 4)The nature of the afferent response to deflection of its sensory hair indicates that the parameter transduced by the afferent is not hair displacement, but change in hair displacement. Thus, a significant portion of the processing which occurs within the cercal sensory system is accomplished at the level of the sensory afferents. Supported by: NSF BNS 85-19416.

154.5

DETERMINATION OF I/O RELATIONSHIPS OF CRICKET CERCAL SENSORY INTERNEURONS USING A MULTI-CHANNEL SPIKE DISCRIMINATOR. S.N. Gozani*, J.P. Miller and G.A. Jacobs. (SPON: E.R. Lewis) Departments of Computer Science and Zoology, UC Berkeley, Ca. 94720.

In the cricket cercal sensory system, information about the direction and velocity of wind stimuli is encoded by the relative firing rates of at least ten pairs of identified sensory interneurons. A full analysis of the input/output properties of this system requires that the activity of these output neurons be monitored simultaneously. We have implemented a computer based system capable of extracting the firing patterns of individual neurons from multi-unit recordings. Extracellular electrodes were arrayed along the abdominal nerve cord. Wind stimuli of varying directions, velocities and frequencies were presented to the animal. The responses of the cells were analyzed by spike discrimination software based upon an algorithm originally described by Roberts and Hartline (1975). The algorithm employs multiple linear filters, and is capable of discriminating spikes that are coincident in time. The number of spikes that could be discriminated was roughly equal to the number of independent recording electrodes. Using this tool we have characterized the output of the cercal sensory system in terms of the simultaneous activity patterns of ten identified interneurons. Supported by NSF BNS 85-19416.

ELECTRO-ANATOMICAL PARAMETERS OF SENSORY INTERNEURONS IN THE CRICKET CERCAL SENSORY SYSTEM. R. Nevin*, J.W. Tromp*, J.P. Miller and G.A. Jacobs. (SPON: D.A.Weisblat) Zoology Dept., UC Berkeley, Ca. 94720

Primary sensory interneurons in the cricket cercal sensory system extract information about the direction and velocity of wind stimuli from the afferent map of "wind space" within the terminal abdominal ganglion. The morphology of these 1st order interneurons determines their functional properties to a great extent. We have characterized the major structural features of these interneurons and determined the extent to which variability in their structure may affect their function. The structural features we have examined are: 1) location of dendrites within the afferent map, 2) total length of specific dendrites, 3) number and order of the branches, and 4) daughter-to-parent branch diameter ratios. Anatomical reconstructions were carried out using a computer controlled microscope integrated with a video frame grabber and graphics system, and software developed in the lab. This system allows 3-D reconstructions of neurons accurate to the limit of resolution of light microscopy. Based on this morphological analysis we have modeled the electrical properties of the neurons using SPICE. As a control to these modeling calculations, the effects of variations in structural features that are unresolvable at the light microscope level were also investigated. Supported by NSF BNS 85-19416

154.7

SENSORY ADAPTATION OF NEURONS INNERVATING THORACIC BRISTLES OF Drosophila melanogaster. G. Corfas* and Y. Dudai (SPON: I. Ginzburg). Dept. of Neurobiology, Weizmann Institute, Rehovot, Israel.

The macrochaetae that cover the thorax of *Drosophila* are each innervated by single sensory neurons that respond to deflection of the hairs. Stimulation ultimately elicits a behavioral response wherein the fly cleans the area covered by the bristles. This cleaning reflex undergoes habituation, which is abnormally brief in the memory mutant *rutabaga* (Corfas and Dudai, *Soc. Neurosci. Abs.* 13:388, 1987). To analyse the physiological basis of this behavior and its modification by experience, we have recorded with extracellular electrodes the receptor potential and the action potentials generated in the sensory neurons upon deflection of the hairs. Upon sustained deflection, and depending on the direction of the deflection, there is a negative receptor potential and a burst of superimposed positive action potentials that can reach a firing frequency higher than 250 Hz. The cells are rapidly adapting and fire for less than one second. The sensory neurons can also respond to brief (450 msec) transient deflections. Upon repetitive presentation of these brief stimuli, bursting activity diminishes and finally vanishes in a frequency dependent manner. At 0.2 Hz the cells continue to fire without substantial decrement for more than 100 stimuli. At frequencies higher than 0.5 Hz the response vanishes faster. The response recovers after 1-2 minutes of rest. The temporal characteristics of adaptation and the effect of memory mutations on this phenomenon are being investigated. THE ROLE OF SCORPION TRICHOBOTHRIA IN WIND AND PREY DETECTION. E. J. Teufel*, S. C. Folta* and T. M. Root. Dept. of Biology, Middlebury College, Middlebury, VT 05753.

Trichobothria are fine sensory hairs on the pedipalps (claws) of scorpions. Some studies have suggested that they function in menotactic orientation or in prey detection, but experimental evidence to support these ideas is lacking. In response to weak air currents these hairs oscillate strongly in a single plane, and both the location of all 94 hairs and their planes of oscillation are consistent in every animal. Extracellular recordings from single trichobothria in response to direct mechanical stimulation showed phasic bursts of spikes from multiple receptor cells, but with no apparent directional differences. Similar recordings from freely-walking animals in response to both natural and simulated flying prey, however, showed directional attack behavior correlated with neural responses in the hairs. The attack behavior was lost when the hairs were removed. The findings suggest that trichobothria could mediate both wind orientation and prey detection by providing the animal with a precise sensory map of changes in air flow.

PHYSIOLOGY AND MORPHOLOGY OF HIGHER-ORDER NEURONS IN OLFACTORY PATHWAYS OF THE BRAIN OF THE MALE MOTH MANDUCA SEXTA. R Kanzaki, EA Arbas, NJ Strausfeld, JG Hildebrand. ARL Div. of Neurobiol., Univ. Ariz., Tucson AZ 85721.

In our ongoing studies of olfaction in Manduca, we have used intracellular recording and staining and reconstruction from serial sections to characterize the responses and structure of brain neurons that link the antennal lobes (ALs) with the protocerebrum (PC) (n=27), neurons local to the PC (n>40), and neurons that descend from the brain in the ventral nerve cord (n>10). Neuronal arborizations in the ALs were restricted either to the male-specific macroglomerular complex (MGC) or to ordinary glomeruli (Gs). Neurons innervating the Gs branched in a single G (uni-glomerular), many or all Gs of one AL (multi-glomerular), or in one case, single Gs in both ALs (bilateral uniglomerular). Bombykal or crude sex pheromon extracts excited all MGC neurons, although some were inhibited by other odors. G neurons were excited or inhibited by non-pheromonal odors. Some also showed mechanosensory responses. Both MGC and G neurons typically showed prominent branches in the calyces of the ipsilateral mushroom body and in the lateral protocerebrum with some differences in termination sites of the two classes noted. Neurons local to the PC and descending neurons showed diverse responses to the odors tested. Examples will be discussed. Many neurons of the latter two classes were multimodal, also showing responses to visual stimuli.

154.10

IMMUNOCYTOCHEMICAL IDENTIFICATION OF OLFACTORY RECEPTOR NEURONS FROM MALE *MANDUCA SEXTA* PUPAE IN VITRO M. Stengl, J.G. Hildebrand, ARL Div. of Neurobiol., Univ. of Ariz., Tucson, Arizona 85721

Only *Manduca* males are able to detect the females' sex pheromones with sex-specific antennal sensory hairs, the long trichoid sensilla. The olfactory receptor neurons (ORNs) innervating olfactory sensilla are not easily accessible for electrophysiological recordings in situ. In order to study the development of excitable membrane properties and the olfactory transduction processes in the ORNs, we have developed a primary cell culture system of ORNs from *Manduca sexta* pupae.

Because conventional morphological criteria could not be used to distinguish neuronal from non-neuronal cells, the ORNs were identified immunocytochemically with the help of two antibodies that are known to stain ORNs in vivo. These were: the OSA-Ab (olfactory specific antibody) and the MOSA-Ab (male olfactory specific antibody) [*J. Neurosci* 8:296-307; 308-315 (1988)]. Both antibodies, which specifically recognize ORNs in intact *Manduca* at defined times in development, labeled cells at specific times in antennal-cell cultures, in good correlation with the in situ findings. These immunocytochemical results make anatomical identification of cultured ORNs possible by assigning certain morphological characteristics to OSA- and MOSA-antigenic cells. Patch-clamp recordings will be used next to determine the physiological properties of the ORNs at different stages of development in vitro.

154.11

VOLTAGE-GATED CURRENTS IN INSECT CENTRAL OLFACTORY NEURONS IN PRIMARY CULTURE. J.H. Hayashi and J.G. Hildebrand ARL Div. of Neurobiol., Univ. Ariz., Tucson, AZ 85721. Studies of the antennal lobe (AL) of the moth Manduca sexta have revealed much about physiological mechanisms underlying central processing of olfactory information. Attempts to study membrane currents using voltage-clamp methodology, however, have been frustrated by an inability to achieve space clamp owing to the extensive arborizations of the neurons. Thus we have dissociated cells from pupal ALs and grown them as solitary cells with limited arbors. We find at least five different types of neuron-like cells based on their morphology in culture and immunoreactivity to GABA antisera. In current-clamp recordings, some of the cells in culture generate action potentials as do neurons in intact ALs. One morphologically distinct cell type responds to a depolarizing current pulse in a manner that resembles an AL interneuron in situ: it displays a burst strikes of variable height that outlasts the stimulus. We examined cells grown in culture for 3-21 days with the whole-cell patch-clamp technique. Cells of a particular morphological class have similar, characteristic voltage-gated membrane currents. Of particular interest are cells that display a fast inward Na^+ current that apparently gives rise to the action potential. These cells also have a delayed rectifier K^+ current, which does not inactivate within the 50 msec pulse. In other cells we found an "A" type K^+ current that activates rapidly (t_{peak}<10 msec), inactivates slowly ($t_{0.5}$>50 msec), and is abolished at holding potentials positive to -40 mV. (Supported by NIH AI-23253, Monsanto Co., and an NIH postdocoral fellowship.)

154.12

RESPONSES OF OLFACTORY INTERNEURONS IN THE BRAIN OF LARVAL *MANDUCA SEXTA*. H. Itagaki and J.G. Hildebrand. ARL, Div. Neurobiol., Univ. Arizona, Tucson, AZ 85721.

Behavioral experiments have shown that caterpillars use odor cues for the initial location and identification of foodplants (e.g. Dethier, 1937, 1941; Hanson and Dethier 1973). Caterpillars possess a relatively small number of olfactory receptor neurons (32 cells in the 2 antennae) with which to identify possible foodplants (Schoonhoven and Dethier, 1966). To investigate how so few receptors can mediate the complex task of foodplant choice in lepidopterous larvae, we study central olfactory mechanisms in tobacco hornworms (larval *Manduca sexta*).

Using standard intracellular recording techniques, we have recorded from over 1700 neurons in larval *Manduca* brains while stimulating the antennae with foodplant odors (tomato, tobacco) and with an important constituent of the volatiles given off by leaves (E-2-hexenal). We recorded excitatory responses in about 75% of the responding neurons, inhibitory responses in 21%, and mixed responses in 4%. We have found no evidence of specific "labelled lines" in the neurons: most olfactory interneurons are broadly tuned in their response spectra. Dose-response curves with E-2-hexenal show that different interneurons have different responses to a single dose of odorant: a finding consistent with mediation of plant recognition being by the "across-fiber" firing pattern of the neurons. (Supported by USDA grant 87-CRCR-1-2362, NIH Postdoctoral Fellowship 1-F32-NS07990, and the Monsanto Company.)

154.13

PROJECTION NEURONS IN THE GYNANDROMORPHIC ANTENNAL LOBES OF FEMALE *MANDUCA SEXTA* WITH GRAFTED MALE ANTENNAE. T.A. Christensen and J.G. Hildebrand. ARL Div. of Neurobiol., Univ. Arizona, Tucson, AZ 85721.

Previous studies using trans-sexually grafted antennae have shown that pheromone-sensitive sensory axons in the antennal nerve (AN) can induce (or permit) the formation of the male-specific macroglomerular complex (MGC) in the antennal lobe (AL) of female moths (Schneiderman et al., *Nature 298*:844; 1982). In normal males, the MGC is the area of neuropil where axons from pheromone receptors on the ipsilateral antenna terminate. Local and projection neurons that process pheromonal information also arborize in the MGC. In female gynandromorphs with grafted male antennae, at least some local neurons were found to be similar to those in normal male ALs, but the projection neurons that convey olfactory information to higher-order centers in the protocerebrum were not examined.

Out of 87 gynandromorphs examined, 36 had an AN innervating the AL. We obtained stable intracellular recordings from 18 neurons. Nine cells were excited by electrical stimulation of the AN or pheromonal stimulation of the antenna. One such neuron had dendritic arbors in the induced MGC and sent an axon through the inner antenno-cerebral tract to the protocerebrum, as do comparable neurons in normal male ALs. The other 9 cells responded to pheromone either with a mixed response (4 cells) or with complete inhibition (5 cells). One of the inhibited cells was identified as a projection neuron with dendrites confined to an "ordinary" (non-sexually dimorphic) glomerulus. Such cells in normal males have never been shown to respond to sex pheromones. Cobalt staining of trichoid sensilla on the grafted antenna revealed that some pheromone-receptor axons terminate in areas other than the MGC in the gynandromorphic AL.

CODING IN OLFACTION: EFFECT OF STIMULUS CONCENTRATION ON QUALITY CODING BY CELL POPULATIONS IN SPINY LOBSTERS. M.-N. Girardot and C.D. Derby. Dept of Biology, Georgia State University, Atlanta, GA 30303

The primary olfactory tract lobster identifies chemicals by the absolute response magnitude (ARM) and the relative response magnitude (across-neuron pattern, ANP) of cell population; the former seems to encode concentration, the latter, type. The present study is aimed toward evaluating these differential effects of concentration and type, and the effects of concentration on quality coding, using a discrimination index (D.I.) for each stimulus, which takes into account the Euclidean distances within-type (between the 3 concentrations) and between-type (between the 3 concentrations of a type and all other stimuli). The distances were derived from the stimulus coordinates resulting from multidimensional scaling applied to extracellular responses of neurons isolated from the antennular nerve to stimulation of the antennule with either four types of natural extracts, or four types of artificial mixtures based on the chemical composition of the extracts. All stimuli were applied at .005, .05 and .5 mM. The results confirm that stimulus concentration is encoded predominantly by ARMs, and slightly (but only for the artificial mixtures) by ANPs, and that stimulus type is encoded essentially by ANPs. They further demonstrate that the stimuli could not be identified by their overall population responses because of stimulus concentration. For the natural extracts, concentration affects quality coding only by its effect on ARM: removing this effect improved mean D.I. from -.11 to .49 ($0<D.I.<1$, $D.I.\leq 0$ = no discrimination). For the artificial mixtures, the effect of concentration was divided between ARM and ANP: sequentially removing these two effects improved mean D.I. from -.10 to .23 to .37. The results have important implications for choice of parameter in the field of chemical quality coding.

PROJECTION PATTERN OF OLFACTORY NEURONS IN CRAYFISH BRAIN. DeF. Mellon and S. Munger. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

In the crayfish, Procambarus clarkii, the primary olfactory receptor organs are blunt antennular hairs called aesthetascs. Within each aesthetasc are branched distal dendrites from about 175 functionally heterogeneous primary olfactory neurons in a ganglionic cluster. In older Procambarus there are more than 150 aesthetascs; thus the major olfactory field comprises about 30,000 elements on each side. Axons of the primary olfactory neurons run within the antennular nerve to the brain and enter the ipsilateral olfactory lobe. Each olfactory lobe is comprised of local, afferent, and efferent fiber tracts, and regions of dense neuropile organized into more than 100 columnar arrays, or glomeruli. We used axoplasmic transport of tritiated leucine to examine the afferent projection to the olfactory lobe. If each sensory neuron penetrates only one glomerulus, several patterns are possible: 1) sensory neurons from any one aesthetasc all may project to the same glomerulus; 2) functionally identical neurons in every aesthetasc may project to the same glomerulus; 3) there may be random projection. By restricting uptake and transport of tritiated leucine to just a few aesthetascs we could test the validity of possibility #1, since the number of labeled glomeruli should then equal the number of exposed aesthetascs. Instead, we found uniform labeling of every glomerulus in the ipsilateral olfactory lobe, although the density of label was considerably less on the experimental side compared to the maximally exposed control side. Our data eliminate possibility #1, suggesting multiglomerular targeting by neurons in each sensory ganglion. Supported by the Whitehall Foundation.

IDENTIFIED DESCENDING INTERNEURONS IN THE MALE GYPSY MOTH RESPOND TO COMBINATIONS OF SEX-PHEROMONE, VISUAL AND WIND STIMULI. M.A. Willis* and R.M. Olberg. *Dept. of Entomology, University of Massachusetts, Amherst MA 01003 and Dept. of Biological Sciences, Union College, Schenectady NY 12308.

Like many insects, gypsy moths use an airborne pheromone for mate location. In response to female pheromone, the male flies a zigzagging course upwind. This anemotactic behavior is visually guided, the moth detecting his drift relative to the environment to determine wind direction and velocity.

In an effort to understand the neural basis for this complex orientation behavior, we studied the responses of large descending interneurons to pheromone, visual pattern movements, and wind. We presented varying levels of these three stimuli alone and in combinations designed to simulate conditions experienced in flight.

About 80% of axons penetrated with microelectrodes showed responses to the female sex-pheromone, and of these, most also responded to other modality stimuli. After recording sensory responses we injected each neuron with Lucifer Yellow. Pheromone-sensitive descending neurons originate in the protocerebrum and run dorsally in the VNC, passing through the prothoracic ganglia via the median dorsal tract and extending to the pterothoracic ganglia.

Of particular interest is an interneuron whose visual responses are gated by pheromone. This cell showed no obvious response to either onset or offset of pheromone or to wide-field visual pattern movement. When the same visual stimuli were presented with pheromone in the airstream the neuron became strongly directionally selective, with leftward and forward movements inhibiting it and backward and rightward movements exciting it. Such pheromone-modulated visual responses are what we might expect from the neural elements involved in steering the complex upwind flight path of these insects.

154.17

INPUT-OUTPUT ORGANIZATION OF THE SNAIL PROCEREBRUM. R. Chase and B. Tolloczko*. Dept. of Biology, McGill Univ., Montreal, Quebec, H3A 1B1.

The procerebrum is a distinctive region occupying one-third the total volume of the brain in all terrestrial molluscan species. Hänstrom, in 1925, described a massive afferent input via the tentacular (olfactory) nerve and an intrinsic population of small neurons having no axons. However, a neural pathway has not yet been identified leading from the procerebrum to any other part of the CNS. We have investigated the functional connections of the procerebrum by a series of labelling experiments employing the anterograde and retrograde movement of hexamminecobalt. We have identified a population of about 20 neurons in Achatina fulica which send lengthy dendrites into the procerebral neuropile from the pedal ganglion. These are small cells, arranged in 2 groups at a posterior, medial position on the dorsal surface of each pedal ganglion. With the EM, we see labelled postsynaptic processes in the procerebrum after application of hexamminecobalt to the cerebral stump of the cerebro-pedal connective. The procerebral neuropile contains a finely textured intermingling of processes derived from the tentacular nerve (input), the procerebral neurons (local interneurons) and the pedal neurons (output).

TRANSMITTERS IN INVERTEBRATES II

RESPONSES OF THE SPINE LIGAMENT OF THE SEA URCHIN EUCIDARIS TRIBULOIDES TO CHOLINERGIC DRUGS. M. Morales*, J. del Castillo* & D.S. Smith*+. (spon. by C. Zuazaga), Inst. of Neurobiol. UPR-MSC, 201 Blvd. del Valle, San Juan, Puerto Rico, 00901 and + Dept. of Zoology, U. of Oxford, Oxford OX1 3PS, England.

The spine-test articulation of the sea urchin is surrounded by a collagenous ligament whose consistency can change reversibly from compliant to stiff. Acetylcholine (ACh) induces stiffness at concentrations as low as 10^{-7}M (Takahashi, K., J. Fac.Sci.U.Tokyo, 11:121-130,1967) suggesting the presence of ACh receptors. To characterize them we have examined the effects of several compounds: carbamylcholine, nicotine, methacholine, tetramethylammonium, choline and d-tubocurarine induced stiffness, while dimethylphenylpiperazine, a potent agonist, and decamethonium relaxed it. Muscarine and atropine had weak and inconsistent effects thus discarding the presence of muscarinic receptors.

It seems improbable that the observed responses are mediated by conventional nicotinic receptors. However, all the drugs tested are likely to establish ionic bonds with the acidic sites of the proteoglycans. The response (relaxation or stiffening) resulting from this interaction may reflect the overall physicochemical properties of the compounds bound to the matrix rather than a chemical complementarity.

155.2

LOCALIZATION OF DROSOPHILA CHOLINERGIC NEURONS WITH IN SITU HYBRIDIZATION. R.P.Barber,* M.Lee,* H.Sugihara,* P.M. Salvaterra, and J.E.Vaughn. Div. of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

An antisense cRNA probe complementary to Drosophila ChAT mRNA has been localized within the cortical rind and primary sensory neural regions of Drosophila using *in situ* hybridization methods. Substantial concentrations of the probe were observed in cellular regions of the cerebral and optic lobe cortices. Hybridized probe within the monopolar cell layer of the lamina appeared to be homogeneously distributed. This contrasted to that in other cortical regions where the probe concentration in some areas was very heavy, whereas in others it ranged from moderate to none. No significant amount of probe was found in cell body sparse neuropil regions. There were substantial amounts of hybridized probe in the antennae and significant amounts in the compound eye. The sense (control) probe, a sequence of RNA not complementary to ChAT mRNA, did not hybridize in significant amounts in either cortical or neuropil regions. A quantitative analysis revealed that the highest concentration of probe was in the laminae and cerebral cortical regions. About half of that concentration was observed in the second and third order optic lobe cortex and in the antennae. The probe was less concentrated in the compound eye than in the antennae, possibly reflecting the reduced density of retinule cell packing. Supported by NIH grant NS18858.

CHOLINERGIC MODULATION OF AN IDENTIFIED MOTONEURON AND ITS AFFERENT INPUT IN THE NICOTINE-RESISTANT INSECT MANDUCA SEXTA. B.A. Trimmer and J.C. Weeks. Dept. of Entomological Sciences, Univ. of California, Berkeley, CA 94720.

The tobacco-feeding insect Manduca sexta, like other insects, uses acetylcholine (ACh) as its primary sensory neurotransmitter. Thus, unitary EPSPs evoked in the motoneuron PPR by direct afferent input from mechanosensory hairs can be blocked with cholinergic antagonists. Our studies suggest that nicotinic ACh receptors in M. sexta may be adapted to have a low affinity for nicotine itself. In addition, muscarinic agents evoke responses in PPR that are distinct from those caused by nicotinic agents. These effects include agonist-induced suppression of the afferent EPSPs, resting potential oscillations, and a decrease in the spike threshold. Local application of muscarine by iontophoresis suggests that the change in spike threshold is mediated by receptors on PPR itself. Muscarinic antagonists can block these effects and also potentiate the unitary EPSP. These results are consistent with the presence of modulatory postsynaptic muscarinic receptors and another group of inhibitory receptors that act presynaptically to regulate ACh release from the afferents. We are presently using physiological and biochemical methods to determine the location and actions of these putative muscarinic acetylcholine receptors. Supported by a research grant from the Whitehall Foundation.

155.4

IMMUNOCYTOCHEMICAL LOCALIZATION OF HISTAMINE IN THE PHOTORECEPTORS AND SEGMENTAL GANGLIA OF THE BARNACLE, *BALANUS NUBILUS*. J.C. Callaway, A.E. Stuart, and J.S. Edwards. Dept. Zoology, Univ. of Washington., Seattle, WA 98195 and Dept. Physiol., Univ. of North Carolina, Chapel Hill, NC 27599.

Recent biochemical (M.S. Elias and P.D. Evans, *J. Neurochem.*, **41**:562-568, 1983) and physiological (R.C. Hardie, *J. Comp. Physiol.*, **161**:201-213, 1987) studies designate histamine as an insect photoreceptor (PR) neurotransmitter. The barnacle also appears to use histamine as a PR transmitter. Histamine is synthesized from histidine in PRs and also mimics the action of transmitter on second-order visual cells (A.E. Stuart and J.C. Callaway, *Invest. Opthal. Vis. Sci.*, **29**:223, 1988).

To determine whether histamine is localized to the PRs we used an antiserum provided by P. Panula against a histamine-protein conjugate (P. Panula et al., *J. Histochem. Cytochem.*, **36**:259-269, 1988). The antiserum labeled each of the barnacle PRs. The terminals were intensely labeled. Though label could be detected in the PR axons and cell bodies, it was sparse and appeared in small punctate granules rather than spread evenly through the cytoplasm. Incubation of PRs with 100μM histidine 18 hrs. prior to fixation significantly increased the signal in the cell bodies, but it was still punctate.

In the segmental ganglia of the barnacle only eight neurons were labeled. Label was found in the cell bodies, neurites, and terminals and was not obviously punctate. These cell bodies were located in only the most posterior segments of the fused ventral ganglion but had had an extensive network of processes and endings in every segment of this ganglion. None of these cells sent processes to to supraesophageal ganglion which contains the PR terminals. Supported by NIH grants NS07778 to JSE and EY03347 to AES.

155.5

HISTAMINE IMMUNOREACTIVITY IN THE COCKROACH BRAIN AND VISUAL SYSTEM. U. Pirvola *and P. Panula. (Spon. L. Kivipelto). Department of Anatomy, University of Helsinki, Finland.

The distribution of histamine immunoreactivity (HA-ir) in carbodiimide-fixed brain of the cockroach, Blaberus craniifer, was revealed immunocytochemically with an antiserum against HA. The results showed a widespread distribution of HA-ir somata and fibers in the brain, particularly in the visual system. The most intense immunolabelling was seen in the retinal photoreceptors and in the lamina, where short visual fibers terminate. HA-ir long visual fibers as well as reactive monopolar neurons traversed the outer chiasma and terminated in the distal medulla. HA-ir inside photoreceptors was revealed also in samples prepared for electronmicroscopy. HA-ir neurons and tracts of immunolabelled fibers were seen as well in other parts of the optic lobes and in the protocerebrum. Central parts of the brain, including the central body, contained strongly fluorescent varicose processes. In addition, substantial HA-ir was seen in the antennal lobes, but not in the antennal nerves. These results support strongly the hypothesis of HA acting as a neurotransmitter in the insect central nervous system and particularly in the photoreceptors.

155.6

GABA-IMMUNOREACTIVITY IN THE BRAIN OF LARVAL AND PUPAL *MANDUCA SEXTA*. U. Homberg and J.G. Hildebrand ARL Div. of Neurobiol., Univ. of Ariz., Tucson, Arizona 85721

The sphinx moth *Manduca sexta* is a holometabolous insect with 5 larval instars and adult development of about 3 weeks (18 pupal stages P0-P17). During metamorphosis, its nervous system undergoes dramatic changes: some neurons die, many neurons are remodeled, and many new neurons are born [*TINS* 9:315 (1986)].

We have investigated the distribution of GABA-immunoreactivity (GI) in the larval brain of *Manduca* and changes in GI during metamorphosis. GI in the adult brain has been studied previously [*Cell Tiss Res 248*:1 (1987)].

In the larva, about 300 cells per brain hemisphere exhibit GI. All brain neuropils are innervated by immunoreactive fibers. The staining pattern and the number of immunoreactive cells change little during the 5 larval instars. Shortly before pupal ecdysis, GI starts to decrease and later disappears in many neurons in the central brain, while it first appears in the optic lobes and in a thin layer of fibers in the central body. GI in the ventro-lateral protocerebrum and in the circumoesophageal connectives remains unchanged. Starting at pupal stage P5, the adult pattern of GI slowly emerges. In lamina monopolar cells, mushroom-body Kenyon-cells, and some cells in the pars intercerebralis, GI is expressed in the pupa but disappears before adult ecdysis.

The changes in GI partly correlate with peaks in ecdysteroid-titers. The results suggest that many larval GABA-immunoreactive cells do not express GI during morphological reorganization or die, while others express GI only during a certain period of pupal life. [Supported by NIH Grant AI-23253 and Monsanto Company.]

THE GABA RESPONSE OF THE ISOLATED HEART OF LIMULUS POLYPHEMUS EXHIBITS NOVEL PHARMACOLOGY. J.A. Benson, R & D Plant Protection, Agricultural Division, CIBA-GEIGY Ltd., CH-4002 Basel, Switzerland.

GABA (gamma aminobutyric acid) causes a dose-dependent decrease in the beat frequency of the isolated heart of Limulus. The GABA receptor or receptors mediating this response are potently activated by muscimol and isoguvacine, $GABA_A$ agonists. Baclofen, the diagnostic $GABA_B$ agonist, is without effect. However, bicuculline, the diagnostic $GABA_A$ antagonist does not block the GABA-induced inhibition at concentrations up to 10^{-4} M and the response is affected only weakly or not at all by pitrazepine, a more potent $GABA_A$ antagonist. Picrotoxin, which blocks $GABA_A$ Cl^- channels, reduced the GABA response weakly or not at all (up to 10^{-4} M). Taurine and glycine are inactive. The response is not modulated by 10 min. preapplication of the benzodiazepine flunitrazepam (10^{-6}, 10^{-5} M) nor by sodium pentobarbital (10^{-6} - 10^{-4} M). Thus, although exhibiting $GABA_A$ agonist characteristics, the Limulus heart GABA response differs in pharmacological profile from both of the vertebrate GABA receptor types, and does not seem to be functionally associated with either benzodiazepine or barbiturate modulatory receptors.

155.8

A MAP OF THE GABAergic NEURONS IN SEGMENTAL GANGLIA AND THE STOMATOGASTRIC SYSTEM OF THE CRAYFISH. B. Mulloney and W.M. Hall*. Dept. of Zoology, Univ. California, Davis CA 95616.

Gamma-aminobutyric acid (GABA) is known to be a transmitter at inhibitory peripheral synapses in crustaceans (Otsuka, et al. 1966). We have mapped the locations of all the nerve cell bodies that show GABA-like immunoreactivity in the segmental ganglia and stomatogastric system of the crayfish, *Pacifastacus leniusculus*, using a polyclonal antibody specific for GABA fixed *in situ* (Hoskins, et al. *Cell Tis. Res.* 244: 243-252 1986).

To localize GABA reliably, we fixed the nervous system by perfusion under pressure. Primary fixation with 4% formaldehyde-0.1% glutaraldehyde in PBS at pH 7.4 for 15 min was followed by a secondary fixation with picric acid-formaldehyde for 6 hr. To label GABAergic neurons in whole-mounts, ganglia were desheathed, washed in PBS, dehydrated to 70% EtOH overnight, rehydrated and soaked in a blocking solution with 0.03% Triton X-100. Ganglia were incubated with primary antibody (1:750) for 24 hours, washed repeatedly with blocking solution, and incubated overnight with an FITC-conjugated secondary antibody, before being dehydrated, cleared and photographed.

These methods label known GABAergic motor neurons in each abdominal ganglion, e.g. FI and fi, but fail to label other motor or sensory neurons that run in the same peripheral nerves. Therefore, interneurons and other motor neurons labeled by these procedures are probably also GABAergic.

In ganglia that innervate swimmerets, each nerve to a swimmeret contained three labeled axons, one projecting to return-stroke muscles and two to power-stroke muscles. Other labeled neurons in the OG, CGs, SOG and terminal abdominal ganglion will also be described.

EVIDENCE THAT GABA IS A NEUROTRANSMITTER IN THE CRAYFISH MEDULLA. C.L. Pfeiffer, L. Wang-Bennett, and R.M. Glantz, Department of Biology, Rice University, Houston, TX. 77001.

There is growing evidence that Gaba is a neurotransmitter in arthropod optic lobes. We examined the distribution of Gaba in the eyestalk of the crayfish with an antisera to a Gaba-glutaryl-protein conjugate. Tissues were fixed in a modified Bouin's fixative. Optic lobes and cryostat sections were incubated in primary antibody at 1:1000. Reactive sites were visualized by the PAP procedure. Controls included preabsorption with immunogen and tests for nonspecific secondary antibody binding. Gaba-like reactivity was observed in photoreceptor R8; in the outer and inner lamina cell body layers and in a thin layer of lamina plexiform. Reactivity was also strong in 3 layers of each medullary neuropile (ME, MI), the medullary cell body region and in localized regions of the medulla terminalis.

Pharmacological actions of Gaba were examined in sustaining fibers (SF), tangential (Tan 1) and medullary amacrine cells (MA) in the ME. SFs are tonic "on" interneurons, synaptically depolarized by light and subject to surround inhibition by MA. The MAs act presynaptic to the SFs. Gaba and muscimol mimic the action of MA on SF light response. MA neurites also overlie Tan 1 dendrites. Tan 1 exhibits an Ach mediated, chloride dependent hyperpolarization to light and depolarize to light off. Gaba and muscimol mimic the light off response. Thus, Ach and Gaba have antagonistic effects on medullary interneurons. These results support the hypothesis that Gaba is an important neurotransmitter in the ME. Supported by NSF Grant BNS87-11141.

EFFECTS OF ACH AND GABA ON CONTRACTIONS OF THE OPENED FILARIID, DIPETALONEMA VITEAE. D. Christ, M.J. Goebel* and H.J. Saz*. South Bend Center for Medical Education, Indiana University School of Medicine and Department of Biological Sciences, University of Notre Dame, Notre Dame, IN 46556.

ACh and GABA are putative neuromuscular transmitters in nematodes, however they are relatively inactive on intact D. viteae. The cuticle may block the penetration of these substances; thus ACh and GABA were tested on adult, female D. viteae which were isolated from hamsters, slit open longitudinally, and mounted in an isolated tissue bath containing warmed, aerated physiological solution. ACh (10^{-7} M) induced rapid, reversible increases in the spontaneous isotonic contractions. At higher concentrations contractures were produced. Nicotine (10^{-6} M) and pilocarpine (10^{-6} M) were also effective agonists, however their potencies were similar to the potencies on intact D. viteae. The cholinoceptor antagonists, atropine, d-tubocurarine and hexamethonium, were relatively inactive in reducing either spontaneous activity or the effect of ACh. GABA (10^{-7} M) depressed the spontaneous activity. This effect was rapid in onset and readily reversible. Muscimol (10^{-5} M) had a similar action, however the potency of muscimol was the same as in the intact D. viteae. The GABA antagonists, picrotoxin and penicillin G, did not affect the action of GABA. These results indicate that ACh and GABA do not readily penetrate the body wall of D. viteae. Also, the filariid receptors have unique pharmacological properties. (Supported in part by NIH Grant AI 09483)

155.11

THE PRESENCE OF DOPAMINE IN NERVE RICH TISSUE OF THE HYDROZOAN *Polyorchis penicillatus*. J.M. Chung* and A.N. Spencer, Dept. Zoology, Univ. of Alberta, Edmonton, AB, CANADA T6G 2E9.

Several lines of morphological and physiological evidence support the existence of chemical transmission in the Cnidaria. However, there are no conclusive data on the nature of these neurotransmitters. Some histochemical and chromatographic studies implicate the biogenic amines in several cnidarian species while other studies deny the presence of known catecholamines. In the present study, we have quantitatively demonstrated the presence of dopamine (DA) using HPLC with electrochemical detection (LCED) and confirmed its presence qualitatively using gas chromatography/mass spectrometry (GC/MS) in the hydrozoan *Polyorchis penicillatus*.

Selected tissues were dissected from live animals starved for a minimum of 2 days and treated with activated alumina to extract catecholamines. The alumina extracts gave complex chromatograms with peaks having retention times similar to those of norepinephrine (NE), epinephrine (E), dihydroxyphenylalanine (DOPA), and DA. We therefore used two sets of LCED conditions (LCED-1 and -2), in which the columns and mobile phases were different. The chromatograms using LCED-1 showed peaks which retention times corresponding to NE, E, and DA while the chromatograms using LCED-2 showed peaks corresponding to DOPA and DA. GC/MS confirmed the presence of DA. Alumina extracts were dried, derivatized using trifluoroacetic anhydride and ethyl acetate, and then introduced to the GC/MS. Negative ion chemical ionization mass spectra and selective ion current chromatograms demonstrated the presence of DA and not NE, E, DOPA in tissue samples of *Polyorchis penicillatus*.

Three types of tissue were analyzed: nerve-rich tissue from the margin, endoderm-rich tissue from the radial canals, and mesoglea. Nerve-rich tissues contain DA at the highest concentration (120±30 fmol/mg wet wt.) followed by endoderm-rich tissues and mesoglea (30±5 fmol/mg wet wt. and 10±1.5 fmol/mg wet wt., respectively). Any substances existing as a neurotransmitter can be expected to be found in relatively higher concentrations in nerve-rich tissues than tissues having few or no neurons. Thus, these results suggest tentatively the biological role of DA as a putative neurotransmitter in the hydrozoan *Polyorchis penicillatus*.

155.12

OCTOPAMINE IMMUNOREACTIVE NERVE TERMINALS ARE FOUND ON A SINGLE IDENTIFIED MUSCLE FIBER OF THE *DROSOPHILA* LARVAL BODYWALL. M.E. Halpern, M.S. Anderson, J. Johansen and H. Keshishian. Dept. of Biology, Yale University, New Haven, CT 06511.

Previously we described the segment and muscle fiber specific distribution of proctolin nerve terminals on the bodywall musculature of *Drosophila* larvae. Using antisera against the neurotransmitter octopamine, we have discovered that octopamine immunoreactive nerve endings are located on a single muscle type, the pleural external longitudinal fiber #12. Although muscle #12 homologs are found in the metathorax and in all the abdominal segments, the stained endings are principally located on this muscle in abdominal segments 2 through 5. Fewer than 5% of the muscles examined in the first abdominal segment exhibited octopamine immunoreactive nerve endings, and they were never found on the #12 homologs in the metathorax or in the abdominal segments 6 and 7. As was shown with proctolin, the pattern of octopamine immunoreactive innervation can be altered in larvae that are haploinsufficient for Bithorax complex function, resulting in an increase of A1 endings and endings on an inappropriate target, muscle #13. Since the mature distribution pattern is present in first instar larvae, we are examining when it is established in embryogenesis in both normal and mutant embryos.

Double labeling experiments indicate that the octopamine immunoreactive terminals also contain glutamate, and that they comprise a subset of the total innervating processes found on muscle #12. This muscle fiber also receives proctolin innervation and we are determining whether this peptide also is present in the octopamine immunoreactive motor endings. Neurochemical techniques are underway to demonstrate whether the immunoreactive material is authentic octopamine. and physiological approaches will enable us to dissect the functions of the segmental, muscle fiber, and nerve terminal neurochemical specializations. (The octopamine antisera were generously provided by Dr. E. Kravitz.)

155.13

OCTOPAMINE AND FORMAMIDINES INCREASE PROTEIN SYNTHESIS IN Drosophila NERVOUS SYSTEM. M. Ofarim* and Y. Dudai (SPON: V. Teichberg). Department of Neurobiology, Weizmann Inst., Rehovot 76100, Israel.

Low concentrations of formamidines selectively interfere with behavior and development in insects and acarides. In Drosophila, formamidines disrupt sensory and motor functions and reduce learning ability; this is at least partially due to stimulation of the cAMP cascade via octopamine receptors (Dudai et al., J. Comp. Physiol. 161: 739, 1987). Since cAMP, in addition to activating protein kinase, may also regulate gene expression, we have tested whether formamidines affect protein synthesis in Drosophila nervous system. Larval brains were incubated with [^{35}S]methionine in the absence and in the presence of chlordimeform, N,N-dimethyl-N2-(2,4-dimethylphenyl)-formamidine-HCl, and octopamine. Following incubation, the brains were homogenized and subjected to SDS-gel electrophoresis. Increased radiolabeling was detected in brains incubated with octopamine and formamidines, especially in polypeptides of MW of ca. 76 and 53 kDa. The results support a potential role for octopamine in modulating protein synthesis in the nervous system, and suggest that whereas the acute effects of formamidines on behavior probably result from interference with ongoing aminergic transmission, their effects on development may result from cAMP-mediated alteration in gene expression. (Supported by the US-Israel Agricultural Research and Development Fund (BARD)).

Modulation of two portions of the cockroach escape circuit by biogenic amines. R. S. Goldstein, & J.M. Camhi, Dept. Zoology, Hebrew University, Jerusalem, Israel

We have studied the effects of serotonin (5-HT), dopamine (DA) and octopamine (OA) on the neural circuit underlying cockroach escape behavior. The release of one or more of these neuromodulators may be responsible for the natural variability of the behavioral response to wind stimuli (J.M. Camhi, this volume).

The first synapse in the escape circuit is in the terminal abdominal ganglion (A6), from afferents of wind-receptive hair cells on the cerci (paired abdominal appendages), onto interganglionic giant interneurons (GI's). 5-HT and DA perfused locally over A6 had little or no effect on the wind-evoked response recorded from the axons of these interneurons. However, OA dramatically enhanced the sensitivity and duration of the wind-evoked response of GI's of both the dorsal and ventral groups, and the effect of OA was reversed by rinsing with normal saline.

The next synapses of the circuit are located in the thoracic ganglia, where GI's activate motorneurons innervating the legs, via thoracic interneurons. We studied the effects of these amines on the response of metathoracic (T3) leg motoneurons to activation of the abdominal GI's. In contrast to their lack of effect in A6, both 5-HT and DA had profound effects on the circuit in T3. 5-HT consistently depressed, and DA enhanced the magnitude of the motor response to GI activation when perfused over the metathoracic ganglion. 5-HT also increased the rate of habituation of the motor response. OA's effects were less clear.

We are now beginning to study the cellular basis of these central aminergic effects, as well as examine behaviorally their modulation of cockroach running and flying escape.

155.15

SELECTIVE DEPLETION OF DOPAMINE, OCTOPAMINE AND 5-HYDROXYTYPTAMINE IN THE NERVOUS TISSUE OF THE COCKROACH (***PERIPLANETA AMERICANA***). B.D.Sloley* and S.Orikasa* (SPON: J.S. Richardson). Neuropsychiatric Research Unit, Dept. of Psychiatry, Univ. of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0.

High performance liquid chromatography with electrochemical detection (HPLC/ED) was used to measure the concentrations of 3,4-dihydroxyphenylethylamine (dopamine, DA), 5-hydroxytryptamine (5-HT), p-hydroxyphenylethanolamine (octopamine), α-methyl-p-tyrosine and tryptophan in the cerebral ganglia of cockroaches (*Periplaneta americana*) after peripheral administration of α-methyl-p-tyrosine or α-methyltryptophan. In addition, the levels of DA, 5-HT, octopamine, α-methyl-p-tyrosine and tryptophan were determined after injection of α-methyly-p-tyrosine, 6-hydroxydopamine or 5,7-dihydroxytryptamine directly into the cerebral ganglia by means of microinjection needles. Peripheral administration of α-methyl-p-tyrosine 400-1600 µg/insect) caused a reduction in dopamine and 5-HT concentrations in cockroach cerebral ganglia although the reduction in DA concentrations was more pronounced. Peripheral injections of α-methyl-p-tyrosine also reduced octopamine levels in the cerebral ganglia. Peripheral injection of α-methyltryptophan (400-1600 µg/insect) caused a marked reduction in 5-HT and tryptophan concentrations in cockroach cerebral ganglia without altering dopamine or octopamine concentrations. Central injections of α-methyl-p-tyrosine (80 µg/insect) reduced DA concentrations in the cerebral ganglia. However, neither 6-hydroxydopamine (20 µg/insect) nor 5,7-dihydroxytryptamine (20 µg/insect) caused reductions in amine levels when applied near or directly into the cerebral ganglia. The results suggest that specific lesions of aminergic neurons in insects by either 6-hydroxydopamine or 5,7-dihydroxytryptamine are impractical. The specific, long lasting depletion of 5-HT by α-methyltryptophan suggests that this chemical may be useful in elucidating the functions of 5-HT in insects. Research supported by the Saskatchewan Health Research Board.

RESERPINE DEPLETES SEROTONIN FROM THE CNS OF THE LEECH (HIRUDO MEDICINALIS) AND DRASTICALLY ALTERS BEHAVIOR. B. A. O'Gara and W. O. Friesen, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Serotonin is known to have an important role in the control of swimming and feeding in the leech (Willard, J. Neurosci. 1:936-944, 1981; Lent, Brain Res. Bull. 14:643-655, 1985). As a first step in characterizing the effects of serotonin on the neural elements involved in swimming activity, we have determined the extent and time course of reserpine-induced depletion of serotonin from the nervous system. Injection of reserpine into the crop (100 µg/leech) causes depletion of serotonin (determined with HPLC-EC) from about 20 pmoles/ganglion in normal leeches to undetectable levels (< 0.1 pmoles/ganglion) by 3 - 5 days post-injection. Recovery of serotonin levels occurs slowly, taking weeks to months.

Reserpine-injected leeches show grossly abnormal behavior. The animals are lethargic and are less responsive to stimuli than normal. With sufficient prodding, the animals will swim, but the swimming movements appear abnormally stiff. However, after continued swimming, the movements become normal in appearance. When handled, the leeched show these abnormal behaviors: dorsal-ventral flattening, increased body wall tonus, erected annuli, reduced sucker attachment, reduced exploratory movements of the head, and occasional swimming movements. Biting behavior is eliminated by reserpine with a time course similar to serotonin depletion. However, biting reappeared when serotonin levels were still very low. Supported by NIH grants NS08263 (B.A.O.) and NS21778 (W.O.F.)

SEROTONIN MODIFIES SYNAPTIC TRANSMISSION IN NEURONAL CIRCUITS OF THE LEECH (HIRUDO MEDICINALIS). W. O. Friesen, A. K. Cometa and H. Hashemzadeh, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The ventral nerve cord obtained from untreated leeches exhibits episodes of swimming activity subsequent to appropriate electrical stimulation. Treatment of leeches with reserpine depletes serotonin from the nervous system and engenders a reduction in the activity levels of these animals (see abstract by O'Gara and Friesen, this volume). We found that nerve cords obtained from treated animals rarely exhibit swimming activity, even when subjected to strong electrical stimulation. Following bath application of 50 μM serotonin these previously quiescent nerve cords express swimming activity both spontaneously and following electrical stimulation.

To determine the mechanisms by which serotonin restores swimming activity in these preparations, we searched for serotonin-induced alterations in the synaptic interactions between neurons in the neuronal circuits that generate leech swimming activity. We tested synaptic transmission between swim-related neurons prior to and then following bath application of 50 μM serotonin in isolated leech nerve cords obtained from animals treated previously with reserpine. Inhibitory synaptic interactions between motor neurons exhibited synaptic fatigue following, but not prior to the application of serotonin. Similarly, synaptic fatigue in the inhibitory synapse between oscillator cell 115 and DI-102 increased substantially with the application of serotonin. Recovery from synaptic fatigue occurs more rapidly in the presence of serotonin. Such modifications can facilitate oscillations in neuronal networks with reciprocal inhibition. Supported by NSF grant BNS84-14988.

MODULATION OF THE ELECTROTONIC STRUCTURE OF APLYSIA NEURONS BY SUBTHRESHOLD VOLTAGE SHIFTS AND SEROTONIN. M. Spira,* I. Segev,* R. Werman* and Y. Yarom* (SPON: M.J. Gutnick), Dept. Neurobiology, Hebrew Univ., Jerusalem 91 904, Israel.

Aplysia metacerebral neurons have an inherent capability to dynamically alter their input-output characteristics. We have studied this capability in isolated, cultured adult neurons by analyzing their cable properties (R_N, τ_0 and L) and correlated them with a compartmental model based on their structure, reconstructed from light-microscopy photographs. The membranes of these neurons exhibit marked nonlinear behavior at sub-threshold potentials, -30 to -70 mV. High conductance states were observed at -30 to -40 mV and at -60 to -70 mV. As a result, L (estimated from transient analysis) increases more than three-fold over a potential range of 20 mV. A close correlation between τ_0, L and R_N was always observed. Since the membrane time constant τ_0 was in the range of hundreds of msec, a short L (0.2 - 0.3) could, for the first time, be resolved using the peeling technique. Under such circumstances, the decay of a voltage response to a short current pulse injected into the soma was characterized by two clearly separable time constants of decay. This behavior, as well as the increase in L seen in the high conductance state, was predicted from the compartmental model. This serotinergic cell is also remarkably sensitive to 5-*HT*, which increased R_N significantly (1 μM). This increase in R_N, however, was always restricted to the voltage range where R_N usually peaked, indicating a voltage dependence of the 5-*HT* response. A corresponding decrease in L and an increase in τ_0 were observed physiologically and predicted theoretically. Our study provides, for the first time, a demonstration that the electrotonic structure of a neuron and, thus, its integrative capabilities can be dramatically altered by subthreshold potentials and by neuromodulators.

THE RELEASE OF SEROTONIN FROM THE PERIPHERAL NERVOUS SYSTEM OF THE BLOOD-FEEDING INSECT, RHODNIUS PROLIXUS STÅL, IN RESPONSE TO FEEDING. T. Orchard, A.B. Lange and F.M. Barrett*, Dept. of Zoology, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A1

A peripheral role for serotonin in the blood-feeding bug Rhodnius prolixus has been implied by the presence of a plexus of serotonin-like immunoreactive processes lying on several of the abdominal nerves (Flanagan, T.R.J., Brain Res. 306:235, 1984). We have now examined the serotoninergic system in Rhodnius in more detail and show here, using HPLC, that serotonin is contained within these neurohaemal areas and that it can be released in a calcium-dependent manner. Serotonin-like immunoreactive processes also extend along the full length of the abdominal nerves and form an extensive plexus covering the epidermis. The immunoreactivity over the abdominal integument is barely visible in fifth instars 15 min after the onset of gorging. Furthermore haemolymph serotonin concentration is elevated 16-17 fold within 5 min of the onset of gorging on blood or an artificial diet. The stimulus for the release of serotonin is not associated with merely the onset of feeding since the serotonin levels do not continue to rise in insects allowed to gorge for only one minute. These findings indicate that serotonin is associated with feeding in Rhodnius and we are examining the action of the neurotoxin 5',7'-dihydroxytryptamine upon serotonin content and feeding activity.

BILATERALLY HOMOLOGOUS CELLS IN LYMNAEA CONTAIN DIFFERENT NEUROTRANSMITTERS. BJ Chiasson*, RP Croll, PC Kind*, JD Boyd*, RL Cowling*, MM Meriam*, DN Chilibeck*, LC Boghiar*. Dept Psychol, Dalhousie Univ, Halifax, NS, Canada B3H 4J1

RPeD1 and LPeD1 are two large central neurons located in symmetric positions in the right and left pedal ganglia, respectively, of Lymnaea. In addition to size and position, these cells are distinct from most pedal cells since they have no processes in any pedal roots. (Slade et al, 1981, J Exp Biol). Dye fills reveal basic symmetry between neurites of LPeD1 and RPeD1 (see Haydon & Winlow 1981, J Exp Biol); both cells project to ipsilateral pleural and parietal ganglia and into the visceral ganglion. Few other pedal cells are revealed by backfills of parietal and visceral nerves. In spite of their similarities the two cells differ in one important regard. Previous work has shown that RPeD1 contains dopamine whereas LPeD1 contains serotonin (Cottrell et al, 1979, Neurosci). We further show that RPeD1 contains no detectable serotonin and that LPeD1 contain little or no dopamine. As a likely consequence of the biochemical differences, the functional output of the cells is quite different. RPeD1 elicits discrete psp's in several parietal and visceral cells (Winlow et al, 1981, J Exp Biol), whereas our initial studies reveal no corresponding cells post-synaptic to LPeD1. Since morphological similarities suggest bilateral homology, very specific cues might dictate different transmitter phenotypes during what is probably the otherwise similar development of these cells.

BIOLOGICAL RHYTHMS: CELLULAR MECHANISMS

156.1

EXTRACELLULAR CALCIUM AND CALCIUM CHANNEL DEPENDENCY OF PHASE SHIFTS OF THE BULLA OCULAR CIRCADIAN PACEMAKER. S.B.S. Khalsa and G.D. Block. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

The in vitro ocular circadian pacemaker of Bulla is phase-shifted by light and other depolarizing treatments of the putative pacemaker cells (the basal retinal neurons). McMahon & Block (J. Comp. Physiol. 161:335, 1987) observed that light-induced phase delays were blocked in low Ca^{2+} EGTA artificial seawater (ASW) suggesting that extracellular Ca^{2+} is essential for phase-shifting.

We now report that light-induced phase advances and both delays and advances to depolarizing high K^+ ASW are also blocked in low Ca^{2+} EGTA ASW, verifying that extracellular Ca^{2+} is a general requirement for light and depolarization-induced phase-shifting.

Light-induced phase delays were also blocked in ASW without EGTA at Ca^{2+} concentrations of 400 uM or lower; concentrations of 1 mM and 3.5 mM yielded reduced phase shifts relative to those in normal ASW ($[Ca^{2+}]$=10 mM). These data suggest that it is not the EGTA which blocks phase shifts and that the threshold Ca^{2+} concentration for phase-shifting in this study is at least 400 uM.

The calcium channel blocker Ni^{2+} (5 mM NiCl) was found to be effective in blocking light-induced phase delays and advances. Phase delays to high K^+ pulses were also blocked by Ni^{2+}, however the concentration required was higher (50 mM NiCl) and the treatment produced long term changes in the waveforms of the circadian activity record. Other blockers were toxic, produced their own shifts or were ineffective. It is likely that calcium channels mediate light and depolarization-induced phase shifting. Support: NS09621, NS15264

156.2

LOW CALCIUM ATTENUATES PERIOD LENGTHENING IN CONSTANT LIGHT OF BULLA OCULAR RHYTHM: G.D. Block and L.B. Latham. Department of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The Bulla ocular pacemaker can be phase shifted by depolarizing agents but only if extracellular calcium is present (McMahon & Block, J. Comp. Physiol. **161** 1987). When calcium levels are reduced below 1 mM or when Ni^+ is added to the bath, phase shifts are blocked (Khalsa & Block, this volume).

In addition to light's phase shifting action, constant illumination (L:L) affects the free-running period. In Bulla the ocular free-running period is lengthened from 23.5 to 24.4 hr in bright L:L (McMahon & Block, J. Comp. Physiol. **161** 1987). The relationship between the phase shifting action of light pulses and the effects of constant light on free-running period has been formally addressed (Daan & Pittendrigh, J. Comp. Physiol. **106** 1976) but it is not known whether the same cellular mechanisms subserve both phenomena.

We now report that reducing the extracellular calcium level to 1 mM attenuates the period lengthening observed in L:L. We find that in normal seawater the Bulla ocular rhythm lengthens to 24.3 hr (0.13, N=5) in continuous dim light (22 lux). When calcium is reduced to 1 mM the free-running period in L:L is indistinguishable from D:D (23.7 hr, 0.16, N=5). Eyes run in 1 mM calcium seawater continue to show elevated impulse rates in L:L suggesting that the lack of period lengthening in not due to a reduced sensory response. These data indicate that similar to phase shifting, the period lengthening effects of light are calcium dependent and support the hypothesis of a common mechanism for both processes. NS15264, NS00714.

156.3

EFFECTS OF LIGHT ON CIRCADIAN MELATONIN RELEASE FROM CHICK PINEAL CELLS: CALCIUM-DEPENDENT AND -INDEPENDENT MECHANISMS. L.M. Robertson and J.S. Takahashi. Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

Chick pineal cells express a circadian oscillation of melatonin release that persists in constant conditions. The cells are photoreceptive and exposure to light has 2 major effects: 1) entrainment of the circadian oscillator and 2) acute inhibition of melatonin production. We explored the effects of calcium (Ca) on both the acute and phase-shifting effects of light on dissociated chick pineal cells. During the subjective night of the 5th day in culture cells were exposed to treatments which decreased extracellular or increased intracellular Ca. Low Ca treatment resulted in a dose-dependent decrease in melatonin release. Treatment with the Ca ionophore A23187 or the Ca channel agonist BAY K8644 blocked the light-induced reduction in melatonin release. We used a flow-through culture system to determine whether variations in Ca affect the phase-shifting effects of light. Cultures exposed to a light pulse beginning at circadian time (CT) 20 were advanced relative to dark controls. Treatment with low Ca, A23187 or BAY K8644 had no effect on either the phase of the rhythm in constant darkness or the phase-shift induced by light. Thus, the phase-shifting effects of light do not appear to involve Ca pathways. In contrast, the acute effects of light can be mimicked by low Ca treatment and blocked by treatments which increase intracellular Ca.

156.4

CALMODULIN REGULATES MELATONIN PRODUCTION IN CHICK PINEAL CELL CULTURES. S. S. Nikaido and J. S. Takahashi. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

Dissociated chick pineal cells express a circadian rhythm of melatonin release. Melatonin production in chick pineal cells is regulated by both cAMP and Ca^{2+}. Melatonin levels can be elevated with cAMP analogs, forskolin and 3-isobutyl-1-methylxanthine. Melatonin levels can be depressed by lowering Ca^{2+} levels with EGTA and with Ca^{2+} channel blockers. Furthermore, melatonin levels can be increased with the dihydropyridine Ca^{2+} channel agonist, Bay K8644.

The effect of Ca^{2+} on melatonin production appears to be mediated by calmodulin. Calmodulin antagonists, calmidazolium, W7 and W13, inhibit melatonin production during the night in a dose-dependent manner. Inactive naphthalenesulfonamides, W5 and W12, have no effect on melatonin production up to 10^{-4} M. In addition, calmidazolium blocks the increase in melatonin seen with Bay K8644, yet only partially blocks the increase in melatonin seen with 8-Br cAMP and forskolin.

These results suggest that melatonin is regulated by Ca^{2+} through a calmodulin-dependent process and that part of the cAMP regulation of melatonin also occurs through a calmodulin-dependent process.

THE SCN CIRCADIAN CLOCK IS RESET IN VITRO BY NIGHTTIME APPLICATIONS OF A cGMP ANALOG. R. A. Prosser and M. U. Gillette. Neural and Behavioral Biol. Program and Dept. of Physiol. and Biophysics, Univ. of Illinois, Urbana IL 61801.

Recent investigations on the biochemical substrates of the mammalian circadian clock in the suprachiasmatic nuclei (SCN) have found that daytime but not nighttime applications of cAMP analogs in vitro reset the SCN clock. In contrast, pulses of high K^+ are effective only during the night. Here we show that, like high K^+, pulses of a cGMP analog reset the SCN clock.

Rat SCN were isolated in a brain slice preparation and maintained in perifusion culture. Electrical activity recorded extracellularly from a population of single SCN cells normally shows a 24 hr rhythm that peaks at circadian time (CT) 7.0. 1 hr pulses of the cGMP analog Br-cGMP ($5x10^{-4}$M) between CT 16 and 18 significantly advanced the time of peak electrical activity (6.58±.37 hr advance; N=3) while 1 hr treatment between CT 7 and 10.5 had no effect on the rhythm (0.42±.74 hr advance; N=3). Thus, cGMP appears to affect the SCN clock at times similar to those when high K^+ is effective, but when cAMP is ineffective. These results suggest that these cyclic nucleotides may affect the SCN circadian clock in an antagonistic relationship.

156.6

CIRCADIAN PACEMAKER PROPERTIES ARE RETAINED BY ISOLATED SUPRACHIASMATIC NUCLEI IN VITRO. M.U. Gillette and R.A. Prosser. Neural & Behavioral Biology Prog. and Dept. of Physiol. & Biophys., Univ. of Illinois, Urbana, IL 61801.

Our previous studies on rat hypothalamic brain slices demonstrated a circadian rhythm of SCN neuronal firing rate that can be reset in vitro. In this study we determined whether the circadian pacemaking and resetting properties attributed to the SCN in vitro are endogenous, or whether there is contribution by peripheral regions in the slice. 500 µm coronal slices were surgically reduced on three sides to within 50 µm of the SCN; the chiasmatic border was not disturbed. The circadian pattern of neuronal activity was then measured in both controls and SCN exposed to $5x10^{-4}$ M 8-benzylamino cAMP (BAcAMP) for 1 hr at circadian time 7.

We found that 500 µm slices (N=4) reduced to SCN and optic chiasm maintained circadian rhythms of single unit firing rate. The amplitude and phase were unchanged from SCN rhythms in much larger hypothalamic slices including periventricular, paraventricular and supraoptic nuclei. BAcAMP induced phase-advances of 4.92±.44 hr (N=3). We conclude that these pacemaker properties are endogenous to the SCN.

156.7

PHASE-SHIFTING RESPONSES OF SUPRACHIASMATIC EXPLANTS TO IONIC MANIPULATION *IN VITRO*. D.J. Earnest, S.M. DiGiorgio and C.D. Sladek. Dept. of Neurobiology/Anatomy, Univ. of Rochester Med. Ctr., Rochester, NY 14642

Consistent with the well-established role of the suprachiasmatic nucleus (SCN) as a circadian pacemaker, we have demonstrated that vasopressin (VP) is released in a circadian fashion for multiple cycles from perifused SCN explants. To characterize the phase-shifting effect of KCl on the circadian pattern of VP release from SCN explants and better understand the formal properties of circadian rhythms generated by the SCN *in vitro*, the present study entailed systematic analysis of this circadian effect of KCl with regard to its dependence on the time of administration.

SCN explants were dissected from the hypothalami of male rats housed under LD 12:12. Individual explants were placed in a perifusion culture system under conditions of constant darkness and serial samples of the perifusate were collected at 1 or 2 hr intervals for 4 days. On day 2 in culture, test explants were exposed to medium containing KCl (peak conc. = 41mM) for 45 min at various circadian times. Control explants were exposed to NaCl-supplemented medium that provided an osmotic challenge equivalent to that generated by KCl treatment. VP levels in the medium were measured by RIA and the VP patterns expressed by control and test explants were assessed for evidence of phase shifts in comparison with untreated explants.

Concomitant with an acute stimulation of VP release, KCl exposure yielded advances, delays, or no change in the phase of the VP rhythm. This effect of KCl pulses was dependent on the time during the circadian cycle at which the pulse was administered. KCl treatment consistently induced phase delays of the rhythm, when administered near the middle of the subjective day, but elicited phase advances when this perturbation occurred either late in the subjective day or early in the subjective night. KCl pulses delivered late in the subjective night and osmotic challenges associated with NaCl treatment had no effect on the phase of the VP rhythm. These findings indicate that the cellular mechanisms underlying the phase-shifting effect of KCl on SCN neurons may be important in the neural regulation of circadian rhythms. Moreover, the phase-dependency of the circadian effect of KCl on SCN explants serves to underscore the similarities in the properties of SCN-generated rhythms *in vitro* and *in vivo*, and suggests that this system may provide a basis for examining the roles of various transmitters in regulating the circadian clock located in the SCN. THE SINGLE UNIT RESPONSE OF NEURONS WITHIN THE SUPRACHIASMATIC NUCLEUS TO LOW CHLORIDE PERFUSATE IS PHASE-DEPENDENT. Liou S.Y.*, and H.E. Albers (SPON: K. Wallen). Lab. of Neuroendocrinol. and Behav., Depts of Biol. and Psychol., Georgia State Univ., Atlanta, GA 30303.

SCN neurons maintain a circadian rhythm of spontaneous activity in isolated brain explants. The present study examined whether chloride ions are involved in maintaining circadian rhythms of spontaneous neural activity within the SCN. Extracellular single unit recordings were made from spontaneously firing cells in hamster hypothalamic slice preparations. Coronal brain slices containing the SCN were cut during the light phase of the LD cycle (CT 12h corresponding to the time of light off). Exposure of the slice to low Cl- medium (80% of NaCl was replaced with equimolar Na isethionate) during the late light period or early dark period (CT 7-15h) abolished spontaneous activity of most cells (12/14). However the neurons discharged in response to advancing the electrode and the inhibition was reversed when chloride was replaced. During the dark phase (CT 12-22h) exposure to the low Cl- medium excitated most spontaneously firing cells (9/11) and initiated activity in some silent cells (5). The present results indicate that chloride channels may be involved in the circadian variation of neural firing within the SCN.

156.9

SEROTONIN BLOCKS LIGHT-INDUCED PHASE DELAYS BUT NOT ADVANCES IN APLYSIA. C.S. COLWELL* (SPON:D.Hudson). Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The phase shifts induced by 6 hour treatments of light (200 lx), 5-HT (10^{-5}) and light in combination with 5-HT were determined. These treatments were given at two time points: one during Ct 6-12 when light causes a phase delay of 1.37 hr ($^{+}$ 0.31, 95% Conf. Int., n=6) and one during Ct 18-24 when light causes a phase advance of 2.64 hr ($^{+}$ 0.51, n=7). Serotonin produces an advance of 1.66 hr ($^{+}$ 0.63, n=6) at Ct 6-12 and a 1.5 hr ($^{+}$ 0.63, n=6) delay at Ct 18-24. Serotonin plus light at Ct 6-12 results in no phase shift (0.08 hr, $^{+}$ 0.74, n=6) while at Ct 18-24 light plus serotonin results in a 3.84 hr ($^{+}$ 0.66, n=8) phase advance. This phase advance is not distinquishable from a phase shift produced by light alone. These results suggest that the phase shifts produced by light and 5-Ht are non-additive and implies that the light and 5-HT phase shifting pathways converge and interact. Studing the points of convergence may provide new insights into the functional role of 5-HT in this system as well as help to identify meaningful components of the oscillatory mechanism.

156.10

LIGHT INDUCED PHASE SHIFTS OF THE BULLA EYE IN THE PRESENCE OF PROTEIN SYNTHESIS INHIBITORS. B.L. Bogart and G.D. Block Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Our laboratory is currently involved in an effort to identify the cellular events underlying pacemaker entrainment in the basal retinal neurons of the marine snail Bulla gouldiana. Recent studies have implicated depolarization and a calcium flux in the phase shifting pathway (McMahon and Block, J. Comp. Physiol. 161:1987).

Protein synthesis inhibitors have been shown to phase shift the circadian pacemakers of numerous systems, suggesting a role for protein synthesis in oscillator function. More specifically, Eskin and coworkers (PNAS 81: 1984) have demonstrated that protein synthesis is required for phase advancing the Aplysia ocular pacemaker by pulses of 5-HT. In the current study, we have attempted to determine whether light induced phase shifts are likewise blocked by simultaneous exposure of the retina to protein synthesis inhibitors.

We initially determined that 3 hr pulses of anisomycin ($7.5x10^{-7}$ M) at both CT 13-16 and CT 21-24 generated phase delays (-168 min $^{+}$56; 95% C.I., N=5), indicating the inhibitor was affecting the pacemaker. For the light phase shifting experiments, both the control and experimental eye received the 3 hr anisomycin pulse at either CT 13-16 or CT 21-24, while the experimental eye also received a concurrent light pulse. We report that light still causes phase delays at CT 13-16 despite the presence of the protein synthesis inhibitor (-75min $^{+}$24, N=10). The phase advances to light normally seen at CT 21-24, were highly variable in the presence of anisomycin and not statistically significant (21 min $^{+}$37, N=9).NS15264

156.11

INHIBITORS OF PROTEIN SYNTHESIS PHASESHIFT THE CIRCADIAN CLOCK IN CHICK PINEAL CELLS. N. Murakami* and J. S. Takahashi. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208

Dissociated chick pineal cells contain circadian oscillators that regulate the rhythmic release of melatonin. To determine whether protein synthesis is required for the generation of circadian oscillations, dispersed chick pineal cells were perfused in flow-through microcarrier culture in constant darkness and treated with 10^{-6}M anisomycin, an inhibitor of 80s ribosomal protein synthesis, for 6 hrs at various circadian times. Phase shifts were analyzed by comparison with controls as described by Robertson and Takahashi (J. Neurosci. 8:22, 1988). Single pulses of anisomycin shifted the phase of the circadian oscillation in a phase dependent manner. Phase delays were observed for drug pulses beginning late in the subjective night and early in the subjective day (CT 18-3). Conversely, phase advances were observed for drug pulses in the late subjective day (CT 6, 9). No phase shift was observed for pulses at CT 12. The magnitude of phase delay observed for anisomycin pulses at CT 3 was dose-dependent and was correlated with the magnitude of inhibition of protein synthesis measured by ^{35}S-methionine incorporation.

These results suggest that there is a phase-dependent requirement for protein synthesis in the circadian clock of chick pineal cells and that protein synthesis may be a component of the circadian pacemaking mechanism.

156.12

LIGHT AND SEROTONIN: EFFECTS ON PROTEINS BY TWO MODULATORS OF THE CIRCADIAN RHYTHM IN THE APLYSIA EYE. R. E. Zwartjes*, S. J. Yeung*, and A. Eskin. (SPON: G. F. Gwilliam). Biol. Dept., Univ. of Houston, Houston, TX 77004.

Light and serotonin (5-HT) both regulate the circadian rhythm in the eye of Aplysia californica. Since the two have interacting effects on the rhythm, we compared the effects of both on protein synthesis and phosphorylation. Both light and 5-HT affected the incorporation of ^{3}H-leucine into a 34 kilodalton (kDa) ^{32}P protein, and both increased incorporation of ^{32}P into a 57kDa protein. Light affected incorporation of ^{3}H-leucine into four additional proteins (46kDa, 66kDa, 30kDa and 52kDa), and affected incorporation of ^{32}P into two additional proteins (50kDa and 30kDa). The effects of light and 5-HT on the incorporation of ^{3}H-leucine into the 34kDa protein were phase dependent. However, at the phase when 5-HT produces an advance and light a delay, both increased incorporation into the 34kDa protein. These results indicate that the phase shifting effects of light and 5-HT cannot simply be explained by changes in the 34kDa and 57kDa proteins, but the convergence of information from light and 5-HT on these two proteins suggests an important role for each in circadian timing.

156.13

CIRCADIAN RHYTHMICITY IN BULLA EYES: REGULATION BY PROTEIN PHOSPHORYLATION. M.H. Roberts, V. Bedian* and Y. Chen*, Dept. of Biology, Clarkson Univ., Potsdam, NY 13676

We have investigated the involvement of protein phosphorylation in the regulation of circadian rhythmicity for three reasons: 1) Phosphorylation of ion channels is a common mechanism for changes in neuronal excitability. 2) Zwartjes and Eskin have shown that phase shifts of the Aplysia eye rhythm by 5-HT may involve the phosphorylation of specific proteins. 3) Gillette et al. have found daily changes in kinase activity in the rodent circadian clock.

In our studies we find that: 1) labeling Bulla eyes with 32P from CT 23-1 or from CT 11-13, reveals consistent differences in the phosphorylation of a number of proteins. 2) The circadian rhythm is not affected by PK-C activation, since the phorbol ester TPA is ineffective in phase shifting the eye rhythm when applied from CT 23-1 or CT 11-13. 3) Finally, phosphorylation by PK-A may be involved in the regulation of circadian rhythmicity since an inhibitor of PK-A, H-8, can affect the phase of the eye rhythm. Initial studies indicate that application of 50uM H-8 from CT 12-15 results in a small phase delay (-0.41 $\pm$ 0.23 SEM, n=6), while application from CT 23-1 generates a small phase advance (0.5 hrs, 1.0 hrs, n=2).

The correlation of phosphorylation changes with the effects of kinase inhibitors, suggests a mechanistic relationship between cyclic nucleotide dependent protein phosphorylation and the generation of circadian rhythmicity

156.14

PHOSPHORYLATION OF THE 122 KD PROTEIN IN VIVO IN LIMULUS LATERAL EYES BY EFFERENT STIMULATION. S.C. Edwards[1], A.C. Wishart[1]*, G.H. Renninger[2], E.M. Wiebel[1]*, B-A. Battelle[1]. [1]The Whitney Laboratory, Univ. of Florida, St. Augustine, FL 32086, and [2]Biophysics Group, U. Guelph, Guelph, ON.

Limulus eyes are innervated by efferent fibers that are driven by a circadian clock. Activation of these fibers during the animal's subjective night produce anatomical and physiological changes resulting in increased light response of both the lateral and ventral eyes. We have shown that octopamine, the putative neurotransmitter of the efferent fibers stimulates the cAMP-dependent phosphorylation of a 122 kD protein in vitro in slices of the lateral eye and in ventral eye photoreceptor cell body-rich fractions.

Here we show that the 122 kD protein is phosphorylated in vivo in response to efferent stimulation. Using a "back phosphorylation" technique (Valtorta et al., Anal. Biochem. 158:130-137 (1986)) we found that the 122 kD protein becomes phosphorylated in vivo at night in response to activation of efferent fibers by the circadian clock, as well as during the day when efferent fibers were electrically stimulated.

The distribution of the 122 kD is restricted to those tissues in Limulus involved in vision. Since it can become phosphorylated in response to both efferent activity as well as light, we postulate that it plays an important role in the photoresponse and its modulation. (Supported by the NSF, the Whitehall and Grass Foundations).

156.15

AUTORADIOGRAPHIC CHARACTERIZATION OF 2-^{125}I-MELATONIN BINDING SITES IN RODENT AND HUMAN BRAIN. D.R. Weaver, S.A. Rivkees, S.M. Reppert & E.G. Stopa. Children's Service, Massachusetts General Hospital & Neuropathology Division, Tufts University Schoool of Medicine, Boston, MA 02114.

The availability of a biologically active melatonin analog, 2-[125-I]-melatonin (IMEL), has allowed the autoradiographic localization of putative melatonin receptors in brain (Brain Res 435:359, 1987; FEBS Lett 228:123, 1988). In rats and Djungarian hamsters, we observed a remarkably discrete pattern of specific (e.g., displaced by 1 uM melatonin) binding. The suprachiasmatic nuclei (SCN) and the external zone of the median eminence were consistently and most intensely labelled. In human hypothalamus, only the SCN contained specific IMEL binding sites. In all species, specific binding of IMEL (100 pM) was prevented by inclusion of melatonin or 6-chloro-melatonin (1 uM) in the incubation solution. IMEL binding was only slightly reduced by inclusion of serotonin or norepinephrine (1 uM). Experiments in which the melatonin concentration was varied from 10 pM to 1 uM revealed monophasic competition curves, with IC50 values for melatonin below 1 nM. The results suggest that IMEL binding sites in the central nervous system represent high affinity, saturable melatonin receptors. These putative melatonin receptors in the hypothalamus may mediate the effects of melatonin on circadian rhythms and reproductive function in a variety of mammalian species.

156.16

BINDING CHARACTERISTICS OF 2-[125I]-IODOMELATONIN TO DJUNGARIAN HAMSTER BRAIN MEMBRANES. M.J. Duncan, J.S. Takahashi, M.L. Dubocovich. Dept. Pharmacol., Northwestern Univ. Med. School, Chicago, Il 60611; Dept. Neurobiol. and Physiol., Northwestern Univ., Evanston, Il 60208.

2-[125I]-Iodomelatonin selectively labels high affinity melatonin binding sites in Syrian hamster brain (Endocr. 122, 1988). We now report the binding characteristics of 2-[125I]-iodomelatonin to membranes from Djungarian hamster brains. Specific binding of 2-[125I]-iodomelatonin, as defined by 10 uM 6-Cl-melatonin, was 90% of total binding. In time course studies, specific binding reached a plateau within 10 min, was stable for at least 60 min and was completely reversible. Competition studies showed that the relative order of potency (IC50, nM) of several drugs is: 2-I-melatonin (3.2) > 6-Cl-melatonin (5) > melatonin (30) > 5-OCH3-tryptophol (300) > N-acetyl-tryptamine (1,000) > serotonin = methysergide (5,000). Scatchard analysis using 2-[125I]-iodomelatonin (0.05-11.00 nM) demonstrated that specific binding was saturable. Injections of melatonin (15 ug/day) for 7 weeks affected neither the affinity nor the maximal number of binding sites (Kd = 2.95 $\pm$ 0.68, Bmax = 268.9 $\pm$ 41.9 for melatonin-injected animals vs. Kd = 3.32 $\pm$ 1.58, Bmax = 251.7 $\pm$ 26.2 for vehicle-injected animals). These binding and pharmacological characteristics of 2-[125I]-iodomelatonin to Djungarian hamster brain resemble those demonstrated in Syrian hamster brain. (Supported by DK 38607 and 5T32NS07140.)

EARTH-STRENGTH MAGNETIC FIELDS SELECTIVELY ALTER ACTIVITY OF THE PINEAL GLAND AND HIPPOCAMPUS. A. Chicz-DeMet, E. DeMet, H. Wu*, R. Coopersmith, M. Leon. Depts. of Psychiatry and Psychobiology, Univ. of Calif., Irvine, CA. 92717.

The effects of low intensity magnetic fields on pineal function and regional neuronal activity were studied. Neuronal activity was measured by 14C-2-deoxy- glucose (14C-2DG) autoradiography in the presence and absence of an earth strength magnetic field. The horizontal component of the earth's magnetic field was compensated in one of paired animals using an air core Helmholtz coil. The experiments were conducted under red light between 2400-0300 hrs. Parallel 30% decreases were found in 14C-2DG uptake and N-acetyl transferase activity of the pineal glands of magnetically compensated rats. No significant differences were found in other brain regions with the exception of an increase in the hippocampus. A highly significant inverse relationship between this region and the pineal was amplified by the treatment. The latter probably reflects an indirect action of melatonin decreases on adrenal function. Therefore, the results suggest that low intensity magnetic fields may have a selective action on the activity of the pineal gland which can indirectly alter hippocampal function.

156.18

CIRCANNUAL VARIATIONS OF SEROTONIN UPTAKE AND 3H-IMIPRAMINE BINDING IN HUMAN PLATELETS. D. Marazziti, M. Falcone*, G.M. Pacifici*, G.F. Placidi*, P. Castrogiovanni*. Depts. of Psychiatry and General Pathology, Medical School, University of Pisa, I-56100 Pisa, Italy. (SPON:European Neuroscience Association).

The similarities between blood platelets and presynaptic serotonin (5HT) neurons offer an interesting research tool to explore 5HT system. The binding sites for 3H-imipramine (3H-IMI) seem to be allosterically coupled to 5HT utake sites both in platelets and in neurons. Rhythmicity is postulated to be an attribute of several neurotransmitters and neuroreceptors. We thus measured IMI binding parameters and 5HT uptake in platelets of 8 healthy drug-free volunteers (age between 21 and 43 years). The results showed that the maximum binding capacity (Bmax) of 3H-IMI binding followed seasonal variations, with highest values in the spring, and lowest in autumn. A similar trend was observed also for the maximum velocity (Vmax) of 5HT uptake. It would be interesting to investigate whether or not psychiatric illnesses influence such seasonal variations.

RETINAL CHANGES IN DEPRESSION. J. Seggie, M. Steiner, J. Martin, S. Fawcett, M. Fairman and J. Simpson, Departments of Biomedical Sciences, Psychiatry, Medicine and Surgery, McMaster University and Clinical Studies Program, St. Joseph's Hospital, Hamilton, Ontario L8N 3Z5.

Altered perception of light and hence the use of light and dark cues for entrainment of circadian rhythms has been suggested in depressive disorders. We assessed retinal function in control subjects (N=3) and acutely depressed inpatients (N=6) following a 10 day drug washout and after clinical improvement. During the depressive episode patients evidenced increased amplitude of response on the electro-retinogram (ERG) to 7 stimuli ($0.05<p<.10$). Following clinical improvement (14 days after the last ECT) non medicated patients evidenced decreased amplitude of response to all 7 stimuli of the ERG. Changes reached signficance ($p<.05$) for the blue/dark adapted, red/dark adapted, red-yellow light adapted and blue-green/ light adapted responses. Visual Evoked Potentials and Electrooculograms did not differ between controls and patients in either the ill or well condition. Changes in sensitivity to light in depression appear to be specific to retinal photoreceptors and not post-retinal elements or visual pathways.

Supported by the Canadian Psychiatric Research Foundation and St. Joseph's Hospital Foundation. J. Seggie is an Ontario Mental Health Foundation Associate.

THE EFFECT OF ACTIVATION TASKS ON PARKINSONIAN RIGIDITY.
E.S. Dannenbaum*, P.L. Weiss, R.E. Kearney, S. Gauthier. School of Physical and Occupational Therapy, Biomedical Engineering Unit, Center for Studies in Aging, McGill University, Montreal, Canada, H3G 1Y5.

Clinically it can be seen that the level of parkinsonian rigidity increases when going from a relaxed state to conditions of greater stress. The objective of this study was to assess quantitatively the effect of different levels of activity on parkinsonian rigidity and to investigate the peripheral mechanisms involved. Subjects lay supine while their left ankles were slowly driven (0.05 rad/s) through most of its range of motion. Joint position, torque and surface EMGs from tibialus anterior and triceps surae were recorded. Recordings were done under four conditions; 1) relaxed, 2) while executing preferred cadence flexion/extension of the elbow, 3) while performing fast elbow/flexion extension and 4) while engaged in a maximal pincer grasp.

In 10 stage III parkinsonian patients the work required to drive the foot through its range of motion increased when an activation task was performed. Frequently the most dramatic increase occurred when the maximal pincer grasp task was performed during the displacement. Activation had little or no effect in the age matched controls. These findings demonstrate the importance of activation in the evaluation and detection of parkinsonian rigidity.

157.2

ON THE MECHANISM OF PRODUCING MULTIPLE CYCLES OF EMG ACTIVITY IN PARKINSON'S DISEASE.
N. Teasdale*, G.E. Stelmach, and J.G. Phillips*. Motor Behavior Laboratory, University of Wisconsin-Madison, WI 53706.

In normal individuals, simple arm movements are performed with a single biphasic or triphasic pattern of EMG. For bradykinetic patients, additional cylces of alternating bursts in the agonists and antagonists are necessary to produce those simple arm movements. An EMG saturation of the agonist muscle and an underestimation of necessary EMG activity have been suggested to explain the increased EMG cycles. According to these hypotheses, movements of shorter durations and movements of longer amplitudes should be characterized by an increased number of EMG cycles. However, movement amplitude and movement time were confounded in those experiments. The aim of this experiment was to determine whether the increased EMG cycles are associated with the production of faster or slower movements. Patients and age-matched control subjects were asked to produce movements that were percentages of their maximum speed. Although slower, the patients were able to vary their movement speed. The increased EMG cycles in patients were associated with the production of slower movements. We suggest that the problem of additional EMG cycles in bradykinetic patients is due to irregular and low motor units firing frequencies as well as pauses and delays in recruitment.

THE STATISTICAL RELATION BETWEEN PARKINSONIAN RESTING TREMOR IN OROFACIAL AND LIMB MUSCLES.
C.J. Hunker & J.H. Abbs, (SPON: F. SIEGEL) Dept. of Rehab. Med. & Speech Motor Control Labs., Waisman Center, University of Wisconsin, Madison, WI 53706-2280.

The neural substrate of Parkinsonian (PD) resting tremor remains controversial. From neurosurgical intervention and single unit studies, this tremor appears due either to (1) rhythmical activity within the cortex or within the ventrolateral region of the thalamus, or (2) oscillatory neural networks between the thalamus and the cortex. In contrast, aberrant segmental reflexes or longer latency peripheral loops have also been postulated as responsible for resting tremor. Hunker & Abbs (1983) observed coincident tremor frequencies in the lip, jaw, tongue, and index finger, supporting the notion that resting tremor is based exclusively on peripheral pathways.

To extend this finding, the statistical relation between simultaneously recorded resting tremor epochs from limb and orofacial sites was examined in predominantly tremorous PD subjects, including power spectra and cross-correlations. The frequency of PD resting tremor was remarkably uniform at orofacial and finger sites despite their substantial differences in biomechanics and peripheral neurophysiology. Cross-correlations of 1 second segments yielded coefficients greater than 0.8. However, in the analyses of samples of longer duration, the cross-correlation coefficients rarely exceeded spurious levels. A single central pacemaker is perhaps too simple. The CNS may have multiple somatotopically-organized pacemakers, each activated in the same general manner by a common source, but separately driving lower motoneurons to generate resting tremor; this would give rise to partially correlated tremor in diverse muscle groups, but would also permit variations in these relations. Supported by NIH grants NS-13274 & HD-03352.

NEUROPSYCHOLOGICAL AND ELECTROPHYSIOLOGICAL EFFECTS OF BRAIN AUTOGRAFT OF ADRENAL MEDULLARY TISSUE TO THE CAUDATE NUCLEUS FOR THE TREATMENT OF PARKINSON'S DISEASE.
F. Ostrosky-Solís*, S. Meneses*, L. Quintanar*, M. Pérez*, D. Zarabozo*, I. Madrazo and R. Drucker-Colín. (SPON: A. Tay). Depto. de Psicofisiología, Fac. de Psicología, Fac. de Medicina, Instituto de Fisiología Celular, UNAM, México.

We studied the pre and post-operative auditory event related potentials (ERP) and the neuropsychological profiles of ten patients who received an autograft of adrenal medullary tissue to the caudate nucleus for the treatment of Parkinson's Disease (PD). The pre-operative neuropsychological evaluations revealed specific cognitive deficits which varied in degree. The patients showed frontal lobe-type deficits with alterations in behavioral programming leading to difficulties in the organization of motor sequences and alternating programs. They also showed memory disorders and visuospatial and visuoperceptual deficiencies. The post-operative evaluation suggested amelioration of most frontal lobe-type symptoms, and of the visuospatial deficits. Post-operatively, the ERPs elicited in a target detection stimulus paradigm showed significant changes in the amplitude of the N2-P2 EP components without significant changes in the earlier N1-P2 components. The neuropsychological and electrophysiological post-operative changes suggest that there are no negative effects in the cognitive area as a result of the surgery and that the graft has positive effects on specific cognitive symptoms.

DIFFERENTIAL REGULATION OF STRIATAL DA D1 AND D2 RECEPTOR SYSTEMS IN PARKINSON'S DISEASE (PD) AND EFFECTS OF ADRENAL MEDULLARY TRANSPLANT
J. Costello, H.I. Hurtig*, J.O. Trojanowski, J. Sladek and J.N. Joyce. Dept. Psychiatry and Pharmacology, Univ. Pennsylvania School of Medicine, Philadelphia, PA

Coronal slabs that included striatum were removed at autopsy from 3 control, 2 PD, 2 PD with dementia and 2 PD with Alzheimer's disease cases. In addition, coronal slabs from the left and right (transplant side) hemispheres of a PD case having received an adrenal medulla transplant into the dorsal striatum 4 months prior to death were removed for analysis. Coronal sections (25 um) were processed for autoradiographic analysis of D1 ([^{3}H]SCH 23390) and D2 ([^{3}H]spiroperidol) receptors and DA uptake sites ([^{3}H]mazindol) located on DA terminals. All cases of PD showed profound loss (>92%) of [^{3}H]mazindol labeling in the dorsal putamen (PUT) and caudate nucleus (CN) but showed significant preser-vation in the NAS and medial CN. The density of DA D2 receptors was reduced in the PD cases, by 22-44%. In contrast, the density of D1 receptors was increased significantly, 48% in dorsal PUT, 30% in dorsal CN and 12-13% more ventrally. Immunohistochemical results indicated that the cells in the adrenal medulla transplant could be identified as adrenal chromafin cells but without neurites or processes. The striatum of the unoperated (left) side of the transplant case showed DA receptor density similar to the other PD cases, but with somewhat higher D2 receptor density. The striatum of the transplant side showed normalization of D1 receptor density, particularly in the region of the highest surviving density of DA terminals (visualized with [^{3}H]mazindol binding). **Supported in part by a grant from American Federation for Aging Research to JNJ.**

ADRENAL AUTOTRANSPLANT IN BEHAVIORALLY TRAINED, MPTP-TREATED MONKEYS.
B. Brooks-Eidelberg, E. Eidelberg, J. Story, R. Barret-Tuck, F. Boop, and S. Murk. Dept. of Physiol., Univ. of TX Hlth Sci. Ctr, San Antonio, TX 78284.

Adolescent cynomolgus monkeys were trained to bar press rapidly with either hand as an objective measure of motor function. After stable baseline press rates were achieved, the monkeys underwent MPTP intoxification by: 1) unilateral internal carotid artery injection via transfemoral catheterization, or 2) systemic injection of the femoral vein (dose 0.5 mg/kg). These treatments resulted, respectively, in: 1) unilateral, or "Hemi-Parkinsonian" symptoms, or 2) bilateral bradykinesia, rigidity, and tremor. In hemiparkinson animals, pressing in the ipsilateral hand was unaffected by MPTP-injection, while pressing with the contralateral hand ceased. Oral L-Dopa-Carbidopa resulted in transient improvement in both bilateral and unilateral preparations. Autologous adrenal medulla to caudate transplantation was performed, and was followed within 1-3 weeks by some degree of statistically significant improvement in behavioral measures, which persisted until sacrifice several weeks post-transplant. Histological examination revealed typical chromaffin cells with dense core granules in the head of the caudate nucleus, and degeneration of pars compacta neurons in the substantia nigra. Finally, one animal received transplant into the frontal cortex anterior to the caudate. This individual showed no behavioral improvement in the 12-week post-transplant period.

157.7

CHARACTERIZATION OF THE EFFECTS OF MPTP HEMIPARKINSONISM ON THE KINEMATICS OF A VISUALLY GUIDED ARM MOVEMENT IN THE RHESUS MONKEY. R.G. Parker*, L. Gao*, S.-K. Park, S.J. Haines*, D.A. Turner, S.N. Chou* and T.J. Ebner. Depts. Neurosurgery and Physiology, Neuroscience Grad. Prog., Univ. of MN, Mpls., MN 55455.

This study quantifies and analyzes the kinematic properties of a visually guided, multi-joint arm movement in a MPTP treated hemiparkinsonian monkey. A Rhesus monkey was trained to perform a visually guided arm movement throughout 2-dimensional space. The task required the positioning of a cursor by a manipulandum into video displayed target boxes while kinematic parameters of arm movement and muscle EMG activity were recorded. After 8 months MPTP was administered via unilateral intra-carotid injection and the animal extensively retested. Trajectory profiles were markedly abnormal following MPTP injection, characterized by a striking decomposition of the movement during deceleration. Tangential velocity and time to peak velocity were significantly increased ($p<.01$, 2-tailed, T test) for small and medium movements to most targets while larger movements were absent. Oral L-dopa increased velocity and made larger movements possible. Bradykinesia and akinesia were quantitatively demonstrated. The results suggest the nigrostriatal pathway is crucial to the organization of smooth, continuous multi-joint movements. 157.8

BILATERAL AND HEMI-PARKINSONIAN MONKEYS SPONTANEOUSLY RECOVER FROM THE EFFECTS OF MPTP. J.C.Brewer*,J.S.Schneider, T.Hawk*, J.M.Hoffman*, J.R.Barrio*, S.C.Huang*, A.Luxen,* N. Satyamurthy*, J.C. Mazziotta, and M.E. Phelps. (SPON: T.J.Bak) UCLA Sch. Med., Los Angeles, CA 90024-1769.

Nemestrina monkeys were trained to perform a bar press (BP) task or a reaction time (CRT) task which required a bar press and response to 1 of 3 lights. Two monkeys (one for each task), trained to work with both hands, were given unilateral intra-carotid (i.c.) MPTP injections. Performance on the CRT task ceased with the "affected" limb for 4 wks while the "unaffected" limb performed accurately but with increased movement time (MT). When the "affected" limb was again used, reaction time (RT) and MT were increased and accuracy decreased. Task accuracy, MT and RT have shown improvement over a 3-month period. The other monkey had decreased BP rate in both limbs acutely following i.c. MPTP, which has continued to recover over an 18-week period. 6-[F-18] fluoro-L-dopa (FD) PET scans during recovery periods showed negligible FD activity on the "affected" side and a normal-appearing caudate on the other side. Similar effects have been observed in bilateral parkinsonian monkeys in terms of behavioral recovery and abnormal FD PET findings. These data suggest that i.c. MPTP may acutely affect bilateral striatal functioning and that the hemi-parkinsonian disorder has a similar propensity for recovery as the bilateral syndrome induced by i.v. MPTP. Furthermore, recovery of function may not be entirely linked to striatal dopamine levels.

157.9

EFFECTS OF MPTP ON HABIT FORMATION AND MOTOR FUNCTION IN RHESUS MONKEYS. R.Q. Wan*, T.G. Aigner, and M. Mishkin (SPON:R. Schneider). Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

To test the hypothesis that the formation of visual discrimination habits in monkeys depends on cortico-striatal interactions, we administered MPTP, a neurotoxin known to damage the nigrostriatal dopaminergic system. Two monkeys received a total dose of 4.8 mg/kg in 14 doses (0.1 - 0.5 mg/kg, i.v.) with long interdose intervals (up to 30 days). Between doses, the animals were trained in object discrimination learning with 24-hr ITIs, a measure of habit formation, as well as on a simple motor task. Discrimination learning rates were slowed after each dose increment, but deficits were most evident when the cumulative dose exceeded 3.8 mg/kg. Motor task impairments were minor until the cumulative dose exceeded 4.3 mg/kg, and did not correlate with learning rates. Both impairments resolved within 2 weeks after the last dose of MPTP. Two additional monkeys were given 4 doses of 0.5 mg/kg MPTP (3 doses at 1-week intervals and 1 dose 40 days later). After the third dose, both animals showed severe motor impairment that resolved within 2 weeks, but only 1 showed a slower learning rate. The impairments were similar, though less severe, after the last dose of MPTP. The results suggest that MPTP impairs learning as well as motor abilities and that the magnitude of the impairment depends strongly on the dosing regimen.

157.10

IMPAIRED DETOUR REACHING IN RHESUS MONKEYS AFTER MPTP LESIONS. J.A. Saint-Cyr, R.Q. Wan*, D. Doudet, and T.G. Aigner. Lab of Neuropsychology and Clinical Brain Imaging Section, NIMH, Bethesda, MD, 20892.

Young adult monkeys were injected with MPTP under 2 regimens. Two animals had a low cumulative dose with short interinjection intervals (3 x 0.5 mg/kg, 1 week apart; 1 x 0.5 mg/kg 40 days later); 2 others had a high cumulative dose with long interinjection intervals (14 x 0.1-0.5 mg/kg, up to 30 days apart, total dose 4.8 mg/kg). Above a threshold that varied among animals, transient impairment followed by recovery was observed in 3 of the 4 animals on a discrimination learning task and in all 4 animals on a motor task. Eighteen months after the last injection of MPTP, all animals were significantly impaired on a detour reaching task compared to normal controls. At that time, PET scanning revealed a substantial decrease in 6-F-DOPA accumulation in the basal ganglia in the lesioned monkeys compared to controls. Presumably the recovery from the learning and motor impairments was due to utilization of ancillary neural circuits. The deficit in detour reaching may reflect a generalized inefficiency in acquiring novel adaptive strategies or may be a specific deficit uniquely dependent on striatal-complex-loop circuits intimately linked to premotor and prefrontal cortical regions.

157.11

CHRONIC TREATMENT WITH SKF 38393 DOES NOT MODIFY THE BEHAVIORAL AND BIOCHEMICAL RESPONSE TO BROMOCRIPTINE IN PARKINSONIAN MPTP-TREATED MONKEYS. C. Rouillard[1], T. Di Paolo[1]*, P.J. Bédard[2] and R. Boucher[2] [1]School of Pharmacy, Laval Univ. and Dept. of Molecular Endocrinology, Laval University Medical Center, Quebec, G1V 4G2; [2]Dept. of Anatomy, Fac. Med., Laval Univ., Québec, G1K 7P4.

The neurotoxin 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP) causes destruction of nigrostriatal dopamine (DA) neurons and symptoms resembling Parkinson's disease in humans and subhuman primates. We have recently reported different effects of chronic treatments with various DA agonists in MPTP-treated monkeys (Brain Res., 379: 294, 1987; Soc. Neur. Abs., 17: 567, 1987). D_2 receptors were increased by 30% in the striatum of MPTP-treated animals. Chronic treatment with L-DOPA, Bromocriptine (BRC) or SKF 38393 (SKF) reversed the effects of denervation. No dyskinesia was seen in monkeys on BRC or SKF as opposed to the L-DOPA treated animals. However, SKF alone was ineffective in relieving the parkinsonian symptoms. In the present study, we have investigated the behavioral and biochemical effects of chronic treatment with BRC and BRC + SKF (5 mg/kg). No dyskinesia was seen in either group and there was no difference in motility. Monkeys were sacrificed three days after the last dose. [^{3}H]-spiperone binding studies in caudate and putamen showed no significant difference among Bmax and K_D values of the two groups. We also examined the density of D_1 receptors by using two concentrations of [^{3}H]-SCH 23390 (0.2 and 0.3 nM). At these concentrations, both groups had similar specific binding to D_1 receptors in the caudate and putamen. These results demonstrate that chronic treatment with SKF 38393 does not modify the behavioral and biochemical response to Bromocriptine in an animal model of Parkinson's disease. Supported by the MRC and the Parkinson Foundation of Canada.

157.12

DIFFERENT METABOLIC RESPONSES TO APOMORPHINE AND L-DOPA IN MPTP-INDUCED HEMIPARKINSONIAN MONKEYS. E. Palombo[1]*, K.S. Bankiewicz[2], J.J. Viola[1,3], A.M. Crane[1]*, I.J. Kopin[2], L. Sokoloff[1], and L.J. Porrino[1,3]. [1]NIMH; [2]NINCDS; [3]HHMI, Bethesda, MD 20892.

MPTP-induced hemiparkinsonism (HP) in monkeys is accompanied by selective metabolic changes in the striatum (↑), external pallidum (↑), and subthalamus (↓), as shown by the 2-[^{14}C]deoxyglucose method. Acute L-DOPA (200 mg P.O. with 20 mg carbidopa; n=4) reverses hemiparkinsonian signs and normalizes the metabolic activity in the striatum and subthalamus, but not in the external pallidum. It also produces metabolic activation in the substantia nigra reticulata (SNpr) and internal pallidum and depression in the lateral habenula ipsilateral to the lesion. In contrast to L-DOPA, apomorphine (0.5 mg/kg I.M.; n=2) reduces the metabolic hyperactivity of the external pallidum; induces metabolic depression in the subthalamus to levels lower than in untreated animals; produces bilateral metabolic depression in the lateral habenula; and causes a patchy increase in metabolism in the striatum ipsilateral to the lesion. Similarly to L-DOPA, apomorphine induces metabolic activation in the SNpr. These results show that L-DOPA and apomorphine act differently in MPTP-induced HP, with both agents having effects beyond mere reversal of the metabolic disturbances associated with the untreated syndrome.

157.13

TRANSMITTER HYBRIDISATION AND HISTOCHEMISTRY:APPLICATION TO MOVEMENT DISORDERS

S.J. Augood*, P.C. Emson & A.R. Crossman*, MRC Group,AFRC Institute of Animal Physiology & Genetics Research, Babraham, Cambridge CB2 4AT, U.K.

To investigate the biochemical organisation of the "Parkinsonian" basal ganglia we used in situ hybridisation with cDNA/cRNA probes. Hybridising fresh MPTP treated monkey striatum with a 35S cDNA probe we have shown an increase in enkephalin gene expression in the denervated striatum, with the enkephalin positive cells being homogenously distributed. Recent histochemical studies have shown that this mRNA increase is translated into an increase in enkephalin-LI in the denervated pallidum (GPe) of 6-OHDA lesioned rats. cRNA probes have been used to monitor the extent of nigral cell death in the 6-OHDA rat and MPTP treated monkey. The recent finding of a calcium binding protein (CaBP) as a matrix marker has led to the study into its sites of localisation. Using a CaBP radiolabelled probe we have shown specific localisation of this protein mRNA in the substantia nigra pars compacta cells. A double staining (AChE and CaBP) immunohistochemical technique shows that these cells are localised in the dorsal tier of the pars compacta. These cells correspond to the dopaminergic innervation of the striatal "matrix".

ALTERATIONS IN THE DISTRIBUTION OF DOPAMINE D1 AND D2 RECEPTORS IN MPTP-INDUCED HEMIPARKINSONIAN MONKEYS.

JJ Viola[1,2], LJ Porring[2,3], KS Bankiewicz[3], AM Crane[2*], J Jehle[2*], IJ Kopin[3]. [1]HHMI, [2]NIMH, [3]NINCDS Bethesda MD

The distribution of dopamine D1 and D2 receptors in striatum and substantia nigra (SN) of MPTP-induced hemiparkinsonian monkeys was determined autoradiographically by means of in vitro binding with 3H-SCH 23390 for D1 receptors and 3H-spiperone for D2 receptors. D1 receptor density was greatest in the medial striatum and medial SN reticulata. On the MPTP lesioned side D1 receptor density was moderately increased in the dorsomedial and ventral caudate. D2 receptor density in anterior striatum was greatest in the lateral caudate and lateral putamen in agreement with previous findings (Joyce et al,'87). D2 receptor density in posterior putamen was also greatest laterally. Within the SN the highest D2 receptor density was located medially. On the MPTP lesioned side D2 receptor density was markedly increased in the striatum, particularly in the lateral anterior striatum. D2 receptor density was decreased in the lesioned SN compacta due to the loss of dopaminergic cells. In conclusion, first, there are opposite medial to lateral gradients of D1 and D2 receptors in the striatum. Second, in MPTP-induced hemiparkinsonism both D1 and D2 receptor density is increased in striatum ipsilateral to the lesion. These increases are primarily in regions of highest respective receptor density.

BEHAVIORAL ASPECTS OF AGING

158.1

DEFICITS IN MEMORY FOR PASSIVE AVOIDANCE OCCUR IN AGED C57BL/6NNia AND YOUNGER AUTOIMMUNE MICE.

M.J. Forster, M.J. Flores*, and H. Lal. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

We previously reported that autoimmune NZB/BINJ mice exhibited accelerated, age-dependent declines in their ability to learn an active avoidance response (Forster, M.J. et al., *Beh. Neural. Biol.*, 49:139, 1988). In order to further clarify the possible relationship between autoimmunity and decline of learning or memory, the current studies examined retention for passive avoidance learning in separate age groups of non-autoimmune C57BL/6NNia (1.5, 4, 7, 13, or 27 months) and autoimmune NZB/BINJ mice (1.5, 4, or 7 months). Following a single light/dark, step-through passive avoidance trial, separate groups from each age received retention tests after delays of either 1, 24 ,or 168 h. One- and 24-h retention was nearly equivalent for all ages of C57BL/6NNia mice, although 1.5- and 27-month-olds showed deficient performance at 168 h relative to the middle age groups. Retention performance of the two strains at 1.5 months was nearly equivalent, but retention performance after 24- and 168-h delays became poorer with advancing age for NZB/BINJ mice, whereas improvement in retention performance was evident for C57BL/6NNia mice during the same period (1.5 to 7 mo). These findings indicate that age-related increases in the rapidity of "forgetting" for passive avoidance learning occur at earlier ages in autoimmune NZB/BINJ mice than in C57BL/6NNia mice. [Supported by NIH grant AG06182 (M.J.F.)]

158.2

OXOTREMORINE-INDUCED HYPOTHERMIA: ABSENCE OF AGE-RELATED DIFFERENCES IN C57BL/6NNIa AND AUTOIMMUNE NZB/BINJ MICE.

D. Benjamin*, M.J. Forster, H.Lal, and K.C. Retz.Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

Mature autoimmune NZB/BINJ mice exhibit an attenuated hypothermic response to oxotremorine when compared with age-matched C57BL6NNia mice (Retz, K.C. et al., *Neuropharmacol.*, 26: 445, 1987). Other investigations have suggested accelerated, age-related changes in behavioral capacities (Forster et al., *Beh. Neural. Biol.*, 49:139,1988) and pharmacological responsiveness (Forster, M.J. et al., *Life Sci.*, 38:1433, 1987) in NZB/BINJ mice. Therefore, the current studies investigated the possibility that the attenuated oxotremorine-hypothermia response of mature NZB/BINJ mice reflected the end point of an age-related decline. Male NZB/BINJ (2, 6, or 10 mo.) and C57BL/6NNia mice (9, 13, or 28 mo) received oxotremorine (0.01 to 0.64 mg/kg, i.p.) in a counterbalanced repeated measures design with a 2-3 day washout elapsing between each drug presentation. Colonic temperature was measured 15 minutes prior to injection and at regular intervals up to three hours thereafter. Each of the strains showed an age-related decline in basal colonic temperature, between 13 and 28 mo for C57BL6NNia and between 2 and 10 mo in NZB/BINJ. However, neither strain showed substantial age-related differences in peak temperature drop or total degrees of hypothermia following oxotremorine. As demonstrated in previous investigations, the C57BL/6NNia mice of all ages were considerably more sensitive to the hypothermic effects of oxotremorine than NZB/BINJ mice. The finding that mature NZB/BINJ mice show an age-related decline in colonic temperature may reflect an accelerated decline in thermoregulatory capacity. However, senescent C57BL/6NNia mice evidenced no change in oxotremorine-induced hypothermia, and the attenuated oxotremorine-hypothermia response of NZB/BINJ mice showed no relationship with age. [Supported by NIH grant AGO6182 (M.J.F.)]

158.3

EFFECT OF AGE ON BEHAVIORAL RESPONSE TO COCAINE ADMINISTRATION IN RATS.

J.I. Javaid, R.F. Schlemmer, B. Duslak* and J.M. Davis* (SPON: G.N. Pandey). Illinois State Psychiatric Institute and University of Illinois at Chicago, Il 60612.

There is evidence in the literature that the intensity of pharmacological responses to a given dose of a drug can be affected by age. For example, Flemenbaum (Neuropsychobiology, 5, 213, 1979) reported that older rats showed significantly more stereotyped behavior with d-amphetamine administration than younger animals. In the present studies we report the behavioral effects (locomotor activity and stereotypic behaviors) of cocaine in young (ave. wt. 220 grams, approximately 50 days old) and older rats (ave. wt. 377 grams, approximately 110 days old). Animals in each group were injected intrapearetoneally with various doses (0-40 mg/kg) of cocaine (N = 4-6 at each dose). Locomotor activity was monitored by placing individual animals in Digiscan Animal Activity Monitors. Individual components of stereotypy, including sniffing and repetitive movements of the heads and limbs were rated according to their duration. In both groups 20 and 40 mg/kg cocaine injection produced behavioral effects significantly different than saline ($p < 0.05$). Older rats, however showed significantly decreased locomotor activity and stereotypy behaviors at 20 mg/kg of cocaine ($p < 0.01$). Contrary to our expectation, these results suggest a decrease responsivity of dopaminergic receptors with age as measured by stereotypy in rats.

158.4

PROGRESSIVE CHANGES PRODUCED BY RADIATION-INDUCED HIPPOCAMPAL DAMAGE

G.A. Mickley, J.L. Ferguson, M.A. Mulvihill*and T.J. Nemeth*. Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145

Neonatal rat cerebral hemispheres were partially exposed to a fractionated dose of x-rays. This procedure produced hypoplasia specific to the granule cell layer of the hippocampal dentate gyrus while sparing other brain neurons. Control animals were sham irradiated. Between 71-462 days of age, we conducted 3 replications of the following behavioral tests: (1) spontaneous locomotion, (2) passive avoidance acquisition, and (3) spontaneous turning in a large bowl.

Rats with radiation-induced hippocampal damage exhibited longer bouts of slow turns (without reversals) than did control subjects. This radiation effect was statistically significant at all ages tested. However, over time, spontaneous perseverative turning was significantly potentiated in rats with hippocampal damage but increased only slightly in controls. Measures of spontaneous locomotor hyperactivity decreased in irradiated animals throughout the course of the experiment while remaining stable in controls. Passive avoidance learning did not change significantly over time.

These data suggest that radiation-induced damage to the hippocampus produces behavioral deficits that change over time as a function of subject age and test replications.

158.5

NOREPINEPHRINE NEURON GRAFTS IMPROVE SPATIAL MEMORY PERFORMANCE OF AGED RATS AND FORESTALL DEVELOPMENT OF AGE-RELATED MEMORY DEFICITS IN RATS GRAFTED AS YOUNG ADULTS. H. Barold*, J.R. Sladek Jr. and T.J. Collier. Department of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, N.Y. 14642.

Previous work in our laboratory indicates that 40% of 22-24 m.o. male F344 rats exhibit significant impairment of inhibitory avoidance memory performance. This deficit is accompanied by decreased norepinephrine (NE) histofluorescence in the locus coeruleus (LC), and can be ameliorated by third ventricular implants of fetal LC neurons. We report here an expansion of these studies to examine spatial memory performance in a swim maze. Six 24 m.o. F344 rats were screened for deficient performance of a spatial reference memory task, transplanted with 13-15d. fetal LC neurons, and retrained and tested to a different location in the swim maze eight weeks post-surgery. All 6 animals had grafts with well-developed clusters of NE neurons. Three rats with grafts restricted to the third ventricle showed no improvement in retention of the spatial task. In contrast, three rats with grafted cells in the parenchyma of the midline hypothalamus, thalamus and overlying cingulate cortex showed significant enhancement of retention performance. These initial results suggest specificity of targets of NE supplementation for particular memory tasks. An additional 6 rats received third ventricular grafts of fetal LC at 5 months of age, and were tested at 24 months of age on inhibitory avoidance and spatial reference memory tasks. All rats had large transplants containing clusters of NE neurons 19 mos. after grafting. All rats also exhibited maximal retention on the inhibitory avoidance task. Spatial memory performance is being analyzed and will be discussed. These findings support the view that NE neuron implants performed in adult rats continue to provide a behaviorally therapeutic effect in old age. ADRDA FSA 85-015 (TJC), AG 00847 (JRS).

THE RELATIONSHIP OF AGE-RELATED DEFICITS ACROSS SEVERAL BEHAVIORAL DOMAINS. R. Burwell*, and M. Gallagher (SPON: J. Wilson) Department of Psychology, Univ. of North Carolina, Chapel Hill, NC 27599

Young (6-8 mth) and aged (25-27 mth) male Long-Evans rats were tested on several behavioral tasks to assess the relationship among a set of measures that are sensitive to aging. These measures included spatial learning in a water maze, neophobia/recovery from neophobia for a novel taste, and the diurnal pattern of drinking. An age-related decline in spatial learning has been previously well characterized. A subpopulation of the aged rats (N=13) learned the water maze task as readily as young animals (N=29), whereas the remainder of the aged subjects (N=19) were impaired in this task. Our results indicated that young and aged rats exhibit a comparable neophobia when initially exposed to a novel taste. Aged rats were, however, significantly slower to recover from neophobia when the same taste was presented at 3 day intervals. As reflected in the diurnal pattern of drinking, there was also an age-related change in circadian rhythmicity: the percentage of water intake during the light phase of the light/dark cycle was significantly higher for the aged rats. The results of these experiments further indicated a consistent relationship between spatial learning ability and recovery from neophobia: within the aged cohort, impaired acquisition of spatial information was associated with a diminished recovery from taste neophobia. Spatial learning capacity did not, however, distinguish the degree to which diurnal behavior was affected among the aged subjects.

The results of these experiments reveal relatively distinct behavioral domains in that are sensitive to aging in rats. It is possible that neurobiological alterations in different systems may underlie those behavioral changes that do not intercorrelate. Experiments are underway to examine this hypothesis. ELEVATION OF DYNORPHIN-LIKE IMMUNOREACTIVITY IN THE AGED HIPPOCAMPUS AND SPATIAL LEARNING. M. Gallagher, H.-K. Jiang, and J.-S. Hong*. Dept. Psyc., Univ. N. Carolina, Chapel Hill, NC 27599 and Lab Molecular and Integrative Neuroscience, NIEHS/NIH, Research Triangle Park, NC 27709.

Within the hippocampal formation, the opioid peptide dynorphin is primarily localized to dentate granule cells and their mossy fiber projections to CA3. A relationship was found between dynorphin A(1-8)-like immunoreactivity (dynA(1-8)LI) in the hippocampal formation and the spatial learning ability of aged rats. An initial experiment comparing naive young and aged male Long Evans rats indicated that dynA(1-8)LI was significantly elevated in the aged hippocampus. A subsequent experiment examined dynA(1-8)LI in young (4-5 mth), middle-aged (14-16 mth), and aged (25-27 mth) rats that were trained in the Morris water maze prior to sacrifice. The behavioral results revealed an age difference in the acquisition of spatial learning: aged (but not middle-aged) rats had a significant deficit relative to the young group. These animals were subdivided into an impaired group (N=13) that performed outside the entire range of the young group, and groups of aged (N=11) and middle-aged animals that acquired the task as readily as the young group (N=18). Hippocampal dynA(1-8)LI for the unimpaired middle-aged and aged groups was not significantly different from the young group. In contrast, dynA(1-8)LI was significantly elevated in the impaired group (expressed as pmoles/g tissue, wet weight: young=11.14+0.53, impaired=16.85+1.13). Another notable finding was that dynorphin did not differ as a function of age in most other brain areas (hypothalamus, basal forebrain, striatum, parietal cortex). However, a significant age-related elevation in dynA(1-8)LI was also found in frontal cortex in two separate experiments. These data point to a dysregulation of dynorphin containing neurons in specific limbic/cortical circuitry during aging. HIPPOCAMPAL N-METHYL-D-ASPARTATE RECEPTORS ARE DECREASED IN AGED RATS THAT ARE ALSO IMPAIRED IN THE MORRIS WATER MAZE. M.A. Pelleymounter, G. Beatty and M. Gallagher. Dept. of Psych., Univ. of N. Carolina, Chapel Hill, N.C. 27599.

Hippocampal N-methyl-d-aspartate (NMDA) receptor characteristics of young and aged naive rats were examined by measuring the specific binding of 3H-3-[(+/-)-2-carboxypiperazin-4-propyl-1-phosphonic acid (CPP) (3.1-100 nM), a potent NMDA ligand, to frozen tissue. 10 uM L-glutamic acid was used to define non-specific binding. Bmax values for 3H-CPP binding were decreased in aged rats (Young=247.3fmol/mg protein; Aged=137.2fmol/mg protein)($p<.05$). Kd values were similar in both age groups (Young=39.54 nM; Aged=24.2 nM). A group of young and aged rats were then trained on the place version of the Morris water maze until they reached a criterion for spatial learning. Aged rats required more training to meet criterion than young rats ($p<.016$), although there was a subpopulation of aged rats that met criterion in the same number of trials as young animals. Rats were then allowed to remain in their home cages for 10 days, at which time they were sacrificed. Hippocampal Bmax values for aged rats were again significantly lower (133.2 fmol/mg protein) than those of young rats (226.6 fmol/mg protein)($p<.01$), although there was a subpopulation of aged rats that had Bmax values similar to young animals. Further, Bmax values for aged rats correlated significantly with trials to criterion ($r = -.58$; $p<.05$). There were no age-related differences in the Kd values for 3H-CPP binding (ave.= 42.0 nM). These data are interesting in light of evidence that aged rats also show altered acquisition and decay rates of long term potentiation (LTP). Further, there is evidence that NMDA receptors mediate the induction of LTP, and therefore, could be involved in the spatial learning deficits found in aged animals. Funded by NRSA Award AG-05407 to MAP, and an NIMH Research Scientist Development Award (KO2-MH00406) and NIMH grant MH39180 to M.G.

SUPERSENSITIVITY TO MORPHINE IN SENESCENT RATS FOLLOWING CHRONIC NALTREXONE. J. L. Neisewander, A. J. Nonneman, and M. T. Bardo. Dept. of Psychology, University of Kentucky, Lexington, KY 40506.

The present experiment examined whether there are age-dependent differences in sensitivity to morphine following chronic naltrexone treatment. Fisher 344 rats (3, 10, or 24 months) were implanted with a slow-release naltrexone pellet or were given sham surgery. Ten days later the pellets were removed or another sham surgery was given. Twenty-four hours after pellet removal, half the rats in each group were injected subcutaneously with either 5 mg/kg morphine sulfate or saline. Thirty min post-injection the rats were given a test for analgesia in which they were placed on a 53°C hot-plate, and latency to perform a paw lick response was recorded. Locomotor activity was then assessed in a wooden chamber equipped with photocells. The results indicated that at all ages, animals pretreated with chronic naltrexone showed enhanced sensitivity to the analgesic and locomotor depressant effects of morphine. These results suggest that middle-aged and senescent rats are capable of responding to chronic opiate antagonist treatment in a manner similar to young adult rats.

(We gratefully acknowledge Dr. Charles Mactutus for supplying the aged animals. Also supported in part by USPHS grant DA03460 and a Sigma Xi Grant-in-Aid of Research.)

BEHAVIOURAL RESPONSES TO DOPAMINERGIC STIMULATION IN AGED RATS: DECREASED YAWNING AND LOCOMOTION, BUT INCREASED STEREOTYPY A.J. Stoessl*, M.T. Martin-Iverson, T. Barth, C.T. Dourish, S.D. Iversen* (SPON: E.N.A.), Merck Sharp & Dohme Research Laboratories, Neuroscience Research Centre, Terlings Park, Harlow, Essex, U.K.

We have studied the behavioural responses to apomorphine and the selective D2 agonist (+)-4-propyl-9-hydroxynaphthoxazine(PHNO) in aged (23-26mos) and mature control (6-12mos) Sprague-Dawley rats. Low doses (10-50µg/kg sc) of apomorphine, which preferentially activate dopamine autoreceptors, elicited yawning, mouth movements and penile grooming (PG). Apomorphine-induced yawning and PG were significantly decreased in the aged rats ($p = 0.01$, $p = 0.003$, respectively, 2-way ANOVA). This was associated with a 25% decrease in striatal dopamine levels, and is compatible with previous evidence for blockade of apomorphine-induced yawning in animals with 6-hydroxydopamine-induced destruction of the nigrostriatal projection. In contrast, 200 µg/kg apomorphine induced stereotyped sniffing and licking, and these behaviours were increased in the aged animals ($p \leq 0.0001$). In separate experiments, the locomotor response to infusion (14 days by osmotic minipump) of PHNO (10µg/h) was examined. PHNO increased the amplitude of circadian rhythms in locomotor activity, and daytime tolerance to this effect was reversed by stress. Both effects were significantly attenuated in aged rats ($p < 0.05$, age x drug or age x drug x stress interaction, respectively). These findings suggest that the behavioural responses to stimulation of dopamine autoreceptors and postsynaptic D2 receptors decrease with age, while the response to postsynaptic stimulation with a mixed agonist increases.

158.11

LACK OF AGING EFFECTS ON HUMAN MOVEMENT RELATED CORTICAL POTENTIALS Jaswinder Singh*, R. T. Knight, David L. Woods, D. J. Beckley* and Clay Clayworth*; (SPON: T. NAKADA). Clinical Neurophysiology Lab, Department of Neurology, VAMC; Martinez, CA 94553

We recorded movement related cortical potentials (MRCPs) in 13 young (age range =23-40, mean age=29.6) and 13 old (age range=45-78, mean age=65.8 years) normal adults in right, left (RHP and LHP) and bimanual (BMP) self-paced button press conditions. Data epochs beginning 1200 msec prior to and 800 msec after each button press were extracted from scalp sites over precentral, central and parietal regions. The initial MRCP consisted of a Readiness Potential (RP) onsetting at 950 to 1050 msecs prior to button press. RP was bilaterally distributed and maximal at the vertex in all conditions with comparable amplitudes for unimanual and bimanual conditions. A negative Motor Potential (MP) onset at 200 msec prior to movement and had a peak amplitude over scalp sites contralateral to unilateral movement. Scalp distributions were compatible with an RP source in premotor or supplementary motor cortices and an MP source in motor cortex. In contrast to prior reports, topographical distribution, onset latency and peak and mean amplitude were comparable between young and old subjects for the RP and MP components of the MRCP. The results indicate that motor programming as indexed by RP and motor cortex activity (MP) is unaffected by normal aging.

NIMODIPINE FACILITATES TRACE CONDITIONING OF THE EYE-BLINK RESPONSE IN AGING RABBITS. R.A. Deyo*, K.T. Straube* and J.F. Disterhoft. Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Nimodipine (NIM), a Ca^{++} channel blocker, may enhance learning in aging humans but neither effect nor mechanism has been well studied. In the present experiment, we evaluated the effects of NIM on a task in which acquisition is known to be associated with reductions in a Ca^{++} mediated potassium current (Disterhoft, et al., PNAS, 83:2733-2737, 1986).

Nine young (3 month) and 11 aging (30-49 month) rabbits with intrajugular catheters were assigned to 1 of 4 groups based on age and drug received. These groups were young-vehicle (n=5), young-NIM (n=4), aging-vehicle (n=5) and aging-NIM (n=6). Beginning 10 min prior to training and continuing through each session animals received intrajugular infusion of either NIM (1.0 µg/kg/min) or vehicle. Animals were habituated and then trained in a trace conditioning paradigm in which the CS was a 100 ms 85 db, 6 KHz tone followed by a 500 ms trace interval (neither the CS or UCS present) followed by a 150 ms 2.5 psi corneal airpuff (UCS). An unconditioned response (UCR) was the eye-blink occurring in response to the UCS. A conditioned response (CR) was any response occurring after the CS onset but prior to the UCS onset. Animals were trained until performance reached a criterion of 8 CRS in any block of 10 trials.

NIM accelerated acquisition in both young and aging rabbits relative to vehicle controls ($F(1,16)= 11.69$, $p < .005$) but did not alter the amplitude of responses to the CS ($F(1,16)= 3.24$, n.s.) or UCS ($F(1,16)=3.30$, n.s.). Aging rabbits also showed significant learning impairments when compared to young animals ($F(1,16)= 7.77$, $p < .05$).

The present data do not directly test the the mechanism by which NIM facilitates associative learning. They do show that NIM enhances speed of CR acquisition directly without altering CR or UCR size, arguing against nonspecific arousal. These results are consistent with earlier reports of associative learning deficits in aging rabbits. Finally, they indicate that rabbit eye-blink conditioning is a useful model with which to study the neurobiological mechanisms underlying NIM's enhancement of learning.

AGE DIFFERENCES IN CLASSICAL CONDITIONING OF THE NM/EYEBLINK RESPONSE IN RABBITS IN THE DELAY PARADIGM. D. S. Woodruff-Pak, Dept. of Psych., Temple Univ., Philadelphia, PA 19122

While age differences in the NM response in rabbits in the trace paradigm are clearly documented, the existence of age differences in the delay paradigm is debated. We present here data from two studies using two types of CS in young and older rabbits. Both types, (85 dB, 1 KHz tone; 200 Hz train of 0.1 msec constant current to pontine nucleus) were paired with a 3 psi airpuff US and resulted in significant age differences. [Supported by 1 F33 AG05312].

VISUAL ACUITY LOSSES IN AGED PIGEONS. W. Hodos, R.W. Miller* and K. V. Fite. Dept. of Psychology, Univ. of Maryland, College Park, MD 20742 and Dept. of Psychology, Univ. of Mass., Amherst, MA 01003.

The visual acuities of 15 pigeons ranging in age from 2-16 years were tested in an operant-conditioning chamber. The stimuli were high-contrast, square-wave gratings. A systematic decline in acuity with age was observed that was well described by a logarithmic function. Pupil diameter also decreased with age, which resulted in a decrease in retinal illumination and an increase in depth of focus. The decrease in retinal illumination and presbyopia were able to account only for about 40% of the acuity loss, but this was in part compensated for by the increased depth of focus. No relationship between corneal or lenticular density and age was observed. Ophthalmoscopic examination of the optic media revealed no abnormalities that were correlated with age. Microscopic examination of epon-embedded, thin sections of both the fovea and area dorsalis of the retina revealed no age-correlated differences in the thickness of the retinal layers nor in the densities of photoreceptors and ganglion cells. The authors speculate that losses of central neurons may in part account for the decline in acuity with age.

158.15

AGE-RELATED DIFFERENCES ON A CONTINUOUS PERFORMANCE TASK IN RHESUS MONKEYS. M.J. Callahan and R.E. Davis. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

Performance of aged (23+ yrs old) and young adult (5-16 yrs old) rhesus monkeys was measured on a task which depends heavily on the sustained and efficient selection and processing of information over relatively long time epochs. Using this continuous performance task, differences in performance of young adult and aged rhesus monkeys were observed under scopolamine treatment and nondrug conditions within a variety of paradigms.

This task required a monkey to respond quickly and accurately to a colored square randomly selected and positioned on a color television monitor. Initial studies using a nondiscriminative choice-reaction test showed no difference in the ability of young adult and aged monkeys to respond to a stimulus for a food reward. With the addition of a discriminative component, aged but not young adult monkeys exhibited a decrease in performance attributable to a waning of attention as the test progressed. Parametric studies in which stimulus duration (1, 3 or 6 sec) or intertrial interval (2 or 4 sec) was varied systematically, maximized the differences in performance of young adults and aged monkeys with aged monkeys performing poorly at short stimulus durations when attentional demands are high.

Scopolamine dose dependently decreased the performance of both young and aged monkeys with young monkeys being more sensitive to the disruptive effects of this agent than aged monkeys. Results of other parametric manipulations involving increases in the numbers and colors of different stimuli and altering the duration of stimulus presentation within a test session also revealed age-related differences in rhesus monkey performance. It appears that aged-rhesus monkeys are less attentive or vigilant than young adult monkeys. These differences are maximal when a new paradigm is first introduced suggesting that aged monkeys exhibit less behavioral plasticity than young monkeys.

158.16

COGNITIVE IMPAIRMENT IN THE AGED RHESUS MONKEY. P.R. Rapp and D.G. Amaral. The Salk Institute for Biological Studies, La Jolla, CA 92037.

In the initial phase of a research program designed to provide an animal model of normal human aging, 5 aged (approximately 23-27 years old) and 4 young adult (9 years old) female rhesus monkeys were trained in a variety of behavioral testing procedures. All animals were experimentally naive prior to this research. Behavioral testing was conducted in a Wisconsin General Test Apparatus. Monkeys were initially trained in a delayed response task (DR) which required subjects to remember the spatial location of a reward presented prior to a delay interval. Although both age groups reached a learning criterion (90% correct) in an equivalent number of trials with a zero second delay, the performance of aged subjects was disproportionately impaired compared to young animals as retention intervals were increased from 0 to 30 seconds. In contrast to their performance on DR, aged subjects appeared to be impaired relative to young subjects in achieving a 90% learning criterion on a recognition memory task (i.e., delayed nonmatching to sample). When retention was tested across delays as long as 10 min., however, only relatively mild age-related deficits were apparent. These results suggest that specific aspects of memory and other cognitive functions may be differentially compromised during aging in the nonhuman primate. These findings therefore provide a framework for identifying selective neural alterations which underlie age-dependent cognitive deficits.

159.1

DIAMETERS AND PERCENTAGES OF DORSAL ROOT AXONS IMMUNOREACTIVE FOR CALCITONIN GENE-RELATED PEPTIDE (CGRP), SOMATOSTATIN (SOM), BOMBESIN (BOM) AND SUBSTANCE P (SP). R.E. Coggeshall, D.L. McNeill* and K.N. Westlund (SPON: S. Melville). Marine Biomedical Institute and the Department of Anatomy and Neurosciences, University of Texas Medical Branch, Galveston, TX 77550.

CGRP, SOM, BOM and SP immunoreactivity have been observed in small diameter primary afferent perikarya and in the superficial lamina of the dorsal horn. In the present study the diameters and percentages of axons in the L2, L4 and L6 dorsal roots immunoreactive for these peptides were obtained from normal rats. The animals were perfused with a solution of 3% glutaraldehyde, 3% paraformaldehyde and 0.1% picric acid. The roots were then removed, treated with sodium borohydride, immunostained and embedded. Thin sections were examined with an electron microscope. Preliminary data indicate that approximately 14.1% of the unmyelinated fibers are immunoreactive for CGRP, 8.6% for SP, 6.7% for SOM and 3.1% for BOM. CGRP immunoreactivity was also observed in myelinated fibers (2.3%). Immunostained unmyelinated axon diameters were approximately 0.16 $\pm$ 0.13 μm while CGRP myelinated fibers were approximately 0.60 $\pm$ 0.34 μm. These data indicate that immunocytochemical labeling of dorsal root axons can be used as an assay for experimental procedures. (Supported by grants from NIH NS11255, NS21996, Kent Waldrep National Paralysis Foundation, Marie Hall Foundation and Bristol-Meyers.)

SOMATIC SENSORY NEURONS OF THE RAT SCIATIC NERVE J.E. Swett, Y. Torigoe, V.R. Elie* and C.M. Bourassa*. Dept. of Anatomy & Neurobiol., College of Medicine, U.C.I., Irvine, CA 92717.

This laboratory reported on the locations and numbers of motoneurons (about 2000) in the rat's sciatic nerve as revealed by retrograde labeling of its branches with HRP or WGA-HRP (Swett et al., Exp. Neurol. 93:227, '86). Using identical procedures, neurons in dorsal root ganglia (DRGs) L3 to L6 were reconstructed using a mathematical factor to correct for split cell error (Hendry, J. Neurocytol., 5:337, '76; Rose & Rohrlich, J.C.N. 263:365, '87). The sciatic nerve contains 8210 ($\pm\approx$25%) DRG cells, more than 4 times the number of motoneurons. The subdivisions of the sciatic nerve contain numbers of cells as follows (mean $\pm$S.D.): sural, 1416 $\pm$397; peroneal, 2639 $\pm$576; tibial, 3804 $\pm$535. The correction factor assumes that cell shape is spherical; however, as cell shape is non-spherical, cell numbers are probably underestimated by nearly 5%. The pure muscle nerve branches supplying the triceps surae group contain 341 $\pm$30 motoneurons and 298 $\pm$25 DRG neurons; motor/sensory innervation ratios of muscle are about 1:1. Assuming that all muscles innervated by the other branches of the sciatic nerve have similar ratios, one quarter of all afferent fibers must be innervating deep tissues while the remaining 6200+ innervate skin. For each afferent supplying muscle there are 3 supplying skin. Based on perimeter measurements, mean diameter of muscle DRG neurons (36.5 $\pm$4 μm) is greater than those supplying skin (25.7 $\pm$4 μm) due to the large numbers of small DRG neurons in the latter. Thus, the population profile of skin DRG neurons is heavily skewed toward small diameters. This difference probably represents DRG neurons for C-fiber afferents, of which there are very few in muscle nerves. (Supported by NIH grants NS-17630, NS-23707)

159.3

LEVELS OF mRNA CODING FOR SUBSTANCE P, SUBSTANCE K AND SOMATOSTATIN IN SENSORY NEURONS ARE AMONG THE HIGHEST OF ANY REGION OF THE RAT OR RABBIT BRAIN. C.G. Boehmer*, R.P. Zimmerman, T.S. Gates*, and P.W. Mantyh. C.U.R.E.; Brain Research Institute; UCLA School of Medicine, LA, CA 90024

Past studies which have demonstrated the presence of certain neurotransmitters in sensory ganglia required pretreatment with colchicine to raise the neuropeptides to detectable levels. This raises the question whether sensory neurons normally synthesize these neuropeptides in quantities that are functionally significant.

We performed in-situ hybridization using ^{35}S-labeled DNA probes (30 mers) for somatostatin, preprotachykinin (substance P and substance K), vasoactive intestinal peptide and vasopressin in order to compare levels of mRNA found in individual sensory neurons with those found in neurons in other brain areas. Of the probes tested only somatostatin and preprotachykinin were detectable and their mRNA levels were among the highest of any region of the rat or rabbit brain examined. These results suggest that selected sensory neuropeptides are normally synthesized in very high levels in sensory neurons.

159.4

LECTIN BINDING TO GLYCOCONJUGATES IN CHICK SPINAL CORD AND DORSAL ROOT GANGLIA. N. Patel* and S. A. Scott. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

Dorsal root ganglia (DRG) contain a diversity of sensory neurons. We are interested in identifying markers for functional subsets of DRG neurons in the chick. To this end we have screened a variety of lectins with different sugar specificities to determine whether any label distinct subpopulations of DRG neurons. Of the lectins examined only those specific for N-acetyl-galactosamine (galNAc) labeled subsets of sensory neurons in hatchling chicks. For example, Dolichos biflorus (DB) intensely labeled small diameter neurons in the dorsomedial DRG, as well as their projections in dorsal horn laminae 1 and 2 and Lissauer's tract. Specific DB staining first appeared in DRG neurons at about St.38 (d12), and in the dorsal horn at about St.42 (d16). At all stages DB staining was blocked with excess galNAc and eliminated by chloroform:methanol extraction, suggesting that in the chick a subset of DRG neurons can be distinguished by the presence of glycolipids containing galNAc residues. (Supported by NS16067 to SAS).

159.5

DIAMETER AND PERCENTAGE OF DORSAL ROOT AXONS IMMUNOREACTIVE FOR GLUTAMATE. K.N. Westlund, D.L. McNeill* and R.E. Coggeshall. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

Glutamate is a candidate excitatory amino acid neurotransmitter for spinal cord sensory processing. The diameters and percentages of dorsal root axons immunoreactive for glutamate were obtained from the L2, L4 and L6 dorsal roots from normal rats. The animals were perfused with aldehydes (3% glutaraldehyde, 3% paraformaldehyde), the roots removed and cut into 3mm lengths, and treated with sodium borohyride. The roots were then immunostained using mouse monoclonal antibody specific for fixative-modified glutamate (generously provided by A.J. Beitz) at a dilution of 1:10,000. The root segments were dehydrated, embedded, and thin sectioned. Preliminary data indicate that approximately 10% of the unmyelinated axons of the root are immunostained. The percentages of labeled axons do not differ in the sampled levels. Myelinated axons are also stained, but are fewer than the unmyelinated axons. Thus axonal labeling is predominantly in fine fibers. Axonal diameters are being determined. These data, when complete, can serve as a baseline for experimental studies. Supported by National Institutes of Health grants NS11255 and NS21996, the Kent Waldrep National Paralysis Foundation, the Marie Hall Foundation and Bristol-Meyers.

159.6

MAGNETIC SENSITIVITY OF THE AVIAN OPHTHALMIC NERVE. R.C. Beason, P. Semm* and A.J. Mackie*. Biology Dept., State Univ. of New York, Geneseo, NY 14454.

The bobolink (Dolichonyx oryzivorus), a transequatorial migratory bird, has demonstrated behavioral responses to earth-strength magnetic field (MF) stimuli (Beason, R.C. J. Ornithol., 128:317, 1987), which may involve a magnetite-based MF transducer (Beason, R.C. & Brennan, W.J. J. Exp. Biol., 125:49, 1986). Deposits of a magnetic material lie in the ethmoid region and appear to be innervated by branches of the trigeminal nerve, especially the ophthalmic branch. Extracellular recordings, made with glass microelectrodes filled with 4 M NaCl, indicate a sensitivity to changing orientations of earth-strength MF stimulation. The rate of spontaneous activity was modified in 15% of the 195 units recorded from 18 birds. The most common response was a 20% to 100% increase in firing rate, which sometimes outlasted the 4-6 s stimulus by 1-2 min. Additional fiber responses included inhibition, ON-OFF, and OFF responses.

160.1

NEOSTRIATAL UNIT ACTIVITY DURING LEARNING ENHANCED IN RABBITS WITH FIBER SPARING LESIONS IN THE ANTERIOR CINGULATE CORTEX. M. Gabriel, Y. Kubota, A. Cox*, and C. Cuppernell*. Dept. Psychol., Univ. Illinois, Champaign, IL 61820

Past studies have implicated limbic cortical and thalamic neural circuitry in the mediation of discriminative avoidance conditioning in rabbits. A theoretical working model based on these studies generates the hypothesis that conditional stimulus (CS) driven activity of Layer V corticostriatal cells in cingulate cortex is involved in triggering the conditioned response (CR, stepping in an activity wheel). A study to test this hypothesis showed that bilateral electrolytic and aspirative lesions in the cingulate cortex (Brodmann's areas 24 and 29) blocked acquisition of the avoidance response. However, the neostriatal multi-unit discharges elicited by the CSs were significantly greater during training in rabbits with lesions than in intact controls (Lambert & Gabriel, Soc. Neurosci. Abstr. 86.19, 1982). Moreover, the discharges in the rabbits with lesions were induced by the conditioning procedure and they were associative in character (i.e., greater in response to the positive CS [CS+], the stimulus that predicted a footshock unconditioned stimulus and called for the CR, than to the negative CS [CS-]). These associative properties were absent in the intact rabbits. Here, multi-unit activity in the dorsal anterior neostriatum was recorded during conditioning in 7 rabbits given bilateral ibotenic acid (IBO) lesions in area 24 during surgery for implantation of the recording electrodes. The recordings were compared to those obtained in 7 controls. Three controls received saline instead of IBO injections and four received IBO injections that caused only minimal lesions. Neostriatal training-induced discharges were significantly greater in rabbits with lesions than in controls. In this study however, with more restricted lesions, behavioral acquisition was only mildly impaired. These results confirm the previous findings and they suggest that the lesion-induced enhancement of neostriatal discharges is not due to damage to passing fibers in cingulate cortex. (Supported by NIMH Grant MH37915 to MG).

CUE ELICITED NEURONAL DISCHARGES IN LIMBIC THALAMIC NUCLEI PEAK AT DIFFERENT TRAINING LEVELS DURING AVOIDANCE LEARNING IN RABBITS. Y. Kubota, J. Shenker, M. Mignard, D. Parish*, and M. Gabriel. Dept. Psychol., Univ. Illinois, Champaign, IL 61820

Rabbits with chronically implanted multi-unit recording electrodes in the anterodorsal (AD), anteromedial (AM), anteroventral (AV), laterodorsal (LD), and mediodorsal (MD) nuclei of the thalamus were trained to avoid a shock unconditioned stimulus (US) by stepping in an activity wheel in response to a tone (positive conditioned stimulus, CS+). They also learned to ignore a different tone (negative conditioned stimulus, CS-) that was presented equally as often as the CS+. Daily training sessions consisting of 60 trials with each CS in an irregular order were given until conditioned avoidance response (CR) performance reached a criterion, and 3 additional sessions were given after criterion. In all nuclei except the AM, the neuronal discharge in response to CS presentation increased as conditioning progressed and this increase was greater to the CS+ than to the CS-. The maximal neuronal discharge in AD, LD, and AV/MD nuclei occurred in the first training session, the session of the first significant CR performance, and the session of criterial CR performance, respectively. The discharge magnitudes then declined as training continued beyond sessions of the maximal discharge. This pattern of results indicates that the spatial distribution of CS driven training-induced thalamic excitation arriving in the limbic cortex varies with the stage of training. Such variation may provide a neural code for the age of the discriminative habit, a code that is likely to be of importance in relation to retention and recall. A hypothetical mechanism for the neural coding of habit age remarkably similar to the present data has been proposed by Deutsch (In Neurobiology of Learning and Memory, G. Lynch, J. McGaugh and N. Weiberger [Eds.], 1984, 105-110). (Supported by NIMH grant MH37915 to MG).

160.3

DOPAMINERGIC AND CHOLINERGIC RECEPTOR BLOCKADE, AVOIDANCE BEHAVIOR, AND TRAINING-INDUCED LIMBIC CORTICAL AND THALAMIC UNIT ACTIVITY IN RABBITS. S. Poonawala*, V. Henzi*, Y. Kubota, and M. Gabriel (SPON: P. Johnston). Dept. Psychol., Univ. Illinois, Champaign, IL 61820

Past studies of the neuronal correlates of training and the effects of lesions have indicated that neurons of the limbic thalamus and cingulate cortex are importantly involved in mediating discriminative avoidance behavior in rabbits (Gabriel, Kubota & Shenker, in Information Processing by the Brain, H. Markowitsch [Ed.], 1988). As a prelude to manipulating dopamine and acetylcholine in these areas, we recorded the multi-unit activity of the cingulate cortex (Brodmann's areas 29c, 29b and 24) and the anterior ventral (AV) nucleus of the thalamus during conditioning in rabbits systemically injected with scopolamine hydrobromide (SH, 1, 2, & 4 mg./kg.) and haloperidol (HA, .025, .10, & .40 mg./kg.). The rabbits learned to avoid a footshock by stepping in an activity wheel in response to a tone CS+ and they learned to ignore a tone CS- of different frequency. After training to asymptotic performance each rabbit received daily training sessions preceded by subcutaneous injection of either saline, scopolamine methylbromide (SM), or one of the drug doses. A given rabbit received either HA or SH/SM injections, but not both, in a counterbalanced order. A partial reinforcement procedure was adopted to control for the effects of shock induced arousal on the neuronal response profiles for different drug treatments. Both drugs reduced significantly the frequency of conditioned avoidance responses (CRs). This effect was monotonically related to HA dose, but all doses of SH reduced CRs equally. SM did not reduce CR frequency. As in the case of CRs, all doses of SH significantly and equally attenuated Area 29 and AV nuclear training-induced neuronal discharges. HA injections which had abolished CRs had no effect on the activity in these areas. These results suggest that the behavioral impairments produced by SH resulted from impaired neuronal processes of the cingulate cortex and anterior thalamus. However, the behavioral impairment produced by HA is more likely due to disruption of nigrostriatal and mesolimbic dopaminergic circuitry. (Supported by NIMH grant MH37915 to MG).

160.4

ELECTROPHYSIOLOGICAL CHARACTERISTICS OF DENTATE GYRUS GRANULE CELLS FOLLOWING CLASSICAL TRACE CONDITIONING. J. Black, R.A. Deyo*, and J.F. Disterhoft. Dept. of Cell Biology and Anatomy, Northwestern University Medical School, Chicago, IL, 60611.

Our laboratory has demonstrated a reduction in the spike afterhyper-polarization (AHP) in hippocampal CA1 neurons obtained from rabbits trained in a classical eye-blink task (Disterhoft et al., 1986). CA1 and dentate gyrus neurons also exhibit conditioning-related firing changes *in vivo*, but those patterns of changes differ (Berger and Weisz, 1985). Thus, it is of interest to test dentate gyrus granule cells for a conditioning-linked AHP reduction similar to that in CA1.

26 young adult male rabbits (1-1.5 kg) were trained according to 1 of 3 procedures: 1 TRACE animals (n=6) were habituated to test apparatus and then trained using a 100 ms tone CS followed by a 300 ms trace interval (neither CS or UCS present), then a 150 ms corneal air puff (UCS). Animals received daily training to a criterion of 80% CRs. 2 PSEUDO animals (n=9) were habituated and then received an equal number of randomly-presented unpaired CS and UCS trials as a matched TRACE animal. 3 NAIVE animals (n=11) received neither habituation nor training. Following training, rabbits were sacrificed and 500µm hippocampal slices prepared. During recording, slices were maintained in ACSF at 31°C in a submerged-type recording chamber. Intracellular recordings were obtained from the granule cell layer of the dentate gyrus, using microelectrodes (filled with 3M KCl, tip impedances 80-100MΩ). Investigator performing electrophysiological tests was blind to the type of training each animal had received.

GROUP	N (cells)	MEMBRANE POTENTIAL	INPUT RESISTANCE	SPIKE HEIGHT	AHP (4-SPIKE)
NAIVE	17	-72.0 ± 2.0mV	98.2 ± 8.6MΩ	90.5 ± 4.5mV	4.7 ± 0.6mV
PSEUDO	13	-73.4 ± 2.3mV	99.2 ± 9.0MΩ	96.5 ± 3.6mV	4.3 ± 0.5mV
TRACE	7	-74.3 ± 2.3mV	98.8 ± 9.6MΩ	88.0 ± 3.0mV	4.1 ± 0.9mV

These preliminary results suggest that postsynaptic conditioning-induced AHP changes reported for CA1 neurons are not seen in granule cells. Since *in vivo* data also show that changes in CA1 firing during conditioning are qualitatively different from those in dentate, these results may indicate that different mechanisms are responsible for conditioning-induced changes in different areas of the hippocampus.

160.5

CHANGES IN ELECTROPHYSIOLOGICAL CHARACTERISTICS OF HIPPOCAMPAL CA1 NEURONS AFTER TRACE EYE-BLINK CONDITIONING. M.C. de Jonge, R.A. Deyo*, T.P. Bleck and J.F. Disterhoft. Dept. of Cell Biology & Anatomy, Northwestern University Medical School, Chicago, IL 60611.

It has previously been shown that the magnitude of the intracellularly evoked afterhyperpolarization (AHP) in CA1 cells is reduced after short-delay eye-blink conditioning in rabbits (Disterhoft et al., PNAS, 83:2733-2737, 1986). Trace conditioning, whereby CS and UCS do not overlap, is a more difficult associative task. In the present experiments we investigated whether different types of cellular changes would occur from those observed with the delay conditioning paradigm.

Trace conditioned rabbits (N=9) were habituated and then conditioned to a 100 ms, 85 db, 6 KHz tone (CS) followed by a 300 ms trace interval before a 150 ms, 2.5 psi corneal airpuff (UCS). Animals were trained to a criterion of 80% conditioned responses during an 80 trial training session. Pseudo conditioned animals (N=11) were habituated and then received an equal number of randomly presented unpaired CSs and UCSs for the same number of days as matched Trace animals. Naive animals (N=11) received no behavioral training. One day after rabbits reached criterion, slices were prepared from the dorsal hippocampus. Responses, recorded through KCl-filled glass microelectrodes, were digitally stored and, later, computer analyzed

An ANOVA showed a significant (F(2,46)=5.2; P<.009) reduction of AHP magnitude in trace conditioned animals vs controls. This reduction was still apparent 700 ms after the

GROUP	N (cells)	MEMBRANE POTENTIAL	INPUT RESISTANCE	SPIKE HEIGHT	AHP (4-SPIKE)
NAIVE	15	-67.1± 2.3mV	55.3± 2.6MΩ	94.1± 3.0mV	4.3± 0.5mV
PSEUDO	19	-64.8± 1.4mV	59.6± 3.5MΩ	97.8± 1.3mV	4.8± 0.4mV
TRACE	15	-70.7± 2.1mV	62.4± 4.9MΩ	96.6 ± 2.9mV	2.9 ± 0.4mV

offset of the depolarizing current. No significant effects of trace conditioning on resting membrane potential, input resistance or action potential magnitude were observed.

It is concluded that the medium and late AHPs are reduced after trace as well as delay conditoning. Trace conditioning does not appear to cause any additional ionic changes to those seen in previous studies of short-delay conditioning.

ACTIVITY OF SINGLE HIPPOCAMPAL CA1 PYRAMIDAL NEURONS DURING TRACE EYE-BLINK CONDITIONING. E. Akase*, R.A. Deyo*, and J.F. Disterhoft (SPON:T.P. Bleck). Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Recording from single hippocampal neurons during short-delay eye-blink conditioning has demonstrated that CA1 neurons fire in a pattern mimicking the learned response (Berger & Thompson, PNAS, 75:1572-1576, 1978). The function of this neuronal response as related to performance of the conditioned response is unkown. In the present experiment, we sought to further define the conditions of neuronal modeling of behavior by examining neurons in left and right hippocampus during trace conditioning using unilateral CS and UCS.

Subjects were 5 young adult male rabbits (1-1.5 kg) implanted bilaterally with Trent Wells recording chambers overlaying each hippocampus. Animals were habituated and then trained in a trace conditioning paradigm in which the CS was a 100 ms 85 db, 6 KHz monaural tone presented to the right ear followed by a 300 ms trace interval (neither the CS or UCS present) followed by a 150 ms 2.5 psi corneal airpuff (UCS) presented to the right eye. Animals were trained until performance reached a criterion of 80% CRs. During the next 3-4 training sessions single neuron activity was recorded by alternating from right to left hippocampus every 20-40 trials. After each recording the site was lesioned and the location of the electrode tip was verified. To date, recordings have been made from a total of 18 CA1 neurons (12 left, 6 right).

Examination of data suggests that while both left and right hippocampi exhibit modeling of the conditioned response, the magnitude of the effect in the right is much less pronounced than that observed in the left hippocampus. A second interesting finding is a marked tendency (> 50% of neurons) for inhibition of firing at CS onset followed by the typical neural modeling later in the trial as the CR was elicited. These data suggest that CA1 neurons in the hippocampus contralateral to the conditioned eye are more involved in mediating the CR than are those in the ipsilateral hippocampus. These neurons also seem to be playing an important role in timing CR onset.

PURKINJE CELL RESPONSES IN THE CEREBELLAR VERMIS DURING PAVLOVIAN FEAR CONDITIONING IN THE RABBIT. W.F. Supple and B.S. Kapp. Dept. of Psychology, University of Vermont, Burlington, VT. 05405.

Research has demonstrated that lesions of the vermis block Pavlovian conditioned heart rate responses (HR) in rats (Supple, 1986). This study therefore examined the responses of vermal Purkinje cells during differential HR conditioning in the rabbit.

Extracellular single-unit recordings were obtained from anterior lobe Purkinje cells in response to CS+ and CS- presentations during retention testing. Many of the units demonstrated differential responding to the two stimuli. The CS+ elicited a greater increase in activity compared to the CS- in 20 neurons with spontaneous rates between 1.8 - 31.6 Hz. The responses of several neurons were significantly correlated with the magnitude of the conditioned HR response. Additional groups of neurons showed greater responses to the CS- compared to the CS+, as well as differential decreases in activity during the CS's.

These data, together with the previous lesion results, suggest that the cerebellar vermis is importantly involved in the acquisition and/or expression of conditioned HR responses.

BILATERAL TRANSFER OF CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE: IMPLICATIONS FOR NEURAL SUBSTRATES. M.M. Patterson, J. C. Greiner,* A. G. Hutchins* and L. A. Wilson*. Dept. of Psychology and Coll. of Osteopathic Med., Ohio Univ., Athens, OH 45701.

In previous studies (Polenchar & Patterson, Neuro. Abst., 11:1041, 1985; Polenchar, Aluko, Donahue & Patterson, Neuro. Abst., 51.8:181, 1986), we examined neural activity during transfer of the conditioned response (CR) from trained to untrained sides during classical conditioning of the rabbit's nictitating membrane (NM). R.F. Thompson and his colleagues (e.g., McCormick & Thompson, J. Neurosci., 4:2811, 1984) have shown that the ipsilateral cerebellar dentate/interpositus nuclei appear to be the site of organization of the CR, and that their destruction causes a complete abolition of the CR following conditioning. If the unconditioned stimulus (UCS) is shifted to the opposite eye after the lesion, conditioning occurs in the newly trained eye with considerable savings. In our studies, we showed that CRs occur in both eyes during training in one eye, with the pattern of CRs being somewhat lower in the untrained eye. In addition, the pattern of unit activity which occurs in the dentate/interpositus nuclei of the untrained side is similar to that of the trained side during the initial training, when both sets of nuclei display both tone and airpuff evoked neural responses. Increases in neural activity which parallel the amplitude/time-course of the CR were also present bilaterally, but of smaller magnitude on the untrained side. When training was shifted to the untrained side, activity in the nuclei of the previously trained side increased dramatically, with a smaller increase on the now trained side. CR rates on the now trained side increased almost immediately in response to the presence of the UCS on that side. The present study determined the behavioral response in both eyes to conditioning on one side to asymptote followed by continued conditioning to the previously untrained eye. Animals were given 10 days of conditioning sessions with responses recorded from both eyes and the UCS on the left eye. The UCS was then switched to the right eye for another 10 conditioning sessions. The results indicated that there was a significant difference in conditioned responding between the two eyes during the first 10 days, with fewer responses occurring in the untrained eye. Following the UCS switch, the rate of responding in the left (previously trained) eye dropped over 2-3 days to the previous level of the right (now trained) eye, while the response rate in the right eye rose to the level formerly achieved by the left eye. These results, coupled with the results of the neural recordings, suggest a spatial effect of UCR placement operating in NM conditioning, independent of simple performance factors.

INHIBITION OF DENTATE GYRUS ACTIVITY DURING APPETITIVE CLASSICAL CONDITIONING OF THE RABBIT JAW MOVEMENT RESPONSE. R.A. Swain*, C.G. Oliver* and S.D. Berry. Department of Psychology, Miami University, Oxford, Ohio 45056.

New Zealand White rabbits were surgically implanted with 50u stainless steel multiple unit recording electrodes in the dentate gyrus under general anesthesia (Ketamine, 50mg/kg and Xylazine, 10mg/kg). Topical anesthetics and antibiotics were applied as necessary to minimize discomfort during postoperative recovery. One week later, each rabbit was adapted to restraint and conditioning apparatus, and placed on a 22 Hr water deprivation schedule. Classical conditioning was established using a 350 msec, 85 dB, 1 KHz tone as the conditioned stimulus (CS) and 1 cc, 100 msec duration, .022% saccharin-water solution as the unconditioned stimulus (UCS). Control animals received explicitly unpaired presentations of tone and saccharin. Twelve blocks of 9 training trials were given in 2 sessions.

The results showed that spontaneous dentate activity was rhythmic at approximately 8 cps. Within the first block of trials, both trained and control animals displayed inhibitory responses to CS and UCS. This inhibition remained stable in unpaired animals but showed a progressive suppression in paired animals over the course of training. These data contrast with the excitatory dentate responses reported for nictitating membrane conditioning in the rabbit (Weisz, et al., 1982) suggesting a different role for dentate neurons in jaw movement training.

160.10

HIPPOCAMPAL UNIT RESPONSES TO TRIAL SEQUENCE DURING DISCRIMINATION TRAINING IN RABBITS. C.G. Oliver*, R.A. Swain* and S.D. Berry (SPON: J. Czajа). Dept. of Psychology Miami University, Oxford, Ohio 45056.

Conditioned hippocampal and dentate responses in discrimination training may depend upon a particular sequence of prior trials (Deadwyler et al., Behav. Neural Biol., 44:201 1985; Eichenbaum et al., J. Neurosci., 7:716, 1987). After training rabbits in a nictitating membrane (NM) and jaw movement (JM) discrimination paradigm, we averaged multiple unit responses in CA1 according to whether the prior trial was the same or opposite to the current trial.

Ten New Zealand White rabbits were implanted with electrodes in the CA1 region. Surgery was performed under anesthesia (Ketamine 50 mg/kg, Xylazine 10 mg/kg) and rabbits were treated with antibiotics and local anesthetics to minimize discomfort. Each animal was given 10 days of discrimination training. JM trials consisted of a tone conditioned stimulus (CS: either 1 KHz or 8 KHz, 85 dB, 800 ms) and introral saccharin as the unconditioned stimulus (US: 0.022%, 1 cc, 100 ms). NM trials consisted of the alternative tone CS and an airpuff US (210 g/cm^2, 100 ms). Unit response histograms were generated by averaging the digitized spike trains with respect to CS and US onset.

While NM trials did not differ, JM trials showed greater rhythmicity in the autocorrelation function if preceded by another JM trial than by an NM trial. While this demonstrates an effect of trial sequence, it is the opposite of the alternation enhancement found in rats.

160.11

SINGLE UNIT ACTIVITY IN PYRIFORM CORTEX OF RATS DURING OLFACTORY DISCRIMINATION LEARNING. J. McCollum, J. Larson*, T. Otto, and G. Lynch. Center for the Neurobiol. of Learning & Memory, Univ. of Calif., Irvine, CA 92717.

The olfactory system has a number of advantages for studies of cortical memory operations in rodents. Rats learn olfactory discriminations very rapidly, and relatively early processing of olfactory cues take place in primary olfactory cortex. However, there is very little information available regarding single unit activity in olfactory cortex in freely-moving animals. The present study was undertaken to characterize unit activity in pyriform cortex of rats performing olfactory discriminations.

Animals were prepared with a chronic microdrive system for lowering recording electrodes into layer II of the pyriform cortex as identified by responses to lateral olfactory tract stimulation. After recovery from surgery the animals were trained on a series of two odor successive-cue discrimination 'go-no go' tasks. Animals required approximately 6 sessions to reach criterion performance (90% correct in 20 consecutive trials) within 20-25 trials. After training on approximately 12 sessions with different odor pairs, the activity of isolated pyriform units were recorded using etched tungsten microelectrodes. The animals were given a series of odor discrimination sessions and the unit firing activity was observed for one sec before and after odor-cue onset for all odors presented. Histograms of the mean number of cell spikes for selected time bins within the 2-sec observation period were made for each individual odor tested while recording from a unit. Responses of 15 units to odors have been analyzed in detail; an average of 8 odors was tested for each cell.

Two categories of cells based on background firing rate were observed. Spontaneous activity of type I units (90% of the recorded cells) ranged from 0.5 to 5 Hz, whereas type II units fired much faster (>10 Hz). Most type I cells occasionally fired in a high frequency burst resembling the complex-spike discharges observed in hippocampal cells. Of the type I cells analyzed, 27% increased their firing rates for more than 90% of the odors tested on these cells. Most increases in firing rate began 200 msec after odor onset. Sixty percent increased their firing rates for less than 10% of the odors tested. Analysis of the type II cells also indicated a similar distinction. Two type I cells did not fall into either category responding to an average of 50% of the odors. These data suggest that whereas some pyriform cells respond to odors non-selectively, the majority are relatively specific.

BEYOND THE TRISYNAPTIC LOOP: EVIDENCE FOR DISTRIBUTED SPATIAL REPRESENTATIONS IN HIPPOCAMPAL CIRCUITS. B.L. McNaughton, J. Meltzer, R.J. Sutherland, and C.A. Barnes. University of Colorado, Boulder CO, 80309, and University of Alberta, Lethbridge, Alberta, Canada T1K 3M4.

A predominant theme concerning information processing in hippocampal circuitry has been the notion of a "trisynaptic loop", consisting of afferents from the entorhinal cortex (perforant path), the granule cells of the fascia dentata, pyramidal cells of CA3 and, finally, CA1 pyramidal cells, organized as a series of transverse ("lamellar") subunits. Single units were recorded (using the "stereotrode" method) from fields CA1 and CA3 in freely behaving rats several weeks following selective neurotoxin (colchicine) lesions of the granule cells of the fascia dentata (Goldschmidt et al., 1982). Apparently normal spatially selective units were recorded in CA1 and CA3 after severe loss of dentate granule cells, amounting to at least 95% within several mm in the septal and temporal directions on each side of the recording electrode (and an overall loss of about 50%). Given the strict restriction of granule cell axons to less than about 400 μm in the transverse plane (Blackstad and Kjaerheim, 1961; Gaarskjaer, 1978; Claiborne et al.,1986), we conclude that most spatial selectivity must be conferred on CA3 pyramidal cells either through interactions via the longitudinally extensive CA3 intrinsic axonal collateral system (Ishizuka et al., 1986), or via the direct entorhinal-CA3 collaterals of the perforant pathway. CA1 pyramidal cells may also receive spatial information via the direct projection from layer III of the entorhinal cortex. In spite of the apparent integrity of at least some spatially selective firing, the animals were, nevertheless, impaired on spatial tasks including the Barnes circular platform, Morris swimming pool, and radial arm maze.

160.13

INFLUENCE OF MOTOR SET ON PLACE-RELATED HIPPOCAMPAL COMPLEX SPIKE CELL ACTIVITY. T.C. Foster*, C.A. Castro, and B.L. McNaughton (SPON: A. S. Schwartz). Dept. of Psychology, University of Colorado, Boulder, Colorado 80309.

Neuronal activity in the hippocampus is known to be modulated by the animal's behavior. In the freely moving rat, both pyramidal (CS) cells and interneurons (theta cells) have been shown to fire in phase with the rhythmic EEG activity (theta,RSA) which accompanies translational movement, and both cell types are to some extent tuned to movement velocity. In the large majority of CS cells, a striking sensitivity to spatial location is superimposed on this movement correlated modulation. In the present study, rats were trained to tolerate immobilization, implemented by snugly wrapping the body and limbs in a towel fastened with clips. Single unit activity and associated EEG were recorded using the "stereotrode" technique. CS cells were tested for location and RSA correlated activity in both the freely moving state and under restraint, by simply manually moving the animal into and out of a previously determined "place field". As reported previously by Kubie, Fox and Muller (1984), CS cell place-specificity in the freely moving rat was greater during movement associated type I theta slow wave activity (> 7 Hz) ($p < .05$). Immobilization resulted in a nearly complete suppression of place-specificity for all CS cells ($p < .001$) and an over all decrease in the discharge rate of CS ($p < .001$) and theta cells ($p < .01$). Immobilization induced changes in unit activity were accompanied by a decrease in type I theta and increased low frequency and type II theta (< 7 Hz) activity which was eliminated by atropine (50 mg/kg). We conclude that CS place-specificity and discharge activity of theta and CS cells is dependent not on motion *per se*, but on the animal's motor set, and that type II theta slow wave activity is not sufficient to drive CS cell place-specificity. The dependence of location specific discharge on the animal's perceived ability to engage in active movement through space may partly account for the relatively small number of spatially selective neurons recorded from hippocampus in restrained primates and rabbits.

160.14

LOCATION- AND DIRECTION-SPECIFIC DISCHARGE OF RAT HIPPOCAMPAL COMPLEX-SPIKE CELLS IN AN OPEN FIELD AND ON THE RADIAL 8-ARM MAZE. B. Jones Leonard, B. L. McNaughton, and C. A. Barnes. Dept. Psychology, Univ. Colorado, Boulder, CO 80309.

Several studies on the behavioral correlates of hippocampal complex-spike cell activity have shown that, on various elevated mazes, discharge is related not only to spatial location but also to the animal's directional orientation within the preferred location (e.g., Hill, 1979; McNaughton, et al., 1983; O'Keefe, 1976; Olton, et al., 1978). In the present study, we investigated whether such directional modulation is a general property or whether it is restricted to environments such as elevated mazes in which the rat's movement trajectories are highly constrained. Complex-spike cells were recorded from CA1 and fascia dentata in freely moving rats under two environmental conditions: an elevated square (1.2m) platform and an elevated 8-arm maze centered on the same spot in the same room. On the platform rats were trained to find food in a direct path when placed on its surface. This allowed trajectories of any direction to be assessed in relation to place cell discharge. On the 8-arm maze a forced choice procedure was used. Directional selectivity was assessed relative to the center of the previously determined maximum firing rate field. Rates were compared between the preferred direction and the nonpreferred direction by computing a standard measure consisting of the difference between the rates divided by their sum. Thus, no directional preference would result in a score of 0, whereas absolute directionality would result in a score of 1.0. The average score on the open platform was 0.71 ± 0.05 (SEM), $n = 9$, whereas the score for the same cells on the radial maze was 0.52 ± 0.10 (SEM), $n = 8$. (One cell did not have a field on the maze.) These results indicate that the directional modulation of "place cells" is not accounted for by the restricted orientational experience of animals on the 8 arm maze. It appears, therefore, that the role of these cells in spatial processing can more accurately be thought of as representation of local views of the animal's environment.

PERSISTENT ALTERATIONS OF PERFORANT PATH EVOKED RESPONSES ASSOCIATED WITH MAZE RUNNING. J.R. Keith*, B.L. McNaughton, E.J. Green, S. Scott* and C.A. Barnes. (SPON: L. NADEL). Dept. Psychology, University of Colorado, Boulder, Colorado 80309.

Exploratory behaviors are associated both with an increase in the amplitude of the synaptic component (EPSP) of perforant path evoked field responses in the fascia dentata and a general decline in the area of the population spike (Sharp et al., 1987, Soc. Neurosci. Abstr.). It is generally accepted that the hippocampus plays a critical role in the processing of new spatial information. If translocation through an environment provides such information, then the population EPSP and spike magnitudes could be sensitive to the extent to which the task requires translocation through the environment. In the present experiment we collected evoked responses from animals which were running for a food reward on 2 arms of an elevated maze, situated in an environment rich in distal cues, or restricted to the center portion of the same maze.

EPSP amplitudes were greater following sessions during which subjects had run on the maze than when they had been restricted to the center of the maze. Additionally, running on the maze produced a greater (23%, $p < .01$) reduction in the area of the evoked population spike compared to sessions when the same subjects were restricted to the center of the maze. This attenuation of granule cell excitability persisted beyond the period during which animals were required to run on the maze, suggesting that this effect can not be attributed to movement *per se*. Taken together, these data suggest that movement through a spatially informative environment produces moderately persistent alterations in perforant path to granule cell synaptic strengths as well as a pronounced attenuation of granule cell excitability. These alterations may reflect a "gating" or neural selection process which modulates the flow-through in information in the hippocampal formation.

INVOLVEMENT OF DOPAMINERGIC AND CHOLINERGIC SYSTEMS IN POSITIVE AND NEGATIVE CUE SIGNAL LEARNING BY RAT LATERAL HYPOTHALAMIC NEURONS. K. Nakamura*, T. Ono, H. Nishijo* and T.L. Zhou* (SPON: A. Sato). Dept. Physiol., Fac. Med., Toyama Med. & Pharmaceu. Univ. Sugitani, Toyama 930-01, JAPAN

Unit activity in rat lateral hypothalamus (LHA) was recorded during discrimination learning of cue tone (CTS) stimuli predicting reward (glucose or ICSS) or aversion (weak electric shock or tail pinch). Activity of 264 neurons in the LHA were investigated by electrophoretic application of dopamine (DA), ACh and their antagonists. Of these, 234 responded during CTS learning in one or more phases. Of 121 neurons tested for both reward and aversion, 86 discriminated them and their respective CTSs. DA sensitive neurons (mostly inhibition) responded to ACh (mostly excitation) more often than DA insensitive neurons. DA sensitive neurons responded to reward and aversion and their respective CTSs more than DA insensitive neurons. DA effects were similar to those of rewarding stimuli and CTS^+. ACh sensitive neurons responded to aversion and CTS^- more than ACh insensitive neuron. ACh effect were similar to those of aversion and CTS^-. Responses to CTS^+ were blocked by spiperone, while those to CTS^- were blocked by atropine. Data suggest that inputs from dopaminergic and cholinergic systems involve the same LHA neuron in CTS learning of positive and negative reinforcement, respectively.

160.17

EFFECTS OF KYNURENIC ACID INJECTIONS INTO THE NUCLEUS ACCUMBENS ON RADIAL MAZE PERFORMANCE. G.B. Schacter*, C.R. Yang*, N.K. Innis* & G.J. Mogenson (SPON: K.L. Harburn) Depts. of Physiology & Psychology, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

The nucleus accumbens (NAC), which receives glutamatergic afferents from the hippocampus (HIPP), has been implicated in integrating limbic signals to motor movements (Mogenson, 1984). The present study investigated the role of the HIPP-NAC pathway in radial maze performance.

Rats (n=6) were food deprived and trained in an 8-arm radial maze with 8 arms baited. Bilateral injections of the glutamate antagonist, kynurenic acid (5ug/0.2ul), into the NAC had no effect on performance accuracy (no. of correct responses in the first 8 choices and returning to previously visited arms, i.e. working memory). However, the rats spent an increased amount of time on the central platform ($t=4.99$, $p<0.005$) and on the arms of the maze ($t=2.75$, $p<0.05$) compared to control tests after saline injections. This effect was due to an increased latency to initiate movement and not due to a reduction in the speed of movement.

Bilateral injections of kynurenic acid into the NAC of rats trained in an 8-arm radial maze with 4 arms baited, resulted in a deficit in performance accuracy (no. of correct responses in the first 4 choices and visits to arms not baited, i.e. reference memory) as well as an increased latency to initiate movement.

DIFFERENTIAL HIPPOCAMPAL AND CORTICAL CHOLINERGIC ACTIVATION AS A FUNCTION OF BOTH TYPE AND DURATION OF MEMORY TESTING OF MICE IN A RADIAL MAZE. T.Durkin, A. Toumane and R. Jaffard, Lab. Psychophysiologie, UA CNRS n° 339, Univ. Bordeaux I, Avenue des Facultés, 33405 TALENCE FRANCE

We showed previously that spatial discrimination learning by mice in an 8-arm radial maze induces differential activation of both the cholinergic septo-hippocampal and nBM-cortical pathways. Whereas the amplitudes of activation did not vary significantly in either hippocampus or cortex 30 sec post-session over the 9 days of acquisition evidence was obtained that the duration of activation in each structure might vary differentially as a function of acquisition. The hypothesis that the duration of cholinergic activation varies in each structure as a function both of the type of memory (reference or working) tested and of the duration of testing (days) was investigated by measuring sodium-dependent high affinity choline uptake in both hippocampus and cortex at different times after specific reference or working memory tests. Tests (simple two-choice procedures) were administered over 15 days. Both types of memory testing induced similar and significant cholinergic activation in each brain region 30 sec post-test each day. However cholinergic activity remained elevated particularly in frontal cortex, 15 min following reference tests over the 15 days whereas progressive attenuation of the duration of cholinergic activation was observed in both brain regions following repetitive testing for working memory.

MEASUREMENT OF MET-ENKEPHALIN AND ENCRYPTED MET-ENKEPHALIN IN HUMAN CEREBROSPINAL FLUID. D.L. Lucas[1]*, D.E. Byer[2]*, V.L.W. Go[1]* and T.L. Yaksh[3] (SPON: B.F. Westmoreland). Departments of [1]Gastroenterology, [2]Anesthesiology, and [3]Neurosurgery, Mayo Clinic, Rochester, MN 55905.

Met-enkephalin like immunoreactivity (MEI) has been observed in human CSF. To further characterize this activity and that of extended enkephalin encrypting forms, CSF samples from individuals undergoing largely elective surgery (34 males, ages 25 to 82; 17 females, ages 28 to 85) were collected on ice and subjected to radioimmunoassay for MEI and for total encrypted MEI (TMEI) after trypsin/carboxy peptidase B treatment. Mean MEI values were 232 pg/ml (±105) and the mean ratio of TMEI/MEI was 6.5 (±2.5). Several observations were made: 1) MEI values increased with age ($R = 0.54$, $p < 0.001$); 2) the ratio of TMEI/MEI varied inversely with MEI levels ($R = -0.64$, $p < 0.001$); 3) the TMEI/MEI ratio did not change significantly with age ($R = -0.11$); 4) no detectable differences between males and females were observed for MEI or TMEI/MEI ratios. Pools of several samples were concentrated with a Sep-Pak C-18 column and assayed for MEI and TMEI before and after passage through a YM-2 filter. The ratio of TMEI/MEI after filtration fell to near 1.0, suggesting that the principal fragments encrypting Met[5]-Enkephalin are larger than 2000 daltons. (Supported by grant NS-16541 (TLY).)

161.2

GALANIN-LIKE IMMUNOREACTIVITY (GLI) IN NORMAL HUMAN SPINAL CORD. S.R. Michener*, T.L. Yaksh, L.D. Aimone and V.L.W. Go* (SPON: D.W. Klass). Mayo Clinic, Rochester, MN 55905.

A radioimmunoassay (RIA) for galanin, a 29 amino acid peptide was developed using rabbit galanin antibody #31 (1:7000) and I^{125}-galanin (coupled by chloramine-T). Human spinal cord and ganglia were removed within 6 h of death from four neurologically normal subjects (ages 17-55). Rat studies showed no loss of GLI in this interval. Tissues were dissected into ventral (VH) and dorsal (DH) horns at each segment of the cervical, thoracic, lumbar and sacral regions of the cord and extracted by boiling 0.1 N HCl for galanin RIA. GLI in representative segments are reported (μ:ng/g wet weight; SEM<10% of μ).

	Cervical			Thoracic			Lumbar			Sacral		
	C1	C4	C7	T3	T6	T9	L1	L3	L5	S2	S4	S5
DH	*	*	3.4	2.4	*	*	4.1	4.2	5.4	8.8	11.7	12.8
VH	*	*	*	*	*	*	2.7	3.3	3.3	4.5	7.2	8.0

* Below assay sensitivity in two or more samples.

GLI in dorsal root ganglia ranged from 2-4 ng/g. GLI was characterized using reverse phase HPLC with detection by RIA. The principal peak of immunoreactivity in human cord coeluted with galanin standard and a smaller second peak eluted 7 minutes earlier. Antibody #31 does not crossreact with preprogalanin 65-105 and 108-123. These results suggest the presence of GLI in human spinal cord with highest levels in dorsal sacral cord. (Supported by NIDDK Core Center Grant #DK34988-D).

161.3

COMPARISON OF CHOLECYSTOKININ (CCK) CONCENTRATIONS IN RAT AND HUMAN SPINAL CORDS, USING TWO CCK ANTIBODIES. D.R. Roddy*, J.E. Bailey*, V.L.W. Go* and T.L. Yaksh (SPON: J.A. Gilbert). Mayo Clinic, Rochester, MN 55905.

We determined concentrations of CCK-8 (characterized by HPLC reverse phase chromatography) in dorsal horn (DH) and ventral horn (VH) of the spinal cords in Sprague-Dawley rats (n=6) and humans (n=4), aged 17-55, utilizing two specific antibodies: Ab216 is specific for the N-terminal of sulfated CCK-8; Ab3438 recognizes the amidated C-terminal, common to the CCK and gastrin molecules.

Spinal Cord Region			Cervical		Thoracic		Lumbar		Sacral	
			Con[1]	Ratio[2]	Con	Ratio	Con	Ratio	Con	Ratio
Ab216	Rat	DH	5.8	1.5	6.2	1.6	7.8	1.6	15.8	1.5
		VH	1.8	0.9	2.0	0.9	3.1	0.8	6.1	1.0
	Human	DH	1.6	1.4	1.5	1.2	3.7	1.6	9.1	1.9
		VH	1.5	1.5	1.5	1.4	2.9	1.7	7.6	1.9
Ab3438	Rat	DH	8.8		9.7		12.3		24.0	
		VH	1.7		1.8		2.6		6.3	
	Human	DH	2.2		1.8		6.1		17.1	
		VH	2.3		2.1		5.0		14.7	

[1]Con=ng/gm CCK; μ (SE<10% of μ). [2]CCK-LI: Ab3438 ÷ Ab216.

The Ab3438/Ab216 ratio was constant along the rostrocaudal axis, in rat and man. As expected, the ratio was greater than 1 in man (DH, VH) and in rat (DH). However, in rat, the DH ratio was greater than in VH. In the absence of evidence for spinal gastrin, this emphasizes the possibility of differential processing of the CCK family of peptides in DH and VH of the spinal cord. (Grant DK-34988-D.)

161.4

PLASMA UPTAKE AND METABOLISM OF [LEU]ENKEPHALIN FOLLOWING INTRAPERITONEAL ADMINISTRATION IN RATS. J.L. Martinez, Jr., G. Schulteis, L. Chisholm* & S.B. Weinberger. Dept. of Psych., Univ. Calif., Berkeley, CA 94720.

Male Sprague-Dawley rats received ip injections of ^{3}H-[Leu]enkephalin (LE) (3 μg/kg). Blood samples (0.4 ml) were collected through indwelling femoral artery cannulae at 1, 2, 3, 4, 5, 7.5, and 15 minutes following injection; blood volume was immediately replaced with saline. Plasma was immediately separated by microcentrifugation and then proteins were denatured with 0.1% TFA in MeOH. Degradation during the time between collection and denaturation was minimized by the presence of 500 μM bestatin. Total plasma ^{3}H was counted in a portion of each sample. The remainder of each sample was subjected to thin-layer chromatography (TLC) to separate LE from its combined metabolites.

The steepest rise in plasma levels of total ^{3}H was in the first minute following injection; peak levels were typically reached within 3-5 min. Substantial ^{3}H was still detectable in plasma at 15 min. TLC separation indicated that greater than 95% of plasma ^{3}H represented metabolic fragments of LE at all sampling time points. Since LE has an *in vitro* 1/2-life of about 2.5 min in rat plasma (*c.f.* Behav Neural Biol, 49:192-221, 1988), plasma degradation alone cannot account for the present data; rather, the data suggest that LE undergoes substantial metabolism before or during its uptake into plasma. These results have important implications for the design and interpretation of studies on the behavioral and physiological effects of LE following ip administration. (Supported by PHS grants DA #04195 [JLM], NRSA #1 F31 DA05334-01 [GS], & NRSA #1 F32 DA05313-01 [SBW])

EVIDENCE FOR DISSOCIATION OF POMC BIOSYNTHESIS AND RELEASE IN THE RAT ANTERIOR PITUITARY FOLLOWING DOPAMINERGIC BLOCKADE. J.H. Meador-Woodruff, B. Pellerito* and H. Akil. Mental Health Research Institute and Department of Psychiatry, University of Michigan Medical School, Ann Arbor, MI 48109.

Proopiomelanocortin (POMC) biosynthesis and processing has been previously demonstrated to be in part regulated by dopaminergic systems in both the anterior (AL) and intermediate (IL) lobes of the rat pituitary. We have previously reported on the effects of chronic (14 day) haloperidol administration on mRNA and POMC peptide levels as well as post-translational modifications in both IL and AL; we now extend these findings to include secretion of POMC products from IL and AL following chronic haloperidol treatment, as reflected by both circulating plasma levels and *in vitro* releasability studies. In IL, acute haloperidol treatment promotes rapid release of peptide products. Chronic treatment results in compensatory elevations of levels of both POMC mRNA and processed peptides, and the IL is able to continue to release peptides at pretreatment levels. In AL, however, a radically different and paradoxical situation develops. Acute haloperidol administration also results in rapid release of product; chronic treatment, however, results in decreased POMC mRNA levels, diminished peptide stores, and an inhibition of the production of processed forms of POMC. Both basal and stimulated release from the AL are not affected. These results suggest that biosynthesis may be dissociated from release in the AL; despite reduced levels of processed peptides, the AL is able to continue to maintain pretreatment levels of release. This may reflect the existence of different pools of POMC storage in AL: the reduction of total peptide content following haloperidol treatment may occur in a nonreleasable pool, whereas the releasable fraction is maintained at a constant level.

MORPHINE MODULATING PEPTIDES: DISTRIBUTION IN RAT CNS AND PITUITARY AND INTERSPECIES HETEROGENEITY. E.A. Majane and H.-Y.T Yang, NIMH, St. Elizabeths Hosp., Wash., D.C. 20032.

FLFQPQRF-NH_2 (F-8-F-NH_2) and AGEGLSSPFWSLAAPQRF-NH_2 (A-18-F-NH_2) are two FMRF-NH_2 like peptides we have previously, isolated from bovine brain. Using antisera developed against these peptides, the distribution of F-8-F-NH_2 in rat CNS was studied and FMRF-NH_2 like immunoreactivity (IR) in spinal cords of various species was characterized by HPLC coupled with RIA. F-8-F-NH_2 was found to be unevenly distributed with the highest concentration found in posterior pituitary and dorsal spinal cord (1008 and 502 fmol per mg prot. respectively). Hypothalamus and pons medulla contain intermediate concentrations of F-8-F-NH_2-IR (202 and 136 fmol per mg prot. respectively); lowest values are in cortex and anterior pituitary. In spinal cord of rat, mouse, bovine, guinea pig and human, at least one major F-8-F-NH_2 IR was detected, however, the retention times (RT) of the material varied from species to species. Though there is an interspecies molecular heterogeneity, F-8-F-NH_2-IR is found in high concentration in spinal cord of every species. This result and the opiate modulating activity of F-8-F-NH_2 taken together suggest that F-8-F-NH_2 may have a role in antinociception.

MODULATION OF STRIATAL ENKEPHALIN AND TACHYKININ TURNOVER BY THE D1 DOPAMINE RECEPTOR. A.E. Pollack, C.J. Cruz, R.M. Beckstead, and G.F. Wooten. Dept. of Neurosci, Univ. of Va. Sch. of Med., Charlottesville, VA 22908.

Chronic treatment of rats with the dopamine D2 antagonist haloperidol (HAL) increases striatal met-enkephalin (ME) and preproenkephalin (PPE) mRNA, but decreases striatal substance P (SP) and preprotachykinin (PPT) mRNA. Chronic treatment with the D1 antagonist, SCH23390, leads to the same change in striatal ME and PPE mRNA as does HAL. In this study, we examined the time course of SCH23390 induced changes in striatal ME, SP and their precursor mRNAs. Adult rats were treated with SCH23390 (1 mg/kg/d, s.c.) or vehicle for 1, 3, 7, or 21 d, and their striata and substantia nigrae processed for radioimmunoassay or RNA extraction. Striatal PPE and PPT mRNA of drug and vehicle treated rats were compared by dot blot hybridization using 32-P labeled oligonucleotide probes. After SCH23390 treatment for 3 or 7 d, striatal ME doubled, but fell to control levels after 21 d of treatment. Although striatal SP did not change at any time, nigral SP increased at 7 and 21 d. Striatal PPE and PPT mRNA increased after 21 d of treatment. These results suggest that the D1 receptor modulates the turnover of both striatal enkephalins and SP in the striatonigral projection. Moreover, this evidence implies that D1 and D2 receptors mediate similar effects on striatal PPE gene transcription, but opposing effects on PPT transcription.

PURIFICATION AND CHARACTERIZATION OF γ-ENDORPHIN GENERATING ENZYME ACTIVITY IN THE BRAIN. N.M. Soeter* and J.P.H. Burbach* (SPON: Tj.B. van Wimersma Greidanus). Rudolf Magnus Institute of Pharmacology, University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands.

α- and γ-Endorphin are endogenous neuropeptides with opposite biological activity and it is suggested that the balance between these peptides is essential for adequate brain functioning. γ-Endorphin is generated from β-endorphin by a single cleavage of the Leu 17 - Phe 18 bond. The enzyme activity catalyzing this reaction has been called γ-endorphin generating endopeptidase (γ-EGE).

γ-EGE is a thiol-peptidase with a pH optimum between 8.5 and 9 and it is found in many brain areas. In order to obtain specific antibodies and inhibitors for biological investigations we are purifying the enzyme activity. Rat brain cytosol was applied to a Q-Sepharose Fast Flow column and a concentrated pool of this column was subsequently chromatographed on a Sephadex G-200 column. Fractions were further purified by ion-exchange (Mono Q) and size-exclusion (Zorbax GF-450) HPLC. On a gelfiltration column (Sephadex G-200, TSK G-3000, Zorbax GF-450) the enzyme behaved as a protein with a molecular weight of 200kDa. So far the enzyme seems different from known peptidases including the enkephalin-generating enzymes. Endo-oligopeptidase A (a gift from Dr. A. Camargo) did not cleave β-endorphin. The EC 3.4.24.15 inhibitor cF-A-A-F-pAB (a gift from Dr. M. Orlowski) inhibited our enzyme but the general inhibition profile of the two enzymes is different.

SUBCELLULAR FEATURES OF LHRH NEURONS IN CYCLING FEMALE RATS. G.R. Seiler*, P.G. Brunetta*, and J.C. King. Dept. of Anat. & Cell Bio., Tufts University Health Sciences Campus, Boston, MA 02111.

Release of LHRH from hypothalamic neurovascular terminals is essential to induce the preovulatory LH surge. Little is known about intracellular synthesis and processing of LHRH precursor to generate the decapeptide during the estrous cycle. We compared the ultrastructure of LHRH immunopositive cells of intact females sacrificed in the morning of each day. The most dramatic changes within LHRH neurons from the rostral preoptic area, surrounding the OVLT, occurred in diestrous and proestrous females. Protein-synthesizing organelles increased from diestrus to proestrus with polysomes predominant in the cytoplasm of LHRH neurons from diestrous females. Rough endoplasmic reticulum [RER] and Golgi complexes, with associated dense-cored and small, clear transport vesicles, were pronounced in LHRH neurons from proestrous females. In estrous females, the Golgi complex was less immunoreactive, so that only the dilated regions were immunopositive; few RER cisternae were present. Many dense bodies with crystalline inclusions were also present. Finally, nematosomes differed in texture with a greater filamentous character displayed during estrus. These ultrastructural features are consistent with the hypothesis that LHRH synthesis is increasingly augmented from diestrus to proestrus and that degradation is the primary event occurring in estrus. NSF DCB 8702388.

161.10

CYCLIC CHANGES IN NUMBERS OF LHRH NEURONS IN FEMALE RATS. E.S. Hiatt*, G.R. Seiler*, P.G. Brunetta*, and J.C. King. (SPON: D.A. Damassa), Dept. of Anat. & Cell. Bio., Tufts University Health Sciences Campus, Boston, MA 02111.

We have shown that augmented release of LHRH following gonadectomy is correlated with enhanced synthesis and/or processing of LHRH precursor [King and Seiler, Brain Res., in press]. In this immunocytochemical study we examined changes in the numbers of LHRH neurons in cycling females using LHRH antisera directed to either amino acid sequences 4-8 [Millar 1076] or 3-9 [Arimura 419]. Rats [16] were sacrificed on the morning of each day [n=4] of the estrous cycle. Between- [cycle day] and within-[antiserum and forebrain region] subject effects were analyzed in a repeated measures ANOVA. The analyses confirmed the concentration of LHRH neurons in the OVLT/POA forebrain region. The influence of cycle day on the number of LHRH neurons detected with 419 was significant, with the greatest number observed on proestrus. In contrast, AS 1076 detected a significantly greater number of LHRH neurons than did 419 on all days of the cycle. These data may reflect differences in both antiserum sensitivity and ability to detect multiple molecular forms of LHRH. Variations in abundance and subcellular distribution with cycle stage are suggested by ultrastructural studies of these neurons [Seiler et al. 1988]. The increase in LHRH neurons detected on proestrus may represent coordinated activation of a larger segment of the population. NSF DCB 8702388; NIH 5 R01 HD19803.

REGULATION OF THYROTROPIN RELEASING HORMONE DEGRADING ENZYMES BY THYROID HORMONE IN VIVO. C.S. Suen* and S. Wilk. Dept. of Pharmacology, Mount Sinai School of Medicine, New York, NY 10029.

Thyrotropin releasing hormone (TRH, pGlu-His-Pro-NH_2) is cleaved at the pGlu-His bond by two distinct pyroglutamyl peptidases. Pyroglutamyl peptidase I (EC 3.4.19.3), a cytosolic cysteine protease, has a broad substrate specificity cleaving all pGlu-amino acid bonds except pGlu-Pro. Pyroglutamyl peptidase II (EC 3.4.19.-.), a synaptosomal membrane-bound metalloprotease appears to be specific for TRH. We have previously reported on the regulation of pyroglutamyl peptidase I by L-3,5,3'-triiodothyronine (T_3) in GH_3 cells (Suen and Wilk, Endocrinology 121, 770 (1987)). We now report on the effect of T_3 on the activities of both pyroglutamyl peptidases in rat brain regions, pituitary and serum. In acute studies, rats received an sc injection of 100 μg T_3 and were killed after 24h. The activity of pyroglutamyl peptidase I was unaltered whereas pyroglutamyl peptidase II was increased 3 fold in pituitary, and 70% in frontal cortex. In chronic studies, animals received daily sc injections of 100 μg T_3 for 10 and 14 days. Pyroglutamyl peptidase I was significantly elevated in pituitary, hypothalamus, thalamus, hippocampus and olfactory bulb. Pyroglutamyl peptidase II was significantly elevated in frontal cortex and serum. This study demonstrates regulation of these enzymes by T_3 in vivo. These enzymes may play a role in the control of the biological activity of TRH and may mediate in part the negative feedback regulation of thyroid status by T_3. (Supported by an NIH grant NS-17392 and a Research Scientist Award MH 00350 to S.W.).

161.12

PYROGLUTAMATE AMINO PEPTIDASE (PGAII) IS LOCALIZED IN NEURONS. C.Cruz*, J.L.Charli*, M.A.Vargas* and P. Joseph-Bravo* (SPON: J. Alanis). CEINGEBI, Universidad Nacional Autónoma de México, A.P. 510-3, Cuernavaca, Mor. 62270, México.

PGAII is a membrane-bound enzyme mainly localized at the nerve terminal (Garat et al, Neuropeptides 6, 27, 1985 ; Torres et al, Neurochem. Int. 9, 103, 1986). It has high specificity for TRH and evidence supports PGAII as an ecto-enzyme (Charli et al, Neurochem. Int., in press). In an attempt to define its cellular localization, we have measured PGAII in primary cell cultures of fetal brain. Using 3H-TRH as substrate, PGAII activity was detected in intact cells or membrane fractions from 4 to 12 days cultures. When non-neuronal cell proliferation was abolished by cytosine arabinoside treatment PGAII/DNA values were increased (2.2± 0.3 vs. 0.9± 0.2, n=8, p 0.005). Treatment of cortical cells with the neurotoxic agent glutamate reduced PGAII activity by 80%, 48 h after treatment. Glial cell cultures expressed PGAI activity or lactate deshydrogenase but not PGAII. The localization of PGAII in neuronal cells strengthens the hypothesis that it is a neuropeptidase degrading released TRH. This is further supported by preliminary experiments where inhibition of PGAII increased TRH recovery in medium from hypothalamic slices incubated in vitro. (Supported in part by grants from CONACyT)

161.13

DIAZEPAM PRETREATMENT PREVENTS KAINIC ACID-INDUCED INCREASES IN TRH CONTENT OF RAT BRAIN. B.L. Wolfinger*, A. Winokur and M.S. Kreider. Dept of Psychiatry, Univ. of Penna., Phila., Pa. 19104

Previous studies in our laboratory have shown that induction of limbic seizures by systemic administration of kainic acid (KA) produced large increases in the concentration of TRH in limbic regions of the rat central nervous system (Kreider et al, Neurosci. Abs. 13:1656, 1986). We investigated whether pretreatment with the anticonvulsant diazepam would prevent KA-induced elevations in TRH content.

Male Sprague-Dawley rats (180-200 g) received i.p. injections of diazepam (5 mg/kg) or 0.9% NaCl/ethanol (1:1) vehicle. Thirty minutes later, rats received kainic acid (12 mg/kg) s.c. or saline. All rats were sacrificed 3 days later. Brain regions were homogenized, extracted with methanol and assayed for TRH content by radioimmunoassay.

In agreement with our previous study, significant elevations in the concentration of TRH in the corpus striatum (2 fold), anterior cortex (2.5 fold), amygdala/ piriform cortex (4 fold), posterior cortex (16 fold), and hippocampus (18 fold) were observed 3 days following KA administration. Pretreatment with diazepam significantly attenuated the increase observed in corpus striatum and posterior cortex without affecting the response in the other brain regions. These results indicate that there is a differential effect of diazepam on the responsiveness of TRH systems to limbic seizure activity.

161.14

THYROTROPIN-RELEASING HORMONE (TRH) mRNA IS PRESENT IN THE RAT HIPPOCAMPUS. M.J. Kubek, S.H. Larsen* and A. Melendez* Depts. of Anatomy, Psychiatry, Microbiology and Immunology and Program in Medical Neurobiology, Indiana University School of Medicine, Indianapolis, IN 46223.

Previous studies from our laboratory have shown that: 1) the hippocampus (HC) contains relatively low levels of TRH; 2) following generalized seizures (48 hrs), these levels increase at least 5-fold; 3) lesion studies revealed both extrinsic (60%) and intrinsic (40%) sources of HC TRH; and 4) immunocytochemical staining revealed the presence of TRH in pyramidal and granule cells of the HC (Neurosci. Abs. 13:995). If TRH is synthesized de novo in such cells, the corresponding TRH mRNA should be present in the HC. Total RNA was extracted from rat HCs. In order to increase sensitivity, we modified the polymerase chain reaction technique to amplify a 300 bp region of the mRNA sequence. A 300 bp amplified DNA fragment was obtained and shown to be similar to authentic TRH mRNA by: 1) containing three known restriction enzyme cleavage sites at the proper locations and 2) to hybridize predictably to a cloned cDNA fragment. DNase treatment of the RNA sample prior to amplification did not eliminate the 300 bp fragment, indicating that the template used for amplification was not DNA.

These results indicate that the HC contains TRH mRNA and is capable of de novo TRH synthesis.

Supported by grants from MDA, VA and NS 25661 to M.J.K.

4-NITROIMIDAZOLE-TRH: BINDING TO TRH RECEPTORS IN THE RAT BRAIN. **S. Vonhof*, V. M. Labroo*, L. A. Cohen*, I. Paakkari*, and G. Feuerstein. (SPON: H. Bryant) Dept. Neurology , USUHS, Bethesda, MD, 20814 and Laboratory of Chemistry, NIDDK, NIH, Bethesda, MD, 20892.**

In addition to its TSH- and prolactin-releasing properties, thyrotropin-releasing hormone (TRH) elicits analeptic responses affecting cardiovascular and ventilatory functions. We have previously shown that 4-NO_2-Im-TRH exerts cardiovascular responses similar to those of TRH, while its prolactin-releasing potency is substantially reduced. In order to determine whether the cardiotonic effects of this analog are mediated through TRH receptors, binding properties of 4-NO_2-Im-TRH were evaluated in different regions of the rat brain. Fresh tissue samples were incubated with [^{3}H]-3-Me-(His^2)-TRH and increasing analog concentrations. The analog displaced the radioligand only at concentrations where binding may be considered nonspecific (IC_{50} = 0.1 to 7.1 mM). The data show that the loss of prolactin-releasing activity of 4-NO_2-TRH is due to its lack of binding to pituitary TRH receptors. Its cardiotonic activity, however, seems to be mediated through mechanisms other than those involving the high-affinity TRH receptors recognized by [^{3}H]-3-Me-(His^2)-TRH.

ALTERED CATABOLISM OF THYROTROPIN RELEASING HORMONE [TRH] IN TRH-TREATED AMYOTROPHIC LATERAL SCLEROSIS [ALS] PATIENTS: INCREASED SPINAL CORD TRH-OH FORMATION. B.R. Brooks, J. Turner*, T. Schwartz*, W.W. Tourtellotte. Wm. S. Middleton Mem. VA Med. Ctr., Madison, WI 53705 and Wadsworth VA Med. Ctr., Los Angeles, CA 90073

We have studied the catabolism of [^{3}H-pro] TRH in cerebral ctx, cerebellar ctx, and spinal cord obtained from male controls [7] and ALS patients before [9], during [4], and after [2] alternate day subcutaneous TRH [2-4 mg/kg] administration. Homogenates were prepared in 100 mM KPO_4, pH 7.5; or 2 mM DTT, 100 mM KPO_4, pH 7.5, incubated with 9400 fM [1 uCi] TRH for 0, 10, 20, 30 and 60 minutes at 37°C and analysed by HPLC [Neurosci Lett 71: 209, 1986]. Cerebral ctx TRH degradation was increased [$p < 0.02$] in TRH-treated ALS patients [115 ± 14(SD) fM/min/mg protein] compared with controls [76 ± 15] and untreated ALS patients [85 ± 18] as was cerebellar ctx TRH degradation. Spinal cord TRH degradation was increased [$p < 0.03$] in TRH-treated ALS patients [65 ± 10] compared with controls [45 ± 9] but not untreated ALS patients [57 ± 21]. TRHOH formation was increased [$p < 0.02$] in TRH-treated ALS patients [464 ± 137 fM/mg protein] compared with controls [223 ± 193] or untreated ALS patients [169 ± 107]. Increased TRH degradation occurs at many CNS sites during TRH treatment but TRHOH formation is increased only in the spinal cord suggesting specific activation of the deamidation pathway at this site. COMBINED IMMUNOHISTOCHEMICAL AND *IN SITU* HYBRIDIZATION ANALYSIS OF NEUROTENSIN-PRODUCING NEURONS IN THE RAT MIDBRAIN. F. G. Williams and A. J. Beitz. (Spon: Jane Clements). Department of Veterinary Biology, College of Veterinary Medicine, University of Minnesota, St. Paul, MN 55108.

A novel anti-neurotensin monoclonal antibody (NT8) was used to examine rat midbrain neurons that produce neurotensin (NT). The NT8 paratope requires that NT residues Pro_7-Arg_8-Arg_9 be intact. EM immunohistochemistry using either peroxidase-DAB staining before Epon embedding or colloidal gold staining after LR Gold embedding resulted in immuno-stained axon terminals, proximal dendrites, and rough ER within neuron perikarya. Although the distribution of stained neurons was enhanced by intra-ventricular colchicine injection, immunoreactive perikarya were also visible without colchicine. The apparent staining of protein-synthetic organelles suggests that NT8 can recognize putative NT synthetic precursors. Thus, NT8 may be useful for identifying and quantitating neurons that are active in NT biosynthesis.

To further establish that the immunostained neurons can produce NT, we performed *in situ* hybridizations on 10µ rat midbrain cryo-sections that had been incubated with NT8 and stained with peroxidase-DAB. Thirty-six base cDNAs to the peptide-coding region of canine enteric pro-NT were synthesized and 3' end-labeled with ^{35}S-dATP using terminal transferase. In 4-6 hour hybridizations followed by overnight washing at 37 °C and autoradiography, the antisense strand hybridized to neurons containing NT8 reaction product while the sense strand did not hybridize. Properties of the neuronal mRNA are currently being investigated. The ability to simultaneously visualize the products of NT transcriptional and translational biosynthetic activity is expected to permit further insights into the mechanisms that control NT biosynthesis. Supported by DE06682, NS19208 and BNS8607520.

APPEARANCE OF VASOACTIVE INTESTINAL POLYPEPTIDE-LIKE IMMUNOREACTIVITY IN THE PERFUSATE OF THE ISOLATED RAT ADRENAL MEDULLA AFTER FIELD STIMULATION. R.K. Malhotra,* M. Blank,* T.D. Wakade* and A.R. Wakade (Spon: H.L. Cohen) SUNY Health Science Center, Brooklyn, NY 11203.

Our previous studies have shown that in addition to acetylcholine (ACh), a noncholinergic substance(s) released from presynaptic neurons contributes to the secretion of catecholamine (CA) from the rat adrenal medulla (J. Physiol, 383:639, 1987). Among various peptides present in splanchnic neurons, vasoactive intestinal polyteptide (VIP) proved to be the most probable candidate (J. Physiol, 383:285, 1987). In the present study we have collected further evidence to support this idea. VIP content was estimated in perfusate of isolated adrenal gland before and after nerve stimulation. The respective values were 25.1±4.8 fg and 73.2±8.6 fg. VIP content in perfusate of denervated adrenal glands did not increase after nerve stimulation. Infusion of Ach in normal and denervated adrenal glands did not release VIP. CA secretion evoked by field stimulation was partially blocked (65%) by cholinergic antagonists, and inclusion of VIP antagonist (Ac-Tyr^{1}h-GRF, 10 µM) further inhibited (90%) the secretion. These findings provide direct evidence that VIP is released during stimulation of splanchnic neurons and may act as a neurotransmitter in evoking CA secretion from adrenal medullary cells.

REGULATION OF INSULIN AND GLUCOSE PLASMA LEVELS BY CNS BETA-ENDORPHIN IN PREWEANLING RATS. J. V. Bartolome*, M. B. Bartolome*, E. B. Harris* and S. M. Schanberg*. (SPON: J. M. Bell). Dept. Pharmacol. Duke Univ. Med. Ctr., Durham, N.C. 27710.

Insulin administration to rat pups increases ornithine decarboxylase (ODC) activity, a "critical" growth-related enzyme, throughout the body. This agrees with the well established role for insulin as a major regulator of somatic growth. Recently, we have found that central administration of beta-endorphin (BE) markedly alters tissue ODC responses to insulin and decreases metabolic activity in vital organs including liver and kidney. Since these organs are the major sites of insulin catabolism it seemed possible that plasma insulin levels could also be affected. To test this hypothesis rat pups were injected with BE i.c. followed by insulin s.c. and plasma levels of insulin were measured at different times after insulin.

Pretreatment of 6-day-old rat pups with BE i.c. markedly increased the apparent half-life of administered insulin. BE also prolonged the half-life of endogenous insulin. Hypoglycemia in rats injected with BE and insulin was more marked than in animals given insulin alone. Peripheral administration of BE had no effect. BE influences on plasma insulin/glucose levels seem to be restricted to early development as no changes were noticed in similarly treated 30-day-old rats.

In as much as insulin is necessary for normal growth during early life, these findings suggest that CNS BE by modulating insulin catabolism could have an important role in the regulation of perinatal development.

HYPOTHALAMO-PITUITARY-ADRENAL (HPA) AXIS TOLERANCE TO MU AND KAPPA AGONISTS IN NEONATAL RATS. D.M. Ignar and C.M. Kuhn. Pharmacology Dept., Duke Univ. Med. Ctr., Durham, NC 27710

We have shown that chronic treatment of adult rats with morphine (M) or U50,488 (U) results in specific mu or kappa HPA tolerance, respectively and that HPA stimulation by serotonergic and cholinergic agonists is decreased after chronic U, but not M. In the present study, we have compared mu and kappa HPA tolerance in neonatal rats to that seen in adults. Neonatal rats were injected sc twice daily from day 5 to 9 with M (5-25 mg/kg) or U (0.5-2.5 mg/kg). Thirty six hrs after the last treatment, animals were injected with M, U, quipazine (Q), or physostigmine (P), and serum CS determined 45 min later. M treatment affected only responses to M. Chronic U diminished responses to M, Q, and P, but not U. Acute CS elevation after M or U was more prolonged in pups than adults. The specific mu antagonist naloxonazine completely blocked responses to M and partially blocked responses to U. These results suggest that mu tolerance develops in neonatal rats, but that kappa tolerance is not observed despite the development of mu cross-tolerance and the decreased cholinergic and serotonergic responses seen in adults.

162.3

STRYCHNINE BLOCKS DYNORPHIN-INDUCED HINDLIMB PARALYSIS AND LOSS OF THE TAIL-FLICK REFLEX IN RATS. P. Stewart and L. Isaac, Depts. of Occup. Ther. and Medical Pharmacol., Univ. of Ill. at Chicago, Chicago, IL 60612.

Previously, we showed that repeated intrathecal (i.t.) injection of dynorphin A (1-13) (DYN) in rats results in a temporary (30 min) hindlimb paralysis (HP) after each injection with a permanent loss of the tail-flick reflex (TFR) after the 1st injection. We questioned whether an inhibitory pathway was involved in the HP. Rats (n=31) were implanted with an i.t. cannula and injected 3 days later with either I. (n=11) strychnine sulfate (10 nMoles) (STRY) and 10-20 min later saline, or II. (n=10) saline followed with DYN (25 nMoles), or III. (n=10) STRY followed with DYN. TFR and motor performance on an inclined plane were assessed over 24 hrs.

STRY-SAL injection resulted in a decreased TFR latency (5.3 to 3.6 sec, $p<0.05$) for 30 min without altering motor performance. Of the rats injected with the SAL-DYN combination, 80% lost TFR and exhibited HP. Only 40% of the rats in the STRY-DYN group lost TFR and demonstrated HP ($p<0.05$).

Because a major action of STRY is to antagonize glycine sites, we concluded that a glycinergic pathway is involved in both the HP and loss of TFR to i.t. DYN. Thus, it is conceivable that spinal cord DYN may modulate Renshaw cell activity in vivo.

162.4

DYNORPHIN A-INDUCED RAT HINDLIMB PARALYSIS IS NOT ALTERED BY THE κ OPIOID ANTAGONIST NOR-BINALTORPHIMINE (nBNI). J.B. Long, B. deCosta*[1], A. Martinez, R.E. Tidwell*, K. Dosaka*, K.C. Rice*[1] and J.W. Holaday, Dept. of Med. Neurosci., WRAIR, Wash., D.C. 20307, and [1]Sect. on Drug Design and Synth., NIDDK, Bethesda, MD 20205.

The κ opioid agonist dynorphin A (1-17) [DYN] causes hindlimb (HL) paralysis and nociceptive loss when injected into the rat lumbar subarachnoid space. Since these effects are shared by non-opioid DYN fragments, they appear not to require interaction with opioid receptors. However, the opioid antagonist naloxone has been reported to block paralytic effects of DYN, indicating possible involvement of both opioid and non-opioid actions. To distinguish a κ opioid component of DYN-induced HL paralysis, we directly compared dose-related HL paralytic effects of DYN and the non-opioid DYN fragment (2-17), and attempted to antagonize the effects of DYN with the selective κ opioid receptor antagonist nBNI. HL motor function and nociceptive responsiveness were evaluated in male SD rats following L4-L5 spinal subarachnoid injections of DYN or DYN (2-17) [1.6-25 nmols]. The potency and persistence of DYN and DYN (2-17) effects on motor and nociceptive function were indistinguishable. DYN and DYN (2-17) had paralytic ED_{50}s (95% C.I.s) of of 3.3 (1.9-5.8) and 6.0 (3.4-10.6) nmols, respectively, at 10 min postinjection. Furthermore, immediate preinjection of nBNI (20 nmol, i.t.) failed to alter the neurological disruptions produced by 5 and 20 nmols of DYN. Thus, DYN-induced HL motor and nociceptive loss appears to be totally attributable to its non-opioid action(s).

STIMULATION OF MU RECEPTORS INDUCES CHANGES IN HIPPOCAMPAL OPIOID PEPTIDE METABOLISM. W. Lason*, J.N. Simpson*, J.B. Daunais, J.F. McGinty, Department of Anatomy and Cell Biology, School of Medicine, East Carolina University, Greenville, NC 27858-4354 USA (SPON: W.R. Wooles).

When injected into the ventral hippocampus, mu opioid receptor agonists induce wet dog shakes and convulsions (Lee et al., Brain Res., 441: 381-385, 1988). In this study, wet dog shakes and convulsions induced by a single intrahippocampal injection of a specific mu agonist, DAGO (10 ug/0.5 ul), are accompanied by changes in hippocampal opioid peptide metabolism which persist for several days. Both behavioral and biochemical changes were prevented by naloxone (1 mg/kg, s.c.). Immunohistochemical analysis revealed that Leu^5-enkephalin (L-ENK) and dynorphin A 1-8 (DYN) immunoreactivity (IR) in mossy fibers and perforant path fibers was decreased by 1 hr and was increased markedly at 3, 24, and 72 hr after DAGO administration. By 6 days, L-ENK and DYN IR had returned to normal. In situ hybridization, using a synthetic oligonucleotide probe (Young et al., PNAS 83: 9827, 1986) revealed that the proenkephalin A mRNA in the dentate gyrus and in entorhinal cortex was increased markedly at 1 hr, 3 hr, and 24 hr following the DAGO injection. These changes in hippocampal opioid peptide metabolism are similar to those observed after kainic acid administration (Kanamatsu et al., J. Neurosci. 6: 3094, 1986), a fact which supports a role for mu receptor stimulation in limbic seizures.

162.6

OPIOIDS DECREASE MEMBRANE CONDUCTANCE DURING EARLY AND LATE IPSPs IN HIPPOCAMPAL CA1 AND CA3 PYRAMIDAL CELLS. E.S. Swearengen, R.M. Caudle* and C. Chavkin. Dept. Pharmacol., Univ. of Washington, Seattle, WA 98195.

We measured significant decreases in CA1 and CA3 pyramidal cell membrane conductance during both early and late IPSPs following bath application of opioids to submerged rat hippocampal slices. Membrane conductance was measured before and after activation of IPSPs by the voltage deflection produced by hyperpolarizing current pulses. In CA1, 10 μM normorphine or 1 μM PL017 reduced membrane conductance during early and late IPSPs, increased EPSP width and produced a second action potential during the EPSP. Addition of the NMDA receptor antagonist, D-APV (50 μM), blocked the second action potential and further blocked the membrane conductance resulting from NMDA receptor-activated currents unmasked by normorphine. Bicuculline (3 μM) decreased early IPSP conductance (to the same extent as normorphine plus D-APV) and produced a second action potential during the EPSP; neither action of bicuculline was affected by D-APV. These findings are consistent with the lessor inhibitory effect of D-APV on bicuculline- compared to normorphine-induced afterpotentials detected in extracellular recordings. In CA3, pyramidal cells with identifiable early and late IPSPs responded to 1 μM PL017 with decreased conductance during both IPSPs. In both CA1 and CA3, the predominant effect of opioid receptor activation is presynaptic inhibition of inhibitory input. Our findings suggest that opioids, presumably by inhibiting GABA release from interneurons, reduce activation of Cl^- and K^+ conductances associated with $GABA_A$ and $GABA_B$ receptors respectively. In CA1, these opioid actions are accompanied by the opening of NMDA receptor-associated channels.

MORPHINE TOLERANCE DECREASED MAXIMAL EXCITATION PRODUCED BY μ AND ∂ SELECTIVE OPIOID AGONISTS IN RAT HIPPOCAMPUS. T.L.Wimpey* and C. Chavkin. Dept. of Pharmacology, University of Washington, Seattle, WA 98195

Chronic morphine treatment reduced opioid effects on hippocampal CA1 pyramidal cells. Extracellular recordings of population spikes in hippocampus were compared in slices prepared from rats either implanted 7 days with morphine pellets, sham-pelleted, or untreated animals. In control groups, both μ and ∂ selective opioid agonists decreased the S1/2 (stimulus intensity producing 1/2 maximum primary response). The μ agonist PL017 induced a greater shift in S1/2 and caused a larger secondary spike than the ∂ agonist DPLPE. Maximal doses of DPLPE and PL017 together did not produce additive effects. Following morphine treatment, the maximal effects of PL017, DPLPE, normorphine and DAGO on the S1/2 were reduced without significantly affecting agonist ED_{50}. No apparent signs of withdrawal or residual morphine were detected in tolerant slices by the addition of the antagonist naloxone. Treatment of slices from naive animals with the irreversible opioid receptor alkylating agent ß-CNA produced changes that mimicked the tolerant state. ß-CNA treatment reduced the maximal change in the S1/2 caused by PL017. ß-CNA treatment also reduced or eliminated secondary population spikes induced by PL017. The ß-CNA experiments and the reduction in maximal opioid response caused by tolerance indicate that there is not a significant number of spare receptors controlling opioid response in CA1. Our results also suggest that tolerance is caused either by a change in functional receptor number or a change in receptor coupling as was shown in guinea pig ileum and locus coeruleus. Supported by DA04123.

OPIOID CONTROL OF THE RELEASE OF CALCITONIN-GENE RELATED PEPTIDE FROM PRIMARY AFFERENT FIBERS AT THE SPINAL LEVEL. Besson, J.M., Bourgoin, S., Carayon, A., Cesselin, F., Hamon, M., Lombard, M.C. and Pohl, M. INSERM, U. 161 and EPHE, 2 rue d'Alésia, 75014 Paris and INSERM, U. 288, 91 bd de l'Hôpital 75013 Paris, France.

Calcitonin-gene related peptide (CGRP) is particularly concentrated in thin primary afferent fibers and in the superficial layers of the dorsal horn and might participate in the transmission of nociceptive messages. We have examined the fate of spinal CGRP following dorsal rhizotomy in adult rats, and the possible modulation of spinal CGRP release by opioids. Ten days after the unilateral rhizotomy (from C4 to T2), a dramatic reduction of CGRP levels was found ipsilaterally in the dorsal (-89%) but not in the ventral zone of the cervical enlargement (CE). In contrast, no alteration of CGRP levels was noted controlaterally. In vitro superfusion of CE slices allowed the measurement of the spontaneous and K^+ (30mM)-evoked release of CGRP. Dorsal rhizotomy reduced CGRP outflow to undetectable levels, indicating that the peptide originates exclusively from primary afferent fibers. A marked reduction of the K^+-evoked CGRP overflow was found in the presence of 3 μM DTLET or 10 μM DAGO, each effect being antagonized by 50 μM ICI-154129 or 3 μM naloxone respectively. These results suggest that δ and μ opioids exert a presynaptic control of CGRP release from primary afferent fibers.

162.9

OPIOID MODULATING PEPTIDE INDUCES QUASI-ABSTINENCE SYNDROME IN RAT. D.H. Malin, J.R. Lake*, P.E. Prasco*, V. Balasubramanyam*, W.H. Potter*, M.K. Wiggins*, and J.E. Leyva*. Univ. of Houston-Clear Lake, Houston, TX 77058.

Malin et al (Life Sci. 41:377, 1987) found that CSF from morphine dependent rats contained a peptide that precipitated opiate abstinence syndrome when infused icv. Yang et al (PNAS 82:7757, 1985) have isolated an endogenous peptide ("opioid modulating" or "morphine modulating" or "FMRF-like peptide") with strong anti-opiate effects. In the present study, icv infusion of this peptide into normal rats induced a strong abstinence-like syndrome.

Eighteen rats were divided into three groups: A. received opioid modulating octapeptide (2 μg/min. for 7.5 min. in saline with 0.002 ug/μl bestatin); B. received the above plus 3.5 mg/kg morphine sulfate s.c.; C. received the bestatin vehicle alone. Rats were observed for a standard checklist of opiate abstinence signs for 30 min. under "blind" conditions with the following results:

OVERALL ABSTINENCE SIGNS M ± SEM		
OCTAPEPTIDE ICV	OCTAPEPTIDE ICV + MORPHINE SC	VEHICLE ICV
67.8 ± 12.3 **	3.8 ± 1.7	16.2 ± 7.0

The first group was different, $p<.01$, from both others (Tukey's HSD). The behavioral syndrome resembled opiate abstinence in that it was readily reversed by morphine and included shakes, writhes, teeth chatter, chewing, scratching, ataxia, ptosis, diarrhea, tremor, yawning, ejaculation and jumping.

162.10

SINGLE POTASSIUM CHANNELS OPENED BY OPIOIDS IN RAT CENTRAL NEURONS. M. Miyake,* M.J. Christie, and R.A. North, Vollum Institute, Oregon Health Sciences University, Portland, OR 97201

Using the cell-attached patch clamp technique, we have studied single K channels in neurons freshly dissociated from locus coeruleus of postnatal rats. The patch electrode contained (mM) 150 K gluconate, 2.5 $CaCl_2$, 1.3 $MgCl_2$, 3 TEA-Cl and 5 Mops-KOH and the μ-opioid agonist Tyr-D-Ala-Gly-MePhe-Gly-ol (DAGO, 0.1 - 2 μM). Inward currents flowed through channels of unit conductance about 80 pS in the potential range from -50 to -120 mV, and usually occurred in bursts. This activity was eliminated by 1 μM naloxone in the electrode, and was not observed by agonist application outside the electrode. During the bursting periods (10 - 200 s), the open times of the channel were well fitted by a single exponential distribution; the closed times were fitted by the sum of two exponential functions. The mean open time was strongly dependent on the agonist concentration (τ = 2.3 ms at 0.1 μM DAGO, and 10.5 ms at 0.3 μM DAGO). By contrast, there was no obvious correlation between the DAGO concentrations and the close times (τ = 1.2 ms and 15-40 ms). Channels having very similar properties could also be activated by α_2 receptor agonists and somatostatin. The results indicate the μ-opioid, α_2-adrenaline and somatostatin receptors couple to the same potassium channels without a diffusible cytoplasmic messenger.

162.11

OPIOID PHARMACOLOGY OF THE CAPSAICIN-EVOKED RELEASE OF SUBSTANCE P (SP) FROM THE RAT SPINAL CORD IN VIVO. L.D. Aimone and T.L. Yaksh, Dept. of Neurosurgical Research, Mayo Clinic, Rochester, MN 55905.

Capsaicin has been shown to evoke the release of SP from small primary afferents. This study examined the pharmacology of opioid receptor systems which could modulate this capsaicin-evoked release. In chloralose-urethane anesthetized rats, an intrathecal catheter (PE-10) was inserted to the level of the sacral spinal cord, while a second catheter was placed at the level of the atlanto-occipital membrane to allow the push-pull perfusion (100 μl/min) of artificial cerebrospinal fluid. The addition of capsaicin (200 μM) to the perfusate raised the SP-like immunoreactivity (SP-LI) from resting levels which were below assay sensitivity (<15 pg/ml) to 43±10 pg/ml. The identity of released SP-LI was verified using reverse phase chromatography. Opioid receptor agonists were added to the capsaicin perfusate and their ability to inhibit the capsaicin-evoked release of SP was assessed. Morphine (10-100 μM), DAGO (1-100 μM), DPLPE (10-100 μM), but not U50488H (100 μM) produced a dose-dependent reduction in the capsaicin-evoked release of SP. Pretreatment with naloxone (1 mg/kg IP) antagonized the opioid-produced inhibition of capsaicin-evoked SP release. These data indicate that the release of SP from primary afferent fibers can be modulated by μ or δ but not κ opioid receptors.

PERIAQUEDUCTAL LEVELS OF CHOLECYSTOKININ OCTAPEPTIDE INCREASE AFTER ACUTE BUT NOT CHRONIC MORPHINE. M. Rattray*1and J. de Belleroche*2(SPON:J.E.Johnson).1:Gene Neuroscience Unit,NIDA, Addiction Research Center, Baltimore MD21224 & 2:Dept. Biochemistry., Charing Cross & Westminster Medical School, London W6 8RF, U.K.

The periaqueductal grey (PAG), a primary locus for opiate modulation of pain thresholds contains densities of opioid receptors and moderate concentrations of cholecystokinin octapeptide (CCK). PAG pools of CCK may be involved in the modulation of pain thresholds since locally applied CCK produces antinociception and CCK has been shown to antagonise opiate-dependent antinociception. We have previously studied opiate - CCK interactions in PAG slices and shown that CCK release from PAG slices *in vitro* can be modulated by morphine: after initial inhibition of CCK release, morphine enhances K+-evoked CCK release in a time-dependent manner.

Here we report that opiates can modulate CCK levels *in vivo*. Groups of adult male CFY rats were injected with morphine (10 mg/kg, i.p.) 5 min, 30 min and 1 hour before sacrifice. PAG CCK levels as measured by RIA. increased to 182% of controls one hour after injection (control levels were 0.98 ± 0.18 ng CCK/mg protein, n = 5). Similar significant increases in PAG CCK levels occured 1 hour - 3 hours post injection in weanling female LH rats. However no such rises were observed in groups of rats treated chronically with morphine (daily injection of 10 mg/kg morphine-HCl, i.p. for 4 days).

The increases observed after acute injection agree with the findings of others in hypothalamus and spinal cord, although unlike those studies, we observed no increases in CCK levels after chronic treatment. In view of our *in vitro* data, it is likely that morphine increases PAG CCK levels by modulating CCK synthesis rather than release.

OPIOIDS CAN ENHANCE AND INHIBIT THE ELECTRICALLY EVOKED RELEASE OF METHIONINE-ENKEPHALIN FROM THE ENTERIC NERVOUS SYSTEM. H. Xu*, I. Smolens* and A.R. Gintzler. Depts. of Biochemistry, SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203.

This laboratory has previously demonstrated that evoked release of myenteric met-enkephalin is negatively modulated by morphine (Glass, et.al., J.P.E.T. 239:742-747, 1986). Recent experiments suggest that mu, delta and kappa opiate receptors, all of which are present in the myenteric plexus can modulate the electrically evoked release (40 Hz) of met-enkephalin. The direction of this modulation is not fixed but is bimodal. Both an inhibition and an enhancement of evoked release has been observed depending upon the concentration of opioid agonist that is utilized. Low concentrations enhance release while higher concentrations substantially attenuate release. The bimodal regulation of evoked enkephalin release could suggest that an alteration in the balance of these two opposing responses resulting from long term opiate exposure could be relevant to some of the physiological sequelae of tolerance and dependence that has been observed in this preparation. Specifically, it could provide a basis for the observation that the presence of morphine is a prerequisite for the manifestation of evoked enkephalin release from 15 min withdrawn tolerant/dependent preparations (Gintzler, et al., PNAS 84:2537-2539, 1987).

162.14

INCREASED CONTENT OF IMMUNOREACTIVE LEU-ENKEPHALIN AND ALTERATION OF δ OPIOID RECEPTOR IN HEARTS OF SPONTANEOUSLY HYPERTENSIVE RATS. M. Dumont and S. Lemaire. Dept. of Pharmacology, University of Ottawa, Ottawa, Ontario, Canada K1H 8M5.

The levels of immunoreactive Leu-Enkephalin (ir-Leu-Enk) and binding characteristics of δ opioid receptors were investigated in hearts of adult normotensive (WKY) and spontaneously hypertensive (SHR) rats. The levels of ir-Leu-Enk in acid extracts of hearts of adult SHR rats were significantly higher (2.67 pmol/g protein) than those in hearts of WKY rats (1.5 pmol/g protein). Reverse phase high performance liquid chromatography of heart extracts indicated that the increase in ir-Leu-Enk seen in whole heart extracts of SHR rats is an authentic increase in Leu-Enk since it coelutes with synthetic Leu-Enk. Binding characteristics of the δ opioid receptors were obtained at 37°C for 30 min with [^{3}H]-[D-Pen^2,D-Pen^5]-Enk. Saturation studies indicate the presence of two distincts receptors in membrane preparations of hearts of WKY rats with K_D of 1.2 and 22.8 nM and B_{max} of 3.5 and 15 pmol/g protein, respectively. However, the binding with the heart membrane preparation of SHR rats displayed only one high affinity δ receptor with a K_D of 1.5 nM and B_{max} of 6.5 pmol/g protein. These results indicate that the hypertensive state in SHR rats is accompanied by a rise in heart content of Leu-Enk and a down regulation of the low affinity δ opioid receptor. Supported by HSFO.

OPIOID PEPTIDE REGULATION OF NEURONS IN THE BED NUCLEUS OF THE STRIA TERMINALIS. **M. Dalsass and A. Siegel. Neurology, V.A. Medical Center, E. Orange, N.J. 07019, and Dept. of Neurosciences, UMDNJ, Newark, N.J. 07103.**

Recently, we described the electrophysiological properties of neurons in the bed n. of the stria terminalis (BNST) [Brain Res., 425:346, 1987]. Since the BNST contains numerous enkephalinergic axon terminals and cell bodies, we sought to examine the effects of iontophoretic application of opioid peptides upon these neurons.

Rats were anesthetized with chloral hydrate [400mg/kg]. A multibarrel pipette, designed for single unit recording [5-20 Mohms] and drug ejection, was utilized to sample neurons from the BNST in response to single or combined delivery [2-30 nA] of naloxone hydrochloride [50 mM] and D-ALA^2-MET^5-enkephalinamide (DAME) [10 mM]. Of 29 neurons examined to date, 20 responded with increased firing rates (>40%) following the application of DAME but were largely unaffected by naloxone. However, when both DAME and naloxone were delivered concurrently, the excitatory effects produced by DAME were significantly attenuated within 30 sec. of drug administration.

These results demonstrate that BNST neurons show a predominantly excitatory response to the application of opioid peptides. The mechanisms for this phenomenon are currently under examination.

DERMORPHIN ANALOG TYR-D-ARG^2-PHE-SAR: OPIOID ANALGESIA WITHOUT RESPIRATORY DEPRESSION. **P. Paakkari*, I. Paakkari* and G. Feuerstein. Department of Neurology, USUHS, Bethesda, MD 20814.**

Tyr-D-Arg^2-Phe-Sar^4 (TAPS), a N-terminal tetrapeptide analog of the specific μ-opioid agonist dermorphin, exceeds in potency the parent heptapeptide Tyr-D-Ala-Phe-Gly-Tyr-Pro-Ser-NH$_2$ (De Castiglione, R. and Rossi, A.C., Peptides 6,suppl.3:117,1985). In the present work the analgesic and respiratory effects of TAPS were studied in conscious, unrestrained male Sprague-Dawley rats (300±40 g). Analgesia was evaluated by tail-flick method, and respiration was recorded by a noninvasive Oxymax 85 system (Columbus Instrument).

TAPS 0.9 and 3 μmol/kg i.v. induced analgesia which was 40 % and 100 % of the maximal possible effect (MPE) for about 60 min. The effect of i.c.v. administered TAPS was longer lasting: analgesia induced by 1 nmol/kg i.c.v. was maximal for 90 min and >80 % MPE for 180 min. The rats were also cataleptic for about 60 min. The dose of 3 μmol/kg i.v. increased ventilatory minute volume by 30 % mainly due to increase in respiration rate (RR). I.c.v. injection of 1 nmol/kg decreased tidal volume by 25 %, but since RR increased simultaneously by 30%, the net effect was a slight increase (10%) in minute volume. According to these results the opioid peptide TAPS causes no respiratory depression at doses which induce complete, long lasting analgesia and catalepsy.

EFFECTS OF EXERCISE ON PLASMA ß-ENDORPHIN-LIKE IMMUNOREACTIVITY IN MEN AND WOMEN. D. Treat* and C. Cahill. Univ. of MD Sch. of Nsg. Baltimore, MD 21218

Stressors activate the hypothalamic/pituitary/adrenal axis, resulting in the secretion of ß-Endorphin-like immunoreactivity into the plasma. The study of stress in humans has primarily been limited to those naturally occurring events presumed to be stressful. This approach limits the researchers ability to describe the entire phenomenon from beginning to end. Exercise is a physical stressor which can be quantified through control of length of exercise and maximal heart rate achieved. The purpose of this study was to determine the effect of the standardized stressor of exercise on ß-END-1-i in men and women. 40 men and women were asked to exercise on an Ergometer exercise bicycle for twenty minutes at a rate sufficient to increase their heart rate to 75% of the calculated maximal level. Blood samples were collected before exercise began and immediately after the session. An indwelling catheter was inserted into a vein thirty minutes prior to the beginning of exercise. Plasma samples will be extracted and ß-END-1-i measured by radio-immunoassay. Our previous studies suggest that ß-END-1-i increases following the physical stress of exercise.

NEONATAL PLASMA LEVELS OF ß-ENDORPHIN IN PREMATURE AND TERM INFANTS WHO DEVELOP APNEA M. P. Leuschen, L. S. Nelson*, D.L. Bolam*, L.D. Willett*, R. M. Nelson Jr.*, Division of Newborn Medicine, University of Nebraska Medical Center Omaha, NE 68105.

Plasma ß-endorphin (ß-E) levels were measured during the immediate post-natal period in 30 term and 62 premature (33-38 wk) infants. At discharge, the Medical Director of the Center for Breathing Disorders (blinded to the ß-E levels at birth, reviewed the charts of all infants and determined whether an infant had experienced a documented apneic episode (instrument documented cessation of breathing for at least 20 seconds). In term infants, neither gender nor the presence of apnea were significant variables in predicting changes in ß-E levels (P=.77). In premature infants, both gender and apnea were significant for prediciting ß-E levels (P=.03). Premature males who did not experience apnea while hospitalized had ß-Es of 102.1 pg/ml ± 65.2 SD at birth; males who later had apneic episodes had ß-E levels of 71.4 pg/ml ± 50.5 SD. Premature male infants without apnea had significantly higher ß-E levels than similar females (64.4 pg/ml ±36.7 SD, P=.01). Premature male infants who developed apnea did not have significantly different ß-E levels than either premature females with apnea or any term NICU infant group; their levels were significantly higher than levels reported for term well babies. The results support the concept that ß-E may modulate the perinatal stress response but developmental status, particularly in respiratory control, as well as gender, may affect that modulation.

162.19

PET QUANTIFICATION OF ALTERED OPIATE RECEPTOR BINDING OF C-11 DIPRENORPHINE AND C-11 CARFENTANIL IN EPILEPSY. J.J. Frost, H.S. Mayberg, B. Sadzot, R. Fisher, R.F. Dannals, A.A. Wilson, J. Lever, H.T. Ravert, H.N. Wagner, Jr. The Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Increases in mu opiate receptors in temporal lobe epilepsy have been demonstrated previously using C-11 carfentanil (CFN) and PET (Frost, et al. Ann Neurol 23:231-237, 1988).

C-11 diprenorphine (DPN) labels opiate receptor subtypes in addition to mu receptors. Six patients with unilateral temporal lobe epilepsy were studied using CFN, DPN and FDG to measure cerebral glucose utilization. DPN demonstrated increases in the temporal cortex ipsilateral to the seizure focus and in a wider distribution as compared to CFN. Two patients showed ipsilateral increases in CFN and DPN binding and hypometabolism in the contralateral temporal lobe.

DPN demonstrates more widespread abnormalities in temporal lobe epilepsy probably due to elevation in kappa opiate receptors in the temporal neocortex. Quantification of opiate receptors may aid in the localization of seizure foci and supplement metabolic imaging.

NALOXONE EFFECTS ON IDENTIFIED ENKEPHALINERGIC AND NON-ENKEPHALINERGIC NEURONS OF HELIX ASPERSA. R.Gutiérrez (SPON: A.Fernández-Guardiola) Lab. Neurophysiology, Instituto Mexicano de Psiquiatría. Calzada México-Xochimilco 101 CP 14370 México, D.F.

Evidences from several methodological approaches point out that it is unlikely that naloxone at high doses exerts a pure antagonistic opiate activity. There is strong experimental work dealing with its actions on several neurotransmitter systems other than the opiate one. Moreover, actions upon the Na-K pump and calcium fluxes have been documented. In order to further analyze whether the excitatory actions of naloxone seen in epileptogenesis studies (Fernández-Guardiola et al., 1988*) are due to an opioid-mediated mechanism or a non-specific action on membrane properties, experiments were conducted on identified neurons of the snail Helix aspersa. Intracellular recordings were carried out in the presence and absence of different concentrations of naloxone hydrochloride. It was found that naloxone at low concentrations† is able to produce membrane polarization changes in both directions, being depolarization the more frequent, with a concomitant increase in R_{input} and reduction of τ. Naloxone effects were not always reversible by either opiate agonists or wash out. A possible action of naloxone upon Ca^{++} currents is stressed since the afterhyperpolarization and the pacemaker potential, primarily due to $I_{K[Ca]}$ are affected.

CATECHOLAMINES II

163.1

NEW INSIGHTS INTO THE CATECHOLAMINERGIC SYSTEMS OF REPTILES. W.J.A.J.Smeets[1] and H.W.M.Steinbusch[2], Department of Anatomy[1] and Department of Pharmacology[2], Vrije Universiteit, 1007 MC Amsterdam, The Netherlands.

The catecholaminergic systems in the lizard Gekko gecko have been studied with specific and sensitive antibodies against dopamine (DA), noradrenaline (NA), TH, DBH, and PNMT. Our results demonstrate that: (1) the periventricular organ (PVO) contains both DA and NA CSF-contacting cells; (2) the cells are immunonegative for TH and DBH which indicates that they accumulate rather than produce these amines; (3) at several places, particularly in the olfactory bulb, the hypothalamus and the pretectal region, only TH immunoreactive neurons were observed suggesting that these neurons contain DOPA; (4) the lateral reticular formation at obex levels, contains adrenergic and dopaminergic cells, whereas the nucleus of the solitary tract contains DA and NA immunoreactive cells; (5) antibodies against TH demonstrate primarily DA fibers and terminals, whereas the distribution of DBH immunoreactive fibers corresponds to that shown by antibodies against NA. In conclusion: combined studies with antibodies against the various catecholamines and their synthetizing enzymes provide detailed information on the distribution of the major catecholaminergic systems. Some indication is found for a, as yet, unknown DOPA-system.

163.2

SPECIES VARIATION IN EXPRESSION OF AROMATIC L-AMINO ACID DECARBOXYLASE IN CEREBELLUM, OLFACTORY BULB AND ADRENAL MEDULLA. J. Lugo*, C. Abate, T. Joh, and H. Baker. Lab. Mol. Neurobiology, Cornell Univ. Med. Coll. White Plains, NY 10605.

The enzyme aromatic l-amino acid decarboxylase (AADC) is expressed in monoamine neurons as well as a number of other cell types in brain and periphery. Recently, species differences were found among rat, mouse and hamster in both the distribution and amount of AADC-immunostaining. The present studies confirmed and quantitated the differences in AADC expression. In hamster, but not mouse or rat, AADC was co-localized in some GABA neurons in cerebellum. Western blot analysis and AADC activity measurements confirmed that the immunogen was AADC. The AADC cells in cerebellum did not exhibit immunostaining for the other monoamine markers, tyrosine hydroxylase (TH) and serotonin. In addition, the zona fasciculata of the male hamster adrenal cortex exhibited anomalous AADC staining and activity. AADC and TH staining in adrenal medulla did not differ from that in rat or mouse. Lastly, AADC-immunostaining and activity, while robust in rat and hamster, was only weakly detected in mouse olfactory bulb. These data demonstrate species and tissue specific expression of AADC. Supported by #NS23103 & #MH42626.

163.3

DOPAMINE NEURONS IN THE MIDBRAIN PERIAQUEDUCTAL GREY. B.R. Frydel*, M.T. Shipley and M.M. Behbehani. Univ. of Cincinnati Med. School, Cincinnati, OH 45267.(SPON:S.-H. Tsai.)

One of the most well characterized subpopulations of neurons in the midbrain periaqueductal grey (PAG) is the dorsal raphe nucleus (DR). The DR contains an abundance of serotonergic (5HT) neurons that perferentially innervate the forebrain. The existence of dopamine containing neurons in the dorsal raphe has been noted, but comparatively little attention has been paid to these cells.

Using antibodies specific for TH, DBH, PNMT and 5HT, we have confirmed the probable DA identity of neurons in DR and have observed that these neurons comprise a surprisingly large proportion of the neurons in DR. Estimates of the numbers of 5HT and DA neurons and their sizes will be presented. Plots of 5HT and DA neurons stained in serial, adjacent series of sections suggest that the two populations of cells are largely separate. One subpopulation of DA neurons is localized immediately adjacent to the ventral part of the aqueduct where there are very few 5HT cells. Double label ICC studies are needed to determine if some neurons contain both 5HT and DA.

The extrinsic projections of DA neurons in DR are unknown. The dendrites and possibly some axon collaterals of DR-DA neurons arborize in the ventral part of PAG where there are neurotensingeric (NT) neurons and dense plexis of NT terminals. There is evidence that NT modulates DA release in other parts of the CNS. We have shown that NT activates neurons in PAG and causes analgesia. NT-induced central anagesia is not reversed by naloxone and thus appears to be a non-opiate analgesic mechanism. The present observations suggest the DR-DA neurons could be involved in the modulation of NT anti-nociceptive circuitry in PAG. (Supported by NIH NS 20643, 23348 and 24698.)

163.4

PROPERTIES OF AM ADRENERGIC NETWORK IN THE RAT PERIAQUEDUCTAL GRAY (PAG). S.D. Chandler*, M.M. Behbehani and M.T.Shipley (SPON T.I. Mandybur). Dept. of Physiology and Biophysics and Dept. of Anatomy and cell biology. U. Cincinnati College of Med. Cincinnati OH 45267-0576.

Using anatomical and physiological techniques we have examined the characteristics of an adrenergic network within the PAG. In the anatomical studies the location of cell bodies, fibers and terminal that were immunoreactive to specific antibody to PNMT were mapped. The results indicated that a circumscribed forms of terminals and fibers were located in the ventral and the ventrolateral parts of mid rostral PAG. There was only sparse labeling in the dorsal half of PAG. The density of fibers decreased at the rostral levels of the PAG.

Physiological experiments showed that the PAG neurons are responsive to both epinephrine (EP) and norepinephrine(NE). The response to NE was mixed; 46% (29/71) of the cells were excited, 38% (27/71) were inhibited and the remaining cells did not respond. The excitatory effect was long lasting and in many instances the baseline firing rate remained elevated for 2 to 20 minutes. The inhibitory effect had a shorter duration than the excitatory response. Both effects could be partially reversed by phentolamine and prazosin. Both types of responses were observed in all regions of the PAG. However the majority (53%) of neurons in the rostral PAG responded by excitation. It is concluded that the PAG contains an adrenergic network that is anatomically concentrated in its caudal ventral and ventrolateral regions. However, neurons in all regions of the PAG are responsive to EP and NE suggesting that an adrenergic network may be involved in the PAG local circuitry. CATECHOLAMINERGIC PROJECTION FROM THE MEDULLA TO THE MIDBRAIN CENTRAL GRAY MATTER. H. Herbert and C.B. Saper, Dept. of Animal Physiol., Univ. of Tübingen, 7400 Tubingen, FRG and Dept. of Pharm. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637

The periaqueductal gray matter (PAG) in the rat contains large numbers of catecholaminergic fibers. We traced the origin of this innervation using combined neuronal tracers and immunohistochemistry for tyrosine hydroxylase, dopamine β-hydroxylase and phenyletholamine N-methyltransferase.

After injections of fast blue or fluorogold into the ventrolateral PAG, we found retrogradely labeled noradrenergic neurons in the A1 and A2 groups, and adrenergic neurons in the C1-C3 groups. After injections of PHA-L into these cell groups, a double immunofluorescence method was used to identify anterogradely labeled (PHA-L immunoreactive) fibers that also stained for tyrosine hydroxylase. Individual varicose dual-labeled fibers were found throughout the PAG. These results indicate that the PAG is a major site of catecholaminergic innervation from medullary noradrenergic and adrenergic cell groups.

ARCHITECTURE OF THE PERICOERULIAR REGION IN THE RAT. Li-bang Fu*[1], M.T. Shipley[1], G. Aston-Jones[2], C. Chiang[2] and V. Pierjbone[2] [1]Univ. of Cinti College of Med., Cinti, OH 45267,[2]New York Univ., New York, NY 10003.(SPON:G.D.Adamek)

In the rat noradrenergic neurons (NE) in LC project throughout the neuraxis and provide all NE innervation of the forebrain. Our recent studies indicate that the major afferents to LC derive from only two medullary nuclei, nucleus paragigantocellularis and the region of nucleus prepositus hypoglossie. Many previously reported afferents to LC do not impinge on this nucleus but rather in adjacent pontine regions. New physiological data indicate that some inputs adjacent to LC do not directly influence LC neurons. In contrast to the wealth of anatomical observations on LC there is surprisingly little information on the architecture of the regions immediately adjacent to this nucleus.

Immunocytochemistry, Nissl and myelin staining were used to investigate the architecture of the pericoeruleus region in the rat. There are several neuronal groups in close association with LC. Rostrally, dense Nissl stained neurons of the lateral dorsal tegmental nucleus are adjacent to LC; a second population of densely stained cells, tentatively identified as Barrington's nucleus nestle along the ventromedial border of LC. At most rostrocaudal levels there are two or three additional populations of pale, small-to-medium size neurons adjacent to LC. Dendritics of LC neurons preferentially extend medially and ventrally among these pericoerulear neurons.

Afferent terminals in the region medial to the cellular core of LC could contact LC dendrites, peri-LC neurons or both. Experiments are needed to determine if there are anatomical and functional interactions among these inputs, LC and peri-LC neurons.

N-METHYLADRENALINE IN RAT RETINA, BRAIN AND SPINAL CORD. C.J. Plummer,* I.C. Kilpatrick,* M.W. Jones,* B. Goodwin* and O.T. Phillipson.* (SPON. R. Bruce Holman) Dept. of Anatomy, University of Bristol, BS8 1TD. U.K.

Phenylethanolamine N-methyltransferase (PNMT) is found in high concentratons in localised regions of both retina and brain. However, only low concentrations of adrenaline are detectable. In vitro, PNMT may further methylate adrenaline to form N-methyladrenaline (MA), (Axelrod, 1966 Pharm. Rev. 18:95). We now report the preliminary identification of MA in the central nervous system.

Brain regions and retinae were prepared from adult Wistar-derived rats and analysed by HPLC (Kilpatrick et al., 1986 J. Neurochem. 46:1865). In retina, as well as the expected catechol and indole derivatives, an additional peak was encountered. Its chromatographic behaviour was studied over a wide range of mobile phase pH and sodium-1-octanesulphonic acid concentrations. In each condition the unknown peak and MA standard coeluted precisely. Oxidative voltammetric spectra of the endogenous peak and standard MA were similar. Alumina adsorption confirmed that the unknown contained a catechol moiety since reruns of acidified alumina eluate spiked with MA again showed perfect coelution.

PNMT-positive brain areas were assayed for MA content. Thalamus, hypothalamus, pontine central grey, medulla (including C1 and C2/3) and T1/T2 spinal cord all displayed peaks which coeluted precisely with standard MA. Conversely, samples of rat adrenal gland were found to contain barely detectable quantities of MA.

Thus, MA is reported in the CNS for the first time. Its production and pharmacology are now being studied.

163.8

PHENYLETHANOLAMINE N-METHYLTRANSFERASE (PNMT)-IMMUNOREACTIVE (IR) TERMINALS SYNAPSE ON ADRENAL PREGANGLIONIC NEURONS IN THE RAT SPINAL CORD. H. Bernstein-Goral & M.C. Bohn. Dept. of Neurobiology and Behavior, State University of New York, Stony Brook, 11794 and Dept. of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, New York 14642.

Adrenergic neurons in the C1 region in the ventrolateral medulla oblongata project to the intermediolateral cell column (IML) of thoracic spinal cord. The ultrastructure of adrenergic axons and synaptic boutons in the IML of mid-thoracic spinal cord was studied using immunocytochemistry for PNMT, the epinephrine-synthesizing enzyme. PNMT-IR terminals form synaptic contacts with dendritic processes at all postnatal ages examined, including 7, 9, 24, 30, 60, and 90 days. In addition, axo-somatic synaptic contacts were observed in young rats, but rarely observed in adult rats.

To determine whether adrenergic axons synapse with preganglionic neurons which project to the adrenal medulla, adrenal preganglionic neurons (APGN) in IML were retrogradely labeled with HRP. At postnatal ages 7, 9, 24 and 30 days, PNMT-IR boutons were observed to form symmetrical axo-somatic and axo-dendritic synaptic contacts with HRP labeled APGN, as well as with other unidentified neurons in IML. This synaptic association provides an anatomical substrate for central adrenergic regulation of adrenal medullary development and function.

163.9

TOPOGRAPHY OF RAT BRAINSTEM NEURONS IMMUNOLABELED WITH ANTISERA RAISED AGAINST PREDICTED SYNTHETIC EPITOPES OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE. T.J. Gorcs*, A. Csiffáry* and é. Mezey*,*. (SPON: A. R. Light). 1st Dept. of Anat., Semmelweis Univ.Med.School, Budapest, Hungary and *LCB-NIMH, Bethesda, MD 20892, USA.

The nucleotide and deduced amino acid sequence of phenylethanolamine N-methyltransferase (PNMT) catalyzing the synthesis of epinephrine from norepinephrine shares significant homology with the sequence of tyrosine hydroxylase (TH). Using combined antigenic site prediction analyses 4, probably continuous epitopes of PNMT were determined (PNMT-SP-1 to 4) without major sequence homology to TH. These peptides were synthesized by a solid phase method and antisera (AS) were raised in rabbits. Neurons resembling adrenaline- or PNMT-immunostained neurons were immunolabeled by AS-PNMT-SP-2 and 4 in the lower brainstem in rats without colchicine treatment. In contrast to these, AS-PNMT-SP-3 revealed only dense neuronal network but no neuronal perikarya. The specificity of AS-PNMT-SP-2 to 4 for PNMT was proved both with appropriate ELISA and immunohistochemical methods.Epitope prediction analysis combined with sequence homology search provides a useful tool to raise specific antisera to proteins of known or deduced amino acid sequences.

163.10

EVIDENCE FOR THE PRESENCE OF PNMT-CONTAINING CELL BODIES IN HYPOTHALAMUS. M.I. Masana,* I.N. Mefford* (SPON: P. Newhouse). Lab. Clin. Science, NIMH, Bethesda, MD 20892.

The presence of the epinephrine (E)-converting enzyme phenylethanolamine-N-methyltransferase (PNMT) in hypothalamic cell bodies is still a matter of controversy. In the present study, 2 µg of kainic acid (KA) (which selectively destroys local neurons) was injected into the lateral hypothalamus, where the presence of PNMT-containing neurons has been reported (Ruggiero et al., J. Comparat. Neurol. 239: 127, 1985). Male Sprague-Dawley rats (200-300 g) were killed 1, 2, 4, 8, and 12 days post-injection, the PNMT activity determined as described by Trocewicz et al. (J. Chromat. 227:407, 1982) and the catecholamines measured by HPLC with electrochemical detection. E content was reduced at 1 and 2 days post-injection (control 35.1 ± 2.5 ng/g, n = 10, KA lesioned 19.4 ± 2.0 ng/g, n = 4, contralateral control 18.2 ± 2.3 ng/g, n = 4, $p < 0.05$, 2 days) probably due to the extensive releasing effect of KA and the stress provoked by the treatment. At day 1 post-injection, there was a significant decrease in PNMT activity (KA lesioned 48.4 ± 11.9% of the contralateral, n = 4, $p < 0.05$). The decrease was maintained over the 12 days of the study (KA lesioned 81.9 ± 10.5%, n = 7, 2 days; 65.6 ± 9.8%, n = 9, 4 days; 68.8 ± 23.6%, n = 4, 8 days; 71.4 ± 15.4%, n = 4, 12 days). These results suggest that there are PNMT-containing cells in the hypothalamus, although, as the KA treatment is nonspecific, it is not possible to elucidate which type of neurons or other cells, such as astrocytes or ependymal cells, are involved.

163.11

PROJECTIONS FROM THE VENTROMEDIAL MEDULLARY RETICULAR FORMATION TO THE ROSTRAL A5 GROUP. J.F. Miller, M.R. Monsen, and H.K. Proudfit. Dept. of Pharmacology, Univ. of Illinois at Chicago, Box 6998, Chicago, IL 60680.

The afferent brainstem connections of the A5 noradrenergic cells of the rostral ventrolateral pons were investigated by retrograde tracing techniques. Adult female Sprague-Dawley rats received a unilateral iontophoretic injection of the retrograde tracer Fluoro-Gold into the ventrolateral pontine tegmentum. Survival time was 5-7 days. The brainstem was sectioned at 30-40 um and every other coronal section was thaw-mounted, cleared, and examined using trans- and epifluorescence microscopy. Alternate sections through the injection site were processed for dopamine-beta-hydroxylase (DBH) immunocytochemistry by the indirect fluorescent method of Coons. In those rats in which the tracer injection encompassed DBH-immunoreactive neurons, retrogradely-labelled neurons were observed bilaterally within the nucleus reticularis paragigantocellularis lateralis throughout most of its rostral-caudal extent. In addition, smaller numbers of retrogradely-labelled neurons were observed within the ipsilateral nucleus raphe magnus and adjacent nucleus reticularis gigantocellularis, pars alpha. Labelling in these medullary areas was minimal with tracer deposits situated lateral to the A5 group. These results suggest that the ventromedial medulla may exert an important regulatory control on the A5 cell group. (supported by USPHS Grant DA 03980)

163.12

LACK OF COORDINATE EXPRESSION OF TYROSINE HYDROXYLASE (TH) AND DOPAMINE-β-HYDROXYLASE (DBH) IMMUNOREACTIVITIES IN ADULT ENTERIC NEURONS. G. Baetge* and M.D. Gershon (SPON: H. D. Coulter). Dept. Anat. & Cell Biol., Columbia Univ., New York, NY 10032.

Transient catecholaminergic cells appear in the mesenchyme of the developing bowel; nevertheless, with few exceptions, such as the avian gizzard and the guinea pig proximal colon, intrinsic catecholamine neurons have not been reported to be present in the gut. On the other hand, reports of the immunocytochemical detection of catecholamine biosynthetic enzymes in some enteric neurons have appeared. The present study was done to determine whether TH or DBH immunoreactivities are valid markers of noradrenergic neurons in the bowel. Antibodies to TH or DBH raised in different species were used for the simultaneous visualization of each marker in tissue whole mounts or frozen sections. TH-immunoreactive (TH+) neurons were found in adult mouse, rat, guinea pig and rabbit colon as well as in the adult mouse stomach. These neurons measured 20-40 μm in diameter, occurred singly or in pairs, and were present in only a subset of myenteric ganglia. In guinea pig all TH+ neurons were also DBH+. In contrast, in the rat colon there were many more DBH+ than TH+ neurons, because many neurons were found that were DBH+, but TH-. Most of these DBH+/TH- neurons were surrounded by DBH+/TH+ sympathetic nerve fibers. The rat colon also contained a third category of TH+/DBH- cell. These observations indicate that neither TH nor DBH immunoreactivities, by themselves, are reliable markers for noradrenergic neurons in the bowel. The expression in adult enteric neurons of some, but not all, of the properties of a noradrenergic neuron may reflect the persistence of these traits in non-catecholaminergic neurons that are derived from a transiently catecholaminergic precursor. Supported by NIH grants #NS 15546 and NS 07062.

Flow Cytometric Detection of Tyrosine Hydroxylase Immunoreactivity on the Surface of Striatal Synaptosomes: Paradoxical Presence on Non-Dopaminergic Synaptosomes. Hiroyuki Hasegawa, Marina E. Wolf and Gregory Kapatos. Lab. of Neurochemistry, Center for Cell Biology, Sinai Research Inst., Detroit, MI 48235.

Complement-dependent lysis studies (Docherty et al., Brain Res., 1985) have suggested that tyrosine hydroxylase (TH) or a related molecule may be present on the surface of dopaminergic (DA) synaptosomes. To investigate this possibility, striatal synaptosomes were incubated with a polyclonal antibody to TH followed by a fluorescein-conjugated secondary antibody. Labeled synaptosomes were detected using a fluorescence-activated cell sorter (FACS). Approximately 10-20% of striatal synaptosomes expressed TH immunoreactivity on their surface. However, when labeled synaptosomes were isolated by FACS and analyzed for TH content using SDS-PAGE and Western blot techniques, they were depleted for TH relative to control synaptosomes. Labeled synaptosomes may represent non-DA terminals which were apposed to DA terminals in the striatum. During synaptosome preparation, pieces of DA terminal membrane with TH attached to their cytoplasmic side may have remained associated with the surface of apposed non-DA terminals. Thus, labeled synaptosomes may be derived from non-DA terminals which were in synaptic contact with DA terminals.

DIFFERENCES BETWEEN ALBINO AND PIGMENTED RAT STRAINS IN TYROSINE HYDROXYLASE, DIHYDROXYPHENYLALANINE DECARBOXYLASE, PHENYLETHANOLAMINE N- METHYLTRANSFERASE AND TRYPTOPHAN HYDROXYLASE ACTIVITIES OF BRAIN REGIONS AND ADRENAL GLANDS. H.S. Park*, T.H. Joh and D.H. Park (SPON: J. Carroll). Lab. Mol. Neurobiology, Cornell Univ. Med. Coll., Burke Reh. Ctr., White Plains, NY 10605.

Strain-dependent differences in the activities of catecholamine biosynthetic enzymes in tissues of rats and mice have been previously reported. However, there has been no study specifically directed at possible variance of the enzyme activities between albino and pigmented animals. In the present study, we selected two strains of rats, albino Sprague-Dawley (SD) rats and Long Evans pigmented (LE) rats and examined activities of tyrosine hydroxylase(TH), dihydroxyphenylalanine decarboxylase(DDC), phenylethanolamine N-methyltransferase (PNMT) and tryptophan hydroxylase (TPH). Brainstem and hypothalamic TH activity was higher in LE rats. Hypothalamic PNMT and brainstem DDC activity was higher in SD rats. All other enzyme levels were equivalent. Adrenal TH, DDC and PNMT activities of LE rats are lower than the respective enzyme activities of SD rats. Our results indicate that there is no obvious relationship between enzyme activities in albino and pigmented rat strains. Difference ,if any, in the enzyme activities of strains seems to depend upon both tissue and brain regions. Supported by NIH grants, MH 24285 and 1PO1MH 42626.

LOCUS COERULEUS LESIONS FACILITATE RECOVERY OF LOCOMOTOR FUNCTION AFTER SENSORIMOTOR CORTEX CONTUSION IN RAT. M.S. Weaver*, M.J. Chen, V.S. Westerberg* and D.M. Feeney (SPON: G.K. Hodge). Depts. of Psychol. and Physiol., UNM, Albuquerque, NM 87131.

Norepinephrine (NE) appears to have an important role in recovery of function after cortical injury (see CRC Critical Reviews in Neurobiol., 3(2):135-197, 1987). This study examined effects of bilateral locus coeruleus (LC) lesions on recovery of beam-walking ability 2 weeks prior to a right sensorimotor cortex contusion in rats. Bilateral injections of 6-hydroxydopamine (6-OHDA; 5 ug in 2.5 ul per side) decreased NE levels bilaterally (HPLC) in frontal and cerebellar cortex as compared to sham controls but did not affect beam-walking. Cortical contusion 2 weeks after LC lesions produced similar decreases in NE (measured 16 days post contusion). Contusion alone also bilaterally reduced NE in frontal and cerebellar cortices and these preliminary results indicate greater reduction in the right than left cerebellar cortex. One day after contusion alone or LC lesions followed by contusion, beam-walking was significantly impaired. Although recovery from the locomotor deficit was significantly faster for rats receiving LC lesions prior to contusion than for those receiving only contusion, perhaps more complete lesions will result in a different effect on recovery. Supported by U.S. Army Contract No. DAMD17-86-C-6144.

THE NEUROTOXIC EFFECTS OF DSP-4 ON NORADRENERGIC NEURONS ARE RESTRICTED TO AXON TERMINALS OF THE LOCUS COERULEUS. J.M. Fritschy and R. Grzanna. Dept. of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Systemic administration of DSP-4, a selective noradrenergic (NA) neurotoxin, produces nearly complete depletion of norepinephrine in neocortex, hippocampus, cerebellum and spinal cord, but only partial depletion in hypothalamus and brainstem. In the present study we have used immunohistochemistry (i) to assess to structural damage produced by DSP-4 on NA neurons and (ii) to determine whether a subset of NA axons is spared in regions only partially depleted of norepinephrine by DSP-4. Two weeks after treatment of rats with 50 mg/kg of DSP-4, brain and spinal cord sections were processed for dopamine-ß-hydroxylase immunohistochemistry using the avidin-biotin method.

The staining results identified terminal axons of NA neurons as the principal site of action of DSP-4; NA cell bodies and preterminal axons were not affected. DSP-4 produced an almost all or none neurotoxic effect on NA axon terminals in different brain regions. Nearly all NA axon terminals were destroyed in neocortex, hippocampus, olfactory bulb, thalamus, tectum, cerebellum, spinal cord dorsal horn. In contrast, NA axons were almost completely unaffected in the basal forebrain, hypothalamus, reticular formation, brainstem motor nuclei, and spinal cord ventral horn. These remaining NA axon terminals differed morphologically from DSP-4 sensitive axons by their thickness, size and spacing of their varicosities and their dense arborizations within terminal fields. The distribution of NA axons ablated by DSP-4 correlates very closely with the distribution of locus coeruleus axons. Conversely, most NA axon terminals unaffected by DSP-4 are likely to originate in non-locus coeruleus NA neurons (A1, A2, A5 and A7 cell groups).

This study provides the first direct evidence that DSP-4 destroys axon terminals of the locus coeruleus, but not those of non-locus coeruleus NA neurons. Based upon this profound differential sensitivity to DSP-4, NA axon terminals may be divided into two populations which differ in their cells of origin, topographic distribution, and morphology. DSP-4 thus offers a unique tool to study the functional organization of non-locus coeruleus NA projections. Support: NIH Grant MH41977.

NORADRENERGIC CELLS OF A5 AND A7 GROUPS BUT NOT THOSE OF THE LOCUS COERULEUS PROJECT TO THE VENTRAL HORN OF THE SPINAL CORD. W. E. Lyons*, J. M. Fritschy, and R. Grzanna. Johns Hopkins University School of Medicine, Baltimore, Md. 21205.

Descending noradrenergic (NA) projections to the rat spinal cord originate in cells of the locus coeruleus (LC), subcoeruleus, and A5 and A7 groups. We have previously shown that the LC distributes axons to the dorsal horn but not to the ventral horn of the spinal cord (Fritschy et al., Brain Res. 437: 176, 1987).

In this study we have taken advantage of our recent observation that systemic treatment of rats with the norepinephrine neurotoxin DSP-4 results in a complete loss of NA axon staining in the dorsal horn and the intermediate zone of the spinal cord with little effect on the staining of NA axon terminals in the ventral horn and the intermediolateral cell column. Following systemic administration of 50 mg/kg of DSP-4, retrograde transport of the fluorescent tracer True Blue (TB) was used in combination with dopamine-β-hydroxylase (DBH) immunohistochemistry to determine the location and number of NA cells that project to the ventral horn and intermediolateral cell column. Fourteen days after drug treatment, rats were injected with a suspension of TB into either thoracic or lumbar segments of the spinal cord. Identical injections were made in untreated rats. Following a two week survival period, 40 micron sections through the brainstem were processed for DBH staining. In DSP-4 treated rats, the number of retrogradely labeled neurons in the LC was reduced to 8% of that observed in control rats while the number of retrogradely labeled cells in the A5 and A7 groups decreased to 50-70% of control. The results reveal a distinct topography of the descending NA projections to the spinal cord: the coeruleo-spinal projection terminates mainly in the dorsal horn and the intermediate zone while cells of the A5 and A7 groups project to somatic motor neurons and preganglionic sympathetic neurons. (Support NIH grant MH 41977).

NEUROTOXIC EFFECTS OF DSP-4 ARE RESTRICTED TO A SUB-POPULATION OF NORADRENERGIC AXONS: STUDIES OF ACUTE AND LONG-TERM EFFECTS. U. Berger*, J.M. Fritschy and R. Grzanna. (Spon: A. Sastre). Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

The noradrenergic (NA) neurotoxin DSP-4 produces severe depletion of norepinephrine in rat cerebral cortex and cerebellum but only a moderate reduction in hypothalamus. Immunohistochemical analysis two weeks after drug treatment revealed that these regional variations are due to the existence of two populations of NA axons with differential sensitivities to DSP-4: NA axons in cortex and cerebellum are completely ablated while those in basal forebrain and hypothalamus are not affected (see Fritschy and Grzanna, this volume). In cortex, massive depletion of norepinephrine occurs within hours after drug administration. The present study was conducted to determine whether this early sign of neurotoxicity also occurs in NA axons of the basal forebrain and hypothalamus or whether this acute effect is restricted to NA axons ablated by DSP-4.

Rats (8/group) were sacrificed 6 hours, 24 hours or 2 weeks after systemic injections of 50 mg/kg DSP-4. Norepinephrine concentrations in cortex, cerebellum, basal forebrain and hypothalamus were determined by HPLC with electrochemical detection. In DSP-4 treated rats, norepinephrine levels in cortex and cerebellum were reduced to 31% and 38% of control at 6 hours, to 22% and 31% at 24 hours and to 5% and 13% at 2 weeks. In contrast, levels in basal forebrain and hypothalamus were reduced to 78% of control at 6 hours, 80% and 70% at 24 hours and 81% and 71% at 2 weeks.

Compared to cortex and cerebellum, levels of norepinephrine in basal forebrain and hypothalamus were affected only to a small degree and did not change between 6 hours and 2 weeks after treatment. We interpret this finding as evidence that DSP-4 does not produce acute depletion of norepinephrine in those NA axons found to be spared by DSP-4 in our immunohistochemical analysis. These data provide further support for the existence of two distinct populations of NA neurons that differ in the pharmacological properties of their axons. (Support NIH grant MH 41977).

GABA-ERGIC INNERVATION OF THE RAT LOCUS COERULEUS M.T. Shipley[1], V. Pieribone[2], G. Aston-Jones[2] and M. Ennis[1] 1. Univ. of Cincinnati Coll. Med., Cincinnati, OH 45267. 2. New York University, New York, NY 10003.

The nucleus locus coeruleus (LC) provides noradrengeric (NE) innervation for the entire neuraxis and is the sole source of NE inputs to the forebrain. Neurons in LC are preferentially activated by novel events and they appear to be discharge concomitant with sympathetic activation. The regulation of LC activity has been hypothesized to depend upon phasic excitatory and tonic inhibitory inputs. Recently we reported that the major afferent projections to LC arise in two medullary regions - the nucleus paragigantocellularis (PGi) in the rostro-ventro-lateral medulla and the region of the nucleus prepositus hypoglossi (PrH) in the dorsomedial medulla. Our physiological studies demonstrate that there is a potent excitatory amino acid synaptic input to LC from PGi; at this meeting we show that there is a strong inhibitory synaptic input from PrH.

The present study used GAD and GABA immunocytochemistry to demonstrate a dense GABAergic terminal-like staining at all rostrocaudal levels of LC. There are large and small punctate profiles in LC. The small puncta fill the entire central core of the nucleus; the larger puncta surround the cell dense core of the nucleus particularly along the dorsomedial border of LC. Adjacent structures in the pontine tegmentum also contain GABA-ergic terminals.

These results suggest that there is a dense GABAergic terminal plexus in LC. These terminals could provide tonic inhibitory regulation of LC neurons. Experiments to determine whether this innervation derives from PrH, activation of which potently inhibits LC neurons, are in progress. (Supported by: NS20643, 24698 and US Army DAMD-17-86C-6005.)

A GABAERGIC INPUT TO LOCUS COERULEUS FROM THE ROSTRAL DORSOMEDIAL MEDULLA. M. Ennis[1], G. Aston-Jones[2] and M.T. Shipley[1] Dept. Biol., New York Univ.[2], New York, NY 10003, Dept. Physiol., U. Cincinnati Coll. Med.[1], Cincinnati, OH 45267.

Our recent experiments identified a strong projection from nucleus prepositus hypoglossi in the rostral dorsomedial medulla to rat locus coeruleus (LC). Here, we have characterized the effects of PrH activation on LC discharge and examined the transmitter(s) in this pathway.

PrH activation inhibited 84% of LC cells (85/101) at a mean latency of 19.5 msec; 2 cells were activated, 1 cell was antidromically driven, and 13 cells were unaffected. PrH activation attenuated excitation of LC from sciatic nerve stimulation ($p < 0.02$).

PrH-evoked inhibition of 5/7 LC neurons was blocked by the $GABA_A$ antagonist picrotoxin (3-6 mg/kg, iv; $p < 0.03$). Local microinfusion (0.5-5.0 ng) or microiontophoretic application of the $GABA_A$ receptor antagonist bicuculline (BIC) blocked PrH evoked inhibition of 10/11 ($p < 0.02$) and 19/22 cells ($p < 0.01$), respectively. Iontophoretically-applied strychnine did not affect PrH-evoked inhibition of LC. In contrast, excitation of LC from sciatic nerve stimulation and postactivation inhibition following such excitation were not significantly altered by picrotoxin of BIC. In addition, PrH-evoked inhibition of LC was not affected by the alpha-2 receptor antagonist idazoxan or the opiate receptor antagonist naloxone (0.1-0.5 mg/kg and 1.0 mg/kg, iv, respectively).

These results demonstrate that PrH potently inhibits LC through a GABAergic mechanism, and are consistent with the findings of Shipley et al. (this meeting) of a rich GABAergic terminal plexus in LC. CATECHOLAMINES: ELECTROPHYSIOLOGY I

164.1

PREFRONTAL CORTEX (PFC) DOPAMINERGIC MODULATION OF ACETYLCHOLINE-EVOKED, AND STIMULUS-EVOKED RESPONSES TO VENTRAL PALLIDAL/NUCLEUS BASALIS (VP/NB) STIMULATION. C.R. Yang* & G.J. Mogenson Dept. of Physiology, Univ. Western Ontario, London, CANADA, N6A 5C1. (SPON: W. Blume).

Medial PFC receives converging inputs from acetylcholinergic(ACh) neurons of VP/NB and midbrain dopaminergic (DA) neurons. The electrophysiological interactions between DA and ACh in PFC was studied in urethane-anesthetized rats.

Iontophoretic application of ACh excited PFC neurons. DA (5-15nA) applied concurrently suppressed spontaneous firing (noise)relatively more than ACh-evoked excitation (signal), yielding an enhanced signal to noise ratio (S/N)(n=18). D2 receptor antagonist sulpiride(30nA) reversed this DA effect (n=7) whereas DA enhanced the S/N further after D1 receptor blockade (SCH23390,6mg/kg,n=11), suggesting D1 receptor inhibited D2 receptor functions in PFC.

Excitation elicited from VP/NB stimulation was ACh-mediated since it was atropine-reversible and ACh-sensitive. DA mainly attenuated this stimulation-evoked (S-E) response in 18 output neurons to the N.Accumbens. In DA-depleted(αmpt pretreated) rats, D2 agonist quinpirole(QNP,5-35nA)enhanced (n=22), but D1 agonist SKF38393(5-15nA) suppressed (n=10), this S-E excitation. Co-stimulation of D1 and D2 receptors resulted in opposing changes to both the ACh-evoked and S-E responses previously enhanced by QNP, or suppressed by SKF. Thus, DA modulate ACh-evoked and S-E responses in diverse ways which may be part of the cognitive-integrative processes in the PFC. (Funded by M.R.C. of Canada).

CLONIDINE REGULARIZES THE FIRING OF VENTRAL TEGMENTAL DOPAMINE NEURONS. J. Grenhoff* and T.H. Svensson. (SPON: B. Hedlund) Dept. of Pharmacology, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden.

The α_2-adrenoceptor agonist clonidine is effective in the treatment of certain neuropsychiatric disorders with a presumed dopaminergic pathogenesis. We used electrophysiological methods to study effects of clonidine on midbrain dopamine (DA) neurons of the ventral tegmental area (VTA) which give rise to the mesolimbic DA system commonly implied in e.g. schizophrenia. Neuronal activity of single identified DA cells in the VTA was extracellularly recorded in the chloral hydrate anesthetized male rat before and after intravenous drug administration, with respect not only to cell firing rate, but also to burst firing and regularity of firing.

Clonidine (5-20 μg/kg) produced a marked regularization of firing without affecting the firing rate. This effect was blocked or reversed by the α_2-antagonists idazoxan and yohimbine, which by themselves caused a marked excitation of the cells with prominent burst firing. Reserpine (5 mg/kg, s.c.) 4 hrs before recording abolished the clonidine effect, indicating that the effect is mediated via monoaminergic neurons. The present results, together with our previous finding of a similar effect on nigrostriatal DA neurons (Life Sci. 42: 2003, 1988), suggest that certain therapeutic effects of clonidine could result from a neuromodulatory action on midbrain DA systems.

164.3

SELECTIVE ACTIVATION OF MESOLIMBIC DOPAMINE NEURONS BY AMPEROZIDE, A PUTATIVE ANTIPSYCHOTIC DRUG. T.H. Svensson, J. Grenhoff* and L. Ugedo*. Dept. Pharmacology, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden.

The psychotropic drug amperozide, which binds selectively to 5-HT_2-receptors (Haskins et al., Brain Res Bull 19:465, 1987), is currently evaluated for antipsychotic efficacy. We used electrophysiological methods to study the acute effects of amperozide on the ascending midbrain dopamine (DA) systems commonly implied in antipsychotic drug action. Neuronal activity of single identified DA cells in the substantia nigra (SN) and ventral tegmental area (VTA) was extracellularly recorded in the chloral hydrate anesthetized male rat before and after intravenous drug administration with respect not only to firing rate, but also to firing pattern of the cells.

SN neurons (n=8) showed no significant response to amperozide (0.25-4.0 mg/kg). In contrast, VTA neurons (n=11) responded in two ways to amperozide in a similar dose range (0.5-4.0 mg/kg). Six of the neurons were markedly excited with variable effects on firing pattern, while the other five displayed a regularization of the firing pattern with no clearcut effect on firing rate. Cells of both types were inhibited by apomorphine, excluding DA autoreceptor block in the action of amperozide. These results suggest that selective activation of mesolimbic versus nigrostriatal DA function could be a basis for an antipsychotic action of amperozide.

PEDUNCULOPONTINE TEGMENTAL NUCLEUS LESIONS REDUCE THE NUMBER OF SPONTANEOUSLY ACTIVE SUBSTANTIA NIGRA PARS COMPACTA DOPAMINE CELLS. M. Beninato, H.S. Pan and J.R. Walters. NIH, Bethesda, MD 20892.

The pedunculopontine tegmental nucleus (PPN) projects to the substantia nigra (SN; Beninato and Spencer, 1987) and has an excitatory effect on this region (Scarnati et al., 1984). This study further investigated the relationship between the PPN and SN using extracellular single unit recording techniques in locally anesthetized, gallamine immoblized, artificially respired rats 7 days following 2 nmole kainic acid injections in the PPN. Lesioned animals were those in which the destruction of the PPN was >50% as determined by acetylcholinesterase histochemistry. Activity in the SN was measured in a population study using 9 electrode passes through the SN arranged in a 3x3 grid. No significant differences in firing rates between control (n=6) and lesioned (n=5) rats in either substantia nigra pars reticulata (SNr) or substantia nigra pars compacta (SNc) neurons were found. Likewise, the number of SNr cells/pass was not different between the 2 groups. However, in the SNc there was a significant 67% reduction in the number of spontaneously active cells/pass in control (1.2 $\pm$ 0.2) vs. lesioned (0.4 $\pm$ 0.05) groups. Striatal dopamine and DOPAC levels and dopamine/DOPAC ratios in lesioned (n=10) and control (n=4) rats were not significantly different. These results suggest that the reduction in the number of spontaneously active SNc cells following PPN lesions is the result of the silencing, not the death, of a large portion of this cell group. Furthermore, the PPN appears to exert a tonic influence on SNc dopamine cell activity.

ACTIVITY OF LOCUS COERULEUS NEURONS IN BEHAVING PRIMATES: RELATIONSHIP WITH VIGILANCE. G. Aston-Jones, T. Alexinsky*[1] AND S. Grant[2], Dept. Biology & Center for Neural Science, New York Univ., NY 10003; [1]Dept. Psychophysiologie, Univ. de Paris V, France; [2]Dept. Psychology, Univ. Delaware, Newark 19716.

In initial studies, recordings were obtained from locus coeruleus neurons in unanesthetized, chair-restrained monkeys during presentation of a range of sensory stimuli. Tonic impulse activity was higher during alertness or agitation than during behavioral inattentiveness and drowsiness. Low-level simple stimuli elicited minimal response in LC activity, while more intense, conspicuous stimuli evoked phasically pronounced discharge. Pronounced responses were also elicited by aversive air puffs and by naturalistic stimuli such as actions by the experimenter. While the sensory responsiveness of LC neurons in primate appeared to be more selective than that reported for rat or cat, a feature found for LC neurons in monkey as well as other species is that pronounced responses occurred to stimuli which elicited orienting behaviors. Thus, a common dimension for stimuli effective in eliciting LC responses in different species may be conspicuousness: Unexpected conspicuous stimuli which generate orientation and a change in the apparent focus of attention are most effective in eliciting responses in primate LC neurons, similar to results in other species. These findings are consistent with previous hypotheses that the LC functions in the control of vigilance and initiation of adaptive behavioral responses to unexpected imperative stimuli. Additional studies are underway to examine primate LC activity during a behavioral paradigm in which vigilance is manipulated and measured. SYSTEMIC, BUT NOT LOCAL, ADMINISTRATION OF BENZODIAZEPINES ATTENUATES EVOKED ACTIVITY OF LOCUS COERULEUS NEURONS. P. E. Simson and J. M. Weiss. Department of Psychiatry, Duke University Medical Center, Durham, NC 27710.

Recently, we provided evidence that alpha-2 receptors preferentially regulate the responsiveness of locus coeruleus (LC) neurons to excitational influences (Simson, P. E. and Weiss, J. M., J. Neurosci., 7:1732, 1987). In this study, we examined whether benzodiazepine receptors also regulate LC responsiveness.

Systemic administration of diazepam (0.5 mg/kg, i.v.), chlordiazepoxide (2 mg/kg, i.v.), and alprazolam (0.25 mg/kg, i.v.) in anesthetized rats attenuated the responsiveness of LC neurons to sensory stimulation by 55%, while decreasing spontaneous LC firing rates by 25%. Lower doses of diazepam (0.2 mg/kg, i.v.) significantly attenuated LC responsiveness while leaving spontaneous activity unchanged.

To test whether systemically administered benzodiazepines produce these effects by acting directly on receptors in the LC, benzodiazepines were infused into the LC region. Similar to systemic administration, local infusion of diazepam (50 ng) and chlordiazepoxide (100 ng) decreased spontaneous LC firing rates by 30%; however, unlike systemic administration, LC infusion produced no attenuation of LC responsiveness. These findings suggest that, when given by the normal systemic route, benzodiazepines decrease spontaneous LC firing by acting on benzodiazepine receptors in the LC, but markedly attenuate LC responsiveness by acting on receptors outside the LC to decrease excitatory input to the LC.

164.7

EFFECT OF IPSAPIRONE ON LOCUS COERULEUS (LC) ACTIVITY. J.A. Cook*, H.L. Williams*†, B.A. McMillen† and M.K. Sanghera. (SPON. H.P. Roffwarg) Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, TX 75235; †Department of Pharmacology, School of Medicine, East Carolina University, Greenville, NC 27858.

The aryl-piperazine derivatives, ipsapirone (ISA) and buspirone are potent anxiolytics and exhibit high affinity for 5HT1a receptors. However, buspirone also activates impulse flow recorded from the noradrenergic LC neurons. The purpose of the present study was to determine if ISA altered LC impulse flow and brain noradrenergic metabolism (MOPEG-SO4 levels) in a manner similar to buspirone. Extracellular single cell recordings were made from electrophysiologically identified and histologically verified LC cells in chloral hydrate anesthetized male rats. Intravenous ISA produced sustained increases in LC firing rates (7-62% after 0.01 - 3.2 mg/kg) and MOPEG-SO4 levels increased 78% and 63% in cortex and brainstem after 3.0 mg/kg s.c. 90 min prior to decapitation. The effect of ISA on LC activity was completely blocked by dibozane (0.5 mg/kg; 4 of 4 cells), but was unaffected by propranolol (0.5 - 2.0 mg/kg; 7 of 7 cells). These data indicate that ISA, like buspirone, activates the LC noradrenergic system in a manner such that prior inhibition of α2-adrenoceptors, but not β-receptors, prevents the effect. (Supp. by NS-24290)
